A further important environmental factor studied extensively in both diseases is smoking. The link between smoking and (IBD) was first made in 1982 when Harries *et al*[6] noticed a low proportion of ulcerative colitis patients were smokers. Two years later a case-control study by Somerville *et al*[7] reported that the relative risk of developing Crohn's disease was 4.8 in those who smoked before disease onset, and 3.5 for those with a current smoking habit. In recent years, IBD has been classified into subtypes/phenotypes that are distinct and based on age at onset, disease location, and clinical behaviour. Knowledge of this heterogeneity has led to the re-examination of genetic and environmental influences on IBD. The relationship between smoking and IBD however, is far more complex than previously realized as clinical subtypes have become apparent. In this article, the authors give an updated review on the role of smoking in IBD.

EFFECT OF SMOKING CESSASION AND SMOKING ON THE RISK OF DEVELOPING IBD

Risk for developing ulcerative colitis

Ulcerative colitis affects predominantly non-smokers and former smokers. The percentage of current smokers (smoking more than seven cigarettes per week) in a group of patients with UC is about 10%-15%[8,9]. These percentages are significantly lower than those observed in a control population matched for sex and age (25%-40%). The meta-analysis by Calkins[10], conducted more than 15 years ago, yielded a pooled odds ratio of 0.41 (0.34-0.48) for current smokers compared with lifetime non-smokers. The effect of smoking seems to only postpone the event,

as the relative risk of UC was also higher in former smokers (OR: 1.64; 95% CI: 1.36-1.98). In a recent meta-analysis by Mahid *et al*[11] comparable values were reported, which also included new available data. Current smoking decreased the risk for UC (OR: 0.58; 95% CI: 0.45-0.75), while former smoking was associated with an increased risk (OR: 1.79; 95% CI: 1.37-2.34). Interestingly, in patients who stopped smoking, UC developed in 52% of patients, in the first three years after cessation, as reported by Motley *et al*[12] in concordance with other studies[13]. In contrast, active smoking in early childhood was associated with a gradually increased risk for developing UC (OR for smoking start < 10 years: 7.02 and < 15 years: 3.46)[14]. The same trend was observed for passive smoking by the mother (OR: 1.53, 95% CI: 0.93-2.49).

The relationship between smoking and ulcerative colitis has also been examined at a population level. The prevalence of UC was five-fold increased in patients from the Mormon Church in Britain and Ireland, where smoking is strongly discouraged, compared with that of the general population. In contrast, CD was equally as common[15]. In addition, a review of 56 epidemiological studies in Sweden over the time period from 1930 to 1990[16] demonstrated that the sex distribution of UC had changed from an earlier female predominance to a later male predominance. Over the same period, the proportions of smokers and ex-smokers among men and women have undergone reciprocal changes with an increase in women smokers relative to men, while the same change in predominance was not observed in contemporary pediatric studies. Somewhat contradictory, in a recent population-based case-control study[17], among others, ever smoking was also associated with increased risk (1.66; 95% CI: 1.17-2.35).

There are only very few data regarding the effect of smoking in indeterminate colitis[8,18]. The effect seems to be similar to that observed in UC, that is, a protective effect against the development of colitis and a possible beneficial effect on disease course.

Risk for developing Crohn's disease

The percentage of current smokers in a group of patients with CD is significantly higher than that observed in a control population matched for sex and age (45%-55% *vs* 30%-40%)[19]. In concordance, an increased life-time risk was reported in current smokers when compared with non-smokers by both Calkins *et al*[10] (OR: 2.0; 95% CI: 1.65-2.47) and in the more recent meta-analysis by Mahid *et al* (OR: 1.76; 95% CI: 1.40-2.22).

Compared with never-smokers, former smokers were reported to have an increased risk of developing CD[10]. This risk decreased only after four years of having quit smoking. In a recent population-based study by Bernstein *et al*[19], similar data were reported, both current smoking (OR: 1.96) and ever smoking (OR: 1.78) were associated with increased risk to develop CD. However, this later association could not be replicated in the recent meta-analysis by Mahid *et al* although a trend was observed ($P = 0.08$). In contrast, ever smoking was associated with increased risk (OR: 1.61; 95% CI: 1.27-2.03). The effect of passive smoking remains controversial[20]. In one recent prospective study[14] CD patients were more likely than controls to have prenatal smoke exposure (OR: 1.72; 95% CI: 1.1-2.71). In addition, the passive smoke exposure during childhood, with parents or other household members being smokers (OR: 2.04; 95% CI: 1.28-3.31) was also associated with increased risk, in concordance with previous data by Lashner *et al*[21].

EFFECT OF SMOKING AND ITS CESSATION ON DISEASE PHENOTYPE AND COURSE

Effect of smoking and its cessation on clinical course and extent of ulcerative colitis

Although the extent at diagnosis is not affected by smoking, UC usually runs a more benign disease course in smokers compared with non-smokers. Flare-up, hospitalization rates[13], the need for oral steroids[22] and colectomy rates[22,23], are reported to be lower, while age at onset is older in smokers compared with non-smokers, though not in all studies. Relapse rates are lower in patients who began smoking after the diagnosis of UC[24]. In concordance, in a recent Europe-wide population-based cohort[25] the relapse rate was lower (Hazard Ratio: 0.8; 95% CI: 0.6-0.9) in smokers compared with non-smokers, while it was higher in women. In a retrospective analysis of a large series of patients with UC, current smoking was found to decrease the 10-year cumulative colectomy risk from 0.42 to 0.32[22]. In concordance, a meta-analysis of several large series with a total of 1489 UC patients also found the risk for colectomy to be lower (OR: 0.57; 95% CI: 0.38-0.85) in current smokers compared with non-smokers[26].

In addition, in smokers with distal UC at diagnosis, the proximal extension of the disease is less frequent[22,27], while primary sclerosing cholangitis is observed almost exclusively in non-smokers[28]. Disease regression[29] was also more likely to occur in smokers compared with non-smokers or ex-smokers 5 years (30% *vs* 5% *vs* 8%), but not 10 years after the diagnosis. Also, those with extensive disease were the lightest smokers, whereas those with healthy colons were the heaviest smokers. Finally, current smokers have a lower incidence of pouchitis following coloproctectomy with ileal reservoir when compared with non-smokers[30,31].

In contrast, intriguing new data by Aldhous *et al*[29] showed that current and non-smokers had an almost identical age at onset (31.1 *vs* 29.4 years) and this was delayed only in ex-smokers (46.5 years). Colectomy rates were not different. This group however, had a greater exposure to smoking compared with the group of current smokers.

A link between smoking habits and the course of UC has also been reported. In intermittent smokers, many patients note symptom exacerbation when they stop smoking, followed by symptom relief when they smoke again[12]. In contrast, almost half of the intermittent smokers thought that their colitis symptoms improved while smoking at least 20 cigarettes per day[32]. Moreover, smokers with UC who quit, experience an increase in

disease activity, hospital admissions, and the need for major medical therapy (oral steroids, immunosuppressants), within the first years following the cessation of smoking[33]. However, the risk of colectomy in the short-term was not increased compared with matched non-smokers and continuing smokers.

Effect of smoking and its cessation on disease location, behaviour, and disease progression in Crohn's disease

Smoking is associated with disease location: most, but not all, studies report a higher prevalence of ileal disease and a lower prevalence of colonic involvement in smokers[34-36].

A recent review[36] and previous data have demonstrated that smoking, when measured up to the time point of disease behavior classification, was associated more frequently with complicated disease, penetrating intestinal complications[34,37,38], and greater likelihood to progress to complicated disease, as defined by development of strictures or fistulae[36], and a higher relapse rate[2,39]. Of note, previous severity of the disease, as assessed from the therapeutics needs, was found to be similar in young patients who started smoking and in their matched controls[10]. The need for steroids and immunosuppressants is increased in smokers compared with non-smokers[35]. Whether the daily dose (eg, more than 15 cigarettes per day) or the total pack years smoked is more important in the abovementioned associations remains questionable.

The risk of surgery as well as the risk for further resections during disease course is also higher in smokers, in most studies[34,41,42]. These findings were reinforced by Cottone *et al*[43] who have shown that macroscopic lesions on the ileal site of the anastomosis were observed 1 year after surgery in 70% of smokers, *versus* 35% of non-smokers and 27% of ex-smokers. The risk of symptomatic postoperative recurrence was more marked in heavy smokers than in mild smokers[43]. Noteworthy, immunosuppressive therapy was found to neutralize the effect of smoking on the need for surgery[40].

However, the harmful effect of smoking on the course of CD is not a universal finding. Studies in patients from Israel and Hungary have not found differences in the need for surgery or for immunosuppressants between smokers and non-smokers[2,44,45], and patients with only colonic involvement are less sensitive to the harmful effects of smoking[8]. Finally, the development and severity of perineal complications do not seem to be influenced by the smoking status[39].

In a recent paper by Aldhous *et al*[46] using the Montreal classification, the harmful effect of smoking was only partially confirmed. Although current smoking was associated with less colonic disease, the smoking habits at diagnosis were not associated with time to development of stricturing disease, internal penetrating disease, perianal penetrating disease, or time to first surgery. Age at diagnosis was also similar in current smokers and non-smokers (28.3 years and 28.9 years) and was only delayed in ex-smokers (43.2 years). However, the way in which they measured tobacco exposure was different from previous studies. "Current smokers" were defined as those who were smoking at the time of diagnosis or event (penetrating or stricturing complication) and "ex-smokers" had stopped for at least one year before the diagnosis or event (eg, a patient could have continued smoking up to 1 year before developing a complication but was considered an "ex-smoker").

The rationale for this may be that after surgery, the risk of endoscopic and clinical recurrence in former smokers who have not smoked for at least 1 year is similar to that of non-smokers[43]. Similarly, CD activity in ex-smokers is not different from that of non-smokers, and is less marked than in current smokers[39]. The beneficial effect of quitting smoking might be seen within the year following cessation. A large prospective intervention study by Cosnes *et al*[47] performed in a selected group of 59 patients who stopped smoking following a smoking cessation intervention, examined the disease course from 1 year following smoking cessation onwards. The flare-up rate, therapeutic needs, and disease severity were similar in patients who had never smoked and in those who stopped smoking, and both had a better course than current smokers. Quitters had a 65% lower risk of flare-up compared with continuing smokers. The need for corticosteroids, immunosuppressive therapy, or a dose increase of immunosuppressants was also lower. Interestingly, after quitting, some patients developed UC-like lesions of the distal colon, whereas previously they had typical CD.

Finally, in a prospective study during pregnancy, the improvement of disease activity was observed only in smokers, in parallel with a decrease in the daily cigarette smoking[48].

The role of gender, familial disease, and ethnicity

The effect of smoking is to some extent different between male and female patients. In CD, women are affected more drastically by smoking. The relative risk associated with smoking for women may be greater than for men: one study demonstrated a three-fold difference[20].

This was already demonstrated by Sutherland *et al*[42] in 1990, who reported that in a group of 174 patients who required surgery for Crohn's disease, smokers had a 29% greater risk than non-smokers, over 10 years. However, the increased risk was more marked in females than males (OR: 4.2; 95% CI 2.0-4.2 in females and 1.5; 95% CI 0.8-0.6 in males). In Crohn's colitis, smoking is clearly harmful for women, whereas colitis in men is not affected by smoking[8]. In the study by Cosnes *et al* current smoking hastened disease onset (from 35 to 29 years of age) and increased the need for immunosuppressants, only in women.

In UC, current and ex-smoking delayed disease onset in men (from 25 to 42 years of age), but not in women[50]. Similarly, when compared with non-smokers, male UC patients who smoked ran a more benign disease course as assessed by the decreased need for immunosuppressive therapy (8% *vs* 26%), whereas this difference was not observed in females as reported by Cosnes *et al*[8] and again smoking delayed the onset of disease, only in males.

Thus, the effect of smoking in both UC and CD seems to be modulated by gender, with women being affected more disadvantageously than men. This phenomenon deserves even more attention, since smoking habits are changing in the Western population, with a trend to a greater prevalence of smokers among young women[50].

Table 1 Smoking in IBD: Practice points

Ulcerative colitis (UC)	Crohn's disease (CD)
Current smoking decreases the risk for UC by app. 50%, in contrast former smoking is associated with an app. 2-fold increased risk	Both current and former smoking (presumable also passive smoke exposure during childhood) increases the risk of CD almost 2-fold
The protective effect is smaller in females	The risk is greater in females compared with males
Proximal extension of the disease is less likely in smokers as well as disease course is milder but the risk of lung cancer and vascular disease is higher	Smoking is associated with complicated (stricturing or penetrating) and ileal disease
Patients who stop smoking experience an increase in disease activity at least during the first year after cessation	Smokers with CD need more steroids, more immunosuppressants and more operations than non-smokers
The effect of smoking is similar in indeterminate colitis (less evidence is available)	Smoking cessation improves rapidly the course of CD
Nicotine-replacement therapies and antidepressants are useful in heavy smokers motivated to stop smoking	
Geographic differences exists (e.g. Israel, Korea)	

A gender difference in smoking habits may be a possible explanation, since women use more filtered cigarettes and lighter cigarettes, and might consequently have a higher relative exposure to smoke than to nicotine[51]. In addition, the negative effect of estrogens[52] on proinflammatory cytokine gene regulation and lymphocyte interactions might also play an important role.

In Israel, no association was reported between smoking and CD in Jewish patients, although the opposite association was found for UC[53]. Similarly, smoking was not associated to the risk for CD in some studies from Asia[54]. The reason why CD in Israeli Jews or Koreans is not as sensitive to smoking as in other populations is not clear. Explanations might include differences in genetic and/or environmental factors (eg, type of tobacco, way of smoking or other alimentary factors).

A further interesting question is whether the effect of smoking is similar in familial versus sporadic cases. Family studies have reported a high concordance rate within families, between smoking habits and the phenotype of IBD, CD developing in smokers, and UC in non-smokers[55]. The above association was refined in more recent studies. Tuvlin *et al*[56] reported that ex-smokers made up an increasing percentage of older patients diagnosed with UC, accounting for more than 35% of the attributable risk of late onset (> 45 years) UC and a large component of the second peak in diagnosis. In contrast, current smoking accounted for a large percentage of patients diagnosed at a younger age with familial CD but not with sporadic CD (Table 1).

MECHANISMS BEHIND THE EFFECT OF SMOKING ON IBD

The reason behind the opposite effects of smoking observed in CD and UC remain obscure. The effects of smoking and nicotine are numerous and since the pathogenesis of inflammatory bowel disease is only partially understood, any discussion on the possible mechanisms can only be speculative. In addition, although nicotine is thought to be the most important agent responsible for the effect of smoking, one should be careful, as some effects usually associated with smoking may not follow the use of therapeutic nicotine formulations. Of note in most studies, side-effects (nausea, headache, dermatitis) of nicotine therapies were frequent and tended to be greater than the clinical benefit[57].

Smoking has numerous specific and non-specific effects. It has been shown to affect the immune system, by influencing cellular and humoral immunity. Nicotine has been shown to decrease the synthesis of proinflammatory molecules, for example, interleukin (IL)-1β and TNFα by mouse colonic mucosa as well as the production of mucosal eicosanoids[58] and some proinflammatory cytokines by human mononuclear cells (eg, IL-2[59], IL-8, and TNFα[60]) partly by its action on the nicotinic acetylcholine receptor a7 subunit. Further evidence for anti-inflammatory properties comes from a surgically-induced ileus model, where carbon monoxide-treated mice were shown to have three times higher levels of IL-10. Macrophages from smokers express a selective functional deficiency in their ability to kill intracellular bacteria[61]. Finally, chronic exposure of rats to nicotine inhibits the antibody-forming cell response, impairs the antigen-mediated signaling in T-cells and induces T-cell anergy[62]. Other effects of nicotine or smoking on the intestine include the alteration of gut motility, the reduction of smooth muscle tone and contractility (modulated by nitric oxide)[63], decreased permeability[64], and alterations in the microcirculation[65], Furthermore, smoking also increases lipid peroxidation.

In UC, the colonic mucosal layer is thin or absent, in contrast to CD where it is significantly thicker[66], with nicotine having been shown to increase mucin synthesis[67,68]. Smokers with IBD have a significant reduction in mucosal cytokine levels, specifically, IL-1b and IL-8 in patients with UC, and IL-8 in patients with CD[69]. Beneficial effects of nicotine in active UC may be associated with a decrease in IL-8 expression. Hypoperfusion of the rectum and of acutely damaged colonic tissue may play an additional role[70]. On the contrary, in CD, several plasma antioxidant parameters are altered, the total radical-trapping antioxidant potential is decreased[71], and abnormalities are present in the microvasculature[65]. Smoking through increased carbon monoxide concentration might amplify the impairment in the vasodilation capacity of chronically inflamed microvessels, resulting in ischemia and perpetuating ulceration and fibrosis[70]. Furthermore, smoking is known to increase the thrombotic potential associated with vascular damage. A defect in bacterial clearance or macrophage deficiency might also play an important role.

CONCLUSION

In conclusion, smoking plays a dual role in IBD by increasing the risk for CD and decreasing that of UC. In an individual who is genetically at risk for IBD, smoking might be an important factor in determining disease phenotype. In addition, smoking also affects the disease course. It improves UC and worsens CD, more markedly in women, while smoking cessation is followed rapidly by a reversed effect. Since smoking is associated with several additional deleterious effects (eg, cardiovascular, lung cancer risk), gastroenterologists should encourage both UC and CD patients to quit smoking. Before stopping, UC patients should be informed about the potential risk of increase in disease activity, without a higher risk for surgery. In CD, the benefit of smoking cessation is well-proven, since patients who continue to smoke have a more severe course of disease with more complications, while ex-smokers run a similar course of disease to non-smokers.

Abstract

Capsule endoscopy has revoluzionized the study of the small bowel by providing a reliable method to evaluate, endoscopically, the entire small bowel. In the last six years several papers have been published exploring the possible role of this examination in different clinical conditions. At the present time capsule endoscopy is generally recommended as a third examination, after negative bidirectional endoscopy, in patients with obscure gastrointestinal bleeding. A growing body of evidence suggests also an important role for this examination in other clinical conditions such as Crohn's disease, celiac disease, small bowel polyposis syndromes or small bowel tumors. The main complication of this examination is the retention of the device at the site of a previously unknown small bowel stricture. However there are also some other open issues mainly due to technical limitations of this tool (which is not driven from remote control, is unable to take biopsies, to insufflate air, to suck fluids or debris and sometimes to correctly size and locate lesions).The recently developed double balloon enteroscope, owing to its capability to explore a large part of the small bowel and to take targeted biopsies, although being invasive and time consuming, can overcome some limitations of capsule endoscopy. At the present time, in the majority of clinical conditions (i.e. obscure GI bleeding), the winning strategy seems to be to couple these two techniques to explore the small bowel in a painless, safe and complete way (with capsule endoscopy) and to define and treat the lesions identified (with double balloon enteroscopy).

Key words: Capsule endoscopy; Double balloon enteroscopy; Obscure glycemic index bleeding; Crohn's disease; Nonsteroidal anti-inflammatory drugs

INTRODUCTION

The small bowel (SB) has been considered for a long time technically difficult to evaluate for many anatomical (i.e. distance from external orifices, length) and physiological (i.e. active peristalsis) reasons.

Until the introduction of Video Capsule Endoscopy (VCE) in clinical practice the small bowel was studied mostly with radiological or nuclear medicine techniques such as abdominal Computed Tomography (abdominal CT), abdominal Magnetic Resonance Imaging (abdominal MRI), small bowel follow through (SBFT), small bowel enteroclysis (SB enteroclysis) and 99_{m}TC scan. Although CT scan and abdominal MRI are highly sensitive in recognizing the presence of abdominal masses and allow an accurate evaluation of solid organs, lymph nodes and vessels, they are able to provide limited information about the small bowel wall. On the other hand, small bowel follow-through and small bowel enteroclysis, although specifically designed to evaluate the small bowel, have low sensitivity and specificity in recognizing small and flat lesions[1].

Additionally these two techniques are often poorly tolerated by patients and sometimes difficult to interpret.

The endoscopic evaluation of the small bowel represents the best possible approach to small intestinal diseases, allowing a direct visualization of small bowel mucosa, the collection of targeted biopsies and sometimes an effective treatment. Sonde enteroscopy, introduced because of its theoretical capability to visualize the entire small bowel (achievable in about 80% of examinations in clinical practice)[2,3], had been abandoned at the end of the 90's because of several technical limitations (angulation of the tip due to the presence of the balloon, duration of the examination, patient discomfort, inability to take biopsies)[4]. Push Enteroscopy (PE) is limited by the depth of insertion of the instrument to the proximal jejunum (about 90-150 cm from the oral route) and to

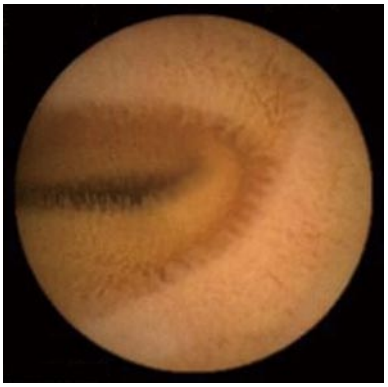

Figure 1 Normal small bowel.

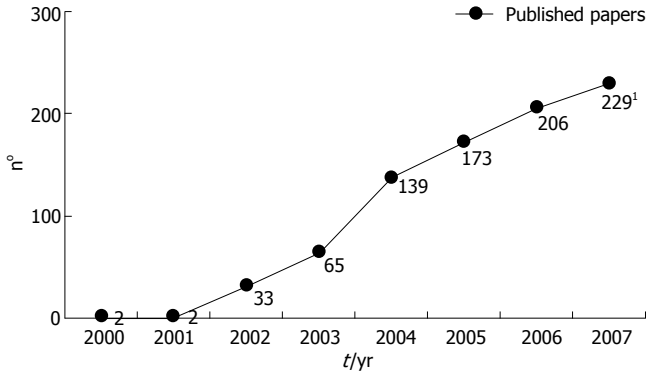

Figure 2 Published papers about capsule endoscopy between 2001 and 2007 (search engine: www.pubmed.org, key words: Capsule endoscopy OR capsule enteroscopy). [1]Estimated number of published articles in 2007 based on the number of papers published in the first seven months of the year.

the terminal ileum (50-80 cm in the retrograde way) and, despite sedation, is still poorly tolerated[5-7]. Intraoperative enteroscopy (IOE) is the most complete but also the most invasive means of examining the small bowel[7].

The introduction (in 2001)[8] and further continuous development of capsule endoscopy opened a new chapter in the study of small bowel diseases allowing, finally, to cross the frontier of the endoscopic examination of the small bowel. In fact this revolutionary technique made it possible, for the first time, to obtain high resolution endoscopic images of the entire small bowel (Figure 1) avoiding sedation, surgical intervention or radiation exposure. Capsule endoscopy showed, in everyday clinical practice, that the small bowel can be involved in several diseases (i.e. inflammatory, vascular, neoplastic, iatrogenic diseases). The knowledge of the large spectrum of lesions and diseases that can affect the small bowel stimulated the development and/or the implementation of other diagnostic and therapeutic techniques such as double balloon enteroscopy (DBE), MRI-enteroclysis and CT enteroclysis.

Performing a recursive search in the literature (by means of the most common search engine www.pubmed.org; using "capsule endoscopy OR capsule enteroscopy" as key words) we found a number of papers, increasing over the years, up to 754 (Figure 2). On the one hand this phenomenon certainly represents a proof of the revolutionary potential of this diagnostic tool in the field of small bowel endoscopy and, on the other hand, demonstrates the effort to establish the appropriate role of this device in different clinical conditions. Unfortunately about a quarter of published papers are case reports (187) or collections of small case series and 131 published papers are expert reviews. Following the rules of evidence based medicine[9] we can classify these papers at the lowest level of scientific evidence while, among the huge number of publications about capsule endoscopy, there are only 8 randomized controlled studies [five about bowel preparation, 2 about Nonsteroidal anti-inflammatory drugs (NSAIDs) induced damage and 1 about obscure GI bleeding (OGIB)][10-17] and 4 metanalyses (about OGIB or Crohn's disease)[18-21]; all these papers can be ranked as evidence grade 1c.

Mainly on the ground of the former 12 mentioned papers three Practice Guidelines have been published so far, two (in 2004 and 2006) on behalf of the European Society of Gastrointestinal Endoscopy (ESGE) and one on behalf of the American Society of Gastrointestinal Endoscopy (ASGE)[22-24] in 2006.

The aim of the present paper is to briefly review the evidence, available to date, about the use of capsule endoscopy for the study of the small bowel (starting from the studies providing the highest grade of evidence), to highlight the benefits of this technique but also to highlight risks and limitations which have emerged in these six years of use of the device in clinical practice.

INDICATIONS

Obscure GI bleeding

So far, OGIB is the main clinical indication for capsule endoscopy: about 70%-80%[25,26] of patients undergoing capsule endoscopy suffer from OGIB. The majority of studies published at the beginning of the experience with this new tool reported a high, although widely variable, diagnostic yield (ranging between 38% and 93%, about 75%-80% in most studies[27]). These studies, mainly performed in tertiary referral centres, collected highly selected patients with a long standing history of obscure GI bleeding, with low levels of haemoglobin at the time of the examination, who had undergone a huge number of prior examinations with negative results[28]. Subsequent studies performed on larger populations of patients, similar to those undergoing this examination in everyday clinical practice, showed a slightly lower diagnostic yield (about 50%)[29].

Although recent studies showed a decrease in the diagnostic yield of capsule endoscopy, two metanalyses[18,19] clearly demonstrated that capsule endoscopy in patients with obscure GI bleeding is superior to traditional radiological techniques (SBFT and SB enteroclysis) and PE. The latter comparison has been also recently confirmed in a specific prospective randomized controlled study[11]. The authors hypothesized that the high diagnostic yield of capsule endoscopy in this subgroup of patients may depend on the capability of the capsule to evaluate the mid-distal small bowel (particularly in comparison with PE) and/or to show small and flat lesions (vascular-

Figure 3 Artero-Venous Malformation (AVM) of the distal duodenum in a patient undergoing capsule endoscopy for obscure GI bleeding.

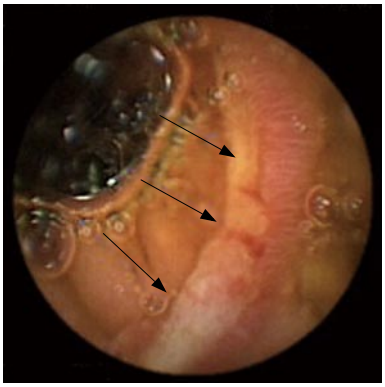

Figure 4 Jejunal ulcers in a patient with Crohn's disease.

Figure 3- or inflammatory-Figure 4) that are often missed by conventional radiological techniques.

As far as the possible factors potentially affecting the diagnostic yield of capsule endoscopy are concerned, the presence of active bleeding at the time of examination[30] or a short interval between the last episode of acute bleeding and capsule endoscopy[28-30], low levels of haemoglobin and high transfusion requirement have been found to be associated with a high diagnostic yield[31,32].

Since capsule endoscopy was introduced in clinical practice 6 years ago, some papers explored also the impact of this new technique on the outcome of patients with obscure GI bleeding. As expected, capsule endoscopy has been found to significantly modify the diagnostic and therapeutic work up immediately after the examination[33], decreasing the number of further examinations and reducing the length of hospital stay[10,34,35]. Nevertheless capsule endoscopy seems also to have a positive impact on long term follow up (mostly evaluated at 12-18 mo after the examination) in about 50%-66%[28,32] of patients and even patients with negative capsule endoscopy have a low probability of experiencing a new bleeding episode (the negative predictive value of capsule endoscopy ranges between 83% and 100%)[34,36].

On the ground of this large amount of published papers capsule endoscopy is now proposed by experts, in patients with obscure GI bleeding, as a third step after a negative bidirectional endoscopy[33], and scientific societies[22,23] define capsule endoscopy as a very valuable tool for investigating obscure gastrointestinal bleeding with the potential capability to improve outcomes.

Recently some Authors evaluated the possible role of capsule endoscopy in the diagnostic work up of patients with isolated iron deficiency anaemia. These studies[37,38], although small, reported that the diagnostic yield of capsule endoscopy in this clinical setting seems quite similar to that reported in patients with obscure GI bleeding (about 50%). These studies confirmed that capsule endoscopy is superior to conventional radiological techniques also in patients with iron deficiency anaemia.

Crohn's disease

We know that Crohn's disease can affect the small bowel: in approximately 45% of Crohn's disease patients the disease involves both the small bowel and the colon and in about 25% the disease is confined to the small bowel, primarily the ileum[39], that can be often difficult to evaluate with endoscopic (retrograde ileoscopy) or radiological methods. For these reasons and because of an increasing number of patients with ulcerative lesions suggesting Crohn's disease[28] has been discovered among subjects undergoing capsule endoscopy for other indications, capsule endoscopy has been also proposed to evaluate the small bowel mucosa of patients with Crohn's disease. However the possible presence of asymptomatic stenoses hampered, at least at the beginning of the experience, the use of this device in patients with a previously established Crohn's disease.

In fact, the first published papers[40,41] on this topic (in 2003) evaluated the diagnostic yield of capsule endoscopy in patients with suspected Crohn's disease (with negative traditional work up, including bidirectional endoscopy and mostly SBFT). The diagnostic yield of capsule endoscopy in this subset of patients (ranging between 33% and 70%)[18,19] has been found, in two independent metanalyses, to be higher when compared with other diagnostic techniques (such as SBFT, SB enteroclysis and retrograde ileoscopy). Marmo *et al*[18] comparing capsule endoscopy with radiological techniques also calculated that the number needed to diagnose (NND) for this subgroup is 2 (95% CI 2-3). Unfortunately the majority of studies aimed at evaluating the role of capsule endoscopy in patients with suspected Crohn's disease included a heterogeneous group of patients, seldom verified over time the final diagnosis by means of other independent diagnostic techniques (i.e. histology), and often used different criteria to classify the lesions identified. A recently published paper[42] tried to overcome possible confounding factors by clearly defining patients with suspected Crohn's disease and by verifying the diagnosis over time. In this paper Girelli *et al*[42] confirmed that capsule endoscopy is an effective tool to diagnose (positive likelihood ratio: 5.8) or to rule out (negative likelihood ratio: 0.08) small bowel Crohn's disease in this particular subset of patients. The authors also pointed out that, in patients with suspected Crohn's disease, assuming a 50% pre-test probability of disease, a positive capsule endoscopy gives a post-test probability of 85%.

The low frequency of capsule retention in patients undergoing capsule endoscopy for suspected Crohn's disease (approximately 1.5%, quite comparable with that reported in patients with obscure GI bleeding)[25]

encouraged the application of this new technique also in patients with established Crohn's disease[43-45]. As expected, in these patients capsule endoscopy showed a high diagnostic yield, significantly superior to that of retrograde ileoscopy and conventional radiological techniques[18,19]. Initial reports comparing capsule endoscopy with CT enteroclysis[46] in patients with established Crohn's disease, although small in size, seem to confirm that capsule endoscopy has a high capability of identifying small inflammatory lesions in the small bowel, and to significantly modify the subsequent management of the patients. However, Golder *et al*[47], using MRI enteroclysis to evaluate the small bowel in patient with Crohn's disease highlighted that, although capsule endoscopy is able to identify a larger number of lesions in the proximal -mid small bowel, in the distal small bowel, which is mostly affected by Crohn's disease, capsule endoscopy and MRI enteroclysis are closely comparable. The authors also pointed out that in these patients MRI enteroclysis identified significant extra intestinal findings in about 30% of cases.

When trying to compare different diagnostic tools for the study of the small bowel in patients with established Crohn's disease, we must keep in mind that capsule endoscopy has been performed exclusively in patients with non stricturing-non penetrating Crohn's disease. In fact all patients in whom a radiological technique showed a stenosis (or a fistula or an abscess) that must be considered as a positive finding of these examinations, were excluded from the comparative studies, leading to a significant and systematic underestimation of the true diagnostic yield of the radiological techniques. Nevertheless, although in the majority of cases, patients with strictures identified with radiological examinations were excluded from capsule endoscopy studies, capsule retention occurred in 5%-13% of cases[25,48]. Capsule retention in patients with established Crohn's disease can be managed, and sometimes partially solved, by giving steroids[49] or using DBE (both for capsule retrieval and stricture dilation)[50,51]. In this subset of patients, capsule endoscopy can be considered as a major complication because it often requires surgical intervention. The development of a dissolvable capsule (see below) may represent, in the near future, the best way to test intestinal patency before capsule endoscopy, in order to avoid capsule retention, especially in patients with Crohn's disease.

Practice guidelines from ESGE[22] suggested that capsule endoscopy, owing to its high diagnostic yield, should have a very important place in the diagnostic work up of patients with known or suspected Crohn's disease, but more large prospective studies are needed to evaluate the specificity of inflammatory lesions, the impact on long term outcome, the clinical significance of the assessment of the extent and severity of small bowel involvement and the risk of capsule retention.

Recent published studies showed also that VCE may have a role in assessing tissue healing after therapy with biologics, relapse after surgical intervention and small bowel evaluation in patients with ulcerative colitis undergoing total colectomy[52].

NSAIDs induced damage

Surprisingly two[13,15] of eight randomized controlled studies published on capsule endoscopy evaluated the role of this technique in assessing small bowel lesions due to NSAIDs consumption. This probably derived from the fact that these widely used drugs can induce small, spotty and superficial mucosal lesions (i.e. mucosal breaks) difficult to identify with other techniques.

Goldstein *et al*[15] clearly demonstrated that NSAIDs (i.e. naproxen), even if associated with proton pump inhibitors (omeprazole), caused more small bowel mucosal lesions than placebo, while Gomez *et al*[13], comparing different NSAIDs, showed that Ibuprofen seems to cause small bowel mucosal damage less frequently than other drugs (dexibuprofen and diclofenac). Another study by Goldstein *et al*[53] comparing COX2-inhibitors with naproxen plus omeprazole showed that among healthy subjects with no endoscopic lesions at baseline, celecoxib was significantly associated with fewer small bowel mucosal breaks than ibuprofen plus omeprazole.

Nevertheless the most important information in this field is the demonstration that small mucosal inflammatory lesions (such as mucosal breaks, small isolated erosion or superficial ulcers) have been detected in about 10%-13% of healthy subjects[15]. Although the clinical implications of these findings remain unclear, the occurrence of these lesions in young healthy subjects, define a new benchmark that must be considered in any further clinical study about capsule endoscopy.

Other indications

As far as celiac disease is concerned two studies[54,55] explored the performance of capsule endoscopy compared with histological evaluation of small bowel biopsies taken during gastroscopy in patients with suspected celiac disease.

Although both studies showed a high agreement between these two techniques (capsule endoscopy sensitivity 85%-87.5%, specificity 90.9%-100%, positive predictive value 96.5%-100% and a negative predictive value of 71.4%-88.9%) the authors underlined that, at present, traditional gastroscopy with duodenal biopsies remains the method of choice to assess mucosal atrophy in patients with suspected celiac disease. However, capsule endoscopy can be a suitable tool in patients, with high clinical suspicion of celiac disease, unable or unwilling to undergo traditional endoscopy.

At the present time, the main obstacle to the extensive use of capsule endoscopy in the diagnosis of celiac disease remains the high costs of the procedure, but also, as highlighted by Biagi *et al*[55], the difficulty in the graduation of mucosal atrophy (see below).

Two studies[57,58], published in 2005 and 2007 respectively, evaluated the role of capsule endoscopy in patients with complicated/refractory celiac disease. In this particular subset of patients capsule endoscopy has been performed to rule out malignant neoplasms [primarily enteropathy associated T-cell lymphoma (EATL)] or other complications (i.e. ulcerative jejunitis). The study of Culliford[57] depicted for the first time the spectrum

of findings (such as scalloping of folds, nodularity and villous atrophy, but also strictures, intussusceptions or submucosal masses), identified by capsule endoscopy in patients with complicated celiac disease, while Daum *et al*[58], demonstrated that capsule endoscopy adds significant clinical information affecting further management mostly in patients with refractory celiac disease type Ⅱ. Nevertheless, both studies included a small number of patients with refractory/complicated celiac disease undergoing a huge number of examinations to exclude strictures; in fact, as previously mentioned for Crohn' s disease, refractory celiac disease can also result in a structuring disease. For these reasons, and mainly because of its capability to take targeted biopsies, double balloon enteroscopy can represent, in this field, a reasonable alternative to capsule endoscopy[59].

Small bowel tumours are still considered, particularly when compared with gastric or colonic neoplasms, a rare disease accounting for 1% to 3 % of all primary gastrointestinal tumours[60], however, since the introduction of capsule endoscopy in clinical practice, some small studies have been published reporting a frequency of small bowel tumours ranging between 6% and 9%[61-65]. These studies, including a series of patients undergoing capsule endoscopy in which this tool was able to identify the presence of small bowel tumours, showed a higher than expected frequency of these tumours. However, two recently presented studies[66,67], published to date only in abstract form, showed a frequency of small bowel tumours ranging between 1.6% and 2.4%. There are no obvious explanations for this discrepancy between studies but the huge number of patients enrolled in the last two studies (more than 6000), the histological confirmation of all reported cases and the substantial concordance with data coming from surgical series, strongly decrease the reliability of earlier data.

All published series about capsule endoscopy in the diagnosis of small bowel tumours underlined that the main clinical indication for capsule endoscopy in these patients is obscure GI bleeding.

In agreement with previously published surgical series, small bowel tumours have been described at capsule endoscopy mostly as polyps (or masses) and stenoses, leading to capsule retention in about 10%[63] to 25%[67] of cases. The most frequent treatment in patients with small bowel tumours is surgical intervention, which, at the same time, allows the retrieval of capsules in case of retention of the device. Therefore, capsule retention in patients with small bowel tumours is considered nowadays as a minor complication.

Capsule endoscopy has also been proposed for the diagnosis and surveillance over time of patients with hereditary polyposis syndromes. The main advantage of this technique in this setting is the capability of this system to inspect the entire small bowel, avoiding radiation exposure and increasing patients' compliance, which is a key point in surveillance programs. Several studies evaluated the possible role of capsule endoscopy in patients with polyposis syndromes[68-70] confirming that, also in this field, capsule endoscopy is more accurate than conventional radiology (SBFT and SB enteroclysis)[71]. Nevertheless the same Authors underlined that the main limitation of this technique, particularly when compared with MRI-enteroclysis, is related to the estimation of size (see below) and location of polyps[68]. At the present time it is suggested that CE should be performed, instead of SBFT, at the time of diagnosis and, as a part of surveillance programs, every 2-3 years, but also as a first diagnostic step in patients with symptoms (i.e. abdominal pain or anaemia)[69,72]. Indeed, keeping in mind the limitations of capsule endoscopy in patients with polyposis syndromes, double balloon enteroscopy can become an important tool, to accurately size and locate lesions, but also to remove polyps identified by capsule endoscopy[73].

The role of CE is less established in patients affected by familial adenomatous polyposis. In fact the quick passage of the capsule through the proximal duodenum can hamper the accurate visualization of the periampullary area. For these reasons, at present, capsule endoscopy is not recommended when the diagnosis of FAP is already established, but may be considered as a part of surveillance for patients with severe duodenal polyposis[69,70]. In a recently published prospective study Wong *et al*[74] compared CE with push enteroscopy and lower endoscopy in 32 patients with FAP. They showed that, in a defined segment of the small bowel, CE diagnosed significantly fewer small-bowel polyps than standard endoscopy, showed only fair agreement with PE in determining polyp counts, and was fairly inaccurate in detecting large polyps and in sizing them.

Abdominal pain, as a possible indication for capsule endoscopy, is still largely debated. Although small bowel tumours have sometimes been identified in patients undergoing capsule endoscopy for unexplained abdominal pain[52], two studies[75,76] evaluating a group of 36 patients with chronic abdominal pain of unknown origin and previous negative diagnostic work-up, found that capsule endoscopy was negative or not clinically relevant in more than 85% of subjects. On the other hand May *et al*[77] clearly demonstrated that when chronic abdominal pain is associated with other signs or symptoms (weight loss > 10% of body weight, inflammation shown by laboratory tests, chronic anemia, or suspected mid-gastrointestinal bleeding) relevant, or potentially relevant, findings are diagnosed by capsule endoscopy in about 60% of cases.

Capsule endoscopy has also been used, with promising results, in other rare clinical conditions such as indeterminate colitis[78,79], small bowel transplantation[80], graft versus host disease[81,82], protein losing entheropathy[83], primitive lymphangectasia[84] (mostly in the pediatric population), Whipple disease[85] and irritable bowel syndrome (with clinical suspicion of celiac disease)[86].

RISKS AND LIMITATIONS

The majority of published papers we mentioned pointed out that the results obtained using capsule endoscopy in clinical practice mainly depend on the revolutionary technical characteristics of this device; however the same technical characteristics can represent, from a certain point of view, limitations of capsule enoscopy. These technical limitations can also explain, in the majority of cases, the clinical limitations of this examination.

Lewis *et al*[87] analyzing a master database, provided

by Given Imaging Ltd (Yoqneam, Israel), found that the global miss rate of capsule endoscopy is about 11% ranging between 0.5% for ulcerative disease and 18.9% for neoplastic disease. Despite the estimated miss rate, capsule endoscopy is significantly lower than that of conventional examinations (global miss rate: 73.3%, miss rate for ulcerative lesions and neoplastic disease: 78.7% and 63.2% respectively) these percentages, in some selected subgroups of patients (i.e. patients with small bowel tumour) are alarming.

Unfortunately there are no conclusive explanations for false negative capsule endoscopies but several factors such as the incompleteness of examination (that can occur in 15%-20% of cases), technical limitations (battery life duration, field of view) and the suboptimal cleanliness of the small bowel (mostly in distal segments) can play a role[88].

At present, although all published papers strongly underlined that small bowel cleanliness is a key point to ensure a complete and accurate examination, and several papers aimed at evaluating factors (dietary restrictions and/or laxatives and/or prokinetic and/or postural tricks) potentially affecting small bowel cleanliness[12,14,16,17,89-93] have been published, there are still no recommendations about small bowel preparation for capsule endoscopy.

This mainly depends on the fact that most studies are published in abstract form, the methodological quality of these studies is rather low, because randomized comparisons are only a small minority, different regimens (with different combinations of drugs) are compared in each study, and an accepted and validated scale to evaluate bowel cleanliness does not exist yet. Four[12,14,16,17] out of 8 controlled randomized studies published on the field of capsule endoscopy are aimed at identifying the best preparation regimen for VCE but, unfortunately, this is only another proof of the relevance of this point.

Despite the lack of any clinical study on this field, all Authors used an overnight fast. An agreement has been reached, basically on the ground of two studies[12,17], about the helpful role of simethicone, administered 20 min before the procedure, in reducing bubbles all along the small bowel, but, the main issue (the presence of liquid stools or fecal debris) which can affect the diagnostic yield of capsule endoscopy, remains to be solved.

In fact, although in 2004[24] the ESGE guidelines, on the ground of the study of Viazis *et al*[16], suggested 2-liters of a poly-ethylen-glycol (PEG) based solution the day before the examination, as small bowel preparation, the updated release of guidelines from the same scientific society (published in 2006)[22] does not recommend any particular schedule of preparation.

The absence of a remote control and of the capability of taking biopsies significantly decrease the specificity of capsule endoscopy findings, since the diagnosis can be based only on the endoscopic appearance. The low specificity of lesions observed at capsule endoscopy is an issue that affects all fields of application of this technique, especially regarding inflammatory lesions (i.e. erosions, ulcers-Figure 4) which can derive from acute and chronic inflammatory bowel diseases[94], ischemic[95], neoplastic[61-67], infectious[96,97] or iatrogenic[98] diseases. As previously mentioned, small and initial inflammatory lesions have also been described in healthy subjects[15].

Another clinical problem strictly dependent on the technical characteristics of the system is the problem of sizing and locating small bowel lesions. This problem, mainly highlighted in studies performed in patients with small bowel hereditary polyposis syndromes[68-70] has important clinical consequences. In fact the size and the location of the lesions are a key point to define, ultimately, the clinical significance of capsule endoscopy findings and to direct further management. In patients with obscure GI bleeding some Authors[99,100] suggested a possible three grade scale (from P0 to P3) to rank capsule endoscopy findings depending on the likelihood of these lesions to explain the reason for referral while, for patients with Crohn's disease two possible scores[43,101] have been proposed but not yet validated. In the field of celiac disease Biagi *et al*[56] clearly demonstrated a large inter- and intra-observer variation in the evaluation of the grade of mucosal atrophy (compared with traditional histology).

In patients with hereditary polyposis syndromes capsule endoscopy tends to overestimate the number of polyps while MRI-enteroclysis seems to be more reliable to correctly estimate the size of polypoid lesions, particularly for polyps of 1-2 centimetres, generally considered clinically relevant[71,74,102].

To improve the capability to estimate the size of polyps Racz *et al*[103] suggested the ingestion, 20' before the procedure, of mesalazine granules as "reference" while Greapler *et al*[104] demonstrated that training with a capsule with a graduated dome might be helpful.

Although awareness of this complication existed at the time of the introduction of this device in clinical practice, the risk of capsule retention at the site of a previously unknown small bowel stricture remains the main complication of capsule endoscopy. This complication seems to be seldom predictable by conventional radiology[105] but the development of a specific dissolvable capsule, even if its safety profile is still under discussion, seems to be a reliable test to screen patients at high risk for capsule retention[107,106-109]. As we know the frequency of capsule retention seems mostly dependent on the clinical indication for capsule endoscopy, ranging between 0% in healthy subjects and 21% in patients with intestinal obstruction[25]. Although capsule retention is the most feared complication of capsule endoscopy, in some selected patients (i.e. patients with small bowel tumor in which capsule retention has been described in 10%-25% of cases) it can be considered as "positive" or minor complication being a sort of "red flag" identifying the presence of the disease. On the contrary, capsule retention must be considered a serious and major complication in patients in whom surgical intervention must be avoided as long as possible (i.e. patients with Crohn's disease, in which capsule retention has been described in about 5%-13% of cases).

Although some case reports described a possible acute obstruction[110] or a possible perforation[111], due to capsule retention, these complications are nowadays considered exceptional. Retained capsules can be retrieved by means of surgical interventions (possibly in a laparoscopic

setting)[112] or by means of enteroscopy (PE or DBE, depending on the site of retention)[113].

Several studies demonstrated the safety of capsule endoscopy in patients with thoracic pace-makers or implanted defibrillators[114-116] and recently a capsule endoscopy has also been performed on a woman in her third trimester of pregnancy because of a life threatening haemorrhage showing a carcinoid tumor[117].

Last but not least, although recently published studies confirmed that this examination is cost-effective in patients with obscure GI bleeding[118], the cost of the procedure can prevent the use of this potentially helpful device in everyday clinical practice. To partially reduce costs of the procedure a possible "two steps" strategy (first step; revision of the video by the nurse and second validation of results by a physician) has been proposed[119,120].

CONCLUSION

Capsule endoscopy, introduced into clinical practice in 2001, revolutionized the study of the small bowel, providing for the first time, a reliable and painless method to evaluate this organ endoscopically. In this paper we critically evaluated the body of evidence produced in these last six years. Unfortunately the majority of published papers are case reports or expert reviews.

Capsule endoscopy has been proven to be significantly superior to conventional radiological techniques (SBFT or SB enteroclysis) for any clinical indication. However studies comparing capsule endoscopy with new imaging techniques (MRI-enteroclysis or CT-enteroclysis) are still few, small and mainly focused on some selected topic (i.e. polyposis syndromes). At the present time capsule endoscopy is recommended as the third examination, after negative bidirectional endoscopy, in patients with obscure GI bleeding. A growing body of evidence suggests also that capsule endoscopy can have a key role in other clinical conditions such as Crohn's disease, celiac disease, small bowel polyposis syndromes or small bowel tumours.

Although awareness of this complication existed at the time of the introduction of this device in clinical practice, the risk of capsule retention at the site of a previously unknown small bowel stricture remains the main complication of capsule endoscopy today. This complication seems to be seldom predictable by means of conventional radiology but the development of a specific dissolvable capsule might, in the near future, provide a safe and reliable test to identify patients at high risk for capsule retention.

Capsule endoscopy still suffers from some technical limitations (there is no remote control, it cannot take biopsies, insufflate air, suck fluids or debris) which can partially explain the clinical limitations/complications of this device (i.e. the difficulty in interpreting inflammatory lesions, in sizing and locating polyps, in grading mucosal atrophy).

The recently developed double balloon enteroscope, owing to its capability to explore a large part of the small bowel and to take targeted biopsies, although invasive and time consuming, can overcome some limitations of capsule endoscopy. At the present time, in the majority of clinical conditions (i.e. obscure GI bleeding), the winning strategy seems to be to couple these two techniques to explore in the most painless, safe and complete way the small bowel (with capsule endoscopy) and to define and treat the lesions identified (with double balloon enteroscopy).

ACKNOWLEDGMENTS

We would like to thank Erik Herdes for the tremendous, essential and continuous technical support.

Abstract

Three hundred and fifty million people worldwide are estimated to be chronically infected with hepatitis B virus. 15%-40% of these subjects will develop cirrhosis, liver failure or hepatocellular carcinoma during their life. The treatment of chronic hepatitis B has improved dramatically over the last decade merits to the advent of nucleoside/nucleotide analogues and the use of pegylated interferons. Approved drugs for chronic hepatitis B treatment include: standard interferon-alpha 2b, pegylated interferon-alpha 2a, lamivudine, adefovir dipivoxil, and entecavir. Unfortunately, these agents are not effective in all patients and are associated with distinct side effects. Interferons have numerous side effects and nucleoside or nucleotide analogues, which are well tolerated, need to be used for prolonged periods, even indefinitely. However, prolonged treatment with nucleoside or nucleotide analogues is associated with a high rate of resistance. Telbivudine is a novel, orally administered nucleoside analogue for use in the treatment of chronic hepatitis B. In contrast to other nucleoside analogues, Telbivudine has not been associated with inhibition of mammalian DNA polymerase with mitochondrial toxicity. Telbivudine has demonstrated potent activity against hepatitis B with a significantly higher rate of response and superior viral suppression compared with lamivudine, the standard treatment. Telbivudine has been generally well tolerated, with a low adverse effect profile, and at its effective dose, no dose-limiting toxicity has been observed. Telbivudine is one of the most potent antiviral agents for chronic hepatitis B virus and was approved by the FDA in late 2006.

Key words: Telbivudine; Chronic hepatitis B; Hepatitis B virus; Nucleoside analogue; Antiviral agents; Pegylated interferons; Lamivudine; Adefovir dipivoxil; Entecavir

INTRODUCTION

Hepatitis B virus (HBV) infection is a significant health problem worldwide. Of the 6 billion worldwide populations, an estimated 2 billion have been infected by HBV[1]. It is estimated that 350-400 million people have chronic hepatitis B (CHB) infection[2]. There is clear epidemiologic evidence that chronic HBV infection can result in the development of hepatocellular carcinoma (HCC) and cirrhosis[3,4]. Approximately 15%-40% of HBV carriers develop cirrhosis, liver failure, and HCC; worldwide, more than 50% of primary HCC is related to chronic HBV infection[5]. Each year, 500 000 deaths are expected because of complications related to hepatitis B[6].

EPIDEMIOLOGY IN INDIA

In India nearly 3%-4% of the population is infected by the virus, and chronic hepatitis B constitutes more than 50% of the chronic hepatitis cases in the country[7]. The prevalence ranges from 1.1% to 12.2% with maximum incidence in Madhya Pradesh, Arunachal Pradesh and South India and least in Kashmir and Kerala[8]. There is a peak prevalence after the second decade of life. Most (90%) of these HBV infected subjects are HBeAg negative; the majority (80%) have normal ALT[9]. The prevalence of HBeAg among asymptomatic HBsAg positive persons varies from 9%-20%[9,10].

This, in the context of a large population and absence of a national immunization program would spell off a projected increasing burden of infection and liver disease due to HBV in this country in the years to come. In this perspective, the HBV epidemiology in India becomes relevant not only nationally, but also internationally, because of the possibility that India may soon have the largest HBV infection pool in the world. Economic burden is high and management is affected by cost and availability of diagnostic modalities and patients' awareness and compliance of various treatment options available. Though there have been several guidelines published by various organizations including the Indian association of Study of Liver, the management of HBV infection varies widely in the country. Many physicians in India still find it difficult to make satisfactory management decisions[11].

COST EFFECTIVENESS OF TREATMENT

The main obstacle to treatment in developing countries like India is the expenditure of drug therapy. Cost effective studies have shown savings in countries with intermediate or low endemicity[11]. In India cost of treatment with oral drugs like lamivudine and adefovir range from Rs. 3000 to Rs. 7000/year, a drastic reduction in cost compared to subcutaneous therapy. Additionally the orally used drugs are associated with a good response rate, excellent safety profile and making the overall treatment with oral drugs cost effective. However, the main limitation of these drugs is the emergence of drug-resistant viral strains during the course of treatment.

HBV INFECTION - NATURAL HISTORY

The natural history of CHB is complex and understanding it is important for the selection of patients for treatment. Infected individuals can go through four phases of infection: the immune tolerance phase, the immune reaction or clearance phase (HBeAg-positive, chronic HBV), the inactive carrier (low replication) phase, and the reactivation phase (HBeAg-negative chronic HBV)[1].

In the natural history of HBV infection, the most important event is HBeAg seroconversion characterized by loss of HBeAg and development of antibody to HBeAg (Anti HBe)[12]. The prognosis of chronic HBV infection is dependent upon the amount of inflammation, necrosis and fibrosis in the liver at this point of seroconversion. If significant liver damage is already present at this point, then the prognosis after seroconversion, spontaneous or treatment related is unlikely to be good, despite suppression of viral replication. On the other hand, if the seroconversion has occurred early and is maintained, then the long-term prognosis is excellent. In a subset of persons, this relationship between seroconversion and suppression of viral replication does not hold true. In them, despite anti-HBe positivity, active viral replication persists due to the emergence of mutants in the 'precore' and basal core promoter regions of HBV. This state, characterized by continuing viral replication despite anti HBe positivity has been termed as HBeAg negative CHB[13-15]. Compared with HBeAg-positive CHB, HBeAg negative CHB can follow an aggressive course, requires long or even infinite treatment, and leads to the rapid development of cirrhosis and HCC.

Goals of treatment

The ultimate goal of treatment is the eradication of HBV before it causes irreversible damage including cirrhosis and/or HCC. The eradication of HBV is impossible with currently approved drugs. This is because of extrahepatic reservoirs of HBV, integration of HBV DNA into host DNA, and the presence of covalently closed circular DNA (cccDNA) in the hepatocyte nucleus. Such cccDNA serves as a transcriptional template for HBV replication without the need for reinfection[16,17]. Current antiviral agents have little inhibitory effect on cccDNA, leading to high relapse rates after discontinuation of treatment.

The more realistic goals of therapy are early and prolonged viral suppression, remission of chronic liver disease, a decreased rate of cirrhosis, liver failure, HCC, and reduced morbidity and mortality.

TREATMENT OF CHB

The treatment of CHB has undergone tremendous change and continues to evolve with the advent of potent antiviral agents. The FDA currently approves interferon alpha-2b, pegylated interferon alpha-2a (PEG-IFN-α2a), and four oral agents, adefovir dipivoxil, entecavir, lamivudine and telbivudine as monotherapeutic agents[18].

IFN-α was the first FDA-approved medication for the treatment of CHB. Polyethylene glycol, an inert water soluble molecule when attached to standard interferon to form pegylated interferon decreases the clearance and antigenicity of interferon, thus extending and sustaining its activity *in vivo* allowing for once-weekly administration.

IFN-α and PEG-IFN-α2a have significant side effects, require injection therapy and are less efficacious in patients acquiring CHB during early childhood, for example Asian patients. Furthermore IFN treatment fails to decrease the chance of development of cirrhosis-related complications and HCC[19].

Lamivudine, an oral nucleoside analogue, was the second FDA-approved medication for the treatment of CHB. Viral breakthrough remains a problem with lamivudine with incidence of resistance ranging from 16%-32% after 1 year of therapy to as high as 58% with 2-3 years of therapy[20]. Furthermore, disease progression has been shown to resume following viral breakthrough.

Adefovir dipivoxil, an oral nucleotide analogue, was approved by the FDA in September 2003. Although resistance is less frequent with adefovir compared to lamivudine, this agent may be restricted by nephrotoxicity and a relatively modest potency[18].

Entecavir, a deoxyguanosine nucleoside analog, has recently been licensed by the FDA. Early trials have shown it to be more potent than lamivudine. However, care must be taken when using entecavir in individuals with renal dysfunction[18].

The newest antiviral nucleoside analogues like telbivudine was approved by the FDA based on the results of a Phase Ⅲ clinical trial for the treatment of CHB. The aim of this review article is to introduce and review current information on telbivudine for the treatment of CHB.

TELBIVUDINE

Telbivudine (LdT) is a novel agent for the treatment of CHB. It is an HBV-specific L-nucleoside analogue of thymidine. The chemical name of telbivudine is β-L-2-deoxythymidine (LdT). Telbivudine is an unsubstituted, unmodified β-L-2-nucleoside and the first compound of this series.

Mechanism of action

Telbivudine must be activated by phosphorylation and is efficiently metabolized to 5-triphosphate derivative.

5-triphosphate metabolite of β-L-2-deoxynucleosides interacts with the viral polymerase and inhibits viral replication and results in obligate chain termination of DNA synthesis[21]. This inhibition occurs mainly in the synthesis of the second strand of DNA (DNA-to-DNA transcription) for telbivudine (in contrast to lamivudine which strongly inhibited first strand DNA synthesis; RNA-to-DNA reverse transcription). Since transcription fidelity is higher in DNA-to-DNA synthesis than RNA-to-DNA synthesis, telbivudine treatment may have a slower rate of emergence of drug-resistant virus when compared to lamivudine[21].

Preclinical studies

There is no demonstrable toxic effect on human DNA polymerases α, β and γ by telbivudine after phosphorylation in the experiments using hepatoma cell lines, primary human peripheral blood monocyte cells and human foreskin fibroblasts and other cell types of mammalian origin[21].

In preclinical studies, telbivudine was investigated in rats and monkeys at concentrations substantially greater than the anticipated dose in humans. No significant toxic effects were observed in animal models, suggesting a minimal risk of cumulative, carcinogenic or reproductive toxicity in humans[22].

Pharmacokinetics

A phase Ⅰ/Ⅱ a dose-escalation study in HBV-infected patients showed that telbivudine is rapidly absorbed with the peak concentration reached within approximately 1-3 h. The plasma concentration of telbivudine increased proportionally with increasing doses in the 25-800 mg/d range studied. There were no serious adverse events in all the subjects either receiving telbivudine or placebo[23].

Systemic telbivudine is predominantly cleared unchanged by the kidneys with minimal metabolism and elimination via the hepatic route. Zhou *et al*[24] studied the pharmacokinetic profile of telbivudine administered to patients with moderate to severe renal impairment and hepatic impairment with regards to peak concentration and overall drug exposure [area under the curve (AUC)]. In patients with renal impairment, the AUC was two to three-fold higher in subjects with moderate renal impairment when dosing was normalized to 600 mg/d, suggesting that telbivudine dosage needs to be adjusted in renally impaired patients preferably by reducing the daily dose. Pharmacokinetic profiles were comparable in subjects with normal and impaired hepatic function. The pharmacokinetics are not altered by the food intake[24].

CLINICAL STUDIES

Dose ranging study

The excellent results achieved in the early human PK and safety studies led to the phase Ⅰ/Ⅱ clinical trial in patients with CHB[25]. In this first clinical study of telbivudine, safety, antiviral activity, and pharmacokinetics were assessed in 43 adults with hepatitis Be antigen-positive chronic hepatitis B. This placebo-controlled dose-escalation trial investigated 6 telbivudine daily dosing levels (25, 50, 100, 200, 400, and 800 mg/d); treatment was given for 4 wk, with a 12 wk follow-up. Serum HBV DNA levels were monitored *via* quantitative polymerase chain reaction (PCR). The results indicate that telbivudine was well tolerated at all dosing levels, with no dose-related or treatment-related clinical or laboratory adverse events. Telbivudine plasma pharmacokinetics was dose-proportional within the studied dose range. Marked dose-related antiviral activity was evident, with a maximum of telbivudine doses of 400 mg/d or more. In the 800 mg/d cohort, the mean HBV DNA reduction was 3.75 $\log_{10}$ copies/mL at wk 4, comprising a 99.98% reduction in serum viral load. Correspondingly, post treatment return of viral load was slowest in the high-dose groups[25].

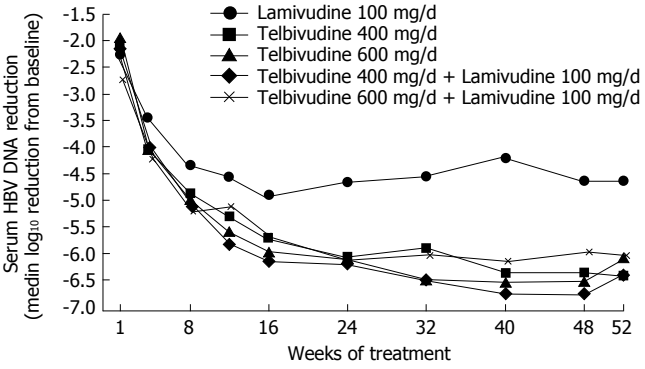

Figure 1 Median reductions in serum hepatitis B virus (HBV) DNA levels at wk 52 (log10 copies/mL) in all treatment groups.

Phase Ⅱb studies

Owing to the encouraging results in the phase Ⅰ/Ⅱ study, a multicenter, international phase Ⅱb trial was initiated. This randomized, double-blind trial evaluated the efficacy and safety of telbivudine 400 or 600 mg/d and telbivudine 400 or 600 mg/d plus lamivudine 100 mg/d (Comb400 and Comb600) compared with lamivudine 100 mg/d in hepatitis Be antigen (HBeAg)-positive adults with compensated chronic hepatitis B[26].

A total of 104 patients were randomized 1:1:1:1:1 among the 5 groups. Median reductions in serum hepatitis B virus (HBV) DNA levels at wk 52 ($\log_{10}$ copies/mL) are shown in Figure 1.

At wk 52, telbivudine monotherapy showed a significantly ($P < 0.05$ for each comparison) greater mean reduction in HBV DNA levels (Figure 1), clearance of polymerase chain reaction-detectable HBV DNA, and normalization of alanine aminotransferase (ALT) levels compared with lamivudine monotherapy, with proportionally greater HBeAg seroconversion and less viral breakthrough (Figure 2). Combination treatment was not better than telbivudine alone. All treatments were well tolerated[26]. This study also examined the prognostic significance of the magnitude of HBV DNA reduction at wk 24 during therapy. For patients with HBV DNA less than 3 log at wk 24 none developed viral breakthrough at wk 52. More importantly 100% of these patients had undetectable HBV DNA by PCR assay at wk 52. In

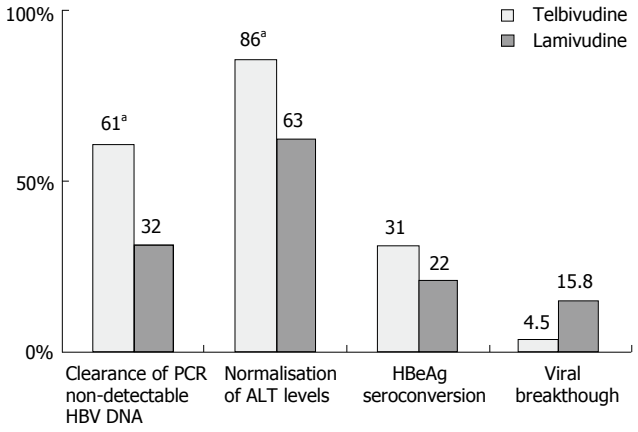

Figure 2 Comparison of telbivudine and lamivudine monotherapy. [a]$P < 0.05$.

addition, these patients had a higher rate of loss of HBeAg and higher chances of ALT normalization at wk 52. These important findings emphasize that treatment should target a rapid and maximal suppression of viral replication[26].

Phase Ⅲ studies

Efficacy *vs* lamivudine: Globe is a phase Ⅲ, double-blinded, randomized, international, multicenter clinical trial designed to compare telbivudine vs lamivudine in over 1369 individuals with CHB over a 2 years period[18].

Individuals entered into the study were screened for HBeAg positivity, and required HBV DNA more than 6 $\log_{10}$ copies/mL by Roche COBAS® Amplicor PCR assay, an ALT greater or equal to 1.3-10 times the upper limit of normal and compensated liver disease. They were stratified for HBeAg status (positive or negative) and ALT value (less or greater than 2.5 times the upper limit of normal). Individuals were randomized to receive 2 years of either: (1) Lamivudine 100 mg qd or (2) Telbivudine 600 mg qd.

The primary end-point of Globe was 'Therapeutic Response', a composite serological end-point comprising suppression of serum HBV DNA to below 5 $\log_{10}$ copies/mL.

Secondary end-points included reduction in serum HBV DNA, normalization of serum ALT, HBeAg loss, seroconversion, and safety[18].

At 1 year[18], a significant reduction in HBV DNA in the telbivudine exposed individuals compared with lamivudine was observed, there being a greater HBV clearance to PCR non-detectable levels in this group also (Table 1). Telbivudine was associated with fewer flares of serum ALT levels when compared to lamivudine. On reviewing histological findings, 65% of HBeAg positive individuals exposed to telbivudine had a significant improvement in histology *vs* 56% of those exposed to lamivudine ($P < 0.01$)[18].

For all clinical and virological efficacy parameters, efficacy at 1 year was proportional to HBV DNA level at wk 24 (Table 2). Achieving HBV DNA < 300 copies/mL at wk 24 with lamivudine or telbivudine was highly predictive of not developing resistance at wk 52. Overall significantly less resistance was seen in the telbivudine arm than the lamivudine arm (2%-3% *vs* 7%-8%). The ability to predict

Table 1 Efficacy at 1 yr in HBeAg positive and HBeAg negative individuals in the Globe study receiving telbivudine or lamivudine

	Telbivudine	Lamivudine	*P* value
HBeAg positive patients			
HBV DNA fall (mean $\log_{10}$)	-6.5	-5.5	< 0.01
HBV DNA non-detectable by PCR (%)	60	40	< 0.01
Treatment failure (%)[1]	5	13	< 0.01
HBeAg negative patients			
HBV DNA fall (mean $\log_{10}$)	-5.2	-4.4	< 0.01
HBV DNA non-detectable by PCR (%)	88	71	< 0.01
Treatment failure (%)[1]	< 1	3	NS

[1]Defined as HBV DNA > 5 $\log_{10}$ copies/mL.

Table 2 Efficacy at 1 yr against virological suppression at 24 wk in HBeAg positive and negative individuals in the Globe study

	Virological suppression at wk 24 (%)			
	< 300 copies/mL	300-1000 copies/mL	> 1000-10000 copies/mL	> 10000 copies/mL
HBeAg positive patients (wk 52)				
HBV DNA (< 300 copies/mL)	90	70	30	5
ALT normalization	90	89	80	54
Viral breakthrough	1	3	8	11
HBeAg negative patients (wk 52)				
HBV DNA (< 300 copies/mL)	93	66	38	10
ALT normalization	83	74	63	36
Viral breakthrough	0	9	18	32

subsequent outcomes at 24 wk enables clinicians to estimate a response and plan future therapeutic interventions.

The 2 years results of this study[27] were presented recently at the AASLD annual meeting at Boston. At 2 years telbivudine showed significantly greater therapeutic response, a greater reduction in HBV DNA from baseline and greater HBV DNA clearance to PCR negative. Telbivudine showed significantly less primary and secondary failure, breakthrough and resistance. Clinical adverse event profiles were similar between the two treatment groups (Table 3). Both study drugs were generally well-tolerated, with similar patterns of clinical adverse events. Clinical and virological efficacy at 2 years was also linked to magnitude of HBV suppression at wk 24 (Table 4)[28].

Another phase Ⅲ trial compared telbivudine with lamivudine in Chinese individuals with CHB[29], 87% of whom were HBeAg positive. At 52 wk, 70% of telbivudine exposed individuals had undetectable HBV DNA levels (defined as < 300 copies/mL by PCR) compared with only 43% of lamivudine treated individuals ($P < 0.001$). Telbivudine was superior to lamivudine in normalizing ALT levels (89% *vs* 76%, respectively, $P < 0.005$). In telbivudine exposed individuals who were HBeAg positive, on entering the study, 25% had seroconverted at 52 wk, compared with 18% of those treated with lamivudine. Both Telbivudine and lamivudine were equally well tolerated.

Table 3 Efficacy at 2 yr in HBeAg positive and HBeAg negative individuals in the Globe study receiving Telbivudine or lamivudine

	Telbivudine	Lamivudine	*P* value
HBeAg positive patients			
HBV DNA fall (mean $\log_{10}$)	-5.7	-4.4	< 0.05
HBV DNA non-detectable by PCR (%)	54	38	< 0.05
Treatment failure (%)[1]	4	12.3	< 0.05
HBeAg negative patients			
HBV DNA fall (mean $\log_{10}$)	-5	-4.2	< 0.05
HBV DNA non-detectable by PCR (%)	79	53	< 0.05
Treatment failure (%)[1]	0	3	< 0.05

[1]Defined as HBV DNA > 5 log10 copies/mL.

Efficacy *vs* adefovir: A third major phase Ⅲ study has compared the use of telbivudine and adefovir in HBeAg positive individuals with CHB for 24 wk[30]. At the end of the study, a significantly greater HBV DNA reduction was seen in those individuals exposed to telbivudine (6.37 *vs* 5.11 $\log_{10}$ copies/mL; $P < 0.01$). In individuals exposed to adefovir, 42% failed to reach a HBV DNA below 5 $\log_{10}$ copies/mL, compared with 5% in the telbivudine arm ($P < 0.01$). There was no significant difference in HBeAg loss or normalization of ALT levels between the two arms. There was no difference in adverse events between the two arms.

Resistance: Of the 1367 individuals included in the Globe ITT analysis, 81 patients experienced viral breakthrough[18]. Among these, genotypic resistance was confirmed in 69:17 telbivudine-treated patients and 52 lamivudine recipients. Following sequencing, all resistance was associated with M204 variants in the YMDD motif of the genome. Individuals failing lamivudine had acquired either M204I, M204V or a mixed picture of M204M/I/V. In those exposed to telbivudine, M204I was the only mutation detected in 16 of 17 telbivudine patients with resistance; the other patient carried a mixture of M204M/I/V.

The M204V lamivudine resistant mutation was associated with the 180M compensatory mutation, thus forming a double mutant, whereas the M204I telbivudine mutation was not. These results imply that telbivudine may suppress the emergence of fully resistant HBV *via* the M204V pathway that is dominant with lamivudine.

FUTURE TRENDS IN THE MANAGEMENT OF CHRONIC HEPATITIS B

Emerging data suggest that the magnitude of reduction in serum HBV DNA levels that are achieved early in the course of therapy with nucleos(t)ides predicts the likelihood of subsequent efficacy outcomes. Data from the GLOBE study suggest that patients who have rapid and profound viral response to treatment (serum HBV DNA < 300 copies/mL at 24 wk) tend to have a higher probability of maintaining the response and a lower probability of resistance over time. Conversely, patients who have a lower initial viral response tend to have a higher probability of low rates of response and resistance over time.

Table 4 Efficacy at 2 yr against virological suppression (PCR negative) at 24 wk in HBeAg positive and negative individuals in the Globe study

	Yr 2 outcome	Probability (%)
HBeAg positive	HBeAg seroconversion	45
	ALT normalization	79
	HBV DNA non-detectable by PCR	77
HBeAg negative	ALT normalization	77
	HBV DNA non-detectable by PCR	74

Understanding the factors that predict poor response and resistance can potentially permit treatment modification to optimize response to treatment. Therefore, the response to a single agent after 24 wk of therapy may be used effectively by the clinician to determine whether the patient is likely to benefit from continued monotherapy or if the addition of another agent may offer a better probability for improved long term outcomes.

A clinical trial to assess this approach with telbivudine will be conducted in India. The trial design will involve assessment of response, based on serum HBV DNA levels, at specific early time points starting at 24 wk. Based on the degree of viral suppression at these time points, telbivudine may be continued or another agent could be added.

CONCLUSION

Owing to its good safety profile and high antiviral potency, telbivudine is one of the most promising drugs for the treatment of CHB. Telbivudine is one of the new β-L-nucleoside analogues with potent antiviral activity against HBV. Telbivudine is an obligate chain terminator, incorporating into HBV DNA, and exerts a preferential effect on second strand DNA synthesis. The promising results of the early *in vitro* and animal studies paved the way for phase Ⅰ/Ⅱ human clinical trials. Phase ⅡB human clinical studies demonstrated superior antiviral efficacy of telbivudine, significantly better ALT normalization and better HBeAg loss as compared with lamivudine. Further large international multicenter phase Ⅲ studies have confirmed these results with telbivudine in comparison not only to lamivudine but also to adefovir.

Overall, telbivudine appears to be efficacious, easy to take with a good safety profile, proving to be a valuable therapeutic option in the management of hepatitis B.

Abstract

Low bone mineral density and the increased risk of fracture in gastrointestinal diseases have a multifactorial pathogenesis. Inflammatory bowel disease (IBD) has been associated with an increased risk of osteoporosis and osteopenia and epidemiologic studies have reported an increased prevalence of low bone mass in patients with IBD. Certainly, genetics play an important role, along with other factors such as systemic inflammation, malnutrition, hypogonadism, glucocorticoid therapy in IBD and other lifestyle factors. At a molecular level the proinflammatory cytokines that contribute to the intestinal immune response in IBD are known to enhance bone resorption. There are genes influencing osteoblast function and it is likely that LRP5 may be involved in the skeletal development. Also the identification of vitamin D receptors (VDRs) and some of its polymorphisms have led to consider the possible relationships between them and some autoimmune diseases and may be involved in the pathogenesis through the exertion of its immunomodulatory effects during inflammation. Trying to explain the physiopathology we have found that there is increasing evidence for the integration between systemic inflammation and bone loss likely mediated via receptor for activated nuclear factor kappa-B (RANK), RANK-ligand, and osteoprotegerin, proteins that can affect both osteoclastogenesis and T-cell activation. Although glucocorticoids can reduce mucosal and systemic inflammation, they have intrinsic qualities that negatively impact on bone mass. It is still controversial if all IBD patients should be screened, especially in patients with preexisting risk factors for bone disease. Available methods to measure BMD include single energy x-ray absorptiometry, DXA, quantitative computed tomography (QCT), radiographic absorptiometry, and ultrasound. DXA is the establish method to determine BMD, and routinely is measured in the hip and the lumbar spine. There are several treatments options that have proven their effectiveness, while new emergent therapies such as calcitonin and teriparatide among others remain to be assessed.

Key words: Inflammatory bowel disease; Osteoporosis

INTRODUCTION

Patients with inflammatory bowel disease (IBD) are at increased risk of developing disorder in bone and mineral metabolism because of several factors, including the genetic influence, cytokine-mediated nature of the inflammatory bowel disease, the intestinal malabsorption resulting from disease activity or from extensive intestinal resection and the use of glucocorticoids to control disease activity. Apparently these disturbances may also be seen since childhood, and environmental factors such as malnutrition, immobilization, low body mass index (BMI), smoking and hypogonadism may also play a contributing role in the pathogenesis of bone loss. In IBD several studies demonstrate a negative correlation between bone mineral density (BMD) and glucocorticoid use, though there is evidence that may support the opposite. In order to answer the questions about the pathogenesis, we first have to determine the factors that are involved in this extraintestinal complication. The aim of this paper is to review the basic and molecular aspects with the clinical and therapeutic features and have an overview about the trends of the bone disease related to IBD.

EPIDEMIOLOGY

Bone mineral density is decreased in a proportion of subjects with IBD as shown by epidemiological studies. The current understanding about IBD and BMD is that

the overall risk of fracture may be slightly increased in IBD patients. IBD has been associated with an increased risk of osteoporosis and osteopenia and epidemiologic studies have reported an increased prevalence of low bone mass in patients with IBD. The prevalence rates from 2% to 30% for osteoporosis (OP), from 40% to 50% for osteopenia[1] and the overall prevalence of low bone mineral density is estimated in 15%. A population-based study compared IBD patients with the general population and reported similar increases in the fracture risk between Crohn's disease (CD) and Ulcerative colitis (UC)[2] and in comparison to control patients, similar to what other population-based studies have reported[3,4]. Some series have reported that in newly diagnosed IBD patients a reduced BMD has been found and this prevalence is slightly higher in patients with CD[3,5] whereas approximately 15% of patients with CD have osteoporosis[6]. There is contrasting data from a Danish case-control study where an increase in the risk of fracture among women with CD was seen, but not men with CD or patients with UC[7,8], also another study reported that the overall fracture rate in UC was similar to that of control subjects[9]. In regard to age and gender as risk factors, elderly have the highest risk of fracturing and this increased risk is evident across all age groups[3]. Some case control studies have demonstrated that gender, age, and body weight are the major determinants of bone mineral density in patients with CD. As in healthy individuals, the combined effect of these factors account for up to 50% of the variability in bone mineral density[10]. Male sex and increasing age were considered risk factors in predicting those with osteoporosis although most series report no significant difference between the genders.

Longitudinal studies show that the BMD changes are not excessive[11,12] and there is no exclusive pattern of low BMD that involves spine of the hip. The risk of hip fracture is increased by 86% in patients with CD and by 40% in patients with UC[2]. However the hip has been reported more frequently affected than the spine[13,14]. In a study of Stockbrugger *et al* significant number of fractures in IBD patients as in the general osteoporotic are asymptomatic, about 14.2% of the fractures seem to be underreported[15], though it is important to mention that osteoporosis occurrence is often underestimated[15].

GENETICS

Low bone mineral density and the increased risk of fracture in all gastrointestinal diseases including IBD have a multifactorial pathogenesis. There are a number of factors that can lead to enhanced bone loss, these also include genetic factors.

LRP5

Because of the central role of osteoblasts in bone formation, it is easy to think there are genes influencing osteoblast function and it is likely that LRP5 may be involved in the skeletal development. The protein encoded by *LRP5* is a member of the low-density lipoprotein-receptor (*LDLR*) gene superfamily[16] and is closely related to *LRP6*[17]. *LRP5* is transcribed in human bone tissue as well as in numerous other tissues. There is convincing findings that deleterious (loss of function) mutations in *LRP5* result in loss of function and cause bone defects such as the ones seen in pseudoglioma syndrome further supporting the critical role of this gene in skeletal integrity[18]. There is some data about the identification in normal healthy individuals of a gain of function mutation in the LDL receptor-related protein 5 (LPR5) gene resulting from a autosomal dominant high bone mass trait[19] and this gain of function mutation described in LRP5 produces increased bone mass with no adverse effect on skeletal structure, contrasting the loss of function mutation that maps to the same genomic region that contains LRP5 causes the osteoporosis pseudoglioma syndrome[20]. Polymorphisms rs491347 rs1784235 could be important to human osteoporosis phenotypes and may be considered as possible susceptibility factors for osteoporosis and fractures in humans[21]. A Japanese study found that the A1330 V polymorphism may contribute to osteoporosis susceptibility[22] and also was associated with reduced BMC and BMD values in healthy young Finnish men, providing evidence for the crucial role of LRP5 in peak bone mass acquisition[23].

VDR (Vitamin D receptor gene)

The identification of vitamin D receptors (VDRs) in peripheral blood mononuclear cells sparked the early interest in vitamin D as an immune system regulator[24]. Vitamin D deficiency has been linked to several different diseases, including the immune system-mediated OP such as IBD. The association of VDR gene BsmI polymorphism with OP has been studied by several investigators[24-28]. In addition, TaqI, FokI and ApaI polymorphisms of the VDR gene have also been described[25]. Regarding OP, most data concern to the BsmI polymorphism of the vitamin D receptor (VDR) gene.

Candidate genes

There are other candidate genes that seem involved with bone loss. Estrogen receptor alpha (ER alpha) play an important role in increasing BMD *via* mechanical strain and muscle mass[29]. The results of studies regarding the association between some common polymorphisms of the aromatase gene and bone mineral density and the risk of osteoporotic fractures are recognized[30]. Thus, aromatase is also an attractive osteoporosis candidate gene. The gene encoding TGFβ1 is a strong functional candidate for genetic susceptibility to osteoporosis. Several polymorphisms have been identified in TGFβ1, and previous work has suggested that allelic variants of TGFβ1 may regulate BMD and susceptibility to osteoporotic fracture[31]. During the last years, about 170 candidate genes have been published. There have been (e.g., VDR, ER-α, and COL1A1), as well as novel genes recently discovered to be important in bone and mineral metabolism. The newly studied genes include a big list CYP17 (17-hydroxylase)[32], CYP1B1 (cytochrome P450)[33], DBP (vitamin D-binding protein)[34], GH1 (growth hormone 1)[35], GnRH (gonadotropin-releasing

hormone 1[35]), IGF-Ⅱ (insulin-like growth factor Ⅱ)[37], LEPR (leptin receptor)[38], LRP5 (low-density lipoprotein receptor-related protein 5)[39], BMP2 (bone morphogenetic protein 2)[40], CCR2 (chemokine)[41], CLCN7 (chloride channel 7)[42], COMT (catechol-O-methyltransferase)[43], CTSK (cathepsin K)[44], DRD4 (dopamine receptor D4)[45], I-TRAF (TRAF family member-associated NF-κB activator)[46], LCT (lactase)[47], MIF (macrophage migration inhibitory factor)[48], MMP-1 (matrix metalloproteinase 1)[49], among many others, but their relationship with inflammation as a possible mechanism of osteoporosis still is not clear and the interaction with IBD bone disease has not been elucidated. The mechanisms involved and the potential usefulness of those genetic data in the prevention and management of osteoporosis need further investigation, also to determine the direct relation with IBD.

PATHOPHYSIOLOGY

Inflammation has now moved to the center of the physiopathologic mechanisms involved in the process of bone loss in IBD, there has been a considerable increase in knowledge surrounding the genetic determinants of osteoporosis. As well as genetic markers are potentially helpful in identifying high risk patients, the genetic variations of cytokines plays a key role in the regulation of the inflammatory response. Several studies are focused trying to identify genetic risk factors for rapid bone loss in IBD patients as a model of disease and inflammation-associated bone loss. Evidence accumulated in the past years support that interleukin 6 (IL-6) is a pathogenic factor in osteoporosis that results from the loss of either male or female sex steroids and have implicated IL-6 in the physiopathology of several other diseases caused by increased osteoclastic bone resorption including diseases such as Rheumatoid arthritis[50]. Genetic variations in the IL-6 and interleukin 1 receptor antagonist (IL-1ra) gene identify IBD patients at risk for increased bone loss. Allele status of the IL-1ra, IL-6, heat shock protein 70-2 and 70-hom (hsp 70-2, hsp hom) gene has been typed and correlated with clinical course of IBD and extent of bone loss[51]. These variations are independent determinants of bone loss in the setting of IBD, and have been identified as independent predictors of bone loss in the setting of postmenopausal osteoporosis, suggesting that IL-6 and IL-1ra determine the response of bone to different stressors such as the hypoestrogenic state or systemic inflammation[52,53]. Apparently, estrogen loss results in increased production of IL-6 by *ex vivo* bone marrow cell cultures and increased production of IL-6 follows the withdrawal of estradiol from primary culture[54,55]. It seems that IL-6 is responsible for increased bone resorption after loss of sex steroids and that gonadectomy prevents the increase in osteoclastogenesis in bone marrow and the increase in the number of osteoclasts in sections of trabecular bone[56]. The cytokines IL-1ra and IL-6 also have a central role in the paracrine stimulation of osteoclast development and regulation of the process of bone resorption[50,55]. Increasing evidence suggests that IL-6 type cytokines also promote the development of osteoblasts[50]. It has been observed that the carriage of the A2 allele of the IL-1ra gene is associated with reduced bone loss[52].

The interleukine-2 (IL-2) deficient mouse model of colitis is known to develop both osteopenia and colitis. Osteopenia was not evident in IL-2 deficient mouse cross-bred to be T-cell deficient, and osteopenia could be induced in T-cell-deficient mice by adoptive transfer of T cells from IL-2 deficient mice[57]. These data suggest that activated T cells are critical for mediating the osteopenia.

OPG-RANK-RANKL system

The receptor activator of nuclear factor κB ligand (RANKL) osteoprotegerin (OPG) system represents a potential link between inflammation and bone homeostasis and also an example of inflammation-mediated osteopenia such as IBD-associated osteopenia. The balance between RANKL and OPG (the soluble decoy receptor preventing ligation of RANKL) is of major importance to the regulation of osteoclastogenesis. The interaction of RANK on the surface of osteoclasts with its ligand RANKL induces osteoclastogenesis and conversely the interaction with the osteoblast derived soluble decoy receptor, osteoprotegerin (OPG)[58] blocks RANK-RANKL interaction inhibiting osteoclasts formation. Whether compounds stimulate RANK ligand or OPG will affect whether they induce or inhibit osteoclastogenesis. Pro-inflammatory cytokines induce RANKL and promote bone resorption with consecutive bone loss. Activated T cells can directly trigger osteoclastogenesis through RANKL leading to bone loss while OPG can block those effects[59-61]. Increased OPG levels may represent a continuing homeostatic response, attempting to reverse established osteopenia and RANKL driven osteoclastogenesis, thus maintaining normal bone mass. Inflammation seems to play an important role in the regulation of the OPG-RANK-RANKL system. To correlate it with chronic inflammatory states comparable to IBD, there have been some reports that show a direct correlation between serum OPG and erythrocyte sedimentation rate and a score of disease activity in patients with rheumatoid arthritis[62]. Soluble RANKL as well as OPG levels are elevated in rheumatoid arthritis, while high OPG and decreased RANKL levels have been reported in primary biliary cirrhosis[63,64]. Some of the osteoclastogenic factors released from the IBD mucosa (for example IL-1, IL-6 and TNFα) are thought to function indirectly via specific receptors on stromal osteoblastic cells to enhance RANKL expression[60,65,66]. Data suggests that OPG may be a protective host response that partially offsets the adverse skeletal effect created by the inflammation state. Moshen *et al*[67] described the alterations in the RANKL/OPG system in IBD and its relationship to decreased BMD. It has been demonstrated increased plasma levels of OPG as well as increased release from the inflamed colon in IBD, suggesting the macrophages and dendritic cells as colonic source of OPG in IBD. Apparently, no correlation was evident between corticosteroid and serum OPG[63] contrasting partially with other findings.

Corticosteroids

The controversial participation of glucocorticoid (GC) therapy in the pathogenesis of bone loss in IBD still has gaps to be fulfilled. It seems that there is an important relationship between dosage, duration and pattern of GC therapy and these factors are related to the incidence of pathological fractures[68]. Some studies indicate that fractures are present in 30%-50% of patients on GC therapy for chronic diseases[69] and several studies have demonstrated that dosage is associated with BMD[51,70-73]. On the other hand, several studies have reported the opposite[8,13].

The epidemiological data on fracture risk and bone loss in GC therapy do not distinguish the effects of drug and the effects of the underlying disease. It is known, for example, in rheumatoid arthritis, the risk of fracture is increased even in the absence of GC exposure, also it has been observed that osteoporosis is rapidly developed in recently diagnosed Crohn's disease without any effect of corticosteroids in the follow up. One study showed that the prevalence of osteoporosis in pediatric patients with IBD is approximately the same as in adult patients, showing that osteoporosis was already present before steroid treatment[74]. Contrasting data from other studies show that the extent of bone loss was no correlated to clinical severity of disease or application of corticosteroids[75-77]. The participation of GC in the pathophisiology of bone loss is complex. GCs influence the production and action of hormones that regulate bone and calcium metabolism and also have direct effects of GCs on bone. GCs increase the expression of receptor activator of nuclear factor κB ligand (RANK-L) and decrease the expression of its soluble decoy receptor osteoprotegerin (OPG) in stromal and osteoblastic cells[78] and also enhance the expression of macrophage colony-stimulating factor (M-CSF), which in the presence of RANK-L induces osteoclastogene sis[78-80]. GCs have direct effects on osteoclasts also by suppressing the expression of an autocrine cytokine, such as interferon I , that normally exerts inhibitory effects on osteoclastogenesis[80]. Also they inhibit the function of mature osteoblasts and suppress the synthesis of insulin-like growth factor- I , an agent that enhances bone formation[78,79].

The wingless-type (Wnt) signaling has emerged as a novel, key pathway for promoting osteoblastogenesis. The Wnt signal transduction comprises three intracellular pathways: the canonical pathway, the Wnt/planar-cell-polarity (PCP) pathway, and the Wnt/Ca^{2+} pathway[81,82]. Wnt signals are extracellularly regulated by several secreted antagonists including secreted frizzled-related protein (sFRP), Cerberus, Wnt inhibitory factor-1 (WIF-1), and dickkopf (Dkk)[83]. Some studies strongly suggest that the canonical pathway plays a central role in promoting bone formation[84-86]. Some groups have reported that glucocorticoid enhances the expression of dickkopf-1 (Dkk-1) in cultured human osteoblasts[87] by suppressesing the canonical Wnt signal[88].

DIAGNOSIS

Diagnosis of osteoporosis in IBD patients

Due to the low absolute risk of fracture remains controversial if all IBD patients should be screened, but it is suggested for avoiding the complications of osteoporosis, especially in patients with a preexisting bone disease, older than 65, and with risk factors for low bone mass as long-term steroid therapy (prednisone 5 mg daily for 6 mo or more)[88-91].

Both, the American College of Gastroenterology (ACG) and American Gastroenterological Association (AGA) issued position papers to offer guidance to the practicing clinician in the diagnosis and management of bone loss in IBD. These position papers recommended the selective screening of IBD patients with dual energy x-ray absorptiometry (DXA) scanning, and the criteria for DXA screening included: postmenopausal state , ongoing corticosteroid treatment, cumulative prior use of corticosteroids exceeding 3 mo, history of low trauma fractures, and age over 60. These criteria led to the detection of osteopenia or osteoporosis and initiation of specific therapies in the majority of patients[92].

Available methods to measure BMD include single energy x-ray absorptiometry, DXA, quantitative computed tomography (QCT), radiographic absorptiometry, and ultrasound. DXA is the establish method to determine BMD, and routinely is measured in the hip and the lumbar spine[93].

The T score was proposed by the World Health Organization (WHO) as the strongest determinant of fracture risk. T score is defined as the number of standard deviations (SD) by which a given BMD measurement exceeds or falls below the normal mean BMD of healthy 30-year-old individuals (peak bone mass). A BMD that is up to 1 SD below the peak bone mass is considered normal; between 1 to 2.49 SD below peak BMD is considered as osteopenic and to have mild to moderate bone deficiency; and $\geqslant$ 2.5 SD below the peak BMD are labeled osteoporotic and with marked bone deficiency. Individuals who have a fracture as a result of bone fragility are considered to have severe osteoporosis[93]. The z score is useful too, and is defined as the number of SDs by which a given BMD measurements exceeds or falls below the mean BMD of healthy individuals of the same age group. For the International Society for Clinical Densitometry (ISCD), z scores are preferred, and the WHO classification should not be applied in women before menopause and in men younger than 50[94].

TREATMENT OPTIONS

Calcium and vitamin D

It is known that calcium and vitamin D are essential in the metabolism of bone and so multiple trials have studied their benefit as treatment of osteoporosis. The use of calcium or/and vitamin D or its analogues have shown, in 2 meta-analysis, 1 Cochrane Review, and in a large placebo-controlled study, to have a small benefit in BMD and a controversial age-dependant trend, and not totally clear reduction of bone fractures, specially of the spine, in postmenopausal women[95-98]. In a randomized, placebo-controlled trial in glucocorticoid-using patients with IBD, the intake of vitamin D 250 IU and calcium 1000 mg/d had no significant benefit in bone density at 1 year of follow-up[99]. So, as described in a recent

consensus report, the supplementation with calcium and vitamin D is accepted as a cost-effective medication, and essential but insufficient, in the prevention and treatment of osteoporosis. The dosage that showed best is calcium 1200 mg/d and vitamin D 800 IU/d. The maximum benefit of calcium and vitamin D will generally be derived from combination therapy with an antiresorptive agent[100].

Bisphosphonates

The group of this antiresorptive analogue of pyrophosphate includes etidronate, pamidronate, tiludronate, alendronate, risedronate, and ibandonate.

Both, alendronate and risedronate, have shown to be effective in increasing BMD and reducing fractures in spine, hip and wrist for the treatment of osteoporosis in postmenopausal women. In a systematic review, meta-analysis and double blind and randomized study, they reduce vertebral fractures by 30% to 50%, with superiority for 70 mg once-weekly alendronate than daily 5 mg or once-weekly 35 mg of risedronate, and with similar tolerability profiles, at 1 or 2 years[101-105].

For the prevention and treatment of glucocorticoid-induced osteoporosis, in a randomized, double-blind, placebo-controlled, multicenter study, in patients receiving a minimum of 7.5 mg prednisone or its equivalent for diverse pathologies, all receiving 800-1000 mg elemental calcium and 250-500 IU of vitamin D, alendronate at a dosage of 5 or 10 mg/d significantly increased bone density compared to placebo at 1 year and reduced the incidence of bone fractures too, at 2 years[106,107].

In patients with moderate to high doses of corticoid therapy, a significant increase of BMD and a reduction of 70% in vertebral fracture risk was observed with risedronate 5 mg/d compared with the placebo group ($P = 0.01$). Risedronate was efficacious, irrespective of underlying disease and duration of corticosteroid therapy, and had a favorable safety profile, with a similar incidence of upper gastrointestinal adverse events to placebo[108,109].

Etidronate have shown to be superior to placebo for increasing BMD in lumbar spine and femoral neck, and reducing incidence of vertebral fractures with no effect in non-vertebral fractures in postmenopausal women[110].

A meta-analysis reported that intermittent cyclical etidronate (400 mg/d for 14 d, followed by 500 mg calcium daily for 76 d) in corticoid treated patients was effective in preventing bone loss, increasing bone mass but with no statistical significance on reduction of fractures[111].

Other bisphosphonate approved for the treatment of osteoporosis in postmenopausal women is the ibandonate in oral dosage of 2.5 mg/d, or intravenous dosage of 2 mg every 2 mo, or 3 mg every 3 mo, had shown to be better than placebo, increasing BMD and reducing bone fractures, with superiority of intravenous regimens[112].

For corticoid-induced osteoporosis, in an open-label, single-center, parallel-group, controlled study, participants received 500 mg/d calcium plus either 3-montly intravenous injections of 2 mg ibandronate or oral 1 mg/d alfacalcidol for 3 years, showing that the increase in BMD was much greater and the fractures were lower in the ibandronate than those in alfacalcidol group[113].

For the treatment of osteoporosis in IBD, bisphosphonates have been evaluated in few studies. In a 12-mo double-blind, randomized, placebo-controlled study of 10-mg daily dose of alendronate, that include 32 patients with CD in remission and without glucocorticoid treatment the BMD of the lumbar spine increased 4.6% ± 1.2% versus a decrease of 0.9% ± 1.0% in the placebo group ($P < 0.01$). BMD of the hip increased 3.3% ± 1.5% *vs* an increase of 0.7% ± 1.1% in the placebo group ($P < 0.08$)[114].

In 31 patients with CD and 30 with UC, in a double-blind placebo-controlled study, all taking 600 mg daily of calcium, after 1 year in the risedronate group the BMD of the spine and hip significantly increase in 2% and 1.9%, respectively[115]. After one year of monthly infusions of 30 mg iv pamidronate plus 500 mg calcium with 400 IU vitamin D in patients with CD, the BMD increased 2.6% (95% CI: 1.4-3.0) at the spine and 1.6% (95% CI: 0.6-2.5) at the hip versus 1.6% (95% CI: 0.1-3.2) at the spine and 0.9% (95% CI: 0.4-2.1) at the hip in the group with vitamin D and calcium supplements[116]. Stokker PC *et al*[117] reported a significant improve in T scores of lumbar spine and hip in 49 patients with IBD that received 30 mg iv pamidronate every 3 mo, plus 1000 mg of calcium and 400 IU of vitamin D daily.

Estrogens

Estrogens alone or with progestin stop progression of bone loss in postmenopausal women, increasing the BMD and reducing the incidence of spine and hip fractures by 34%[118]. Good response in preventing bone loss in patients under glucocorticoid treatment has been observed but the effect on prevention of bone fractures remains unclear, estrogens are not recommended for this purpose[119,120].

Raloxifene, a selective estrogen receptor modulator was approved for the prevention and treatment of postmenopausal spinal osteoporosis. In a meta-analysis of 7 clinical studies, raloxifene reduced the risk of vertebral fractures by 40% with a dose of 60 mg/d[121]. No studies with raloxifene have done yet in IBD patients.

EMERGENT THERAPIES

Calcitonin

Calcitonin intranasal spray, at doses of 200 IU/d plus 1000 mg calcium and 400 IU vitamin D, has been reported to reduce the risk of spine fractures by 33% in a 5-year follow-up time in postmenopausal women[122].

The efficacy of calcitonin for fracture prevention in steroid-induced osteoporosis remains to be established[123,124]. No studies have done for IBD-associated osteoporosis.

Teriparatide

The genetically engineered fragment of human parathyroid hormone, Teriparatide, stimulates new bone formation, leading to increased BMD. Teriparatide, at 20 and 40 micrograms daily subcutaneous injection, reduced the risk of vertebral and non-vertebral fractures in postmenopausal women[125]. It's also approved for FDA to increase bone mass in men with primary or hypogonadal osteoporosis[126].

The efficacy of teriparatide in preventing of treating glucocorticoid-induced or IBD-associated osteoporosis remains to be assessed. Hodsman AB[127] suggests that should be considered as treatment for patients with established glucocorticiod-induced osteoporosis who require long-term steroid treatment.

CONCLUSION

IBD has been associated with an increased risk of osteoporosis and osteopenia and epidemiologic studies have reported an increased prevalence of low bone mass in patients with IBD. While genetics play important role, there are other factors in the pathogenesis that play an important interaction and together with environmental influence lead to the an intriguing multifactorial pathogenesis that still has gaps to be fulfilled. Through the knowledge and understanding of basic aspects of bone disease in an autoimmune gastrointestinal scenario we can find leads to a better clinical performance and to bear new diagnostic techniques and breakthrough therapies for a better outcome in IBD patients.

Abstract

AIM: To identify the relationship between DNA hypermethylation and histone modification at a hypermethylated, silenced tumor suppressor gene promoter in human gastric cancer cell lines and to elucidate whether alteration of DNA methylation could affect histone modification.

METHODS: We used chromatin immunoprecipitation (ChIP) assay to assess the status of histone acetylation and methylation in promoter regions of the *p16* and *mutL homolog 1 (MLH1)* genes in 2 gastric cancer cell lines, SGC-7901 and MGC-803. We used methylation-specific PCR (MSP) to evaluate the effect of 5-Aza-2′-deoxycytidine (5-Aza-dC), trichostatin A (TSA) or their combination treatment on DNA methylation status. We used RT-PCR to determine whether alterations of histone modification status after 5-Aza-dC and TSA treatment are reflected in gene expression.

RESULTS: For the *p16* and *MLH1* genes in two cell lines, silenced loci associated with DNA hypermethylation were characterized by histone H3-K9 hypoacetylation and hypermethylation and histone H3-K4 hypomethylation. Treatment with TSA resulted in moderately increased histone H3-K9 acetylation at the silenced loci with no effect on histone H3-K9 methylation and minimal effects on gene expression. In contrast, treatment with 5-Aza-dC rapidly reduced histone H3-K9 methylation at the silenced loci and resulted in reactivation of the two genes. Combined treatment with 5-Aza-dC and TSA was synergistic in reactivating gene expression at the loci showing DNA hypermethylation. Similarly, histone H3-K4 methylation was not affected after TSA treatment, and increased moderately at the silenced loci after 5-Aza-dC treatment.

CONCLUSION: Hypermethylation of DNA in promoter CpG islands is related to transcriptional silencing of tumor suppressor genes. Histone H3-K9 methylation in different regions of the promoters studied correlates with DNA methylation status of each gene in gastric cancer cells. However, histone H3-K9 acetylation and H3-K4 methylation inversely correlate with DNA methylation status of each gene in gastric cancer cells. Alteration of DNA methylation affects histone modification.

INTRODUCTION

Multiple recent reviews have shown that virtually all human cancer types have epigenetic abnormalities that collaborate with genetic changes to drive cancer development and progression[1-7]. Hypermethylation of DNA in promoter CpG islands of tumor suppressor genes (TSGs) is known to inhibit transcriptional initiation and cause permanent silencing of the genes, which play a crucial role in carcinogenesis[1,2]. It was reported that hypermethylation of DNA in promoter CpG islands and diminished expression are present in a number of tumor-related genes in gastric cancer, which is one of the major current causes for cancer death in Asian countries[8]. For example, silencing of the cyclin-dependent kinase inhibitor *p16* gene induced by hypermethylation can lead to disruption of cell cycle regulation and provide a growth advantage to affected cells[9]. A mismatch repair

gene, *MLH1*, is often silenced with aberrant CpG island hypermethylation in gastric cancers[10,11]. Except for DNA methylation, recent studies have demonstrated the importance of histone modification as another epigenetic mechanism in the organization of chromosomal domains and gene regulation[12-18]. Acetylation of H3-K9 and methylation of H3-K4 are associated with open chromatin configurations such as that found at transcriptionally active promoters. In contrast, methylation of H3-K9 is a marker of condensed, inactive chromatin of the sort associated with the inactive X-chromosome and pericentromeric heterochromatin[16,17,19,20].

It has also been shown that histone modification is crucial to the process of DNA methylation in some organisms and abrogation of H3-K9 methylation in Neurospora results in loss of DNA methylation[21]. It was reported that histone H3-K9 methylation directly correlates with DNA methylation of some tumor suppressor genes, while histone H3-K9 acetylation and histone H3-K4 methylation inversely correlate with DNA methylation of some tumor suppressor genes[22]. These data suggest a functional linkage between DNA methylation and histone modifications in gene repression. To better understand the relationship between DNA methylation and histone modification in cancer-associated gene silencing, we performed ChIP assay to assess the methylation and acetylation of H3-K9 and the methylation of H3-K4 at the *p16* and *MLH1* genes in two gastric cancer cell lines. We also treated the gastric cancer cell lines with the DNA methylation inhibitor, 5-Aza-dC, and the histone deacetylase inhibitor, TSA, to elucidate whether alteration of DNA methylation affects histone modification.

MATERIALS AND METHODS

Cell lines and culture conditions

Two cell lines derived from human gastric cancer, SGC-7901 and MGC-803, were cultured in RPMI 1640 supplemented with 10% fetal bovine serum(Gibco), penicillin (100 IU/mL) and streptomycin (100 μg/mL), and incubated in a humidified incubator containing 50 mL/L CO_2 at 37℃.

Treatment with 5-Aza-dC and TSA

TSA and 5-Aza-dC were purchased from Sigma. TSA was dissolved in absolute ethanol at a stock concentration of 3.3 mmol/L and stored at -80℃. 5-Aza-dC was dissolved in water at a stock concentration of 1 mmol/L and stored at -80℃. Cells were seeded at a low density in a 100 mm tissue culture dish and incubated for 24 h prior to treatment with 5-Aza-dC and TSA. 5-Aza-dC (5 μmol/L) was used for 72 h in the treatment. Culture medium containing 5-Aza-dC was exchanged every 24 h. TSA (300 nmol/L) was used for only 24 h in the treatment. 5-Aza-dC was used for 48 h followed by TSA for an additional 24 h in the combined treatment. Mock-treatment with an identical volume of absolute ethanol or water was used as a control.

Methylation-specific PCR

The genomic DNA was modified by bisulfite treatment, as described previously[23]. DNA was purified using a Wizard DNA clean-up system (Promega), precipitated with ethanol, and resuspended in 30 μL of Tris-EDTA buffer. Two microliters of the aliquot was used as a template. The primers used for MSP and additional PCR conditions are described elsewhere[22]. PCR products were separated by electrophoresis on 2% agarose gels and quantitated with the FluorChem 2.0 system. The experiment was repeated three times.

RT-PCR analysis of p16 and MLH1 expression

Total cellular RNA was extracted from each of the two cell lines with TriZOL (Invitrogen) according to the manufacturer's protocol. RNA was resuspended in nuclease-free water and quantitated with a spectrophotometer. Reverse transcription (RT) reactions were done on 2 μg of total RNA following the manufacturer's protocol (Promega). cDNA was amplified by PCR using primers as described previously. Reaction conditions for each PCR are described elsewhere[24]. PCR products were resolved on 2% agarose gels and quantitated using the Fluor Chem 2.0 system. The level was determined by quantifying the intensities of the PCR product versus *glyceraldehyde-3-phosphate dehydrogenase* (*GAPDH*). The experiment was repeated three times.

Chromatin immunoprecipitation assay

ChIP assays were performed as described previously with some modifications[24]. Briefly, proteins were cross-linked to DNA by adding formaldehyde directly into the culture medium to a final concentration of 4 g/L for 20 min at 37℃. After washing, the cell pellets were resuspended in 500 μL lysis buffer and sonicated thirty-five times, 2 s each. The average fragment size after sonication was 500 bp. The lysate (500 μL) was then divided into three fractions. The first and second fractions (200 μL each) were diluted in 1800 μL of lysis buffer, and the third fraction (100 μL) was used as an input control. The first lysate was incubated overnight at 4℃ with 5 μL anti-Lys-9 acetylated histone H3 antibody, 5 μL anti-Lys-9 dimethylated histone H3 antibody, or 5 μL anti-Lys-4 dimethylated histone H3 antibody (all antibodies from Upstate Biotechnology) overnight at 4℃. The second lysate was incubated with Tris-EDTA buffer (5 μL) as a negative control. Immune complexes were collected with 20 μL protein A-sepharose beads for 1 h at 4℃ with agitation. The cross-links were reversed by heating the sample at 65℃ for 5 h. After elution, the samples were digested with proteinase K. DNA was recovered by phenol extraction, precipitated with ethanol, and resuspended in Tris-EDTA buffer.

PCR analysis of immunoprecipitated DNA

Amplification was carried out with 2 μL of an immunoprecipitated DNA, a control without antibody or a 1:10 dilution of input DNA that was not immunoprecipitated. The primers used for ChIP and PCR conditions are described elsewhere[22]. We selected *P16-3, P16-6, MLH1-2* and *MLH1-3*. PCR products were electrophoresed on 2% agarose gels and quantitated with the FluorChem 2.0 system. The level of histone acetylation and methylation in each immunoprecipitation was measured by quantifying the intensities of the PCR product in

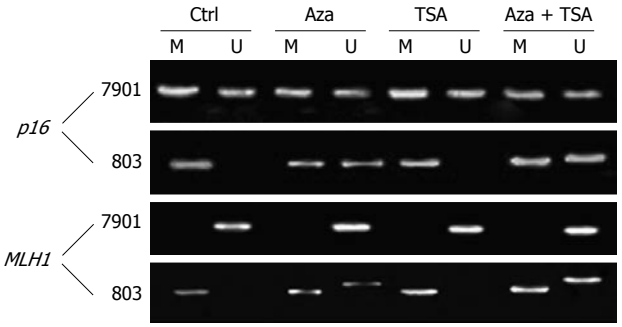

Figure 1 MSP analysis for promoter regions of gastric cancer cells after treatment with 5-Aza-dC, TSA or their combination. M: Methylated alleles; U: Unmethylated alleles; Ctrl: No treatment.

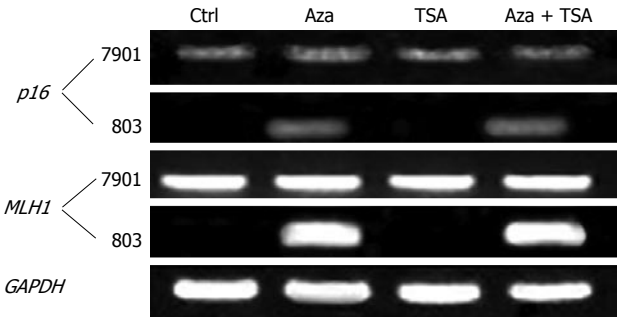

Figure 2 Expression and reactivation of *p16* and *MLH1* in gastric cancer cells after treatment with 5-Aza-dC, TSA or their combination. Ctrl: No treatment.

immunoprecipitated DNA versus input DNA diluted at 1:10 (total chromatin). The experiment was repeated three times.

RESULTS

MSP analysis for each promoter region after treatment with 5-Aza-dC, TSA or their combination

The two cell lines showed a characteristic DNA methylation status in each promoter region. As shown in Figure 1, *p16* was hypermethylated (both alleles methylated) in MGC-803 and partially methylated (only one allele methylated) in SGC-7901. *MLH1* was hypermethylated in MGC-803 but not methylated in SGC-7901.

5-Aza-dC and combined 5-Aza-dC and TSA resulted in demethylation of *p16* and *MLH1* in MGC-803, in which the silenced gene was associated with DNA hypermethylation. In contrast, TSA alone did not affect the DNA methylation status of *p16* and *MLH1*.

RT-PCR analysis for expression and reactivation of p16 and MLH1 after treatment with 5-Aza-dC, TSA or their combination

As shown in Figure 2, *p16* was expressed in SGC-7901 and minimally affected by TSA. *p16* was silenced in MGC-803 and TSA was not able to activate gene expression. In contrast, 5-Aza-dC alone reactivated expression of the *p16* in MGC-803. Similar results were obtained in *MLH1*, which was expressed in SGC-7901 but silenced in MGC-803. TSA had no effect on gene expression, while 5-Aza-dC reactivated the silenced gene. The combined

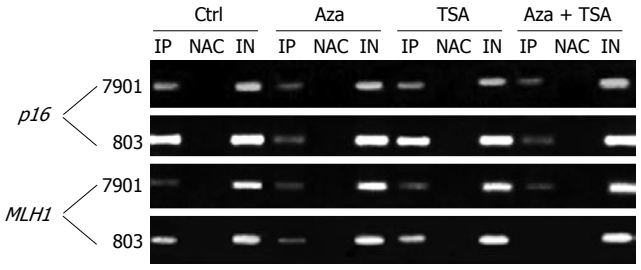

Figure 3 Status of histone H3-K9 methylation across TSGs and change in gastric cancer cells after treatment with 5-Aza-dC, TSA or their combination. Ctrl: No treatment; IP: Immunoprecipitated DNA; NAC: No-antibody control; IN: Input DNA from whole-cell lysate.

treatment with 5-Aza-dC and TSA increased gene expression.

ChIP assay for histone H3-K9 methylation across the promoter of TSG and change after treatment with 5-Aza-dC, TSA or their combination

The results of ChIP studies were almost identical in different regions of each promoter, and the values for each gene were averaged to present the data. In the promoter region of the *p16* gene, H3-K9 methylation was higher for MGC-803 than for SGC-7901. Similar results were seen at *MLH1*. SGC-7901 having no promoter DNA methylation at this locus, showed a low degree of H3-K9 methylation. MGC-803 had a higher degree of H3-K9 methylation across the promoter (Figures 3 and 4).

TSA alone had no effect on H3-K9 methylation, irrespective of DNA methylation status. In contrast, 5-Aza-dC had effects on H3-K9 methylation at the silenced loci, reducing histone H3-K9 methylation in the promoter showing partial methylation or hypermethylation (the promoter region of *p16* in both cell lines and the promoter region of *MLH1* in MGC-803). The combination of 5-Aza-dC and TSA had similar effects on histone H3-K9 methylation.

ChIP assay for histone H3-K9 acetylation across the promoter of TSG and change after treatment with 5-Aza-dC, TSA or their combination

The promoter region of the *p16* gene showed a higher degree of H3-K9 acetylation in SGC-7901 (partially methylated) than in MGC-803 (hypermethylated). Similar results were seen in the *MLH1* gene showing a low degree of H3-K9 acetylation in all parts of the promoter region in MGC-803. In contrast, a higher degree of H3-K9 acetylation was detected in SGC-7901 (both alleles non-methylated) at all *MLH1* regions studied (Figures 4 and 5A).

For the *p16* gene, treatment with TSA alone had no effect on H3-K9 acetylation in the SGC-7901 (partial DNA methylation) but slightly increased H3-K9 acetylation in the silenced MGC-803. Identical results were seen in *MLH1*. 5-Aza-dC increased H3-K9 acetylation at the loci with DNA hypermethylation (*p16* and *MLH1* in MGC-803) but had no effect on the loci with partial or no DNA methylation (*p16* and *MLH1* in BGC-7901). However, the combination of 5-Aza-dC and TSA increased H3-K9

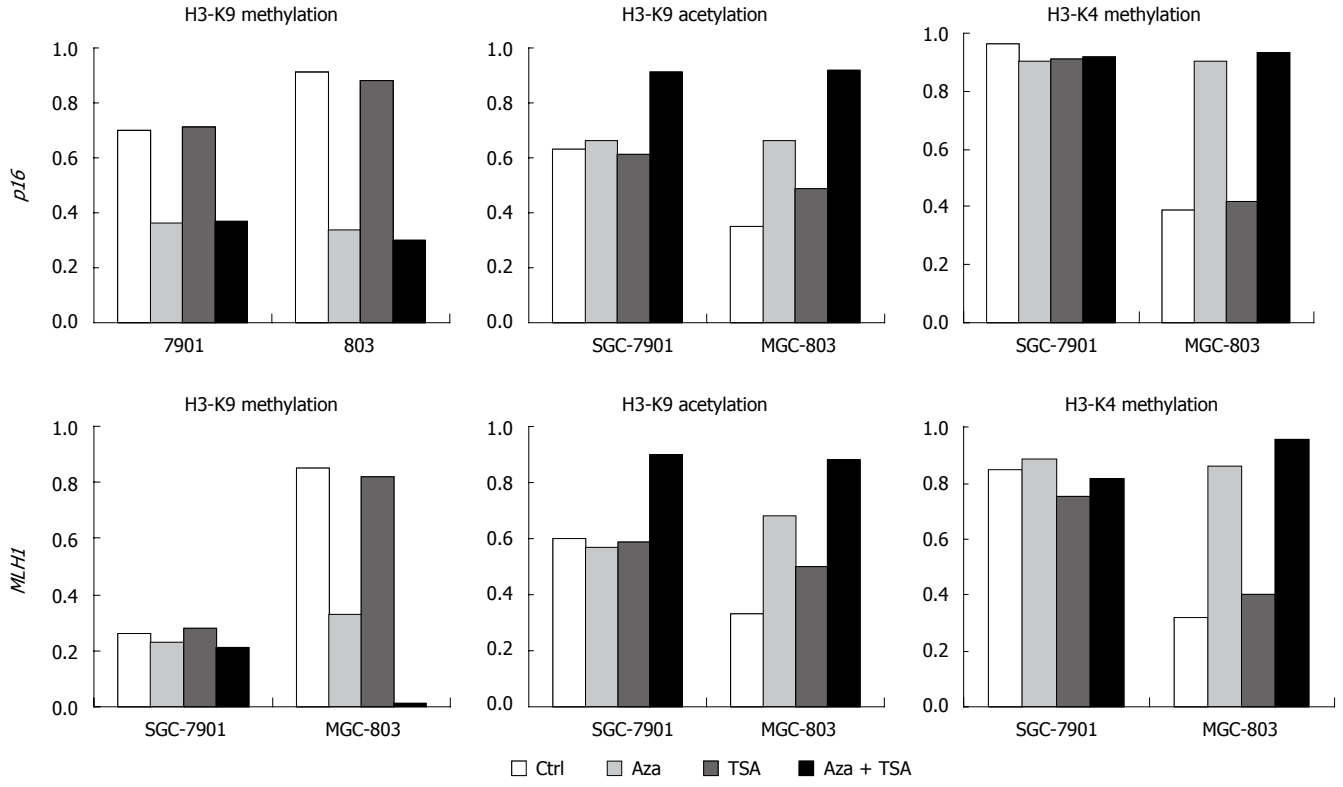

Figure 4 Summary of quantitative analysis for ChIP assays. Ratios of precipitated DNA over input DNA were used to calculate the relatively precipitated fold enrichment on the y axis.

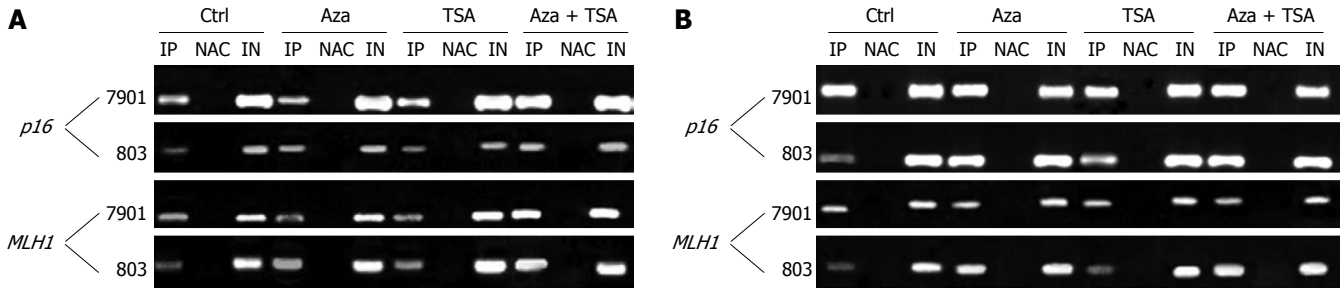

Figure 5 Status of histone H3-K9 acetylation (**A**) and histone H3-K4 methylation (**B**) across TSGs and change in gastric cancer cells after treatment with 5-Aza-dC, TSA or their combination. acetylation effectively at all loci irrespective of DNA methylation status. The results of ChIP studies were almost identical in different regions of each promoter.

ChIP assay for histone H3-K4 methylation across the promoter of TSG and change after treatment with 5-Aza-dC, TSA or their combination

For the *p16* and *MLH1* genes, H3-K4 methylation was higher in SGC-7901 than in MGC-803. TSA did not affect H3-K4 methylation. However, 5-Aza-dC, or the combination of 5-Aza-dC and TSA, increased H3-K4 methylation at all silenced loci in MGC-803. Little change in H3-K4 methylation was observed in SGC-7901, where only partial or no methylation was observed (Figures 4 and 5B).

DISCUSSION

Silencing of tumor suppressor genes is related to epigenetic regulation of both DNA methylation and histone modification[25]. In the present study, hypermethylation in promoter CpG islands was significantly associated with *p16* and *MLH1* silencing. Furthermore, aberrantly silenced and DNA hypermethylated genes in gastric cancer cells were characterized by histone H3-K9 hypermethylation, H3-K4 hypomethylation and H3-K9 hypoacetylation.

DNA methylation and histone modification may act synergistically or antagonistically on gene expression[26,27]. We carried out ChIP assays to explore the relationship between DNA methylation and histone modifications. ChIP is a powerful technique to test for the presence of certain DNA-binding proteins that might modulate chromatin structure and/or transcriptional characteristics of the specific region of DNA with which they are associated. We made use of polyclonal antibodies generated against methylated and acetylated histone H3, all of which are proteins linked to chromatin modification

and regulation of transcription. In colorectal cancer, histone H3-K9 methylation directly correlates and histone H3-K4 methylation inversely correlates with DNA methylation of *p16, MLH1* and the O6-methylguanine-DNA methyltransferase gene, *MGMT*[22]. We demonstrated that histone H3-K9 methylation correlated, and histone H3-K9 acetylation and H3-K4 methylation inversely correlated very well with DNA methylation of *p16, MLH1* in SGC-7901 and MGC-803.

To further explore the relationship between DNA methylation and histone modification, we treated cancer cells with 5-Aza-dC and TSA. 5-Aza-dC, a DNA methyltransferase inhibitor, is sufficient to cause demethylation of the promoter region and reactivate expression of the hypermethylated, silenced gene[28,29]. TSA, a specific histone deacetylase (HDAC) inhibitor, has been permitted evaluation of the role of HDAC in silencing a variety of methylated genes[14]. It was reported that re-expression of DNA hypermethylated and silenced cancer genes can be induced through 5-Aza-dC-induced DNA demethylation, demethylated genes and the active marks, acetylated H3-K9 and methylated H3-K4 can be detected in HCT116 and DKO colon cancer[29-34]. However, one silencing mark, dimethylated H3-K9, is strikingly decreased[34]. In our study, when the CpG islands were hypermethylated, TSA increased histone acetylation, but had almost no effect on gene expression. In contrast, 5-Aza-dC reactivated expression of hypermethylation-induced silenced genes. Our findings on histone acetylation are consistent with previous reports linking the effect of DNA methylation and histone deacetylation on transcriptional silencing, demonstrating that DNA methylation is dominant over histone deacetylation in maintaining a silent state at hypermethylated promoters[22]. Furthermore, TSA and 5-Aza-dC play a different role in histone methylation. In the present study, 5-Aza-dC, but not TSA, could reactivate expression of the silenced genes and completely reverse key histone methylations surrounding the gene promoter, indicating that reactivation of silenced genes correlates much better with decreased histone H3-K9 methylation and increased H3-K4 methylation than with increased H3-K9 acetylation. We speculate that histone methylation plays a critical role in the maintenance of promoter DNA methylation-associated gene silencing in gastric cancer.

After 5-Aza-dC treatment, we observed a complete reversal of histone modification at the *p16* and *MLH1* promoter in MGC-803 cells. Acetylated H3-K9 and methyl-H3-K4 levels were increased, whereas methyl-H3-K9 levels decreased, suggesting that DNA hypermethylation may be essential for maintaining histone modification at gene promoters silenced due to aberrant DNA hypermethylation. DNA methylation plays a direct role in both genes silencing and maintaining a repressive histone modification at a hypermethylated gene promoter in cancer. Data show that DNMT1 interacts with HDAC activity in complexes bound to DNA, suggesting that it can recruit histone modifiers to DNA[33-35]. It was reported that DNA modification itself, or components of the DNA methylating machinery such as DNMTs or methyl-CpG binding proteins, can directly interact with histone methyltransferases or proteins in regions containing DNA methylation and allow them to set up an alterative histone modification[2], showing that histone methylation depends on DNA methylation.

COMMENTS

Background

Gastric cancer is a malignant tumor threatening human health worldwide. It has been shown that epigenetic mechanism plays an important role in the occurrence and development of gastric cancer. However, the role of histone modification and the relationship between DNA hypermethylation and histone modification at a hypermethylated, silenced tumor suppressor gene promoter in human gastric cancer remain unclear.

Research frontiers

Histone modification plays a prominent role in the epigenetic regulation of gene transcription. There is evidence that dysregulation of epigenetic process causes transcriptional repression of a subset of genes, contributing to the pathogenesis of many cancers. The relationship between aberrant epigenetic changes and tumorigenesis is still to be identified.

Innovations and breakthroughs

In some cancers, histone H3-K9 methylation directly correlates and histone H3-K4 methylation inversely correlates with DNA methylation of some TSGs. Our findings may reflect the mechanism underlying inactivation of tumor suppressor genes by DNA hypermethylation and histone modification during gastric tumorigenesis. DNA methylation may affect histone modification in human gastric cancer.

Applications

Reactivation of the *p16* and *MLH1* gene by DNA methyltransferase inhibitor alone or in combination with histone deacetylase inhibitor suggests that the two agents can be used in treatment of gastric cancer.

Terminology

Histone is the major component of chromatin functioning as a DNA packaging unit and as a transcriptional regulator. The amino-terminal tails of histones protrude from the nucleosome and are subjected to chemical modifications including phosphorylation, acetylation and methylation. These modifications of histones affect the access of regulatory factors and complexes to chromatin and influence gene expression. These different combinations of histone modifications at different residues may act synergistically or antagonistically on gene expression.

Peer review

This is an important and interesting study, and the manuscript is well-written. The major finding in this paper is that treatment with 5-Aza-dC, a DNA methylation inhibitor and TSA, a histone deacetylase inhibitor, affects the expression of tumor suppressor genes, including *p16* and *MLH1*, by reversing the hypermethylation and inhibiting histone deacetylation in human gastric cancer cells.

Abstract

AIM: To investigate the effect of exogenous erythropoietin (EPO) administration on acute lung injury (ALI) in an experimental model of sodium taurodeoxycholate-induced acute necrotizing pancreatitis (ANP).

METHODS: Forty-seven male Wistar albino rats were randomly divided into 7 groups: sham group (n = 5), 3 ANP groups (n = 7 each) and 3 EPO groups (n = 7 each). ANP was induced by retrograde infusion of 5% sodium taurodeoxycholate into the common bile duct. Rats in EPO groups received 1000 U/kg intramuscular EPO immediately after induction of ANP. Rats in ANP groups were given 1 mL normal saline instead. All animals were sacrificed at postoperative 24 h, 48 h and 72 h. Serum amilase, IL-2, IL-6 and lung tissue malondialdehyde (MDA) were measured. Pleural effusion volume and lung/body weight (LW/BW) ratios were calculated. Tissue levels of TNF-α, IL-2 and IL-6 were screened immunohistochemically. Additionally, ox-LDL accumulation was assessed with immune-fluorescent staining. Histopathological alterations in the lungs were also scored.

RESULTS: The mean pleural effusion volume, calculated LW/BW ratio, serum IL-6 and lung tissue MDA levels were significantly lower in EPO groups than in ANP groups. No statistically significant difference was observed in either serum or tissue values of IL-2 among the groups. The level of tumor necrosis factor-α (TNF-α) and IL-6 and accumulation of ox-LDL were evident in the lung tissues of ANP groups when compared to EPO groups, particularly at 72 h. Histopathological evaluation confirmed the improvement in lung injury parameters after exogenous EPO administration, particularly at 48 h and 72 h.

CONCLUSION: EPO administration leads to a significant decrease in ALI parameters by inhibiting polymorphonuclear leukocyte (PMNL) accumulation, decreasing the levels of proinflammatory cytokines in circulation, preserving microvascular endothelial cell integrity and reducing oxidative stress-associated lipid peroxidation and therefore, can be regarded as a cytoprotective agent in ANP-induced ALI.

INTRODUCTION

Acute pancreatitis (AP) is a life-threatening necro-inflammatory disease with significant morbidity and mortality rates, especially when complicated by systemic inflammatory response syndrome (SIRS) and multiple organ failure (MODS)[1,2]. Death occurs in 60% of the patients within the first 6 d of disease onset and pulmonary complications including acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)

account for a significant number of these deaths[3]. The exact mechanisms by which diverse etiological factors induce an attack are indefinite, but once the disease process is initiated, common inflammatory and repair pathways are invoked. Within the first few days following the onset of AP, lung injury occurs as a consequence of AP, whereas sepsis is a dominant cause for lung injury and mortality in the later phase of the disease process[4]. Despite improved understanding of the pathogenesis of ARDS, pharmacological modalities are ineffective in decreasing its mortality. None of the randomized clinical trials using novel therapeutic agents has demonstrated an improvement in patient outcome. Consequently, effective therapeutic interventions are thus called for.

Erythropoietin (EPO), a 30.4-kDa glycoprotein and a member of the type I cytokine superfamily, was first introduced as a hormone that regulates erythroid progenitors within the bone marrow to mature into erythrocytes, through binding to its specific cell surface receptors[5]. Hence, EPO is approved for the treatment of anemia as a consequence of a variety of disorders. In the current era, the premise that EPO is essential only for erythropoiesis has been changed according to the researches demonstrating the existence of EPO and its receptor in other organs and tissues outside of liver and kidney, such as brain, heart, pancreas, as well as vascular, gastrointestinal and reproductive systems[6,7]. Beyond its hematopoietic properties, EPO modulates a broad array of vital cellular processes including progenitor stem cell development, cellular integrity, and angiogenesis[8,9]. Additionally, in various tissues, EPO inhibits the apoptotic mechanisms of injury, including preservation of cellular membrane asymmetry to prevent inflammation[10-12]. Experimental evidence supports a vigorous cytoprotective effect and EPO is now considered to have applicability in a variety of disorders, such as cerebral ischemia, myocardial infarction, and chronic congestive heart failure[12-15]. Wu *et al*[16] demonstrated that pretreatment with EPO appears to attenuate ischemia-reperfusion-induced lung injury. This function is partly related with the ability of EPO to inhibit the accumulation of polymorphonuclear leukocytes (PMNL) in lung tissue and decrease the systematic expression of tumor necrosis factor-α (TNF-α). In addition to these studies, it has been reported that EPO can attenuate different kinds of lung injuries, showing that rats exposed to hyperoxia exhibit well-maintained alveolar structure and enhanced vascularity when treated with EPO[17]. Importantly, EPO can protect the ultrastructure of tracheobronchial epithelia and pulmonary type Ⅱ epithelia of rats during traumatic brain injury[18,19].

AP associated lung injury is a multifactorial phenomenon with various phases. In the light of the above-mentioned findings, the present study was to evaluate the hypothesis that EPO administration offers pulmonary protective effect against pancreatitis induced lung injury in rats.

MATERIALS AND METHODS

Animals

Forty-seven male Wistar albino rats weighing 250-300 g were housed under constant temperature (22℃) and humidity in a 12-h dark/light cycle.

Experimental design

The experiments were conducted following the Ethic Committee Faculty of Medicine, University of Zonguldak Karaelmas guiding principles for the care and use of laboratory animals. The animals were randomized into seven experimental groups as follows: sham group in which rats received sham operation (n = 5), 3 ANP groups in which acute necrotizing pancreatitis (ANP) was induced by retrograde infusion of sodium taurodeoxycholate and 1 mL normal saline (0.9% NaCl) was given intramuscularly immediately after induction of AP (n = 7 each), 3 EPO groups in which AP was induced by the same way and 1000 U/kg EPO (Eprex, Epoetin alfa, Janssen-Cilag AG, Sweden) was injected intramuscularly immediately after induction of AP. All animals in the ANP and EPO groups were sacrificed at postoperative 24 h, 48 h and 72 h, respectively. Histopathological, biochemical and immunohistochemical evaluations were performed.

Induction of acute pancreatitis

Anesthesia was induce by injecting ketamine HCL at 100 mg/kg im and laparotomy was performed under strict sterile conditions. An upper midline abdominal incision was made to identify the common pancreaticobiliary duct. The duodenal wall was punctured at its antimesenteric aspect with a 24-gauge Ⅳ catheter (Novacath, Medipro A.Ş., Istanbul, Turkey). The catheter was advanced 5 mm into the common duct through the papilla of Vater. ANP was induced by retrograde infusion of 0.2 mL 5% sodium taurodeoxycholate (Sigma, St.Louis, MO, USA) over 3 min using an infusion pump as previously described[20] and the pacreaticobiliary duct was clamped near the liver hilum throughout the inraductal infusion in all groups, except for sham group. Animals in sham group were subjected to anesthesia, laparotomy and duodenal manipulation, but not to biliopancreatic duct cannulation. The midline incision was closed in two layers with 4/0 silk suture (Ethicon, Edinburg, UK). Rats were allowed to recover from anesthetic and returned to their cages with free access to water and food after surgery.

Sampling procedures

All the rats were sacrificed by aortic puncture method. The abdominal and thoracic cavities were entered to obtain blood and lung samples. Blood samples were centrifuged at 1800 × g for 15 min at 4℃ to obtain plasma and stored at -80℃ for biochemical analysis. Then, the rats were killed with the lung removed immediately. Random cross-sections of the lung tissue were fixed in 10% neutral phosphate-buffered formalin and embedded in paraffin wax for histopathological examination. Samples of lung tissue were weighed and stored at -85℃ for subsequent biochemical and immunohistochemical measurements.

Assessment of pulmonary effusion

The thorax was opened to collect pleural effusion (PE) by suction which was measured volumetrically. Care was also taken to eliminate blood contamination with PE. The

lungs were then removed and all surrounding tissues were dissected and weighed with an analytical balance. The volume of PE (mL) and the lung weight/body weight (LW/BW) ratios were calculated and considered as an index of pulmonary edema.

Biochemical analysis

Serum amylase, IL-2 and IL-6 assay: Serum amylase levels were measured by a Beckman Coulter LX-20® system analyzer (Fullerton, CA, USA) using Beckman kits (Fullerton, CA, USA), following the manufacturer's instructions. IL-2 and IL-6 levels in the serum were measured with commercially available kits (Biosource International, Commercial ELISA Kit, California, USA).

Lung tissue malondialdehyde (MDA) assay: MDA levels in the lung tissue were measured in tissue homogenate. In brief, tissue was homogenized with cold 1.15% KCl to make a 10% homogenates, and 0.2 mL of 8.1% SDS, 1.5 mL of 20% acetic acid solution adjusted to pH 3.5 with NaOH and 1.5 mL of 0.8% aqueous solution of thiobarbituric acid were added to 0.2 mL of 10% tissue homogenates. The mixture was made up to 4.0 mL with distilled water and heated in an oil bath at 95℃ for 60 min. After cooling with tap water, 1.0 mL of distilled water and 5.0 mL of the mixture of n-butanol and pyridine (15:1, v/v) were added and the solution was shaken vigorously. After centrifugation at 4000 r/min for 10 min, the organic layer was taken with its absorbance measured at 532 nm on a Shimadzu UV 1601 spectrophotometer. As a standard, 1.1.3.3 tetraetoxypropane was used. MDA concentration per gram tissue was calculated (nmol/gr tissue).

Immunohistochemical method for screening IL-2, IL-6 and TNF-α in the lung tissue: Cryostat sections of lung tissue (7 μm) were fixed with absolute ethanol and stained with avidin biotin complex based immunohistochemical method. Immunohistochemistry was performed to observe peroxidase diaminobenzidine reaction. Cytokine staining was performed with biotinylated mouse anti-rat IL-2, IL-6, TNF-α antibodies (Biosource International, California, USA). Streptavidin-peroxidase (HRP) and diaminobenzidine (DAB) were purchased from DAKOCytomation (Denmark). Ethanol-fixed tissue sections were treated with biotinylated mouse anti-rat IL-2, IL-6 and TNF-α for 30 min, washed three times with PBS, incubated for an additional 30 min with streptavidin-HRP and washed three times with PBS. The sections were then treated with 0.03% 3, 3-diamino benzidine tetrahydrochloride plus 0.01% hydrogen peroxide in 50 mmol/L Tris-HCl buffer (pH 7.4) for 10 min. All incubations were performed at room temperature. The sections were examined under a light microscope by an independent observer, blind to the study.

Immune-fluorescent staining method for screening ox-LDL in the pancreas and lung tissues: Rat lung and pancreas were obtained and stored at -85℃. Slides were prepared from the 7 μm-thick frozen lung biopsy sections. Slides were further divided into two pieces: one for the test and the other for the negative control. Thirty μL human polyclonal anti-ox-LDL IgG solution as primary antibody was added only on the test slides and the control slides were manipulated with phosphate- buffered solution (PBS) as the same amount of primary antibody. After a 30-min incubation in a humid chamber at room temperature, both the control and test slides were washed with phosphate-buffered saline and 30 μL fluorescent isothiocyanate (FITC)-labeled anti human IgG was administered as a conjugate substance. The slides were incubated for a further 30 min at room temperature and washed with the standard PBS solution. After drying, the slides were covered with a mounting medium and examined under a fluorescent microscope (LEICA DMRX, Germany).

Histopathologic analysis

The lung tissue samples were fixed in 10% formalin immediately after removal, embedded in paraffin, sectioned at 5 μm intervals, stained with hematoxylin and eosin, and examined under a light microscope. Histopathological evaluation and scoring of the parameters were performed by a single pathologist unaware of the treatment groups. Morphometric analysis of histological sections was accomplished with the point counting technique. For this purpose, we used an optical microscope provided with an integrating eyepiece containing 100 points and 50 lines. The following parameters were evaluated as previously described[21,22].

Alveolar distension and collapse index: At a magnification of × 100, we analyzed 10 randomly selected fields of the proximal and 10 fields of the distal sections. We designated grades 0, 1, 2, and 3 to microscopic fields respectively as 0%, 25%, 50%, and over 50% of the area with either alveolar distension or alveolar collapse.

Alveolar edema index: At a magnification of × 400, we analyzed 10 randomly selected fields of the proximal and 10 fields of the distal sections. The relationship between the number of points of the eyepiece falling on alveolar edema and the number of points falling on the whole alveolar lumen was determined.

Alveolar cellularity index: We analyzed 10 microscopic fields from each lung slide at a magnification of × 1000. The alveolar cellularity index was obtained by the relationship between the lines of the integrating eyepiece crossing a nucleus and the lines crossing alveolar septa.

Polymorphonuclear cell (PMNL) index: We analyzed 10 microscopic fields from each lung slide at a magnification of × 1000. PMNL index was obtained by the relationship between the lines of the integrating eyepiece crossing a nucleus and the lines crossing alveolar septa.

Statistical analysis

Statistical analysis was performed using SPSS version 11.5 for Windows XP. The results were expressed as mean + standard deviation (SD). The differences in serum amylase, IL-2 and IL-6 were assessed by Welch test and *post hoc* Games-Howell test or one way ANOVA and *post hoc* Tukey

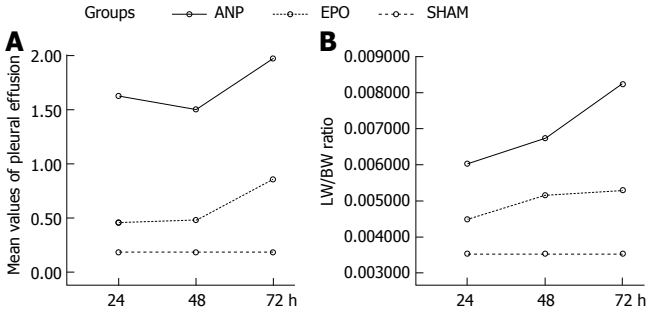

Figure 1 Values of pleural effusion volumes (**A**) and calculated LW/BW ratios (**B**) (mean ± SD).

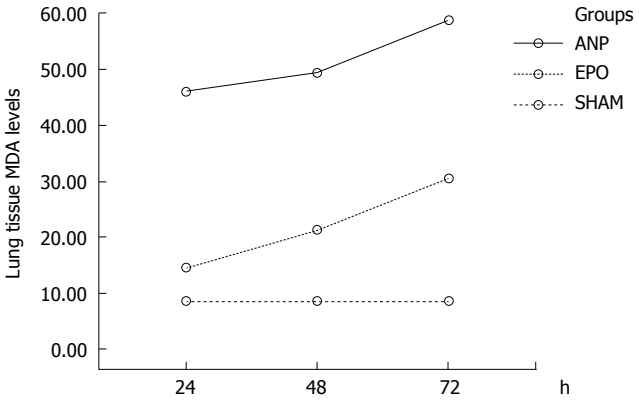

Figure 2 Values of MDA in lung tissue (mean ± SD).

HSD test where appropriate. The differences betweeen groups (ANP, EPO, sham), time course (three different hours) and its interaction in terms of tissue MDA levels, pulmonary effusion volume, calculated LW/BW ratio, and mean histopathological scores, were analyzed by factorial analysis of variance with a single control. $P < 0.05$ was considered statistically significant.

RESULTS

Pleural effusion and LW/BW ratio

The mean pleural effusion volume (mL) and the calculated LW/BW ratio were significantly increased in ANP groups when compared to EPO groups ($P < 0.0001$). The mean ± SD volume of pleural effusion measured was 1.62 ± 1.08 mL, 1.5 ± 0.33 mL and 1.97 ± 0.39 mL in 3 ANP groups and 0.45 ± 0.37 mL, 0.48 ± 0.38 mL and 0.85 ± 0.13 mL in 3 EPO groups, respectively. No statistically significant difference was detected between sham and EPO groups (0.18 ± 0.08 mL *vs* 0.45 ± 0.37 mL, 0.48 ± 0.38 mL and 0.85 ± 0.13 mL, $P > 0.05$ for each). The volume of pleural effusion was statistically significant higher in ANP groups than in sham group (0.18 ± 0.08 mL *vs* 1.62 ± 1.08 mL, 1.5 ± 0.33 mL and 1.97 ± 0.39 mL, $P < 0.001$ for each).The time course of pleural effusion volume in 3 ANP groups is shown in Figure 1A. In terms of LW/BW ratio, a statistically significant difference was seen from 24 h to 72 both in 3 ANP groups (0.006 ± 0.0022 *vs* 0.008 ± 0.0019, $P < 0.05$) and in 3 EPO groups (0.004 ± 0.0008 *vs* 0.005 ± 0.0011, $P < 0.05$) and the mean calculated ratio was higher at 72 h for each. In comparison to sham group, no statistically significant difference was found in EPO groups (0.003 ± 0.0004 *vs* 0.004 ± 0.0008, 0.005 ± 0.0009 and 0.005 ± 0.0011, $P > 0.05$), where as ANP resulted in a significant increase in calculated LW/BW ratio at 24 h, 48 h, and 72 h (0.003 ± 0.0004 *vs* 0.006 ± 0.0022, 0.007 ± 0.0016, and 0.008 ± 0.0019, $P < 0.05$ for each) (Figure 1B). The pleural effusion values and LW/BW ratio are listed in Table 1.

Biochemical analysis

Serum amylase, IL-2 and IL-6 assay: A statistically significant increase was detected in the mean ± SD serum levels of amylase in 3 ANP groups when compared to sham group (534 ± 124 u/L *vs* 3502 ± 1830 u/L, 3759 ± 1505 u/L and 5056 ± 1872 u/L, $P < 0.05$ for each). The mean ± SD value of serum amylase was 3502 ± 1830 u/L, 3759 ± 1505 u/L and 5056 ±1872 u/L in 3 ANP groups and 1523 ± 514 u/L, 2317 ± 311 u/L and 735 ± 454 u/L in 3 EPO groups, respectively. On the other hand, no statistically significant difference was found between the ANP and EPO groups with respect to the time intervals ($P > 0.05$). The serum levels of IL-6 were significantly lower in 3 EPO groups than in 3 ANP groups ($P = 0.001$ for each). The IL-6 value (mean ± SD) was 24.4 ± 3.26 pg/mL, 27.7 ± 3.74 pg/mL and 33.2 ± 2.1 pg/mL respectively in 3 ANP groups, and 12.2 ± 2.15 pg/mL, 12.8 ± 1.89 pg/mL and 13.8 ± 3.24 pg/mL respectively in 3 EPO groups. We did not observe any statistically significant difference in IL-2 values among these groups (7.4 ± 2.88 pg/mL *vs* 7.7 ± 3.17 pg/mL, 9.3 ± 2.74 pg/mL, 7.2 ± 3.1 pg/mL, 6.9 ± 2.04 pg/mL, 7.7 ± 2.93 g/mL and 10.6 ± 3.9 pg/mL, $P > 0.005$ for each). The mean ± SD values of serum amylase, IL-2, IL-6 and tissue MDA are listed in Table 2.

Lung tissue MDA assay: Pulmonary injury in ANP groups was characterized by an increase in lung tissue MDA levels, an indicator of lipid peroxidation. The lung tissue MDA levels were significantly reduced in EPO groups at 24 h, 48 h, and 72 h, when compared to ANP groups ($P < 0.0001$). The MDA value (mean ± SD) was 45.9 ± 6.8 nmol/gr tissue, 49.3 ± 9.5 nmol/gr tissue, and 58.8 ± 9 nmol/gr tissue respectively in 3 ANP groups and 14.7 ± 2.1 nmol/gr tissue, 21.2 ± 2.7 nmol/gr tissue, and 30.4 ± 2.1 nmol/gr tissue respectively in 3 EPO groups. A statistically significant increase in MDA values was noted at 24 h-72 h (45.9 ± 6.8 nmol/gr tissue *vs* 58.8 ± 9 nmol/gr tissue, and 14.7 ± 2.1 nmol/gr tissue *vs* 30.4 ± 2.1 nmol/gr tissue, $P < 0.0001$) and 48 h to 72 h (49.3 ± 9.5 nmol/gr tissue *vs* 58.8 ± 9 nmol/gr tissue and 21.2 ± 2.7 nmol/gr tissue *vs* 30.4 ± 2.1 nmol/gr tissue, $P = 0.001$) in either ANP or EPO groups. The mean MDA value was higher at 72 h. In comparison with sham group, the MDA levels were significantly higher in all the other groups (8.5 ± 3.1 nmol/gr tissue *vs* 45.9 ± 6.8 nmol/gr tissue, 49.3 ± 9.5 nmol/gr tissue, 58.8 ± 9 nmol/gr tissue, 21.2 ± 2.7 nmol/gr tissue, and 30.4 ± 2.1 nmol/gr tissue, $P < 0.001$ for each) except for EPO groups at 24 h (8.5 ± 3.1 nmol/gr tissue *vs* 14.7 ± 2.1 nmol/gr tissue, $P = 0.224$) (Figure 2).

Table 1 Pleural effusion volume and LW/BW ratios in different groups (mean ± SD)

Groups	Sham	ANP1	ANP2	ANP3	EPO1	EPO2	EPO3
Pleural effusion (mL)	0.18 ± 0.08	1.62 ± 1.08	1.5 ± 0.33	1.97 ± 0.39	0.45 ± 0.37	0.48 ± 0.38	0.85 ± 0.13
LW/BW ratio	0.003 ± 0.0004	0.006 ± 0.0022	0.007 ± 0.0016	0.008 ± 0.0019	0.004 ± 0.0008	0.005 ± 0.0009	0.005 ± 0.0011

Table 2 Serum amylase, IL-6, IL-2 and tissue MDA levels in different groups (mean ± SD)

Groups	Sham	ANP1	ANP2	ANP3	EPO1	EPO2	EPO3
Amylase (U/L)	534 ± 124	3502 ± 1830	3759 ± 1505	5056 ± 1872	1523 ± 514	2317 ± 311	735 ± 454
IL-6 (pg/mL)	4.7 ± 2.01	24.4 ± 3.26	27.7 ± 3.74	33.2 ± 2.1	12.2 ± 2.15	12.8 ± 1.89	13.8 ± 3.24
IL-2 (pg/mL)	7.4 ± 2.88	7.7 ± 3.17	9.3 ± 2.74	7.2 ± 3.1	6.9 ± 2.04	7.7 ± 2.93	10.6 ± 3.9
MDA (nmol/gr tissue)	8.5 ± 3.1	45.9 ± 6.8	49.3 ± 9.5	58.8 ± 9	14.7 ± 2.1	21.2 ± 2.7	30.4 ± 2.1

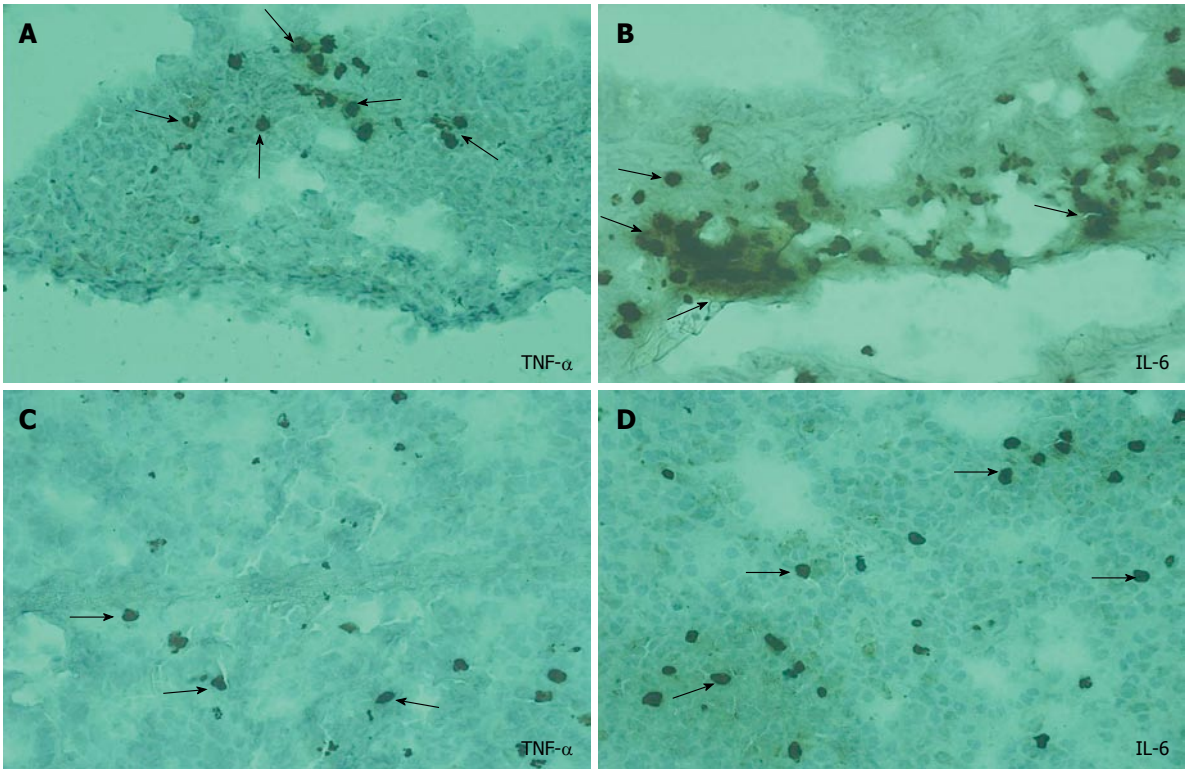

Figure 3 Light microscopic view of immunohistochemical staining for intracellular accumulations of TNF-α and IL-6 in the lung sections of ANP groups (**A** and **B**) and EPO groups (**C** and **D**) at 72 h. Arrows indicate the significantly positive staining in ANP groups (**A** and **B**) and less intensive immnunohistochemical staining in EPO groups (**C** and **D**).

Immunohistochemical screening: The intracellular accumulation of TNF-α and IL-6 was evident in the lung tissues of ANP groups (Figure 3A and B) when compared to EPO groups, particularly at 72 h (Figure 3C and D). No significant difference in IL-2 accumulation was detected among the groups.

Immune-fluorescent screening of ox-LDL: As we did not observe any positive immunofluorescent staining either in pancreas or in lung tissue of sham and EPO groups, a significant positive staining for ox-LDL was determined in ANP groups, which became much evident at 72 h (Figure 4A and B).

Histopathologic analysis

Alveolar distention and collapse: Alveolar distention and collapse were significantly intense in ANP groups at 24 h, 48 h and 72 h when compared to EPO groups ($P < 0.0001$). The alveolar distention and collapse scores (mean ± SD) for ANP and EPO groups calculated at 24 h, 48 h and 72 h were 0.85 ± 0.69, 1.57 ± 0.78, and 1.71 ± 0.75 *vs* 0.71 ± 0.75, 1 ± 0.57 and 0.42 ± 0.53 respectively. Only ANP groups demonstrated a significant difference at 72 h in comparison with sham (1.71 ± 0.75 *vs* 0.4 ± 0.54, $P = 0.03$) (Figure 5A).

Alveolar edema index: Alveolar edema index was

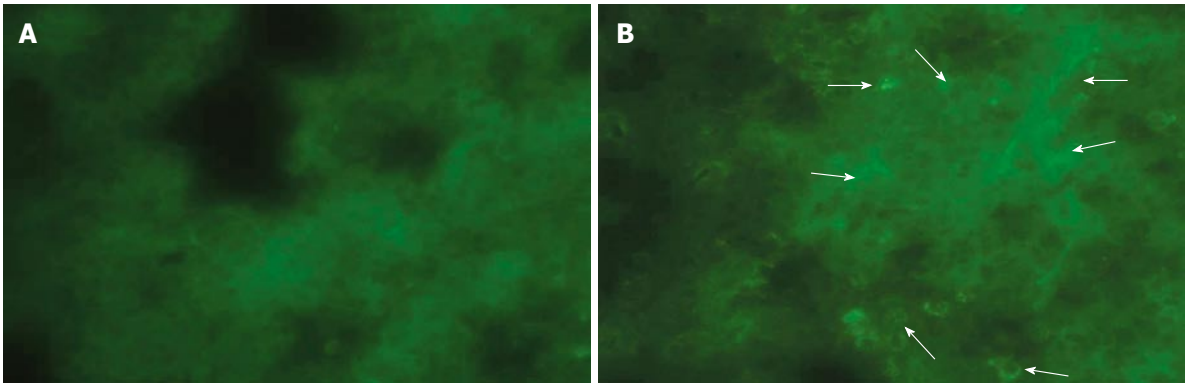

Figure 4 Lung tissue sections from EPO groups and ANP groups showing no fluorescent staining (**A**) and positive fluorescent staining (**B**) at 72 h. Arrows indicate the accumulation areas of ox-LDL in the lung.

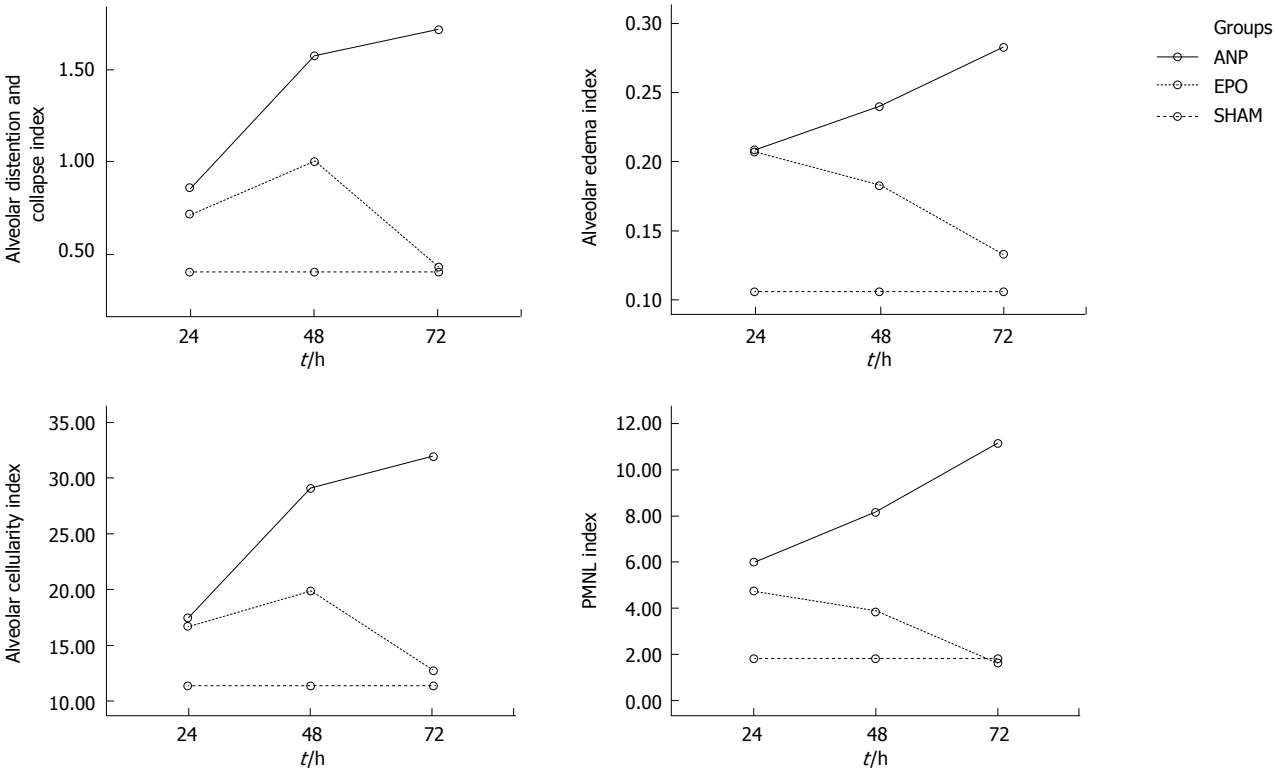

Figure 5 Mean values of alveolar distension and collapse index (**A**), alveolar edema index (percentage of the alveolar lumen filled with edema) (**B**), alveolar cellularity index (**C**) and polymorphonuclear cell index (**D**) obtained in the seven groups.

significantly different both in ANP groups and in EPO groups depending on the time course ($P = 0.002$). Alveolar edema was more intense in ANP groups at 48 h and 72 h, when compared to EPO groups (0.24 ± 0.05 *vs* 0.18 ± 0.03, $P < 0.05$ and 0.28 ± 0.03 *vs* 0.13 ± 0.04, $P < 0.01$). Moreover, at 72 h the mean alveolar edema index determined was the highest in ANP groups and the lowest in EPO groups (0.28 ± 0.03 *vs* 0.13 ± 0.04). In comparison with sham group, ANP groups had a significantly increased mean alveolar edema index at 24 h, 48 h and 72 h (0.1 ± 0.02 *vs* 0.2 ± 0.08, $P = 0.019$; 0.1 ± 0.02 *vs* 0.24 ± 0.05, $P = 0.001$; and 0.1 ± 0.02 *vs* 0.28 ± 0.03, $P = 0.0001$; respectively). On the other hand, no statistically significant difference was detected between sham group and EPO groups at 48 h and 72 h (0.1 ± 0.02 *vs* 0.18 ± 0.03, $P = 0.149$ and 0.1 ± 0.02 *vs* 0.13 ± 0.04, $P = 0.968$), which might propose that EPO treatment could decrease alveolar edema index at 48 h and 72 h (Figure 5B).

Alveolar cellularity index: Alveolar cellularity index was significantly different in either ANP groups or in EPO groups depending on the time course ($P = 0.011$). There was no significant difference in alveolar cellularity index between ANP and EPO groups at 24 h (17.42 ± 9.16 *vs* 16.71 ± 8.61, $P > 0.05$), whereas the mean value for ANP groups was significantly increased at 48 h and 72 h (29.14 ± 8.39 *vs* 19.85 ± 5.89, $P < 0.05$ and 32 ± 6.42 *vs* 12.71 ± 7.11, $P < 0.01$). Additionally, the mean alveolar cellularity index at 72 h was the highest in ANP groups and the lowest in EPO groups (32 ± 6.42 *vs* 12.71 ± 7.11).

Table 3 Histopathological index scores of lung injury (mean ± SD)

Groups	Sham	ANP1	ANP2	ANP3	EPO1	EPO2	EPO3
Alveolar distention collapse	0.4 ± 0.54	0.85 ± 0.69	1.57 ± 0.78	1.71 ± 0.75	0.71 ± 0.75	1 ± 0.57	0.42 ± 0.53
Alveolar edema index	0.1 ± 0.02	0.2 ± 0.08	0.24 ± 0.05	0.28 ± 0.03	0.2 ± 0.04	0.18 ± 0.03	0.13 ± 0.04
Alveolar cellularity index	11.4 ± 8.14	17.42 ± 9.16	29.14 ± 8.39	32 ± 6.42	16.71 ± 8.61	19.85 ± 5.89	12.71 ± 7.11
PMNL cell index	1.8 ± 1.78	6 ± 3.51	8.14 ± 3.48	11.14 ± 5.55	4.71 ± 2.36	3.85 ± 2.19	1.57 ± 1.61

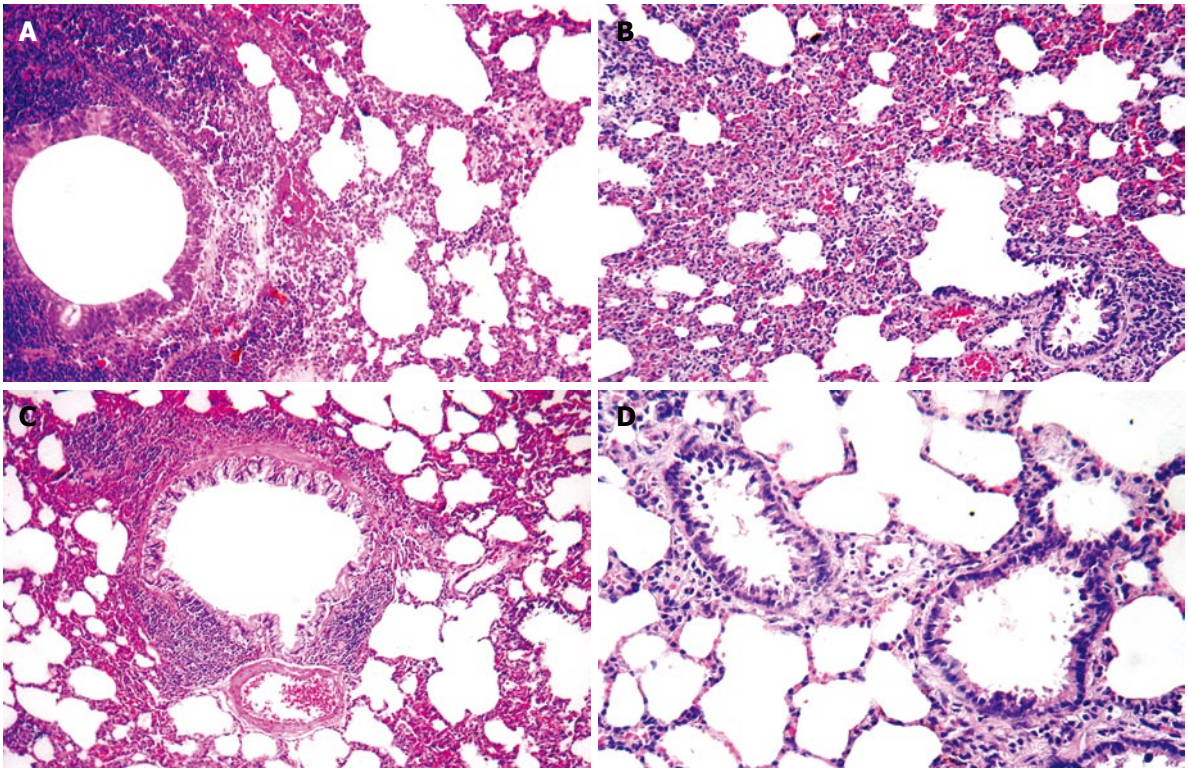

Figure 6 Light microscopy revealing significant lung injury-associated alveolar septal thickening, interstitial edema, infiltration of inflammatory cells, destruction of alveolar wall (emphysema), and microabscess formation in ANP groups at 48 h (**A**) and 72 h (**B**), and attenuation of inflammatory reaction, edema and emphysema in EPO groups at 48 h (**C**) and 72 h (**D**).

Compared with sham group, alveolar cellularity index was significantly increased in only ANP groups at 48 h and 72 h (11.4 ± 8.14 *vs* 29.14 ± 8.39, $P = 0.006$ and 11.4 ± 8.14 *vs* 32 ± 6.42, $P = 0.001$). This might suggest that EPO administration following ANP could decrease alveolar cellularity index at 48 h and 72 h (Figure 5C).

PMNL index: A statistically significant difference was observed in PMNL index between ANP and EPO groups with respect to the time intervals ($P = 0.009$). PMNL index was similar either in ANP groups or in EPO groups at 24 h (6 ± 3.51 *vs* 4.71 ± 2.36, $P > 0.05$). However, EPO treatment significantly decreased the mean PMNL index at 48 h and 72 h (8.14 ± 3.48 *vs* 3.85 ± 2.19, $P < 0.05$ and 11.14 ± 5.55 *vs* 1.57 ± 1.61, $P < 0.01$). The mean ± SD value at 72 h was the greatest in ANP groups and the lowest in EPO groups (11.14 ± 5.55 *vs* 1.57 ± 1.61). There was no statistically significant difference in PMNL index at 24 h, 48 h and 72 h between ANP and EPO groups (1.8 ± 1.78 *vs* 4.71 ± 2.36, $P = 0.315$; 1.8 ± 1.78 *vs* 3.85 ± 2.19, $P = 0.930$; and 1.8 ±1.78 *vs* 1.57 ± 1.61, $P = 1.00$, respectively), whereas ANP induction resulted in an increased PMNL index at 48 h and 72 h (1.8 ± 1.78 *vs* 8.14 ± 3.48, $P = 0.028$ and 1.8 ± 1.78 *vs* 11.14 ± 5.55, $P = 0.0001$, respectively) but not at 24 h (1.8 ± 1.78 *vs* 6 ± 3.51, $P = 0.725$). This might be explained as EPO administration could decrease PMNL index at 48 h and 72 h (Figure 5D). The histopathological indexes of lung injury (mean ± SD) are listed in Table 3. The representative light microscopic views of lung injury at 48 h and 72 h, and inecrotizing pancreatitis with severe fatty necrosis in ANP and EPO groups are shown in Figures 6 and 7. According to the above-mentioned criteria, it might be speculated that EPO administration could alleviate pulmonary injury by decreasing alveolar edema, alveolar cellularity and PMNL indexes at 48 h and 72 h following taurocolic acid-induced pancreatitis. The effect of EPO on alveolar distention and collapse was restricted at 72 h.

DISCUSSION

ANP is an inflammatory disorder with various systemic

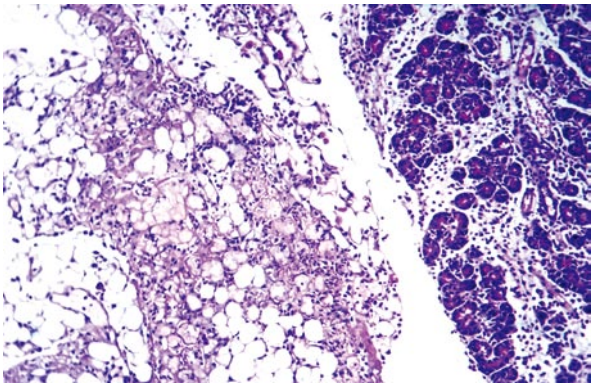

Figure 7 Light microscopic view of pancreatitis with severe fatty necrosis.

complications. ALI and ARDS are the most dreadful complications of ANP and impending catastrophe which is difficult to deal with clinically. Various medications directed at key stages of the pathophysiology are not clinically efficacious as indicated in the preceding experimental trials[23]. Therefore, therapies for preventing or reversing lung injury would be ideal for the treatment of AP[1,2,21,24-26].

Randomized studies of AP in the clinical setting do have limitations. In this regard, reliable AP animal models are of paramount importance. Taurocholate infusion model is a well-established ANP rat model that induces multiple organ failure involving the lung[27]. Moreover, Milani *et al*[28] found that mechanical and morphologic alterations in pancreatitis-associated pulmonary injury in rats are similar to those observed in humans.

The pathophysiology of ALI/ARDS and most of other pulmonary complications is multifactorial in ANP. The major pathway is the induction of a strong inflammatory response both in experimental models and in patients[29]. Regardless of the priming process, the disease progression can be viewed as three phases in continuum: local inflammation of the pancreas (a generalized inflammation stage and SIRS), and the final stage of multiorgan dysfunction[24,25]. The first sign of MODS is often the impaired lung function that manifests itself clinically as ARDS[1,2,24,25,30]. SIRS is one of the crucial reasons for pancreatitis-associated lung injury and PMNL plays a central role with various inflammatory cytokines and reactive oxygen species (ROS)[2,29,31]. Many researchers have focused their efforts on preventing AP-induced lung injury by pharmacologic interventions. Attractively, recent works have discovered the potential role of EPO as a multifunctional endogenous mediator offering cytoprotective effect against injury in various tissues including lung[16-19]. In multiple species including humans, many tissues injured by ischemia, mechanical trauma, excitotoxins, and other stressors are significantly improved by administration of EPO following injury[32]. The presence of a therapeutic window dictates specific time constraints for efficacious administration of exogenous EPO as a cytoprotectant[5]. According to this hypothesis we administered EPO immediately following the induction of pancreatitis and evaluated its effect in three different time courses.

The principle mechanism by which EPO confers tissue protection involves the modulation of cellular apoptosis. EPO inhibits the apoptotic mechanisms of injury, including preservation of cellular membrane asymmetry to prevent inflammation, can therefore be regarded as a general tissue-protective cytokine[11,12,14]. Agents that can prevent apoptosis can be effective long after the occurrence of injury[5]. This phenomenon might describe the long protective effect of EPO on lung injury in our study, particularly at 48 h and 72 h. We would also like to emphasize that, in patients with a severe attack, the effects of distant organ damage including lung injury, are often not fully established and become apparent only over the following 48 h. There is thus a therapeutic window between hospital presentation and development of distant organ dysfunction. As an obvious time window existed in this process, therapeutic approach should focus on it during this period. From this assumption, the animals were sacrificed on postoperative hours 24, 48 and 72 for histopathological and biochemical evaluations in our study.

Another crucial determinant for observing the cytoprotective effect of EPO is the serum concentration. The serum concentration of EPO required for tissue protection is higher than that required for erythropoiesis. Preclinical data suggest that the minimum therapeutic level needed for protection against tissue injury appears to be 300-500 mIU/kg body weight (intravenously or intraperitoneally) for the organs to be adequately investigated. EPO administration (100-1000 U/kg body weight) achieves possible systemic protective effects whereas high doses of EPO (3000-5000 U/kg body weight) are necessary for cardioprotection and neuroprotectin[33]. According to this, we administered EPO at the dose of 1000 mIU/kg body weight to observe the cytoprotective effects.

EPO plays a dual role in vascular protection by preserving endothelial cell integrity[6,8,9], thus playing a role in maintaining the integrity of microvasculature[11]. One of the major factors for the development of alveolar edema in ANP is the increased microvascular permeability. The experimental protocol we performed let us to measure the amount of edema within alveoli. We used alveolar edema index and alveolar distension and collapse index as markers of ALI according to the previous observations suggesting that histologic evidence of pulmonary tissue injury can appear before the development of clinically relevant respiratory mechanical changes[22]. We prefer three different time courses, since pulmonary injury indexes are quite intense in taurocolic acid induced acute pancreatitis on d 1 and 3, some of which persist through d 8[22]. In the present study, pulmonary edema, alveolar cellularity index and PMNL index (pulmonary injury index) were significantly reduced in EPO groups at 48 h and 72 h, suggesting that EPO can preserve endothelial cell integrity.

Oxidative stress has been implicated as a crucial landmark by increasing endothelial permeability in ARDS[1]. ROS scavengers possess protective effect against local acute pancreatitis-associated with lung injury[21,34,35]. In addition to other effects, EPO has been demonstrated in various tissues to be an antioxidant as it can decrease

the plasma iron concentration and increase the ability of plasma to inhibit lipid peroxidation[36,37]. In the present study, we determined the tissue levels of thiobarbituric acid reactant MDA, which is considered a good indicator of lipid peroxidation, and found a significant decrease in EPO group when compared to ANP groups in all three time courses. This might be attributed to the antioxidant effect of EPO. Furthermore, the tissue damage induced by ANP was associated with a significant ox-LDL accumulation either in pancreas samples or in lung tissue specimens. Ox-LDL is an early product of lipid peroxidation and ox-LDL accumulation in pancreatitis is associated with lung injury.

At present, the role of inflammatory mediators in the pathogenesis of ARDS has become a hot issue in the research field. EPO has been demonstrated to prevent cellular inflammation by inhibiting several proinflammatory cytokines, such as IL-6, TNF-α, and monocyte chemoattractant protein[7,38]. Attractively, these effects of EPO can be mediated by both hormonal and paracrine modalities[38]. There is mounting evidence that proinflammatory cytokines are the agents behind the systemic complications of AP[1,2]. It was reported that systemic inflammation plays a role in development of ALI triggered by pancreatitis[30]. The critical players of this process include proinflammatory cytokines including IL-1β, TNF-α, IL-6, IL-8, and platelet activating factor (PAF)[29]. Among these, the serum and/or tissue levels of TNF-α, IL-2 and IL-6 were analyzed in this study. Regardless of the model of acute pancreatitis, inhibition of the potent cytokine TNF-α might decrease organ injury and improve survival[39]. The tissue levels of TNF-α in the lungs were analyzed with immunohistochemical staining. Since no quantitative analysis was possible unavailable techniques, we evaluated this parameter not statistically but morphologically. IL-6 is another proinflammatory cytokine, and its high circulating level has been shown to be an excellent predictor of the severity of ARDS with different etiologies, including AP[40]. Moreover, IL-6 has been proposed to be one of the best prognostic parameters for pulmonary failure in human AP[30,41]. Mayer *et al*[41] have confirmed the important role of soluble IL-2 receptors (a lymphocyte activation marker), as a marker for severe AP, especially when complicated by lung or kidney failure or sepsis during lethal course of the disease[41]. In the present study, pulmonary injury in ANP groups was characterized by the increased serum or tissue IL-6 and TNF-α level. EPO treatment significantly decreased IL-6 and TNF-α level which might be due to the antiinflammatory properties of its molecule. However, we did not determine a statistically significant difference in the IL-2 level among the groups. This result might reflect the ineffectiveness of EPO on lymphocyte activity.

In conclusion, EPO administration plays a crucial role in preventing histological changes of ALI induced by experimental ANP. Moreover, it can significantly reduce the circulating and tissue levels of proinflammatory cytokines which have been considered the key factors for ALI. Additionally, oxidative stress markers are decreased particularly at 72 h following the induction of pancreatitis that might be attributed to the long-lasting antioxidant effect of EPO. All these findings show that EPO can attenuate ANP-induced lung injury by inhibiting PMNL accumulation, decreasing the circulating levels of proinflammatory cytokines, preserving microvascular endothelial cell integrity and reducing oxidative stress-associated lipid peroxidation. Years of clinical application in patients with anemia and chronic renal disease indicate that EPO is safe and well tolerated and can act as an ideal cytoprotective agent[7,42,43]. Nevertheless, the issue which should also be taken into consideration is that EPO is not an absolutely innocent agent with subsequent clinical toxic effects. Therefore, it would be of value to investigate its pharmacodynamics, pharmacokinetics, side-effects, administration routes and doses before used as a potential candidate for the treatment of ANP-associated ALI in routine clinical practice. In other words, this is a preliminary study and more experiments are necessary for the efficacy and potentially cytoprotective mechanisms of EPO action.

COMMENTS

Background

Pulmonary complication is the major cause for mortality in acute necrotizing pancreatitis (ANP). Since no absolutely effective treatment is available at present, therapies for preventing or reversing lung injury would be ideal for the treatment of AP.

Research frontiers

Erythropoietin (EPO) has long been known as a glycoprotein hormone that regulates erythropoiesis in mammals. Beyond its hematopoietic properties, EPO modulates a broad array of vital cellular processes including progenitor stem cell development, cellular integrity, and angiogenesis. EPO has recently been demonstrated to play a role in prolonging cell survival by acting as an antiapopitotic agent. EPO inhibits the apoptotic mechanisms of injury including preservation of cellular membrane asymmetry to prevent inflammation, and can therefore be regarded as a general tissue-protective cytokine. Additionally, experimental evidence supports a vigorous cytoprotective effect of EPO, which is now considered to have applicability in a variety of disorders, such as cerebral ischemia, myocardial infarction, and chronic congestive heart failure.

Related publications

The present study was an experimental study addressing the beneficial effects of EPO on lung injury. We cited several articles from other investigators reporting researches of EPO action on various tissues including lungs.

Innovations and breakthroughs

Recent works have discovered the potential role of EPO as a multifunctional endogenous mediator offering cytoprotective effect against injury in various tissues including the lungs. Pretreatment with EPO appears to attenuate ischemia-reperfusion-induced lung injury and hyperoxic lung injury in neonatal rats. From this point of view we evaluated the potantial protecting effects of EPO against acute lung injury in a rat model of ANP. Our data show that EPO administration can alleviate pulmonary injury parameters in experimental pancreatitis.

Applications

The impending catastrophe in ANP is generally preceded by acute lung injury. Despite improved understanding of the pathogenesis of ARDS, pharmacological modalities are ineffective in decreasing its mortality. None of the randomized clinical trials using novel therapeutic agents has demonstrated an improvement in patient outcome. The verification of cytoprotective effects of EPO on acute lung injury in a model of experimental pancreatitis might shed some valuable light on the novel effective therapeutic interventions.

Terminology

Erythropoietin (EPO), a 30.4-kDa glycoprotein and a member of the type I

cytokine superfamily, was first introduced as a hormone that regulates erythroid progenitors within the bone marrow to mature into erythrocytes, through binding to its specific cell surface receptors. Acute necrotizing pancreatitis (ANP) is a life-threatening necroinflammatory disease of pancreas with significant morbidity and mortality rates. Acute lung injury (ALI) is one of the most dreadful complications of AP which might be described as the continuum of pathological responses to pulmonary parenchymal injury. Acute respiratory distress syndrome (ARDS) is a severe form of ALI and acute pulmonary inflammation syndrome and resultant increased capillary endothelial permeability with clinical features of severe dyspnea and extreme hypoxemia refractory to a high inspired oxygen concentration.

Peer review

This is a well-designed and interesting study about the beneficial effects of EPO on lung injury in an experimental model of ANP. Since this is a preliminary study as discussed by the authors, more comprehensive experiments should be carried out to reveal the underlying cellular mechanisms of EPO's cytoprotective action against lung injury.

Abstract

AIM: To determine whether Carbon (CO) liberated from CO-releasing molecules attenuates leukocyte infiltration in the small intestine of thermally injured mice.

METHODS: Thirty-six mice were assigned to four groups. Mice in the sham group (n = 9) were underwent to sham thermal injury; mice in the burn group (n = 9) received 15% total body surface area full-thickness thermal injury; mice in the burn + CORM-2 group (n = 9) were underwent to the same thermal injury with immediate administration of tricarbonyldichlororut henium (Ⅱ) dimer CORM-2 (8 mg/kg, i.v.); and mice in the burn+DMSO group (n = 9) were underwent to the same thermal injury with immediate administration of 160 μL bolus injection of 0.5% DMSO/saline. Histological alterations and granulocyte infiltration of the small intestine were assessed. Polymorphonuclear neutrophil (PMN) accumulation (myeloperoxidase assay) was assessed in mice mid-ileum. Activation of nuclear factor (NF)-κB, expression levels of intercellular adhesion molecule-1 (ICAM-1) and inducible heme oxygenase in mid-ileum were assessed.

RESULTS: Treatment of thermally injured mice with CORM-2 attenuated PMN accumulation and prevented activation of NF-κB in the small intestine. This was accompanied by a decrease in the expression of ICAM-1. In parallel, burn-induced granulocyte infiltration in mid-ileum was markedly decreased in the burn mice treated with CORM-2.

CONCLUSION: CORM-released CO attenuates leukocyte infiltration in the small intestine of thermally injured mice by interfering with NF-κB activation and protein expression of ICAM-1, and therefore suppressing the pro-adhesive phenotype of endothelial cells.

INTRODUCTION

Systemic inflammatory response syndrome (SIRS) and multiple organ failure (MOF) still continue to be leading causes of morbidity and mortality in severe burn patients[1,2]. The intestine is considered to be the critical organ in the development of organ dysfunction in trauma, burns, and intensive care unit patients[3]. Thermal injury is accompanied by complex events that exert deleterious effects on various organs, such as the small intestine, distant from the original burn wound. Following thermal injury, the small intestine is subjected to ischemia, and consequently, especially during burn resuscitation, reperfusion injury occurs[4]. Intestinal ischemia-reperfusion results in organ injury through both tissue hypoxia and reperfusion phenomena mediated by neutrophils[5,6]. A variety of cytokines are released into the microcirculation by neutrophils, endothelial cells and monocytes during phases of hypoxia and reperfusion[7,8]. Although the pathophysiological basis of organ damage remains unclear, there is increasing evidence that leukocyte infiltration into intestinal tissue plays an important role in bacterial or endotoxin translocation and development of SIRS after thermal injury[9-12].

A lot of evidence indicates that endogenous Carbon (CO), a by-product of inducible heme oxygenase (HO-1), modulates inflammation. In addition, some experiments have determined that the administration of exogenous CO inhibits lipopolysaccharide (LPS)-induced production

of cytokines both *in vivo* and *in vitro*, and consequently exhibits an important cytoprotective function and anti-inflammatory properties that are beneficial for the resolution of acute inflammation[13-15].

Recently, transitional metal carbonyls have been identified as potential CO-releasing molecules (CORMs), with the potential to facilitate the pharmaceutical use of CO by delivering it to tissues and organs[16]. CORMs have been shown to act pharmacologically in rat aorta and cardiac tissue in which liberation of CO induced vasorelaxant effects[17-20] and decreased myocardial ischemia-reperfusion injury[21,22], respectively. Our previous studies[23,24] have shown that burn-induced overexpression of adhesion molecules [such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1] on endothelial cells and leukocytes may contribute to liver and lung tissue injury, subsequently leading to multiple organ dysfunction syndrome (MODS). We also confirmed that CORM-released CO attenuated leukocyte sequestration in the liver and lungs of burned mice by interfering with NF-κB activation and protein expression of ICAM-1, therefore suppressing the pro-adhesive phenotype of endothelial cells. However, it is still unknown if CORM-released CO can exert its anti-inflammatory and protective effects in the small intestine. Based on these preliminary observations, in this study we employed tricarbonyldichlororuthenium (Ⅱ) dimer (CORM-2), one of the novel group of CORMs, to determine whether it attenuated leukocyte infiltration to the intestinal tissue of thermally injured mice.

MATERIALS AND METHODS

Materials

CORM-2 was obtained from Sigma-Aldrich and was solubilized in DMSO to obtain a 10 mmol/L stock solution. Polyclonal or monoclonal antibodies against ICAM-1 and HO-1 were purchased from Santa Cruz Biotechnology. All other chemicals were reagent grade and obtained from Sigma unless otherwise stated.

Animals and burn protocol

C57BL/6 mice (36 male; body weight 20 ± 2 g) were fed a standard laboratory diet and water *ad libitum*. Mice were assigned to four groups. Mice in the sham group (n = 9) were underwent to sham thermal injury; mice in the burn group (n = 9) received 15% total body surface area (TBSA) full-thickness thermal injury; mice in the burn + DMSO group (n = 9) were underwent to the same thermal injury with immediate administration of 160 μL bolus injection of 0.5% DMSO/saline; and mice in the burn + CORM-2 group (n = 9) were underwent to the same thermal injury with immediate administration of CORM-2 (8 mg/kg, i.v.). The experimental protocol was approved by The Council on Animal Care at Jiangsu University for the protection and welfare of animals. Under anesthesia with spontaneous inhalation of isoflurane/N_2O (Abbott Laboratories, Mississauga, ON, Canada) in a 60% oxygen/40% nitrogen mixture, the dorsum of each mouse was shaved and the animal was subjected to 15% TBSA full-thickness thermal injury as previously described[25,26]. Sham animals were immersed in a water bath at room temperature. All animals were resuscitated with 1.5 mL saline immediately after thermal (or sham) injury. No wound care was required for the burn wounds. This burn method achieves a histologically proven, full-thickness scald injury[27,28]. The animals were sacrificed at 24 h after experimental manipulation.

	Granulocyte infiltration			Hydropic degeneration		
	0	1	2	0	1	2
Ileum	No	Moderate	Intense	No	Moderate	Intense
Jejunum	No	Moderate	Intense	No	Moderate	Intense

Ileum histologic studies

The mid-ileum specimens harvested from different groups of animals were immersed in 4% formaldehyde solution at 24 h after thermal injury. The tissue was embedded in paraffin wax, serially sectioned, and stained with hematoxylin-eosin. Ileal morphologic characteristics were evaluated by light microscopy. Ileum tissue was evaluated for density of granulocytes and degree of hydropic degeneration. Tissues were evaluated in a semi-quantitative manner by two experienced independent examiners that were blinded to the experimental groups (Table 1). A scoring system was used for each item using 0 up to 2 points for the different states of organ damage (with 2 being most granulocytes, edema and degeneration; Table 1). Afterwards, the mean ± SEM of each item was calculated.

Preparation of intestinal homogenates

Immediately after withdrawing blood, the intestine was exposed. Leaving approximately the first 5-cm-long proximal segment of the intestine, 3-cm-long segments of jejunum and ileum were removed, cleaned, and snap-frozen in liquid nitrogen. The samples were stored at -70℃. Equal weights (100 mg wet weight) of intestine from various groups were suspended in 1 mL PBS and sonicated (30 cycles, twice, for 30 s) on ice[29]. Homogenates were cleared by centrifuging at 12000 r/min at 4℃, and the supernatants were stored at -70℃. Protein levels in the homogenates were determined using the Bio-Rad (Hercules, CA, USA) assay kit.

Myeloperoxidase (MPO) activity

MPO activity was measured in ileum tissue using a procedure similar to that documented by Hillegas *et al*[30,31]. Tissue samples were homogenized in 50 mmol/L potassium phosphate buffer (PB) (pH 6.0), and centrifuged at 10000 × g (10 min); pellets were suspended in 50 mmol/L PB containing 0.5% hexadecyltrimethylammonium bromide. After sonication, the samples were centrifuged at 10000 × g for 10 min. Aliquots (0.3 mL) were added to 2.3 mL of reaction mixture containing 50 mmol/L PB, o-dianisidine, and 20 mmol/L H_2O_2 solution. One unit of enzyme activity was defined as the amount of MPO

Table 2 Histological scoring (score in Table 1) of ileum and jejunum tissue stained with hematoxylin/eosin 24 h after thermal injury

Jejunum	0.54 ± 0.1	1.5 ± 0.2[a]	0.64 ± 0.2[c]	0	1.6 ± 0.1	1.6 ± 0.2

0, no injury; 1, moderate injury; 2, severe injury. Values are presented as mean ± SEM. [a]$P < 0.05$ *vs* sham group; [c]$P < 0.05$ *vs* burn group.

present that caused a change in absorbance measured at 460 nm for 3 min. MPO activity was expressed as U/g tissue.

Measurement of ICAM-1

ICAM-1 levels in ileum tissue homogenates were measured using enzyme-linked immunosorbent assay (ELISA) kits (R&D Systems, Minneapolis, MN, USA) following the manufacturer's instructions.

Western blot analysis

Tissues were homogenized for extraction in ice-cold mild lysis buffer, containing 1% Nonidet P-40, 0.15 mol/L NaCl, 0.01 mol/L sodium phosphate (pH 7.2), 2 mmol/L EDTA, 50 mmol/L sodium fluoride, 0.2 mmol/L sodium vanadate, and 1 μg/mL aprotinin. The tissue homogenates were centrifuged at 20000 × *g* for 15 min and supernatants were collected. SDS-PAGE was performed on equivalent amounts of protein samples using precast 7% resolving/4% stacking Tris/HCl gels (Bio-Rad, Hercules, CA, USA). Separated proteins were then transferred to PVDF membranes (Amersham Pharmacia Biotech, Piscataway, NJ, USA). Membranes were blocked in 5% non-fat milk in TBS buffer containing 0.1% Tween 20 (TBST) for 1 h at room temperature. Blocked membranes were incubated with primary antibodies specific for mouse ICAM-1 and HO-1 at a concentration of 1:1000 and 1:5000, respectively, in TBST overnight at 4℃. Then, the membranes were washed and probed with horseradish-peroxidase-conjugated secondary antibody (Amersham Pharmacia Biotech, Piscataway, NJ, USA) for 1 h at room temperature. Chemiluminescence detection was performed with the Amersham enhanced chemiluminescence detection kit according to the manufacturer's instructions. To ensure a similar amount of protein in each sample, the membranes were "stripped off", reprobed with actin, developed with horseradish-peroxidase-conjugated secondary antibody, and visualized by enhanced chemiluminescence.

Preparation of nuclear extracts and electrophoretic mobility shift assay (EMSA)

Nuclear protein from ileum tissue was extracted using our previously described method[32,33]. Briefly, frozen tissues were weighed, transferred to Corex tubes and homogenized in four volumes (w/v) of PBS containing 2 mmol/L phenylmethylsulfonyl fluoride (PMSF). The homogenate was centrifuged at 3000 × *g* for 10 min, and the pellet was then resuspended in 2 mL buffer A [0.3 mol/L sucrose, 5 mmol/L dithiothreitol (DTT), 5 mmol/L $MgCl_2$ 10 mmol/L Tris/HCl, 0.1% Triton X-405], and further homogenized using a Dounce homogenizer. After filtration through a 100-μm nylon mesh, the suspension was centrifuged at 1000 × *g* for 5 min at 4℃. The pellet (nuclei) was washed in buffer A (without 0.1% Triton X-405) and centrifuged (1000 × *g* for 5 min at 4℃), and then the nuclei were extracted on ice for 30 min in 60 μL buffer B containing 20 mmol/L HEPES, 0.75 mmol/L spermidine, 0.15 mmol/L spermine, 0.2 mmol/L EDTA, 2 mmol/L ethylene glycol-bis (b-aminoethyl ether)-*N, N, N', N'*-tetraacetic acid, 2 mmol/L DTT, 20% glycerol, and 1 mmol/L PMSF (4℃) in the presence of 0.4 mol/L NaCl. Finally, the samples were centrifuged for 10 min at 21000 × *g* (4℃), and the supernatants were collected and stored at -80℃ as the nuclear protein fraction.

For EMSA, 5 μg total nuclear proteins was incubated with 1.0 pmol double-stranded γ[^{32}P] ATP end-labeled oligonucleotides containing consensus binding sequences for NF-κB (sense strand 5'-AGGGACTTTCCGCTG GGGACTTTCC-3') in a binding buffer (10 mmol/L HEPES, pH 7.9, 80 mmol/L NaCl, 3 mmol/L $MgCl_2$, 0.1 mmol/L EDTA, 1 mmol/L DTT, 1 mmol/L PMSF, and 10% glycerol), as described previously[34]. Samples were incubated for 30 min at room temperature and then run through a 4% non-denaturing polyacrylamide gel (0.5 × TBE buffer) at 280 V for 1 h. The gel was dried and then exposed to X-ray film (Kodak) for 4-6 h in cassettes at -80℃. Signal detection and quantification were performed by computer-assisted densitometry.

Statistical analysis

All the values are presented as mean ± SE. Statistical analysis was performed by ANOVA and Student's *t* test for the comparisons. $P < 0.05$ was considered to be statistically significant.

RESULTS

Histology

Histological analysis showed that the ileum from sham mice had the normal architecture of the intestinal epithelium and wall, while thermal injury induced severe edema and sloughing of the villous tips, as well as infiltration of inflammatory cells into the mucosa (Figure 1). Semi-quantitative analysis of histological samples of ileum and jejunum showed that granulocyte infiltration in the burned mice was significantly increased compared to that in the sham group. Administration of CORM-2 (8 mg/kg, i.v.), significantly decreased granulocyte infiltration. However, CORM-2 did not improve the hydropic degeneration induced by thermal injury in either the ileum or jejunum (Table 2).

Effect of CORM-2 on MPO activity in small intestine of thermally injured mice

To determine whether the burn-induced increase in polymorphonuclear neutrophil (PMN) accumulation in the small intestine was effectively prevented by CORM-2,

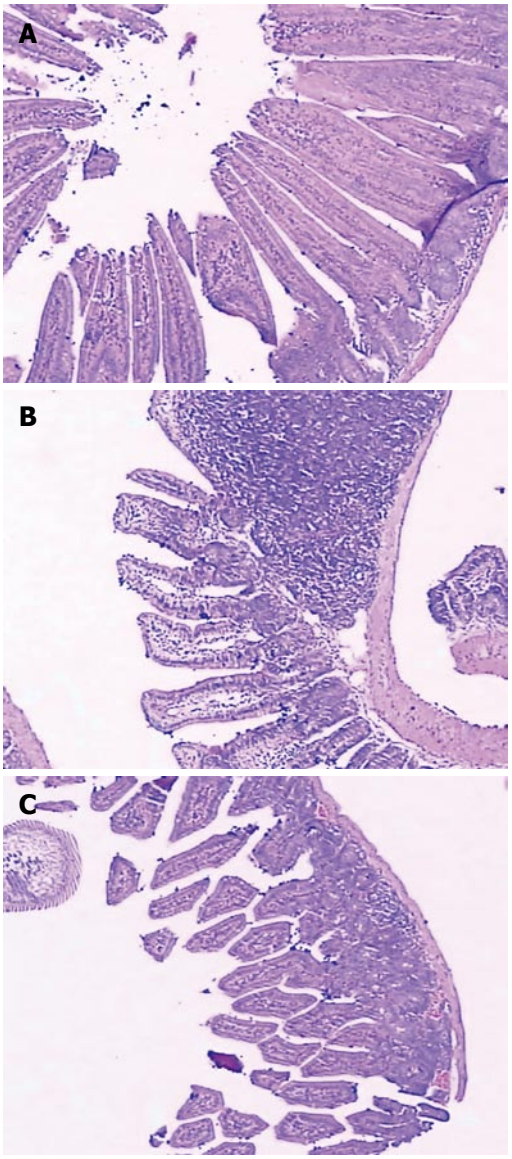

Figure 1 Effects of CORM-2 on small intestine injury in thermally injured mice. Mice were injected i.v. with CORM-2 (8 mg/kg) immediately after thermal injury. Mice in the DMSO group received a 160-μL bolus injection of 0.5% DMSO/saline. Mid-ileum sections from sham-treated mice had normal architecture of the intestinal epithelium and wall (**A**); Mid-ileum sections from thermally injured mice showed inflammatory cell infiltration through the wall, concentrated below the epithelial layer, edema of the distal portion of the villi, and necrosis of the epithelium at the villous tips (**B**); Ileum section from burned mice treated with CORM-2 (**C**) showed a significant decrease in granulocyte infiltration, while no marked improvement of hydropic degeneration. The figure is representative of at least three experiments performed on different days.

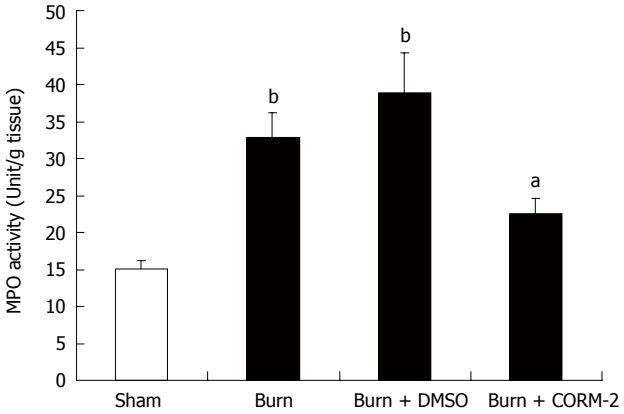

Figure 2 Effects of CORM-2 on MPO activity in the small intestine of thermally injured mice. Mice were challenged with thermal injury and treated with CORM-2 as described in Figure 1. MPO activity in the mid-ileum was assessed 24 h following thermal injury. Results are mean ± SE, $^{b}P < 0.01$ *vs* sham mice. $^{a}P < 0.05$ *vs* burned mice.

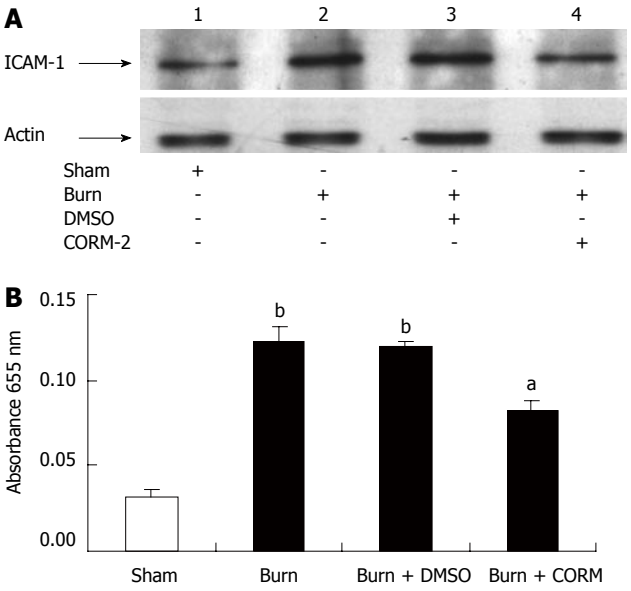

Figure 3 Effects of CORM-2 on protein expression of ICAM-1 in the ileum tissue of thermally injured mice. Mice were challenged with thermal injury and treated with CORM-2 as described in Figure 1. Protein expression of ICAM-1 was analyzed by Western blotting (**A**) and ELISA (**B**) 24 h after thermal injury. A representative experiment is shown in A. $^{b}P < 0.01$ *vs* sham-treated; $^{a}P < 0.05$ *vs* burned mice.

the activity of MPO, an enzyme in azurophilic granules of neutrophils, was assessed. Extracts of the ileum samples were examined for content of MPO 24 h after thermal injury. The mean MPO levels are shown in Figure 2. MPO activity in organs obtained from burned mice was markedly increased compared to that in the sham group ($P < 0.01$), while it was significantly decreased by treatment with CORM-2 ($P < 0.05$).

Effect of CORM-2 on expression of ICAM-1 in the small intestine of thermally injured mice

At 24 h after a 15% TBSA full-thickness thermal injury, the expression of ICAM-1 in the ileum was significantly increased compared to that in the sham-treated animals. Administration of CORM-2 (8 mg/kg, i.v.) significantly decreased expression of ICAM-1 (Figure 3).

Effect of CORM-2 on expression of HO-1 in the small intestine of thermally injured mice

At 24 h after 15% TBSA full-thickness thermal injury, the expression of HO-1 in the small intestine significantly increased compared to that in the sham-treated animals. *In vivo* administration of CORM-2 (8 mg/kg, i.v.), expression of HO-1 in the ileum tissue of burn mice was more significantly increased compared to burn group (Figure 4).

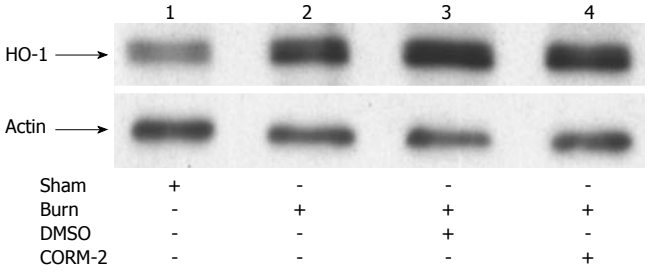

Figure 4 Effects of CORM-2 on protein expression of HO-1 in the ileum tissue of thermally injured mice. Mice were challenged with thermal injury and treated with CORM-2 as described in Figure 1. Protein expression of HO-1 was performed by Western blotting 24 h after thermal injury. A representative experiment showed that HO-1 was significantly up-regulated by thermal injury (lane 2). Expression of HO-1 in the small intestine of thermally injured mice treated with CORM-2 was more significantly increased compared to burned mice without CORM-2 (lane 4).

Effect of CORM-2 on activity of NF-κB in the small intestine of thermally injured mice

Binding of nuclear protein to the radiolabeled consensus binding sequences of NF-κB was assessed by EMSA. At 24 h after 15% TBSA full-thickness thermal injury, NF-κB activation in the ileum was markedly increased, and this was markedly inhibited by administration of CORM-2 (8 mg/kg i.v.) (Figure 5).

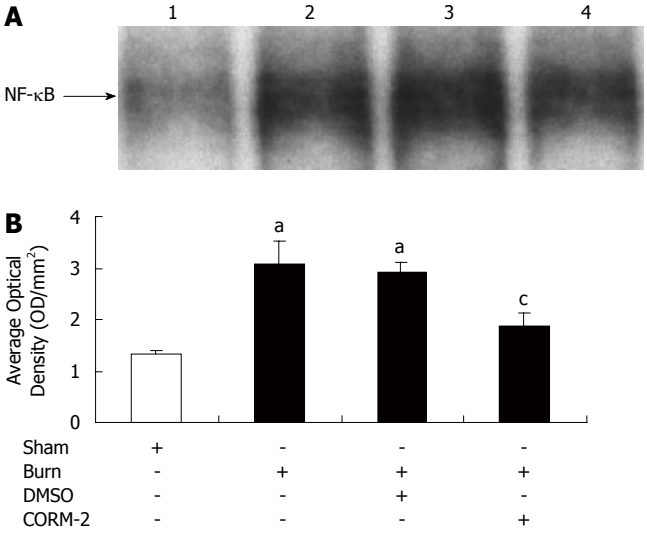

Figure 5 Effects of CORM-2 on NF-κB activation in the ileum tissue of thermally injured mice. Mice were challenged with thermal injury and treated with CORM-2 as described in Figure 1. Measurement of NF-κB activity was performed by EMSA with ^{32}P-labeled NF-κB probe and 5 μg nuclear extract from the ileum of sham, burn, burn + DMSO and burn+CORM-2 mice at 24 h after thermal injury. NF-κB activation in the ileum of thermally injured mice was markedly increased (lane 2), and this activity was inhibited by CORM-2 (lane 4). A representative experiment is shown in **A**, and quantitative results (average optical density) of three experiments are shown in **B**. $^{a}P < 0.05$ *vs* sham-treated; $^{c}P < 0.05$ *vs* burned.

DISCUSSION

Major burns alter immune function, which produces an imbalance between pro- and anti-inflammatory cytokine synthesis, and increases susceptibility to post-burn infection and sepsis[35-37]. Also, severe burns cause damage to multiple organs distant from the original burn wound, leading to MOF, a serious clinical problem. The intestine is one of the most sensitive tissues to ischemia and reperfusion induced by thermal injury. PMNs may play an important role in ischemic injury, and reperfusion of intestine is associated with accumulation of PMNs in the intestinal tissue. It has been suggested that tissue accumulation of PMNs is a key event that determines the severity of ischemia-reperfusion injury[8].

We report here that CORM-released CO exerts a protective effect against the pathological changes caused by thermal injury of the small intestine. Importantly, this exogenous CO showed effective inhibition of activation of NF-κB and expression of ICAM-1. Thus, we propose that CORM-2 contributes to the attenuation of leukocyte infiltration to the intestinal tissue after burn challenge. What is, then, the mechanism by which attenuation of PMN infiltration to the intestine is caused by thermal injury?

Many experimental studies have highlighted the specific and independent role of exogenous CO (i.e. CO inhalation) in the modulation of inflammation[38,39]. Recently some new metal carbonyl-based compounds (CORMs) that have the ability to release CO in biological systems have been identified and synthesized. The vasoactive, antihypertensive and anti-rejection effects of CORMs have been demonstrated to be due to the CO liberated by the compounds. CORM-2, a DMSO-soluble CORM, also has exhibited anti-inflammatory actions in an *in vitro* model of LPS-stimulated murine macrophages[40].

MPO is an enzyme that is found predominantly in the azurophilic granules of PMNs. Tissue MPO activity is frequently utilized to estimate tissue PMN accumulation in inflamed tissues, and correlates significantly with the number of PMNs determined histochemically in tissues[41]. In the present study, we found that intestinal MPO activity was markedly elevated after thermal injury, and administration of CORM-2 led to significant down-regulation of MPO activity. This indicates that CORM-2 effectively prevents PMN chemotaxis and infiltration in the small intestine after thermal injury, which consequently decreases the production of oxidants and reduces tissue oxidative injury, which contributes to MODS. In parallel, histological analysis in this study indicated that mid-ileum sections from thermally injured mice showed inflammatory cell infiltration through the wall, concentrated below the epithelial layer, edema of the distal portion of the villi, and necrosis of the epithelium at the villous tips. On the contrary, ileum sections from mice treated with CORM-2 showed a significant decrease in leukocyte infiltration.

PMN-endothelial cell interactions are supposed to play a central role in the pathogenesis of intestinal barrier failure following thermal injury and ischemia-reperfusion[42]. The presence of ICAM-1, which mediates leukocyte adhesion, correlates with infiltration of leukocytes into inflammatory lesions[43,44]. It seems to be the initial marker of inflammatory reactions and is involved in the acute inflammatory reaction following burns[45]. ICAM-1 activates leukocytes and endothelial cells, which in turn, prompt the release of various inflammatory mediators. This may result in SIRS, acute respiratory distress syndrome, and MODS, which may develop further into progressive MOF and death[46-48]. The present

results showed that at 24 h post-burn, the expression of ICAM-1 in intestinal tissue was markedly up-regulated. CORM-2 was able to inhibit the up-regulation of ICAM-1 induced by thermal injury. Our findings strongly indicate that CORM-2 appears to inhibit leukocyte activation and adhesion, and consequently, might effectively decrease the inflammatory response in the small intestine induced by burns.

HO is a rate-limiting enzyme that is responsible for the catabolism of heme into bilirubin, free iron, and CO. Three HO isoforms have been identified: HO-2 and HO-3 isoforms are believed to be constitutive and physiologically expressed, whereas HO-1 isoform is a stress-responsive protein that is induced by various stimuli. The adaptive response of HO-1 to various stimuli suggests that it may play an important role in protection against the inflammatory response and oxidative injury[49]. Other studies have shown that up-regulation of endogenous HO-1 ameliorates inflammatory responses and/or tissue damage[50]. In this study, we found that HO-1 was significantly up-regulated by thermal injury. Interestingly, the expression of HO-1 in the small intestine of thermally injured mice treated with CORM-2 was more significantly increased compared to burned mice without CORM-2 (Figure 4). This result indicates that not only major burn injury might significantly induce the expression of HO-1, but also the increase in HO-1 expression can be further enhanced by the administration of CORM-2. Through the by-product (CO and/or biliverdin), the potent cytoprotective and anti-inflammatory functions were ultimately led to exert.

NF-κB family members control transcriptional activity of various promoters of proinflammatory cytokines, cell-surface receptors, transcription factors, and adhesion molecules that are involved in intestinal inflammation[51,52]. Stimuli like oxidative stress, cytokines (interleukin-1, interleukin-6, tumor necrosis factor-α), bacteria and viruses can release NF-κB from its inactive cytoplasmic form to the nucleus[53,54]. Thermal injury has been known to induce hepatic NF-κB expression associated with hepatic cell apoptosis and proliferation[55], but its effect on NF-κB activation in the intestine has never been clarified. Previously, using a thermal injury model in mice, we have shown that CORM-2 plays a pivotal role in inhibition of NF-κB activity in the liver, which subsequently decreases hepatocellular secretion of inflammatory cytokines and burn-related hepatic dysfunction. In this study, NF-κB activity in mid-ileum was elevated by thermal injury, while it was markedly inhibited by administration of CORM-2. These results show that CORM-2 plays, at least partly, an important role in inhibition of NF-κB activity in the small intestine. Therefore, the role of NF-κB activation and the regulation of CORM-2 in thermal-injury-induced intestinal damage requires further study.

In conclusion, the present study serves to clarify the role of CORM-2, one of the novel CORMs, on the mechanisms of anti-inflammation and cytoprotection. Application of CORM-2 to thermally injured mice attenuated PMN accumulation, and prevented activation of NF-κB in the small intestine. This was accompanied by a decrease in expression of ICAM-1, and an increase in expression of HO-1. Taken together, these findings indicate that CORM-released CO modulates gut inflammation in burned mice by interfering with NF-κB activation, and protein expression of ICAM-1 and HO-1, and therefore suppresses the pro-adhesive phenotype of endothelial cells. Further studies are now required to understand the detailed mechanisms of the anti-inflammatory effects mediated by CORMs, and to contribute to the development of a therapeutic approach to protect against gut damage during severe burn injury.

COMMENTS

Background

SIRS and MOF still continue to be leading causes of morbidity and mortality in severe burn patients. The intestine is considered to be the critical organ in the development of organ dysfunction in trauma, burn and intensive care unit patients. Thermal injury is accompanied by complex events that exert deleterious effects on various organs, such as the small intestine, distant from the original burn wound. Following thermal injury, the small intestine is subjected to ischemia, and consequently, especially during burn resuscitation, reperfusion injury occurs. Intestinal ischemia-reperfusion results in organ injury through both tissue hypoxia and reperfusion phenomena mediated by neutrophils. A variety of cytokines are released into the microcirculation by neutrophils, endothelial cells and monocytes during hypoxia and reperfusion. Although the pathophysiological basis of organ damage remains unclear, there is increasing evidence that leukocyte infiltration into intestinal tissue plays an important role in bacterial or endotoxin translocation, and development of SIRS after thermal injury.

Research frontiers

Major burns alter immune function, which produces an imbalance between pro- and anti-inflammatory cytokine synthesis, and increases susceptibility to post-burn infection and sepsis. Also, severe burns cause damage to several organs distant from the original burn wound, which leads to MOF, a serious clinical problem. The intestine is one of the most sensitive tissues to ischemia and reperfusion induced by thermal injury. PMNs may play an important role in ischemic injury, and reperfusion of the intestine is associated with accumulation of PMNs in the intestinal tissue. It has been suggested that tissue accumulation of PMNs is a key event that determines the severity of ischemia-reperfusion injury.

Innovations and breakthroughs

Our study is believed to be the first to observe that CORM-released CO attenuates leukocyte infiltration in the small intestine of thermally injured mice, and the possible mechanisms involved.

Applications

Our research observed that CORM-released CO attenuates leukocyte infiltration in the small intestine of thermally injured mice by interfering with NF-κB activation and protein expression of ICAM-1, and therefore suppresses the pro-adhesive phenotype of endothelial cells. This may have a significant clinical impact in the future.

Terminology

CORMs: transitional metal carbonyls that have been identified as potential CO-releasing molecules with the potential to facilitate the pharmaceutical use of CO by delivering it to tissues and organs.

Peer review

This is a well-written paper that suggests the benefit of CORMs after burn injury. Although the mechanism remains to be determined, I think it may be suitable for publication in WJG. It will be nice to detail other experiments using other doses of CORMs.

Abstract

AIM: To investigate the function of monocytes in Crohn's disease (CD) patients and to correlate this with disease-associated nucleotide-binding oligomerization domain-2 (*NOD2*) gene variants.

METHODS: Monocytes from 47 consecutively referred CD patients and 9 healthy blood donors were cultured with interleukin (IL)-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF), and stimulated with lipopolysaccharide (LPS) or muramyldipeptide (MDP), the putative ligand of *NOD2*.

RESULTS: We found that monocytes from CD patients differentiated *in vitro* to mature dendritic cells (DCs), as determined by immunophenotype and morphology. *NOD2* genotype was assessed in all subjects, and we observed high CD86 expression on immature and LPS-stimulated DCs in *NOD2* mutated CD patients, as compared with *wtNOD2* CD patients and controls. By contrast, CD86 expression levels of DCs induced to maturity with MDP derived from *NOD2*-mutated subjects were comparable to those of normal subjects. The amount of IL-12p70 in patient-cell cultures was larger than in controls after LPS treatment, but not after treatment with MDP.

CONCLUSION: Our results suggest that DCs obtained from patients with mutations in the *NOD2* gene display an activated phenotype characterized by high CD86 expression, but have a diminished response to MDP when compared to the terminal differentiation phase. We speculate that the altered differentiation of monocytes might lead to an imbalance between inflammation and the killing ability of monocytes, and may be relevant to the pathogenesis of CD.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract, influenced by both environmental factors and genetic predisposition[1-3]. A significant advance in the understanding of its pathogenesis was achieved by the identification of nucleotide-binding oligomerization domain-2 (*NOD2*) as the first susceptibility gene for CD in Caucasian populations[4,5]. This was the demonstration that a frameshift mutation (1007fs) and two nucleotide polymorphisms (R702W and G908R) in the coding region of *NOD2* predispose people to the disease. Since the identification of *NOD2* mutations associated with CD, much attention has been given to the function of monocytes in which this gene is constitutively expressed[6-8].

The idea that the NOD2 protein is involved in the induction of nuclear factor-kappa B (NF-κB) pro-inflammatory signaling pathways in response to bacterial infections may be relevant for understanding the role of intestinal bacteria in CD[9-12]. Indeed, functional assays on CD-associated isoforms of NOD2 have yielded controversial results concerning the production of inflammatory cytokines and responses to bacteria. NOD2 has been shown to act as both an inducer and a regulator of NF-κB and cytokine production[13,14]; more precisely, muramyldipeptide (MDP)-induced activation of NF-κB lacks mononuclear cells in CD patients homozygous for the 1007fs mutation[15]. Conversely, interleukin (IL)-12 production induced by toll-like receptor 2 (TLR2) is negatively regulated in mice by MDP co-stimulation of *NOD2*; although this effect is absent in *NOD2*-/- mice[14]. Moreover, cells obtained from knock-in mice for the 3020insC *NOD2* mutation show enhanced NF-κB activity,

as well as increased production of IL-1β after MDP stimulation[10]. It is noteworthy that this pro-inflammatory phenotype is also associated with an impaired response to *Listeria monocytogenes* challenge[13]. These data show that CD patients' lymphomonocytes have a defect in the stress-induced production of IL-8, which may be responsible for the impaired response to bacteria[16,17].

Taken together, these data suggest a complex pathogenic model of CD, in which genetic factors favor an imbalance between the inflammatory response and the killing of mucosal bacteria. This is similar to the picture observed in some primary immunodeficiencies. Indeed, a histological lesion typical of CD, chronic granuloma, is common also in some deficiencies of the phagocytic immune system such as chronic granulomatous disease, congenital neutropenia and Wiskott-Aldrich syndrome[18,19]. Based on this, granulocyte-macrophage colony-stimulating factor (GM-CSF) has been beneficially used in patients affected by CD, probably through strengthening their natural immunity[20-22], although it shows no direct anti-inflammatory activity.

We thus hypothesized that, besides the inflammatory response itself, the function of the monocyte-derived immune system may be impaired in CD patients because of mutations in the *NOD2* gene. Therefore, we looked for possible defects in monocyte differentiation in CD patients and the relationship with the *NOD2* genotype.

MATERIALS AND METHODS

Patients

The subjects in this study were 47 patients consecutively referred to our institute for CD, 28 males and 19 females, with a mean age of 16.6 (range 4-33) year, and a mean age at diagnosis of 12.8 year (range 1 mo-18 year). All 47 CD patients were sporadic cases. Thirty had active disease and 17 had clinical, echographic and endoscopic remission at the time of analysis. For *NOD2* genotyping, a control group of 69 blood donors was analyzed. For the functional study of monocytes, the control group was 9 healthy adult blood donors (5 males and 4 females, mean age 24.3 years, range 21-38) who tested negative for CD-associated *NOD2* variants. The study was approved by our local independent ethics committee, and informed consent was obtained from all patients (or their parents) and blood donors.

Genetic analysis

Patients were genotyped for R702W and G908R mutations (identified by PCR amplification and enzymatic digestion) and for the 1007fs mutation (analyzed by amplification and sequencing). DNA was extracted from peripheral blood of patients and controls using a Genomix kit (Talent, Italy). PCR reactions were performed using specific primers for the three mutations (sequences are shown in Table 1), Taq polymerase (Amplitac Gold, Applied Biosystems, Foster City, CA, USA) and a thermal cycler Gene Amp 9700 (PE Applied Biosystems). After denaturing at 95℃ for 10 min, amplification was obtained after 35 cycles at 95℃ for 30 s, 55℃ for 30 s, and 72℃ for 30 s. For just the 1007fs mutation, 10 amplification cycles at 95℃ for 30 s, 53℃ for 30 s, and 72℃ for 30 s, followed by another 35 cycles at 95℃ for 30 s, 53℃ for 30 s (touch down step: decrease of 0.5℃/cycle), and 72℃ for 30 s. A final step at 72℃ for 7 min was used to stop the reactions. A restriction enzyme digestion assay was performed to detect both R702W and G908R using Msp1 and HhaI, respectively. After digestion, the presence of a wild-type allele resulted in an intact fragment, whereas the variant was characterized by two bands. PCR reaction products underwent electrophoresis on 1.5% agarose gels and were visualized by ethidium bromide staining. Sequencing was carried out for 1007fs detection. Reactions were performed with a Big Dye Terminator Cycle Sequencing Ready Reaction kit (PE Applied Biosystems) and on an ABI PRISM 3100 Sequence Detector. Subjects with at least one heterozygous CD-associated variant were categorized as *mtNOD2*, while patients with a homozygous wild type *NOD2* sequence were categorized as *wtNOD2*.

Cell isolation and dendritic cell generation

To generate *ex vivo* dendritic cells (DCs) from patients and controls, mononuclear cells were isolated by Ficoll separation density-gradient centrifugation, resuspended at a concentration of 2-5 × 10^6 cells/mL in complete RPMI-1640 medium containing 0.1% fetal calf serum (FCS), and allowed to adhere to the well surface of 24-well flat bottom plates (Corning, New York, USA) for 30 min at 37℃ in a 5% CO_2 incubator[23]. After washing twice with PBS to remove non-adherent cells, monolayer cells were cultured for DC differentiation in 0.5 mL RPMI-1640 supplemented with 10% FCS, 100 U/mL penicillin, 100 μg/mL streptomycin, 500 ng/mL GM-CSF (Strathmann Biotec AG, Germany), and 500 ng/mL IL-4 (Strathmann Biotec). After a 3-d culture, 100 μL medium was replaced with a fresh one containing the above-mentioned cytokines. Cell morphology was monitored by light microscopy. Analysis of cell surface marker expression was performed on a suspension of cells harvested on d 8.

Stimulation of DCs

On d 6 of culture, immature DCs were further maturated by adding either 100 ng/mL lipopolysaccharide (LPS; Sigma-Aldrich, Italy) plus 500 ng/mL interferon-γ (INF-γ; Strathmann Biotec) or 500 ng/mL MDP (Sigma-Aldrich) plus 500 ng/mL INF-γ for two more days. After 48 h stimulation, cells were harvested and analyzed by flow cytometry.

Flow cytometry analysis

Cell surface marker expression was evaluated by triple

Table 2 Genotype and allelic frequencies for *NOD2* variants in CD patients and controls

	CD (n = 47)	Healthy controls (n = 69)
Genotype		
Hz	17/47 (36.1%)	4/69 (5.8%)
Double Hz	3/47 (6.4%)	0

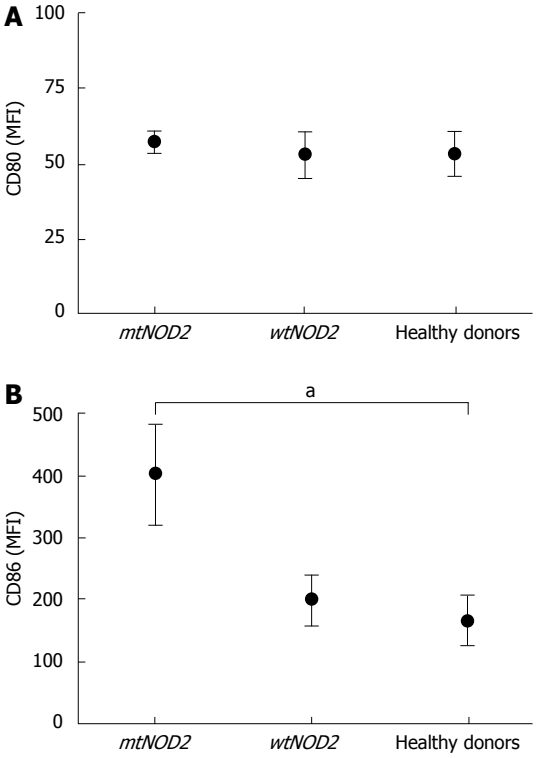

Figure 1 Expression of CD80 (**A**) and CD86 (**B**) in immature DCs, derived from healthy donors, and *mtNOD2* and *wtNOD2* patients. $^{a}P < 0.05$, Student's t test.

immunofluorescence staining with the following monoclonal antibodies: anti-CD80-FITC, anti-CD86-PE, anti-CD83-PE, anti-CD1a-PE, anti-CD33-TC (Caltag Laboratories, Burlingame, CA, USA), anti-CD14-FITC (clone TUK4; Dako Cytomation, Denmark) and anti-HLADR FITC (Becton Dickinson, San Jose, CA, USA). Samples were acquired using a FACScan flow cytometer (Becton Dickinson) and data analysis was performed using CellQuest software (Beckton Dickinson, San Jose, CA, USA). A total of 5000 events were analyzed for each sample.

Cytokine quantification

Supernatants of cell cultures were harvested and stored at -80℃ until measurement of cytokines. Production of IL-12p70 was quantified using an ELISA (Bender MedSystems, Burlingame, CA, USA) according to the manufacturer's instructions.

Statistical analysis

The t test was used to evaluate significant differences. Statistical analysis was performed with the GraphPad Prism program (San Diego, CA, USA), and $P < 0.05$ was considered significant.

RESULTS

NOD2 allelic variants in CD

Seventeen of the 47 CD patients were heterozygous for *NOD2* allelic variants associated with CD, and 3 were double heterozygous for two mutations. The allelic frequencies of R702W, G908R and 1007fs *NOD2* variants in CD patients and healthy donors are shown in Table 2. There was no correlation in our series between disease activity, pharmacological treatment, inflammatory localization and *NOD2* genotype. The mean Crohn's Disease Activity Index (CDAI) and pharmacological treatments are summarized in Table 3.

High CD86 expression in immature DCs derived from NOD2-mutated CD patients

In order to obtain immature DCs, monocytes were first cultured with IL-4 and GM-CSF for 6 d and analyzed for the expression of the two co-stimulatory molecules CD80 and CD86. Under microscopy, the cells from CD patients and controls showed a typical dendritic morphology. Immunocytometry showed no significant differences in CD80 expression in either *mtNOD2* or *wtNOD2* patients as compared with controls. However, CD86 expression was higher in CD patients than in controls, although the difference was not significant; however, it tended to be much higher when *mtNOD2* patients were compared to *wtNOD2* patients and controls ($P = 0.04$) (Figure 1).

Greater effect of LPS as compared to MDP on CD86 upregulation in NOD2-mutated CD patients

After LPS stimulation, terminal differentiation was obtained in DCs in patients and controls. Cells expressed high levels of activation/maturation markers, such as CD83, HLADR and CD1a, without any statistically significant differences among groups (Figure 2). Indeed, DCs from *mtNOD2* patients tended to show higher CD83 expression levels, while those from *wtNOD2* patients presented lower CD1a expression levels. MDP stimulation did not alter these results. Different behavior was shown

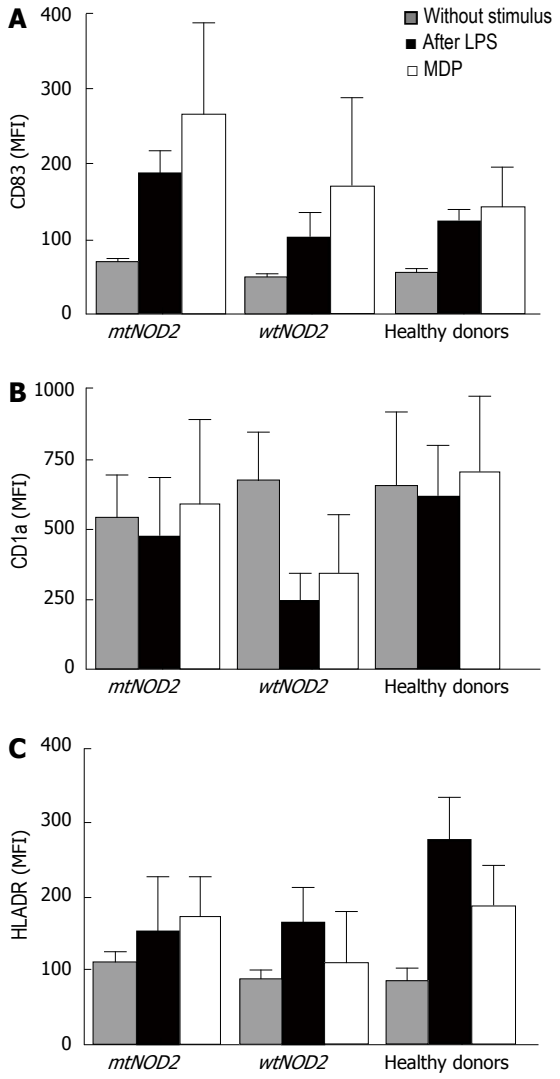

Figure 2 Expression of CD83 (**A**), CD1a (**B**) and HLADR (**C**) in DCs, derived from healthy donors, and *mtNOD2* and *wtNOD2* patients, without stimulus , after LPS or MDP stimulation.

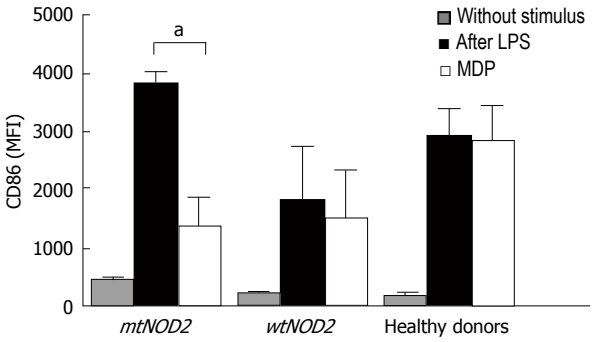

Figure 3 Expression of CD86 in DCs derived from *mtNOD2* and *wtNOD2* patients and healthy donors without stimulus, after LPS or MDP stimulation. [a]$P < 0.05$ LPS- *vs* MDP-stimulated *mtNOD2* patients, Student's *t* test.

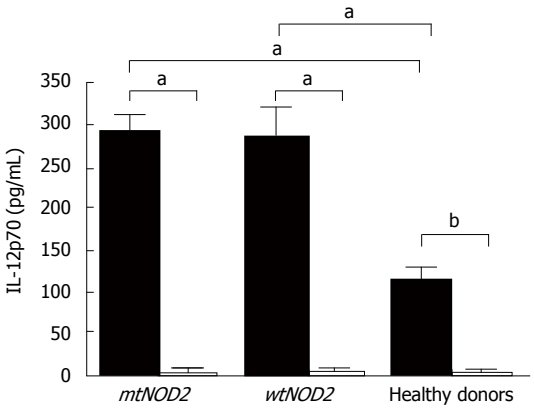

Figure 4 IL-12p70 levels (pg/mL) in monocyte-culture supernatants after stimulation with LPS (■) or MDP (□) in *mtNOD2* and *wtNOD2* patients and healthy controls. [a]$P < 0.05$ LPS- *vs* MDP-stimulated *mtNOD2* patients, LPS- *vs* MDP-stimulated *wtNOD2* patients, LPS-stimulated *mtNOD2* patients *vs* LPS-stimulated healthy donors, LPS-stimulated *wtNOD2* patients *vs* LPS-stimulated healthy donors; [b]$P < 0.01$ LPS- *vs* MDP-stimulated healthy donors; Student's *t* test.

by CD86 in *mtNOD2* patients compared to *wtNOD2* patients and healthy donors (Figure 3). A significantly greater up-regulation of CD86 was shown in *mtNOD2* after LPS stimulation compared to after MDP stimulation ($P = 0.016$). This difference was completely absent in *wtNOD2* and controls.

High levels of IL-12p70 expression in LPS-matured DCs from CD patients

MDP and LPS stimulation of monocyte cultures from patients and healthy donors was evaluated by measuring the production of the bioactive form of IL-12p70 (Figure 4), a major regulatory cytokine of the adaptive immune response. LPS induced higher levels of cytokines in CD patients (whether *mtNOD2* or *wtNOD2*) (mean values ± SD: 291 ± 42 pg/mL in *mtNOD2* and 285 ± 61 pg/mL in *wtNOD2*) in comparison to controls (112 ± 38.2 pg/mL), which showed a statistically significant difference ($P < 0.05$). MDP, on the other hand, was inactive, thus preventing cytokine production in DCs from CD patients (mean values ± SD: 3.2 ± 7.15 pg/mL in *mtNOD2* and 2.8 ± 6.2 pg/mL in *wtNOD2*) and healthy donors (1.94 ± 3.46 pg/mL, $P = 0.0079$).

DISCUSSION

Although several genes involved in CD have been described to date, the pathogenesis of the disease remains largely unknown[24,25]. It is thought that the disease arises from abnormal crosstalk between a changing intestinal flora and the host in the presence of a genetic background able to influence the integrity of the intestinal barrier and/or the functioning of the innate immune response[1,26]. Since the identification of *NOD2* mutations is associated with CD, much attention has been placed on the functions of monocytes in which this gene is constitutively expressed[6]. It has been hypothesized that some slight innate immunity defects may underlie the pathogenesis of CD. Kramer *et al* have recently identified a defect in response to MDP stimulation of DCs obtained from patients with homozygous 3020insC *NOD2* mutations, which suggests that a defect in the production of cytokines like IL-10 plays a role in the pathogenesis of the disease, by diminishing immune tolerance to intestinal bacteria.

In this work, we tested the ability of monocytes from CD patients to differentiate *in vitro* into DCs. The results indicated that monocytes differentiated into DCs using conventional stimuli. However, DCs obtained from CD patients with *mtNOD2* showed some differences in their expression of activation antigens before and after stimulation. These differences are not likely to depend on disease activity or drugs, as the *NOD2* genotype did not influence such aspects in our study (as in other published series). The most striking difference is the elevated expression of CD86 on immature *mtNOD2* DCs. Moreover, the *mtNOD2* group displayed a greater difference in CD86 up-regulation after LPS as compared to MDP stimulation. This was partially in agreement with the observations of Kramer *et al*[27] in patients with a homozygous 3020insC *NOD2* mutation, whose DCs failed to up-regulate CD80 and CD86 upon MDP stimulation. In our experiment, it was of particular interest that the expression of these activation markers was higher in immature cells, thus suggesting a continuous stimulation of these cells *in vivo*. Indeed, a high expression of activation markers on peripheral blood monocytes from CD patients has been reported[28]. Moreover, it is noteworthy that we could see these differences in heterozygous *mtNOD2* subjects when compared to *wtNOD2* CD patients and controls. This suggests some interference of mutated and normal proteins, perhaps in the process of homodimerization[29].

In conclusion, we showed that DCs obtained from patients with mutations in *NOD2* tended to be more activated than those obtained from *wtNOD2* and controls. However, during terminal differentiation, these DCs were less responsive to MDP compared to LPS. This may be the cause of an imbalance between inflammation and the killing ability of monocytes that may be relevant to the pathogenesis of CD.

COMMENTS

Background

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract. The incidence of the disease is rising in countries with improving socio-economic conditions. Although several hypotheses have been raised about the environmental factors involved in the risk of CD, the issue remains unresolved. Genetic data have recently identified genes responsible for susceptibility to CD and provided new tools for studying interactions between the immune system and the environment in the pathogenesis of CD.

Research frontiers

Several lines of evidence suggest that the disease may arise from an altered sensing of the microbial environment in the gut by the innate immune system. (1) CD patients produce antibodies against common intestinal commensal microbes. (2) Elemental diet is an effective treatment for CD. (3) Variants of the *NOD2* gene, which is involved in control of inflammatory responses to bacteria in monocytes, confer susceptibility to CD. (4) An inflammatory disease of the gut is typical of most primary immunodeficiencies involving the innate system. (5) Granulocyte monocyte-colony stimulating factor (GM-CSF) has been shown to ameliorate CD. However, the study of *NOD2* mutants has brought controversial results regarding the interpretation of CD pathogenesis. The study of the behavior of CD monocytes can help clarify this issue.

Innovations and breakthroughs

Most previous studies have analyzed *NOD2* mutations in cellular models, and have concluded that the consequences of *NOD2* mutation are either pro-inflammatory (activation of nuclear factor-κB) or a deficiency in response to bacteria. However, the situation *in vitro* is more complex. We demonstrated abnormal behavior of monocytes from CD, with an easier capacity to become activated but with only minor ability to complete differentiation. While other studies have shown a defective differentiation only for *NOD2* homozygous patients, we demonstrated that some differences may be present also in heterozygous patients. We hypothesized that the altered differentiation of monocytes might lead to an imbalance between inflammation and the killing ability of monocytes, and therefore is probably relevant to the pathogenesis of CD.

Applications

This study can help in the understanding of the therapeutic paradox of a disease that can be treated both with anti-inflammatory drugs and with cytokines able to strengthen the innate immune response. Further studies will be needed to determine those CD patients who are more likely to receive benefits from these two different treatment options.

Terminology

wtNOD2 represents the form of the gene without mutations. DCs are the most effective cells in presenting antigens to and stimulating T cells. They can develop from monocytes and histiocytes. Muramyldipeptide (MDP) is the minimal bioactive peptidoglycan motif common to all bacteria, and it is the essential structure required for adjuvant activity in vaccines.

Peer review

Generally this is a well written paper and provides further evidence concerning the effects of *NOD2* mutants on immune responses to bacterial stimuli.

Abstract

AIM: To investigate the agreement between esophageal manometry and pH step-up method in two different patient positions.

METHODS: Eighteen subjects were included in the study. First, the distance from the nose to the proximal border of the lower esophageal sphincter (LES) was measured manometrically. Then a different investigator, who was blinded to the results of the first study, measured the same distance using the pH step-up method, with the patient in both upright and supine positions. An assessment of agreement between the two techniques was performed.

RESULTS: In the supine position, the measurement of only one subject was outside the range accepted for correct positioning (≤ 3 cm distal or proximal to the LES). In the upright position, errors in measurement were recognized in five subjects. Bland-Altman plots revealed good agreement between measurements obtained manometrically and by the pH-step up method with the patient in the supine position.

CONCLUSION: In the case of nonavailability of manometric detection device, the pH step-up method can facilitate the positioning of the 24 h pH monitoring catheter with the patient in the supine position. This should increase the use of pH-metry in clinical practice for subjects with suspected gastroesophageal reflux disease if our results are supported by further studies.

Key words: pH monitoring; Esophageal manometry; pH step-up method; Gastroesophageal reflux

INTRODUCTION

Although the number of patients with a confirmed diagnosis with gastroesophageal reflux disease (GERD) is low, the condition is thought to affect many more people worldwide[1]. The evaluation of patients with reflux symptoms often requires using an advisable diagnostic tool both for distinguishing between physiologic and pathologic reflux, and for the purpose of treatment. New diagnostic tests (multichannel impedance monitoring, wireless pH monitoring capsules, *etc.*) have been developed and have become popular over the last decade, especially in leading industrial countries[2]. However, the conventional 24 h ambulatory pH monitoring continues to be the most common diagnostic test for determining pathologic acid reflux in developing countries. Traditionally, the distal pH sensor of the monitoring catheter is positioned 5 cm above the proximal border of the lower esophageal sphincter (LES), since the threshold used to discriminate the diagnostic cut-off level of acid exposure has been validated at this point[3]. The most popular method used for detecting this location is prior esophageal manometry. However, several measures have been employed to accurately determine the location of the LES, since manometric measurement (despite being essential to recognize motility disorders) is time consuming, is an invasive procedure[4-10], is uncomfortable for patients, and

leads to an increase in the cost of the diagnostic work-up.

In the past, the pH step-up method has been used for this purpose, but the results obtained were conflicting[5,11]. It is well known that gravity and body position have an effect on organ position, and in particular abdominal contents[12]. In the present study, we investigated the influence of body position on the location of the pH monitoring catheter during the pH step-up process. We hypothesized that localizing the pH probe with the patient in a supine position was more accurate since it is the same position as is used in manometric measurement.

MATERIALS AND METHODS

Preparation for the study

The study was conducted between May 2004 and July 2005, in a Military Medical Academic Hospital, in the GI Endoscopy and Manometry Laboratory of the General Surgery Department. Eighteen patients with reflux symptoms, but without hiatus hernia, (ten male and eight female), ranging in age from 22 to 68 (median age 46) years, and referred for esophageal manometry and esophageal pH monitoring constituted the study group. All esophageal tests were performed by two physicians, each of whom was blind to the results obtained by the other, however, all therapeutic decisions were made by a multidisciplinary gastroesophageal reflux team.

The tests were explained in detail to each patient, and written consent was obtained. All patients had been investigated endoscopically prior to the study, and only two had esophagitis. Patients with esophagitis had grade B disease according to the Los Angeles Classification[13] and there was no evidence of any serious disease (Barrett's esophagus, carcinoma *etc*.). Esophageal pH monitoring determined the presence of GERD in eleven cases (GERD group) while physiologic acid reflux was observed in the remaining subjects (Non-GERD group). All medications which could potentially impact esophageal motility, LES pressure and acid reflux were discontinued fifteen days prior to the tests.

Study protocol

An eight-lumen polyvinyl catheter with an external diameter of 4.5 mm [four lumens arranged 90º from each other for the most distal openings on the same circle, and the remaining four lumens with openings 5, 10, 15 and 20 cm proximal to the distal one respectively (Solar, MMS B.V. Enschede, The Netherlands)] was used for esophageal manometry. Once perfused and filled with distilled water, each lumen was connected to a pressure transducer-recorder system. Perfusion was maintained by fluid flow of 1 mL/min. After a six hour fast, patients were admitted to the laboratory. Topical anesthesia was applied, and with the patient in the supine position the catheter was introduced through the nose and into the stomach. The distance from the proximal margin of the LES to the nostril, the mean resting pressure and length of the LES, receptive relaxation of the LES, waves of esophageal peristalsis stimulated by wet swallow, and upper esophageal sphincter location were detected by using the stationary pull-through method. Each of the pulling steps was at intervals of 1 cm. The actual location of the proximal margin of the LES was based on the mean location of four radially oriented openings. The catheter was removed after measurements of the upper esophageal sphincter resting pressure and the location site was recorded.

After obtaining the manometric values, a different investigator who was blind to these findings performed the pH study. For this purpose, we used a double electrode ambulatory pH monitoring catheter [first sensor on the tip, and another 15 cm above the first (pH probe meter, MMS B.V. Enschede, The Netherlands)], calibrated with buffer fluids at pH 7.0 and 1.0, immediately prior to the test. The catheter was introduced into the stomach through the nose, with the patient in the upright position and breathing shallow. After confirmation of acidic pH, the catheter was withdrawn gradually until an abrupt rise in pH to > 4.0 (pH step-up) was detected. The pH readings were used to indicate the proximal margin of the LES at the esophagogastric junction. To confirm this point, the catheter was withdrawn at least a further 10 cm and then re-inserted into the stomach. The process was repeated two more times. The mean value of the three readings was used when there was a difference in the three measurements.

All tests after esophageal manometry were repeated with patients in the supine position. Following this stage, the first investigator rejoined the study and positioned the distal electrode of the catheter 5 cm above the upper margin of the LES, based on the actual LES location determined by manometric study. A chest x-ray was obtained to ensure against any bends or rolls. If any bend, roll, or dislocation was noted, the catheter location was re-confirmed after making the necessary corrections. Finally, ambulatory 24 h pH monitoring was initiated, with comments made on the usage rules of the recording machine.

Statistical analysis

The results of statistical analysis are noted in the text as mean ± standard deviation (SD) except for age. To analyze the significance of the results, the SPSS version 11.0 software package program (SPSS Inc, Chicago, IL, USA) was used. All data obtained from manometric measurements were compared between patients with pathologic and physiologic reflux using the Mann-Whitney-*U* test. The results of measurement and analysis with respect to esophageal motility above the LES and upper esophageal sphincter functions were not included in this report. An agreement between methods was assessed using the Bland-Altman analysis. This method tests agreement between two measurements, one of which is generally accepted as the gold standard. In addition, correlation between distances measured manometrically and by pH step-up method was calculated using Spearman's rho test. Results with $P < 0.05$ were considered statistically significant.

RESULTS

Patients referred for esophageal manometry and 24 h ambulatory pH monitoring were identified. None of

Table 1 Comparative results of GERD and non-GERD groups

Variables (mean ± SD)	**GERD group**	**Non-GERD group**
n (male/female)	11 (6/5)	7 (4/3)
Age (yr)	48 (26-68)	43 (22-61)
LES length (cm)	3.27 ± 0.9	2.86 ± 0.7
LES resting pressure, mmHg	10.82 ± 2.6	18.43 ± 4.0[a]
Distance: nose to the PB-LES, cm (by manometry)	42 ± 3.8	41.7 ± 3.5
Distance: nose to the PB-LES, cm (by pH step-up in upright position)	44.7 ± 2.6	43.8 ± 3.5
Distance: nose to the PB-LES, cm (by pH step-up in supine position)	43.4 ± 3.0	42.1 ± 3.3
Clear detection of receptive relaxation of the LES (*n*)	9/11	7/7

[a]$P < 0.05$ *vs* GERD group (Mann-Whitney-*U* test). LES: Lower esophageal sphincter; PB-LES: Proximal border of the LES.

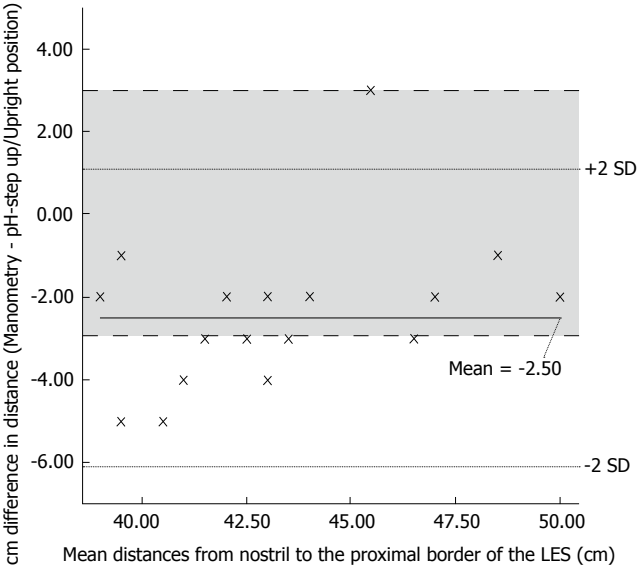

Figure 1 Bland-Altman scatter graph plotted to assess agreement between measurements obtained manometrically and by the pH step-up method with patients in the upright position. Grey area surrounded by longer dashed line indicates clinically acceptable limits.

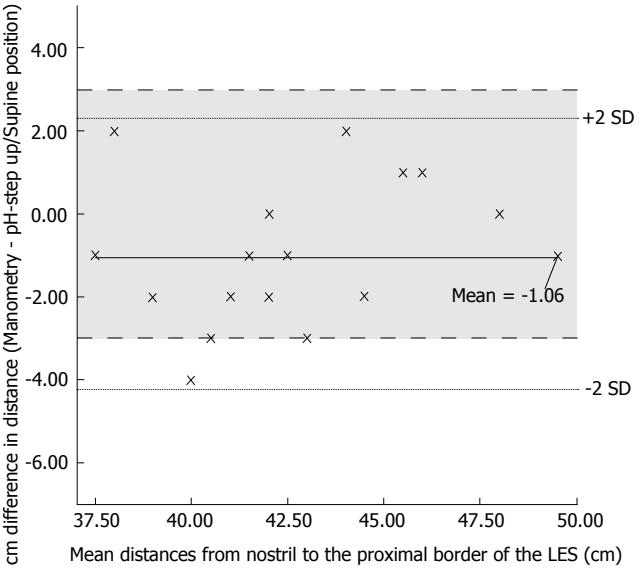

Figure 2 Bland-Altman scatter graph plotted to assess agreement between measurements obtained manometrically and by the pH step-up method with patients in the supine position. Grey area surrounded by longer dashed line indicates clinically acceptable limits.

the subjects had a hiatus hernia, an esophageal motility disorder, or dysfunction of the upper esophageal sphincter. According to the DeMeester reflux scoring system[14], eleven patients had acid reflux above the pathologic level; while the remaining subjects experienced reflux within the physiologic range (data not provided).

The results of comparison between the LES length and the mean resting pressure of the LES are given in Table 1. The LES length was 3.27 ± 0.9 in the GERD group and 2.86 ± 0.7 in the non-GERD group ($P = 0.268$). There was a significant difference between the mean resting LES pressures (10.82 ± 2.6 for GERD group and 18.43 ± 4.0 for non-GERD group, $P = 0.02$). In addition, a receptive relaxation at the level of LES was clearly observed in all but two subjects whose mean resting LES pressures were comparatively lower (7 and 8 mmHg, respectively).

In both study groups, the distance from the nose to the proximal border of the LES, detected manometrically was in the range of 37 to 49 (average 41.89 ± 3.58) cm. The same distance measured by the pH step-up method ranged between 40 and 51 (average 44.39 ± 2.95) cm in the upright position, and between 37 and 50 (average 42.94 ± 3.09) cm in the supine position. Bland-Altman (bias) statistics showed a good agreement between the distances measured manometrically and by the pH step-up method. This agreement was found within clinically acceptable limits (difference ± 3 cm) in measurements obtained with patients in the supine position [difference (mean ± SD): -1.06 ± 1.76, CI 95% for supine position and -2.5 ± 1.82, CI 95% for upright position] (Figures 1 and 2). When the differences are analyzed based on the individual results, a difference of > 3 cm between measurements obtained manometrically and by the pH step-up method in a supine position was observed in only one subject, where as there were five subjects who had a difference > 3 cm in the measurements performed in the upright position. A strong correlation was also noted between the two methods (correlation coefficient: 0.842, $P < 0.0001$ for manometry/pH step-up in the upright position, and correlation coefficient: 0.891, $P < 0.0001$ for manometry/pH step-up in the supine position, respectively, using the Spearman's rho test). A comparison of the GERD *vs* non-GERD patients with respect to the measurement obtained with each method-manometry, pH step-up in an upright position, and pH step-up in a supine position-showed no statistically significant difference between the two groups.

DISCUSSION

Our comparative study of LES function in patients with pathologic *vs* physiologic reflux are in agreement with established data regarding the pathogenesis of GERD. We observed a significant difference in the LES resting pressures of both groups, but not in the LES lengths.

Similar results were reported in a previous study[15]. Another report demonstrated that patients with reflux esophagitis had a lower minimum LES pressure compared with healthy subjects[16]. However, we could not determine the receptive relaxation of the LES during wet swallow in two patients with GERD. This was perhaps due to the presence of very low resting pressures, which made measurement of the relaxation pressure difficult. The results of pH monitoring and the management of patients with pathologic reflux have not been provided in this report.

For an accurate positioning of a pH electrode, esophageal manometry is widely accepted as the gold standard. Almost all of the other methods recommended for precise pH electrode placement (endoscopy, fluoroscopy, transnasal fiberoptic laryngoscopy, *etc.*), require interventions which increase the cost and are more invasive. It is for this reason that we recommend the pH step-up method, which aims at identifying the proximal border of the LES and only requires the use of pH monitoring catheter. Our results are based on the detection of an abrupt rise in the pH as the catheter is withdrawn from the acidic pH of the stomach into the neutral (pH > 4) environment of the esophagus. In contrast to other studies[5,17,18], some reports have stressed that the pH step-up method cannot be used for positioning of the pH electrode in the esophagus[11,19,20]. One of these studies by Marples and colleagues[20], suggested that false positioning of the pH electrode may occur (they detected incorrect positioning of 10 cm above and 16 cm below the LES) if the pH step-up method is used. Pehl and co-workers interpreted this inter-individual variance as a methodological bias, and have explained this on the basis of a lower position of the electrode, presumably because of the inability to detect acidic content secondary to the location of the electrode in the fundic air, when the patient is in the upright position[18]. This explanation supports our results, as it suggests that in the supine position, the withdrawal process may help in the correct positioning of the pH electrode. In fact, it should be recognized that a significant number of physicians interested in GERD and related illnesses have to manage such patients without esophageal manometry, since this test is still not commonly available, especially in community hospitals and small medical centers in developing countries[21]. For example, in the city of Ankara (the second largest city in Turkey), there are ten medical departments using esophageal pH monitoring in adult patients. However, adult participants are investigated by manometry in only five of these centers. This rate is similar to that in pediatric centers; therefore, a correct guide to the use of the pH step-up method is required.

We proposed to answer the following three questions with this study: (1) Could manometric determination of the LES level be safely replaced by the pH step-up method? (2) Does the degree of reliability change with the position of patient during pull-through?, and (3) Is there any difference in the measurements of GERD *vs* non-GERD patients? Esophageal manometry is generally performed when the patient is in a supine position and motionless; this provides the most accurate results from level-oriented pressure sensors. These sensors are properly calibrated prior to each measurement. When an individual reclines from the sitting to the supine position, the fundic air is dispersed throughout the stomach[22], and thus most of the acidic fluid content of the stomach comes into contact with inferior surface of the LES. Therefore, we hypothesized that the distal electrode of the pH monitoring catheter more precisely registers the pH change during the withdrawal process when the patient is in the supine position. Furthermore, as previously reported, LES pressure is higher in the supine position compared to the sitting position, particularly in patients with reflux esophagitis[22]. This may facilitate determining the pH change by preventing the escape of acid fluid into the esophagus, especially in patients whose LES pressure is very low. Despite this, reflux can occur when the patient is in a supine position. Therefore, to avoid a flawed measurement during a possible reflux episode, we repeated the withdrawal process two more times. In another report supporting the reliability of our measurements, the supine position was shown to have no greater influence on the amount of possible acid exposure than that of a 20 degree head-up position in healthy individuals, even if the stomach was full[23]. A previous study by Decktor *et al* showed that the placement of the esophageal pH monitoring catheter across the gastroesophageal junction did not increase gastroesophageal reflux[24]. These findings support our hypothesis with respect to the trustworthiness of the method.

Another possible reason for the difference in the measurements between the upright and supine positions is the effect of gravity on organ placement. It is well known that gravity, plays a significant role in posture and the proprioceptive location of body parts[12]. This effect may change an organ's location if it is sufficiently free from adjacent structures. There is a continuous movement of internal organs, caused by factors such as breathing, postural changes, and muscle contractions, which affects the abdominal contents as well as the diaphragm[25,26]. Although less than that compared to intra abdominal organs, there is measurable movement with changes in posture of organs within the ribcage. The pericardium, a structure that is adherent to adjacent tissues, has been shown to be mobile in the sagittal plane[27]. In light of these observations, it is possible that the LES may have a similar posture-related movement. This would help explain the difference in the measurement between the nostril and the proximal border of LES in the two positions. The present study showed no difference in the distance between nose and the proximal border of the LES between patients with and without GERD. These results were obtained both by the pH step-up technique as well as by the manometric method (Table 1). This finding is of critical importance as it indicates that the pH step-up method can be used in both GERD and non-GERD patients.

Measuring the exact location of the proximal border of the LES is presumably impossible because the LES is a ring that is localized in a diagonal plane in association with complex vector volumes[28]. Therefore, a difference in distance of up to 2 cm may be determined by different radially-oriented openings during manometric measurement. For this reason, an electrode positioned

by any method, at 3 cm above or below the manometric position, is commonly accepted as accurate[11,18]. However, if the electrode is positioned with a difference of 5 cm or more, a significant error in acid detection can occur. Anggiansah and co-workers reported that in nine out of twenty GERD patients, the clinical diagnoses according to the DeMeester reflux scoring system, was altered if the pH electrode was placed 10 cm above the LES[29]. Another study showed that there was a two-fold greater measurement of reflux events if an electrode was positioned at 1 cm compared with 5 cm above the gastroesophageal junction[30]. According to our results, all but one pH step-up measurement (successful in 17 of 18) made in the supine position was in the acceptable range (± 3 cm), whereas five measurements failed to determine the acceptable pH-step up location (successful in 13 of 18) in the upright position. Bland-Altman agreement plots demonstrated the superiority of measurements obtained in the supine position.

These findings clearly indicate the need for accurate placement of the ambulatory pH monitoring catheter with the patient in a supine position rather than in an upright position. However, the relatively small number of patients that were investigated may restrict the power of this conclusion. The total number of individuals tested was low because the study was designed to include subjects without hiatus hernia. Therefore, additional prospective, double-blind trials with larger number of subjects are needed for better understanding of this issue. Although patient position during diagnostic work-up may seem to be of little significance, the overall number of individuals who suffer from suspected reflux symptoms makes this issue quite important. In our opinion, physicians who manage patients with GERD should use this technique in clinical practice, especially in centers where manometric devices are not available.

In summary, we consider 24-h pH monitoring as the most valuable diagnostic tool in GERD; until such time as new methods now under development become widely available. Esophageal manometry is still the most reliable method for determining the proximal border of the LES. However, it has several limitations to its routine use. Hence, we recommend an easy method of placement of the ambulatory pH monitoring catheter. To our knowledge, this is the first study designed to assess the effect of patient's position on pH monitoring catheter location by an evidence-based clinical trial. Further studies with larger number of subjects are needed to confirm these results. We conclude that if the catheter is positioned when the patient is in a supine position rather than an upright position, the results obtained are more accurate. This may increase both the use of pH measurements without manometry and improve the diagnosis rate of GERD in developing regions of the world.

COMMENTS

Background

24-h pH monitoring remains the most crucial test to determine pathologic acid reflux in gastroesophageal reflux disease. Accurate placement of 24-h pH monitoring catheter requires prior esophageal manometry that enables physicians to precisely detect the upper border of the lower esophageal sphincter (LES). Manometric measurement is a relatively invasive procedure, is uncomfortable to patients, and leads to increase in the cost as well as the time spent on investigating each patient. The pH step-up method has been recommended for this purpose; however, published reports provide conflicting results on its usefulness. In the present study, we investigated the influence of patient posture on the pH step-up method, which resulted in improvement in the accuracy of the test.

Research frontiers

In an attempt to find an alternative method to esophageal manometry, different workers have recommended other techniques such as endoscopy, fluoroscopy and transnasal fiberoptic laryngoscopy; however, all of these add new difficulties and additional cost to the diagnostic workup. By contrast, the pH step-up method only requires the use of a monitoring catheter, however any alteration in the location of the pH sensor results in false measurement. This fundamental aspect of the study led us to the finding that the location and level of the pH sensor in the esophagus can alter with posture. To date, this finding has not been reported; and therefore, we decided to prospectively investigate the effect of patient posture on the position of pH monitoring catheter.

Innovations and breakthroughs

The present study revealed that the pH monitoring catheter could be more accurately positioned when the examination is performed with patient in a supine position. Bland-Altman (bias) statistics showed a good agreement between the distances measured manometrically and by the pH step-up method; however, this agreement was found within clinically acceptable limits (difference ± 3 cm) only with the measurements obtained with patients in the supine position. The possible factors and effects leading to this result are discussed in the present article.

Applications

The main debate about the use of the pH step-up method is focused on the ability to accurately position the monitoring catheter. The results of the present study suggest that examination carried out with the patient in the supine position increases the likelihood of accurate placement. Despite these encouraging findings, because of the small number of patients included in the present study, further trials with larger study population will be required to confirm our findings. If confirmed, this technical step will help make 24-hour pH monitoring a routine procedure. We believe that catheter placement for ambulatory pH monitoring can be more easily managed by using the pH step-up method.

Terminology

pH step-up: defines a sudden increase in the pH as the pH monitoring catheter is withdrawn from the acidic content of the stomach into the neutral (pH > 4) environment of the esophagus. It indicates that the pH sensor has crossed the gastroesophageal junction. Blant-Altman analysis: This test is used to compare the bias (the mean of the differences) and limits of agreement (bias ± 2 SD of bias) between two methods, one of which is accepted as the gold standard.

Peer review

In this manuscript, the authors ascertained the accuracy of the step-up method in intra-esophageal pH monitoring. The study was well performed and the conclusion is clear and very interesting.

Abstract

AIM: To investigate the individual and combined effects of allopurinol and hyperbaric oxygen (HBO) therapy on biochemical and histopathological changes, oxidative stress, and bacterial translocation (BT) in the experimental rat acute pancreatitis (AP).

METHODS: Eighty-five Sprague-Dawley rats were included in the study. Fifteen of the eighty-five rats were used as controls (sham, Group Ⅰ). AP was induced via intraductal taurocholate infusion in the remaining seventy rats. Rats that survived to induction of acute necrotizing pancreatitis were randomized into four groups. Group Ⅱ received saline, Group Ⅲ allopurinol, Group Ⅳ allopurinol plus HBO and Group Ⅴ HBO alone. Serum amylase levels, oxidative stress parameters, BT and histopathologic scores were determined.

RESULTS: Serum amylase levels were lower in Groups Ⅲ, Ⅳ and Ⅴ compared to Group Ⅱ (974 ± 110, 384 ± 40, 851 ± 56, and 1664 ± 234 U/L, respectively, $P < 0.05$, for all). Combining the two treatment options revealed significantly lower median [25-75 percentiles] histopathological scores when compared to individual administrations (13 [12.5-15] in allopurinol group, 9.5 [7-11.75] in HBO group, and 6 [4.5-7.5] in combined group, $P < 0.01$). Oxidative stress markers were significantly better in all treatment groups compared to the controls. Bacterial translocation into the pancreas and mesenteric lymph nodes was lower in Groups Ⅲ, Ⅳ and Ⅴ compared to Group Ⅱ (54%, 23%, 50% *vs* 100% for translocation to pancreas, and 62%, 46%, 58% *vs* 100% for translocation to mesenteric lymph nodes, respectively, $P < 0.05$ for all).

CONCLUSION: The present study confirms the benefit of HBO and allopurinol treatment when administered separately in experimental rat AP. Combination of these treatment options appears to prevent progression of pancreatic injury parameters more effectively.

Key words: Experimental pancreatitis; Allopurinol; Hyperbaric oxygen

INTRODUCTION

Acute pancreatitis (AP) is an untreatable condition with a wide clinical spectrum ranging from a mild, self-limited disease to severe organ failure[1]. Translocation of enteric bacteria is the most important cause of infection in the pancreatic tissue, and subsequent events such as sepsis and related complications[2,3]. Currently, several treatment options have been proposed for the septic complications of AP.

Hyperbaric oxygen (HBO) therapy has been investigated in several experimental and clinical conditions which cannot be treated with currently available medical

or surgical options[4,5]. HBO has been shown to have bactericidal activity against anaerobic bacteria[6]. In addition, HBO reduces the incidence of bacterial translocation[7]. It also lowers nitric oxide production and enhances several activities including bactericidal action of neutrophils, angiogenesis and wound healing[8]. Lin *et al* showed that repeated HBO therapy in endotoxic rats reduced inflammatory mediators and free radicals, as well as mortality[9]. In a rat model of tourniquet-induced ischemia-reperfusion skeletal muscle injury, HBO attenuated the reperfusion-induced increase in catalase activity and malondialdehyde (MDA)[10]. These studies demonstrated that HBO treatment, especially when administered in repeated doses has antioxidant rather than oxidative effect.

Xanthine oxidase plays an important role in the migration of microorganisms from the intestinal lumen to intra-abdominal spaces in pathological conditions, an event termed bacterial translocation (BT)[11,12]. Allopurinol (ALPL) has antioxidant properties, and previous studies have shown that antioxidant therapy reduces tissue injury and bacterial translocation in experimental pancreatitis[13,14].

The present study was carried out to investigate the individual and combined effects of ALPL and HBO on biochemical and histopathological changes, oxidative stress, and BT during the course of experimental rat pancreatitis.

MATERIALS AND METHODS

The study was approved by the Institutional Animal Use and Care Committee of the Gulhane Medical Academy and performed in accordance with the National Institutes of Health guidelines for the care and handling of animals.

Animals

Eighty-five male Sprague-Dawley rats weighing from 280 to 350 g were obtained from Gulhane School of Medicine Research Center (Ankara, Turkey). Before the experiment, the animals were fed standard rat chow and water ad libitum and housed in metabolic cages with controlled temperature and 12 h light/dark cycles for at least 1 wk.

Induction of pancreatitis

Anesthesia was induced with Sevoflurane (Sevorane® Liquid 250 mL, Abbott, Istanbul, Turkey) inhalation. Laparotomy was performed through a midline incision. The common biliopancreatic duct was cannulated with a 28 gauge 1/2 inch, micro-fine catheter. One microaneurysm clip was placed on the bile duct below the liver and another around the common biliopancreatic duct at its entry into the duodenum to avoid reflux of enteric contents into the duct. One mL/kg of 3% sodium taurocholate (Sigma, St. Louis, MO, USA) was slowly infused into the common biliopancreatic duct, with the infusion pressure maintained below 30 mmHg, as measured with a mercury manometer[15]. When the infusion was finished, the microclips were removed, and the abdomen was closed in two layers. All procedures were performed using sterile techniques.

Study protocol

Fifteen rats had a sham operation and served as the controls (Group Ⅰ). AP was induced *via* intraductal taurocholate infusion in the remaining seventy rats. Five of seventy rats died during the 6 h induction period. All surviving animals were randomization into four groups, six hours after the induction of pancreatitis. Group Ⅱ (n = 17) received saline (1 mL/kg, bid, sc), Group Ⅲ (n = 16) ALPL (200 mg/kg per day, bid, sc)[16], Group Ⅳ (n = 16) ALPL plus HBO (2.8 atmospheric pressure, bid, 90 min each, total 4 sessions)[17] and Group Ⅴ (n = 16) HBO alone. Five rats in Group Ⅱ, three rats each in Groups Ⅲ and Group Ⅳ, and four rats in Group Ⅴ died during the treatment period. Fifty-four hours after induction, all the surviving animals were killed with an intracardiac injection of pentobarbital (200 mg/kg). Data was collected on serum amylase levels, oxidative stress parameters [MDA, superoxide dismutase (SOD) and glutathione peroxidase (GSHPx)], bacterial translocation and histopathologic scores.

Laboratory tests

Blood samples were taken from the heart before the animals were sacrificed for serum amylase levels. A Hitachi 917 auto analyzer (Roche Diagnostics, Germany) was used for the amylase assay. Amylase level was expressed as U/L.

Histopathologic analysis

A portion of the pancreatic tissue from each rat was fixed in 10% neutral buffered formalin and embedded in paraffin. One paraffin section, stained with hematoxylin and eosin, was examined from each animal. Two pathologists who were blinded to the treatment protocol scored the tissues for edema, acinar necrosis, inflammatory infiltrate, hemorrhage, fat necrosis, and perivascular inflammation, in 20 different fields. The scores for each of the histologic abnormalities were added up, with a maximum score of 24, as defined by Schmidt *et al*[18].

Quantitative cultures and bacterial identification

The areas of the pancreas showing macroscopic necrosis and visible mesenteric lymph nodes were excised, weighed, and homogenized. The homogenates were diluted serially, quantitatively plated in duplicate on phenylethyl alcohol and MacConkey Ⅱ agar, and incubated aerobically at 37℃ for 24 h. The bacterial counts were expressed as colony-forming units (cfu/g tissue), and counts of 1000 cfu/g or higher were considered to be indicative of a positive culture. Gram-negative bacteria were identified with the API-20E system (BioMerieux Vitek, Hazelwood, MO, USA). Gram-positive bacteria were identified to the genus level by means of standard microbiologic methods[19,20].

Evaluation of oxidative stress

Pancreatic tissue samples were homogenized in cold KCl solution (1.5%) in a glass homogenizer on ice. The samples were centrifuged and the supernatant was used for the assays described below.

Tissue MDA concentration was estimated by the method of Ohkawa *et al*[21]. The supernatant was

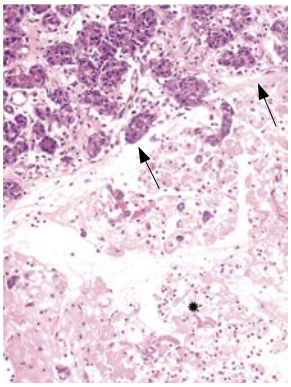

Figure 1 Light microscopy showing extensive necrosis (star) and relatively normal acinar structure (arrows) between the necrotic areas in the control group (HE, × 200).

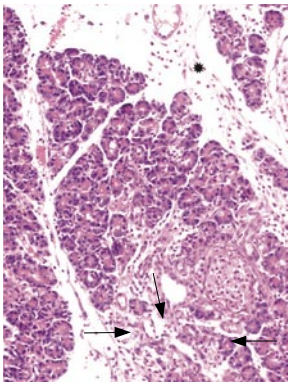

Figure 2 Light microscopy showing interlobular edema (star) and necrotic area (arrows) in the combined treatment group (HE, × 200).

resuspended in 4 mL water, 0.5 mL glacial acetic acid and 0.5 mL 0.33% aqueous thiobarbituric acid solution. The mixture was heated for 60 min in a boiling water bath. After cooling, the complex formed by thiobarbituric acid reactant substances was extracted into an n-butanol phase, and the formed chromogen was measured at 532 nm by spectrophotometer. A standard absorption curve for MDA was prepared using tetramethoxy propane solution. MDA levels were expressed as nmol/g tissue.

For the measurement of SOD activity, the supernatant was diluted 1:400 with 10 mmol/L phosphate buffer, pH 7.00. Twenty five μL of diluted supernatant was mixed with 850 μL of substrate solution containing 0.05 mmol/L xanthine sodium and 0.025 mmol/L 2-(4-iodophenyl)-3-(4-nitrophenol)-5-phenyltetrazolium chloride (INT) in a buffer solution containing 50mmol/L 3-cyclohexylaminol-1-propanesulfonic acid (CAPS) and 0.94 mmol/L ethylenediamine tetraacetic acid (EDTA) at pH 10.2. At this stage, 125 μL of xanthine oxidase (80 U/L) was added to the mixture and the absorbance increase was followed at 505 nm for 3 min against air. Twenty five microlitres of phosphate buffer or 25 μL of various standard concentrations were used as blank or standard determinations. SOD activity was expressed as U/g tissue[22].

For GSHPx measurement, the reaction mixture consisted of 50 mmol/L tris buffer, pH 7.6 containing 1mmol/L of Na_2EDTA, 2 mmol/L of reduced glutathione (GSH), 0.2 mmol/L of reduced nicotinamide adenine dinucleotide (NADPH), 4 mmol/L of sodium azide and 1000 U of glutathione reductase (GR), Fifty microlitres of supernatant and 950 μL of reaction mixture, or 20 μL of supernatant and 980 μL of reaction mixture were mixed and incubated for 5 min at 37℃. The reaction was initiated with 8 mmol/L H_2O_2, and the decrease in NADPH absorbance was followed at 340 nm for 3 min. The enzyme activity was expressed as U/g tissue[23].

Table 1 Serum amylase levels, oxidative stress parameters, bacterial translocation, histopathologic scores, and mortality rates in the different study groups

	Group Ⅰ (n = 15)	Group Ⅱ (n = 12)	Group Ⅲ (n = 13)	Group Ⅳ (n = 13)	Group Ⅴ (n = 12)
Amylase (U/L)	278 ± 44	1664 ± 234	974 ± 110	384 ± 40	851 ± 56
Oxidative stress					
MDA (nmol/g)	12.3 ± 0.4	28.3 ± 0.7	18.2 ± 0.4	16.4 ± 0.4	20.1 ± 0.5
SOD (U/g)	395 ± 7	254 ± 6	345 ± 16	282 ± 8	300 ± 9
GSHPx (U/g)	51.6 ± 2.0	30.8 ± 0.9	35.8 ± 1.5	48.4 ± 0.7	45.6 ± 1.4
Bacterial translocation					
MLNs	2 (13%)	12 (100%)	8 (62%)	6 (46%)	7 (58%)
Pancreas	2 (13%)	12 (100%)	7 (54%)	3 (23%)	6 (50%)
Histopathologic score	2 (1-3)	18 (14.5-19)	13 (12.5-15)	6 (4.5-7.5)	9.5(7-11.75)
Mortality	0/15 (0%)	5/17 (29%)	3/16 (19%)	3/16 (19%)	4/16 (25%)

MDA: Malondialdehyde; SOD: Superoxide dismutase; GSHPx: Glutathione peroxidase; MLNs: Mesenteric lymph nodes.

Statistical analysis

The results of parametric tests were expressed as mean ± SE. Nonparametric values were expressed as median (25-75 percentiles). The significance of differences in the histopathologic scores and serum amylase levels was assessed by the Kruskal-Wallis test. Subgroup analyses were performed by the Mann-Whitney *U* test or *t*-test as appropriate. The significance of differences in oxidative stress parameters was determined by Oneway ANOVA test and Tukey HSD procedure as post hoc test. Probabilities less than 0.05 were considered significant. All statistical measurements were made using SPSS PC ver. 11.05 (SPSS Inc. USA).

RESULTS

All rats except those in Group I developed acute pancreatitis, demonstrated by macroscopic parenchymal necrosis, and abundant turbid peritoneal fluid (Figure 1). Histopathological scores were significantly lower in all treatment groups (Group Ⅲ, Group Ⅳ and Group Ⅴ) compared to Group Ⅱ (13 [12.5-15], 6 [4.5-7.5], 9.5 [7-11.75], 18 [14.5-19]; $P < 0.01$, $P < 0.001$, and $P < 0.001$, respectively). The most favorable results were seen in the combination treatment group (Figure 2, Table 1).

Serum amylase levels were lower in Groups Ⅲ, Ⅳ and Ⅴ compared to Group Ⅱ (974 ± 110, 384 ± 40, 851 ± 56, 1664 ± 234 U/L; $P < 0.05$, $P < 0.001$, and $P < 0.02$, respectively, Table 1). Oxidative stress markers showed significantly lower levels in all treatment groups compared to the controls. Tissue MDA levels in Groups Ⅲ, Ⅳ, and Ⅴ were significantly lower than in Group Ⅱ (18.2 ± 0.4, 16.4 ± 0.4, 20.1 ± 0.5 nmol/g, *vs* 28.3 ± 0.7 nmol/g, respectively,

$P < 0.01$ for all, Table 1). Tissue SOD activity in Groups Ⅲ, Ⅳ, and Ⅴ was significantly higher compared to Group Ⅱ (345 ± 16 U/g, 282 ± 8 U/g, 300 ± 9 U/g, *vs* 254 ± 6 U/g; respectively, $P < 0.01$ for all, Table 1). In addition, GSHPx activity in Groups Ⅲ, Ⅳ and Ⅴ was significantly higher than in Group Ⅱ (35.8 ± 1.5 U/g, 48.4 ± 0.7 U/g, 45.6 ± 1.4 U/g, *vs* 30.8 ± 0.9 U/g; respectively, $P < 0.01$ for all, Table 1). BT to pancreas and mesenteric lymph nodes was reduced significantly in the three treatment groups (Group Ⅲ, Ⅳ and Ⅴ) compared to the control group (pancreatic tissue: 54%, 23%, 50%, *vs* 100%; $P < 0.02$, $P < 0.001$, and $P < 0.002$, respectively; MLNs: 62%, 46%, 58%, *vs* 100%; $P < 0.05$, $P < 0.01$, and $P < 0.05$, respectively, Table 1). Bacterial growth was seen in all tissue specimens obtained from the pancreas and MLNs in the control groups. Of the three treatment groups, combination treatment (Group Ⅳ) was most effective in preventing BT (3/13 [23%] to pancreatic tissue, and 6/13 [46%] in MLNs). The best results in terms of amylase levels, histopathological score, oxidative stress markers and BT were seen in rats receiving the combination treatment, compared to animals receiving a single treatment and the control group. Five rats in Group Ⅱ, three rats each in Groups Ⅲ and Ⅳ, and four rats in Group Ⅴ died before the 54th h of induction of pancreatitis. Mortality rates between groups, except the sham group, were statistically not significant.

DISCUSSION

Pancreatic infection is a serious complication of acute necrotizing pancreatitis. The failure of gut barrier results in bacterial translocation and subsequently septic complication of pancreatitis[2,3,24]. For this reason, prevention of contamination of the necrotic pancreatic tissue is very important, and the new generation antibiotics are of significant advantage in this respect. Although in experimental and clinical studies, the use of antibiotic has been shown to be beneficial[2]; in a randomized, controlled study prophylactic antibiotic therapy was found to have no effect on the mortality[25].

Although the potential role of xanthine oxidase in the presence of barrier failure and translocation of bacteria across the gut lumen has been shown in a previous study[14], the degree to which such a mechanism is involved in the pathogenesis of pancreatic infection is not known, and whether an inhibitor of this enzyme has a preventive effect is not clear[11,12]. The role of HBO therapy in the prevention of infectious complications, mainly through the reduction of oxidative stress and bacterial translocation in experimental acute pancreatitis has been reported previously[7,26]. Our group had previously investigated the efficacy of individual administration of allopurinol and HBO in preventing bacterial contamination of pancreatic tissue. In the present study, we examined the impact of combining allopurinol and HBO therapy[7,14].

We observed that both allopurinol and HBO had beneficial effects on the biochemical and histological abnormalities, oxidative stress and bacterial translocation. The present report represents the first study examining the effects of a xanthine oxidase inhibitor plus HBO therapy in acute pancreatitis. The individual effects of the two treatments on amylase levels were nearly the same. However, HBO treatment resulted in greater reduction in the histopathological scores, while allopurinol alone did not produce satisfactory histological recovery. The histological abnormalities in the combined treatment group were significantly less compared with the use of allopurinol and HBO alone, indicating a potentiation of effect. Allopurinol also decreased the oxidative stress parameters, as it has been reported previously[13,14,27,28], although allopurinol was found to have no effect on the incidence and severity of endoscopic retrograde cholangiopancreatography (ERCP)-induced pancreatitis in studies on human subjects by Budzynska *et al*[29]. When allopurinol was co-administered with HBO at the same doses, the overall antioxidant effect did not increase. These results correlate well with the histological recovery seen in animals treated with individual drugs and combination therapy. However, when the data regarding oxidative stress was examined, it was interesting to note that combination therapy was more effective in increasing the anti-oxidant system. These findings suggest that the improvement in pancreatic morphology was related to the increase in the anti-oxidant system.

Bacterial translocation was very similar in the individual treatment groups. Again, bacterial contamination of the pancreatic tissue was significantly less in the combined treatment group, indicating a potentiating effect. Although xanthine oxidase, an important source of endothelial cell-derived superoxide and hydrogen peroxide, plays a primary role in ischemia-reperfusion injury, which contributes to the failure of the intestinal barrier[11], it can be postulated that even with the addition of antioxidant activity of allopurinol, inhibition of xanthine oxidase was not superior compared to the use of HBO alone. However, a combination of these two agents may produce remarkable inhibition of bacterial translocation, perhaps through different mechanisms including not only xanthine oxidase inhibition and antioxidant activity but also direct antibacterial, immunological, angiogenic and cellular-subcellular effects.

Finally, the present study confirmed our previous observations on the efficacy of HBO and allopurinol in experimental acute necrotizing pancreatitis and also demonstrated that a combination of these treatment options prevented more effectively the progression of pancreatic injury. Nevertheless, the activity and potency of xanthine oxidase, the importance of blocking its activity, and the detailed effects of HBO on this enzyme in the intestines and in the pancreas in acute pancreatitis need further examination.

COMMENTS

Background

The severity of acute pancreatitis may range from a mild, self-limited illness to a catastrophic disease with multiple potentially severe complications and risk of death. Translocation of bacteria from the intestines is one of the most important factors in the development of septic complications and mortality in acute pancreatitis

Research frontiers

Most of the experimental and clinical studies designed to reduce morbidity and mortality in acute pancreatitis are focused on minimizing the extent of necrosis and the prevention of bacterial contamination of necrotic pancreatic tissue.

Innovations and breakthroughs

Several studies have assessed the effect of allopurinol and hyperbaric oxygen on bacterial translocation, oxidative stress, and histology in experimental acute necrotizing pancreatitis. The present study was carried out a rat model to evaluate the effect of combined allopurinol and hyperbaric oxygen treatment on bacterial translocation, oxidative stress and the course of acute necrotizing pancreatitis.

Applications

If these results are confirmed on further studies, combination treatment with allopurinol and hyperbaric oxygen can be applied clinically in patients with acute necrotizing pancreatitis to prevent oxidative stress and bacterial translocation.

Peer review

This paper examines the effects of allopurinol and hyperbaric oxygen on taurocholate infusion-induced acute necrotic pancreatitis in rats. It was observed that both treatments improved the pathological abnormalities, and combination of the two modalities provided further improvement.

Abstract

AIM: To evaluate the use of the trypsinogen-2 dipstick (Actim Pancreatitis) test for early diagnosis and prediction of severity in acute pancreatitis (AP).

METHODS: Ninety-two patients with AP were included in this study. The control group was 25 patients who had acute abdominal pain from non-pancreatic causes. Urine trypsinogen-2 dipstick test (UTDT) and conventional diagnostic tests were performed in all patients. Patients were divided by the Atlanta classification into two groups as having mild or severe pancreatitis.

RESULTS: UTDT was positive in 87 (94.6%) of the AP patients and in two (8%) controls ($P < 0.05$). Positive UTDT was found in 61 (92.4%) of 66 (71.7%) patients with mild pancreatitis and in all (100%) of the 26 (28.3%) with severe pancreatitis ($P > 0.05$). UTDT positivity lasted longer in severe pancreatitis compared with that in mild pancreatitis (6.2 ± 2.5 d *vs* 2.0 ± 1.43 d, $P < 0.05$). The sensitivity, specificity, positive predictive value, negative predictive value (NPV), positive likelihood ratio (PLR) and negative likelihood ratio (NLR) of UTDT were 91%, 72%, 96.6%, 70.4%, 3.4 and 0.1, respectively.

CONCLUSION: UTDT is a simple, rapid and reliable method for use on admission. It has high specificity and low NLR for early diagnosis and prediction of severity in AP. However, its relatively low NPV does not allow trypsinogen-2 dipstick test to be a stand-alone tool for diagnosis of acute pancreatitis; the use of other conventional diagnostic tools remains a requirement.

Key words: Acute pancreatitis; Urine trypsinogen-2 dipstick test; Early diagnosis; Disease severity

INTRODUCTION

Most patients with acute pancreatitis (AP) have a mild and self-limited form of the disease that resolves spontaneously, but approximately 20% of attacks are severe and represented by pancreatic necrosis, sepsis, and fulminant multiorgan/system failure with a life-threatening morbidity and a mortality rate of 20%-30%. Hence, early diagnosis and prediction of severity in AP has particular significance[1-6].

Early prediction of the severity of AP is difficult[3,7]. Multifactorial scoring systems like the Ranson prognostic signs and the Glasgow score can only be evaluated 48 h after admission. The acute physiology and chronic health evaluation Ⅱ (APACHE Ⅱ) score has the invaluable advantage of being useful within a few hours after admission, and it can be assessed serially. However, it is cumbersome, which limits its use in clinical practice[7]. The current gold standard for staging AP combines clinical criteria with computed tomography (CT), but this has limited availability, high costs, exposes the patient to ionizing radiation, and lacks sensitivity and specificity in the early stage of the disease. Several laboratory markers have been evaluated as replacements for the multifactorial scoring systems, with CT being the most widely used[8,9]. Alternatively, magnetic resonance imaging can be used, e.g. in case of contraindications to intravenous CT contrast agents[10]. Various biochemical tests such as the urine trypsinogen-2 dipstick test (UTDT) have been developed over the past ten years for early diagnosis and prediction of severity in AP. Trypsinogen occurs as two major isoenzymes, trypsinogen-1 (cationic) and trypsinogen-2 (anionic), which are secreted at high concentrations into pancreatic fluid with a small proportion escaping into the circulation. Trypsinogen-1 and trypsinogen-2 are eliminated from the blood circulation by the kidneys. In AP, concentrations of trypsinogen-2 in serum and urine are higher than those of trypsinogen-1[11-13]. Although

UTDT has been evaluated in many studies, details of the clinical use of this test for early diagnosis and prediction of severity in AP remain obscure[3,13-15]. The aim of our prospective study was to evaluate the use of the trypsinogen-2 dipstick (Actim Pancreatitis) test in early diagnosis and prediction of severity in AP, and to compare the sensitivity, specificity and prognostic value of the this test with those of serum amylase, serum lipase and APACHE Ⅱ score.

MATERIALS AND METHODS

Materials

The prospective study population consisted of 92 consecutive patients with AP (study group: 69 males, 23 females; median age 58.9 year, range 36-80) and 25 consecutive patients with acute abdominal disease of extrapancreatic origin (control group: 15 males, 10 females; median age 59.2 year, range 34-78) admitted to the emergency unit at Izmir Ataturk Education and Research Hospital between January 2003 and July 2005. The study was approved by the Committee on Research Ethics at our hospital, and all patients gave their informed consent for inclusion in the study.

Study design

Diagnosis of AP was based on a history of prolonged upper abdominal pain, serum amylase at least three times the upper limit of normal and the presence of edema or necrosis on abdominal ultrasonography and/or contrast-enhanced CT. Patients who were admitted after the first 24 h after the onset of abdominal pain were not included in the study. APACHE Ⅱ score values were calculated on admission and at 48 h. Body mass index (BMI) of all patients was calculated. CT was performed selectively in patients with severe pancreatitis as predicted by either one of the two scoring systems (Ranson criteria > 2 or APACHE Ⅱ score > 7). Under the Atlanta classification, AP is predicted as severe if it is accompanied by single or multiorgan failure, local complications, 3 or more on the Ranson criteria, or an APACHE Ⅱ score of ⩾ 8 points[1].

Methods

Serum amylase and lipase concentrations were measured using enzymatic assay (Architect C 8000; Abbott, Abbott Park, IL, USA; reference interval, 26-100 U/L and 13-60 U/L, respectively). The Actim Pancreatitis test strip (Medix Biochemica, Kauniainen, Finland), an immunochromatographic test, was used for urine trypsinogen-2 determination (detection limit 50 μg/L). The tip of the strip was immersed into a urine-containing vial and was held for 20 s before being completely taken out of the vial. The strip was then kept at room temperature for 5 min to observe whether urine reacted with blue latex particles covered by monoclonal antitrypsinogen-2 antibodies. Excess (> 50 μg/L) urinary trypsinogen-2 caused the occurence of 2 blue stripes, while only one stripe (referred to as the control stripe) was observed when urinary trypsinogen-2 concentration was within the normal range. The appearance of the control stripe confirmed the accuracy of the assay, while no blue stripes on the test strip suggested an erroneous test, in which case the test was repeated[16].

Table 1 Diagnosis and/or etiology of pancreatitis in the control and study groups

Control group	*n* (%)	Study group	*n* (%)
Familial Mediterranean fever	5 (20)	Gallstone	58 (63.0)
Acute appendicitis	5 (20)	Idiopatic	18 (19.6)
Acute cholecystitis	4 (16)	Post-ERCP	8 (8.7)
Perforated peptic ulcer	3 (12)	Alcohol	5 (5.4)
Acute cholangitis	2 (8)	Hypertriglyceridemia	3 (3.3)
Pelvic inflammatory disease	2 (8)		
Intestinal obstruction	2 (8)		
Gastric cancer	1 (4)		
Meckel diverticulitis	1 (4)		

ERCP: Endoscopic retrograde cholangiopancreaticography.

Statistical analysis

Data were expressed as the mean ± SE. The Mann-Whitney *U* and McNemar tests were used where appropriate for statistical analysis. All *P* values were two-tailed, and those with $P < 0.05$ were defined as statistically significant. For serum concentrations of amylase and lipase, a threefold increase in the reference values recommended by our laboratory were selected as cut-off values. Using these cut-off points, the sensitivity, specificity, positive (PPV) and negative predictive value (NPV), and positive (PLR) and negative likelihood ratio (NLR) in establishing the diagnosis of AP were calculated. The SPSS/PC 10.0 (SPSS, Chicago, IL, USA) statistical package was used on a personal computer for the analysis of data.

RESULTS

The mean ages of patients in the study and control groups were 58.9 ± 14.2 year ($n = 92$, range, 36-80) and 59.2 ± 13.5 year ($n = 25$, range, 34-78), respectively ($P = 0.928$). No significant difference was found between the two groups in terms of gender (study group, M/F = 69/23; control group, M/F = 15/10; $P = 0.113$). Gallstones were the most common causes of AP ($n = 58$, 63%), while familial Mediterranean fever and acute appendicitis were the most common causes of acute abdominal pain in patients in the control group ($n = 5$, 20% and $n = 5$, 20%, respectively) (Table 1). Mean BMI of patients in the study and control groups were 24.0 ± 3.8 kg/m^2 (range, 16-33) and 23.5 ± 3.4 kg/m^2 (range, 16-30), respectively ($P = 0.902$). Both mean serum amylase concentrations and mean serum lipase concentrations were significantly higher in patients in the study group compared with those in the control [amylase, 600.8 ± 189.7 U/L (range, 376-1250) *vs* 67 ± 32.5 U/L (range, 18-176), and lipase, 96.2 ± 42.4 U/L (range, 58-230) *vs* 33.8 ± 15 U/L (range, 13-65); $P = 0.000$)].

UTDT on admission was positive in 87 (93.5%) of the 92 patients in the study group, and in two (8%) of the 25 patients in the control group ($P = 0.000$). In the control

group, false-positive UTDTs were normalized 1 d later in a patient with acute cholecystitis and 3 d later in a patient with gastric cancer. On the other hand, UTDT positivity lasted for an average of 3.6 ± 2.1 d (range, 2-13) in patients in the study group. APACHE Ⅱ score (cut-off > 8) was 6.1 ± 2.7 (range, 3-13) and 4.6 ± 1.5 (range, 3-8) in the study and control groups, respectively (P = 0.006) (Table 2).

Of the patients with AP, 66 (71.7%) had mild disease and 26 (28.3%) had severe disease according to the Atlanta classification[1]. Gallstones were the most common cause of both mild and severe AP (n = 45, 68.2% and n = 13, 50%, respectively). No significant difference was found between patients with mild and severe AP in terms of BMI (P = 0.217). However, both Ranson and APACHE Ⅱ scores on admission were significantly higher in patients with severe AP than in those with mild AP [Ranson, 3.73 ± 1.04 (range, 2-5) *vs* 1.03 ± 0.82 (range, 0-3), and APACHE Ⅱ, 9.73 ± 1.75 (range, 8-13) *vs* 4.68 ± 1.38 (range, 3-8), respectively; P = 0.000]. Likewise, APACHE Ⅱ score determined at 48 h later was significantly higher in patients with severe pancreatitis than in those with mild pancreatitis (4.24 ± 1.44 *vs* 11.5 ± 2.88, P = 0.000). Sensitivity and specificity of APACHE Ⅱ score on admission were 56.0% and 89.4%, respectively.

Table 4 Sensitivity, specificity, PPV, NPV, PLR and NLR of serum amylase, serum lipase, UTDT and APACHE Ⅱ scoring systems in AP

	Sensitivity %	Specificity %	PPV %	NPV %	PLR	NLR
On admission						
Serum amylase (> 100 U/L)	78.0	87.3	94.8	61.5	6.1	0.3
Serum lipase (> 60 U/L)	86.2	89.4	96.6	76.0	8.1	0.2
UTDT, positive	91.0	72.0	96.6	70.4	3.4	0.1
APACHE Ⅱ > 8	56.0	89.4	61.0	84.2	5.3	0.5

Table 5 Comparisons of sensitivity and specificity of UTDT in AP in present study with those reported previously

Reference	Sensitivity (%)	Specificity (%)
Kemppainen *et al* 1997[29]	94	95
Kylanpaa-Back *et al* 2000[28]	96	92
Lempinen *et al* 2001[5]	62	87
Pezzilli *et al* 2001[27]	53.3	-
Lempinen *et al* 2003[7]	72	81

Saes *et al* 2005[30]	68	86.4
Present study	91	72

Mean serum amylase concentrations were not significantly different in patients with severe and mild AP (658.2 ± 222.5 U/L *vs* 578.6 ± 171.3 U/L, respectively, P = 0.068), while serum lipase concentrations in patients with severe AP were significantly higher than those in patients with mild AP (76.0 ± 23.9 U/L *vs* 110.4 ± 54.2 U/L, respectively, P = 0.000). UTDT was positive in 61 of the 66 (92.4%) patients with mild AP and in all 26 (100%) patients with severe AP (P = 0.351). No significant difference was found between patients with severe AP and those with mild AP in terms of UTDT positivity at 48 h after admission (P = 0.351). Positive UTDT continuation averaged 2.6 ± 0.6 d (range, 2-4) and 6.2 ± 2.5 d (range, 3-13) in patients with mild and severe AP, respectively (P = 0.000) (Table 3).

In AP, the sensitivity, specificity, PPV, NPV and PLR of serum amylase and lipase were 78%, 87.3%, 94.8%, 61.5% and 6.1, and 86.2%, 89.4%, 96.6%, 76.0% and 8.1 respectively, while UTDT sensitivity was 91%; specificity was 72%; PPV was 96.6%; NPV was 70.4% and PLR was 3.4 (Table 4). Sensitivity and specificity rates of UTDT obtained in our study were compared with those reported in the literature and are listed in Table 5.

DISCUSSION

AP presents in various clinical forms ranging from

mild abdominal discomfort to multiple organ failure. After a mild pancreatitis attack, 80% of patients recover completely, while the disease worsens in 20% and has a mortality rate of 30%[1,17-19]. Thus, early diagnosis and determination of severity of AP are of great importance in terms of mortality and morbidity.

Several methods have been used to diagnose AP and determine its prognosis and severity; these include scoring systems (such as Ranson, Glasgow, and APACHE), biochemical parameters [e.g. serum amylase, lipase, C-reactive protein (CRP), trypsinogen-activation peptide (TAP), interleukins 6 and 8, carboxypeptidase B activation peptide, tumor necrosis factor-α, platelet-activating factor, polymorphonuclear elastase, and serum procalcitonin], and imaging techniques (such as CT)[5,20-22]. The methods that can be used to compare the predictive value of different tests have been summarized in a paper by Jaeschke[23]. What is needed is an immediate test with high specificity and low NLR[24].

In the mid 1990s, urine trypsinogen concentration and TAP were reported to be of high sensitivity and specificity in diagnosing and predicting severity of AP. Since then, determinations of urine trypsinogen concentration and TAP have been considered as good alternative biochemical tests[25,26]. Lempinen et al have compared urinary trypsinogen-2 with urinary TAP and serum CRP for early differentiation between severe and mild AP and concluded that urinary trypsinogen-2 is superior to serum CRP, and is as good as or even better than urinary TAP for the early prediction of disease severity in the first 24 h of admission for AP[7].They have also noted that the result of a trypsinogen-2 dipstick test is available within 5 min, whereas TAP requires a laborious ELISA method, which takes several hours and requires skilled laboratory personnel; the rapid urinary trypsinogen-2 test does not require the use of laboratory equipment[7].

Sensitivity and specificity of UTDT in AP has been reported in the literature as 53.3%-96% and 85.7%-95%, respectively[22,25-31]. We calculated a sensitivity of 91% and specificity of 72% for UTDT. Consistent with a previous report, we found higher sensitivity for UTDT compared with that for serum amylase and lipase concentrations (91% *vs* 78% and 86%, respectively)[4]. However, Pezzilli *et al* reported a low sensitivity for UTDT in their study in which 30 patients with AP were investigated, 11 of whom were included at 2-3 d after onset of the attack[27]. We believe that this late inclusion of a considerable number of patients in the aforementioned study might have affected urinary trypsinogen-2 concentrations and, thus might have decreased the sensitivity and specificity of UTDT for AP diagnosis. In agreement with this view, Chen et al have recently reported a gradually decreasing sensitivity for UTDT in diagnosis of AP from the first to the fourth day of admission (i.e. 90.6%, 81.2%, 59.4% and 50% on the first, second, third and fourth days of admission, respectively)[16]. Considering the effect of late admission (which resulted in delayed UTDT), we did not include patients who were admitted 24 h after the onset of abdominal pain. Thus, we obtained a homogeneous study group in terms of timing of UTDT. We found a positive UTDT in 93.5% and 8% of patients with AP and those with acute abdominal pain due to non-pancreatic causes, respectively. This statistically significant difference supports the use of UTDT in AP diagnosis within the first 24 h of acute abdominal pain.

Chen *et al* have concluded that UTDT can be used in the differential diagnosis of AP due to its high NPV[16]. Lempinen *et al* and Kylanpaa-Back *et al* have reported NPV rates for UTDT of 85% and 99%, respectively[5,28]. We found that the NPV for UTDT was 70.4%, which is higher than the NPV of serum amylase and close to that of serum lipase. We believe that AP diagnosis must be confirmed by other biochemical tests and imaging techniques in patients with a positive UTDT. This is because urinary trypsinogen-2 concentrations may also be increased in other diseases such as hepatobiliary and pancreatic malignancies, colon cancers, and chronic pancreatitis[13]. On the other hand, we found that the PPV (96.6%) for UTDT was higher than that of serum amylase and was equal to that of serum lipase. Thus, we believe that the use of UTDT is advantageous for an early diagnosis of AP because of its rapid action, high sensitivity and high PPV.

UTDT has been reported to have a direct correlation with the severity of AP, as its sensitivity increases with increased severity of AP[4,16]. We have been unable to confirm this conclusion, because in our study we found the sensitivity of UTDT was 87.2% in severe AP and 82.8% in mild AP. However, these rates were not significantly different. On the other hand, a longer duration of UTDT positivity in severe AP compared with that in mild AP was detected. These data suggest that repeating UTDT every day may allow a clinician to predict the severity of AP that varies with time. Thus, such patients will probably benefit from admission to a medical center, prophylactic antibiotic administration, early enteral nutrition, and early endoscopic retrograde cholangiopancreatography in pancreatitis of suspected biliary origin[25].

In conclusion, while there are a few studies on the value of the trypsinogen-2 dipstick test as a predictive test for the severity of AP, its relatively low NPV does not allow UTDT to be a stand-alone tool for diagnosis of AP. Thus, the use of other conventional diagnostic tools becomes an additional requirement. However, UTDT is a simple, rapid and a reliable method that can be used on admission with high specificity and low NLR for early diagnosis and prediction of severity in AP.

COMMENTS

Background

Urine trypsinogen-2 dipstick test (UTDT) is simple, rapid and a reliable method that can be used on admission with high specificity and low negative likelihood ratio (NLR) for early diagnosis and prediction of severity in acute pancreatitis (AP).

Research frontiers

Early diagnosis and prediction of severity in AP is of particular significance.

Innovations and breakthroughs

Although UTDT has been evaluated in many studies, clinical use of this test for early diagnosis and prediction of severity in AP is obscure. The aim of our

prospective study was to evaluate the use of a trypsinogen-2 dipstick (Actim Pancreatitis) test in early diagnosis and prediction of severity in AP and to compare the sensitivity, specificity and prognostic value of this test with those of serum amylase, serum lipase and APACHE Ⅱ score.

Applications

UTDT is a simple, rapid and reliable method that can be used on admission for early diagnosis and prediction of severity in AP.

Terminology

Various biochemical tests, one of which is the UTDT, have been developed over the past ten years for early diagnosis and prediction of severity in AP. Trypsinogen occurs as two major isoenzymes, trypsinogen-1 (cationic) and trypsinogen-2 (anionic), which are secreted at high concentrations into pancreatic fluid with a small proportion escaping into the circulation. Trypsinogen-1 and trypsinogen-2 are eliminated from the blood circulation by the kidneys. In AP, concentrations of trypsinogen-2 in serum and urine are higher than those of trypsinogen-1.

Peer review

The authors evaluated the use of a trypsinogen-2 dipstick (Actim Pancreatitis) test in early diagnosis and prediction of severity in AP. UTDT is a simple, rapid and a reliable method that can be used on admission with high specificity and low NLR for early diagnosis and prediction of severity in AP.

Abstract

AIM: To identify the anthropometric, metabolic and mood state in hepatitis C virus (HCV)-infected patients from the west of Mexico and to evaluate the effect of Breathwalk (BW), a combination of walking, synchronized breathing and focussed attention, on those patients.

METHODS: In an experimental study, 17 patients with serological and molecular diagnosis of HCV, not receiving pharmacological treatment, were studied. One hour sessions of BW were practiced 3 times at week for six months. Body composition was assessed by electric impedance. Biochemical profiles and insulin resistance (IR) risk was assessed by conventional methods. Mood state was evaluated with specific and open questions at the beginning and at the end of the program.

RESULTS: Seventy percent of patients were overweight or obese, and 77% of the patients presented with IR at the beginning of the study. Improvements were observed at the 3rd mo, and statistically significant differences were recorded at the 6th mo using the fitness score (76 *vs* 83, $P < 0.01$), in alanine aminotransferase (ALT) (106 ± 93 U/L *vs* 59 ± 32 U/L, $P < 0.01$), total bilirubin (0.09 ± 1 mg/dL *vs* 0.62 ± 0.2 mg/dL, $P < 0.01$), ALT/AST ratio (1.04 *vs* 0.70, $P < 0.01$), triglycerides (165 ± 86 mg/dL *vs* 124 ± 49 mg/dL, $P < 0.01$) and the IR risk (4.0 *vs* 2.7). Most patients (88%) indicated to feel better at the end of BW ($P < 0.01$).

CONCLUSION: Breathwalk has an important effect on body composition, lipid profile and liver enzymes. It is also easy, inexpensive and has a beneficial effect on metabolic and mood state in HCV patients.

Key words: Breathwalk; Chronic hepatitis C; Insulin resistance; Obesity; Quality of life

INTRODUCTION

It has been estimated that hepatitis C virus (HCV) has infected more than 170 million people globally and is responsible for up to 70% of all viral chronic infections[1]. Furthermore, obesity, type 2 diabetes (DM2) and insulin resistance (IR) are current health problems that especially affect chronic HCV patients[2-6]. The occurrence of obesity is an additional risk factor that can further deteriorate the health condition of chronic hepatitis C patients[7], with increased insulin resistance[8] and potential development of diabetes and progression to liver fibrosis[9,10]. Also, poor quality of life related to changes in mood, emotional state, and depressions are common findings among chronic HCV patients[11,12]. This is mainly attributed to the impact of the diagnosis and subsequent anxiety over long-term health[12]. This situation may limit the tolerability of antiviral treatment and reduce compliance[11], together with the fact that HCV patients with excess body weight are known to be poor responders to antiviral therapy in comparison to normal-weight individuals[13,14]. Therefore, it is important to search for additional therapeutic strategies

focused on lifestyle habits in chronic HCV patients that can contribute to improve metabolic and liver function as well as better quality of life.

Conventional therapeutic interventions for chronic HCV patients are primarily focused on antiviral regimens with minor attention on lifestyle modifications[15]. For instance, in the past and up to date, it has been stated that patients diagnosed with liver cirrhosis regardless of the stage must remain in a resting state or maintain minimal physical activity. Even when exercise and/or physical activity is a common therapeutic modality recommended for obese, DM2 and IR patients[16,17], studies related to the modality and strategy of exercise that could be beneficial for the patients with chronic liver disease are limited[18]. Breathwalk (BW) is a novel exercise strategy that is different from conventional walking, in fact it synchronizes walking steps with specific breath patterns and mental sustained attention[19].

Since obesity and IR are dependent on genetic and environmental factors of each population, the identification of such variables and implementation of specific strategies are necessary in order to achieve a better quality of life and response to antiviral treatments. The aim of the present study was to measure anthropometric and metabolic parameters as well as the mood state in HCV-infected patients from the west of Mexico and to evaluate the effect of BW on those parameters.

MATERIALS AND METHODS

Patients

In an experimental study, 22 patients with chronic hepatitis C infection attending the Gastroenterology and Molecular Biology in Medicine Departments at the Civil Hospital of Guadalajara were included. Molecular and serological diagnosis of HCV was performed as described before[20]. All patients had serologic and molecular diagnosis (PCR) of chronic hepatitis C virus and were not receiving interferon or any other specific treatment. The Civil Hospital of Guadalajara is one of the biggest public hospitals in Mexico that mainly attends low income patients that have no other social health security. Due to the cost of interferon, the low income level and the large number of patients with HCV attending the hospital, most of them do not receive specific pharmacological treatment. Patients with HCV infection without interferon treatment were invited to participate in the program. Only those volunteers who signed a written consent were included. Clinical evaluations involved identification of the stage of the disease through Child-Pugh score. Patients with decompensated hepatic disease and/or Child C were not included. Twenty two patients remained until after the third month of the program. At this time period, an important improvement was registered, however 5 patients did not continue and dropped out because of the following reasons: two patients were from out of the city and returned to their villages, one patient felt better and decided not to further attend and 2 more patients did not show up. The protocol was conducted in accordance with the Helsinki declaration and with approval by the ethical committee of the hospital.

Body composition

Body composition was measured by electric impedance technique (In Body 3.0, Biospace, Inc). Patients were indicated to fast at least 8 h, to not carry out any type of exercise 5 d before evaluation and to empty the bladder and bowels before testing[21,22]. The parameters evaluated in body composition were body mass index BMI (kg/m^2), percentage of fat and muscle, waist circumference (WC) and fitness score. Patients were classified for risk of metabolic complications associated with obesity, according to WC. High risk of cardiovascular disease was marked at 94 cm of WC for men and 80 cm for women according to WHO[23]. Also the Official Mexican Norm for the classification of BMI[24] was used.

Biochemical profile

Blood samples for measurement of the biochemical profile were obtained after an overnight fast (12 h minimum). The biochemical profile included lipid profile [total cholesterol, triglycerides, high density lipoprotein (HDL), low density lipoprotein (LDL)], liver function tests aspartate amine transferase (AST), alanine amine transferase (ALT), total bilirubin, glucose and insulin. Routine biochemical test were performed by the use of manual enzymatic assays (Human Gessellschaft für Biochemica und Diagnostica mbH, Germany). Insulin levels were detected by microparticle enzyme immunoassay (Abbott Laboratories, North Chicago, IL). Insulin resistance was measured by the homeostasis model of assessment (HOMA)[25,26] and/or the triglycerides/high-density lipoprotein (TG/HDL) ratio[27].

Evaluation of mood state

Initially and at the end of the BW program, an interview was carried out with specific questions in order to assess the patients' mood regarding their illness during this intervention as described elsewhere[28,29]. Also, an interview was performed with two questionnaires. The first had two types of questions: open and with multiple option answers related to negative and positive mood states. One open question was: How is your mood state actually? Options for positive mood state were: Happy, calm, good in general and negative mood options were: angry, nervous, anguished, fear, bad in general.

The second questionnaire asked specific questions like: "Have you reduced the time spent in your job or other activities?" "Have you been done less of what you like to do?" "Have you done your job or others activities carelessly?" These specific questions had a transformed score after evaluation. Patients were scored in four categories: excellent (100 points), good (66.66 points), regular (33.33) and bad (0 points).

Breathwalk protocol

Breathwalk is an exercise strategy that consists basically of walking with different synchronized breath patterns enhanced with a meditative episode[19]. Physical movements in BW are combined aerobic and resistance exercises. The first and basic tool is a conscious complete deep breathing. While inhaling in a rhythmic and flowing way, air is taken from the stomach and directed smoothly towards the

Table 1 Demographic and clinic characteristics of patients with HCV infection at the beginning of the breathwalking (BW) program

Parameter	HCV group *n* = 17	Reference range
Age (yr)	51 ± 10.2	-
Sex F/M (%)	11/6 (65/35)	-
DM2 (%)	3 (18)	-
BMI (kg/m^2)	27.6 ± 3.2	< 25
Waist circumference (cm)	88.0 ± 10.4	< 80 cm F, < 94 cm M
Fat percentage (mean)	32.3 ± 7.1	< 28% F, < 20% M
Soft lean mass (kg)	44.2 ± 7.9	-
Glucose (mg/dL)	94.0 ± 16.5	< 110
ALT (U/L)	106.7 ± 93.1	< 55

Cholesterol (mg/dL)	157.1 ± 35.0	< 200
Triglycerides (mg/dL)	165.0 ± 86.5	< 160
HOMA ratio	3.7 ± 1.8	< 2.5
Metabolic syndrome (%)	10 (59)	[1]

DM2: Type 2 diabetes mellitus; BMI: Body mass index; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; F: Female; M: Male; HOMA: Homeostasis model of assessment. [1]NCEP (National cholesterol education program) ATP Ⅲ (adult treatment panel Ⅲ) 2001/2 criteria from metabolic syndrome.

thoracic chest and it finishes in a lightly upward movement of the clavicle and the superior part of the chest. While exhaling, all movements are inverted. This breathing pattern is continually practiced throughout the BW session.

The one hour session is composed of five steps. During the first 10 min, the participant began with a series of specific movements to warm up both arm and leg muscles and to relax the entire body, complete deep breathing as described above, in a synchronized pattern with body movements and was mentally focus on breathing. The following 5 min were dedicated to mentally scan the body posture while walking consciously and breathing patterns were continually synchronized. In the next 25 min, the participant was engaged in a quicker walking rhythm in which inhaling and exhaling patterns are performed at different intervals and combined with silently short-repeated phrases. The walking episode was concluded in the next 5 min by gradually reducing the walking pace. In the final remaining time, a new series of resistance exercises were initiated together with stretching and concluded with an episode of meditative visualization. The physical activity of BW was imparted by a qualified doctor trained in this program. Patients practiced a 1 h session of BW, three times a week for 6 mo.

Statistical analysis

Data and statistical analysis only of the 17 patients that remained until the end of the program were included. Numeric data was grouped by mean ± SD and minimum and maximum as indicated. Results at 3 and 6 mo of the program were compared against the basal using the non-parametric Wilcoxon rank test. A P value less than < 0.05 was considered statistically significant.

RESULTS

Demographic and clinical characteristics of HCV patients that participated in the BW program are shown in Table 1. A higher proportions of women than men is in agreement with the frequency of HCV in the west of Mexico as reported before[30,31]. Normal weight was present only in 29.4% of the patients, overweight in 17.6% and obesity in 53%. Five patients had cirrhosis and the rest had fibrosis and liver steatosis. Waist circumference was 84.9 ± 10.0 cm in women and 97.6 ± 11.6 cm in men. Waist circumference above 80 cm for women and more than 90 cm for men is considered a risk factor for the development of type 2 diabetes mellitus and/or insulin resistance in Mexico[24].

Type 2 diabetes was present in 18% of the patients studied, whereas dyslipidemia was in 41.1%. Two patients had isolated hypercholesterolemia and 5 presented with isolated hypertriglyceridemia. Insulin resistance as determined by the HOMA index was present in 77% of the participants.

Anthropometric measurement in HCV patients at baseline, 3rd and 6th mo of the program are shown in Table 2. In spite of minimal changes in body weight, a reduction in BMI and waist circumference was observed during the program period, as well as a statistically significant increase in the fitness score ($P < 0.001$) at the 3rd and 6th mo.

An improvement in the lipid profile and liver function tests was observed during the BW program (Table 3). A statistically significant reduction in triglycerides was detected at 6th mo ($P < 0.01$). This reduction was

Table 3 Biochemical profile in chronic HCV patients at start, 3 and 6 mo of breathwalking (BW) (mean ± SD)

Biochemical parameter	Basal	3 mo	6 mo
Glucose (mg/dL)	94.0 ± 16.5 (77-128)	93.5 ± 21.8 (71-142)	87.2 ± 12.3 (75-121)
ALT (U/L)	106.6 ± 93.1 (18-349)	82.8 ± 63.4 (20-241)	59.4 ± 32.7[b] (17-112)
AST (U/L)	101.4 ± 66.6 (32-265)	87.8 ± 61.8 (20-226)	84.7 ± 61.8 (24-241)
ALT/AST ratio	1.04	0.94	0.70[b]
Total bilirubin (mg/dL)	1.38 ± 1.2 (0.30-5.2)	1.22 ± 1.1 (0.29-4.9)	0.62 ± 0.36[b] (0.0-1.1)
Cholesterol (mg/dL)	157.1 ± 86.5 (103-231)	148.0 ± 38.4 (82-217)	146.0 ± 39.8 (67-205)
Triglycerides (mg/dL)	165.0 ± 86.5 (86-378)	141.9 ± 46.4 (85-210)	124.6 ± 49.2[b] (64-197)
TG/HDL ratio	4.0	3.9	2.7[a]

Data are expressed in mean ± SD. TG/HDL: Triglycerides/high density lipoprotein. [a]$P < 0.05$, [b]$P < 0.01$ between baseline and 3 or 6 mo.

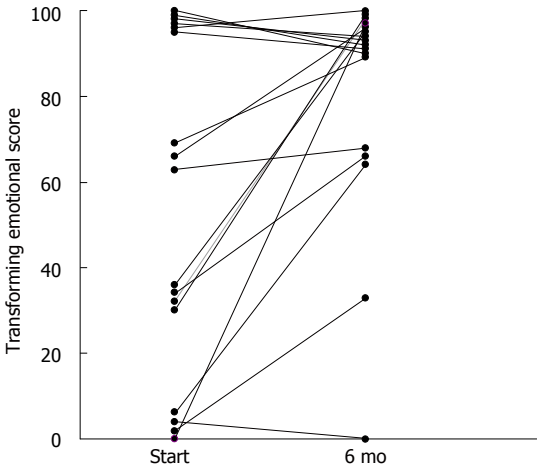

Figure 1 Patients' mood state with respect to disease at the beginning (start) and at the end of breathwalk (BW) after 6 mo. Wilcoxon rank test. $P < 0.01$ between start and 6 mo.

associated with a statistically significant decrease of the TG/HDL ratio. Improvement in liver function tests was documented by a statistically significant decrease in bilirubin ($P < 0.01$) and ALT serum levels after six months ($P < 0.01$), as well as in the ratio ALT/AST ($P < 0.01$).

Viral load was documented only in 7 patients at the beginning and at the end of the BW program. A reduction of the viral load was detected in 4 patients; from 78667 ± 50000 copies baseline levels to 600 ± 0 at the end of BW intervention. Patients that showed an improvement in the viral load had HCV genotype 1b, 2a, 2c and 3. In the other three patients no changes in viral load were detected.

At the beginning of the program, 47% of the HCV patients expressed negative mood states (depression, anger, anguish, fear). At mo 6 of BW, 94% of the patients presented with positive mood states (Figure 1). At the end of BW, the patients report improved emotional state ($P < 0.001$) compared with the beginning in all categories (Table 4). In general, the majority of the patients were motivated towards physical activity, optimistic towards life, and they referred being happy.

Table 4 Mood state based on transformed score evaluation at start, 3 and 6 mo of breathwalking (BW)

Mood state category	Transformed score	Baseline *n* (%)	3 mo *n* (%)[b]	6 mo *n* (%)[b]

Bad	0	4 (23.5)	1 (6)	0 (0)

Wilcoxon rank test; [b]$P < 0.001$ between start and 3 or 6 mo.

DISCUSSION

Obesity and DM2 are an epidemiological problem worldwide, associated with changes in lifestyle. Traditional homeland dietary and physical activity habits have shifted to a mixture of occidentalized and traditional diets combined with more sedentary life. Therefore, the extent of obesity and DM2 in HCV infected patients could be expected to vary in each continent or country mainly due to the diversity of race and environmental factors present in the population. More than fifty percent of the adults are overweight or obese in Mexico[32], and the association of HCV infection with obesity, which by itself is associated with insulin resistance[33], feasibly explains why 77% of the studied patients presented with IR at the time of the study. Hypercholesterolemia and hypertriglyceridemia were the two main dyslipidemia present in 41% of the participants. Indeed, hypertriglyceridemia has been associated with insulin resistance and development of DM2[34]. Therefore, a further rise in DM2 incidence could be expected in these HCV-infected patients in a near future. This reinforces the need to establish specific strategies based on lifestyle changes in order to prevent further metabolic abnormalities or deterioration of liver function.

In order to analyze the effect of BW on lipid profile, only patients that did not vary their dietetic habits during the program were evaluated. A statistically significant decrease in triglycerides at mo 6 of the program was observed as well as the decrease of the TG/HDL ratio. Therefore, BW had an important effect on both types of dyslipidemia and IR without a dietary intervention as seen in other studies[16,17,35]. However, the inclusion of an individualized dietetic program considering their own culture and specific habits could exert a further decrease on dyslipidemia and BMI.

The BW intervention achieved an important effect on the fitness score with a statistically significant increase at 3 mo of the program. The fitness score is an impedance measurement that reflects the muscle/fat ratio, which explains the lack of significant changes in weight, especially during the initial weeks or month of the exercise.

It has been shown that walking requires a longer time period to exert its beneficial effect on lipid metabolism in obese and patients with DM2[36,37]. An advantage that BW has over conventional walking is that it is an aerobic exercise where the patients maintain up to 70% VO_{2max} through rhythmic walking, and during the same session resistance exercise is included and associated with mental attention. Furthermore, it has been shown that anaerobic exercise (exercise load), which could be harmful for the patient with chronic liver disease, does not have significant effect on lipid metabolism at shorter periods of time[38].

An important effect of BW on liver function was also observed in HCV-infected patients. A statistically significant decrease of ALT, the ratio ALT/AST and total bilirubin was detected at mo 6 of the program as well as a decrease of the viral load in four of seven patients, where RNA-HCV was quantified at the beginning and at the end of the program. Little is known about the physiopathological mechanism related to the effect of exercise on the improvement of liver function tests in patients with chronic liver disease. However, even when it is known that exercise can improve insulin resistance at the cellular level[39], it can be speculated that a decrease in fatty liver would cause less liver injury, although further studies are required in order to determine any proposed

mechanism. Also, the small number of analyzed patients with changes in viral load may only indicate the importance of performing further studies with this approach, primarily in those patients that have not responded to antiviral treatment[14] either because of the virus genotype[40] or as a secondary effect of the interferon by itself[41].

At the beginning of the program, only 12% of the patients reported a positive mood state, however, negative mood state shifted towards a positive mood score in 88% of the patients at the end. Most studies focus on analyzing the effect of exercise on metabolic parameters, yet it is unusual to evaluate the emotional state of the patients[42]. The observed significant change in mood state and therefore in quality of life may be attributed to the synchronized breathing patterns combined with walking throughout the BW routine. A meditative state of mind is provoked that allows disconnection from the external environment and liberates negative thought and feeling[43]. Another important factor that may have contributed to the results in this study is the fact that, throughout the six-month program, a close relationship was established between the instructor and the patients. This could have enhanced compliance and adherence of the patients to exercise and therefore to the changes in habits.

The fact that in the past and even in current days exercise has been controindicated in patients with chronic liver disease appears to be proven wrong, since in this study, chronic HCV patients with fibrosis and compensated cirrhosis improved in their metabolic and hepatic profiles at the end of the program. This approach is important because it can be incorporated as a complementary treatment in patients who are candidates for interferon treatment including non-responder patients. However, further studies should be continued to evaluate the effect of an integrative management of the patient that includes antiviral treatment, specific types of exercise, diet and mood state.

In conclusion, this study identifies a specific effect of BW on anthropometric, metabolic and liver functional tests, and demonstrates the importance of the patient's mood state to enhance compliance to the program. Furthermore, this approach could be used in patients living in developing countries, where the cost of the antiviral treatment is expensive and in the mean time government authorities and/or international institutions can aid with financial funding to treat these patients.

We thank Daniel Quezada for his laboratorial and technical support and kind attention to this work and Teresa Salcedo for the typing of the manuscript.

COMMENTS

Background

In the last few years, two different issues have been on top of the table in the hepatology field: the association of obesity and type 2 diabetes in patients infected with hepatitis C virus versus the traditional medical indication of resting in patients with chronic liver disease and, on the other hand, the current problem of the nonresponder patient to antiviral treatments, especially in those who are overweight or obese.

Research frontiers

Whereas it is clear that an increase in physical activity and/or specific exercises are indicated in overweight, obese and type 2 diabetes patients, there are few studies related to the effect of exercise on metabolic and hepatic function parameters in patients with liver disease and even to further approach patient's emotions and well-being. Such strategy intends to involve different research areas so to achieve an integrative evaluation of patients that includes the study of metabolic parameters, liver function tests, emotional state, diet and exercise that are otherwise accessed in an individual manner.

Innovations and breakthroughs

This study represents an initial attempt to use Breathwalk as a specific technique in chronic liver disease patients, and to test in the near future the effect of different physical activity and exercise strategies on metabolic, liver function and anthropometric parameters, as well as emotional states in these patients.

Applications

Breathwalk is an innovative exercise technique that is easy to perform which could be implemented as a tool for patients with chronic liver diseases, especially at early stages of disease and in other chronic pathological conditions such as obesity, metabolic syndrome and type 2 diabetes.

Terminology

Breathwalk: An exercise technique that synchronizes walking steps, specific breathing patterns and focused attention. No-responders: Patients who do not achieve to lower viral loads after administration of the standard doses of antiviral monotherapy or combination therapy after (months) treatment.

Peer review

The manuscript studies the impact of breathwalking exercise on metabolic and fitness paramters in patients with chronic hepatitis C infection. It is interesting and of possible relevance to the field.

Abstract

AIM: To evaluate the effect of inflammatory cytokines on arylamine *N*-acetyltransferase 1 (NAT1), which is a phase-Ⅱ enzyme involved in the biotransformation of aromatic and heterocyclic amines found in food, drugs and the environment.

METHODS: Human cholangiocarcinoma KKU-100 cells were treated with a mixture of proinflammatory cytokines (interferon-γ, interleukin-1β, and tumor necrosis factor-α) for 48 h, and the effect on NAT1 activity was assessed by high performance liquid chromatography, while *NAT1* expression was determined by reverse-transcription polymerase chain reaction. The oxidative stress on the cells was examined by the formation of nitric oxide, superoxide anion and glutathione (GSH) levels. The cells were also treated with *S*-nitroso-glutathione (GSNO), a nitric oxide donor, to see if the responses were similar to those obtained with the inflammatory cytokines.

RESULTS: Cytokines suppressed NAT1 activity, reducing the V_{max} without affecting the K_m. Cytokines also had a significant impact on the induction of nitric oxide production and in reducing the redox ratios of glutathione (GSH) and GSH disulfide. Treatment with GSNO for 2-48 h reduced NAT1 activity without affecting the GSH ratio. Moreover, inflammatory cytokines and GSNO suppressed NAT1 mRNA expression.

CONCLUSION: These findings indicate an association between inflammation and suppression of NAT1, which perhaps contributes to chemical-mediated toxicity and carcinogenesis.

Key words: Arylamine *N*-acetyltransferase 1; Phase Ⅱ drug-metabolizing enzyme; Inflammatory cytokine; Oxidative stress; Cholangiocarcinoma

INTRODUCTION

Arylamine *N*-acetyltransferases (NATs) are well known polymorphic phase-Ⅱ drug-metabolizing enzymes. Human NAT1 and NAT2 are encoded by two closely related *NAT1* and *NAT2* genes[1,2]. NAT1 mRNA and protein are expressed in a wide range of tissues, whereas NAT2 mRNA and protein are present mainly in the liver and the gastrointestinal tract[3]. Biliary epithelial cells do not express NAT2 but retain NAT1 activity[4].

NATs are important enzymes capable of acetylation reactions, which are involved in the detoxification and metabolic activation of various chemicals in drugs, food and the environment[5]. *N*-acetylation is usually considered a detoxification process, because it renders the nitrogen atom less susceptible to oxidation, a process primarily mediated by cytochrome P450 1A2[6]. In contrast, *O*-acetylation is an activation step for heterocyclic and aromatic amines.

Genetic polymorphisms of NAT1 have been identified, but the relationship between genotypes and phenotypes is not clear[7]. Several studies have suggested that NAT1 and NAT2 acetylation polymorphism plays a role in carcinogenesis in humans exposed to certain carcinogenic chemicals[5]. Our previous studies suggested that *NAT1* and *NAT2* polymorphisms may be modifiers of individual risk for cholangiocarcinoma, a cancer of the biliary epithelium[8]. Overexpression of NAT1 in breast tumors is associated with growth properties, as well as chemotherapeutic drug resistance[9] and drug allergy, in particular, cutaneous drug reactions associated with sulfonamides, whereas inactivation of the enzyme may contribute to drug toxicity and cancer risk[10,11]. More recently, NAT1 activity was shown to

be suppressed by oxidant species such as hydrogen peroxide (H_2O_2) and peroxynitrite[12,13]. Peroxynitrite and H_2O_2 irreversibly inactivate NAT1 by oxidation of its conserved catalytic cysteine residue to sulfinic or sulfonic forms[12,13].

Chronic infection and inflammation are important risks factors for several cancers, including cholangiocarcinoma, a highly malignant adenocarcinoma originating from the cholangiocytes. The highest incidence of cholangiocarcinoma worldwide is seen in Northeast Thailand[14]. Infection of the biliary system with liver fluke (*Opisthorchis viverrini*) and possibly exposure to carcinogenic chemicals are believed to be causally related to cholangiocarcinoma[15,16]. The association of cholangiocarcinoma and liver fluke was observed in hospital case series which showed an excessively increased risk in patients with liver fluke infestation. Inflammation of the biliary tract caused by mechanical injury and the release of metabolic products from the flukes, together with the damaging effects of reactive metabolites from endogenous and environmental chemicals have been proposed as the responsible factors[17], which induce alterations in gene expression resulting to cellular hyperproliferation and development of neoplasia[15,16]. In an animal model of cholangiocarcinogenesis, hamster livers infected with liver flukes showed inflammation of the bile duct epithelium, and contained 8-oxo-deoxyguanosine and 8-nitroguanine adducts, which are biomarkers of DNA attack by reactive oxygen and nitrogen species[18]. Thus, inflammatory processes can cause oxidative stress and thereby affect NAT1 activity.

In the present study, we examined the effect of a combination of proinflammatory cytokines on KKU-100 cholangiocarcinoma cells. We also assessed the effect of cytokines on NAT1 activity and the development of oxidative stress; some of these effects were reproduced by a nitric oxide donor.

MATERIALS AND METHODS

Human CCA cell line

The human biliary epithelial cell line KKU-100, derived from intrahepatic cholangiocarcinoma, was established in our institute[19]. The cells were cultured in Ham's F12 containing 4 mmol/L L-glutamine, 1 mmol/L Na-pyruvate, 100 U/mL penicillin, and 100 μg/mL streptomycin and 10% fetal bovine serum and maintained under an atmosphere of 5% CO_2 at 37℃. The media was renewed every 3 d. The cells were trypsinized with 0.25% trypsin-ethylenediamine tetraacetic acid (EDTA) and subcultured in the same media. Twenty four hours after subculture, cells at approximately 70% confluence were exposed to a combination of inflammatory cytokines consisting of human interleikin-1β (IL-1β) (1 ng/mL), interferon-γ (IFN-γ) (400 U/mL), and tumor necrosis factor-α (TNF-α) (500 U/mL) (Biosource International Camarillo, CA) for 48 h or S-nitroso glutathione (GSNO, 100 μmol/L) for 2 or 48 h. In experiments determining nitrite production, KKU-100 cells were cultured in non-phenol red medium.

Biochemical assays

Nitrite assay: After treatment of the cell cultures, the accumulation of nitrite in the culture medium was assessed by mixing an equal volume of the medium with Griess reagent (containing 0.1% N-1-napthylethylenediamine in water and 1% sulfanilamide in 5% H_3PO_4). Absorbance was read at 540 nm with an ELISA plate reader.

Superoxide production: KKU-100 cells were cultured in 35-mm dishes with cytokines for 48 h. Cell cultures were washed with Tris-buffered saline (TBS) (10 mmol/L Tris HCl and 150 mmol/L NaCl, pH 7.3) and incubated for 30 min with phorbol-12-myristate-13-acetate (PMA) (0.68 μg/mL) or with N^G-nitro-L-arginine methylester (L-NAME) (100 μmol/L) or for 5 min with NADPH (200 μmol/L). Lucigenin (100 μmol/L) was added to the culture dishes, and chemiluminescence was recorded using a luminometer (Luminometer model 20/20^n, Turner Biosystems, CA).

Assay of GSH and glutathione disulfide: After treatment with cytokines, the cells were trypsinized and washed with cold tris buffer saline (TBS) by centrifugation at 1500 × *g* at 4℃ for 10 min and resuspended in TBS buffer. One hundred microliters of cell suspensions were reacted with 10 μL of 1-methyl-2 vinylpyridinium triflate (M2VP) (3.3 mmol/L) as a GSH scavenger for assay of GSH disulfide (GSSG)[20] or with distilled water for assay of total GSH, and cell suspensions were stored frozen at -20℃ until analysis. Total GSH and GSSG were assayed according to the Tietze method[21]. The amount of reduced GSH was calculated from total GSH and GSSG. Another aliquot of cell suspensions was used to determine protein content in a Bradford dye binding assay with bovine serum albumin as the standard.

Assay of NAT1 activity: NAT1 enzyme activity was assayed using high performance liquid chromatography according to a previously described method[4], with some modifications. Briefly, the cell cultures were washed with TBS and scraped into a microcentrifuge tube with lysis buffer (1X cell lysis buffer containing 1 mmol/L dithiothreitol [DTT] and 0.1 mmol/L phenylmethylsulfonyl fluoride [PMSF]). The cells were vortexed and centrifuged at 12000 × *g* at 4℃ for 30 min. The supernatant (cytosol) was stored in 10% (v/v) glycerol. The cytosol protein was used for assays of protein concentration and NAT1 activity. The reaction mixture consisted of 40 μL cytosol (final concentration 50 μg/mL), 20 μL acetyl CoA-regenerating system (DL-acetylcarnitine, 5.4 mg/mL, carnitine acetyltransferase (1 U/mL) in NAT assay buffer (225 mmol/L triethanolamine HCl, 4.5 mmol/L EDTA, and 4.5 mmol/L DTT, pH 7.5), and 20 μL acetylCoA (final concentration 100 μmol/L). The reaction was initiated by addition of 10 μL *p*-aminobenzoic acid (PABA) in 2.5% dimethylsulfoxide (final concentration 1.25-100 μmol/L) and incubated for 30 min. The reaction was stopped by addition of 10 μL of 15% perchloric acid and centrifuged at 12000 × *g* at 4℃ for 10 min. The supernatant was injected directly onto a high performance liquid chromatography column (YMC-PACK Pro-C_{18}, 5 μm, 150 mm × 4.6 mm; YMC Co., Japan) and

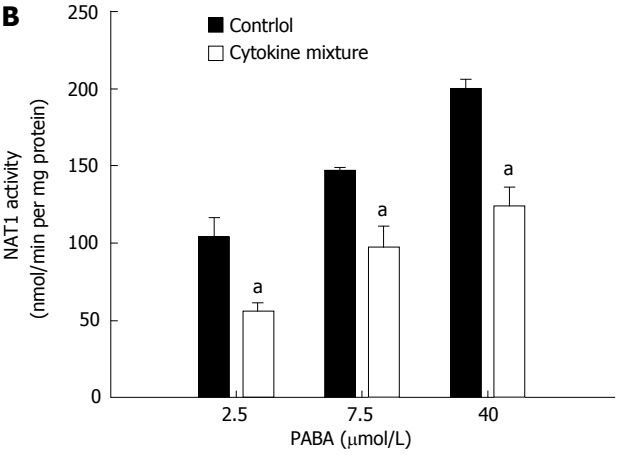

Figure 1 The effect of a mixture of inflammatory cytokines on NAT1 activity in KKU-100 cells. Assays were performed with the cytosol fraction extracted from KKU-100 cells and treated with a combination of cytokines for 48 h. **A**: Kinetic analysis of NAT1 activity; **B**: Activity of NAT1 at various substrate concentrations (PABA) of KKU-100 cells with or without treatment with cytokines. [a]$P < 0.05$ between cytokine treated and control groups.

eluted with a mobile phase consisting of water:acetonitrile: acetic acid:triethylamine:tetrahydrofuran (90.2:8.5:1:0.05:0.25 v/v) at a flow rate of 1.0 mL/min. *N*-acetyl-aminobenzoic acid (Ac-PABA) was detected using a fluorescence detector (Waters 740 scanning fluorescence detector; Waters Corp, Milford) set for excitation at 270 nm and emission at 340 nm. Analytical precision was evaluated by intra- and inter-day assay validation. The coefficients of variation were less than 5% and 10%, respectively. The detection limit of Ac-PABA was less than 1 pmol.

RNA isolation and reverse transcription-polymerase chain reaction

Total RNA was extracted from KKU-100 cells using Trizol®LS reagent according to the manufacturer's instructions. Total RNA (3 μg) was reverse-transcribed in a 20 μL volume containing 0.5 μg oligo(dT)$_{15}$ primer, 20 units RNasin® ribonuclease inhibitor and ImProm-Ⅱ™ reverse trancriptase (Promega, Madison, WI) in 10x polymerase chain reaction (PCR) buffer, 3 mmol/L $MgCl_2$, and 1 mmol/L dNTPs. The first-strand cDNA was synthesized at 42℃ for 60 min. Reverse transcription products were used as a template for PCR. PCR amplification was performed using specific primers for *NAT1* and farnesyl-diphosphate farnesyltransferase1 *(FDFT1)* as an internal control. The PCR primer sequences were: *NAT1* forward primers, 5'-CCTAGAAGACAGCAAATACCG-3'; *NAT1* reverse primers, 5'-AGCCCACCAAACAGTGA-3' (PCR product: 170 bp); *FDFT1* forward primers, 5' -TTTAACTTC TGTGCTATTCCAC-3'; *FDFT1* reverse primers, 5'-TCTCCAGTCTGAACATAGTC-3' (size of PCR product: 325 bp).

PCR was performed in a final volume of 25 μL containing cDNA template, 1.5 μmol/L of each *NAT1* primer or 0.4 μmol/L of each *FDFT1* primer, 1 U Platinum® Tag DNA polymerase (Invitrogen, Carlsbad, CA), 3 mmol/L $MgCl_2$, and 0.8 mmol/L dNTPs using a Px2 Thermal Cycle (Thermo Electron, Milford, MA). After an initial denaturating step at 94℃ for 5 min, 32 PCR cycles were performed for NAT1 and 28 cycles for FDFT1, as follows: denaturating for 1 min at 94℃, annealing for 1 min at 55℃, and extension for 1 min at 72℃. The final extension was performed at 72℃ for 10 min. The PCR products were separated by electrophoresis on a 3% agarose gel containing ethidium bromide. Gels were visualized and photographed. Band density was analyzed with Gel-Pro3 software. The relative amount of NAT1 mRNA was expressed as a ratio of FDFT1 mRNA.

Statistical analysis

Data are expressed as mean ± SE of duplicate assays from three independent experiments. Student's *t*-test was used to determine significant differences between each experimental group. The level of significance was set at $P < 0.05$.

RESULTS

Effect of the cytokine mixture on the kinetics of NAT1 acetylation

NAT1 activity of KKU-100 cells and Michaelis-Menten constants for PABA *N*-acetylation are shown in Figure 1A. Treatment with the mixture of inflammatory cytokines for 48 h did not affect cell viability (data not shown) but resulted in a significant decrease in $V_{max(apparent)}$ without affecting $K_{m(apparent)}$ (Figure 1A). This implies a change in the amount of enzyme but not in its affinity. The initial velocities of PABA *N*-acetylation by the cytosolic enzyme from KKU-100 cells are shown in Figure 1B.

Effect of the cytokine mixture on production of nitric oxide and superoxide

Since direct application of oxidant species has been reported recently to suppress NAT1 activity, our experiment showed that treatment with a mixture of cytokines could induce oxidative stress by overproduction of nitric oxide, detected by nitrite assay. Whereas basal production of nitric oxide by KKU-100 cells was nearly absent, production was greatly stimulated by inflammatory cytokines (Figure 2A).

To determine if KKU-100 cells were capable of releasing superoxide anion, aggravating oxidative stress, the cells were cultured with a mixture of cytokines. The cells exhibited low basal release of superoxide; the levels increased slightly after cytokine treatment (Figure 2B). To determine whether the low levels of superoxide were due to scavenging subsequent to overproduction of nitric oxide, the cells were treated with a nitric oxide synthase inhibitor. Inhibition of nitric oxide synthases by L-NAME did not increase superoxide levels relative to the control or baseline values (Figure 2B). When the cells were incubated with NADPH, the substrate of NADPH oxidases, superoxide production in the control and cytokine-treated groups was greatly increased and reached similar levels. Furthermore, treatment with PMA, a protein kinase C activator, resulted in a marked increase in superoxide production in the cytokine-treated group but not in the controls (Figure 2B).

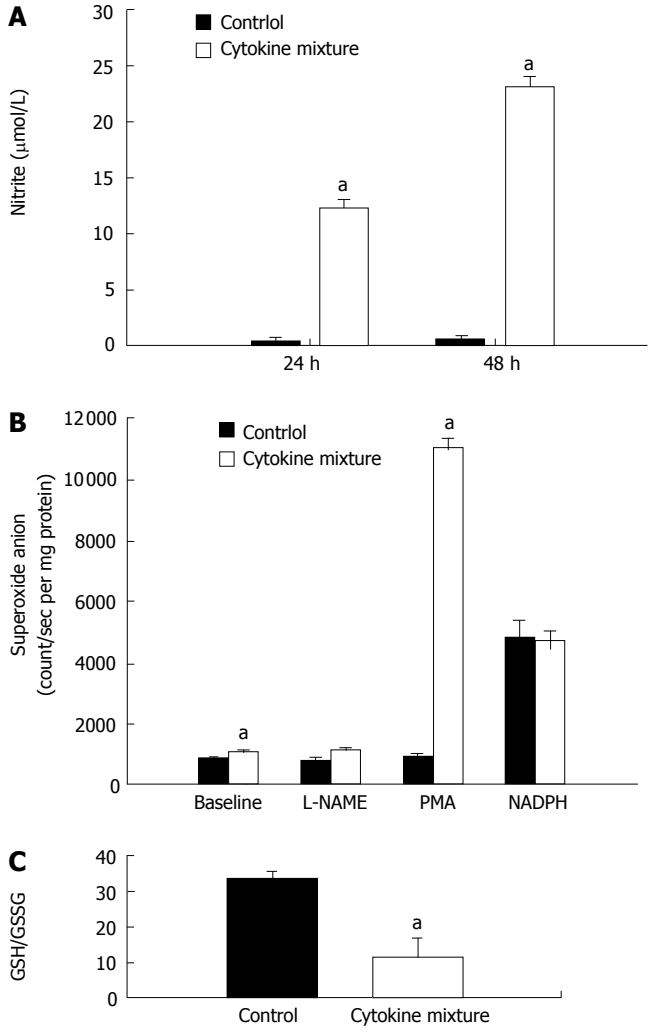

Figure 2 Oxidant status of KKU-100 cells after exposure to a mixture of inflammatory cytokines. **A**: Stimulation of nitric oxide production, assayed as nitrite levels. Cultured media was collected at 24 and 48 h after exposure; **B**: Superoxide formation. Cell cultures were washed and incubated with PMA (0.68 μg/mL), L-NAME (100 μmol/L), or NADPH (200 μmol/L), and superoxide production was measured using the chemiluminescence method; **C**: Redox status was assessed as the GSH and GSSG ratio. Results are presented as mean ± SE from 3 separate experiments. $^{a}P < 0.05$ between cytokine treated and the respective control groups.

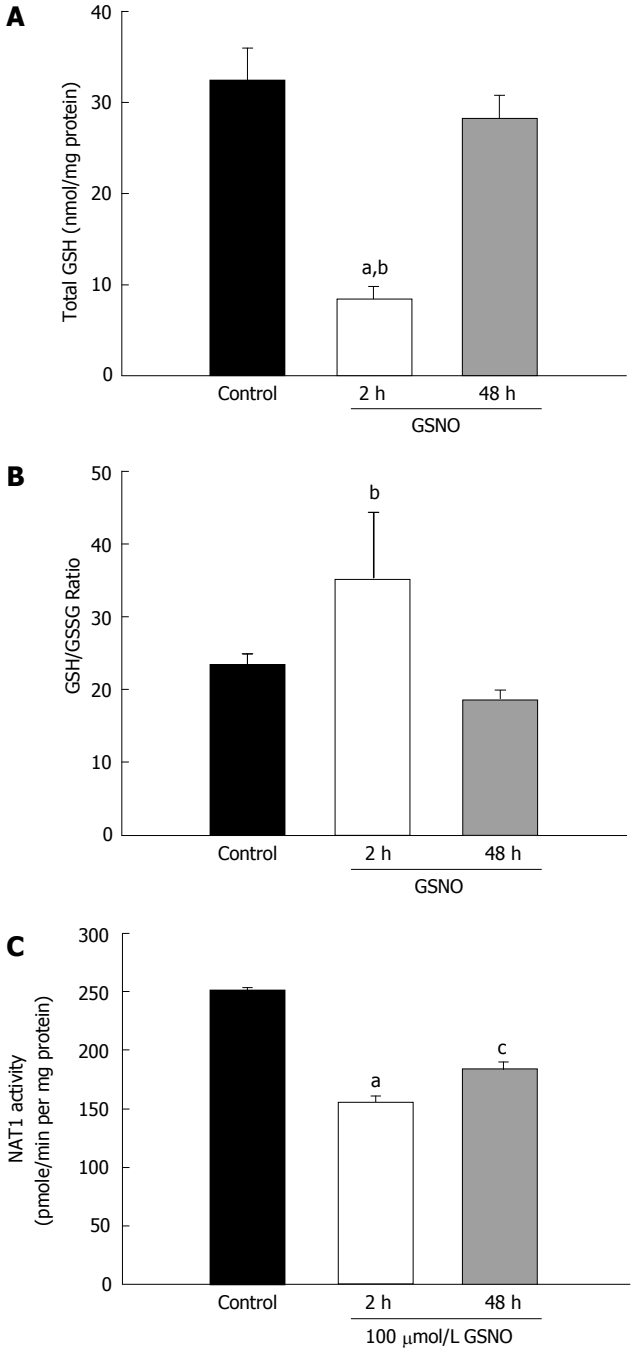

Figure 3 Effect of treatment with the nitric oxide donor GSNO on KKU-100 cells. Cell cultures were treated with 100 μmol/L GSNO for 2 and 48 h. **A**: Total GSH in the cells; **B**: GSH/GSSG ratio; **C**: Activity of NAT1 PABA-acetylation. Bars represent the mean ± SEM from 3 separate experiments. $^{a}P < 0.05$ *vs* control groups, $^{c}P < 0.05$ *vs* the 48-h treatment group.

Effect of the cytokine mixture on GSH levels

Since treatment with inflammatory cytokines may result in the formation of free radicals, further experiments were performed to determine if treatment will alter GSH levels and the oxidative status. KKU-100 cells exposed to the cytokine combination for 48 h showed no significant change in the total GSH levels (control: 36.7 ± 2.8 nmol/mg protein, cytokine-treated: 31.9 ± 14.5 nmol/mg protein). However, there was a marked reduction in redox status (GSH/GSSG ratio; Figure 2C) of the treated cells.

Effect of GSNO on NAT1 activity and redox status

The above noted experiments demonstrated that the mixture of cytokines induced nitric oxide production and oxidative stress. The next experiment investigated whether a nitric oxide donor would produce similar results. Treatment with GSNO elicited a very large decrease in total GSH within 2 h; however, the GSH levels normalized to the control levels at 48 h (Figure 3A). There was no significant change in the GSH/GSSG ratio after GSNO treatment (Figure 3B). However, treatment with GSNO reduced NAT1 activity as early as 2 h, and the suppression persisted at 48 h (Figure 3C).

Effect of the cytokine mixture and GSNO on expression of NAT1

Reverse transcription PCR was used to assess the effects of proinflammatory cytokines and nitric oxide donors on the expression of NAT1 mRNA. The results are shown in

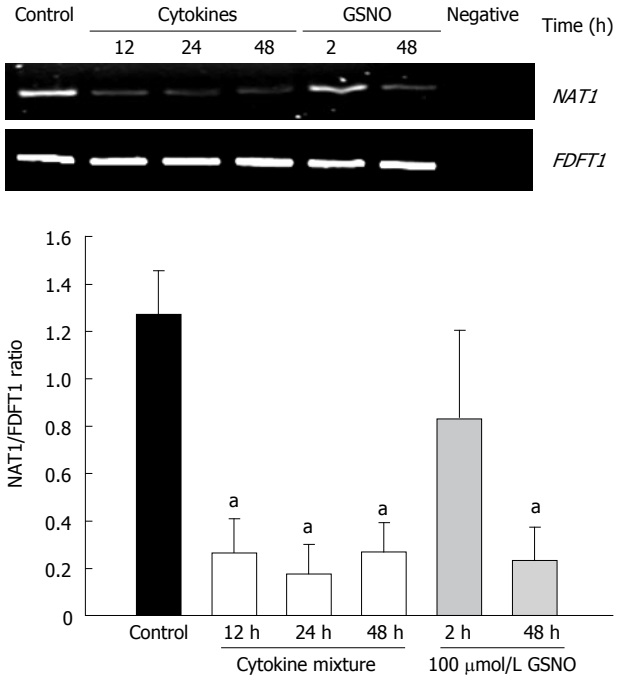

Figure 4 Effect of the cytokine mixture and a nitric oxide donor on the expression of NAT1 in KKU-100 cells. KKU100 cells were incubated with a mixture of cytokines for 48 h or with 100 μmol/L GSNO for 2-48 h. Cells were harvested, and RNA was extracted and analyzed by reverse transcription PCR using FDFT1 as an internal control. $^{a}P < 0.05$ *vs* controls.

Figure 4. Cytokine treatment elicited a decrease in NAT1 mRNA levels. Similarly, GSNO resulted in reduction of the NAT1 mRNA at 48 h, but not at 2 h.

DISCUSSION

The catalytic activity of NAT enzymes is dependent on a reactive cysteine residue, since its activity is inhibited when this residue is modified by *N*-hydroxy-arylamine compounds, hydroxamic acids[22], enzyme substrates[10], as well as oxidant species[12,13,23]. Oxidative stress and chronic inflammation are inseparable such that inflammation inevitably produces oxidant species, resulting in tissue damage[24]. The present study shows that proinflammatory cytokines suppress NAT1 activity similar to treatment with oxidant species[12,13]. Kinetic analysis of NAT1 showed a significant decrease in V_{max}, suggesting that the reduction of NAT1 activity was due to a decrease in the enzyme level. This alteration was probably due to enzyme inactivation or suppression of *NAT1* expression.

Inflammatory cytokines induce the expression of inducible nitric oxide synthase (iNOS) and increase nitric oxide production in cholangiocytes[25]. Our results are consistent with this finding, in fact the basal nitric oxide production was very low but the production increased markedly after treatment with inflammatory cytokines. It is plausible that induction of nitric oxide formation is partly responsible for the suppression of NAT1 activity. Treatment with a nitric oxide donor inhibited NAT1 in a manner similar to cytokine treatment, supporting the possibility that nitric oxide and perhaps peroxynitrite play an important role in modulation of NAT1 activity.

A previous study showed that treatment of breast cancer cells with peroxynitrite irreversibly inactivated NAT1[12]. Peroxynitrite is formed by a reaction between nitric oxide and superoxide anion. In the present study, inflammatory cytokines did not induce a large increase in superoxide, even when nitric oxide formation was inhibited by L-NAME. However, NADPH oxidases, which are membrane bound enzymes that require assembly of subunits from cytosol to become fully functional, are responsible for the formation of superoxide in phagocytic and nonphagocytic cells[26]. They may be upregulated by inflammatory cytokines, as has been shown in smooth muscles and kidney cells[27]. The NADPH oxidases in KKU-100 cells may also be upregulated, however stimulation by PMA, a protein kinase C activator that mediates phosphorylation and recruitment of oxidase subunits[26] may be required to render the NAT1 enzyme fully functional. Together, these findings suggest that superoxide and perhaps peroxynitrite did not play a major role in the cytokine-induced suppression of NAT1 activity in KKU-100 cells. Nevertheless, the role of superoxide and peroxynitrite *in vivo*, a situation where infiltrating macrophages are present, has not been investigated.

The ability of inflammatory cytokines to induce oxidative stress was clearly evident in the present study, as there was a marked increase in pro-oxidant status, evidenced by a decrease in the redox ratio of GSH/GSSG in cultured cells exposed to the mixture of cytokines. In contrast, treatment with GSNO did not affect the redox ratio at any time point. However, total GSH, representing the major intracellular antioxidant pool, decreased substantially after GSNO treatment, especially at the 2-h time point. Altogether, the differences in the effects of cytokines and GSNO suggest that the effects of the cytokine mixture were mediated by nitric oxide and redox-sensitive pathways.

A recent report has shown that intrahepatic cholangiocarcinoma seen in liver fluke endemic areas is characterized by altered expression of drug metabolizing genes, whereas that from non-endemic areas such as Japan shows alteration in the growth factor signaling genes[17]. This may indicate that drug metabolizing genes are involved in the metabolism of potential carcinogenic chemicals. However, information regarding NAT1 expression is currently not available. Regulation of *NAT1* expression has been under study for a long time[23,28]. Previous studies have shown that suppression of NAT1 activity by substrates or oxidant species is due to direct inhibition of the enzyme molecules[13,29], since the expression of NAT1 mRNA does not show any alteration[29]. Our study is the first to demonstrate that treatment with a mixture of cytokines suppresses NAT1 mRNA expression. Using deletion mutant constructs, a promoter site for basal *NAT1* expression was identified[30] comprising of an activator protein 1 (AP-1) binding site. Transcription factor AP-1 is upregulated or downregulated by oxidative stress and inflammatory cytokines, depending upon the oxidant levels and the type of inflammatory cytokines[31,32]. Suppression of *NAT1* expression in KKU-100 cells may involve down regulation or inactivation of AP-1, although specific evidence in this regard remains

to be established. Direct inhibition of NAT1 by oxidant species (nitric oxide) cannot be ruled out, particularly in *in vivo* conditions; this may occur concurrently with suppression of expression.

In summary, treatment with inflammatory cytokines suppresses NAT1 activity and mRNA expression in cholangiocarcinoma KKU-100 cells. This suppression was associated with oxidative stress and nitric oxide production. These findings show that inflammation can suppress NAT1, a key cellular defense enzyme. Moreover, such a suppression may be implicated in drug toxicity and cancer risk.

COMMENTS

Background

Arylamine *N*-acetyltransferases-1 (NAT1) is an important phase Ⅱ drug metabolizing enzyme that is constitutively expressed in most tissues. Its activity is inactivated by oxidant species.

Research frontiers

NAT1 expression has been demonstrated in cholangiocarcinoma cells (CCA), and polymorphism of NAT genes has been implicated as a risk factor for cancer. Inflammation of the bile duct resulting from opisthorchiasis may alter the activity of the drug metabolizing enzymes including cytochrome P450 and NAT1. Modulation of NAT1 activity may be implicated in drug induced-toxicity and carcinogenesis.

Innovations and breakthroughs

Suppression of NAT1 activity and gene expression is associated with cytokine-induced oxidative stress. A combination of proinflammatory cytokines induces changes in cellular redox and nitric oxide production in CCA and these may be involved in down-regulation of NAT1.

Applications

NAT1 activity could be modulated by inflammation and this may be associated with drug induced toxicity and carcinogenesis.

Terminology

Opischorchiasis: liver fluke (Opisthorchis viverrini) infection of the bile duct.

Peer review

This manuscript describes the intriguing idea that inflammatory cytokines, which are known to be upregulated in cholangiocarcinoma, may function in part by suppressing the activity and/or expression of NAT1, an enzyme thought to be involved in the detoxification of xenobiotics. The authors also show a parallel increase in oxidative stress and nitric oxide after treatment with inflammatory cytokines. Treatment of the cell line with nitric oxide donors also shows a similar suppression of NAT1 activity and expression.

Abstract

AIM: To evaluate the predictive value of clinical symptoms and biochemical parameters for prematurity in intrahepatic cholestasis of pregnancy (ICP).

METHODS: Sixty symptomatic patients with ICP were included in this retrospective analysis. Preterm delivery was defined as delivery before 37 wk gestation. Predictors of preterm delivery were disclosed by binary multivariate logistic regression analysis.

RESULTS: Mean time of delivery was 38.1 ± 1.7 wk. No stillbirths occurred. Premature delivery was observed in eight (13.3%) patients. Total fasting serum bile acids were higher (47.8 ± 15.2 *vs* 41.0 ± 10.0 μmol/L, $P < 0.05$), and pruritus tended to start earlier (29.0 ± 3.9 *vs* 31.6 ± 3.3 wk, $P = 0.057$) in patients with premature delivery when compared to those with term delivery. Binary multivariate logistic regression analysis revealed that early onset of pruritus (OR 1.70, 95% CI 1.23-2.95, $P = 0.038$) and serum bile acid (OR 2.13, 95% CI 1.13-3.25, $P = 0.013$) were independent predictors of preterm delivery.

CONCLUSION: Early onset of pruritus and high levels of serum bile acids predict preterm delivery in ICP, and define a subgroup of patients at risk for poor neonatal outcome.

INTRODUCTION

Liver disorders during pregnancy range from benign nuisance to progressive and potentially lethal disorders for mothers and/or children. This is exemplified by intrahepatic cholestasis of pregnancy (ICP), which starts with modest itching and can end in intrauterine fetal demise[1]. ICP is a liver disorder unique to pregnancy and disappears after delivery. However, it frequently recurs in subsequent pregnancies or when women begin taking oral contraceptives.

The condition is very common in Chile and Bolivia (6%-27%), and in Sweden (1%-1.5%). The incidence of ICP is lower elsewhere in Europe (0.1%-1.5%) and the United States (0.7%)[2,3]. Genetic predisposition and hormonal factors have crucial roles in the pathogenesis[2]. There is increasing evidence that genetically determined dysfunction of canalicular transporters may be a risk factor for development of ICP[4-9]. ICP has been linked to adverse maternal and fetal outcomes. The main symptom is pruritus without evidence of skin lesions, which appears most typically in the third trimester of pregnancy. Laboratory tests demonstrate an increase in serum bile acids and aminotransferases[2,10,11]. ICP is essentially benign in mothers. The major consequences of this disease are premature delivery in 19%-60% of cases[12,13], stillbirths in 1%-2%[13,14] and fetal distress in 22%-33%[15,16]. The mechanisms by which ICP leads to poor fetal outcome are unclear. Recent clinical and biochemical studies have provided evidence for altered metabolism of bile acids and progesterone in ICP, although it remains unclear whether these changes are specific for ICP or are rather the consequence of cholestatic injury[17-20]. In a study from Sweden, a correlation between fetal complications and serum bile acids levels was demonstrated[3].

Various strategies have been proposed to improve obstetric outcome. Nevertheless, in several studies, the investigators have concluded that fetal death in ICP may not be predictable by traditional antepartum surveillance, and that delivery after establishment of fetal lung maturity may reduce fetal mortality rate[13-15]. Obstetric management consists of weighing the risk of premature delivery against the risk of sudden death *in utero*. As well, it has to be considered that induction of labor is associated with a higher frequency of complications such as surgical delivery compared to spontaneous labor[2]. To allow term delivery (≥ 37 wk) in patients with ICP, it appears essential to ascertain early prognostic markers for poor fetal outcome.

In our previous prospective therapeutic trial[21], we observed a significant effect of ursodeoxycholic acid (UDCA) in comparison to cholestyramine on pruritus, serum liver tests, and the duration of pregnancy in patients with ICP. However, the treatment groups did not differ significantly in the number of premature deliveries (< 37 wk gestation). Therefore, the aim of the current study was to re-evaluate clinical symptoms and biochemical parameters as potential predictors of spontaneous preterm births in patients with ICP.

MATERIALS AND METHODS

Sixty patients with ICP defined by (1) development of pruritus during the second or third trimester of pregnancy, and (2) total fasting serum bile acids (TBA) ≥ 11 μmol/L, were included in this retrospective analysis. All patients were seen at the Kaunas Medical University Hospital, Lithuania between October 1999 and September 2002. Patients with chronic liver diseases, skin diseases, allergic disorders, symptomatic cholelithiasis, and ongoing viral infections affecting the liver (hepatitis A, B and C virus, cytomegalovirus, herpes simplex virus, and Epstein-Barr virus) were excluded. All patients participated in a randomized parallel-group study as reported previously[21]. In contrast to the previous prospective trial, the actual retrospective analysis included patients with elevated TBA ≥ 11 μmol/L only.

Pruritus intensity was assessed daily by patients using a subjective score: 0, no pruritus; 1, mild pruritus, occasional; 2, moderate pruritus, intermittent during the day with asymptomatic periods prevailing; 3, severe pruritus every day with symptomatic periods prevailing; 4, severe, constant pruritus day and night. Serum liver tests and fasting serum bile acids were evaluated at the time of the first presentation. Serum liver tests were determined using routine laboratory techniques. Bile acids were analyzed by gas-liquid chromatography as described previously[21,22]. Fasting serum samples were stored at -20℃ until analyzed. Ultrasonography of the abdomen and serology of viral hepatitis were performed to exclude other causes of liver disease in every patient before enrollment.

The Obstetric and Gynecology Clinic of Kaunas Medical University Hospital is a tertiary care maternity center that provides all obstetric services for women with complicated pregnancies, for a stable and ethnically uniform population of 2 million inhabitants. Most of the high-risk deliveries in the area took place in this clinic. Fetal status was monitored in the same hospital every week. Pregnancy outcome and newborn status (term and mode of delivery, Apgar score at 1 and 5 min, asphyxial events, and newborn weight) were assessed by obstetricians and neonatologists, who were not given any specific instructions concerning date and form of delivery. Spontaneous preterm birth was defined as delivery before 37 wk gestation after the spontaneous onset of labor.

Statistical analysis

The results are expressed as means ± SD. Comparison of parametric, normally distributed data was performed by Student's *t* test. The difference between two samples was calculated using the Mann-Whitney test. Correlation analysis was assessed by Spearman's rank correlation. Multivariate analysis of significant prognostic factors of delivery before 37 wk gestation was based on binary multivariate logistic regression analysis. Factors found to be significant or having a trend towards significance (TBA concentrations, onset of pruritus) were selected for this model. Statistical analysis was conducted with SPSS 12.0. All reported *P* values were two-sided, and $P < 0.05$ was considered statistically significant.

RESULTS

Sixty patients who met the inclusion criteria were included in the study. Age ranged between 18 and 40 year (median 27.0), median gestational age was 35.0 wk (range, 22-39), median time of onset of pruritus was 32.0 wk (range, 20-37). Twenty-eight (46.6%) women were primiparous and 32 (53.4%) were multiparous. Recurrence of ICP was reported by 19 (31.6%) patients, 14 of these had a history of preterm delivery, and two of intrauterine fetal death. Ten (16.6%) patients had been users of oral contraceptives, of whom three women had experienced pruritus during use. Gallstone disease was diagnosed in seven (11.6%) cases. One (1.6%) patient had a urinary tract infection. No stillbirths were observed. The Apgar score at 1 min was 8.5 ± 0.7, and at 5 min, 9.0 ± 0.6. Delivery was after 38.1 ± 1.7 wk. Postnatal development was normal in all babies. Pregnancy ended prematurely in eight (13.3%) patients: in three receiving UDCA and in five treated with cholestyramine. Table 1 compares the clinical characteristics of patients who had deliveries before 37 wk and those who had delivery after 37 wk gestation. Significantly higher levels of TBA (47.8 ± 15.2 *vs* 41.0 ± 10.0 μmol/L, $P < 0.05$), and a tendency towards earlier onset of pruritus (29.0 ± 3.9 *vs* 31.6 ± 3.3 wk, $P = 0.057$) were found in cases of premature delivery when compared with term delivery. The correlation coefficient between TBA levels and pruritus scores tended to be higher in patients with preterm delivery (0.733) when compared to those with term delivery (0.523). In cases of preterm delivery (< 37 wk gestation), TBA concentration correlated positively with onset of pruritus ($r = 0.678$), bilirubin ($r = 0.538$), alanine aminotransferase ($r = 0.343$), and aspartate aminotransferase ($r = 0.308$), whereas correlation was weaker in term delivery.

To unravel potential factors that may affect the time of delivery, we instituted a binary multivariate logistic

Table 1 Clinical characteristics at the time of first presentation of patients with ICP who had delivery before and after 37 wk gestation

Characteristics	Delivery before 37 wk *n* = 8	Delivery after 37 wk *n* = 52	*P*
Age (yr)	26.6 ± 7.2	28.3 ± 5.4	0.433
Onset of pruritus (wk)	29.0 ± 3.9	31.6 ± 3.3	0.057
Intensity of pruritus (score)	3.1 ± 0.4	2.9 ± 0.6	0.361
ALT (U/L)	187.3 ± 87.2	210.4 ± 149.3	0.721
AST (U/L)	126.6 ± 78.8	140.1 ± 101.4	0.855
AP (U/L)	386.9 ± 132.7	372.1 ± 136.2	0.707
γGT (U/L)	35.6 ± 23.2	24.4 ± 14.1	0.072
Bilirubin (μmol/L)	10.3 ± 4.0	15.5 ± 13.1	0.202
TBA before treatment (μmol/L)	47.8 ± 15.2	41.0 ± 10.0	0.041

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; AP, alkaline phosphotase; γGT, γ-glutamyltransferase; TBA, total bile acids.

Table 2 Potential risk factors for preterm delivery: Predictive value as evaluated by binary multivariate logistic regression analysis

Factor	OR	95.0% CI	*P*
Onset of pruritus (wk)	1.703	1.227-2.947	0.038
Total bile acids before treatment (μmol/L)	2.128	1.126-3.252	0.013

regression model. The factors that were found to be significant or those that had a trend towards significance (TBA concentrations, onset of pruritus) were selected for this model. Binary multivariate logistic regression analysis demonstrated that serum bile acid concentration (OR 2.13, 95% CI 1.13-3.25, $P = 0.013$) and onset of pruritus (OR 1.70, 95% CI 1.23-2.95, $P = 0.038$) were the most important independent variables predicting preterm delivery (Table 2).

DISCUSSION

Although recent studies have improved our understanding of the underlying pathophysiological disturbances and their association with specific symptoms during ICP, the pathogenesis and prognosis of pregnancy have remained obscure. The current study aimed to unravel potential risk factors for fetal prematurity. We found that earlier onset of pruritus and higher TBA concentrations were associated with preterm delivery in our cohort of patients with ICP. The correlation between premature delivery and onset of pruritus is a new and interesting finding; although, high TBA levels have already been described as predictors of fetal outcome in other cohorts[3,23].

ICP is the most common liver disorder unique to pregnancy. In Lithuania, a retrospective analysis disclosed a rate of 0.4% of ICP in 16252 pregnant women over a period of 5 year (1996-2000; J. Kondrackiene, unpublished data). Although essentially benign in the mother, ICP may adversely affect the prognosis of the fetus. ICP has been reported to be associated with increased rates of spontaneous premature delivery[12,13]. According to the Lithuanian Medical Birth Register (2004), the total premature birth rate was 5.3%. Our study showed a 13.3% incidence of preterm delivery in patients with ICP.

The mechanism of preterm delivery remains unclear. Germain *et al*[24] have shown that during ICP, activation of the oxytocin receptor pathway is possibly caused by a cholic-acid-mediated increase in oxytocin-receptor expression. The placenta plays a crucial role in protecting the fetus from the adverse effects of potentially toxic endogenous substances, including TBA[25]. High levels of maternal TBA affect placental transport, placental hormone production, and chorionic vessel constriction[17]. In animal models, maternal hypercholanemia may affect the vectorial transfer of bile acids through the creation of inversely directed gradients, as compared with the physiological situation[26], and by impairing the ability of the trophoblast to transport bile acids[18]. A study from Argentina has shown that asymptomatic hypercholanemia of pregnancy, defined as TBA > 11 μmol/L in healthy pregnant women, does not necessarily lead to ICP[27]. Glantz *et al*[3] have demonstrated that no increase in fetal risk is detected in ICP patients with TBA levels < 40 μmol/L, and have proposed that these women can be managed expectantly. However, a recent case of fetal death at 39 wk and 3 d in a patient with ICP, who had low TBA concentrations at the time of diagnosis, has been reported[28]. This raises a crucial question: is the fasting TBA level sufficient to predict fetal outcome? Should testing be repeated on a weekly basis or discontinued once a less-than-critical level has been determined? What if concentrations increase dramatically over the following weeks, although levels are comparably low at the time of diagnosis for which the prognostic value has been evaluated[29]? Therefore, it is important to evaluate other clinical factors that are possibly associated with prematurity. We found significantly higher levels of TBA, and a tendency towards earlier onset of pruritus, although non-significant, in patients who had premature delivery, when compared with cases of term delivery. The binary multivariate regression analysis revealed that the TBA levels and early onset of pruritus were the most important independent factors predicting premature delivery.

In the current retrospective study, we did not analyze the effect of treatment on preterm delivery. Indeed, among the women who had births before 37 wk gestation, three of eight patients had received UDCA, and five were treated with cholestyramine. The size of the cohort may have been too small to detect any difference in the rate of preterm delivery between patients treated with UDCA and those treated with cholestyramine, although the timepoint of delivery was significantly earlier in patients treated with cholestyramine than in those treated with UDCA in our previous analysis. As well, the rate of preterm delivery in the present cohort was lower than that reported in other studies. This could in part be due to increased attention devoted to ICP during the study[3].

The current analysis indicated that early onset of pruritus, along with markedly elevation of TBA levels, may predict premature delivery, which represents a potential risk factor for the fetus in women with ICP. Because the

prognosis remains unpredictable in some cases[28], our current strategy is to begin pharmacological treatment after confirmation of diagnosis in all ICP patients. The treatment of choice is UDCA, which has improved maternal and fetal morbidity in several clinical trials and observational studies[21,31-34]. When lung maturity is achieved for those patients with risk factors of prematurity, delivery should be considered.

In conclusion, the present study indicated that early onset of pruritus and high levels of TBA were the most important factors associated with preterm delivery in a well-defined cohort of patients with ICP; thereby, defining a group at risk of poor neonatal outcome and so requiring active management.

COMMENTS

Background

Intrahepatic cholestasis of pregnancy (ICP) is characterized by pruritus and an elevation in serum bile acid concentrations. The major consequences of this disease are premature delivery, stillbirth and fetal distress. The mechanisms by which ICP leads to poor fetal outcome are unclear, although a role for bile acids or toxic metabolites of bile acids has been suggested. Currently, the hydrophilic bile acid ursodeoxycholic acid (UDCA) is the most effective treatment for ICP. Various strategies have been proposed to improve obstetric outcome. In several studies, the investigators have concluded that fetal death in ICP may not be predictable by traditional antepartum surveillance, and that delivery after establishment of fetal lung maturity may reduce fetal mortality rate. To allow for term delivery ($\geqslant$ 37 wk) in patients with ICP, it appears essential to disclose early prognostic markers for a poor fetal prognosis.

Research frontiers

There is increasing evidence that genetically determined dysfunction in the canalicular ABC transporters might be risk factors for development of ICP. Heterozygous mutations in the MDR3 gene (encoding for a canalicular phospholipid translocator involved in the biliary secretion of phospholipids) have been found. Recent clinical and biochemical studies provided evidence of abnormal metabolites impairing hepatobiliary carriers for an altered metabolism of bile acids and progesterone in ICP although it remains unclear whether these changes are specific for ICP or are rather the consequence of cholestatic injury in ICP.

Innovations and breakthroughs

We found that earlier onset of pruritus and higher fasting serum bile acid concentrations were associated with preterm delivery in our cohort of patients with ICP. The correlation between premature delivery and onset of pruritus is a new and interesting finding; although, high serum bile acid levels have been described as predictors of fetal outcome in other cohorts.

Applications

The present study indicates that early onset of pruritus and high levels of serum bile acid are the most important factors associated with preterm delivery in patients with ICP; thereby, defining a group at risk of poor neonatal outcome and so requiring active management.

Peer review

This is a well-written manuscript reporting on a cohort of 60 patients with symptomatic ICP. Early onset of pruritus and high levels of serum bile acids predict preterm delivery in intrahepatic cholestasis of pregnancy and define a subgroup of patients at risk of poor neonatal outcome.

Abstract

AIM: To evaluate the combination of bevacizumab with infusional 5-fluorouracil (5-FU), leucovorin (LV) and irinotecan (FOLFIRI) in patients with advanced colorectal cancer (CRC) pretreated with combination regimens including irinotecan and oxaliplatin.

METHODS: Fourteen patients (median age 56 years) with advanced CRC, all having progressed after oxaliplatin- and irinotecan-based combination chemotherapy, were enrolled in this study. Patients were treated with 2 h infusion of irinotecan 150 mg/m^2 on d 1, plus bevacizumab 5 mg/kg iv infusion for 90 min on d 2, and iv injection of LV 20 mg/m^2 followed by a bolus of 5-FU 400 mg/m^2 and then 22 h continuous infusion of 600 mg/m^2 given on two consecutive days every 14 d.

RESULTS: The median number of cycles of chemotherapy was six (range 3-12). The response rate was 28.5%, one patient had a complete response, and three patients had a partial response. Eight patients had stable disease. The median time to progression was 3.9 mo (95% CI 2.0-8.7), and the median overall survival was 10.9 mo (95% CI 9.6-12.1). Grade 3/4 neutropenia occurred in five patients, and two of these developed neutropenic fever. Grade 3 hematuria and hematochezia occurred in one. Grade 2 proteinuria occurred in two patients. However, hypertension, bowel perforation or thromboembolic events did not occur in a total of 90 cycles.

CONCLUSION: Bevacizumab with FOLFIRI is well tolerated and a feasible treatment in patients with heavily treated advanced CRC.

Key words: Bevacizumab; Irinotecan; Leucovorin; 5-fluorouracil; Colorectal cancer

INTRODUCTION

Colorectal cancer (CRC) is the second most common cause of cancer deaths worldwide, with 945 000 new cases and 492 000 CRC-related deaths in 2000[1,2]. Up to 30% of patients present with metastatic disease, and approximately 50%-60% eventually develop metastatic or advanced disease[1]. The management of patients with metastatic CRC has changed dramatically over the last 5 years, with increased chances of prolonged survival. In particular, combination chemotherapy regimens including irinotecan and oxaliplatin have markedly improved response rates and prolonged median survival over fluorouracil (FU) with leucovorin (LV)[3,4]. However, there is a paucity of data about third-line chemotherapy in patients who are resistant to irinotecan- or oxaliplatin-based chemotherapy[5-7].

Angiogenesis is required for tumor growth and metastasis, which makes it an attractive target for biologically based cancer therapy[8-10]. Vascular endothelial growth factor (VEGF) is the most potent and specific target for cancer therapy, and has been identified as a crucial regulator of both normal and pathological angiogenesis, with increased expression being observed in many human tumor types[11-13]. In CRC, increased VEGF expression correlates with invasiveness, vascular density, metastasis, recurrence and prognosis[14,15]. In preclinical studies, a murine anti-human monoclonal antibody directed against VEGF has been shown to inhibit the growth of human tumor xenografts[16-18]. As well, the combination of anti-VEGF antibody and chemotherapy in nude mice injected with human cancer xenografts has demonstrated an increased antitumor effect compared with antibody or chemotherapy treatment alone[19].

Bevacizumab, a recombinant humanized monoclonal antibody targeting VEGF, has been evaluated in various solid tumors[20]. In phase I trials, bevacizumab was generally well tolerated and did not demonstrate dose-limiting toxicity or interactions with commonly used chemotherapy

regimens[21]. In a phase 2 trial of treatment of CRC, the addition of bevacizumab to FU/LV increased the response rate, the median time to disease progression, and the median duration of survival[22]. Recently, it has been shown in randomized phase Ⅲ trials that bevacizumab, when combined with irinotecan plus bolus FU/LV in the first-line treatment of metastatic CRC, and with oxaliplatin plus continuous FU/LV (FOLFOX) in second-line treatment leads to an increased median survival, progression-free survival (PFS), and response rate compared with cytotoxic chemotherapy alone[23,24].

The goal of this trial was to evaluate the safety and activity of bevacizumab plus LV, 5-FU and irinotecan (FOLFIRI) in patients with advanced CRC that had progressed after treatment with both irinotecan- and oxaliplatin-based chemotherapy regimens.

MATERIALS AND METHODS

Eligibility criteria

The eligibility criteria were as follows: histologically confirmed CRC (adenocarcinoma), bidimensionally measurable disease, no secondary malignancy, age > 18 years, Eastern Cooperative Oncology Group (ECOG) performance status (PS) 0-2, and a life expectancy of > 3 mo. Adequate hematological, hepatic and renal function (including urinary excretion of no more than 500 mg protein/d) were also required. Patients should have had and failed both oxaliplatin- and irinotecan-based treatment prior to enrolment. Failure due to significant intolerance to either drug was allowed.

Exclusion criteria included thromboembolism that required therapeutic anticoagulation, central nervous system metastasis, and major surgery within 6 wk, non-healing wounds, uncontrolled hypertension, pregnant or lactating women, bleeding diathesis, active or recent cardiovascular disease or cerebrovascular accident, or prior bevacizumab therapy. The pretreatment characteristics of the patients are presented in Table 1. Written informed consent was required before chemotherapy.

Treatment protocols and dose modification

On d 1, irinotecan (150 mg/m^2) was administered in 500 mL normal saline or dextrose as a 2-h iv infusion. On d 1 and 2, LV (20 mg/m^2) was administered as a iv bolus, immediately followed by 5-FU (400 mg/m^2) given as a 10-min iv bolus, followed by 5-FU (600 mg/m^2) as a continuous 22-h infusion. Bevacizumab administration always followed chemotherapy. Bevacizumab was given at 5 mg/kg as an iv infusion every 2 wk. The first infusion was given over 90 min, the second over 60 min, and if both were well tolerated, subsequent infusions were given over 30 min. No premedication was given.

Dose modifications of irinotecan or 5-FU were made for hematological or non-hematological toxicity, on the basis of the most severe grade of toxicity that occurred during the previous cycle. Treatment was delayed until the absolute number of neutrophils was > 1500/μL, platelets were > 100000/μL, and recovery occurred from mucositis, diarrhea, or skin toxicity to grade 1 or less. The 5-FU dose was reduced after the occurrence of National Cancer Institute Common Toxicity Criteria (NCI-CTC) grade 3 diarrhea, stomatitis or dermatitis. For toxicity of grade 3 or higher, a dose reduction of irinotecan by 20% was prescribed by the protocol. Bevacizumab was retained for uncontrolled hypertension or proteinuria of > 2 g in 24 h. Bevacizumab was discontinued for grade 3 or 4 hemorrhage, thromboembolic events that required full-dose anticoagulation, or any grade 4 toxicity.

Treatment was administered until the disease progressed, unacceptable toxic effects developed, or the patient refused further treatment.

Pretreatment and follow-up evaluation

Pretreatment evaluation included physical examination, complete blood cell counts, blood chemistry, tumor marker level, and radiological examination [chest posterior-anterior (PA) view radiography, computed tomography (CT) and other imaging techniques as clinically indicated] within 1 mo of starting chemotherapy. Tumor responses were determined by WHO criteria[25]. Complete blood cell counts, serum chemistry, including liver and renal function, and chest PA radiography were performed at least every 2 wk, and tumor assessment by CT was performed every three cycles.

Statistical analysis

Efficacy analysis was performed according to the intention-to-treat principle. Patients were considered assessable for response if they were eligible, had measurable disease, and had received at least one dose of study therapy. In the analysis of survival and subsequent treatment, all patients

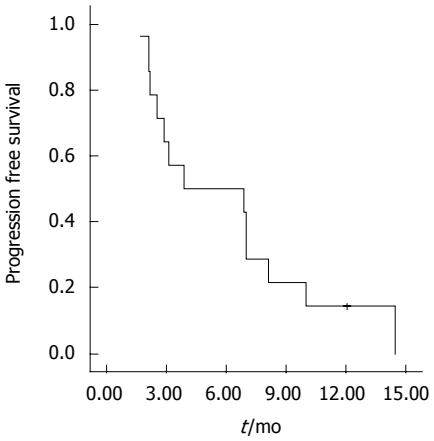

Figure 1 PFS curve. Median PFS was 3.9 mo (95% CI: 2.0-8.7).

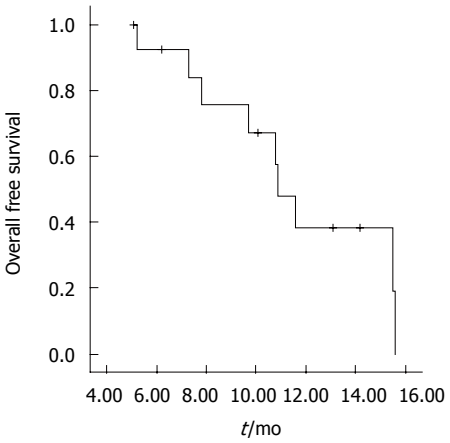

Figure 2 OS curve. Median OS was 10.9 mo (95% CI: 9.6-12.1).

were followed until death, loss to follow-up, or termination of the study.

PFS and overall survival (OS) were calculated using the Kaplan-Meier method. PFS was calculated from the date therapy started to the date of disease progression, and OS was calculated from the date therapy started to the date of death. All data were analyzed using SPSS software (version 12.0, Chicago, IL, USA).

RESULTS

Patient characteristics

Between June 2005 and June 2006, a total of 14 patients were assigned for treatment at the Department of Internal Medicine, Dong-A University Medical Center, Busan, Korea. Demographic details of the patients included in the study are shown in Table 1. There were nine male and five female patients, median age 59 years (range 29-69). All patients had progressed after prior irinotecan- and oxaliplatin-based regimens. All patients used bevacizumab/FOLFIRI treatment within 6 mo after both irinotecan and oxaliplatin treatment failures. All 14 patients were assessable for response and for toxicity and survival.

Objective tumor responses and survival

There were a median six cycles of chemotherapy (range 3-12). Chemotherapy was stopped due to disease progression in 12 patients, one discontinued because of toxicity and another because of unrelated events with no progression. Median follow-up duration was 10.1 mo. Response rate was 28.5% (95% confidence interval (CI) 15.0%-36.5%), one patient had a complete response, and three had a partial response. The median duration of response was 7.7 mo. Eight patients had stable disease, and two had disease progression. PFS was 3.9 mo (95% CI; 2.0-8.7), and median OS was 10.9 mo (95% CI; 9.6-12.1). Figures 1 and 2 show PFS and OS curves, respectively. Oral 5-FU was administered to the 12 patients with disease progression. No objective responses were documented after salvage therapy.

Table 2 Toxicity (n = 14)

	NCI-CTC grade			
	1	2	3	4
Hematological				
Anemia	7	3

Mucositis	1			
Diarrhea		2		
Proteinuria	1	2		
Hematuria	1		1	
Asthenia		4		

Toxicity

A total of 90 cycles of chemotherapy were administered to the patients. All patients who received at least one dose of bevacizumab and chemotherapy were assessable for adverse events. Dose modifications or interruptions were required in 30% of patients. The incidence of hematological and non-hematological toxicity is summarized in Table 2. The major grade 3/4 hematological toxicity included neutropenia (35.7%) and thrombocytopenia (7.1%). There were two cycles of neutropenic fever. Grade 1/2 nausea, vomiting, diarrhea and mucositis developed in 6 patients; however, this toxicity was mild and manageable. In one patient who had rectal cancer with bladder invasion, massive hematuria and hematochezia occurred; he was taken off the study because of toxicity. However, hypertension, bowel perforation or thromboembolic events did not occur. There was no treatment-related death. There have been nine reported deaths, of which eight were because of disease progression, and one was because of pneumonia in the present study.

DISCUSSION

Patients with advanced CRC treated with 5-FU, irinotecan and oxaliplatin in combination or sequentially may survive for 18-21 mo[3,4,26,27]. However, if these three standard drugs fail, there are no accepted treatment options. There have been few clinical trials in a third-line setting that can

provide historical estimates of PFS and OS[5-7,28,29]. A recent study has shown that patients treated with cetuximab in combination with irinotecan achieved significant activity[6]. The response rate was 22.9% and time to progression and OS were 4.1 and 8.6 mo, respectively. Promising data from a small randomized phase Ⅱ trial have recently shown that bevacizumab when added to cetuximab or to cetuximab plus irinotecan has a high activity in chemotherapy-refractory CRC[28]. Panitumumab, a human monoclonal antibody against epidermal growth factor receptor (EGFR), has also been shown to be active in irinotecan- and oxaliplatin-refractory metastatic CRC[23]. However, other reports have shown no clinical benefits[5,7].

The improvement in the clinical outcome afforded by the addition of bevacizumab to 5-FU suggests that blocking VEGF may be a broadly applicable approach to the treatment of CRC[22]. Adding bevacizumab to both first- and second-line combination chemotherapy improves response, time to progression, and OS, but not without toxicity[23,24]. The addition of bevacizumab 5 mg/kg biweekly significantly improved the primary outcome of median survival from 15.6 mo with irinotecan/5-FU bolus infusion/LV (IFL) alone to 20.3 mo with IFL/bevacizumab. Bevacizumab also significantly increased response rate from 34.8% to 44.8%, and prolonged time to progression from 6.2 to 10.6 mo[23]. Compliance was also excellent in this study. As well, results from a phase Ⅲ study in patients with previously treated metastatic colon cancer have revealed improved OS in patients who receive bevacizumab (10 mg/kg) with FOLFOX, as compared with those treated with FOLFOX alone, 12.5 versus 10.7 mo[24].

However, a recent large non-randomized study has shown that the combination of bevacizumab and a bolus regimen of 5-FU/LV is not sufficiently active in heavily pretreated, bevacizumab-naive patients to support the use of bevacizumab with bolus 5-FU/LV in chemotherapy-refractory metastatic CRC. The combination of bevacizumab and 5-FU/LV was associated with a low response rate: 4% based on investigator assessment and 1% based on independent review. Median PFS and OS were 3.7 and 9.1 mo, respectively[7]. This study demonstrated that for patients with advanced CRC that had progressed after treatment with both oxaliplatin- and irinotecan-based chemotherapy regimens, response rate was 28.5%, with approximately 58% of the patients showing stable disease. Median PFS was 3.9 mo and median OS was 10.9 mo. We used irinotecan instead of bolus 5-FU/LV; therefore, the response rate and survival were increased compared with those in the earlier study. Further studies will be needed to confirm these results.

Previous phase 1 and 2 clinical trials have suggested that treatment with bevacizumab alone or with chemotherapy results in an increased incidence of thrombosis, bleeding, proteinuria and hypertension[21,22]. In two phase Ⅲ investigations, the risk of venous thromboembolism was not increased by bevacizumab, but there was a small increased risk of both bleeding and bowel perforations, as well as a consistent increase in hypertension[23,24]. Hemorrhage has also been seen more frequently with bevacizumab treatment as compared with chemotherapy alone[22]. The majority of patients had minor hemorrhage, but 10% of patients had gastrointestinal hemorrhage, and 43% were grade 3/4. However, a larger phase Ⅲ trial did not demonstrate an increased incidence of grade 3/4 bleeding[23]. We did not find any excess of such side effects, compared with previous studies, except for one case of massive bleeding. The reason why there was no thrombosis, hypertension and bowel perforation may have been due to the small number of patients and their relatively young age.

An analysis of predictive markers has shown indeed that bevacizumab increases the activity of irinotecan plus FU/LV, regardless of the level of VEGF expression, thrombospondin expression, and microvessel density[30]. In this study, we evaluated the correlation between expression of VEGF and microvascular density and clinical outcome, and we found no significant results (data not shown).

COMMENTS

Background

There is a paucity of data about third-line chemotherapy in patients who are resistant to irinotecan- or oxaliplatin-based chemotherapy. Bevacizumab, a recombinant humanized monoclonal antibody targeting vascular endothelial growth factor (VEGF), has been evaluated in various solid tumors.

Research frontiers

The goal of this trial was to evaluate the safety and activity of bevacizumab plus irinotecan (FOLFIRI) in patients with advanced colorectal cancer (CRC) that had progressed after treatment with both irinotecan- and oxaliplatin-based chemotherapy regimens.

Innovations and breakthroughs

Bevacizumab with FOLFIRI is well tolerated and feasible in heavily treated patients with advanced CRC.

Applications

We will evaluate correlations between expression of VEGF and microvascular density and clinical outcomes.

Terminology

Bevacizumab: monoclonal antibody against VEGF, which aids growth and metastasis of several cancers. Irinotecan, oxaliplatin: chemotherapeutic agents that are useful in CRC.

Peer review

The manuscript evaluates the safety and activity of bevacizumab plus FOLFIRI in patients with advanced CRC that had progressed after treatment with both irinotecan- and oxaliplatin-based chemotherapy regimens. The method is simple and correct. The manuscript is written in correct English with minor language polishing.

Abstract

AIM: To confirm the predictive factors for interferon (IFN)-α and ribavirin combination therapy for chronic hepatitis patients with hepatitis C virus (HCV) genotype 1b.

METHODS: HCV RNA from 50 patients infected with HCV genotype 1b was studied by cloning and sequencing of interferon sensitivity determining region (ISDR), PKR-eIF2α phosphorylation homology domain (PePHD). Patients were treated with IFN-α and ribavirin for 6 mo and grouped by effectiveness of the therapy. A variety of factors were analyzed.

RESULTS: Our data showed that age, HCV RNA titer, and ISDR type could be used as the predictive factors for combined IFN-α and ribavirin efficacy. Characteristically, mutations in PePHD appeared only when the combination therapy was effective. Other factors, such as sex and alanine aminotransferase (ALT) level, were not related to its efficacy. Adjusting for age and HCV RNA titer indicated that the ISDR type was the most potent predictive factor.

CONCLUSION: HCV RNA ISDR type is an important factor for predicting efficacy of IFN-α and ribavirin combination therapy in Korean patients.

Key words: Hepatitis C virus -1b; Interferon-α; Ribavirin; Interferon sensitivity determining region; PKR-eIF2α phosphorylation homology domain

INTRODUCTION

Hepatitis C virus (HCV) is an enveloped RNA virus with a positive single-stranded RNA genome about 9600 nucleotides in length. This RNA encodes a single polypeptide approximately 3000 amino acids in length. The polypeptide is post-translationally cleaved into structural and non-structural proteins[1-3]. HCV infection is a major cause for chronic liver disease worldwide[4]. Eighty percent or more of acutely infected patients develop chronic hepatitis, which progresses to liver cirrhosis in about 20% of cases and hepatocellular carcinoma in 5%. These complications arise even if the disease remains asymptomatic[5].

Alpha-interferon (IFN-α) treatment effectively reduces viral load, but complete eradication of the virus is achieved in less than 20% of patients treated with IFN-α alone and in 40%-47% of patients treated with combined IFN-α and ribavirin[6-8]. The treatment outcome largely depends on the sensitivity of HCV genotype and IFN-α[9,10]. About 10 years before, IFN-α and ribavirin combination therapy has begun to be used instead of IFN monotherapy. Ribavirin is an oral nucleoside analogue acting on a broad spectrum of DNA and RNA viruses. It has been proposed to have both direct antiviral and immunomodulatory effects[11], but the detailed mechanism remains unclear. Ribavirin used as monotherapy is known to have little or no activity against HCV.

The HCV genotype appears to be a major determinant for IFN efficacy, because patients infected with HCV genotypes 2 and 3 respond better to IFN monotherapy than patients with genotype 1[9]. The IFN-based therapy effectiveness is not satisfactory, especially in patients with HCV genotype 1b[12-14], the most common genotype in Korea[15,16], Japan[17], southern and eastern Europe[18,19]. IFN is also inconvenient to use, costly, and has a variety

of possible complications. Thus, many studies have been carried out to determine the predictive factors for the efficacy IFN therapy[12-19].

Response to interferon monotherapy is associated with several host and viral factors. HCV genotype 1b, low viral load, and rapid HCV RNA clearance from the serum have been identified as favorable predictors for a sustained response to IFN therapy[20-22]. Since Enomoto *et al*[23] reported that genetic variability in a 40 amino acid stretch (amino acids 2209-2248) and mutations in the NS5A region of HCV and in designated interferon sensitivity determining region (ISDR), has become a predictive factor for IFN therapy. Studies from Japan[23], Sweden[24] and Spain[25] have shown that ISDR is an effective predictor. However, studies from Western countries displayed that ISDR is not a good predictor[26-28]. Studies on the relationship between IFN-α and ribavirin combination therapy and ISDR have controversial results[29-32].

Taylor *et al*[31] reported that a HCV envelope protein (E2) contains a sequence similar to the phosphorylation site on eIF2-α for the interferon-inducible cellular protein kinase PKR. The PKR-eIF2-α phosphorylation homology domain (PePHD) on E2 may serve as a pseudosubstrate for PKR and inhibit its function, reducing the antiviral effect of interferon. Thus, the PePHD region might also be involved in IFN resistance of chronic hepatitis C to IFN therapy. However, the role of this region is also controversial so far[31].

In Korea, the HCV prevalence is about 1%-2%, but studies to analyze the predictive factors for combined IFN-α and ribavirin therapy have not been performed. To identify these factors, we investigated the relationship between combined IFN-α and ribavirin efficacy and a variety of factors such as ISDR sequence, PePHD sequence, age, ALT level, and HCV RNA titer in Korean patients with HCV genotype 1b.

MATERIALS AND METHODS

Patents and treatment

Serum was collected from HCV genotype 1b-infected patients admitted to Wonju Christian Hospital. Only HCV genotype 1b was used in this study because it is the most common HCV genotype in the Republic of Korea. Sera were screened by a third generation ELISA method with an anti-HCV antibody. The patients were treated with IFN-α and ribavirin for 6 mo. Three million units of IFN-α was injected every two days, and 9 mg of ribavirin was orally administrated during the same period. The patients who did not receive the treatment were excluded. After the 6-mo combination therapy, the patients were classified into complete response group and no-response group. In the complete response group, HCV RNA titer was less than 50 IU/mL and ALT levels were within the normal range. In the no-response group, HCV RNA titer was over 50 IU/mL even if the ALT levels were normal.

cDNA preparation

HCV RNA was extracted from sera as previously described[33]. After ethanol precipitation, each RNA pellet was dissolved in 10 μL of diethylpyrocarbonate (DEPC)-treated distilled water for cDNA preparation. cDNA synthesis was performed as previously described[34] with certain modifications. For the synthesis of cDNA of HCV, an aliquot of RNA (10 μL) isolated from the sera of patients was mixed with 1 μL of random hexamer (1 μmol/L), 2 μL of reaction buffer (250 mmol/L Tris-HCl pH 8.3, 250 mmol/L potassium chloride, 50 mmol/L magnesium chloride, 50 mmol/L dithiothreitol and 2.5 mmol/L spermidine) and 5.5 μL of DEPC-treated water was added. After the contents were heat-treated for 5 min at 65℃, 20 units (0.5 μL) of RNase inhibitor and 10 units (1 μL) of AMV reverse transcriptase were added. The mixture was incubated at 37℃ for 30 min, followed by at 99℃ for 1 min to inactivate the enzyme. PCR was performed as described previously[16]. The ISDR and PePHD primer sequences are listed in Table 1. PCR products were subjected to agarose gel electrophoresis in Tris-acetate-EDTA buffer and visualized with ethidium bromide staining under an ultraviolet transilluminator.

ISDR and PePHD sequencing

RT-PCR amplified products, including the ISDR and/or PePHD regions, were purified from agarose gel and glass milk (Gene Clean II kit, Bio 101, USA), and then subcloned by inserting the cDNA into a pGEM-T TA-cloning vector (Promega). The clones from each of the individual patient's plates were randomly selected and plasmid prepared from each clone was used as a template for DNA sequencing which was performed as previously described[35].

HCV RNA quantitation

In order to determine the HCV RNA titer, a quantitative and competitive polymerase chain reaction (QCPCR) assay was carried out as previously described[36]. As a first step, cDNA encoding the 5'-untranslated region of HCV was subcloned into a pGEM vector (pGEM5'UTR). Using PCR, the internal control plasmid, pGEM5'UTRDel, was constructed by deletion of nucleotides between the 87 and 165 nucleotides in the 5'-UTR of the HCV genome. The internal control RNA was synthesized *in vitro* by T7 RNA polymerase from a linearized template derived from the pGEM5'UTRDel plasmid. The amount of RNA synthesized *in vitro* was determined by measurement of the absorbance at 260 nm. A known copy number of the RNA was included as an internal control in order to quantify the viral RNA. The data were analyzed by Quantity One® 1-D analysis software (Bio-Rad).

Statistical analysis

Comparisons between groups were made by the Student's *t*-test. The *P* values were determined between the two groups with regard to age, ALT, amino acid mutations in PePHD, and HCV RNA titer. $P < 0.05$ was considered statistically significant. Odds ratios (OR) and 95% confidence intervals (95% CI) were calculated for ISDR to test its predictive value for combination therapy by logistic regression analysis.

RESULTS

Patient characteristics

We collected serum from 50 HCV genotype 1b-infected

Table 1 Primer sequences used to amplify ISDR and PePHD

Region	Primer direction	Sequence (5′ to 3′)	Nucleotide No

ALT: Alanine aminotransferase; ISDR: Interferon sensitivity determining region. [1]○ indicates history of transfusion and × indicates no history of transfusion. [2]The unit of HCV RNA titer before treatment (log copies/mL). [3]ISDR type: 1 (wild type, no amino acid substitution), 2 (intermediate type, 1-3 amino acid substitutions), 3 (mutant type, ⩾ 4 amino acid substitutions).

patients. Among them, 21 patients completely responded to the 6-mo combination therapy, while 29 patients showed no response. Group A was designated as the complete response group and group B as the no-response group. The characteristics of each patient prior to combination therapy are shown in Tables 2 and 3.

HCV RNA quantitation

As shown in Tables 2 and 3, the HCV RNA titer had a wide distribution. In the complete response group the HCV RNA titer was between $10^{3.27}$-$10^{6.12}$ copies per mL and $10^{4.85}$-$10^{7.11}$ copies per mL, respectively, in the no-response group. The average RNA titer of the response and no-response groups was 4.62 ± 0.80 and 5.59 ± 0.61, respectively. These values were statistically significant ($P < 0.05$, Table 4).

ISDR and PePHD amino acid sequences

The ISDR and PePHD amino acid sequences and the HCV genotype 1b prototype sequence (HCV-J) are shown in Figure 1. The complete response group had 1-10 amino acid substitutions while the no-response group had 1-8 amino acid substitutions in the ISDR (Figure 1A and B). The PePHD region had 1-2 amino acid substitutions in several cases of complete response group and no amino acid substitutions in the no-response group (Figure 2).

Figure 1 ISDR sequences (2209-2248) of HCV in complete response group (**A**) and in no-response group (**B**). Dashes indicate the amino acid residues identical to the sequences on the top in each panel.

Response to combination therapy in different groups

As shown in Table 4, patients were younger in the complete response group than in the no-response group. The HCV RNA titer was also significantly different. No differences were found in gender or ALT levels. We classified ISDR sequences into three groups based on the number of amino acid mutations, as previously described[23]. These three groups were analyzed by an odds ratio to define the responsiveness to combination therapy. The ISDR group responses to combination therapy are shown in Table 5. Intermediate (one to three amino acid changes) and mutant (four or more amino acid changes) ISDRs showed an increased responsiveness to the combination therapy. The odds ratio was 2.46 and 7.00, respectively, assuming the wild type had 1.00. The age, PePHD mutations, and HCV RNA titer were significantly different between the two groups (Table 4). Considering these factors, ISDR type might be a better predictive factor for combination therapy responsiveness. After adjusting for age and HCV RNA titer, the odds ratio for intermediate and mutant ISDRs was 3.57

Figure 2 PePHD sequences (659-670) of HCV in complete response group (n = 21) and no-response group (n = 29). Dashes indicate the amino acid residues identical to the sequences on the top in each panel.

Table 4 Statistical analysis of age, ALT and HCV RNA titer before treatment

Group	Male:Female	Age (yr)	ALT	HCV RNA titer before treatment
A	13:08	49.3 ± 5.0[a]	185.2 ± 89.1	4.62 ± 0.80[b]
B	16:13	52.8 ± 5.7[a]	186.5 ± 61.7	5.95 ± 0.61[b]

ALT: Alanine aminotransferase. The data of age, ALT and HCV RNA titer before treatment are shown in mean ± SD. A: Complete response group. B: No-response group. [a]P = 0.032 between A and B. [b]P = 0.001 between A and B.

Table 5 Logistic regression analysis of ISDR

ISDR type[1]	Crude OR	95% CI	Adjusted OR[2]	95% CI[2]
Wild	1.00		1.00	
Intermediate	2.46	0.64-9.39	3.57	0.66-19.36
Mutant	7.00	1.29-37.91	9.67	1.16-80.65

[1]ISDR wild type had no mutation. Intermediate type had 1-3 mutations and mutant type had more than 4 mutations. [2]After adjustment for age and HCV RNA titer before treatment. OR: Odds ratio; 95% CI: 95% confidence interval.

and 9.67, respectively. According to these results, patients with mutant ISDR strains would likely respond better to combination therapy than those with wild type ISDR strains.

DISCUSSION

Identifying host and viral factors can predict the response of HCV-infected patients to IFN-α and ribavirin combination therapy. Studies showed that factors such as the HCV genotype 1b and viral load are associated with resistance of HCV-infected patients to INF therapy[37,38]. It was reported that resistance of HCV genotype 1b-infected patients to INF therapy is influenced by a region of the NS5A viral phenotype[23,39]. Mutations in this region, known as ISDR, are beneficial for patients receiving IFN therapy, whereas the wild type virus is resistant to IFN treatment[23,39]. Other studies fail to confirm the association between ISDR genotypes and IFN responsiveness[26,27,40-44], thus it remains a controversial issue[45,46].

Combined IFN and ribavirin therapy has replaced IFN monotherapy for HCV-infected patients about 10 years before. In the present study, to identify the predictive factors for effective combination therapy, we investigated the relationship between the response to combination therapy and a variety of factors. Only patients with HCV genotype 1b were studied because this genotype is known to be more resistant to interferon treatment than the other genotypes and is the most prevalent genotype in Korea[15,16].

In this study, age, PePHD mutations, HCV RNA titer, and ISDR subtype were found to be the predictive factors for combined IFN-α and ribavirin therapy for HCV genotype 1b infection. On the other hand, gender and ALT level were not associated with the combination therapy efficacy. These results are consistent with many previous studies, but contrary to others[26,27,31]. Such a difference indicates that these factors are not always accurate predictors for IFN response. This effect may be due to the pleiotropic nature of IFN activity, in addition to other cellular and viral

genes that also modulate the effectiveness of INF therapy for chronic hepatitis C. This is the first study to determine the factors that predict the effectiveness of combination therapy in Korean patients. Therefore, this study may reflect the Korean genetic characteristics.

HCV seems to have a defense strategy against the host cellular responses induced by IFN[47]. The E2 protein appears to play a major role as a potential immune response target, and may interfere with cellular effectors induced by IFN[48]. Information about the clinical implications of E2 containing PePHD, is still limited. Analysis of a small series of HCV genotype 1-infected patients showed that amino acid sequence variability in the PePHD region was similar in responders and no-responders, indicating that the PePHD region is very stable over time[49-51]. In our study, a sequence analysis of the PePHD region in 50 patients found mutations in eight cases, all in the complete response group, suggesting that mutations in the PePHD region are associated with the response to combination therapy. In other studies, a few cases showed some PePHD mutations in the no-response group, though more mutations appeared in the complete response group[31,52]. Therefore, further study is needed to determine why mutations only occur in the complete response group of HCV-infected patients in Korea.

Some studies showed that the association of ISDR mutation rate with treatment response, but the other studies did not[31,45]. One of the Korean studies reported that the effect of INF monotherapy is not associated with the ISDR mutation rate[53]. It is not sure, but the different result may be due to the treatment methods and the sample size.

In conclusion, response of HCV genotype 1b-infected patients to combination therapy is influenced, at least in part, by HCV RNA titer, age, PePHD mutations, and ISDR subtype, but not by gender and ALT level. After adjusting for age and HCV RNA titer, ISDR subtype may be the most potent predictive factor for combination therapy efficacy in Korean chronic hepatitis patients with HCV genotype 1b.

COMMENTS

Background

The effectiveness of IFN-α and ribavirin combination therapy in Hepatitis C virus (HCV) infected patients is not satisfactory, especially in patients with HCV genotype 1b. IFN is also inconvenient to use, costly, and has a variety of possible complications. Therefore, it is necessary to determine the predictive factors for IFN therapy.

Research frontiers

It is very important to know the pathogenesis of HCV-infected patients to block the progression of hepatocellular carcinoma.

Innovations and breakthroughs

This is the first study to determine the factors that predict the effectiveness of IFN-α and ribavirin combination therapy in Korean patients. In this study we used a large number of samples to determine the ISDR subtype, HCV RNA titer, age, and PePHD mutations.

Applications

The predictive factors for IFN-α and ribavirin combination therapy in patients with HCV genotype 1b can be used to select its candidates.

Peer review

This article is of theoretical and practical importance. The results show that HCV RNA ISDR type may be an important factor for predicting the efficacy of IFN-α and ribavirin combination therapy in Korean patients.

Abstract

AIM: To investigate the safety of β-L-D4A on DNA polymerase α.

METHODS: Ion exchange chromatography was used to separate DNA polymerase α from crude extract of human Hela cells. Detailed kinetic parameters were determined for β-L-D4A against DNA polymerase α.

RESULTS: DNA polymerase α was purified with 4% yield and 31000 units/mg specific activity. The Michaelis constant (Km = 3.22 μmol/L), 50% inhibition concentration (IC50 = 178.49 μmol/L) and inhibition constant (Ki = 126 μmol/L) of β-L-D4A were determined by kinetic analysis.

CONCLUSION: β-L-D4A is a more safe nucleoside for hepatitis B virus (HBV) infection with a lower host toxicity.

Key words: Nucleoside; β-L-D4A; DNA polymerase α; Kinetic study; Side effect; Hepatitis B virus

INTRODUCTION

Infection with hepatitis B virus (HBV) is a global medical problem[1]. With the support of National Natural Science Foundation of China[2], we have found a novel nucleoside analog (β-L-D4A), a potent and selective inhibitor of HBV replication, which is stronger than lamivudine (3TC)[3,4]. Because the nucleoside and nucleoside analog could serve as substrates for normal DNA polymerases, resulting in inhibition of cellular DNA synthesis, we decided to study the side effect of β-L-D4A on DNA polymerases[5].

It has been found that many kinds of DNA polymerase have a crucial role in DNA replication, among which, the high molecular weight class of eukaryotic DNA polymerase α (EC2.7.7.7), first identified in calf thymus extract and found to be ubiquitous among eukaryotes, constitutes the predominant polymerase species in actively dividing cells[6,7]. So ion exchange chromatography was used to separate DNA polymerase α from crude extract of human Hela cells, which could be used as a substrate to evaluate the safety of nucleoside-β-L-D4A.

MATERIALS AND METHODS

Reagents

β-L-D4 triphosphate was chemically synthesized in our institute with the help of Pharmaceutic College of Wuhan University and identified by infrared mass spectra, nuclear-magnetic resonance. 3TC 5' triphosphate was provided by Professor Cheng YC (School of Medicine, Yale University, New Haven, CT). Hela S3 cells were purchased from Institute of Immunity, Tongji Medical College, DE52 and P11 cellulose resin were from Whatman while HTP was from Bio-Rad. DNA-cellulose and activator calf thymus DNA were obtained from SIGMA. α-^{32}P-dTTP was from Amersham. All other tissue culture reagents were from Gibco.

All operations were performed at 0℃-4℃. Unless otherwise noted, all buffers contained 1 mmol/L β-mercaptoethanol and 1 mmol/L EDTA.

Preparation of cytoplasmic crude extract

Frozen cells (approximately 80 g) were suspended in 300 mL of 2 mmol/L $MgCl_2$, 1 mmol/L p-toluenesulfonyl fluoride, 10 mL/L isopropyl alconol, and 5 mmol/L KPO_4 (pH7.5), and broken in a Dounce homogenizer after 20 min at 0℃. Nuclei were spun down at 800 r/min for 10 min, and mitochondria were pelleted at 13000 r/min for 20 min. The mitochondrial pellet was washed with 80 mL extraction buffer and re-sedimentated with the two supernatants combined (a). Fraction a was dialyzed for 8-12 h against 10 volumes twice with 0.2 mol/L sodium acetate (pH5.5) each time, after which a flocculent precipitate was removed by centrifugation at 13000 r/min for 20 min (b). Fraction b was over-layered with 117 mL/L sucrose in 0.2 mol/L KPO_4 (pH8.2) and spun for 90 min at 40000 r/min in a Beckman rotor. The supernatant was saved (c).

First DEAE-cellulose chromatography

Fraction c was diluted to a final concentration of 0.1 mol/L KPO_4 at 1:1 with 1 mmol/L β-mercaptoethanol, 1 mmol/L EDTA and loaded onto a DEAE-cellulose column (5 cm × 20 cm) equilibrated with the same buffer. The column was washed with 3 volumes of equilibration buffer, and the adsorbed activity was then eluted in a single step with 0.2 mol/L KPO_4 (pH8.2). All the active fractions from the step were pooled (d).

Second DEAE-cellulose chromatography

Fraction d was diluted to a final concentration of 0.1 mol/L KPO_4 with 1 mmol/L β-mercaptoethanol, 1 mmol/L EDTA and loaded onto a second DEAE-cellulose column (2.5 cm × 25 cm). The column was washed with 3 volumes of equilibration buffer and then developed with a 5-6 column volume gradient from 0.1 mol/L to 0.2 mol/L KPO_4 (pH8.2).

Phosphocellulose chromatography

The peak fractions of protein obtained from DE52 were pooled and dialyzed against 300 g/L sucrose, 200 mL/L ethylene glycol, 0.1 mol/L KPO_4 (pH7.2) (e). Fraction e was loaded onto a phosphocellulose column (2.5 cm × 20 cm). The column was developed with a 6-volume gradient from 0.1 mol/L to 0.3 mol/L KPO_4 (pH7.2).

Hydroxylapatite chromatography

The peak fractions of DNA polymerase α from P11 were pooled and dialyzed against 300 g/L sucrose, 0.05 mol/L KPO_4 (pH 6.8) (f). Fraction f was diluted at 1:1 with 1.0 mol/L KCl, 4 mL/L Triton X-100 and loaded onto a hydroxylapatite column (1 cm × 13 cm). The column was eluted with a 15-volume gradient from 0.025 mol/L to 0.2 mol/L KPO_4 (pH7.2).

DNA-cellulose chromatography

The peak fractions were pooled and concentrated by dialysis against 300 g/L sucrose, 0.1 mol/L KPO_4 (pH7.5) (g). Fraction g was diluted to a final concentration of 0.02 mol/L KPO_4 (pH7.5) at 1:4 with 1 mmol/L β-mercaptoethanol, 1 mmol/L EDTA, and loaded onto a DNA cellulose column (1 cm × 10 cm). The column was developed with a 20-volume gradient from 0.02 mol/L to 0.2 mol/L KPO_4 (pH7.5).

Protein concentration

Bradford method was used to measure the protein concentration, which was operated by directions of the reagent box.

Assay of DNA polymerase α

The final volume of reaction mixture was 50 μL containing 2 μL DNA polymerase α, 50 μmol/L d CTP, 50 μmol/L d GTP, 50 μmol/L d ATP, 50 μmol/L α-^{32}Pd TTP (100 cpm/pmol), 100 μg/mL activated calf thymus DNA, 50 mmol/L Tris-HCl (pH7.5), 0.5 mmol/L $MnCl_2$, 100 mmol/L KCl and 2.5 mmol/L DTT. The mixture was Incubated at 37℃ for 15 min, and spotted onto DE81 filter paper. The paper was washed three times with 5% Na_2HPO_4 (10 min each time), twice with water (5 min each time), dried and assayed for the acid-insoluble radioactivity.

Sodium dodecyl sulfatd polyacrylamide gel electrophoresis (SDS-PAGE)

SDS-PAGE was performed to detect the purity of DNA polymerase α.

Western blot

Western blot was performed to confirm the protein bands.

Detailed kinetic parameters were determined using DNA polymerase α which was prepared, pooled and stored at -80℃ until use in experiments. Potential inhibitors at various concentrations were added to 5 μL reaction mixture. Control samples (without inhibitor) included 5 μL solution in PBS, but no inhibitors. DNA polymerase α activity was measured.

Michaelis constant (Km)

To find the inhibition type, α-^{32}P-dTTP(100 cpm/pmol) was performed at the concentration of 1, 3, 5, 7, 10 μmol/L while inhibitors were added at the concentration of 10 μmol/L of each compound. DNA polymerase α was determined. The data were analyzed with GraphPad Prism 4 Demo, which could finish Line weaver-Burk Plot and L-B linear secondary regression with the enzyme kinetics template.

Fifty percent inhibition concentration (IC50)

To determine the concentration required to inhibit DNA polymerase α activity by IC50, initial experiments were designed with the gradient (1 μmol/L-400 μmol/L) of each compound. The concentration of α-^{32}P-dTTP (100 cpm/pmol) was 3 μmol/L. All experiments were performed twice. Inhibition rate = (1 - count of drug class/blank control) × 100%. Half logarithm plot was used to process the data. DNA polymerase α activity in the control sample was set at 100%.

Inhibition constant (Ki)

To find the inhibition constant (Ki), each compound was studied at five different inhibitor concentrations (10, 40, 100, 160, 200 μmol/L), and at various substrate concentrations (2, 5 μmol/L) in duplicate. Dixon plot was used to deal with the data.

RESULTS

DEAE-cellulose chromatography

The first DE52 chromatography was to remove nucleic acid. The curve of A280 showed a broad peak including 74 tubes from the 16th tube (0.115 mol/L) to the 90th tube (0.185 mol/L) in the second DE52 chromatography (Figure 1A). The protein in 74 tubes was collected and the ingredient was confirmed by assay of DNA polymerase α activity. The total protein was 0.36 mg measured by Bradford method.

Phosphocellulose chromatography

Protein determined by A280 was eluted sharply as a

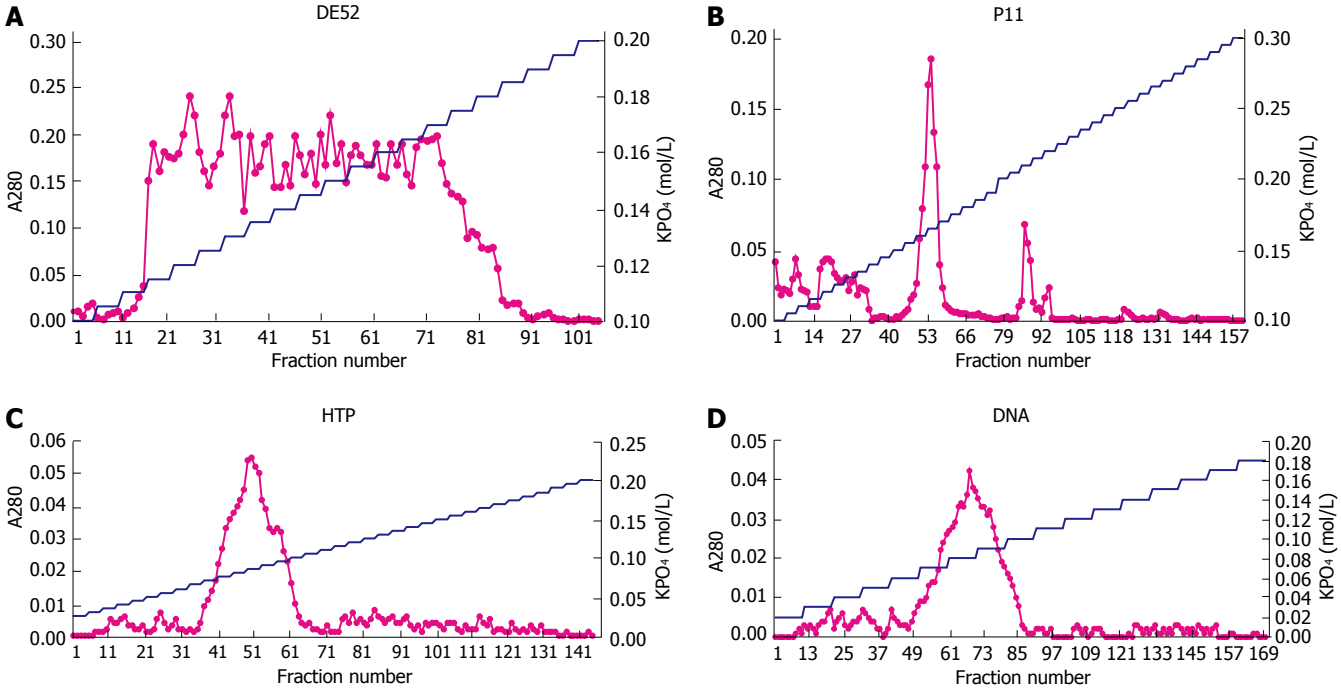

Figure 1 A280 and gradient concentration of KPO_4 in each chromatography. The curve with spots is for A280, the other is for KPO_4. **A**: A broad peak of protein from the 16th tube (0.115 mol/L) to the 90th tube (0.185 mol/L), clearly observed in the second DE52 chromatography; **B**: Phosphocellulose chromatography displaying a major peak of protein identified at 0.165 mol/L KPO_4 and a minor trailing shoulder at 0.21 mol/L; **C**: Hydroxylapatite chromatography showing a single sharp peak of protein at 0.085 mol/L KPO_4; **D**: DNA-cellulose chromatography revealing a single sharp peak at 0.085 mol/L KPO_4.

Table 1 Protein, activity, specific activity, purification times and yield of each step

Step	Protein/ mg	Activity/ units	Specific activity/ (units/mg)	Purification times	Yield(%)
Crude extract	9.000	800	89		
First DEAE	0.880	480	545	6	60
Second DEAE	0.360	260	722	8	33
P11	0.039	240	6154	69	30
HTP	0.008	120	15000	169	15
DNA	0.002	32	31000	348	4

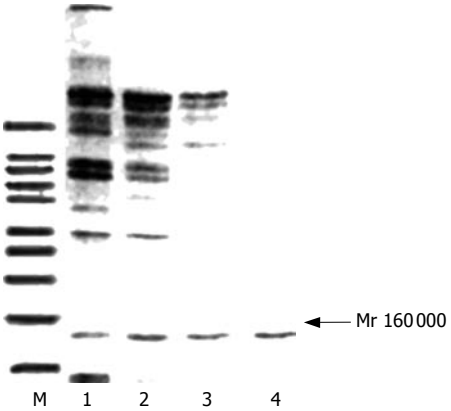

Figure 2 SDS-PAGE displaying decreased bands after purification steps-DE52 (lane 1), P11 (lane 2), HTP (lane 3) and DNA (lane4), and M (marker), While DNA-cellulose chromatography demonstrating only one band (M_r 160 000).

major peak at 0.165 mol/L, with a minor trailing shoulder occasionally present at 0.21 mol/L (Figure 1B). Fractions from 0.15 mol/L to 0.18 mol/L KPO_4 were pooled because the minor peak was not the protein as expected. The total protein was 0.039 mg.

Figure 3 Western blot of the fractions of DNA-cellulose chromatography. When mouse anti-human DNA polymerase α monocloned antibody was used as the primary antibody, the fraction was found to be DNA polymerase α.

Hydroxylapatite chromatography

Fractions from the 37th to the 64th tube were collected because a single sharp peak appeared at 0.085 mol/L KPO_4 (Figure 1C). The characterization was certified by its activity and the protein was 0.008 mg.

DNA-cellulose chromatography

Protein was eluted in a single sharp peak at 0.085 mol/L KPO_4 (Figure 1D). As the activity was measured, the region from 0.07 mol/L to 0.10 mol/L KPO_4 was pooled and concentrated by dialysis against 300 g/L sucrose, 0.1 mol/L KPO_4 (pH7.5).

Analysis of protein and activity

When the specific activity became higher, the total protein, total activity and yield became lower in each stage, illustrating that DNA polymerase α was purified step by step while the other components were removed (Table 1).

SDS-PAGE and Western blot

SDS-PAGE showed that the purification of protein was effective because the bands decreased with the step of purification and finally there was only one band (Figure 2). Western blot revealed that the band was DNA polymerase α (Figure 3).

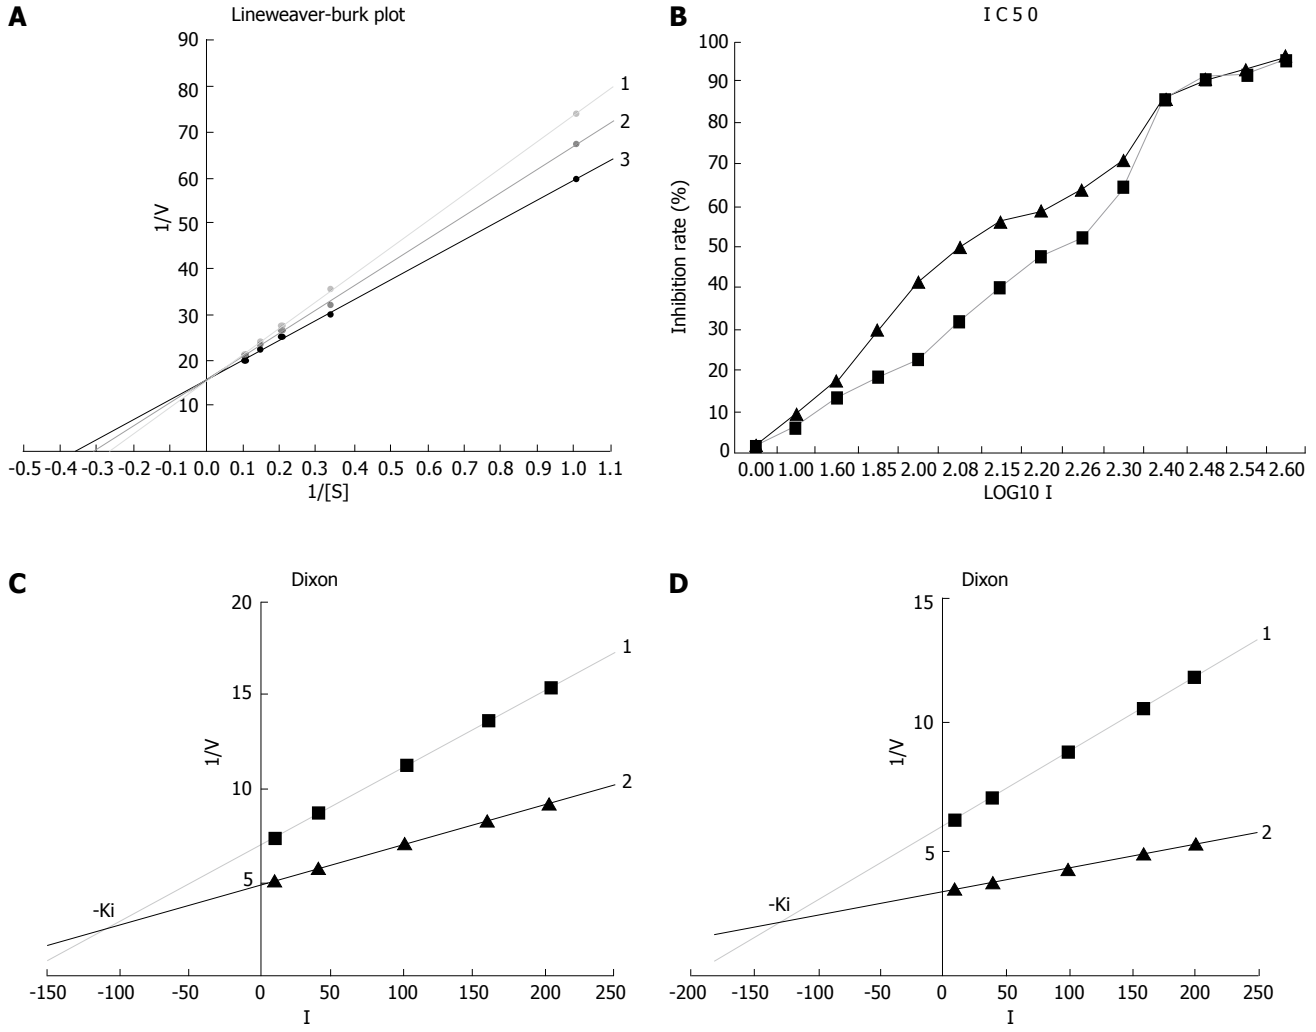

Figure 4 Determination of detailed kinetic parameters Km (**A**), IC50 (**B**), and Ki (**C** for 3TC, **D** for β-L-D4A).

Michaelis constant (Km)

The inhibition mechanism was observed by visual inspection of graphical plots after data linearization (Line weaver-Burk plot) using the GraphPad Prism 4 Demo software. The L-B linear regression equations in Figure 4A showed 3TC5'-triphosphate, y = 15.922 + 57.978x (r^2 = 0.9999), Km = 3.64 μmol/L; β-L-D4A, y = 15.879 + 51.163x (r^2 = 0.9993), Km = 3.22 μmol/L; blank without inhibitor, y = 15.860 + 43.493x (r^2 = 0.9995), Km = 2.74 μmol/L.

Fifty percent inhibition concentration (IC50)

IC50 was calculated using the half logarithm plot, demonstrating that β-L-D4A (178.49 μmol/L) was 1.5 fold more potent than 3TC (122.41 μmol/L) (Figure 4B).

Inhibition constant (Ki)

The Ki was also estimated using the GraphPad Prism 4 Demo software. The two linear regression equations in Figure 4C were 3TC, y = 0.0408x + 6.9594 (r^2 = 0.9998) and y = 0.0212x + 4.8957 (r^2 = 0.9991) while the equations in Figure 4D were β-L-D4A, y = 0.0297x + 6.0389 (r^2 = 0.9965) and y = 0.0095x + 3.4904 (r^2 = 0.9996). The Ki of 3TC was 105 μmol/L which was lower than β-L-D4A (126 μmol/L).

DISCUSSION

HBV infection, associated with the risk of developing liver cirrhosis and hepatocellular carcinoma, is a worldwide public health problem. Two billion people worldwide show evidence of having been infected with HBV, and more than 350 million of them are chronically infected. Persons with chronic hepatitis B are at a high risk of developing hepatic cirrhosis and primary hepatocellular carcinoma, leading to 500000 to 1.2 million deaths annually worldwide. Antiviral chemotherapy remains the only choice of treatment for controlling HBV infection in these individuals, for whom available HBV vaccines provide no benefit. At present, approved therapeutics for chronic HBV infection are α-interferon or nucleoside and nucleoside analogs[8]. Drawbacks of treatment with α interferon include a low sustained response rate, undesirable side effects, the need for parenteral administration, and high cost[9,10]. Treatment with nucleosides such as 3TC is less costly and more convenient[11,12]. The fundamental concern is that while initial treatment of patients with 3TC results in a rapid decrease in HBV DNA blood levels, its efficacy is severely compromised in most patients by the development of antiviral resistance after prolonged therapy[13,14]. Although the use of nucleoside and nucleoside analogs as anti-

hepadnaviral agents is similarly disappointing, prospects for their future use are bright, as several of recently developed analogs have been found to be potent and can be used as selective inhibitors of HBV replication. In our previous work, the novel nucleoside (β-L-D4A) was synthesized and its inhibitiory actions against HBV were studied and found to be much better than 3TC[15,16]. The inhibition of HBV replication by nucleoside analogs results from the recognition of nucleoside analog triphosphates (TPs) by the RNA-dependent DNA polymerase of HBV (HBV Pol). The triphosphate derivatives could serve as substrates for human DNA polymerases, inhibiting cellular DNA synthesis. For the systemic evaluation of the safety of the new drug, kinetic analysis of DNA polymerases must be performed.

Of the multiple DNA polymerases occurring in eukaryotes, only DNA polymerase α is able to initiate the synthesis of new strands[6], because it can initiate the replication of DNA by cooperating with RNA polymerase[17-19].

In the present study, DNA polymerase α was purified step by step because the total protein and activity decreased while the specific activity raised and the number of protein bands was cut down till only one band was left in SDS-PAGE (Mr 160 000). Western blot and the specific activity (31 000 units/mg) confirmed that the scheme was effective. The enzyme obtained lays a foundation for the next research.

Nucleoside analogs are chemically synthesized drugs that are able to mimic natural nucleosides[20,21]. They exert their antiviral effect, after anabolism to the triphosphate form, by acting as alternate substrates for the virally encoded reverse transcriptase[22,23]. Incorporation of the nucleoside analog monophosphate into the viral DNA, results in premature termination of viral DNA synthesis. Nucleoside analogs competitively inhibit DNA-dependent reverse transcriptase activity of the viral polymerase[24,25]. As DNA polymerase α has the similar substrate and mechanism to HBV viral polymerase, the drugs could serve as substrates for human DNA polymerase α, inhibiting cellular DNA synthesis[26,27]. Because DNA polymerase α exhibits neither exonuclease nor endonuclease activity, mistake cannot be repaired[28,29]. To determine the safety of nucleosides on cells in the present study, DNA polymerase α was purified and kinetic analysis was performed under the identical conditions of ionic strength, pH, divalent metal ion concentration, and DNA substrate.

The Km increased and Wmax unchanged (Figure 4A), confirming that both of β-L-D4A and 3TC are the competitive inhibitors of DNA polymerase α. In our study, the drugs inhibited DNA polymerase α activity by acting as competitive alternate substrates. 3TC was more effective than β-L-D4A as inhibitors of DNA polymerase α because IC50 of β-L-D4A was 1.5 fold more potent than 3TC and the Ki of 3TC was 105 μmol/L, much lower than β-L-D4A (126 μmol/L), demonstrating that β-L-D4A is significantly more safe than 3TC.

In conclusion, β-L-D4A is a safe drug for HBV infection because it is endowed with lower host toxicity in comparison to 3TC. Furthermore, combined therapy of β-L-D4A and lamivudine for HBV infection can be explored.

COMMENTS

Background

Since hepatitis B virus (HBV) replication involves a virally encoded reverse transcriptase (RT), a number of L-configuration nucleoside analogs with an inhibitory effect on RT have emerged as potent antiviral agents against HBV infection. However, most anti-HBV nucleoside analogs tested to date have only transient and limited effects on a small number of HBV-infected individuals with moderate to severe side effects. In light of the fact, development of novel antiviral agents is an extremely important undertaking.

Research frontiers

In recent years, a considerable interest has been focused on the use of 2', 3'-dideoxynucleosides (DDNs) in the treatment of chronic HBV infection. β-L-D4A, a novel L-nucleoside, can effectively block the production of HBV in 2.2.15 cells *in vitro*, but no information is available on the safety evaluation of this new compound.

Innovations and breakthroughs

In this research, kinetic analysis of DNA polymerase α cytotoxicity, was investigated to evaluate the safety of this new compound.

Applications

β-L-D4A is a safe drug for HBV infection because it is endowed with a low host toxicity.

Terminology

β-L-D4A, [5-(6-amino-9H-purin-9-yl)-2,5-dihydrofuran-2-yl] methanol, is a novel L-nucleoside.

Peer review

This is an interesting paper describing the effect of β-L-D4A (a novel nucleoside analog) on DNA polymerase α. The authors separated DNA polymerase α from crude extract of human Hela cells and studied its enzyme kinetics, showing that the enzyme is less inhibited than lamivudine, thus β-L-D4A may be an effective nucleoside for HBV infection with a lower host toxicity.

Abstract

AIM: To study the effects of endogeous nitric oxide induced by 5-fluorouracil (5-FU) and L-arginine (L-Arg) on the human liver carcinoma model in nude mice.

METHODS: The human liver carcinoma model in nude mice was established with BEL-7402 cells and normal saline (NS), 5-FU and 5-FU + L-Arg injected intraperitoneally. The tumor size was measured. The necrotic degree and range were observed under microscope. The apoptosis of cancer cell was detected by turmina deoxynucleotidyl transferanse mediated dUTP nick end labeling (TUNEL) method. Immunohistochemical method was performed to determine the expression of iNOS, P16, BAX. The chemical colorimetry was used to test the activity and nitrate reductase method was adopted to test the concentration of nitric oxide (NO) in the tumor tissue. The BI2000 pathological image analyzer was used to analyze the result of immunohistochemistry.

RESULTS: 5-FU combined with L-Arg could inhibit the tumor growth apparently. In NS, 5-FU and 5-FU+L-Arg groups, the changes of tumor volumes were 257.978 ± 59.0, 172.232 ± 66.0 and 91.523 ± 26.7 mm^3, respectively ($P < 0.05$ 5-FU *vs* 5-FU + L-Arg group; $P < 0.05$ NS *vs* 5-FU + L-Arg group; $P < 0.05$, NS *vs* 5-FU group). The necrotic range and apoptosis index were significantly increased after the drug injection. The necrotic range was biggest in 5-FU + L-Arg group ($\chi^2 = 15.963$, $P < 0.05$). The apoptosis indexes were as follows: NS, 17.4% ± 6.19%; 5-FU, 31.3% ± 12.3%; and 5-FU + L-Arg, 46% ± 15.24% ($P < 0.05$, 5-FU *vs* 5-FU + L-Arg; $P < 0.05$, NS *vs* 5-FU + L-Arg; $P < 0.05$, NS *vs* 5-FU). The expression and activity of iNOS were increased in the tumor tissue. The concentration of NO was also increased. *F* of optical density of iNOS, iNOS activity and NO concentration are 31.693, 21.949, and 33.909, respectively, $P < 0.05$. The concentration of NO was related to the expression of P16 and BAX. The correlation coefficient was 0.764 and 0.554.

CONCLUSION: 5-FU combined with L-Arg can inhibit the growth of tumor in nude mice. The effect may be related to inducing the synthesis and increasing the activity of iNOS. The production of NO is increased, and it can enhance the expression of apoptosis-related gene and antioncogene.

INTRODUCTION

Over the past decade or so, it has become evident that free radical gas nitric oxide acts as a novel transcellular messenger molecule in many key physiological and pathological processes. It appears that high levels of nitric oxide (NO) may be cytostatic or cytotoxic for tumor cells[1,2]. NO is a small gaseous molecule generated in a wide variety of cells as a product of the conversion of L-arginine into L-citrulline by the enzyme nitric oxide synthase (NOS). There have been few reports about the antitumor effects of endogenous nitric oxide *in vivo*[3,4]. In this study, we observed the inductive effects of 5-fluorouracil (5-FU) and L-arginine (L-Arg) on the endogenous nitic oxide in the human live carcinoma model in nude mice and proved the antitumor effects of the endogenous nitric oxide in the primary hepatic carcinoma and found effective adjuvant for 5-FU.

MATERIALS AND METHODS

Materials

Male Balb/c nude mice were provided by the animal center of Shandong University. BEL-7402 cells were obtained from Shandong Academy of Medical Sciences, China.

Immunochemical kit and *in situ* cell apoptosis detection kit were purchased from Wuhan Boster Technology Company, China. Nitric oxide synthase and NO detection kits were purchased from Nanjing Jiancheng Bioengineering Institute, China. 5-FU was produced by Shanghai Xudong Haipu Pharmacentical Company. L-Arg was produced by Shanghai Xinyi Jinzhu Pharmacentical Company.

Cell lines and culture conditions

Human primary hepatocellular cancer cell line BEL-7402 was maintained in a humidified, 5% CO_2 atmosphere and cultured in DMEM, supplemented with 10% fetal calf serum and penicillin-streptomycin mixture.

Grouping and animal model

BEL-7402 cells were cultured *in vitro* to the log growth phase, centrifuged and washed with PBS to a concentration of 1×10^7/mL, and 0.2 mL cell solution was subcutaneously xenografted in the neck or the flank of 4-6 wk old male Balb/c nude mice. The mice were housed and maintained in lamina flow cabinets under specific pathogen-free conditions. Ten day after establishment of the model when tumors reached a mean diameter of 0.5 cm, mice were randomly divided into three groups (10 mice per group) and treated as follows: group A was injected intraperitoneally with 0.2 mL normal saline, group B was injected with 5-FU at a dose of 20 mg/kg, and group C was injected with 5-FU at 20 mg/kg and L-Arg at 100 mg/kg. The drugs were injected every other day from d 11 to d 15. The mice were killed at 17d after the experiment finished.

Tumor inhibition rate in vivo

The largest diameter (a) and its vertical diameter (b) of the tumors were measured with caplipers every two days after the tumor appeared. The volume of tumor was equal to $1/2ab^2$. The tumor inhibition rate (TIR) was calculated with the following formula:

TIR = control group (v_1 - v_0) - treatment group (v_1 - v_0)/control group (v_1 - v_0)

(v_0: the volume before injection of drugs, v_1:the volume after injection of drugs).

Histology

The sections were stained with hematoxylin-eosin to evaluate the degree and range of the necrosis. It was divided into 4 degrees according to the percentage of the necrotic area: ≤ 25% (+), 25%-50% (++), 50%-75% (+++), > 75% (++++)[5].

TUNEL

TUNEL method was used to detect the apoptosis of tumor cells according to the instructions of the manufacturer. Cells with brown or yellow nuclei were assumed as apoptotic cells. The number of apoptotic cells and total cancer cells was counted under light microscope at 400 × magnification in 5 fields of version and the average values were used for the calculation of apoptosis index (AI) according to the formula: AI = (apoptotic cells/total cancer cells) × 100%.

Immunohistochemical staining

Tumor specimens were dissected from mice and fixed in 10% buffered formalin solution overnight. They were then embedded in paraffin and sectioned in 4 μm thicknesses. SABC immunohistochemistry was performed according to the manufacturer's instructions to detect the gene expression of iNOS, P16 and BAX. Briefly, the tissue sections were deparaffinized in xylene at 37℃ for 20 min. Endogenous peroxide was blocked by incubating the slides with 30 mL/L H_2O_2 for 10 min at 37℃. Sections were incubated with primary antibodies of iNOS, P16 and BAX at 4℃ overnight respectively. Staining was visualized with DAB for 10 min at room temperature. Finally, the sections were counterstained for nuclei by hematoxylin solution. The results were analyzed with a BI2000 pathological image analyzer and expressed as optical density.

iNOS activity and NO concentration assay

NOS catalyzed the formation of NO and L-citrulline from L-arginine and molecular oxygen, and NO reacted with a nucleophile to generate color compounds. The absorbance of NOS at 530 nm was calculated and expressed as U/mg protein. One unit of NOS activity was defined as the production of 1 nmol nitric oxide per second per mg tissue protein. Total NOS activity was measured as follows: 10% tissue homogenate (100 μL) was incubated with 200 μL substrate buffer, 10 μL reaction accelerator and 100 μL color development reagent at 37℃ for 15 min after mixing. Then 100 μL clearing reagent and 2 mL stop solution were added, mixed and absorbances were read at 530 nm. For measuring iNOS activity, an inhibitor was added before incubation according to the manufacturer's instructions. Total protein concentration was determined using the Coomassie blue method with bovine serum albumin as standard.

Tumor samples were thawed, weighed and homogenized 1:9 w:v in 0.9% saline. The homogenates were then centrifuged at 1000 r/min for 5 min at 4℃, the supernatant was taken for NO assay and total protein determination.

NO was assayed spectrophotometrically by measuring total nitrate plus nitrite (NO_3^- plus NO_2^-) and the stable end products of NO metabolism. The procedure was performed by the manufacturer's instructions. Results were expressed as μmol/g protein.

Statistical analysis

All data were analyzed with SPSS11.0 statistical software. One-way ANOVA, Bonferroni, Kruskal-Wallis H test and correlated analysis were performed.

RESULTS

Tumor inhibition rate in vivo

5-FU could inhibit the growth of the liver carcinoma in nude mice. When the substrate L-Arg was supplemented, tumor inhibition rate increased significantly (Table 1).

Histology

There was different necrosis in the tumor tissues. The

Table 1 Changes of tumor volume and tumor inhibition rate

	n	Changes of tumor volume (mm^3)	Tumor inhibition rate (%)
A: NS group	10	257.978 ± 59.0[a]	
B: 5-FU group	10	172.232 ± 66.0[c]	33.24
C: 5-FU+L-Arg group	10	91.523 ± 26.7[e]	64.52

[a]$P < 0.05$, group B *vs* C; [c]$P < 0.05$, A *vs* C; [e]$P < 0.05$, A *vs* B.

Table 2 Necrotic range in tumor tissues

	+	+ +	+ + +	+ + + +
A: NS group	6	3	1	
B: 5-FU group		5	3	2
C: 5-FU+L-Arg group		1	4	5

$\chi^2 = 15.963$, $P < 0.05$.

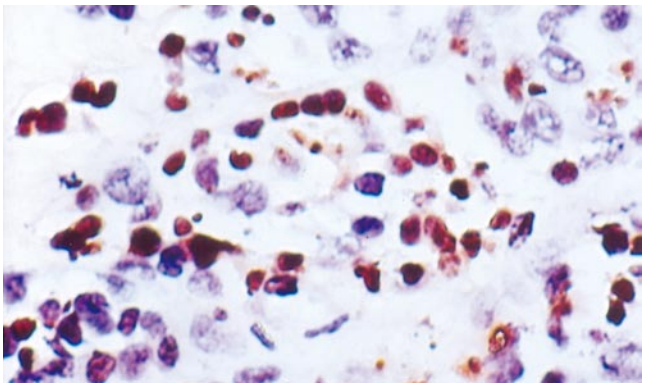

Figure 1 The apoptosis cells in tumor tissues (× 400).

necrotic range enlarged greatly after treatment with 5-FU and L-Arg (Table 2).

Apoptosis index

There were a lot of apoptosis cells in 5-FU and 5-FU+L-Arg groups, while only scattered apoptosis cells in NS group. The apoptosis cells are shown in Figure 1. The apoptosis indexes were as follows: NS group 17.4% ± 6.19%; 5-FU group 31.3% ± 12.3%; and 5-FU+L-Arg group 46% ± 15.24%. [a]$P < 0.05$ group B *vs* group C; [c]$P < 0.05$ A *vs* C; [e]$P < 0.05$ A *vs* B. There was significantdifference between the two groups.

iNOS activity, NO concentration and immunohistochemical results of iNOS

The optical density of iNOS, iNOS activity and NO concentration were increased after treatment with 5-FU. When the substrate L-arg was supplemented, they were increased more significantly (Table 3). The expression of iNOS is shown in Figure 2.

Correlation analysis between concentration of NO and expression of P16, BAX

The expression of P16 and BAX was increased after

Table 3 Optical density of iNOS ,iNOS activity and NO concentration in tumor tissues

	Optical density of iNOS (μmol/L)	Activity of iNOS (U/mg protein)	Concentration of NO
A: NS group	0.4621 ± 0.0115[a]	4.87 ± 2.5[a]	6.58 ± 3.2[a]
B: 5-FU group	0.4783 ± 0.0107[c]	9.83 ± 2.31[c]	17.97 ± 6.16[c]
C: 5-FU+L-Arg group	0.5269 ± 0.0034[e]	15.1 ± 4.91[e]	30.41 ± 8.81[e]

F of optical density of iNOS , iNOS activity and NO concentration are 31.693, 21.949 and 33.909, respectively, [a]$P < 0.05$, B *vs* C; [c]$P < 0.05$, A *vs* C; [e]$P < 0.05$, A *vs* B.

Table 4 The optical density of P16 and BAX in tumor tissues

	Optical density of BAX	Optical density of P16
A: NS group	0.4501 ± 0.0114[a]	0.4565 ± 0.0139[a]
B: 5-FU group	0.4788 ± 0.0068[c]	0.4939 ± 0.041[c]
C: 5-FU+L-Arg group	0.5045 ± 0.0199[e]	0.5451 ± 0.027[e]

F of optical density of BAX andP16 is 23.51 and 16.13. [a]$P < 0.05$, B *vs* C; [c]$P < 0.05$, A *vs* C; [e]$P < 0.05$, A *vs* B.

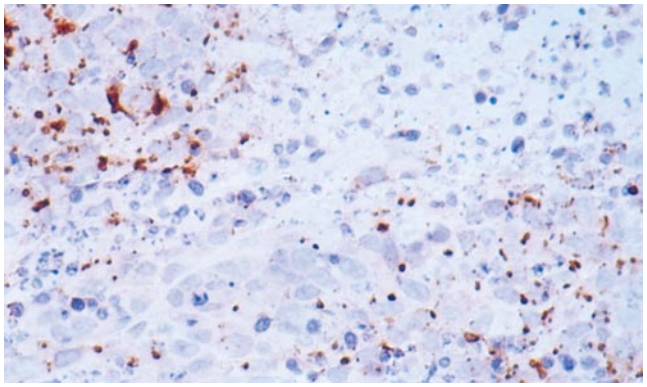

Figure 2 The expression of iNOS in tumor tissues (× 200).

treatment with 5-FU and L-Arg. $P < 0.05$ (Table 4). The result of Pearson analysis showed that the concentration of NO was correlated with the expression of P16 and BAX. The correlation coefficient was 0.764 and 0.554.

DISCUSSION

Hepatocellar carcinoma is one of the most common malignant tumors in China. Surgical resection is the best choice. But many patients could not be treated surgically when diagnosis was made too late. Chemotherapy becomes the important treatment for liver cancer[6,7]. 5-FU is used extensively in the chemotherapy of hepatocellular carcinoma[8,9]. It is well known that mechanism of the anti-tumor effects is to interfere with DNA or protein synthesis[10]. 5-FU can also induce the apoptosis of different tumor cells, but the mechanism is unclear[11,12]. Oshima T *et al* reported that 5-FU induced iNOS expression and NO produced by gastric cancer cells, and NO participated in antitumor activity in gastric cancer cells. These effects may be mediated by TNF-alpha

production[13]. 5-FU could induce the cytokines such as interleukin-1beta (IL-1beta) and TNF-alpha[14]. Other studies showed that the iNOS expression was stimulated by interleukin-1beta (IL-1beta) and TNF-alpha[15]. So we speculated that the 5-FU might induce the iNOS by induction of cytokines. However, this need to be proved by further studies. We found that 5-FU could induce the expression of iNOS of BEL-7402 cells *in vitro*. When the L-Arg was sufficient, the production of NO increased obviously. It caused the increases of apoptosis and necrosis of BEL-7402 cells. NO increased the chemotherapy sensitivity of BEL-7402 cells to 5-FU[16]. In this study, the expression and activity of iNOS increased after the treatment with 5-FU and L-Arg, and the concentration of NO in the tumor tissue was increased at the same time. This suggests that the endogenous NO plays an important role in the anti-tumor effects of 5-FU and L-Arg.

The present study showed that the high concentration of NO could be cytotoxic for tumor cells or inhibit the tumor growth[17,18]. The high concentration of NO could interfere with the citric acid cycle, and arrest the cell in the S stage[19,20]. More importantly, NO has been shown to bind rapidly with high affinity to ferrous iron (Fe^{2+}). As a consequence, NO can bind easily to free iron, iron within iron-sulphur centres, and iron within hemoproteins[21,22]. NO can cause DNA damage via the generation of peroxynitrite (ONOO-) and N_2O_3[23,24]. One of the consequences of the NO-mediated DNA damage is to trigger p53 accumulation, which can induce apoptosis[25,26]. NO can induce the apoptosis of tumor cell by the regulation of the apoptosis and cell cycle related protein, such as P21, BAX, cyclin D *etc*[27-29]. Nicola *et al* reported that NO mediates chemosensitivity in tumor cells, and Hypoxia-induced drug resistance appears to result, in part, from down-stream suppression of endogenous NO production. These results raise the possibility that administration of small doses of NO mimetics could be used as an adjuvant in chemotherapy[30]. In this study, the expression of P16 and BAX was found correlated with the concentration of NO, suggesting that NO can increase the expression of apoptosis-related gene and antioncogene. The necrotic range and apoptosis index increased more significantly in the 5-FU and L-Arg group than other two groups. We think that the high concentration of NO may kill the tumor cells or induce apoptosis of the tumor cells directly. On the other hand, the production of NO also improved the chemosensitivity of tumor cells to 5-FU.

L-Arg is not an essential amino acid, and it can be synthesized in the liver. However, liver function of liver cancer patients is poor, and the concentration of L-Arg in the body is likely low. When patients are undergoing chemotherapy with 5-FU, added with L-Arg to improve the production of endogenous NO in liver cancer cells may enhance the therapeutic effects and improve the antitumor ability of the patients. L-Arg may be an effective adjuvant for 5-FU.

COMMENTS

Background

Hepatocellar carcinoma is one of the most common malignant tumors in China. 5-FU is used extensively for the treatment of liver cancer. The effects of 5-FU alone is not satisfied. It is necessary to find the effective adjuvant for 5-FU.

Research frontiers

The expression of iNOS in the human liver carcinoma and the effects of endogenous nitric oxide on the BEL-7402 cells have been examined.

Innovations and breakthroughs

In the present study, the effects of endogenous nitric oxide on the liver carcinoma in nude mice have been studied.

Applications

The L-Arg can be used as the adjuvant for 5-FU in the treatment of liver cancer.

Terminology

L-Arginine (L-Arg) is a semi-essential amino acid that possesses numerous useful physiologic properties. NOS can catalyzethe L-Arg to form the nitric oxide. When the L-Arg is sufficient, the production of nitric oxide can be increased.

Peer review

This manuscript is very interesting. The title accurately reflects the major contents of the article. The results provide sufficient experimental evidences from which conclusions are drawn. The conclusions are scientifically reliable and valuable.

Abstract

AIM: To detect germline mutations of MLH1, and investigate microsatellite instability and expression of MLH1 in tumor tissues of hereditary non-polyposis colorectal cancer (HNPCC) with two novel germline mutations, and further investigate the pathobiology of the two novel mutations of MLH1.

METHODS: RNA was extracted from the peripheral blood of 12 patients from 12 different families that fulfilled the Amsterdam Ⅱ Criteria for HNPCC. Germline mutations of MLH1 were determined by RT-PCR, followed by cDNA sequencing analysis. PCR-GeneScan analysis was used to investigate microsatellite instability with a panel of five microsatellite markers (BAT26, BAT25, D5S346, D2S123 and mfd15), along with immunohistochemical staining to detect the expression of MLH1 protein in two patients' tumor tissues with novel mutations.

RESULTS: Three germline mutations were found in four patients, one of the mutations has previously been reported, but the other two, CGC→TGC at codon 217 of exon 8 and CCG→CTG at codon 581 of exon 16, have not been reported. The two patients' tumor tissues with novel mutations had high-frequency microsatellite instability that showed more than two unstable loci, and both tumors lost their MLH1 protein expression.

CONCLUSION: The two novel germline mutations of MLH1 in HNPCC families i.e. CGC→TGC at codon 217 of exon 8 and CCG→CTG at codon 581 of exon 16, are very likely to have pathological significance.

Key words: Colorectal cancer; Hereditary non-polyposis colorectal cancer; MLH1 gene; Germline mutation; Microsatellite instability; Gene sequencing

INTRODUCTION

Colorectal cancer remains a serious public health challenge worldwide. According to the different molecular mechanisms, colorectal cancer is divided into two groups: sporadic and genetic. Hereditary non-polyposis colorectal cancer (HNPCC), the most common hereditary colon cancer syndrome[1], is a predominantly inherited disease associated with increased lifetime risk of a range of cancers, including colorectal and endometrial cancers, as well as extracolonic gastrointestinal, genitourinary, ovarian and brain cancers[2-9]. HNPCC development is associated with the functional deficiency of germline MMR genes. Up to now, seven MMR genes have been found, and among these, MLH1 and MSH2 are very closely associated with HNPCC[10-12]. Carriers of germline MMR mutations have a > 80% risk of cancer by the age of 75[13-15]. Twelve patients fulfilling Amsterdam Criteria Ⅱ from China were explored in this study. Two novel MLH1 mutations were detected, and the pathobiology of the novel mutations was investigated.

MATERIALS AND METHODS

Subjects and samples

Twelve patients of Chinese descent from families fulfilling Amsterdam Ⅱ Criteria were selected through the clinic at the Cancer Hospital of Fudan University, Shanghai, China. Personal and family cancer histories were obtained from the patients and participating relatives, and cancer diagnosis was confirmed by reviewing records and pathology reports. Informed consent was obtained from each participant. Three microliters of peripheral blood of each participant was taken. Total RNA of the peripheral blood was extracted using Trizol (Sigma), according to the

Table 1 Sequences and localization of primers used for Amplification of cDNA of MLH1

Sense	Antisense
MLH1-1F (1-18)	MLH1-5R (2198-2175)
CTTGGCTCTTCTGGCGCC	GAGCGCAAGGCTTTATAGACAATG
MLH1-4F (1333-1353)	MLH1-6R (2484-2459)
GCTGAAGTGGCTGCCAAAAAT	TATGTTAAGACACATCTATTTATTTA

manufacturer's instructions. Twenty unrelated volunteers from families without HNPCC were used as controls.

RT-PCR

cDNA was synthesized with RT (Roche Diagnostics), using 0.5 μg total RNA and specific primers complementary to the 3' end of the MLH1 (2484-TATGTTAAGACACAT CTATTTATTTA-2459). cDNA of MLH1 was amplified in two overlapping fragments using primers (Table 1) that generated products of approximately 2000 bp. PCR was performed using Expand Long Template PCR (Roche Diagnostics): 94℃ for 5 min; 10 cycles at 94℃ for 30 s, 59℃ for 30 s, and 68℃ for 3 min; 32 cycles at 94℃ for 30 s, 57℃ for 30 s, 68℃ for 3 min; and a final extension at 68℃ for 7 min[16].

Sequencing

The purified PCR fragments were sequenced directly using a DNA sequencing kit with BigDye Terminators on an ABI3700 automated DNA sequencer (Applied Biosystems, Foster City, CA, USA), according to the manufacturer' s instructions. The cDNA of MLH1 (2484 bp) was sequenced in six overlapping fragments using primers described in Table 2.

Microdissection and minimal amount of DNA extraction

One 5-μm and four 7-μm paraffin-embedded sections of tumor tissues were deparaffinized. The 5-μm sections were stained with hematoxylin and eosin and served as controls. The 7-μm sections were lightly stained with hematoxylin for microdissection. The microdissection was performed under a dissection microscope with a scalpel. Tumor cells should account for at least 80% of the total cells isolated. The microdissected tissues were transferred directly into an Eppendorf tube with 150 μL cell lysis buffer (0.5 mol/L Tris, 20 mmol/L EDTA, 10 mmol/L NaCl, 10 g/L SDS, 0.5 g/L Proteinase K). The subsequent DNA extraction was performed according to the protocol of the DNA extraction kit (Daxia Biotech, Shanghai, China). Genomic DNA was also extracted from peripheral white blood cells.

Microsatellite instability (MSI) analysis

Matched normal and tumor DNA was investigated with a panel of microsatellite markers (mononucleotide repeats BAT26 and BAT25, dinucleotide repeats D5S346, D2S123 and mfd15)[17]. The primer pairs were synthesized by Shenyou Biotech (Shanghai, China). Each forward primer was labeled with a fluorescent dye at the 5' end to enable the PCR products to be detected by an ABI 310 automated DNA sequencer. After successful amplification, the 2-μL PCR products were mixed with 12.5 μL deionized formamide and 2 μL 350 Rox Sizer. The mixture was denatured, snap-cooled and electrophoresed on an ABI 310 automated DNA sequencer according to the manufacturer's recommendation. The electrophoresis results were analyzed by GeneScan Software (Applied Biosystems). MSI was determined according to the method of Gebert *et al*[18]. Additional peaks (bands) at microsatellite loci in the tumor compared with normal tissue from the same patient were interpreted as MSIs. Cases with MSIs in more than two loci were interpreted as exhibiting high MSI.

Immunostaining for MLH1

A monoclonal antibody against MLH1 (Pharmingen, San Diego, CA, USA) was prepared at a 1:40 dilution. The antibody was detected by the EnVision method. Diminished expression of MLH1 in cancer tissues was demonstrated when there was complete absence of detectable nuclear staining of neoplastic cells. Infiltrating lymphocytes, as well as normal colonic crypt epithelium next to the tumor area, served as internal positive controls[19,20].

RESULTS

Germline mutations of MLH1

Four germline mutations were detected at three different sites of MLH1, involving four patients, which were at 649 codon 217 exon 8: CGC→TGC in family H2, at 1742 codon 581 exon 16: CCG→CTG in family H31, and at 1151 codon 384 exon 12: GTT→GAT in family H109 and H114. All three were missense mutations (Table 3, Figures 1 and 2). Their polymorphism possibilities were excluded by visiting the mutation database of MMR genes (www.INSIGHT-group.org). The mutation in families H109 and H114 has been reported to be pathogenic, while the mutations in H2 and H31 are not. The three abnormalities in MLH1 were not found in the control group.

MSI analysis

Four loci in BAT25, BAT26, D2S123 and D5S346 showed MSI in the tumor tissue of the patient from the H2 family, and four loci in BAT25, BAT26, D2S123 and Mfd15 showed MSI in the tumor tissue of the patient from the H31 family. According to the criteria above for MSI, the tumor tissues of the two patients had high MSI (Figure 3).

Immunohistochemistry of MLH1

There was no expression of MLH1 protein in the tissues of the two patients. As a control, MLH1 protein was detected in infiltrating lymphocytes and the normal colonic crypt epithelium next to the tumor area in the patient from the H2 family, and in the stromal cells in the patient from the H31 family (Figures 4 and 5).

DISCUSSION

Colorectal cancer is one of the most common malignant tumors; furthermore, its incidence is increasing continuously. HNPCC, genetic colorectal cancer, accounts for about 10% of all colorectal cancer. Compared with sporadic colorectal cancer, HNPCC shows special characteristics associated with its molecular mechanisms

and clinic features. HNPCC, as the most common hereditary colon cancer syndrome, is characterized by early onset of colorectal cancer, location of tumors in the proximal colon, and an increased risk of neoplasms of extracolonic organs, including endometrium, stomach, urothelium, small intestine, and ovary, multiple metachronous colorectal cancer[21-24], and better prognosis than that in sporadic cases[25-30]. Development of HNPCC is closely associated with deficiency or loss of MMR gene function. Identification of MMR gene germline mutations can have direct clinical implications in counseling and management of HNPCC families[31].

HNPCC has gained worldwide recognition, and several developed countries, such as the United States, Germany, Finland and the Netherlands, have established HNPCC genetic institutions, and several clinical criteria for the diagnosis of concerned families have been suggested. However, at present, there are only are a few institutions in China that are engaged in research on HNPCC. Our hospital collaborative group on HNPCC has been involved in the field for a few years, and has set up an HNPCC database. We detected the 12 random samples from our database that fulfilled Amsterdam Criteria Ⅱ, using an mRNA-based sequencing technique, and three germline mutations of MLH1 were found. All three were missense mutations, two of which have not been reported previously. Diagnosis of HNPCC was based on finding the pathological germline mutation in MMR gene. In the present series, difficulties in the assessment of pathogenicity were mostly associated with missense mutations. Peltomaki *et al* thought the missense mutation meeting the following criteria was pathogenic (1)

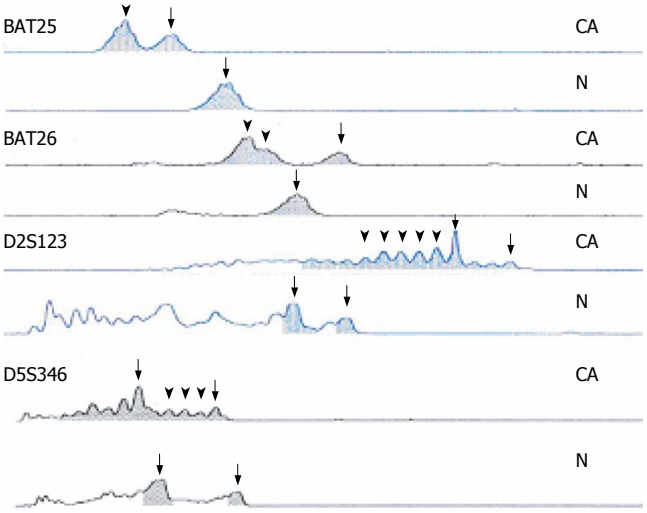

Figure 3 Four sites of MSI in H2 family. CA represents the tumor tissue, N represents the control tissue, the arrow-heads show new waves, and the arrows show wild ones.

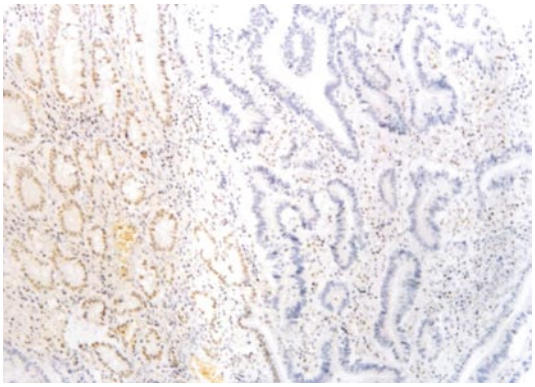

Figure 4 MLH1 protein in H2 was negative in the tumor glands (right), and positive in the mucous glands next to the tumor tissue (EnVison, × 200).

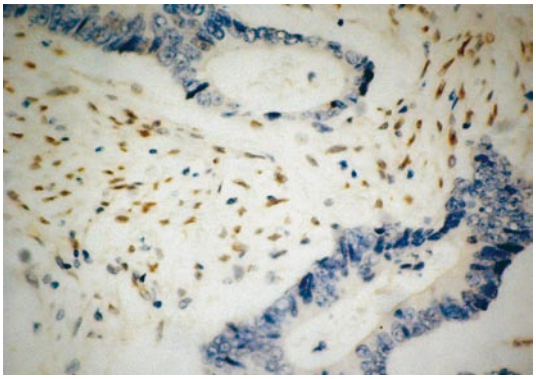

Figure 5 MLH1 protein in H31 was negative in the tumor glands, and positive in the stroma cells (EnVison, × 400).

that it led to a nonconservative aminoacid change, (2) that the involved codon was evolutionarily conserved, (3) that the alteration did not occur in the normal population, and (4) that it cosegregated with the disease phenotype[11]. The patient in the H2 family was affected by colorectal cancer at 36 years of age, his mother was affected by endometrial cancer at 54 years of age, and one of his aunts was affected by colorectal cancer at 48 years of age. The patient in the H31 family was affected by colorectal cancer at 39 years of age, her father was affected by colorectal cancer at 50 years of age, and her uncle was affected by gastric carcinoma at 57 years of age. Their family histories suggested co-segregation of the mutations with the disease. Both of the novel mutations lead to amino acid changes, and the changed amino acids belong to the non-conserved ones. According to the criteria above, we estimated that the two novel mutations were pathogenic. In order to further evaluate the mutations, DNA were isolated from the two patients' tumor tissues, and GeneScan was employed for MSI analysis, and immunohistochemistry was used to detect the expression of MLH1 protein in tumor tissues[32,33]. The tumor tissues of the two patients showed high MSI and lack of MLH1 protein expression. Based on the above results, we concluded that the two novel mutations were very likely pathogenic.

Differentiating HNPCC from sporadic colorectal cancer has practical clinical value, and the identification of HNPCC depends on the detection of germline mutations of the MMR gene. More MMR genes should be investigated besides MLH1, and when a novel mutation is found, its pathogenic evaluation should be carried out so that more HNPCC can be identified.

COMMENTS

Background

Hereditary non-polyposis colorectal cancer (HNPCC) is one of the most common autosomal dominantly inherited cancer syndromes and accounts for 10% of all colorectal cancer. HNPCC shows its own characteristics associated with its molecular mechanisms, clinical features, method of treatment, and management of HNPCC families. It has gained worldwide recognition, and the International Collaborative Group on Hereditary Non-polyposis Colorectal Cancer (ICG-HNPCC) was founded in 1990. At present, there are a few ways to screen HNPCC families; however, only the pathological germline mutation in the mismatch repair (MMR) gene can be used for identifying HNPCC families.

Research frontiers

Development of HNPCC is closely associated with deficiency or loss of function of MMR genes. At least 5 MMR genes, MLH1, MSH2, MSH6, PMS1, and PMS2, have been implicated in HNPCC. Genetic linkage analysis showed that germline mutations of MLH1 and MSH2 account for nearly 90% of all the germline mutations found in HNPCC. Germline mutations of MLH1 were detected in this study.

Innovations and breakthroughs

There are a few ways to screen HNPCC families, however, the most specific method is to detect germline mutations of MMR genes. In present study, a new method, RNA-based sequencing analysis, was used. Two novel germline mutations in MLH1 were found, and their possible pathobiology was investigated by PCR-GeneScan analysis and immunohistochemical staining.

Applications

Identification of pathological germline mutations in MMR genes is the gold standard for HNPCC. Differentiating HNPCC from sporadic colorectal cancer has direct clinical implications for counseling and management of HNPCC family members.

Peer review

HNPCC is different from sporadic colorectal cancer(SCRC), and to differentiate HNPCC from SCRC owns practical clinical implications. The study detected germline mutations of MLH1 with a new method, and investigated the pathobiology of the detected novel mutations in MLH1. The study is a valuable contribution with potential clinical importance.

Abstract

AIM: To investigate the effects of short-term application of low-dose growth hormone on trace element metabolism and blood glucose in surgical patients

METHODS: A total of 48 consecutive patients undergoing abdominal operations were randomized to receive either subcutaneous rhGH (0.15 IU/kg) or placebo (menstruum) injections daily for 7 d after surgery. The two groups had similar nutrition intake. Blood, feces, urine and drain samples were collected to measure zincum, cuprum and ferrum as well as glucose levels. Accumulative intake, excretion and balance of zincum, cuprum and ferrum, apparent absorption (AA) and apparent utilization (AU) of zincum, cuprum and ferrum, blood glucose levels and adverse events were estimated.

RESULTS: There were no differences in accumulative intake and drain excretion between the two groups. The feces excretion and accumulative excretion of cuprum were lower in the rhGH group ($P < 0.05$). The urinary excretion of zincum, cuprum and ferrum was all significantly decreased in the rhGH group ($P < 0.05$) and the accumulative balance of zincum, cuprum and ferrum was improved compared with the placebo group ($P < 0.05$). AA of cuprum in the rhGH group was almost twice as much as the placebo group ($P < 0.05$), and AU of zincum, cuprum and ferrum was all improved in the rhGH group ($P < 0.05$). The mean blood glucose level was significantly higher in the rhGH group than in the placebo group from d 3 to d 6 after operation ($P < 0.05$).

CONCLUSION: Postoperative low-dose rhGH treatment improves the retention of zincum, cuprum and ferrum and decreases the excretion of zincum, cuprum and ferrum, improves the balance of zincum, cuprum and ferrum, and promotes the AA and AU of zincum, cuprum and ferrum. rhGH can be well tolerated without significant adverse effects and the blood glucose level can be well controlled.

INTRODUCTION

Patients undergoing abdominal surgery often suffer from severe trauma or infection caused by catabolic responses[1], which cannot be prevented by conventional parenteral or enteral nutrition formulas[2,3]. Administration of recombinant human growth hormone (rhGH) has been shown to significantly maintain the nitrogen balance and increase the protein synthesis in surgical patients receiving either parenteral or enteral nutrition[4-7]. Most of such studies paid more attention to nitrogen balance and protein metabolism changing associated with rhGH treatment. However, there are few studies focusing on the effects of rhGH on trace element metabolism in patients. The present study was to evaluate the effects of rhGH on trace element metabolism and blood glucose levels in selective abdominal surgical patients.

MATERIALS AND METHODS

Patients

The study was conducted in accordance with the guidelines for Good Clinical Practice and the provisions of the Declaration of Helsinki in 1995 as revised in Edinburgh 2000, and approved by the Ethical Review Committee of West China Hospital. Only those who consented to

participate in the study after explanation of the objectives and protocol were included in the study. Signed, informed consent was obtained from all patients and their close relatives.

Forty-eight adult patients were enrolled in the study and all met the following criteria: undergoing a selective abdominal operation, aged 18-75 years, willing and being able to comprehend the protocol and give written informed consent. Exclusion criteria were as follows: severe bacterial infection, liver and renal dysfunction, previous or current treatment with corticosteroids, diabetis mellitus or fasting glucose levels greater than or equal to 7.0 mmol/L, metabolic diseases, gestation, severe malnutrition (serum albumin < 21 g/L), tumor recrudescence or metastasis.

Study design

The study was a randomized prospective double-blind, placebo-controlled clinical trial. Eligible patients were randomly assigned to rhGH group or placebo group (24 each group). The randomization codes were prepared with the random number table according to the design of a computer. Patients, surgeons and nursing staff members remained blind to the allocation status of the study drugs throughout the experiment.

After operation, all patients received continuous combined intravenous or/and enteral nutrition. The daily total caloric requirement was 20 kcal/kg and total nitrogen requirement was 140 mg of nitrogen/kg. Parenteral nutrition (PN) solution was prepared aseptically using commercially available products, including vitamins, trace elements and electrolytes (Addamel, Vitlipid, Soluvit and Glycophos; Fresenius Kabi Deutschland Gmbh, Bad Homburg, Germany). Amino acid injections were provided as 8.5% and 11.4% Novamin (Fresenius Kabi Deutschland Gmbh). Energy calories were provided with glucose and fat emulsion injections (50% glucose and 20% Lipovenos® MCT; Fresenius Kabi Deutschland Gmbh). All the nutrients were given in all-in-one bag. Enteral nutrition (EN) emulsion (Fresenius Kabi Deutschland Gmbh) was provided orally or via a nasogastric tube with a continuous perfusion pump.

Postoperatively, patients received general intravenous infusion with only glucose on d 1; PN provided only half of total caloric and nitrogen requirement on d 2 and all of total requirement on d 3; on d 4, PN provided 2/3 of total requirement and EN provided another 1/3; on d 5, PN provided 1/3 of total requirement and EN provided 2/3; only EN emulsion was given from d 6 to d 9.

From d 3 to d 10 post operation, patients were randomly assigned to receive identical-looking treatments consisting of either rhGH (JINTROPIN®, 0.15 mg/kg) or menstruum injection (1 mL, consisting of glycin, mannitol, lactose and sodium bicarbonate) subcutaneously once daily. rhGH and placebo were provided by GeneScience Pharmaceutical Co. Ltd, Changchun, China.

Laboratory tests

Blood samples were drawn from each patient before operation to measure baseline values and on d 3 and 10 after operation to study the rhGH effect. Complete blood cell count was estimated by the XE-2100 (Sysmex, Kobe, Japan). Plasma glucose, serum urea nitrogen, creatinine, bilirubin, alanine aminotransferase, alkaline phosphatase, total protein, albumin and electrolytes were estimated using an Olympus AU5400 autoanalyser (Olympus, Tokyo, Japan).

Table 1 Baseline characteristics of patients (mean ± SD)

Variable	Placebo (n = 24)	rhGH (n = 24)	P
Age (yr)	58.50 ± 9.35	59.08 ± 10.93	0.789
	39-75	35-74	
Sex (femal/male)	11/13	9/15	0.558
Weight (kg)	57.90 ± 8.42	56.19 ± 11.83	0.567
Height (cm)	162.42 ± 6.92	162.88 ± 7.16	0.823
Sepsis score	0.79 ± 0.98	0.67 ± 0.87	0.742
Operation position, n (%)			
Resection of stomach	6 (25)	5 (20.8)	0.297
Resection of colon	5 (20.8)	7 (29.2)	
Resection of rectum	12 (50)	9 (37.5)	
Others	1 (4.2)	3 (12.5)	
Acumulative intakes of energy (10^3 kcal)	7.98 ± 0.67	7.76 ± 0.76	0.292
Acumulative intakes of nitrogen (g)	54.84 ± 5.23	53.91 ± 7.05	0.605

Trace element balance

Daily trace element input was assumed to be the trace element contents (zincum, cuprum, ferrum) in PN/or EN solution given. Daily trace element loss was assessed by collecting 24-h output and measuring the trace element contents in feces, urine and drains. Accumulated trace element balance was calculated by subtracting 7 d trace element output from 7 d trace element input. Trace element contents in samples were determined by the inductively coupled plasma atomic emission spectrometry (ICPAES) and estimated by the IRIS ADVANTAGE 1000 (Thermo Elemental, USA).

Statistical analysis

All data were assessed for normality of distribution and equality of variance. Student's t-test and multiple correlation analysis were used to compare normal distribution of data. Data are presented throughout as mean ± SD. All data analyses were performed using the program SPSS 11.5 for Windows. $P < 0.05$ was considered statistically significant.

RESULTS

Patient characteristics

There was no difference in baseline characteristics between the two groups (Table 1).

Accumulative intake, excretion and balance of zincum, cuprum and ferrum

As shown in Table 2, there were no differences in accumulative intake and drain excretion between the two groups. The feces excretion and accumulative excretion of cuprum were lower in the rhGH group. The urinary excretion of zincum, cuprum and ferrum was

all significantly decreased in the rhGH group and the accumulative balance of zincum, cuprum and ferrum was significantly improved compared with the placebo group.

Apparent absorption (AA) and apparent utilization (AU) of zincum, cuprum and ferrum

The cuprum was mostly excreted *via* feces. AA of cuprum in the rhGH group was almost twice as much as that in the placebo group, and AU of zincum, cuprum and ferrum was improved in the rhGH group (Table 3).

Blood glucose levels and adverse events

The main adverse effects seen during the study are summarized in Tables 4 and 5. The mean blood glucose level was significantly higher in the rhGH group than in the control group from d 3 to d 6 after operation (Table 4). Twenty-there patients in the rhGH group experienced hyperglycemia and 5 of them required insulin treatment (Table 5). Furthermore, 3 patients had other mild adverse events (1 with edema, 1 with tetter and 1 with fever). In the placebo group, 3 of 4 patients presenting hyperglycemia required insulin treatment. Five placebo-treated patients experienced mild electrolyte imbalance, which was not related the trial drug used. There was no significant difference in complete blood cell count, liver and renal function, body weight and daily clinical parameters such as temperature, blood pressure, and pulse, between the two groups.

DISCUSSION

Many attempts have been made to reverse the catabolic changes that occur in postoperative patients. Conventional nutrition support is unable to provide adequate nutritional supplements to increase or even maintain body proteins and trace elements in hypercatabolic response conditions[8-10]. Recent studies indicate that rhGH can stimulate body protein synthesis and produce nitrogen-spacing effects[11-13]. However, the impact of rhGH on body trace elements and blood glucose has not been

investigated in patients receiving PN or EN following selective gastrointestinal surgery[14-16]. In the present experiments, we studied the effects of rhGH on trace element metabolism and blood glucose. The number of patients enrolled in the study was based on previous experiments and the dosage of rhGH used[7,17,18].

Massive trace elements are lost after selective operation because of decreased intake, loss from wound surface, redistribution in the body and increased urinary excretion[19,20]. Even supplying adequate nutritional support cannot prevent such a massive loss of trace elements. Zincum, cuprum and ferrum are very important trace elements in the human body and can sensitively reflect changes in gastric diseases[21]. In this study, low-dose rhGH treatment reduced the urinary excretion of zincum, cuprum and ferrum, thus improving their accumulative balance compared with the placebo group. Meanwhile, the apparent absorption and utilization of zincum, cuprum and ferrum in the rhGH group were also increased. However, the AU of zincum in the rhGH group (30.02%) was almost two times higher than that in the placebo group. The AU of cuprum and ferrum in the rhGH group was also about 1.5 times higher than that in the placebo group. These data indicate that low-dose rhGH treatment can reduce the excretion of zincum, cuprum and ferrum, increase their utilization, and maintain the retention and balance of zincum, cuprum and ferrum.

Changes in zincum, cuprum and ferrum metabolism are mainly associated with protein synthesis and breakdown. Since proteins are carriers of many trace elements, rhGH may also improve protein synthesis, reduce protein breakdown, promote recovery of intestinal mucosa, increase mucosa thickness, improve intestinal barrier function, and increase absorption of trace elements[22-24]. In our study, the apparent absorption and utilization of zincum, cuprum and ferrum were improved in the rhGH group.

It was reported that GH given during sepsis can impair immune function and result in hyperglycemia, which may explain why acute critically ill patients do not benefit from GH treatment[25,26]. However, selective surgical patients can safely administer GH after the acute inflammatory response stage. rhGH treatment was generally well tolerated with no serious adverse events occurred in our trial. No death occurred in the GH-treated group, confirming its safety. These results are contrary to the increased mortality among critically ill patients treated with GH[25]. We hypothesize that this discrepancy might be due to the difference in study patients. In our study, the patients were selective surgery subjects. rhGH given during the response to stress leads to uncontrolled systemic inflammation in Takala's study[25].

The main adverse event of rhGH treatment is hyperglycemia. Insulin resistance caused by rhGH plays an important role in the elevation of blood glucose. Other reasons include nutrition support and systemic inflammation syndrome[27,28]. In our study, hyperglycemia caused by rhGH administration was mild and controlled by insulin. Considering the difference between critically ill patients and selective surgery patients, rhGH seems to be well tolerated after operation.

Since our study included 14 cancer patients in the rhGH group, the potential tumor-promoting effect of GH should be addressed. In animal models, the role of rhGH administration in promoting tumor recurrence is controversial[29-31]. It was reported that GH could promote host growth selectively and inhibit tumor metastasis[32,33]. Only two trials have assessed the impact of GH on tumor recurrence in humans. Based on 2632 adverse events, the National Cooperative Growth Study analyzed the recurrence of brain tumors in patients receiving long-term GH replacement, showing that there is no evidence that GH increases tumor recurrence[34]. Only one study has investigated the impact of short-term treatment with three different doses of GH on long-term tumor recurrence in postoperative cancer patients[35], finding that 35% rhGH-treated patients have tumor recurrence in comparison to 44% placebo-treated patients. Based on the above two studies, we believe that when complete resection and appropriate antineoplastic treatment are administered, cancer patients can safely receive short-term GH treatment.

In conclusion, postoperative low-dose rhGH treatment improves the retention and decreases the excretion of zincum, cuprum and ferrum, increases the balance and promotes their apparent absorption and utilization. rhGH is also well tolerated with no significant adverse effects and can control the blood glucose level. A larger trial is required to determine the clinical endpoints such as infection, morbidity, mortality and tumor recurrence.

COMMENTS

Background

Patients undergoing abdominal surgery often suffer from severe trauma or infection caused by catabolic responses, which cannot be prevented by conventional parenteral or enteral nutrition formulas. Administration of recombinant human growth hormone (rhGH) has been shown to significantly maintain the nitrogen balance and increase the protein synthesis in surgery patients receiving either parenteral or enteral nutrition.

Research frontiers

Many studies paid attention to nitrogen balance and protein metabolism associated with rhGH treatment. However, there are few studies focusing on the effects of GH on trace element metabolism in patients. This study was to evaluate the effects of rhGH on trace element metabolism and blood glucose levels in selective abdominal surgical patients.

Innovations and breakthroughs

This study evaluated the effects of rhGH on trace element metabolism and blood glucose levels in selective abdominal surgical patients. Postoperative low-dose rhGH treatment improves the retention of zincum, cuprum and ferrum, and decreases their excretion, increases their balance and promotes their apparent absorption and utilization. rhGH is well tolerated with no significant adverse effects and can control the blood glucose level.

Applications

The results of this study will promote the short-term low-dose rhGH application in clinical practice. Hyperglycemia is the main adverse event of short-term low–dose rhGH treatment.

Terminology

Biosynthetic human growth hormone, also referred to as recombinant human growth hormone, is also called somatropin and abbreviated as rhGH.

Peer review

This is the first study analyzing the effects of growth hormone on trace element metabolism and significantly adds our knowledge on the beneficial effect of short-term GH application.

Abstract

AIM: To study the expression of the inhibitor of apoptosis protein survivin in hepatocellular carcinoma (HCC), and its correlation with clinicopathological factors, cell proliferation, recurrence and prognosis after hepatectomy.

METHODS: Immunohistochemical staining of survivin and Ki-67 was performed by the standard streptavidin-peroxidase technique on paraffin sections of 55 cases of HCC.

RESULTS: The positive rate of survivin in HCC was 52.7% (29/55). Significant correlation was found between survivin expression with portal vein thrombi and intrahepatic matastasistic nodes ($P < 0.05$). The recurrent rate in survivin-positive HCC was significantly higher than that in survivin-negative HCC after hepatectomy, the 1- and 3-year survival rate in patients with survivin-positive tumors was significantly lower than that in patients with survivin-negative tumors (58.62 and 10.34% *vs* 76.92 and 30.77%, $P < 0.05$, log-rank test). The proliferation index (Ki-67) in survivin-positive HCC (33.83% ± 18.90%) was significantly higher than that in survivin-negative HCC (19.60% ± 19.35%) ($P < 0.05$).

CONCLUSION: Survivin may play an important role in progression of HCC by promoting cell proliferation, and may be positively correlated with high risk of disease recurrence and poor prognosis in HCC. Its expression may serve as a prognostic factor for patients with HCC after hepatectomy.

INTRODUCTION

Although surgical resection is the most important method for hepatocellular carcinoma (HCC), the recurrent rates may be as high as 50% at 2 years after hepatectomy[1]. The recurrence of HCC may be related to a variety of factors, including biological markers. Molecular prognostic markers are likely to be of greatest benefit in the effective management of patients with HCC, however, these factors have not yet been sufficiently defined in patients with a high risk of cancer recurrence.

Survivin is a recently described member of the family of inhibitor of apoptosis proteins (IAPs). Recently, it has been shown that survivin is strongly associated with apoptosis, cell proliferation and cell-cycle control[2-5]. Survivin plays a crucial role in the genesis and progression of malignancy and is an important prognostic parameter in tumors[6-10]. This study investigated the expression of survivin in HCC and its correlation with clinicopathological factors, cell proliferation and prognosis.

MATERIALS AND METHODS

Materials

Tissue samples were obtained between December 2000 and December 2003 from 55 patients with HCC (41 men, 14 women; 24-74 years old, mean age, 48.65 years). There were 27 patients with stage Ⅰ-Ⅱ, and 28 with stage Ⅲ-Ⅳ cancer. None of the patients received radiotherapy, chemotherapy or immunotherapy before surgery.

Reagents

Rabbit anti-human survivin polyclonal antibody was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Mouse anti-human Ki-67 monoclonal antibody

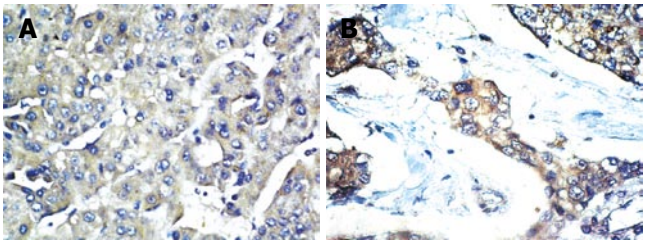

Figure 1 **A:** Positive expression of survivin in HCC (SP, × 200); **B**: Positive expression of survivin in HCC (SP, × 400).

(MBI.1), streptavidin-peroxidase (SP) staining kit and diaminobenzidine (DAB) kit were supplied by Maixin-Bio, Fuzhou, China.

Methods

Expression of survivin and Ki-67 was detected using SP immunohistochemistry. Briefly, after deparaffinization and rehydration, antigen retrieval was accomplished by incubation in 0.01 mol/L citric acid buffer (pH 6.0), boiling for 1 min in a pressure cooker, and cooling and washing in tap water. The sections were incubated with hydrogen peroxide for 10 min and washed in PBS. Non-specific reactions were blocked by incubation in a solution containing normal serum. The sections were incubated with a primary antibody (anti-survivin or Ki-67 antibody) overnight at 4℃. The working dilution of anti-survivn antibody was 1:100. The sections were rinsed with PBS, and then incubated for 10 min at room temperature with biotinylated secondary antibody. After washing, streptavidin-biotin complex conjugated to horseradish peroxidase was applied for 10 min at room temperature. After three rinses with PBS, the sections were incubated with DAB, rinsed with distilled water, counterstained with hematoxylin, and dehydrated and coverslipped. The sections were prepared for microscopy. Colorectal cancer tissues were used as a positive control. As a negative control, PBS was used to replace primary antibody.

Scoring criteria for survivin expression

Intensity and percentage of positive cells were used to evaluate each tissue section. The mean percentage of positive tumor cells and normal epithelial cells in at least five areas at × 400 magnification was determined and assigned to one of five categories: 0, < 5%; 1, 5%-24%; 2, 25%-49%; 3, 50%-74%; and 4, ≥ 75%. The intensity of survivin immunostaining was scored as 0 (achromatic), 1 (light yellow), 2 (yellow), and 3 (brown). The percentage of positive cells and staining intensity were multiplied to produce a weighted score for each case. Cases with weighted scores < 1 were defined as negative; all others were defined as positive.

Determination of the Ki-67 proliferation index

At least five high-power fields were chosen randomly in each section, and 500 cells were counted for each field. The Ki-67 proliferation index was defined as the number of Ki-67-positive nuclei divided by the total number of colorectal cancer cells counted, and was expressed as a percentage.

Table 1 Correlation between survivin expression and clinicopathology in HCC *n* (%)

Clinicopathological factor		*n*	Survivin expression		*P* value
			positive	negative	
Sex	Male	41	23	6	0.392
	Female	14	6	8	
Age (yr)	≤ 55	40	22	18	0.581
	> 55	15	7	8	
Tumor site	Right lobe	30	14	16	
	Left lobe	20	12	8	0.615
	Whole liver	5	3	2	
HBsAg	Positive	42	21	21	0.467
	Negative	13	8	5	
Differentiation	Moderate to well	40	23	17	0.247

	(–)	18	8	10	
Tumor stage	Ⅰ-Ⅱ	27	14	13	0.898
	Ⅲ-Ⅳ	28	15	13	

Statistical analysis

The survival curves were assessed by the Kaplan-Meier method and compared by a log-rank test. The χ^2 test was performed for enumeration data comparison, and the *t* test was used for comparison of measurement data. $P < 0.05$ was considered statistically significant. All data analysis was performed with commercially available statistical analysis software packages (SSPS 11.5, SSPS, Chicago, IL, USA).

RESULTS

Relationship between expression of survivin and clinical pathology

Survivin protein expressed as brown-yellow particles in the cytoplasm after staining, and only one expressed both in the cytoplasm and nucleus after staining. The positive staining rate for survivin in the cytoplasm and nuclei was 29/55 (52.7%) (Figure 1). There was a significant correlation between survivin expression and portal vein thrombi and intrahepatic metastatic nodes ($P < 0.05$). However, it was not related to the following factors: age and sex of the patient, tumor location, tumor differentiation, tumor size, presence of tumor capsule, clinical stage, complicating liver cirrhosis, preoperative alpha fetoprotein (AFP) level, and hepatitis B surface antigen (HBsAg) (Table 1). These findings suggest that the expression of survivin may be significantly associated with metastasis.

Relationship between expression of survivin and proliferation index

Ki-67 showed as brown-yellow particles in the nuclei after

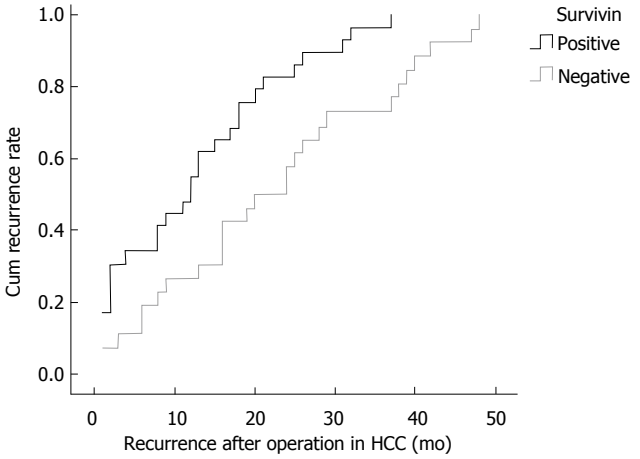

Figure 2 Correlation between survivin expression and recurrence rate of HCC after hepatectomy.

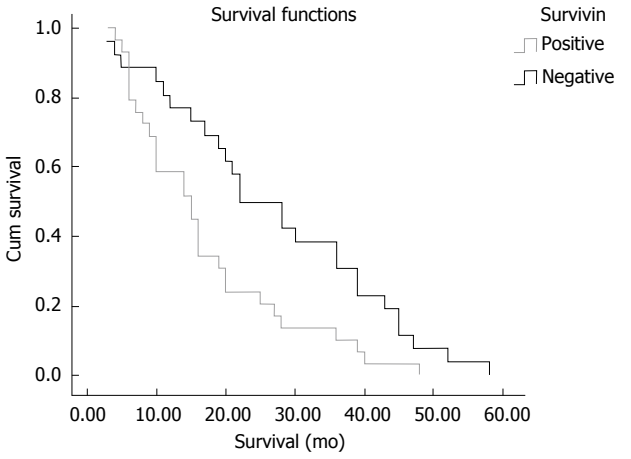

Figure 3 Kaplan-Meier curves for overall survival rates of patients with HCC according to survivin expression.

staining. Ki-67 labeling index in survivin-positive cancer was 33.83% ± 18.90%, while it was 19.60% ± 19.35% in negative tumor. The difference was significantly different ($P < 0.05$). This suggests that the expression of survivin may promote the proliferation of HCC.

Relationship between expression of survivin and recurrence and prognosis of HCC

The 1- and 3-year recurrence rates in survivin-positive HCC were 55.17% and 96.55%, respectively, while the rates were 26.91% and 73.08%, respectively, in survivin-negative HCC after hepatectomy. The recurrent time of survivin-positive HCC was significantly advanced ($P < 0.05$, Figure 2). Furthermore, the 1- and 3-year survival rates in survivin-positive HCC were 58.62% and 10.34% after hepatectomy, respectively, but for survivin-negative HCC, the rates were 76.92% and 30.71%, respectively. The 1- and 3-year survival rates were significantly lower in patients with survivin-positive HCC than those in survivin-negative HCC ($P < 0.05$, Figure 3). The expression of survivin may be used as an indicator for prognosis of HCC.

DISCUSSION

Among the recently described IAP family, survivin is characterized by a unique structure with a single BIR and no zinc-binding domain[11], and is undetectable in terminally differentiated adult tissues, but becomes notably expressed in the most common human cancers, including esophageal, stomach, colorectal, breast and pancreatic carcinoma[12-16]. Survivin has also been implicated in the control of cell-cycle kinetics and inhibition of apoptosis[17-19].

In our current study, we demonstrated that the expression of survivin was detected in 52.7% of patients with HCC, mainly localized in the cytoplasm of the carcinoma cells, with rare appearance in the nucleus. On the other hand, there have also been reports of a nuclear presence of survivin in HCC[20,21]. In previous studies, immunohistochemical analysis or RT-PCR of surgically resected tissues has revealed that approximately 30%-90% of HCC are positive for survivin expression[22-26]. The reasons for the difference may be the following: during the cell-division cycle, mRNA expression for survivin is extremely low in the G1 phase, and in the S phase is six times higher, while in the G2/M phase, the expression level of survivin increases suddenly to be 40 times higher than that in G1[27]. Therefore, the tumor cells in the G1/S phase may represent negative expression, which would lead to different expression rate of survivin in different study. On the other hand, different criteria for positive expression of survivin or experimental methods may explain the different expression rates of survivin.

Ki-67 is considered to be more useful for the determination of the proliferative activity of HCC, and is known as a risk factor for HCC. In our study, we surprisingly found that expression of the proliferation index in survivin-positive HCC was higher than that in survivin-negative HCC. The results suggest that survivin may promote cell proliferation, and contribute to the development of HCC. Survivin may interact with the cell-cycle regulator Cdk4, which leads to Cdk2/cyclin E activation and Rb phosphorylation. As a result of survivin/Cdk4 complex formation, p21 is released from its complex with Cdk4 and interacts with mitochondrial procaspase-3 to suppress Fas-mediated cell death. Survivin can also inhibit the activity of caspase-3/7 directly or indirectly, and this results in the generation and development of HCC[28-30]. The up-regulated expression of the proliferation index in survivin-positive HCC also suggests that survivin plays an important role in tumor progression.

The survivin expression in HCC was significantly correlated with portal vein thrombi and intrahepatic metastatic nodes. Therefore, survivin may play an important role in the development of HCC. Compared to survivin-negative HCC, survivin-positive HCC had a higher recurrent rate and lower 1- and 3-year survival rates. Survivin expression may play a role in the tumor biological characteristics of HCC, and may be a prognostic factor after hepatectomy. The study by Ikeguchi *et al* has also shown that high expression of survivin is associated with high recurrence and low survival rates[23]. Normal shedding of cells initiates the apoptosis process, but the over-expression of survivin exerts an anti-apoptotic effect,

which leads to a high rate of cell proliferation. Therefore, survivin may play an important role in the progression of HCC and may facilitate metastatic spread *via* the blood stream.

In conclusion, survivin expression in HCC was significantly correlated with portal vein thrombi and intrahepatic metastatic nodes. There was a significant positive correlation between survivin expression and proliferation index. Survivin plays an important role in HCC progression through promoting cell proliferation, and may be a prognostic marker for HCC.

COMMENTS

Background

Survivin is a recently described member of the family of inhibitor of apoptosis proteins (IAPs). It has been shown that survivin is strongly associated with apoptosis, cell proliferation and cell-cycle control, and becomes markedly expressed in the most common human cancers.

Research frontiers

Immunohistochemical staining of survivin and Ki-67 was performed by the standard streptavidin-peroxidase (SP) technique for paraffin sections of hepatocellular carcinoma (HCC) tissues.

Innovations and breakthroughs

We demonstrated that the positive rate of survivin in HCC was 52.7%, and a significant correlation was found between survivin expression and portal vein thrombi and intrahepatic metastatic nodes. The recurrence rate in survivin-positive HCC was significantly higher than that in survivin-negative HCC after hepatectomy. The 1- and 3-year survival rates of patients with survivin- positive tumors were significantly lower than those in patients with survivin-negative tumors. The proliferation index (Ki-67) in survivin-positive HCC was significantly higher than that in survivin-negative HCC.

Applications

Survivin may play an important role in progression of HCC by promoting cell proliferation, and may be positively correlated with a high risk of disease recurrence and poor prognosis in HCC. Its expression can serve as a prognostic factor for patients with HCC after hepatectomy.

Peer review

This is an interesting correlative study of survivin expression and survival in a cohort of 55 patients. A significantly worse survival was observed in surviving-positive tumors. The data are of high quality.

Abstract

AIM: To evaluate the relationship between vascular invasion and microvessel density (MVD) of tissue and micrometastasis in blood.

METHODS: Vascular invasion was detected by both hematoxylin and eosin staining and immunohistochemiscal staining. Blood samples were collected from 17 patients with vascular invasion and 29 patients without vascular invasion and examined for cytokeratin20 (CK20) expression by reverse transcriptase-polymerase chain reaction (RT-PCR) analysis. Microvessel density of tissue samples was also determined by immunohistochemistry using antibodies to CD105.

RESULTS: CK20 was detected in 12 of the 17 patients with vascular invasion and in 9 of the 29 patients without vascular invasion. Positive RT-PCR was significantly correlated with vascular invasion (70.6% *vs* 30.0%, $P < 0.05$). The average MVD was significantly higher in patients with positive vascular invasion than in patients with negative vascular invasion (29.2 ± 3.3 *vs* 25.4 ± 4.7, $P < 0.05$). The vascular invasion detected with hematoxylin-eosin staining was less than that with immunohistochemical staining. There was a significant difference between the two staining methods (19.6% *vs* 36.9%, $P < 0.05$).

CONCLUSION: Positive CK20 RT-PCR, depth of tumor invasion, lymph node status, metastasis and MVD are significantly correlated with vascular invasion. Immunohistochemical staining is more sensitive than hematoxylin-eosin staining for detecting vascular invasion.

INTRODUCTION

Vascular invasion is one of the most important clinicopathologic characteristics of malignant tumor. Since the initial report by Brown and Warren in 1938 demonstrating an increased visceral metastasis in rectal cancer patients with vascular invasion, a number of investigators have examined the influence of vascular invasion by colorectal cancer[1].

The presence of vascular invasion which is not a consistent finding is associated with an increased incidence of lymph node and distant metastasis and a corresponding decrease in survival[1]. Since polymerase chain reaction (PCR) invented by Mullis in 1989, it has become a standard and mature laboratory technique to detect micrometastasis in patients with malignant tumor[2]. In this study, we detected cytokeratin20 (CK20) mRNA expression in portal system blood[3-5] and microvessel density (MVD) of tissue to evaluate the relationship between vascular invasion and MVD[6] of tissue and metastasis in blood.

MATERIALS AND METHODS

Blood and tissue samples

Portal system blood was obtained before operation from 27 gastric cancer patients and 19 colorectal cancer patients. A venous catheter was inserted into the right gastric omental veins of gastric cancer patients and corresponding veins of colorectal cancer patients and blood samples were collected. The initial 5 mL blood was discarded to reduce possible contamination and the following 5 mL of blood drawn using a new syringe, was used for RNA extraction[7].

Tissue samples from 27 gastric cancer patients and

Table 1 Oligonucleotide primers

	Inner antisense	5'-ACGTCTTCTCC TTCCAGAAG-3'	
GAPDH	Sense	5'-CAGGGCTGCTT TTAACTCTG-3'	385
	Antisense	5'-CTGTTGTCGGAG TTCTAGTAG-3'	

GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

19 colorectal cancer patients were formalin-fixed and parafin-embedded. The tissue samples were cut into 1 μm-thick sections, mounted onto slides coated with polylysin and examined with hematoxylin-eosin and immunohistochemical staining.

Detecting vascular invasion

Vascular invasion examined with hematoxylin-eosin staining was defined either by the presence of neoplastic cells with fibrin clots, erythrocytes, or both in endothelial cell-lined spaces without erythrocyte extravasation in the surrounding tissues or by the presence of neoplastic cells within the smooth muscle cell-lined spaces[8]. Vascular invasion examined with immunohistochemical staining was defined by the presence of at least one tumor cell cluster which was clearly visible in decorated vascular spaces where endothelial cells were stained brown[9]. According to the immunohistochemical staining, the fibrin clots or erythrocytes surrounding neoplastic cells should be considered. Vascular invasion was confirmed by at least one staning method.

Detecting CK20 mRNA in portal system blood

Isolation of mononuclear cells: Blood mononuclear cells (MNCs) were isolated by density gradient centrifugation through Ficoll-Hypaque, and washed twice with phosphate-buffered saline (PBS). Cell pellets were snap frozen in liquid nitrogen and stored at -80℃ until use.

RNA extraction: Total RNA was extracted from the MNC pellets with TRIzol reagent (Invitrogen Biotech, USA) according to the manufacturer's instructions.

Reverse transcriptase: An aliquot of 2 μg MNC RNA was pre-incubated with 0.5 μg of oligo(dT)$_{15}$ primer in 14 μL solution for 5 min at 70℃. After chilling on ice, 6 μL of 5-fold synthesis buffer, 25 U of RNase inhibitor, 1.5 μL of dNTPs (final concentration of 0.5 mmol/L) and 200 U of Moloney murine leukemia virus (M-MLV) reverse transcriptase were added. The reaction mixture was then incubated for 60 min at 42℃. The reaction was terminated by heating at 95℃ for 5 min.

Table 2 Comparison between HE and immunohistochemical staining

HE staining	9	37	19.087	< 0.05
Immunohistochemical staining	17	29		

McNemar's test for correlated proportions, $\chi^2 = 8.003$, $P < 0.05$ *vs* immunohistochemical staining.

Polymerase chain reaction (PCR): PCR was carried out as described previously[10]. The sequences of primers used are shown in Table 1. To distinguish from contaminating genomic DNA, we selected both upstream and downstream primers at different exons. Integrity of the isolated RNA was demonstrated by RT-PCR analysis of the housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH). PCR products were visualized after electrophoresis with ethidium bromide staining under a UV transilluminator.

Detecting microvessel density of tissue

CD105 antigen was detected by immunohistochemistry on a separate slide using a monoclonal mouse antibody following a standard protocol. Microvessel density was assessed as previously described[11].

Statistical analysis

Statistical analysis was performed using the likelihood chi-squared analysis, Fisher's exact test or Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

Detection of vascular invasion

Vascular invasion was detected in 9 patients with hematoxylin-eosin staining and in 17 patients with immunohistochemical staining. There was a significant difference in vascular invasion detected by the two methods (Table 2, Figure 1A and B).

Relationship between vascular invasion, MVD and micrometastasis

CK20 was detected in 12 of the 17 patients with vascular invasion and in 9 of the 29 patients without vascular invasion. Positive RT-PCR was significantly correlated with vascular invasion. The average MVD was significantly higher in patients with positive vascular invasion (29.2± 3.31) than in those with no vascular invasion (Tables 3 and 4, Figure 2).

Comparison of clinicopathologic features

Clinicopathologic features such as depth of invasion, lymph node status and metastasis were associated with the presence of vascular invasion (Table 3).

DISCUSSION

Since vascular invasion first reported by Brown and

Warren in 1938, a lot of studies have examined the influence of vascular invasion on survival[1]. Horn and colleagues found that vascular invasion is an independent prognostic factor for distant metastasis but not for survival[12]. However, Chapuis and colleagues found that vascular invasion is an independent prognostic factor for survival[13], but this was not confirmed by Wiggers *et al*[14] or Minsky *et al*[15]. In this study, we examined CK20 mRNA expression in patients with or without vascular invasion to evaluate the relationship between vascular invasion and microvessel density of tissue and micrometastasis in blood.

Vascular invasion and micrometastasis

Tumor metastasis is an orchestrated multistep process that may involve direct, hematogenous or lymphatic spread[16,17]. Tumor metastasis requires an exodus of cancer cells from the primaty site, endurance outside the hormonal and nutritional milieu of the primary site, evasion of the body' s immune surveillance, as well as adhesion, invasion, and penetration at a distant site, and organization of metastatic tissue in the secondary site with neovascularization[18]. Primary tumor invades blood and/or lymphatic vessels departing from the primary site[19]. In this study, CK20 mRNA was detected in 12 of 17 patients with positive vascular invasion, and in 9 of 29 patients with no vascular invasion, suggesting that vascular invasion is closely related to micrometastasis in blood, depth of tumor invasion, lymph node status and distant metastasis. Therefore, CK20 mRNA can be considered an indirect prognostic factor for survival. There is evidence that distant metastases are associated with the neoplastic invasion of relatively large veins at the tumor's periphery[20-22].

Vascular invasion and angiogenesis

Angiogenesis is the propelling force for tumor growth and metastasis[23-25]. To progress to a larger size, incipient neoplasms must have an angiogenic ability, which involves the sprouting of new blood vessels from preexisting capillaries, and requires the multiplication and migration of endothelial cells, remodeling of extracellular matrix, tube formation, and recruitment of surrounding structures to maintain the newly formed vessels[26]. In

this study, the average MVD was significantly higher in patients with vascular invasion than in patients with no vascular invasion, suggesting that angiogenesis is closely related with microvessel density of tissue[27] and clinical aggressiveness of tumor[28].

Detection of vascular invasion

Vascular invasion was detected with hematoxylin-eosin staining and immunohistochemical staining, respectively. The heterogeneous positive rate suggests immunohistochemical staining is more sensitive than hematoxylin and eosin staining for the detection of vascular invasion. Fibrin clots, erythrocytes, or both in endothelia-lined spaces without erythrocyte extravasation in the surrounding tissues must be concerned if detected with HE staining. However, we had to decide whether a tumor cell cluster is clearly visible in decorated vascular spaces where endothelial cells are stained brown when detected with immunohistochemical staining. Our results are consistent with the reported data[29,30].

COMMENTS

Background

Since the initial report by Brown and Warren in 1938 demonstrating an increased visceral metastasis in rectal cancer patients with vascular invasion, a number of investigators have examined the influence of vascular invasion by colorectal cancer. The presence of vascular invasion is associated with an increased incidence of lymph node and distant metastasis and a corresponding decrease in survival. However, this is not a consistent finding.

Research frontiers

Horn and colleagues found that vascular invasion is an independent prognostic factor for distant metastasis but not for survival. By multivariate analysis, Chapuis and colleagues found vascular invasion to be an independent prognostic factor for survival, but this was not confirmed by Wiggers *et al* or Minsky *et al*.

Innovations and breakthrough

Though several articles have reported the prognostic value of vascular invasion, the results are not consistent, and no study has focused on micrometastasis in patients with vascular invasion. In this study, we detected cytokeratin20 (CK20) mRNA expression in portal system blood and microvessel density of tissue to evaluate the relationship between vascular invasion and microvessel density of tissue and metastasis in blood.

Applications

We recommend vascular invasion as a method of choice for predicting prognosis of gastric and colorectal cancer patients. Patients with vascular invasion are more likely to need adjuvant therapies.

Terminology

CK20: It belongs to the epithelial subgroup of the intermediate filament family. Because of its restricted range of expression in humans, it has become an important tool for detecting and identifying metastatic cancer cells by immunohistochemistry and PCR analysis. Factor Ⅵ: Vascular invasion is usually defined by the presence of neoplastic cells with fibrin clots, erythrocytes, or both in endothelia-lined spaces without erythrocyte extravasation in the surrounding tissues or by the presence of neoplastic cells within the smooth muscle cell-lined space

Peer review

This subject is valuable for understanding the importance of vascular invasion of cancer in predicting the prognosis of such patients. It also provides a better way to increase the detection rate of vascular invasion with immunohistochemical staining.

Abstract

Various complications have been related to laparoscopic cholecystectomy but most occur shortly after the procedure. In this report, we present a case with very late complications in which an abscess developed within the gallbladder fossa 6 years after laparoscopic cholecystectomy. The abscess resolved after treatment with CT-guided extrahepatic aspiration. However, 4 years later, an endoscopic retrograde cholangiopancreatography (ERCP) performed for choledocholithiasis demonstrated a "gallbladder" which communicated with the common bile duct via a patent cystic duct. This unique case indicates that a cystic duct stump may communicate with the gallbladder fossa many years following cholecystectomy.

INTRODUCTION

Laparoscopic cholecystectomy has been widely accepted as a preferred option for the management of patients with cholelithiasis. Complications such as biliary injuries[1,2] intestinal ischemia[3] and biliary-colonic fistula[4] have been reported, but most occur shortly after surgery. In this report, we present a case with very late complications in which an abscess developed within the gallbladder fossa 6 years after laparoscopic cholecystectomy. Four years later, despite the clinical certainty that it had been removed 10 years previously, a "gallbladder" communicating with the common bile duct *via* a cystic duct was demonstrated by endoscopic retrograde cholangiopancreatography (ERCP).

CASE REPORT

A 73-year-old male presented with complaints of right upper quadrant discomfort, fatty food intolerance and bloating. He eventually underwent an elective laparoscopic cholecystectomy in early October 1996. A J-P drainage tube was placed during the operation. The drainage was initially dark bloody, then became bilious, but gradually became clear over the next several days. The patient was discharged home after 1 wk. A follow-up abdominal CT scan was performed in May 1997, six months after the procedure. There were no fluid collections in the gallbladder fossa or peritoneal cavity.

The patient did well until early October 2002, six years after cholecystectomy, when he presented with complaints of fever, chills and mild pain in the right upper quadrant. Sonographic examination of the abdomen showed a normal sized liver with non-dilated intrahepatic ducts and common bile duct. Of note, a gall bladder-like structure was seen in the gallbladder fossa. An abdominal CT confirmed the presence of a 4 cm encapsulated fluid collection in the gallbladder fossa (Figure 1). A subsequent HIDA scan showed prompt excretion of the radiotracer into the small bowel with no evidence of biliary leak. A CT-guided transhepatic intra-abdominal aspiration was then performed (Figure 2). Turbid-appearing fluid was readily aspirated from the extrahepatic fluid collection. Gram stain of the aspirated fluids showed the presence of many white blood cells. Cultures were positive for moderate Enterobacter SP in the aspirates. The persistent low-grade fever subsided shortly after the CT-guided aspiration, and the patient was discharged home with no abdominal complaints. In August 2004 (22 mo after aspiration), an abdominal CT scan was repeated and no gallbladder fossa fluid collection was observed.

In May 2006, the patient was again admitted with the sudden onset of abdominal pain, icterus and fever. A CT scan showed a dilated common bile duct. MRCP showed intra- and extrahepatic biliary

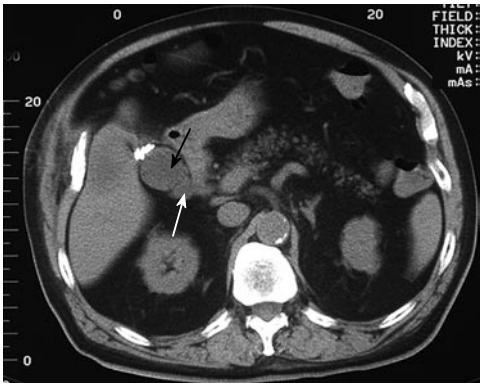

Figure 1 Abdominal CT scan six years after laparoscopic cholecystectomy. A 4 cm encapsulated fluid collection in the gallbladder fossa (black arrow) with adjacent "cystic duct-like" collections was observed (white arrow).

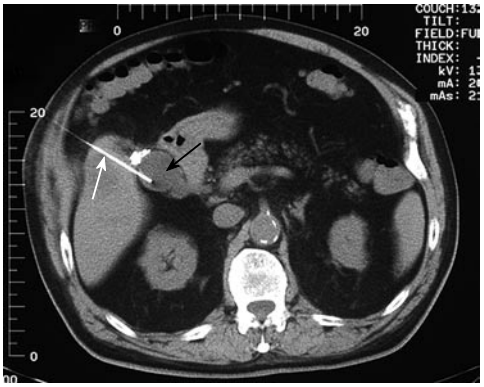

Figure 2 A CT-guided transhepatic percutaneous aspiration needle (white arrow) was seen entering the extrahepatic fluid collection (black arrow).

dilatation as well as a round, low signal filling defect within the distal common bile duct. During ERCP, the cholangiogram revealed a mildly dilated proximal common bile duct with 2 mobile stones (Figure 3A). A gallbladder-like structure that communicated with the common bile duct was also visualized in the gallbladder fossa (Figure 3B). Sphincterotomy was performed, and numerous stone fragments were removed from the CBD. A plastic biliary endoprosthesis (10F) was placed in the distal common bile duct. The patient was discharged home without any complication or discomfort two days after the ERCP. One month later, the stent was removed and the common bile duct appeared normal. A "phantom" gallbladder image reappeared on the cholangiogram.

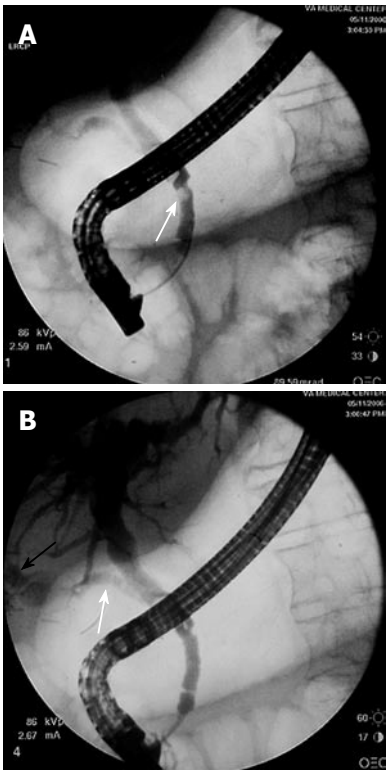

Figure 3 Calculi (white arrow) in the common bile duct were noted during the ERCP (**A**). In addition, a gallbladder-like structure (black arrow) communicated with the common bile duct *via* the cystic duct (white arrow) was also observed (**B**).

DISCUSSION

It is not uncommon to develop a fluid collection in the gallbladder fossa shortly after laparoscopic cholecystectomy. Kang *et al*[5] studied 106 consecutive patients 24 h after laparoscopic cholecystectomy using ultrasound. They identified small fluid collections in the gallbladder fossa in 56 (53.0%) patients. In another study[6], the gallbladder fossa of 70 asymptomatic patients was sonographically examined within two weeks of laparoscopic cholecystectomy. The authors reported the presence of homogeneous echogenic structures in the gallbladder bed in 35 (50%) patients, inhomogeneous structures in 25 (35.7%) cases, and, cystic structures, resembling the normal gallbladder, in 6 (8.5%) cases. The nature of the fluid collection varied, but included seromas, hematomas, abscesses and biloma.

In the present case, the fluid collection inside the gallbladder fossa observed 6 years after the procedure proved to be an abscess on the basis of the turbid, non-bilious, culture positive fluid retrieved during CT-guided aspiration. The abscess resolved after percutaneous transhepatic aspiration and antibiotic treatment. The most recent finding in this patient, a gallbladder-like structure inside the gallbladder fossa that directly communicated with the common bile duct, is likely related in some manner to this prior abscess. One possibility is that the previously documented abscess may have resolved by fistualizing into the cystic duct. Alternatively, increased pressure within the cystic duct as a result of biliary obstruction from choledocholithiasis may have caused rupture of the stump and its subsequent breakthrough into a residual cavity in the gallbladder fossa.

By whatever mechanism, this case demonstrates that, post-cholecystectomy, a cystic duct stump may potentially communicate with extrabiliary structures in and around the gallbladder fossa. In this respect, we believe that this is the first reported case in which a cystic structure resembling a radiologically typical "gallbladder" was seen on ERCP many years after this organ was surgical removed.

CASE REPORT

Prolonged cholestasis following successful removal of common bile duct stones: Beware patients on estrogen therapy

JM Dunn, A McNair

Abstract

There are various well described forms of chronic cholestatic jaundice in adults, such as autoimmune cholangitis, drug-induced cholangitis and intrahepatic cholestasis of pregnancy. We present two cases of prolonged cholestasis following removal of gallstones at endoscopic retrograde cholangiopancreatography (ERCP) and subsequent clear cholangiography. Both patients were taking oral estrogens at the time of presentation, which were subsequently withdrawn. The first case responded rapidly to corticosteroid treatment, and the second case had a much slower resolution with ursodeoxycholic acid. Both cases highlighted the significance of estrogen-induced cholestasis in female patients with protracted jaundice following ERCP and removal of intra-ductal stones. After oral estrogens are discontinued, a short course of steroids needs to be considered.

Dunn JM, McNair A. Prolonged cholestasis following successful removal of common bile duct stones: Beware patients on estrogen therapy. *World J Gastroenterol* 2007; 13(46): 6277-6280

http://www.wjgnet.com/1007-9327/13/6277.asp

INTRODUCTION

Estrogens have been a well-recognized cause of cholestatic jaundice since 1962[1], and are commonly used in an experimental model of hepatocellular cholestasis. The similarity between such drug reactions and the syndrome of intrahepatic cholestasis of pregnancy has been reported[2]. Withdrawal of the estrogenic effect by delivery of the fetus or drug withdrawal leads to improvement of liver function. This tends to occur over several weeks or months[3]. It has been shown in observational studies that estrogen therapy is an important risk factor for gallbladder disease[4]. A recent randomized double-blind placebo-controlled trial of otherwise healthy postmenopausal women has demonstrated that the risk of adverse biliary tract outcomes, such as cholecystitis, is substantially increased by exogenous estrogen therapy[5]. Estrogens are thought to promote gallstone formation by significantly elevating the biliary cholesterol saturation index and a reduction of the nucleation time[6]. We present two cases of prolonged cholestasis after removal of obstructing common bile duct (CBD) stones at endoscopic retrograde cholangiopancreatography (ERCP).

CASE REPORTS

Case 1

A 25-year-old Caucasian woman presented at 6 wk post partum with pruritus and right upper quadrant pain. There was no jaundice evident, and she had been asymptomatic throughout her pregnancy. She had stopped taking Microgynon (ethinlyestradiol 30 μg and levonorgestrel 150 μg) 1 year previously. Her mother had undergone cholecystectomy aged 50 years. Physical examination was unremarkable, and liver function tests showed a total serum bilirubin level of 43 μmol/L, alanine aminotransferase (ALT) 187 IU/L, alkaline phosphatase (ALP) 81 IU/L and gamma-glutamyltranspeptidase (γ-GT) 88 IU/L (Figure 1). Liver ultrasound scan showed multiple calculi in the gall bladder and a CBD of 6 mm, with no evidence of intraductal stones.

She presented again 6 wk later with worsening pruritus, biliary colic and jaundice. The patient had restarted Microgynon in the interim period. She denied exposure to alcohol or illegal drugs. There were no risk factors for viral hepatitis. Her weight had dropped by 8 kg and she had icterus. Abdominal palpation revealed a tender right upper quadrant but no hepatosplenomegaly. Retesting of liver biochemistry showed a total serum bilirubin level of 163 μmol/L and a twofold increase in serum ALP. ALT remained elevated at 163 IU/L. Abdominal ultrasound scanning showed a thick-walled edematous gallbladder with multiple small calculi, one impacted in the neck of the gallbladder. The CBD measured 3.5 mm.

Endoscopic retrograde cholangiopancreatography (ERCP) was performed and revealed two calculi in the CBD, the largest measuring 5 mm. A 12-mm

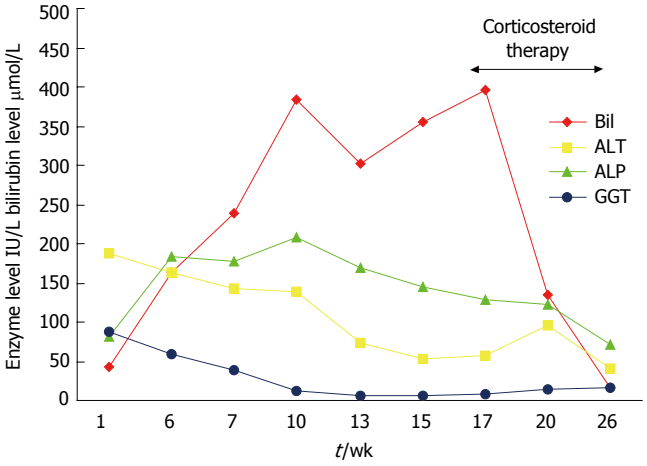

Figure 1 Case 1: Liver biochemistry and response to corticosteroids.

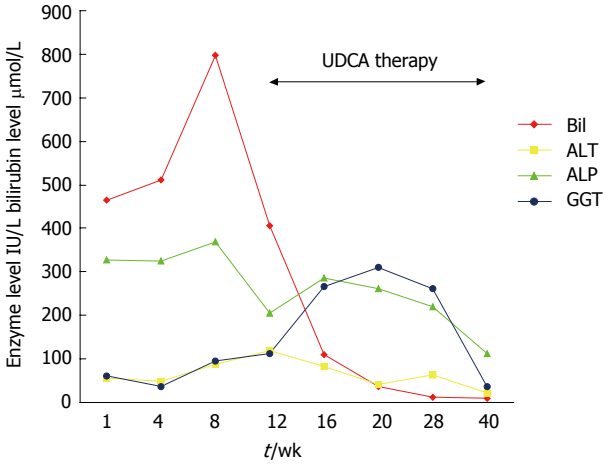

Figure 2 Case 2: Liver biochemistry and response to UDCA.

sphincterotomy was made and the CBD dredged with a balloon. Both stones were removed and an occlusion cholangiogram confirmed clearance of the duct. Her total serum bilirubin level continued to rise over the next 10 wk. A second ERCP performed 3 wk after the first showed a dilated CBD, but no obvious filling defects. The sphincterotomy was extended. A balloon dredge and occlusion cholangiogram confirmed that the duct was clear. Microgynon was stopped at this point. Autoantibody profile and hepatitis A, B and C serology were negative. Ceruloplasmin and ferritin levels were normal. The hemoglobin level was stable and the haptoglobin level normal. Because of persisting jaundice, a third ERCP was performed 3 wk later and revealed a normal condition.

Seventeen weeks following the initial presentation (7 wk after stopping the oral contraceptive pill), total serum bilirubin level continued to rise and reached 386 μmol/L. The patient was treated with prednisolone 40 mg/d, which was reduced by 5 mg/d at weekly intervals over a period of 8 wk. Response to treatment is shown in Figure 1. Her symptoms improved dramatically during treatment with the corticosteroid, with a concomitant restoration of normal liver biochemistry. She has now been followed up for more than 12 mo and is asymptomatic with weight gain of 10 kg.

Case 2

A 66-year-old Caucasian woman presented with a 4-wk history of jaundice, right upper quadrant pain and pruritus. She had a past history of hysterectomy and bilateral salpingo-oopherectomy, carried out when she was 40 years old, complicated by post-operative deep vein thrombosis. She started Premarin (conjugated estrogens) 625 μg for menopausal symptoms when she was 50 years old, and had been taking this continuously up to the time of her presentation. The patient had no history of jaundice, hepatitis, blood transfusion or travel outside Western Europe. She had no risk factors for viral hepatitis and did not drink alcohol. On examination she was jaundiced, with no signs of chronic liver disease, and was afebrile. Tenderness on palpation of the right hypochondrium was evident, and the liver was palpable 2 cm below the costal margin.

Laboratory investigation revealed a total serum bilirubin of 464 μmol/L, ALT 56 IU/L, ALP 328 IU/L and γ-GT 60 IU/L. Serological tests for hepatitis A, B and C were negative. Anti-nuclear factor, and anti-mitochondrial and smooth muscle antibodies were also negative. Ultrasound examination of the liver revealed a dilatated CBD measuring 10 mm and multiple small radio-opaque calculi in the duct.

The patient underwent ERCP and sphincterotomy; all intraductal stones were removed with a balloon. However, 8 wk after her initial presentation, the patient remained markedly jaundiced with worsening pruritus, malaise, anorexia and weight loss of 6 kg. Liver function tests had worsened: total serum bilirubin 798 μmol/L, ALT 87 IU/L, ALP 370 IU/L and γ-GT 96 IU/L (Figure 2). Premarin was stopped.

A CT scan showed a normal gallbladder, with no evidence of malignancy and no biliary tree dilatation. A repeat ERCP showed a normal biliary system with no evidence of retained CBD stones. Ursodeoxycholic acid (UDCA) 1200 mg/d was commenced following ERCP. Four weeks later, her symptoms had begun to improve, and her bilirubin level had fallen to around half its peak value. After a further month, her symptoms had resolved completely, although her liver biochemistry did not completely return to normal until 40 wk after her initial presentation.

DISCUSSION

In both cases, prolonged cholestasis after removal of CBD stones at ERCP was thought to have been caused by oral estrogen therapy. The association between oral estrogen-containing preparations and several cholestatic syndromes has been well recognised since 1962[1]; and of the canalicular type with little portal inflammation. It is thought that these reactions are because of the estrogen component; hence it is widely used as an experimental model of hepatocellular cholestasis. This effect is mediated by its glucuronidated metabolites, which inhibit canalicular bile salt and glutathione excretion, which results in inhibition of bile salt transport[7].

Clinical features include malaise, pruritus, jaundice and

anorexia with subsequent weight loss, were seen in both our patients. These features are also seen in the clinical syndrome of intrahepatic cholestais of pregnancy (ICP). Indeed a Chilean group has found that, in 42 patients with cholestatic jaundice following use of oral estrogen compounds, 27 had previously jaundice and pruritus during pregnancy, which suggests a link between the two disorders[2]. This must be considered in the context of the strong geographical predilection of this disease to Chile. Crucially, withdrawal of the estrogenic effect by delivery of the fetus or drug withdrawal leads to improvement in liver function. This tends to take place over several weeks or months. Neither of the patients described here had a history of ICP, although liver function tests had not previously been performed.

Case 1 had proven gallstones at 6 wk post partum and liver function tests were consistent with stones in the CBD. The rapid deterioration in liver function both clinically and biochemically after commencing oral estrogens, and the resolution on discontinuation of the treatment support the hypothesis that the cholestasis was a drug-induced liver injury. Other potential causes were excluded. In particular, the absence of antimitochondrial antibodies, normal intrahepatic bile ducts on ERCP, and the spontaneous normalization of liver biochemistry excluded both primary biliary cirrhosis and primary sclerosing cholangitis.

Case 2 had been on estrogen replacement therapy for 16 year at the time of her presentation with obstructive jaundice. However, the only factor that could account for the prolonged cholestasis was the estrogen therapy, and the temporal relationship between stopping estrogens and improvement in liver function further supports the conjecture that hormone replacement therapy was responsible (although UDCA therapy may have played a role in the resolution of the cholestasis).

Since estrogen therapy alone did not cause jaundice in this patient, there must have been an interaction between the effects of mechanical obstruction to bile flow and the cholestatic effects of estrogens. The patient has remained off estrogens since the procedure.

The cause of the differences in time for resolution of jaundice in cases 1 and 2 is unclear. The jaundice in both cases was likely to have resolved following the withdrawal of estrogens, and it is possible that the longer duration of jaundice in case 2 was simply a reflection of the variable length of time for estrogen-induced cholestasis to resolve following treatment withdrawal. Typically, this takes several weeks to months, but it has been reported to take up to 10 years[3]. It is also possible that the difference in time for the jaundice to resolve reflected differences in the modes of action of the drugs used to treat the cholestasis. The anti-inflammatory effects of corticosteroids may be of benefit for individuals with a pre-existing mechanical obstruction. It is known that when biliary obstruction occurs, an inflammatory response is mounted with the release of pro-inflammatory cytokines (e.g. tumor necrosis factor-α and interleukin-1), a reduction in the expression of nuclear bile acid receptor, and infiltration of neutrophils, all of which are thought to aggravate cholestatic injury[8].

Corticosteroid use has previously been described in two cases reports of prolonged cholestasis following ERCP and successful removal of gallstones[9]. The patients were not taking estrogens (both were male) and the authors hypothesized that the canalicular function had been directly compromised by a mechanical obstruction. They also postulated that the radiocontrast medium infused under high pressure during ERCP may have had a toxic effect, with disruption of the canalicular membrane, but no evidence was given to support this theory. The two cases presented differed from both our patients, who were taking oral estrogens. Whilst the onset of jaundice appears to have been precipitated by the presence of obstructing intraductal calculi, the estrogen therapy appears to have been responsible for the persistence of cholestasis. Presumably, the biliary obstruction in some way sensitized the biliary canaliculi to the cholestatic effects of estrogens, perhaps through an associated inflammatory response (discussed above) that led to the prolonged cholestasis. The interaction between these two factors may in part be idiosyncratic and/or dependent on genetic factors, since this has not previously been reported.

UDCA was used in the second case because of concerns about side effects, particularly steroid-induced osteoporosis in this postmenopausal woman. Its use resulted in a less impressive response, but it may not have influenced the course of the cholestasis. However, evidence from a number of large studies has confirmed the efficacy of UDCA in ICP, and the drug is now used routinely for treating this condition[10]. The use of UDCA in treating cholestasis secondary to oral estrogen therapy in humans has not been reported, although ethinylestradiol-induced cholestasis in rats has been shown to respond to UDCA[11]. The authors of that study concluded that UDCA increased bile flow by increasing bile acid secretion, through the normalization of the expression of the canalicular bile salt export pump. UDCA has also been noted to decrease the glucuronidation of estrogens, thereby decreasing the production of cholestatic metabolites[12].

Although corticosteroid treatment appeared more effective than UDCA, the two agents have been compared in a randomized study in ICP. Treatment with UDCA led to a significant reduction in ALT and bilirubin and an improvement in pruritus, while dexamethasone had no such effects[13].

Endoscopists who carry out ERCPs should be aware of the potential causes of persistent jaundice following the removal of intraductal stones. In female patients with protracted jaundice, the possibility of estrogen-induced cholestasis should always be considered, and oral estrogens discontinued. In such cases, a short course of corticosteroid treatment should be considered.

Abstract

We report here how a heterotopic penetrating peptic ulcer progressed to cause small bowel obstruction in a patient with multiple previous negative investigations. The clinical presentation, radiographic features and pathological findings of this case are described, along with the salient lessons learnt. The added value of wireless capsule endoscopy (WCE) in such circumstances is debated.

Key words: Non-Meckelean ectopic peptic ulcer; Bowel obstruction

INTRODUCTION

Heterotopic gastric mucosa resulting in peptic ulceration in the absence of a Meckel's diverticulum is a most unusual cause of small bowel symptomatology[1]. Although wireless capsule endoscopy (WCE) enables painless visualization of the small bowel in a non-invasive manner, its added value in cases not presenting with occult gastrointestinal blood loss is unclear. In this report, we consider what extra value this technology added to the care of a patient who had had multiple negative standard investigations, and ultimately required a laparotomy and ileal resection for definitive management.

CASE REPORT

A 77-year-old man presented to the Accident and Emergency Department of our hospital with subacute small bowel obstruction, having complained for many years of intermittent severe central abdominal discomfort associated with episodic distension and constipation. Prior to this admission, these symptoms had been extensively investigated by means of plain radiology, computerized tomography (CT) and barium contrast studies, as well as by both upper and lower gastrointestinal endoscopy, but to no avail. Furthermore, laparotomy at the time of one such presentation had been performed but without therapeutic benefit, as no evidence of overt intestinal pathology or abnormality was found (in particular, there was no evidence of Meckel's diverticulum). On this latest presentation, the clinical examination was consistent with subacute small bowel obstruction (distended but soft, moderately tender abdomen, with hyperactive bowel sounds and signs of extracellular fluid depletion). Plain abdominal radiography revealed the presence of dilated loops of the small bowel, while subsequent abdominal CT confirmed this finding but did not identify a transition point or any mass lesion. Initial treatment involved correction of fluid and electrolyte abnormalities and nasogastric aspiration for symptomatic relief. Mindful of his past history, when the symptoms persisted for more than 48 h, small bowel barium follow-through was performed. This also failed to define any specific pathology, although the barium failed to progress beyond the proximal jejunum.

As the patients symptoms had somewhat relented by this stage and he resumed passing flatus again, he was therefore permitted some oral diet which he tolerated despite some intermittent, colicky pain. Although a second laparotomy was advocated because of the ongoing persistence of low-grade symptoms, the patient was reluctant, on empiric reasons alone, to consider this given the lack of impact from his previous operation. WCE was therefore performed on a somewhat speculative basis. This test again demonstrated a prolonged transit time through the small bowel (the capsule had not progressed through the jejunum after 7 h), but the last frame of the study showed a raised mucosal jejunal lesion adjacent to an area of severe luminal stenosis (Figure 1). Along with the non-resolving symptoms, identification of this suspicious mucosal lesion, compounded by capsule retention, strengthened the case for exploratory laparotomy. The patient consented. At operation, two

adjacent loops of densely adherent jejenum were obvious among other areas of peritoneal adhesions. There were also features of chronic dilatation proximal to an area of luminal stricturing within one of these loops of bowel. Careful adhesiolysis permitted resection of a segment of chronically obstructed aperistaltic small bowel, as well as allowing for the retrieval of the capsule. A primary hand-sewn end-to-end jejunojejunal anastomosis was performed. Opening of the specimen subsequently revealed an underlying oval mucosal ulcer with punched out edges extending through the wall, which caused fibrosis and adhesion to the adjacent loops of bowel (Figure 2). Histological examination of the resected specimen identified foci of heterotopic gastric mucosa adjacent to this deep penetrating chronic peptic ulcer (Figure 3). The patient thereafter made an uncomplicated recovery and remains symptom-free 6 mo later.

DISCUSSION

Heterotopic gastric mucosa in the small bowel, other than in Meckel's diverticulum or other congenitally anomalous bowel, is rare[2]. Such lesions usually cause small bowel obstruction, either secondary to a mechanical lesion in the lumen[1], or intermittently due to intussusception of the ectopic mass[2-5]. Acute presentation with a perforating ulcer is rarely seen; indeed, there have been only five cases reported in the literature[1-4], with a further five being reported as causing hemorrhage due to ulcer penetration[1]. In our patient, an ulcerating ectopic mucosal lesion presented unusually as small bowel obstruction secondary to an extensive fibrotic reaction. In this case, there was no macroscopic evidence of diverticulum, luminal duplication, or congenital anomaly. Due to the dense adhesional mass and desmoplastic reaction, it was not possible to identify whether the ulcer was on the mesenteric or antimesenteric border of the small bowel, but the penetrating jejunal ulcer was clearly present at the site of the transition point between the dilated and normal caliber small bowel. Microscopic examination of the lesion yielded evidence of ectopic gastric mucosa adjacent to the deep penetrating ulcer, associated with features of chronic inflammation and fibrosis. A diagnosis of chronic peptic ulcer, secondary to heterotopic gastric mucosa with reactive adjacent fibrosis and adhesions was therefore concluded.

The development of WCE technology has changed investigative endoscopy of the small bowel into a much less invasive and more complete examination. A now-proven reliable tool for verifying the state of the small bowel[2], it has been particularly successful in finding the cause of obscure gastrointestinal bleeding[3] and chronic diarrhea, and in evaluating the extent of Crohn's disease. It is not generally used in cases of small bowel obstruction, due to the risk of capsule retention that should precipitate surgical intervention. In patients with undiagnosed abdominal pain, the yield from the use of WCE appears low, whereas in this case, it proved useful in securing a pathological diagnosis and furthering management[4], as there was an

understandable reluctance by the patient to proceed to a second laparotomy without a strong positive indication and likelihood of therapeutic benefit. This case therefore adds some weight to the argument that judicicious use of WCE in small bowel obstruction may identify the site of obstruction and guide surgical intervention[5,6]. In particular, this could be of great significance for a surgeon attempting to localize otherwise non-apparent pathology intraoperatively. In this case, WCE was considered only in the setting of multiple negative investigations and a high probability of operative intervention, given the high risk of capsule retention.

While WCE added little objective evidence to the findings at the latter operation, it is intriguing to speculate how this test may have guided intervention at the time of first surgery. Although small bowel ulcers, ileal tuberculosis and even worm infestation have previously been demonstrated by WCE, most small bowel pathology found to date has been Crohn's disease or NSAID-related lesions of the distal small bowel[5]. There is only one previous case in the literature of heterotopic gastric mucosa of the small bowel identified by capsule endoscopy[6]. Although the captured images in this case did not diagnose the specific lesion, they did suggest a mucosal anomaly and secondary stenosis, which was subsequently histologically identified as ulcerating heterotopic gastric mucosa. If knowledge of such an abnormality had been available prior to the first operation, perhaps that intervention could have been tailored with therapeutic benefit.

Abstract

Hepatic hydrothorax is a relatively infrequent but potentially serious complication of liver cirrhosis that often causes respiratory dysfunction. Several hypotheses for the development of hepatic hydrothorax have been suggested to explain a transdiaphragmatic shift of ascitic fluid through small defects between the peritoneal cavity and the pleural space. However, the rapid development of hydrothorax within several hours is seldom encountered. In addition, the causal factors for rapid passage of ascitic fluid into the pleural cavity are unknown. This report describes a patient with liver cirrhosis who suffered rapid development of a hydrothorax after manual compression of the abdomen.

TO THE EDITOR

A 63-year-old female with Child-Pugh grade C liver cirrhosis was admitted to Chihaya Hospital, Fukuoka, Japan because of ascitic fluid and hepatic encephalopathy. Physical examination revealed a markedly distended abdomen and peripheral edema. Her laboratory blood tests showed a white blood cell count of 9550/L, hemoglobin of 7.6 mg/dL, platelet count of 54000/L, aspartate aminotransferase 39 IU/L (normal 7-38), alanine aminotransferase 16 IU/L (normal 4-43), gamma glutamyltransferase 45 IU/L (normal 16-73), alkaline phosphatase 600 IU/L (normal 104-338), serum albumin 2.0 mg/dL (normal 3.8-5.2), total bilirubin 1.5 mg/dL (normal 0.2-1.1), and serum ammonia 255 μg/dL (normal 30-86). Chest radiography showed no pleural effusion (Figure 1), while abdominal computed tomography imaging was characteristic of cirrhosis with a massive amount of ascitic fluid (Figure 2).

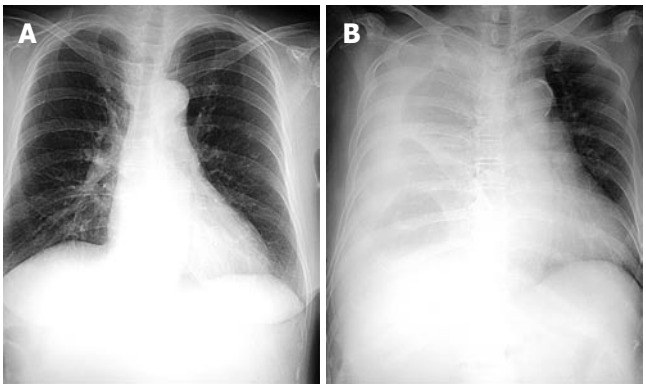

Figure 1 Chest X-ray. **A**: Before manual compression of the abdomen; **B**: on the next day, after manual compression of the abdomen.

Figure 2 Abdominal computed tomography before manual compression of the abdomen shows liver cirrhosis with a massive volume of ascitic fluid.

After admission, the patient was treated with branched-chain amino acid supplementation, diuretics and lactulose enema, in combination with antibiotics for ascites and hepatic encephalopathy. Hepatic encephalopathy had been well controlled; however, it manifested in association with constipation on fourteenth day after admission. Constipation was not relieved after the administration of laxative drugs and a lactulose enema. Therefore,

manual abdominal compression was performed gently for approximately 1 h by a nurse to accelerate bowel movement. After that, a large amount of stool was evacuated and hepatic encephalopathy improved. However, during the following night, progressive dyspnea occurred and analysis of blood oxygen showed hypoxemia. Chest radiography on the next day revealed a massive right-sided pleural effusion (Figure 1), while ultrasonography showed that the ascitic fluid had disappeared. Pleural effusion obtained by thoracenteses showed a transudate, which indicated the rapid migration of ascitic fluid into the right hemithorax.

The transfer of large volumes of fluid from the abdomen to the pleural space through defects in the diaphragm can easily be understood. Once the diaphragmatic communications begin to leak fluid in response to abdominal pressure such as a cough or muscle strain, the combination of a hydrostatic gradient of negative intrathoracic pressure and positive intra-abdominal pressure passively produces a unidirectional flow of ascitic fluid into the pleural space[1,2]. The occurrence of hydrothorax induced by tense and prolonged abdominal compression has not previously been reported, although there have been a few reports demonstrating the actual condition of the rapid occurrence of hepatic hydrothorax[3].

Interestingly, in this case with cirrhosis and a massive volume of ascitic fluid, the imaging data and clinical course strongly suggested that the rapid migration of ascitic fluid into the pleural space occurred due to the manual abdominal compression. Therefore, clinicians need to be aware of the possibility that massaging the abdomen can cause a hepatic hydrothorax in patients with a massive volume of ascitic fluid.

18th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists
8-11 October 2008
Istanbul

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

Despite near-universal embrace of the concept and clinical relevance of lymphatic mapping for sentinel node identification and analysis for cancers of the breast and integument, the same technique has struggled to a find a role in gastrointestinal cancers in general and, perhaps, in colon cancer in particular. Despite many studies demonstrating its feasibility in malignancies of the large bowel, concern is continually aroused by the variable and often unacceptably low sensitivity rates. Additionally, many confess uncertainty as to what benefit it could ever confer to patients even if it were proven sufficiently accurate given that standard surgical resection incorporates mesenteric resection anyway. However, the huge impact sentinel node mapping has had on clinical practice in certain cancers means that each of these aspects merit careful reconsideration, from very first principles.

Key words: Sentinel node; Lymphatic mapping; Colon cancer

Cahill RA. What's wrong with sentinel node mapping in colon cancer? *World J Gastroenterol* 2007; 13(47): 6291-6294

http://www.wjgnet.com/1007-9327/13/6291.asp

Despite being initially proposed many years before, the sentinel node concept has only recently impacted upon clinical practice. The major landmark work in validating the theory took place in melanoma patients[1], but the proof of the concept was quickly (and relatively painlessly) transferred to breast cancer[2]. However, perhaps the most salient aspect evident on reviewing these seminal publications now is their consistent focus on confining the technique to relatively early stage cancers. The rationale underlying this is that larger tumours involve a greater area of lymphatic channels and also that more advanced tumours may demonstrate aberrant lymphatic dynamics, both within the primary and in the lymphatic channels in the immediate vicinity. Lymphatic mapping is, therefore, currently recommended only for intermediate thickness melanoma (1.2 mm to 3.5 mm deep)[3] and T1 and 'early' T2 breast tumours[4,5]. As discussants of the topic with regard to colon cancer largely tend to overlook this basic tenet, it is worth reviewing the literature for *in vivo* sentinel node detection in colon cancer from this perspective (*ex vivo* work has been excluded from this review as it primarily is of interest from the point of view of pathological evaluation rather than surgical approach).

To date, there have so far been 37 publications in the English language describing over 2500 patients (although some studies may have overlapped their patient groups). Explicit cognisance of tumour advancement and mural penetration has mostly only been peripherally addressed in these studies, however, and tumour size hardly at all. Only four studies excluded patients with evident macroscopic lymphadenopathy[6-9] and it is interesting to note that each of these despite being relatively small studies from groups outside of the main proponent centres have excellent results given the other characteristics of their patient cohorts (see below). The authors with the most consistently impressive results have also tended to include relatively high proportions of "early tumours" (approximately 50% or more of their cancers have been T1 or T2)[2,5,10]. However, when collaborating in a multicentre study resulting in patients with tumours of somewhat more advanced T-stage, sensitivity rates reduced. Further examination of these patients led to the conclusion that this was primarily due to lymphatic obstruction by tumour[11]. Furthermore, when a related group described a cohort of somewhat more advanced primary tumours (at least in terms of T-stage) for the purposes of a different study their lymphatic mapping results also appeared worse (82% detection rate with 12% false negative rate) than those previously published[12]. Other authors have also reported high sensitivity rates when dealing with earlier tumours although this aspect of the patient demographic was not specifically teased out[13,14].

Conversely, the studies with the highest false negative rates have also tended to have the greatest proportion of T3/T4 tumours in their study cohorts (with the T3-T4 proportion representing at least two thirds of the total study group)[15-21]. Better results in such patient populations is reported in those studies which specifically excluded those with evident lymph node disease intraoperatively[9]. Of the studies that have considered any potential impact of T-stage, Viehl *et al*[22] found identification rates most significantly affected by tumour size:dye instillate ratio, Saha *et al*[23] found 95 per cent of so called 'skip metastases'

occurred in T3 and T4 tumours while Wood *et al*[24], Bilchik *et al*[25] and Kitagawa *et al*[26] all noted that their false negative cases occurred predominantly in T3/T4 patients. Furthermore, Ratanachaikanont *et al*[27] found significantly lower identification rates in these tumour categories and Yagci *et al*[28] documented lower sensitivities in those with advanced Dukes B cancers. The one exception to this very consistent trend has been the work of Paramo *et al*[29] who initially described a 0% false negative rate in their initial experience with predominantly T3 tumours. However, after further expanding their series (mostly by enlarging their numbers of T3 tumours), they found a 3% false negative rate[30] while, interestingly, neither report included any T4 cases.

Some other important studies have provided no meaningful details at all regarding T stage[31-39] and so do not lend themselves to be scrutinised in this fashion. However, given that they state no pre-selection criteria for their patients, it would seem likely that their patients were representative of typical presentation (which in the case of colon cancer is predominantly with transmural, node positive disease). Indeed, that the majority of studies include all comers in their validation studies is perhaps understandable given that most patients with potentially resectable tumours proceed to operation without particular consideration of tumour diameter or mural penetration. Nonetheless, inclusion of high proportions of more locally advanced tumours seems, both theoretically and empirically, to undermine the validation of the technique in this disease. While other factors such as operator experience and dye pharmacodynamics may, of course, also play a role, it would surely be of great interest to selectively, prospectively study sentinel node mapping in patients with early tumours. This would evidentially necessitate some means of preselection such as endoscopic ultrasound (proven efficacious in this tumour type as in other alimentary malignancies)[40] or by including for study only those with screen-detected cancers but would seem eminently feasible.

The second fundamental difference between SNM for cutaneous and breast tumours and that for colon cancer is in the overall intention of purpose. The fundamental principles ab initio diverge significantly, however, between the two as the intent of the technique when used in the former malignancies is to identify lymph node negative patients (in order to spare them from morbid lymph basin dissections) whereas in the latter it has focussed mainly on detecting lymph node positive patients (to identify those who have otherwise occult dissemination and who, therefore, could benefit from systemic therapy). Prognostic prediction (and, therefore, adjuvant therapy prescription) in colon cancer however is largely determined by lymph node involvement and recently much attention has focussed on the adequacy of nodal harvests (whether by surgeon resection or pathologist detection)[41]. It may well be, therefore, that the value of sentinel node identification and analysis is to confirm that lymphatic dissemination has not taken place in tumours likely to be of early stage in order to save the searching for sufficient numbers of nodes to prove this (in excess of 40 perhaps) that would otherwise be necessary[42]. From this viewpoint, the upstaging of some cancers that are conventionally node negative becomes an added bonus rather than the sole outcome to justify the effort involved. While such a hypothesis can obviously only be purely speculative at present, some proof of concept could perhaps be advanced by the early adopters of lymphatic mapping in colon cancer in examining the survival of their sentinel node negative patients to date in comparison to those deemed node negative by conventional means but with low nodal counts.

Finally, it is intriguing to question the widely held assumption that sentinel node mapping in colon cancer has no value in minimizing the operative morbidity associated with resection of colonic tumours[43]. This basic tenet has become so dogmatic that a sentence to this effect nearly always forms part of the introduction, discussion and/or accompanying editorials of publications concerning the topic[44]. The intent behind the standard operations performed for colonic cancer is, however, to achieve full lymph node basin clearance concomitantly with resection of the primary in every case ("en bloc" or radical resection). The fact that lymphatic drainage closely follows the arterial (rather then venous) regional blood supply is what prompts the level of proximal vascular ligation (a "high-tie") and it is this manoeuvre that then determines the extent of the segmental bowel resection required (in order to minimize the risk of ischemia of the residual bowel). In many cases, the magnitude of visceral resection provoked by radical lymphadenectomy is far in excess of what would be associated with curative surgery in terms of marginal clearance (colonic tumours rarely infiltrate more then 2 cm beyond the area of gross involvement and therefore a resection margin of 5-10 is considered appropriate)[45]. Although there is likely to be a therapeutic value in resecting nodes positive for metastatic disease in colon cancer, the main value of such clearance for truly lymph node negative patients can only be the gain of prognostic information for reassurance. If adoption of sentinel node mapping obviated the need for wide lymph basin clearance for intraperitoneal colon cancers, the potential benefits would include shortened operative times, reduced postoperative convalescence and, perhaps, improved bowel function[46] and diminished rates of anastomotic dehiscence[47]. Furthermore, the potential for ureteric, duodenal and (in the male) spermatic vessel injury would be greatly reduced if root mesenteric dissection became unnecessary as would the hazard of splenic laceration that occurs with mobilization of this flexure [often necessary after high ligation of the inferior mesenteric artery (IMA) to ensure tension-free anastomosis after radical left hemicolectomy for sigmoid tumours] and the risk of sexual impotence that may result if para-aortic nerve injury occurs during flush ligation of the IMA at its origin from the abdominal aorta. Lastly, if a localized resection of the bowel was all that was required, the facility by which excisional colonic cancer surgery is performed by minimally invasive means would be markedly enhanced (and the now arduous learning curve reduced). In short, the clinical significance of localized rather then

radical colectomy is not at present known, but cannot be assumed to be negligible.

The reasons why the basic principles regarding the validation and clinical utility of lymphatic mapping for colon cancer have become so fundamentally divergent from that of breast and melanoma is not entirely clear and, to date, have rarely been discussed. The simplest reason to suspect why it has occurred may be simply that the operative terminology has led to a prevailing mindset. As breast cancer surgeons always considered two operations for their patients (mastectomy/wide local excision and axillary node clearance) and melanoma surgeons always advocated wide excision and lymph basin dissection, perhaps the basic similarities would be easier appreciated if operations such as left hemicolectomy were to have more standardised names such as 'segmental colonic resection with mesenteric lymph node resection'.

A potpourri of pancreatic issues

In this issue of *World Journal of Gastroenterology*, we present a series of articles relating to various aspects of pancreatic disease. Overall, our understanding of the etiology of pancreatic disease is improving, and there is much more of a move towards reserving endoscopic retrograde cholangiopancreatography (ERCP) for cases in which endotherapy is likely and utilising other less invasive modalities such as EUS. In this series, Branch *et al* discuss the utility of ERCP in the evaluation and management of acute pancreatitis, focusing on the need to move away from diagnostic ERCP. With this in mind, Gerke *et al* present an update on the role of EUS in pancreatic disease. What we do for the truly idiopathic pancreatitis population has been the subject of a large body of literature over the last few years and is highlighted here by the paper of Enns *et al*. The perpetually contentious disease process of sphincter of Oddi dysfunction is explored here by Mitchell *et al* and provides some food for thought as to who should be doing manometry and which patients should be exposed to this potentially curative but also risky procedure. Byrne *et al* focus on the emerging burden presented by autoimmune pancreatitis, a condition undoubtedly missed in the past and often confused for pancreatic cancer. Freeman tickles our fancy with some revelations in to the pancreatic endocrine and exocrine manifestations of pancreatic disease. Finally, Meloche presents a delightful review of the current state of play in relation to pancreatic transplantation for type 1 diabetes mellitus.

This is a somewhat mixed bag of topics but hopefully serves to remind us that there are a number of considerations in pancreatic disease, that we have more therapeutic options, safer imaging, and that we have a lot more to learn.

Abstract

Recent advances in understanding of pancreatitis and advances in technology have uncovered the veils of idiopathic pancreatitis to a point where a thorough history and judicious use of diagnostic techniques elucidate the cause in over 80% of cases. This review examines the multitude of etiologies of what were once labeled idiopathic pancreatitis and provides the current evidence on each. This review begins with a background review of the current epidemiology of idiopathic pancreatitis prior to discussion of various etiologies. Etiologies of medications, infections, toxins, autoimmune disorders, vascular causes, and anatomic and functional causes are explored in detail. We conclude with management of true idiopathic pancreatitis and a summary of the various etiologic agents. Throughout this review, areas of controversies are highlighted.

Key words: Idiopathic pancreatitis; Recurrence; Etiology; Endoscopic retrograde cholangiopancreatography; Magnetic resonance cholangiopancreatography; Sphincter of Oddi dysfunction

INTRODUCTION

Pancreatitis is a relatively common disorder with a myriad of etiologies all resulting in a common end result of inflammation within the pancreas. Acute pancreatitis (AP) results in acute inflammation typically presenting as abdominal pain with elevated levels of pancreatic enzymes[1]. Chronic pancreatitis (CP) is defined as a clinical syndrome of progressive inflammatory changes in the pancreas leading to permanent structural damage with subsequent impairment of both exocrine and endocrine function[2]. Chronic pancreatitis is often preceded by recurrent bouts of acute pancreatitis, however, occasionally it can present in a 'silent' fashion.

The label of "idiopathic pancreatitis" (IP) was originally designated to cases of pancreatitis wherein a diagnosis could not be made through a thorough history, physical examination, laboratory studies, and noninvasive imaging modalities such as abdominal ultrasonography/computerized tomography. Previously, this nomenclature had accounted for 8%-44% of cases being termed "idiopathic"[3-9]. Recent new laboratory and technological advances have been able to shred the enigmatic veils of IP to a point wherein with extensive evaluation it is possible to reveal the etiology in 79%-80% of patients previously labeled as having "idiopathic pancreatitis"[10,11]. More modern imaging investigations include, but are not limited to fine cut computerized tomography, endoscopic retrograde pancreatography, magnetic resonance pancreatography as well as endoscopic ultrasound.

EPIDEMIOLOGY

Longitudinal data on incidence trends report an increase in AP[12] which may be attributable to increases in all causes of pancreatitis as well as improved detection methods. The fatality rate for pancreatitis has continued to range between 3%-10%[13-18] despite a marked decrease in pancreatitis case fatality presumably secondary to early recognition of severity and complications as well as improved intensive care management[14,15]. Thomson[6] and others[7,17] have noted that in AP mortality rates are greater when the etiology is IP (14.1%)[6], compared with gallstone pancreatitis (7.2%)[6]. In addition, the clinical impact of IP is further highlighted by the fact that 40 percent (the largest subgroup) of all AP fatalities are attributable to IP[19, 20]. The incidence of IP ranges from 4.21 per 100 000[21] to as high as 45.33 per 100 000[9] depending on the population studied and the time in which data was collected with a trend toward high incidence in populations studied more recently[12,13,22]. The incidence appears to be

Table 1 Etiologies of acute or acute recurrent pancreatitis

Category	Agent/Diagnosis
Vascular	**Atheroembolism**
	Intraoperative hypotension
	Hemorrhagic shock
	Vasculitis (systemic lupus erythematosus and polyarteritis nodosa)
Infectious	**Viral**
	Mumps
	Coxsackievirus type B
	Hepatitis B

Autoimmune	Sjogren's syndrome
	Primary biliary cirrhosis
	Renal tubular acidosis

equal between the two sexes and tends to increase with age in both before starting to plateau around 70 years[18].

Elucidating the etiology of pancreatitis, if possible is paramount as it guides therapy and may theoretically subsequently improve patient outcomes, thereby preventing relapses. Some studies have shown that over 50% of untreated patients with acute IP experience recurrent episodes[23-25]. This contrasts with other studies where only 1 of 31 patients with a first episode of unexplained AP suffered another attack during a median follow up of 36 mo[26]. These conflicting results may reflect different patient populations, perhaps even within the same category known as IP.

Aside from the initial objective to decrease acute patient mortality and morbidity, repeated insults to the pancreas may progress to chronic pancreatitis with irreversible morphologic and functional changes[2,24,27]. This concern typically results in aggressive investigation for those patients with more than one episode of AP. This approach is supported by a study by Kaw and Brodmerkel in a study that included 126 patients with two or more episodes of IP. They demonstrated that investigations including bile for microlithiasis, a secretin stimulation test, and sphincter of Oddi manometry (SOM) was able to clarify the etiologies in 79 percent of patients[11]. In this study they were able to offer 75% of these patients treatment that resulted in the absence of AP in over 60% of cases over a 30 mo follow-up period[11].

However there is ongoing debate against aggressive evaluation. The Kaw and Brodmerkel study confirmed previous morbidity data demonstrating that SOM is not a benign procedure and that complications occur[11]. Additionally, many aggressive techniques for diagnosing the etiology of pancreatitis, including SOM, may not be routinely available. Therefore the generalizability of this study has been brought into question.

This article will examine some of the etiologies that must be excluded prior to a diagnosis of IP. An attempt will be made to highlight the areas of controversy, and make suggestions based on the best available evidence. For the purpose of this IP article, gallstones and alcohol related pancreatic disease will not be discussed as their presentation is usually easily determined. For a more comprehensive list of all etiologies of pancreatitis please refer to Table 1.

PANCREATITIS ETIOLOGIES OFTEN LABELLED AS IDIOPATHIC PANCREATITIS

Microlithiasis and biliary sludge

Biliary sludge refers to the viscous suspension in gallbladder bile formed by modification of hepatic bile by the gallbladder mucosa that may contain small stones (< 5 mm in diameter)[28]. Microlithiasis refers to stones of < 3 mm in diameter and is often used interchangeably at times with "microcrystals" and sometimes with biliary sludge[28-30]. Microscopy of bile in patients with sludge often shows cholesterol monohydrate crystals, calcium carbonate microspheroliths, or calcium bilirubinate granules[31]. A known risk factor for the development of sludge typically includes prolonged fasting states as well as some antibiotics (ceftriaxone)[32]. Microlithiasis has been suggested to be the most common causes of IP[31,33] with a prevalence ranging from 6%-73%[11,25,31,33,34].

It has been demonstrated that treatment with cholecystectomy, endoscopic sphincterotomy, or ursodiol significantly reduces further attacks of IP[31,33]. Therefore it was inferred that in the absence of other identifiable risk factors, the presence of microlithiasis was enough to cause IP[11,26,35]. The caveat to interpreting these studies is that combined, they involved only 74 patients who had IP and treatments were clearly not double blinded[31,33].

An Indian study published earlier this year evaluating 51 patients with recurrent IP found that microlithiasis accounted for a mere 13 percent of these patients (using duodenal bile samples)[36]. In the setting of suspected biliary pancreatitis up to 88% of patients will have microlithiasis demonstrating the difference between these two patient groups[37]. It is speculated that there may be some gender, age, racial, and procedural differences in bile sample collection and analysis as these are not well standardized.

The pathogenesis of AP *via* microlithiasis remains unclear however it is thought that the microlithiasis may transiently impact the papilla, cause pancreatic duct obstruction and thereby pancreatitis[29,37,38]. The diagnostic workup for microlithiasis includes routine abdominal ultrasound (US) which has limited sensitivity when looking for stones less than 3 mm in diameter[28,39]. Endoscopic US (EUS) may be considered as well as it carries a lower risk of complications than endoscopic retrograde cholangiopancreatography (ERCP)[34,40-45]. On average, EUS is able to identify gallbladder sludge in up to 75 percent of IP cases[40-45]. All patients with recurrent IP should have microlithiasis excluded and there is even some evidence that it should be excluded for patients who have their first IP[41-43].

It remains to be clarified which method of bile collection for microscopic analysis is clinically the best and there are no standardized methods or recommendations at this time[46-48].

Cholecystectomy is recommended for patients with biliary sludge/microlithiasis once they recover from their episode of pancreatitis as it reduces the relapse rates[31,33]. In patients who are poor surgical candidates, ERCP with biliary sphincterotomy or ursodeoxycholic acid may be alternative forms of treatment[31,33].

Sphincter of Oddi dysfunction

At times referred to as hypertensive or fibrotic SOD, SOD causes diminished transphincteric flow of bile and/or pancreatic juice due to either organic obstruction (stenosis) or functional obstruction (dysmotility)[3,35,49]. SOD often causes recurrent pain with or without abnormalities of either hepatic/pancreatic profiles as well as duct dilation. It is thought that SOD causes pancreatitis as a result of bile reflux into the pancreatic duct or from pancreatic duct outflow obstruction[25,50]. SOD is considered to cause up to one third of all cases of IP[25,30,51,52].

In order to diagnose SOD, one often needs to perform sphincter of Oddi manometry (SOM)[53,54]. The diagnostic gold standard is a water-perfused catheter system that can be inserted into the common bile duct or pancreatic duct with the positive finding being a hypertensive sphincter of Oddi pressure greater than 40 mmHg[53]. Unfortunately whether ERCP in patients with suspected SOD is done for diagnostic SOM or therapeutic purposes it is undeniable that there have been high complication rates, particularly pancreatitis[51,55-59]. Additionally "severe" pancreatitis that is associated with death has even been quoted in 1-3% in SOM[15,25,51]. Despite this, ERCP with SOM has been advocated for the evaluation of recurrent IP[25,60]. In patients who have normal biliary manometry, pancreatic sphincter manometry may be reasonable to perform[61,62] which does carry a higher risk of pancreatitis[54] that may be reduced by aspirating through the middle port of the triple lumen manometry catheter[63].

Once the diagnosis of SOD is made, endoscopic sphincterotomy is the treatment of choice as it is believed to decrease the risk of recurrent pancreatitis[25,60,64-66].

The Geenen-Hogan (Milwaukee) criteria was devised to predict the overall probability of response to biliary sphincterotomy taking into account the presence of abnormal liver chemistries and dilated bile ducts[44]. On the basis of this, patients with pain and both abnormalities (type Ⅰ) are definitely recommended to have sphincterotomy as they have high response rates ranging from 90%-100% regardless of SOM[67,68]. Along this stratification, type Ⅱ patients have either abnormal liver chemistry or dilated bile ducts. If SOM is abnormal in type Ⅱ patients they will have a response rate to sphincterotomy of 60%-91%[64,67,69] and thus this would be a reasonable course of action. On the contrary, type Ⅲ patients do not have objective biliary abnormalities and even if they have abnormal SOM they have poor response rates of 6-58 percent[69-71], making sphincterotomy of questionable benefit (Table 2) .

If a diagnosis of pancreatic sphincter dysfunction is made in patients who have had biliary sphincterotomy the answer to who best benefits from pancreatic sphincterotomy is less clear. A study by Freeman *et al*[72] this year treated suspected SOD with biliary sphincterotomy with additional pancreatic sphincterotomy at initial or subsequent ERCP if there was abnormal pancreatic manometry in conjunction with pain refractory to biliary sphincterotomy, continuous pain, or a history of amylase elevation. In this study of 121 predominantly female (92%) and post cholecystectomy (87%) patients, all patients underwent biliary sphincterotomy while 40 percent also

Table 2 Sphincter of Oddi dysfunction (Geenen and Hogan Classification)

Biliary type	Pancreatic type
Type Ⅰ	**Type** Ⅰ
Biliary-type pain	Pancreatic-type pain

Type Ⅲ	**Type** Ⅲ
Biliary-type pain only	Pancreatic-type pain only

CBD: Common bile duct; LFT: Liver function tests; PD: Pancreatic duct.

underwent pancreatic sphincterotomy regardless of the modified Milwaukee biliary classification[72]. The result from this study was that a positive response at final follow up was reported in 69 percent of patients and that this response was not significantly different between biliary types Ⅰ, Ⅱ, and Ⅲ[72]. Freeman *et al*[72] concluded that patient characteristics of pancreatic manometry, delayed gastric emptying, daily opioid use, and age < 40 were significant as predictors of outcomes as opposed to the Milwaukee classification. Indeed it is becoming more accepted that a lack of improvement after biliary sphincterotomy may be representative of a failure to relieve pancreatic sphincter pressure[61,62,73-77].

Noninvasive strategies such as a low-fat diet, analgesics, anticholinergics, calcium-channel blockers, nitrates, and proton pump inhibitors are unfortunately seldom effective[78,79].

Pancreas divisum

In Pancreas divisum it is thought that 80%-95% of pancreatic juice volume flows *via* the dorsal duct through the smaller minor papillary orifice *via* the dorsal duct of Santorini as opposed to the more common route through the major papilla *via* the ventral duct of Wirsung[66]. It is postulated that the mechanism is that of relative minor papilla outflow obstruction leading to pancreatitis[23,80-82].

Pancreas divisum occurs as an anatomic variant in 5%-7.5% of patients[23,82]. There are those who are skeptical of the obstructive theory as fewer than 5% of patients with pancreas divisum develop pancreatitis[83-86]. It also appears that the incidence of pancreas divisum is the same in patients with and without pancreatitis[86]. Nonetheless there is consensus that while most individuals with pancreas divisum live normally, a few unfortunate patients are predisposed to develop recurrent AP[23-25,35] and that it accounts for 20 percent of the IP cases[23-25].

One explanation of why some patients with pancreas divisum are more likely to be affected was the smaller than usual minor papillary orifice causing a disproportionately high intrapancreatic dorsal ductal pressure especially during times of active secretion. In this situation a cascade of inadequate drainage leading to ductal distension and eventually pancreatitis could occur[23,87-89]. This theory is supported by at least one surgical study that demonstrated relief of pain as well as diminished attacks of AP with sphincteroplasty[87].

Recently, Choudari *et al*[90] found that prevalence of the cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations was similar in patients with pancreas divisum with recurrent acute pancreatitis and true idiopathic recurrent acute pancreatitis. Interesting, this study also found that the prevalence of CFTR gene mutations in patients with pancreas divisum but without recurrent AP was similar to controls without pancreatitis[90]. The significance of CFTR will be discussed in more detail under "Genetic Causes and Contributions" below, however, these genetic studies call into question the true role of pancreas divisum in IP.

At present, it is accepted that patients who present with severe pancreatobiliary type symptoms or recurrent IP should however be evaluated for pancreas divisum[35,48]. The diagnosis of divisum can be made either by ERCP or magnetic resonance cholangiopancreatography (MRCP)[91,92]. ERCP may be preferred to conventional MRCP as it has a higher sensitivity and specificity[91,92] and can offer therapy albeit with a complication rate that is higher than in MRCP. Secretin may be given intravenously to aid in finding the minor papillary orifice at ERCP[93], finding functional outflow obstructions[94-96], and assessing the relative obstruction of the minor papilla[94-96]. In settings where secretin is either contraindicated or does not produce a visible increase in pancreatic juice flow, a dilute (1:10) methylene blue solution can assist in the location of the minor papilla[97]. Confirmation is recommended to rule out pseudodivisum caused by a tumor.

An emerging area is the role of EUS as it is a minimally invasive tool for the general workup of IP and recurrent IP[48]. It appears that EUS is able to detect pancreas divisum but more research in comparing ERCP to EUS specific to divisum is needed before recommendations are made.

In the setting of recurrent AP, once divisum is diagnosed, ERCP therapy to relieve minor papillary obstruction is recommended to decrease the rate of recurrent pancreatitis[98-101], particularly in patients with a dilated pancreatic duct who may be the most likely to benefit from therapy[98]. The rate of decrease of recurrent pancreatitis is quoted to range from 70%-90%[99,100] with a 40%-60% response rate in patients with CP also demonstrated[102]. The ERCP therapy involves a minor papillotomy usually with temporary stenting[98-101,103]. In one study, more favorable long-term results were achieved with minor papilla sphincterotomy than with repeated stenting in terms of both recurrence and fewer complications (25% *vs* 44% respectively)[98]. Some endoscopists are particularly cautious about endoscopic stenting as the procedure may cause permanent damage to the pancreatic ducts, possibly promoting the development of chronic pancreatic disease[104,105].

Anomalous union of pancreaticobiliary duct

Anomalous union of pancreaticobiliary duct (AUPBD) is defined as an anomalous junction of bile duct and

pancreatic duct at an abnormal proximal site of these ducts[35]. The precise location of the junction is outside the duodenal musculature and independent of the sphincter of Oddi. This independence from the contractility of the sphincter of Oddi results in regurgitation of the pancreatic juice into the biliary tract and vice versa[106]. AUPBD is frequently associated with choledochal cysts which in itself has been linked to IP (see below)[107] and is more common in East Asia[35].

It is thought that in AUPBD reflux of bile into the pancreatic duct may cause recurrent AP[106,108] and that in cases with a dilated common channel the stasis of pancreatic secretion can occur in the common channel leading to pancreatitis[109,110]. Moreover it has also been found that SOD (see above) is sometimes associated with AUPBD[111].

The diagnosis of AUPBD is usually made during ERCP evaluation for IP when one notes a pancreatic duct and choledochus connecting with a long common channel of > 15 mm in adults[112]. Similarly AUPBD is also seen during MRCP[91]. The length of the common channel alone is not an absolute diagnostic criterion as other factors like the form of union, direction, and age and stature of patients need to be considered[108,113]. An alternate method of diagnosis, more importantly a 'clue' to the presence of AUPBD, may be the presence of high amylase levels in aspirated bile[114,115].

In AUPBD, endoscopic biliary sphincterotomy has been shown to prevent further attacks of AP[112] by a postulated mechanism of decreasing resistance at the major duodenal papilla[35]. Due to the fact that AUPBD has a propensity to increase gallbladder and biliary duct cancer[114,116-118], prophylactic cholecystectomy has been recommended in these patients[116]. As well, at this time there is some evidence that patients with AUPBD and choledochal cyst should have an extensive resection of the extrahepatic bile duct inclusive of the cyst in hopes of preventing development of biliary duct cancer[108] which may be relevant in 5% of patients[116]. It is reiterated that the understanding of AUPBD, its pathophysiology and therapy is very limited[35].

Choledochocele

Choledochocele is classified as a type Ⅲ choledochal cyst that represents a prolapse or herniation of the intramural segment of the distal common bile duct into the duodenal lumen which may be either congenital or acquired[35,119]. Pancreatitis and recurrent AP is an important complication occurring in choledochoceles occurring in 12%-30% of patients[120,121]. Choledochoceles do not represent a common cause of IP, especially in adults[25,35,120].

It is thought that the choledochocele may create an obstruction to the pancreatic duct intermittently when the choledochocele becomes distended and that this may lead to reflux of bile into the pancreatic duct[121-123].

A characteristic "bulging" appearance of the papilla at ERCP and a soft "pillow" sign with pressure applied at the catheter tip suggests a choledochocele[120,124]. A CT or US in isolation may miss this diagnosis[120]. The role of MRCP in adults to diagnose this is still undefined[91,125,126].

Treatment can be initiated with endoscopic sphincterotomy combined with "unroofing" of the choledochocele with a papillotome with the goal of creating effective drainage of bile and pancreatic juice[120,127]. Patients that fail this treatment may be considered for a surgical sphincteroplasty[128]. Reports in the surgical literature about choledochal cysts in general recommend a single stage surgery usually comprising of complete cyst resection, cholecystectomy and Rou-en-Y hepatojejunostomy[129-131]. Malignancy is noted in 3-5 percent which may in some cases warrant prophylactic surgery[131,132].

Annular pancreas

Annular pancreas is a congenital condition that represents a band of pancreatic tissue partially or completely encircling the duodenum that is usually at the level of or immediately proximal to the major duodenal papilla[133]. It is thought that this defect occurs in utero due to the failure of the ventral bud to rotate with the duodenum[133]. This abnormality is rare and is detected in 1/7000-1/20 000 autopsies[133,134] and in 1/1500 ERCPs[135-137].

Clinically it usually manifests in childhood with intractable vomiting[136,137] and is thought to result from descending duodenal narrowing leading to duodenal obstruction or recurrent AP[138]. In adults annular pancreas may present with abdominal pain, acute recurrent IP, CP, peptic ulcer disease, postprandial fullness, vomiting, or biliary obstruction[137,139]. Associated congenital anomalies such as Down's syndrome, cardiac defects, tracheoesophageal fistula, Meckel's diverticulum, and imperforate anus may be present[133,136]. If the diagnosis is made in adults it usually occurs between the ages of 20 to 50[140].

From a diagnostic view, barium studies, abdominal CT, or MRCP may suggest the diagnosis but an ERCP is recommended for confirmation[135,136,141]. A typical ERCP is that of the duct of the pancreatic annulus encircling the duodenum[24] and in one third of cases a pancreas divisum is also present[139]. The annular duct may communicate with the central duct but rarely drains into the dorsal duct, common bile duct, or independently into the duodenum[135,139]. In cases where ERCP may not be feasible, an EUS may offer an alternative means of diagnosis[142]. Recently some data has also become available on the role of MRCP which appears encouraging as a non-invasive method of diagnosis[143-145].

Surgery is the procedure of choice in patients in whom symptoms can be attributed to annular pancreas with the goal to relieve duodenal or gastric outlet obstruction[137,146].

Pancreatobiliary tumors

Any mass that obstructs the main pancreatic or biliary ducts, benign or malignant can result in acute pancreatitis. It has been estimated that 5%-14% of patients with pancreatobiliary tumors, benign or malignant, present with apparent IP[147-150]. Pancreatic cancer should be suspected in any patient older than 40 years with IP especially with a prolonged or recurrent course[3,5]. Neoplasia should be suspected in a patient with weight loss, steatorrhea, ductal dilation, new onset diabetes, or evidence of a solid

or cystic pancreatic mass[24,149,150]. In younger patients lesions such as curable islet cell tumors should be in the differential whereas in the elderly they may have potentially curable lesions such as cystic neoplasms[24].

It is well known that CT, MRI, ERCP, and EUS have a role in identifying pancreatobiliary neoplasms[151-154]. It is recommended that if there is any clinical suspicion of malignancy that aggressive investigation including ERCP be performed even on the first attack of IP in older patients. In patients who are less than 40 years old, a CT may be sufficient in first attacks of AP[24]. If a malignancy is suspected, EUS is a favorable technique that can be used for diagnostic and staging purposes[155,156] especially when combined with fine needle biopsy[157,158].

Intraductal papillary mucinous neoplasm of the pancreas (IPMN) is a distinct pathologic entity formed of papillary proliferations of mucin-producing epithelial cells with or without excessive mucus production and or cystic dilation of the pancreatic duct. IPMN represents a precancerous lesion with a well described adenoma and carcinoma sequence that causes recurrent acute IP with symptoms suggestive of chronic obstructive pancreatitis due to intermittent obstruction of the pancreatic duct with mucus plugs[159]. It is worth noting this entity has an insidious nature and lack of awareness often delays diagnosis[160-163]. On ERCP, in cases of main duct involvement, the papilla is patulous and resembles a "fish-eye" frequently with mucus extruding from the orifice[161,164,165]. In terms of management, since the ten-year actuarial risk of high grade dysplasia and invasive cancer is significant[166] surgery is usually recommended, particularly for main duct disease[159,167-169]. It should also be noted that patients with IPMN may be at increased risk for extrapancreatic malignancies and because of this gastricadenocarcinoma and colorectal cancer should be screened for using endoscopy[170,171]. Patients with branch type disease may be at a lower risk of malignancy and theoretically can be monitored in regards to mural wall thickening, size of branch cystic lesion and tumor markers.

Cystic pancreatic tumors including IPMN, serous cystadenomas, mucinous cystadenomas, and mucinous cystadenocarcinomas, can be premalignant or malignant and surgery is generally indicated[172-174]. Tumor markers such as CA 19-9, CA 15-3, CA 72-4, and carcinoembryonic antigen in aspirated cystic fluid along with fluid viscosity and amylase level may be used to increase the diagnostic yield of cyst fluid cytology[175-179].

Ampullary adenomas are premalignant and in general, indicate the need for close monitoring and eventual removal[180,181]. In general, ampullary tumors have a more favorable prognosis than pancreatic tumors and pancreatoduodenectomy has historically been recommended[182-184]. An emerging development for ampullary tumors is the use of endoscopic techniques such as endoscopic ampullectomy for management of patients with small benign lesions or for carcinoma *in situ*[185-188] which appears to be safe and efficacious on long term follow up[188]. If endoscopic management is selected it has been recommended that surveillance and random biopsies be performed[24].

GENETIC ASSOCIATIONS AND CAUSES

An exciting development is the recognition of genetic mutations that are associated with pancreatitis.

CFTR

The cystic fibrosis transmembrane conductance regulator (CFTR) and its gene mutations cause cystic fibrosis in an autosomal recessive pattern. It is well established that CFTR mutations cause disease of the exocrine pancreas[189]. The CFTR gene encodes a chloride-channel protein that is regulated by cAMP. Bicarbonate ion is secreted into the duct lumen by the action of CFTR in the apical membranes and this sets up a gradient in which water follows[190]. In the absence of CFTR, the pancreatic duct cells cannot secrete fluid and bicarbonate and hence CF of the pancreas develops[191].

The actual mechanism that mutations in the CFTR gene causes recurrent AP or CP[90,192-194] is unknown. It may be that mutant CFTR channels are inefficient at flushing digestive enzymes out of the pancreatic duct and thereby limiting the major mechanism that prevents trypsin-associated injury within the pancreatic duct[195]. Along the same lines, it may be that mutant CFTR can limit bicarbonate secretion that can interfere with trypsin activation[195]. What is clear is that CFTR mutations have a demonstrated increased incidence in patients with CP, IP, and alcohol induced CP[194,196-201]. One recent study of 381 patients diagnosed with either CP or recurrent IP that used expansive CFTR genotyping showed mutant CFTR genes in 11% (43/381) of these patients[195]. This frequency is in keeping with previous reports of 28%-45% of IP patients being either heterozygous or homozygous for a CFTR gene mutation[202,203]. One study in Poland showed that the frequency of mutations in CFTR alleles was similar to controls (4.9% *vs* 5%, $P = 0.587$) but this study only looked at 3 CFTR defects[204].

Testing for this gene mutation may be considered in younger patients presenting with recurrent IP who have a positive family history of cystic fibrosis or IP[66,195,205]. If testing is to be done, a broad mutation panel to look for a multitude of mutations of CFTR is recommended[195].

SPINK1

The N34S mutation of the serine protease inhibitor Kazal type 1 (SPINK1) has been reported to be strongly associated with IP and hereditary/familial pancreatitis[206-208]. SPINK1 is a specific trypsin and trypsin activated trypsin like inhibitor expressed within the pancreas that provides a defense against prematurely activated trypsinogen[209,210]. It has been suggested that SPINK1 mutations are disease modifiers in that they lower the threshold for pancreatitis from other genetic or environmental factors[207]. For example this mutation was found in one study to be associated with CP and recurrent IP in 7.7% and 10% respectively[204]. Likewise, a larger study showed that 15.7% of patients with CP or recurrent IP carried at least one SPINK1 mutation[195].

A genetic test for SPINK1 should be done in any younger patient presenting with recurrent AP or CP and a family history of IP or CP-particularly if they have had

prior negative workup with ERCP. When genetic testing is done, it is advised to perform a concomitant CFTR and PRSS1 mutation screen[195].

Cationic trypsinogen gene PRSS1

Two missense mutations R12211[211] and N291[212] in the human cationic trypsinogen gene [protease serine 1 (trypsin 1); PRSS1] were first detected in patients with hereditary pancreatitis and appear to manifest as autosomal dominant mutations[213]. Since the discovery of the first two genes many other PRSS1 mutations have been reported[214-219]. Pathophysiologically this mutation leads to impaired trypsin autolysis and degradation, impairment of SPINK1 defense mechanism, and promotion of auto-activation of trypsinogen all of which can cause AP and lead to CP[211,220].

Symptoms typically arise in childhood but may be delayed until the mid 30 s[221]. These usually include symptoms associated with CP[221]. The lifetime risk of pancreatic cancer is 40% and reportedly 75% with paternal inheritance[222]. Whereas in cases of CFTR and SPINK1 are associated with IP and CP, PRSS1 defects seem to be causative for AP[204].

As in CFTR and SPINK1, the diagnosis is usually suspected if younger patients with affected family members present with CP or recurrent IP. Complications of CP are usually dealt with endoscopically but given the high risk of malignancy surgical resection may be preferred[24].

Celiac disease

The frequent familial occurrence and the remarkably close association with the HLA-DQ2 and/or DQ8 gene locus suggests that celiac disease as an immune disorder that is triggered by an environmental agent, gliadin, in genetically predisposed individuals[223,224]. Intriguingly, recurrent pancreatitis can be caused by celiac disease[225,226]. The mechanism appears to be duodenal inflammation and associated papillary stenosis causing pancreatitis[225]. Endoscopic treatment is recommended at this time to relieve the obstruction.

There are consensus guidelines to the role of genetic testing in IP although they are evolving as our knowledge expands in the area[227].

MEDICATIONS

The list of medications that are associated with or that cause pancreatitis is increasing[228-230]. In one German study 1.4% of all acute pancreatitis was related to medications[231]. Another study reported an even lower association of 0.3%[232]. Drugs with the highest incidence of pancreatitis are azathioprine and mercaptopurine (incidence, 3 to 5%)[233] and didanosine (23%)[234].

Most medication related to pancreatitis is due to idiosyncratic response or a direct toxic effect. A high index of suspicion and astute drug history is crucial for making the diagnosis.

A few areas of medications causing pancreatitis will be highlighted. Firstly, physicians should be aware of a recent development showing an association of proton pump inhibitors and pancreatitis[235-237]. Secondly, some medications, such as pentamidine, valproic acid, and didanosine, appear to cause injury weeks to months after exposure, possibly through the accumulation of a toxic metabolite[238]. Hypersensitivity reactions have been implicated in other drugs, such as azathioprine, mercaptopurine, metronidazole, aminosalicylates, and sulfonamides, and these drugs characteristically lead to pancreatitis within one month after exposure[238]. Lastly, some medications like acetaminophen may cause pancreatitis with a single dose[239].

A complete list of medications that are classified as being definitely associated with pancreatitis derived from multiple references is shown in Table 1[228-230,240-242].

TOXINS

Toxins that have been linked to pancreatitis include the most common alcohol. The more deadly methanol can also cause AP[243]. Although exceedingly rare scorpion bites from Trinidad have been known to cause AP[244,245]. Another rare cause of IP is organophosphorous poisoning[246].

INFECTIOUS CAUSES

A plethora of infectious agents have been associated with AP[247]. A full list of definite and probable etiologic agents is provided in Table 1 from data gathered from Parenti *et al*[247]. It is unclear how often an infectious etiology is responsible for IP but many appear to be associated with it[247].

A clinician must be suspicious of an infectious etiology in the characteristic syndrome caused by the particular infectious agent notwithstanding that this was evident in only 70% of patients in the prior review for definite cases[247]. A routine search for an infectious cause in IP is not recommended unless there is a strong clinical suspicion.

Ascariasis is an important cause of infectious obstructive AP in India where it is the second most common cause of AP[248]. At times this may also present with associated biliary tree infestation requiring endoscopic decompression[249].

An infectious group worth discussing in greater detail is HIV infections and their relation to AP[250]. One large series revealed that 4.7% of hospitalized patients with HIV had AP[251]. While primary HIV infection itself can be a cause of AP[252,253] it is more commonly attributable to a complication of medications taken as part of HIV treatment or medications for opportunistic infections such as Pneumocystis carinii and Mycobacterium avium-intracellulare[250].

METABOLIC

Hypertriglyceridemia

Serum triglyceride concentrations above 11.3 mmol/L are capable of causing AP although admittedly the pathogenesis of inflammation is unclear[254]. It is thought that hypertriglyceridemia represents 1.3%-3.8% of AP

cases[255]. The incidence has been best defined in children with inherited disorders of lipoprotein metabolism that is associated with severe hypertriglyceridemia which are 35%, 15%, and up to 40% in hyperlipidemia types Ⅰ, Ⅱ, and Ⅴ respectively[256,257]. Other acquired causes of hypertriglyceridemia include obesity, diabetes mellitus, hypothyroidism, pregnancy, estrogen or tamoxifen therapy, glucocorticoid excess, nephritic syndrome, and beta blockers[258-260,255].

Drug-induced disease is more likely to occur in patients with underlying hypertriglyceridemia[256]. It is important to not neglect the lactescent serum as it is a vital clue to the diagnosis[255].

Controversy surrounds the contribution of hyperlipidemia in causing AP in alcoholics[261] but it is thought that in most alcohol abusers the moderate elevations of triglyceride levels are transient and likely to be an epiphenomenon rather than a causative agent of pancreatitis[262].

Hypercalcemia

Occurring in uncommon frequency, hypercalcemia of any cause is a known cause of AP[263,264]. Postulated mechanisms include calcium deposition in the pancreatic duct and calcium activation of trypsinogen within the pancreatic parenchyma[265,266].

There are questions however on hyperparathyroidism, a cause of hypercalcemia, and the link to pancreatitis rose in one large study of 1153 patients that found that AP occurred in only 1.5 percent of patients that was of a statistically non significant difference from that of the general population[267]. This finding was mirrored in two other studies[268,269]. This is still an open controversy however as other studies have supported at least an association and a significantly increased relative risk of AP in patients with hyperparathyroidism[270,271]. Until the debate is resolved it is recommended that the parathyroid be checked in recurrent IP if hypercalcemia is present.

VASCULAR DISEASE

Pancreatic ischemia is an uncommon but an established cause of pancreatitis reported in: (1) vasculitis (systemic lupus erythematosus, polyarteritis nodosa, and microscopic polyangiitis)[272-274], (2) atheroembolism[275,276], (3) hypotension and shock[277-279].

While it is true that most patients have mild attacks of pancreatitis secondary to ischemia, fatal necrotizing pancreatitis is a rare occurrence[277].

TRAUMATIC CAUSES

Blunt or penetrating abdominal injuries can cause pancreatitis although it is incredibly rare given the retroperitoneal location of the gland[280]. Types of trauma that cause pancreatitis can range from a mild contusion, severe crush injury, or transection of the gland[280].

Post ERCP pancreatitis remains the commonest severe complication of ERCP found to occur in 5%-7% of patients in a recent review[281]. It may be possible that prophylactic stenting of the pancreatic duct in selective cases and minimally traumatic cannulation techniques may prevent some cases[281] and indeed this has been shown to be cost effective in high risk patients[282]. Octreotide infusion does not prevent ERCP-induced pancreatitis or affect serum amylase levels[283]. Likewise, transdermal glyceryl trinitrate did not improve the rate of success in ERCP cannulation or prevent post-ERCP pancreatitis in either average or high-risk patient groups[284]. Allopurinol at high doses has been shown in a prospective randomized trial to lower the risk of post-ERCP pancreatitis[285] but this study requires further verification as other studies have shown no benefit[285,286]. Risk factors for post-ERCP pancreatitis have been well described[287].

AUTOIMMUNE CAUSES

Autoimmune pancreatitis is a more recently described type of chronic pancreatitis characterized by an autoimmune inflammatory process in which prominent lymphoplasmacytic infiltration with associated fibrosis of the pancreas causes organ dysfunction[288-290]. The reported prevalence of autoimmune pancreatitis is between 5 and 6% of all patients with chronic pancreatitis[291]. A series from the United States shows that 11% of patients (27 of 254) with chronic pancreatitis received a diagnosis of autoimmune pancreatitis based on histological findings[292].

Immunologic abnormalities including hypergammaglobulinemia, elevated serum IgG4 levels, and the presence of autoantibodies against carbonic anhydrase and lactoferrin are important markers of the disease[288]. In particular, autoantibodies against lactoferrin and carbonic anhydrase Ⅱ have been identified as potential serologic markers of autoimmune pancreatitis[293,294]. The finding of increased serum IgG levels or the presence of autoantibodies is supportive of the diagnosis, whereas an elevated serum IgG4 level is nearly diagnostic[288].

CP has also been found to be in association with Sjogren's syndrome, primary biliary cirrhosis, and renal tubular acidosis[295,296]. The diagnosis is usually based on clinical suspicion and serum autoantibody to a pancreatic antigen previously discussed. Inflammatory bowel disease is also occasionally associated with autoimmune pancreatitis[297].

Differentiating the focal form of autoimmune pancreatitis rather than pancreatic carcinoma can be very difficult on the basis of CT imaging only[288]. Diffuse pancreatic-ductal narrowing is highly diagnostic of autoimmune pancreatitis[288,289,291]. There are also nonspecific endoscopic findings in the stomach or colon in patients with autoimmune pancreatitis, foci of slightly pale, thickened mucosa with loss of visible vascular pattern were observed in some cases[298]. The role for MRCP is at this time undefined[288].

EUS is a key tool in the diagnosis of autoimmune pancreatitis and its differentiation from other pancreatic diseases. The most common finding on endoscopic ultrasonography is diffuse or focal pancreatic enlargement along with a diffusely hypoechoic parenchyma, similar to findings on transabdominal ultrasonography[299,300].

The use of corticosteroid therapy is not mandatory in autoimmune pancreatitis, as there are reports of the spontaneous resolution of a pancreatic mass, stricture, and jaundice[301,302]. When steroids are given the response is often dramatic and can be monitored *via* clinical, laboratory and radiological parameters[303-306].

MISCELLANEOUS CAUSES

Recent reports of a new disease known as hyper IgG4 disease has been linked to IP[307] but more data is required before further comment. It is unclear if this is an entirely separate entity from autoimmune pancreatitis.

In renal transplant cases pancreatitis can occur as a result of the procedure itself[308], immunosuppressant medications (see above 'Medications'), opportunistic infections[309] or through allograft pancreatitis[310].

CHRONIC PANCREATITIS

The aforementioned etiologies of IP can all theoretically lead to CP. The diagnosis is best made after considering the results of ERCP, pancreatic function tests, and EUS[24].

It has been suggested that pancreatic function testing may help establish the diagnosis of CP at an earlier stage[311]. It appears based on recent evidence that EUS may be the most sensitive test[311,312] for CP diagnosis with the caveat of false positives[313].

Mortality rates for CP are 3-4 times greater than in controls[314,315]. Pancreatitis in CP accounts for 20 percent of mortality but mortality is usually from non-pancreatic causes[314,315]. CP carries with it many complications such as pancreatic duct strictures, stones, pseudocyst, fistulas, pseudoaneurysm, or ascites[316-320].

TRUE IDIOPATHIC PANCREATITIS

In spite of extensive systematic investigations and exhaustive efforts, there will be patients with true IP (TIP). Recommendations are difficult to make given the heterogeneity of studies that have evaluated this problem. Generally there are 4 therapies that might be applicable in TIP taking into account that TIP most likely represents a group of heterogeneous disorders: antioxidants, ursodeoxycholic acid, pancreatic enzymes, and somatostatin or its analogue octreotide.

Antioxidants (e.g., vitamin C, and E, beta carotene) have been shown to reduce the pain involved in IP[321]. It is postulated that patients with AP or CP may have a deficiency in antioxidants either locally within the pancreatic parenchyma or systemically[322]. A cocktail of antioxidants including 600 μg of selenium, 9000 IU of β-carotene, 0.54 g of vitamin C, 270 IU of vitamin E, and 2 g of methionine daily[321] was shown to have a statistically significant benefit in reducing attacks of pancreatitis. It is again stressed that these trials have limited power since the above study evaluated only 28 patients[321].

In patients who continue to have attacks of pancreatitis despite having cholecystectomy or endoscopic sphincterotomy, or patients with contraindications to surgical and endoscopic treatment, maintenance therapy with ursodeoxycholic acid has also been suggested with some benefit[31,323].

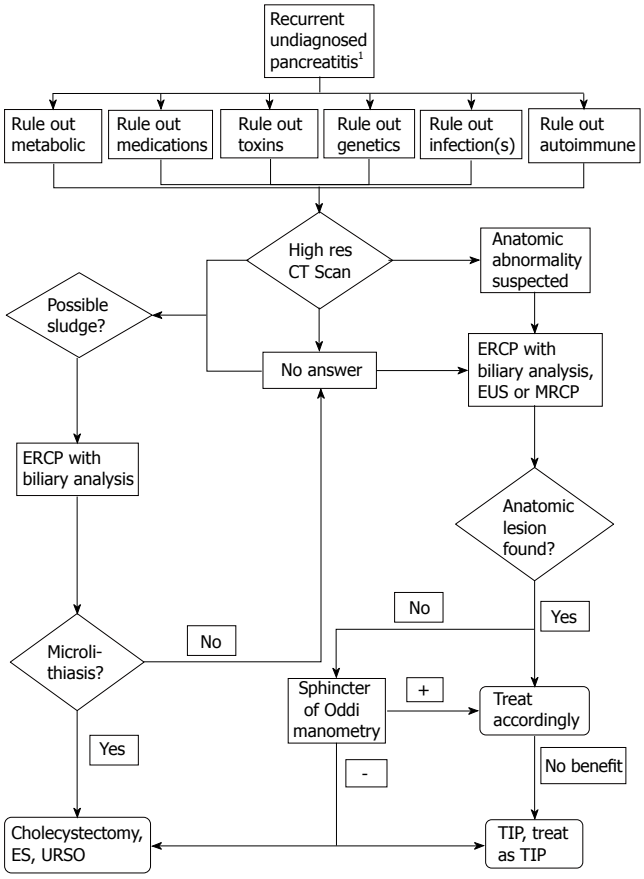

Figure 1 [1]To arrive at the label of recurrent undiagnosed pancreatitis, a history, physical exam, routine laboratory investigations, chest radiograph, abdominal ultrasound, and or computed tomography must fail to find the etiology of pancreatitis. Although sludge may be picked up on transabdominal ultrasound, the low sensitivity precludes exclusion of diagnosis of microlithiasis. ES: Endoscopic sphincterotomy; TIP: True idiopathic pancreatitis; EUS: Endoscopic ultrasound; CT: Computed tomography; URSO: Ursodeoxycholic acid.

Pancreatic enzyme therapy has recently been reviewed and the efficacy in IP or recurrent AP or CP is small[324]. However, given the low risk of enzyme therapy it has been suggested as a therapeutic trial in treating CP and IP[325,326].

Somatostatin or its analogue octreotide has been postulated to reduce pancreatic secretion and thereby be of benefit in the treatment of relapsing pancreatitis. This therapy entails either a continuous infusion or frequent injections in the past[327]. A 1 mo depot injection has recently become available and may make this therapy more attractive but data is limited with existing data on octreotide and somatostatin focused on altering outcomes during an index hospitalization of severe pancreatitis rather than preventing subsequent attacks[327].

APPROACH TO RECURRENT IP

The authors of this review propose the following systematic approach for patients who have had more than one attack of IP. The following is not validated and is meant to be only used as a guide. For specific details please refer to the aforementioned sections (Figure 1).

CONCLUSION

True IP is declining as knowledge and technology advances. IP has been found now to represent a myriad of etiologies that have been elucidated with the advancement of laboratory and endoscopic studies. It is thought that a thorough workup of these cases should reveal an etiology in up to 80% of cases. If genetic screening is applied it is suspected the etiologies may be explained in a much higher percentage of cases. There are still many controversies surrounding some of the IP etiologies and full consensus agreement is lacking in many areas. This review comprehensively outlined the latest evidence in the etiology, pathogenesis, diagnosis, and treatment strategies. It is felt that establishing a diagnosis is key, for it has the potential to direct management. It is recognized, however, that for many of the disorders (particularly genetic abnormalities) there are limited therapies. Elucidating all the causes of IP is a challenge that needs to be faced so that patients can avoid unnecessary morbidity and mortality from subsequent invasive testing.

The treating physician should perform a detailed history to rule out medication, metabolic, and toxin related etiologies. Moreover a detailed history should raise the possibility of genetic associations and causes as well as infectious etiologies so that further testing can be best directed. Celiac disease, vascular disease, and autoimmune causes of pancreatitis should be considered in evaluating the optimal approach to IP.

The most common causes of IP include microlithiasis and biliary sludge, sphincter of Oddi Dysfunction, and anatomic abnormalities. When there is any risk or suggestion of malignancy either as a cause or as an association of the etiology, as in choledochoceles, appropriate management including the necessary diagnostic workup and consideration of surgical excision when the diagnosis is made needs to be considered. In the aforementioned causes it is clear that both imaging techniques such as MRCP, EUS, high resolution CT, and interventional techniques as ERCP play their respective roles.

Indeed with further research additional causes of IP and associations of IP will be revealed. Even with exhaustive efforts and considering all the etiologies in this article there will still be a few patients who will continue to have true IP. In these patients non specific therapy including pain control is often unfortunately the only option. Certainly further advances in pancreatitis will be welcome.

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) is a useful tool in the evaluation and management of acute pancreatitis. This review will focus on the role of ERCP in specific causes of acute pancreatitis, including microlithiasis and gallstone disease, pancreas divisum, Sphincter of Oddi dysfunction, tumors of the pancreaticobiliary tract, pancreatic pseudocysts, and pancreatic duct injury. Indications for endoscopic techniques such as biliary and pancreatic sphincterotomy, stenting, stricture dilation, treatment of duct leaks, drainage of fluid collections and stone extraction will also be discussed in this review. With the advent of less invasive and safer diagnostic modalities including endoscopic ultrasound (EUS) and magnetic retrograde cholangiopancreatography (MRCP), ERCP is appropriately becoming a therapeutic rather than diagnostic tool in the management of acute pancreatitis and its complications.

Key words: Endoscopic retrograde cholangiopancreatography; Acute pancreatitis

INTRODUCTION

Most pancreatologists accept the 1992 Atlanta Symposium definition of acute pancreatitis as an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems[1]. It is recognized that the underlying process is reversible and the gland returns to normal once the injury resolves. The annual incidence is estimated to be 17 per 100 000 in the United States[2]. Over 333 000 hospital admissions and 911 000 physician visits in the United States each year are due to acute pancreatitis[2]. The most common causes in US adults are gallstone disease and excessive alcohol use, although clinically detectable pancreatitis never develops in most persons with these risk factors[3].

The pathogenesis of acute pancreatitis involves the inappropriate activation of trypsinogen to trypsin in excessive quantities to overwhelm the mechanisms of elimination within the pancreas. Activation of these digestive enzymes causes pancreatic injury and an intense inflammatory response which results in microcirculatory injury, leukocyte chemoattraction, release of cytokines and oxidative stress. The release of pancreatic enzymes damages the vascular endothelium, the interstitium and acinar cells. Microcirculatory changes and progressive ischemia occur, which increase vascular permeability and leads to edema of the gland, commonly referred to as interstitial pancreatitis. Translocation of bacteria from the gut into the systemic circulation may occur as a consequence of gut ischemia secondary to hypovolemia and arteriovenous shunting. Severe pancreatitis may ensue, leading to life-threatening complications such as acute respiratory distress syndrome, renal failure, shock, metabolic derangements, and multi-organ failure. Approximately 20% of patients with acute pancreatitis will have a severe course with a 10% to 30% mortality rate[3]. Mortality related to acute pancreatitis decreased substantially from as high as 25%-30% in the 1970s to current rates since the early 1990s; however, since then, the mortality has remained relatively constant[3,4]. Initial improvement appears to have been related to improvements in intensive care treatment rather than a better understanding of the natural history of disease or improved intervention.

Determining the etiology of acute pancreatitis can be challenging in those who do not give a significant history of alcohol use and in those who do not exhibit obvious gallstone disease. In about 20% to 40% of cases, no defined cause may be found and patients are subsequently labeled as having idiopathic acute pancreatitis[5]. Several causes for pancreatitis may be missed in the initial workup using the conventional imaging techniques of

trans-abdominal ultrasound and/or CT scan and routine laboratory tests. Other modalities, including more advanced imaging techniques and endoscopic procedures, are often considered when working up the cause of unexplained acute pancreatitis. Although used primarily for diagnostic and therapeutic purposes in biliary disorders, endoscopic retrograde cholangiopancreatography (ERCP) has evolved as a diagnostic and therapeutic option in evaluating several pancreatic diseases[6].

CLINICAL USE OF ERCP IN ACUTE PANCREATITIS

When clear clinical, laboratory and imaging evidence for persistent biliary obstruction is present, patients should directly proceed to ERCP. As with all invasive procedures, the risk of procedure-related complications must be weighed against the potential benefit of the procedure. ERCP has a reported complication rate of 5% to 7%, with the main complications including pancreatitis, hemorrhage, perforation, cholangitis, cardiopulmonary complications and, rarely, death. Patient-related factors, such as underlying co-morbidities, age, and need for invasive evaluation, are considerable determinants of complication risk in any endoscopic procedures, especially those that carry a higher possibility for complications such as ERCP. Because of the potential morbidity and mortality associated with ERCP and the improvements in other less-invasive imaging modalities, the role of ERCP has become more well-defined in the diagnosis and treatment acute pancreatitis.

In the 30% of patients who may have no identifiable cause for acute pancreatitis with traditional non-invasive methods, ERCP with empiric biliary sphincterotomy is often performed without a more thorough evaluation for cause[7]. Freeman *et al* evaluated this concern and determined the risk of post-ERCP pancreatitis to be as high as 20% with a 3%-4% risk for severe pancreatitis. Though tempting, empiric sphincterotomy appears to have about an equal chance of causing complications as treating the underlying cause of the acute pancreatitis and, therefore, is not advocated[6,8]. Determining the etiology of acute pancreatitis is important, as it helps direct therapy, limits further unnecessary evaluation, and may improve a patient's long term prognosis. Advanced endoscopic procedures, including ERCP, are emerging as valuable tools in the evaluation of this challenging group. The role of ERCP in the diagnostic and therapeutic evaluation of acute pancreatitis will be discussed in this review.

MICROLITHIASIS

Microlithiasis or biliary sludge as a causative etiology for acute pancreatitis remains controversial and not well understood. Several studies have demonstrated the presence of biliary sludge in as many as 75% of patients with unexplained acute pancreatitis[5]. Microlithiasis is a viscous precipitate containing mucin, cholesterol and calcium bilirubinate which can obstruct the pancreatic duct. Ultrasonography has a sensitivity of only about 55% in detecting microlithiasis and does not allow for analysis of the chemical composition of bile[9]. Bile analysis with microscopic examination is considered the gold standard for diagnosis. Bile can be obtained directly while cannulating the bile duct during ERCP or following CCK stimulation on EGD. ERCP with bile aspiration from the common bile duct (CBD) has a reported sensitivity of 83% in detecting microlithiasis[7]. It is recognized, however, that gallbladder bile is preferred over ductal bile for examination, as transit through the hepatic and common ducts can be too rapid to allow formation of crystals large enough to detect on microscopy. Ko *et al*[9] propose the criteria of 2 or more crystals per 100X field or more than 4 crystals per sample as a positive result. It is also recommended to collect bile samples prior to contrast injection to avoid the formation of "pseudomicrolithiasis" from contrast precipitates. Using a guidewire under fluoroscopy with aspiration to clear the collection catheter prior to obtaining the bile sample can minimize contrast contamination and diminish this artifact. The specimen should be centrifuged immediately and examined under polarized microscopy to evaluate for crystals. If specimens are not examined immediately, crystals can precipitate and cause a false positive result. ERCP should be performed after complete recovery from acute pancreatitis, usually 4 to 6 wk after presentation. If microlithiasis is detected, patients should be considered for cholecystectomy or biliary sphincterotomy depending on surgical risk. In post- cholecystectomy patients, bile analysis need not be performed.

PANCREAS DIVISUM

Pancreas divisum (PD) is the most common congenital anomaly of the pancreas and occurs in approximately 7%-10% of the population; however, less than 5% of those with PD are symptomatic[7]. PD is a small or absent ventral pancreatic duct that fails to fuse with the dorsal duct during embryologic development, resulting in a lack of communication between the ducts (Figure 1A and B). This lack of communication leads to a prominent dorsal duct that drains entirely through the minor papilla. Incomplete PD is the partial communication between the ventral and dorsal ducts; however, incomplete PD functions similar to that of complete PD. The divided drainage routes may result in a relative obstruction of flow through the minor papilla, leading to acute pancreatitis. Some controversy exists about recognizing PD as a causative etiology for pancreatitis. Regardless of the debate, several studies have demonstrated that dorsal duct outflow obstruction can lead to both acute and chronic pancreatitis[10,11]. It has been reported that patients with divisum have an increased prevalence of pancreatitis. Parenchymal changes consistent with chronic pancreatitis isolated to the dorsal pancreas have been observed on autopsy studies[6].

ERCP plays a limited role in diagnosis of PD given the less invasive and reasonably accurate modalities of MRCP and EUS. ERCP can, however, offer a therapeutic option in those who experience recurrent acute pancreatitis. Several studies have shown that endoscopic intervention, including sphincterotomy with or without stenting of the minor

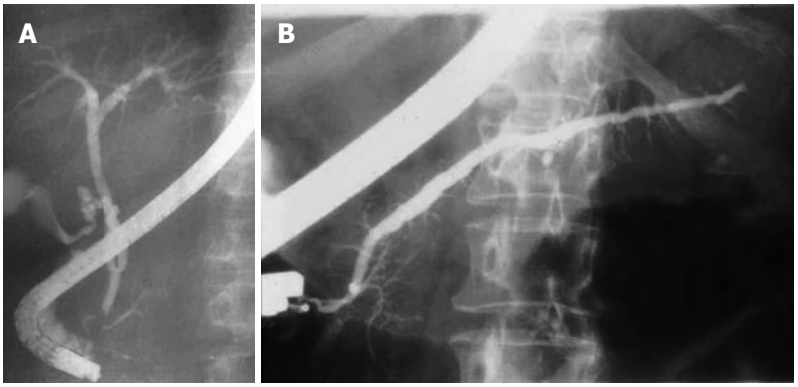

Figure 1 **A**: Pancreas divisum with filling of the small ventral duct; **B**: Pancreas divisum with filling of dorsal duct through the minor orifice.

papilla, has resulted in decreased recurrence rates of acute pancreatitis and improved outcomes in patients with PD (Figure 2A-C)[12-17]. In the only randomized controlled trial evaluating endoscopic therapy in PD, Lans *et al*[18] observed an improvement in 90% of treated patients versus only 11% of controls over a mean of 12 mo follow-up. A retrospective study by Gerke *et al*[19] observed that 60% of patients who underwent minor papillotomy reported immediate improvement, but sustained results were seen in only half of those patients at a mean of 29 mo follow-up. Patients with well-defined bouts of pancreatitis appeared to benefit over those solely with chronic abdominal pain without objective evidence of pancreatitis. It is recognized that pain secondary to PD and chronic abdominal pain with incidentally found PD is difficult to differentiate. In order to distinguish between these two groups, objective criteria such as recurrent pain with ductal dilatation and elevations in pancreatic enzymes can be useful. Secretin stimulation imaging using either ultrasonography or MRI has proven promising as these modalities can give clues to the functionality of the pancreas. The study by Gerke *et al* underscores the importance of defining patients who may benefit from endoscopic therapy and reveals the difficulty in achieving long-term results in patients with PD.

The role of using pancreatic stents in PD is limited to the prevention of post-ERCP pancreatitis and has demonstrated little efficacy in treating PD in comparison to sphincterotomy. The long-term use of pancreatic stents in PD may induce duct strictures or irregularities. Most experts recommend only the short-term use of pancreatic stents (less than 2 wk) in patients without pre-existing duct strictures. Size 3 or 4 French, non-phlanged stents, without an internal flap are recommended to decrease the risk of post-ERCP pancreatitis (Figure 3). These stents can pass spontaneously, therefore, obviating the need for a repeat procedure for stent removal. Note that the use of size 3 French stents requires a separate, smaller guidewire which may increase the overall cost of the procedure.

SPHINCTER OF ODDI DYSFUNCTION

Sphincter of Oddi dysfunction (SOD) as an etiology for acute pancreatitis has been questioned by many due to the lack of concrete pathologic findings[20]. SOD refers to an abnormality in sphincter of Oddi contractility resulting in intermittent biliary and pancreatic duct obstruction. It has been estimated that SOD accounts for approximately 1/3rd of those with recurrent unexplained pancreatitis.

Management depends upon the classification of SOD. A classification system similar to the Milwaukee Biliary Group Classification has been developed for pancreatic SOD (Table 1): type Ⅰ pancreatic SOD includes recurrent pancreatitis or pain suspected to be of pancreatic origin with elevated amylase and/or lipase up to 1.5 times upper limit of normal, a dilated pancreatic duct greater than 6 mm in the head and more than 5 mm in the body, and delayed emptying of greater than 9 min of the pancreatic duct. type Ⅱ SOD includes the presence of presumed pancreatic pain plus at least one additional factor defining type Ⅰ. type Ⅲ is defined by pain alone. Some experts have suggested that due to the high incidence of stone disease, patients suspected to have SOD with an intact gallbladder should undergo cholecystectomy as initial therapy before evaluation for sphincter dysfunction due to less risk involved in surgery compared with manometry. Our approach in patients with intact gallbladder, but no stone disease on standard imaging, is to perform endoscopic ultrasound (EUS) looking for undetected stones or biliary sludge. If EUS is unremarkable, then ERCP with bile analysis is

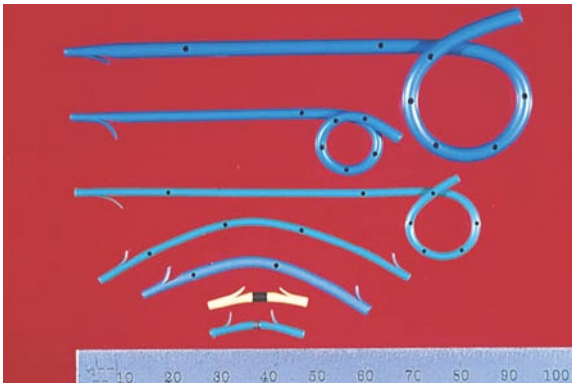

Figure 3 Various designs of pancreatic stents (with permission from Cook Endoscopy).

performed to evaluate for microlithiasis. If microlithiasis is not detected, we will proceed with sphincter of Oddi manometry during the same exam. In those who have previously had a cholecystectomy, dual sphincterotomy becomes the recommended treatment modality. A study by Gelrud *et al*[21] demonstrated significantly better outcomes when dual sphincterotomy was performed over a biliary sphincterotomy alone.

Management of types Ⅱ and Ⅲ disease has posed more of a treatment challenge to the clinician. Patients who meet type Ⅱ classification criteria should undergo sphincter of Oddi manometry (SOM). A resting basal pressure of > 40 mm Hg is the best predictor of response to endoscopic sphincterotomy, with up to 90% demonstrating clinical benefit in 4 years follow-up[20]. Studies advocate the measurement of both biliary and pancreatic sphincter pressures during ERCP, as differences in pressure may be detected if either duct is measured alone[22-25]. There is no role for ERCP without manometry in the evaluation of type Ⅱ SOD patients.

Traditional teaching has been that performing SOM increases the risk for pancreatitis[26]. However, more recently, it appears that performing any ERCP (with or without manometry) in the subset of patients at highest risk for SOD (typically young women with unexplained recurrent abdominal pain, normal anatomy, and normal serum bilirubin) increases the risk for pancreatitis[8,27,28]. Several randomized trials have proven a decreased risk of post-ERCP pancreatitis in this group of patients by performing prophylactic stent placement[29,30]. The NIH has recommended that diagnostic and therapeutic procedures in this select group of patients should be performed ONLY by endoscopist possessing expertise in this particular area because of the high rate of severe complications in this young, otherwise healthy population[20]. Because of this thought, the diagnosis and management of type Ⅲ disease is the most difficult. Invasive procedures should be delayed or avoided if possible. Trials of anticholinergics, antidepressants, nonspecific pain relievers and/or calcium channel blockers should precede invasive approaches. Diagnostic ERCP without manometry has no role in the assessment of type Ⅲ pancreatic SOD patients[20].

OCCULT TUMORS OF THE PANCREAS AND BILIARY TRACT

Approximately 30 000 new cases of pancreatic cancer and 7000 biliary tract cancers are diagnosed annually in the United States. Prognosis remains dismal with less than 20% survival at 1 year and a 5 years mortality rate of > 95%[31]. Infrequently, tumors of the pancreas and biliary tree may present as acute pancreatitis. ERCP has proven to be valuable in the diagnosis and treatment of ampullary tumors and intraductal papillary mucinous tumors (IPMT) of the pancreas, both conditions which may present with acute pancreatitis due to obstruction from the pancreatic duct. ERCP may be the best means for direct visualization of the ampullary and periampullary region and offers the capability of sampling through biopsy. In non-operative patients with obstructing ampullary tumors, palliation or possibly cure can be achieved with endoscopic snare ampullectomy and ablative thermal therapy. Post-procedure stent placement in this clinical scenario has been demonstrated to reduce the risk of post-procedure pancreatitis[6]. IPMT can be diagnosed on ERCP with the classic "fish eye" appearance of the dilated ampulla and mucin extruding from the orifice (Figure 4). In non-operative patients with IPMT, ERCP with stent placement and/or sphincterotomy may offer palliation by decreasing the risk of acute recurrent pancreatitis by minimizing mucin impaction in the pancreatic duct.

Peroral pancreatoscopy (PPS) is useful in cases of suspected IPMT by not only diagnosing but also localizing the tumor for planning surgical resection. PPS may also provide tissue sampling for histologic diagnosis[32].

Table 1 Sphincter of Oddi Dysfunction

Type Ⅰ
1 Typical biliary-pancreatic pain
2 Liver chemistries (total bilirubin, alkaline phosphatase, transaminases) ⩾ 1.5-2X ULN and/or pancreatic chemistries (amylase and/or lipase) ⩾ 1.5-2X ULN
3 Dilated common bile duct (⩾ 12 mm) or pancreatic duct (head ⩾ 6 mm, body ⩾ 5 mm) diameter
4 Prolonged biliary drainage (> 45 min) with patient in supine position or pancreatic drainage (> 9 min) with patient in the prone position
Type Ⅱ
1 Typical biliary-pancreatic pain
2 Positive findings for one or two items (2, 3, or 4) from type Ⅰ
Type Ⅲ
1 Typical biliary-pancreatic pain and no other abnormalities

Modified from Sherman *et al*[25].

GALLSTONES

Gallstones account for nearly half of the cases of acute pancreatitis in the Western world. More than 70% of patients will spontaneously pass the culprit stone into the duodenum, however, approximately 3% to 7% may go on to develop acute pancreatitis[33]. Because differentiating patients who may have an uncomplicated course due to a transiently impacted gallstone from those who may

Figure 4 Classic "fish eye" appearance of IPMT with mucin draining from minor ampulla.

progress on to severe acute pancreatitis with necrosis and sepsis is difficult, several studies have evaluated scoring systems and variables to predict severity[34-36]. Urgent endoscopy is generally reserved for patients who fail to demonstrate liver enzyme improvement within 24 to 48 h of admission, especially in total bilirubin by hospital d 2[34]; those demonstrating persistent choledocholithiasis on imaging; and those with clinical cholangitis. Fan *et al*[37] evaluated the role of early ERCP in patients with acute biliary pancreatitis prior to the onset of complications, regardless of mild or severe presentation. Within 24 h of presentation, patients were randomized to early ERCP versus conservative treatment with selective ERCP. A significant reduction in progression to biliary sepsis was seen in the early ERCP patients. Interestingly, however, the incidence of local and systemic complications was not significantly different, which suggests that removal of the impacted stone may not reverse the damage already occurring in the pancreas during the first hours or days of the illness. Other studies have advocated early intervention within 72 h after admission if persistent CBD stones were suspected[38,39].

Patients who recover from gallstone pancreatitis carry a 29% to 67% risk of recurrent pancreatitis if subsequent cholecystectomy and/or sphincterotomy are not performed[6,40]. In mild to moderate gallstone pancreatitis, ERCP is rarely required before cholecystectomy unless cholangitis or clear evidence of persistent choledocholithiasis by imaging and laboratory data is observed. Chang *et al*[34] evaluated patients with acute gallstone pancreatitis who were suspected of persistent choledocholithiasis. Patients were randomized to either pre-operative ERCP or selective post-operative ERCP if choledocholithiasis was found intraoperatively. Hospital stay was significantly longer in the routine pre-operative ERCP group (11.7 d *vs* 9.0 d). In the post-operative group, ERCP was necessary in only 24% of patients, suggesting that the diagnostic and therapeutic yield of pre-operative ERCP is low. These findings are consistent with the NIH consensus statement recommending that patients suspected of having choledocholithiasis should undergo an operative cholangiogram at the time of cholecystectomy. Operative cholangiogram is efficient and preferable when surgical proficiency in this technique is available. Otherwise, post-operative ERCP is indicated for patients who demonstrate retained stones. In patients who have had a prior cholecystectomy and have a low probability of common bile duct stones, diagnostic evaluation for choledocholithiasis should be performed with less-invasive modalities including MRCP or EUS. In the clinical scenario where the potential for retained common bile duct stones is substantial, ERCP and, when indicated, sphincterotomy with stone removal is the preferred diagnostic and therapeutic option[20]. ERCP with sphincterotomy is the preferred therapeutic modality if cholangitis from retained common bile duct stones is present. Patients should receive close medical care and treatment with IV fluid resuscitation, hemodynamic monitoring, and intravenous antibiotic therapy. Patients who fail to improve should undergo ERCP with sphincterotomy as soon as possible. Those who do improve still require urgent ERCP with sphincterotomy, usually within 24 h, to relieve the obstruction[20].

Recurrence of pancreatitis after ERCP with sphincterotomy for gallstone pancreatitis is rare. Cholecystectomy versus endoscopic sphincterotomy for the treatment of recurrent gallstone pancreatitis remains a controversial topic. Several experts advocate that cholecystectomy should only be considered if there are overt manifestations of gallbladder disease (e.g., biliary pain, cholecystitis, cystic duct obstruction), but not for prevention of recurrent gallstone pancreatitis. Studies have demonstrated that ERCP can be an effective therapeutic option for prevention of recurrent gallstone pancreatitis[41]. Siegel *et al*[42] demonstrate that ERCP with sphincterotomy can be performed safely in both the elective and urgent setting in patients who are otherwise not ideal operative candidates, such as the aged or younger patients at risk for surgical complications. Our approach is to proceed with cholecystectomy if the patient is a good surgical candidate.

PANCREATIC PSEUDOCYSTS AND FLUID COLLECTIONS

Pancreatic pseudocysts occur mainly as a result of acute pancreatitis, pancreatic trauma or chronic pancreatitis. Fluid usually contains a high concentration of pancreatic enzymes and variable amount of tissue debris. Most pseudocysts are sterile. ERCP has a reported success rate of 65%-95% in treatment of pancreatic pseudocysts, with a complication rate of 10%-35%. Drainage of fluid collections is generally reserved for a later date, usually 4-6 wk after the acute pancreatitis episode resolves.

PANCREATIC DUCT INJURY

Pancreatic duct disruptions may result from acute and chronic pancreatitis, or they may be the primary cause for pancreatitis in cases of trauma or surgical injury. ERCP can be successful in detecting the presence of contrast extravasation from the duct, localizing the suspected site of injury, and treating the leak or fistula with stent or drain placement.

Approximately 37%-67% of patients with acute pancreatitis have pancreatic duct injury, suggesting that acute duct injury can be a relatively common finding[43,44]. Lau *et al*[43] observed that the presence of a leak was associated with a higher incidence of necrosis and prolonged length of stay. ERCP in this patient population was determined to be safe and not associated with

increased mortality, prolonged hospital stay or need for necrosectomy provided that pancreatic duct leaks were detected and immediately treated.

ERCP to evaluate for pancreatic duct disruption in acute pancreatitis is controversial and should be reserved for investigational studies. A multidisciplinary approach is advocated when considering pancreatic stenting in the setting of acute necrosis, as the procedure carries a risk of introducing infection into an otherwise sterile environment. In patients with evidence of pancreatic duct injury or leak who are not responding to conservative treatment, ERCP should be considered.

The use of ERCP in the treatment of acute pancreatitis from traumatic pancreatic duct injury has also been evaluated in both the adult and pediatric patient population. Several studies have demonstrated that ERCP with transpapillary stent placement is an effective technique in closing pancreatic duct disruption[45-47]. Successful therapy, however, appears to be associated with positioning of the stent to bridge the disruption and leak, not simply across the papilla as in biliary leaks[48,49]. Several studies in children have also reported successful results in treating traumatic duct injury, however the authors call attention to the risk of iatrogenic ductitis when stenting smaller pancreatic ducts, especially those in children[50,51].

UNUSUAL CAUSES OF ACUTE PANCREATITIS

Type Ⅲ choledochal cysts are dilations of the joined portion of the pancreaticobiliary ducts. These cysts can be large enough to obstruct the pancreatic duct, which may result in recurrent acute pancreatitis[52,53]. Biliary sphincterotomy has been suggested as treatment; however, some patients may require a dual sphincterotomy for long term benefit.

Annular pancreas, anomalous pancreaticobiliary junction, and pancreatic intraductal parasites have all been reported as causes for acute and recurrent acute pancreatitis. ERCP can occasionally offer benefit in treatment of these rare conditions[6].

CONCLUSION

ERCP is a useful tool in the evaluation and management of acute pancreatitis. The main role of ERCP in acute pancreatitis is the diagnosis and treatment of biliary tract stone disease and other potential causes of pancreatic duct obstruction including sphincter dysfunction or anomalies such as pancreas divisum. With the advent of less-invasive and safer diagnostic modalities, ERCP is appropriately becoming a therapeutic tool in the management of acute pancreatitis and its complications.

Abstract

The close proximity of the endoscopic ultrasound probe to the pancreas results in superior spatial resolution compared to CT scan and MRI. In addition, endoscopic ultrasound (EUS) is a minimally invasive procedure that does not share the relatively high complication rate of ERCP. Due to these advantages, EUS has evolved into an important technique to assess pancreatobiliary disease. This review will discuss the role of EUS in patients with pancreatitis. The indications can be divided into acute pancreatitis and chronic pancreatitis. In acute pancreatitis, EUS is used to determine the etiology; in suspected chronic pancreatitis it is helpful to establish the diagnosis. Lastly, this review will discuss biliary pancreatitis with suspicion for persistent choledocholithiasis.

Key words: Idiopathic pancreatitis; Acute pancreatitis; Chronic pancreatitis; Endoscopic ultrasound; Endosonography; Pancreas divisum; Cholelithiasis; Microlithiasis; Choledocholithiasis; Biliary pancreatitis

INTRODUCTION

Overlying intestinal gas and the retroperitoneal location of the pancreas distant from the abdominal wall can impair the visualization of this organ with trans-abdominal ultrasound. This problem has been overcome by integrating the ultrasound probe into an endoscope in order to place it directly into the gastric and duodenal lumen. The close proximity of the endoscopic ultrasound probe to the pancreas results in high spatial resolution that is superior to that of Computer Tomography (CT) and magnetic resonance imaging (MRI). In addition, endoscopic ultrasound (EUS) is a minimally invasive procedure that does not share the relatively high complication rate of endoscopic retrograde cholangiopancreatography (ERCP). Due to these advantages, EUS has evolved into an important technique to assess pancreatobiliary disease.

This review will discuss the role of EUS in patients with pancreatitis. The indications can be divided into acute pancreatitis and chronic pancreatitis. In acute pancreatitis, EUS is used to determine the etiology; in suspected chronic pancreatitis it is helpful to establish the diagnosis. Another indication that will be discussed is biliary pancreatitis with suspicion for persistent choledocholithiasis.

ACUTE IDIOPHATHIC PANCREATITIS

The diagnosis of acute idiopathic pancreatitis (AIP) is applied when an etiology cannot be determined after the initial evaluation that includes a thorough history and physical exam, laboratory evaluation and abdominal ultrasound or CT[1-4]. In-depth evaluation of AIP using EUS often yields the diagnosis of microlithiasis, pancreatic divisum, chronic pancreatitis[1,5-7] or even neoplasm[1,4].

Occult gallstones and microlithiasis

A substantial number of patients with AIP and unexplained biliary pain turn out to have biliary sludge or small gallstones that have gone undetected by abdominal ultrasound (US) or CT. The term 'biliary microlithiasis' was coined to describe gallstones of < 3 mm in diameter[8-10]. Although sonographic characteristics of cholelithiasis do not differ between EUS and trans-abdominal ultrasound, EUS is more sensitive in detecting gallstones[11] due to the proximity of the endoscope tip to the gallbladder. Small gallbladder stones present as bright floating foci. Larger stones have posterior shadowing. Sludge presents as hyperechoic content within the gallbladder or bile duct (Figures 1 and 2).

The reported incidence of occult gallstones in patients with AIP varies widely. It ranges from 10%-73%[12-15]. Gallstones remain the most common cause of pancreatitis in patients with intact gallbladder. Therefore, it is

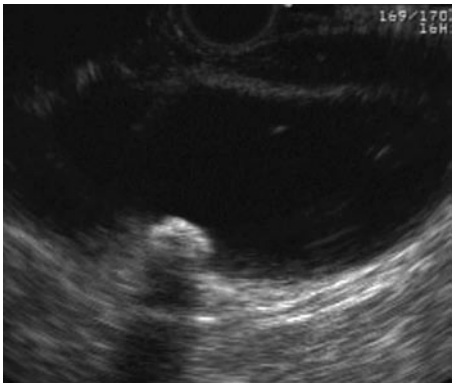

Figure 1 Linear EUS of gallbladder with shadowing stone.

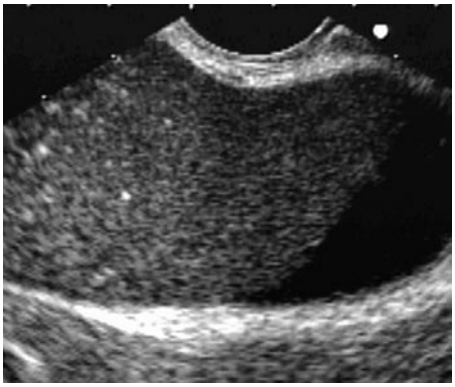

Figure 2 Linear EUS of gallbladder with sludge, and bright shadowing foci representing small stones.

commonly believed that the finding of microlithiasis explains the etiology of the pancreatitis. This has recently been challenged. In a study by Garg *et al*. Seventy-five patients with AIP were studied with duodenal bile microscopy and EUS. Initially, the cause of the recurrent pancreatitis was attributed to biliary microlithiasis in 10 of 75 patients. Eight of these 10 patients underwent cholecystectomy or endoscopic sphincterotomy yet continued to have recurrent pancreatitis flares[16] which implies that gallstones or biliary crystals were innocent bystanders in these patients. In contrast, other studies have demonstrated response to cholecystectomy[5,17], sphincterotomy[11] or ursodeoxycholic acid (UDCA)[10] in patients with microlithiasis suggesting a causal relationship.

Liu *et al* prospectively evaluated 89 consecutive patients who presented with symptoms of acute pancreatitis with trans-abdominal ultrasound, CT, or both. ERCP was performed in all patients with confirmed or suspected biliary pancreatitis. EUS was performed in patients suspected of having idiopathic pancreatitis. Of the 18 patients classified as idiopathic pancreatitis who underwent EUS, 14 had stones that were between 1 and 9 mm in size which was confirmed by cholecystectomy. Three had concomitant choledocholithiasis confirmed by ERCP[17].

Another study retrospectively evaluated 31 patients with AIP who underwent EUS 2-3 wk after resolution of symptoms[5]. Five of 31 patients had microlithiasis diagnosed by EUS (n = 3), or by bile microscopy after EUS (n = 2). All 5 patients underwent cholecystectomy and remained asymptomatic during the follow-up period. Sludge was found on pathology examination in all 5 gallbladders. Gallstones or sludge were not diagnosed in any of the other 26 subjects during the follow-up period.

In summary, EUS is an effective modality in diagnosing microlithiasis and may strengthen the indication for a subsequent intervention. Treatment with cholecystectomy, endoscopic sphincterotomy or ursodeoxycholic acid may reduce recurrent attacks of pancreatitis[10,11]. However, it remains debatable how intensively we have to search for occult gallstones. Statistically, gallstones remain by far the likeliest cause of unexplained recurrent pancreatitis in patients with intact gallbladders. The morbidity of laparoscopic cholecystectomy is very low, and one could argue that this procedure is justified regardless of the findings of cross sectional imaging.

Pancreas divisum

Pancreas divisum is a common congenital malformation. The prevalence is estimated at 5%-10% in a Western population[18]. This abnormality is characterized by lack of connection between the dorsal and ventral pancreatic ducts due to incomplete fusion of the pancreatic buds during embryologic development. As a result, the ventral duct drains only a small portion of the pancreas *via* the major papilla, whereas the dorsal pancreatic duct drains the majority of the pancreas *via* the minor papilla. The small size of the minor papilla in relation to the drainage volume may lead to relative outflow obstruction. Since only a minority of patients with pancreas divisum becomes symptomatic, it has been suggested that symptomatic disease requires additional factors leading to minor papilla stenosis. Symptomatic patients present with recurrent acute pancreatitis, chronic pancreatitis, or chronic abdominal pain without evidence of pancreatitis. Pancreas divisum has been implicated in as much as 20% of patients with AIP[12]. Patients with discrete episodes of acute pancreatitis commonly improve after ERCP with minor papillotomy, whereas the results are less favorable for those with chronic pancreatitis or chronic abdominal pain[19] .

ERCP is the gold standard for the diagnosis of pancreas divisum but poses a risk of post procedure pancreatitis. Small series suggest that EUS enables a fairly reliable diagnosis of pancreas divisum and may therefore present an alternative to ERCP with minimal complication rate[5,7,20,21]. Different EUS-criteria have been used: Bhutani *et al* suggest that the absence of a "stack sign" may be useful in determining the diagnosis. The stack sign is obtained by positioning a radial echoendoscope in the long position with the transducer in the duodenal bulb. The balloon is then inflated and advanced snugly into the apex of the bulb. From this position, the bile duct and the pancreatic duct can be seen running parallel through the pancreatic head. In six patients with known pancreas divisum that underwent EUS, the stack sign was found in only two patients. Of the two patients with presence of a stack sign, one had a ventral duct that was markedly dilated, and the other patient had an unusually large ventral pancreas[20]. Tandon *et al* used different sonographic criteria. The authors required direct visualization of the dorsal duct coursing to the duodenal wall, and excluded patients with a sonographically visible ventral pancreatic duct. The authors feel that their criteria will exclude some

cases of pancreas divisum and many cases of "incomplete pancreas divisum," but may be more specific as compared to the absence of a stack sign[5]. Lai *et al* suggests that evaluation using a linear-array echoendoscope is possible. The main pancreatic duct can be followed continuously from the major papilla into the pancreatic body. The duct can be seen crossing a sonographic border between the ventral and dorsal pancreas. Absence of this feature suggests pancreas divisum. In the retrospective study, of the 78% who had adequate visualization of the pancreatic duct, sensitivity, specificity, positive and negative predictive values for EUS were 95%, 97%, 86%, and 99%, respectively[21].

Occult neoplasm

It has been estimated that pancreatic neoplasms cause pancreatitis at some point in the disease course in up to 7 percent of patients[22]; however, they are a rare differential diagnosis in patients with AIP.

Mujica *et al* surveyed 19 physicians regarding 45 patients who presented with acute pancreatitis prior to a diagnosis of a neoplasm. The patients had a mean number of 2 episodes of acute pancreatitis prior to the diagnosis of neoplasm. The mean time to diagnosis of the neoplasm after the initial episode was 34 wk. The majority of patients were diagnosed using conventional cross-sectional imaging, whereas only 3 patients in the series were diagnosed using EUS[22].

Albeit rare, it has been suggested that pancreatic malignancy should be suspected in patients with unexplained pancreatitis who are older than 40 years of age[23]. EUS is superior to CT in detecting small pancreatic neoplasms[24,25], however, inflammatory changes during a pancreatitis flare may decrease the image quality. Therefore, cross-sectional imaging and/or EUS should be repeated after the resolution of the acute attack.

Single episode of idiopathic pancreatitis

The utility of an evaluation with EUS after a single episode of unexplained pancreatitis is not well studied and remains unclear[4]. In a small series by Tandon *et al*, EUS found an etiology in 7 of 14 patients with a single episode of idiopathic pancreatitis (3 microlithiasis, 1 pancreas divisum, 3 alcoholic chronic pancreatitis). The diagnosis changed in only 1 patient[23] during the follow-up period. A series reported by Yusoff *et al* included 201 patients with a single episode of acute pancreatitis. A presumptive diagnosis was made after EUS in 31%; chronic pancreatitis and sludge were the most common diagnoses in those with a gallbladder, whereas chronic pancreatitis and pancreatic divisum were the most prevalent diagnoses in patients who had a prior cholecystectomy[6].

Although these studies suggest a high yield of EUS in patients with a single episode of unexplained pancreatitis, some skepticism remains. Only 20%-50% of patients will have recurrent symptoms[26] following the initial attack. Furthermore, it is difficult to be sure about the causal relationship of an abnormal EUS finding after a single episode of pancreatitis. Pancreas divisum, for example, is common in the general population, and may be a coincidental finding rather than the cause of the pancreatitis. Even microlithiasis may be a harmless bystander[16]. As discussed in detail in a later paragraph, the diagnosis of chronic pancreatitis with EUS is problematic due to lack of specificity in early stages. In our opinion, further studies are necessary before advocating EUS for every patient after a single episode of idiopathic pancreatitis.

Table 1 EUS criteria of chronic pancreatitis

Parenchymal criteria	Pancreatic ductal criteria
Hyperechoic foci	Dilation (4 mm in head, 3 mm in body, 2 mm in tail)
Hyperechoic strands	Irregularity
Lobularity	Hyperechoic duct margins
Heterogeneity	Visible branch ducts
Shadowing calcifications	Intraductal stones
Cysts	

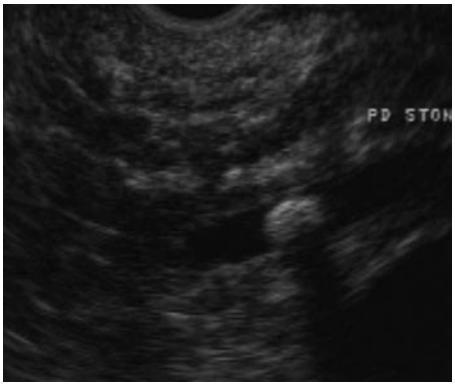

Figure 3 Linear EUS showing a shadowing stone within the pancreatic duct (PD STONE).

CHRONIC PANCREATITIS

The diagnosis of chronic pancreatitis (CP) can be challenging. The normal pancreas has a homogeneous fine granular echo-pattern (salt and pepper appearance), with a thin and regular main pancreatic duct. Certain sonographic changes can be observed in patients with CP. In an attempt to develop diagnostic scores for the EUS-diagnosis of chronic pancreatitis, "EUS criteria" have been developed. These were first described by Jones *et al*[27], and later refined by Wiersema *et al*[28]. The criteria can be divided into pancreatic duct findings and parenchymal findings. Parenchymal findings include hyperechoic foci, hyperechoic strands, lobularity, heterogeneity, shadowing calcifications, and cysts. Pancreatic duct findings include dilation (> 4 mm in the head, > 3 mm in the body, > 2 mm in the tail), irregularity, hyperechoic duct margins, and visible side-branches (Table 1, Figures 3-6). Multiple studies have evaluated the ability of EUS to diagnose CP using the above criteria. In a prospective, blinded study by Sahai *et al*, 126 patients who were admitted for abdominal pain underwent ERCP followed by EUS performed by a blinded operator. ERCP diagnosis of CP was based on Cambridge Criteria. EUS sensitivity was uniformly greater than 85% when the diagnosis of CP was based on the

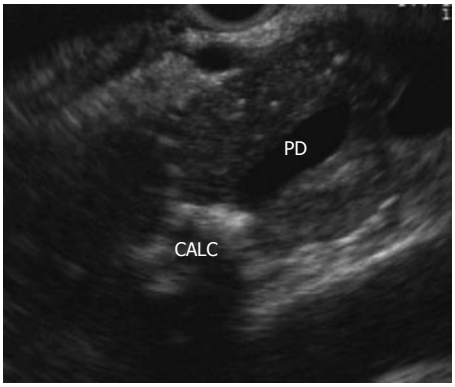

Figure 4 Linear trans-gastric EUS of the pancreas showing parenchymal calcifications (CALC) causing dilatation of the upstream pancreatic duct (PD).

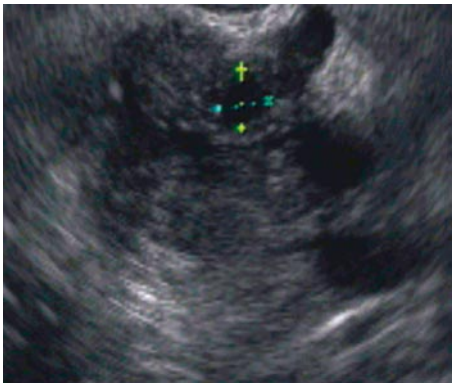

Figure 5 Linear trans-gastric EUS showing a small pancreatic cyst (labeled with measurement markers).

Figure 6 Linear EUS of pancreatic body with echogenic strands and lobularity.

presence of fewer than three criteria, but the specificity was less than 60%. Specificity increased as the number of criteria increased and was greater than 85% when more than five criteria were used. "Moderate to severe chronic pancreatitis" was unlikely (NPV > 85%) when fewer than three criteria were present[29]. When criteria that can easily be detected by other imaging methods (ductal dilation, calcification, and cysts) were excluded, the number of parenchymal EUS criteria remained an independent predictor of CP[29].

There are nuances that need to be considered when using the above score. Firstly, the role of ERCP as a diagnostic "gold-standard" is debatable[30]. Thus, it is difficult to determine whether EUS is over-diagnosing pancreatic disease based on minimal changes or whether ERCP is a false negative in those with abnormal EUS findings but normal ERCP. In a study by Kahl *et al*[31], 32 patients with abnormal EUS but normal initial pancreatogram developed findings of CP on repeat ERCP after a median follow-up of 18 mo suggesting that EUS findings may precede ERCP findings. The sensitivity to diagnose chronic pancreatitis was 100% for EUS, but only 81% for ERCP.

Another concern when using an EUS scoring system to diagnose CP is that not all criteria may be equally important. For example, the presence of intraductal calcifications or parenchymal calcifications alone may be diagnostic of CP even in the absence of other criteria[30]. Age related changes in the pancreas may also affect the diagnostic threshold. The pancreatic duct becomes progressively wider with a hyperechoic wall with increased age. Another aspect to consider is interobserver variability of different criteria. Wiersema *et al*[28] found excellent interobserver agreement among 3 experienced endosonographers reading individual criteria of CP. There was 88% interobserver agreement on presence of echogenic foci, 94% agreement on focally reduced echogenicity, 94% agreement on lobular gland pattern, 83% agreement on the main pancreatic duct echogenicity, and 94% agreement on main pancreatic duct irregularity. On the contrary, Wallace *et al*[32] could not confirm these optimistic results. EUS-exams on 33 patients with suspected CP and 12 controls without suspected CP were videotaped by 3 experienced endosonographers. Eleven expert endosonographers, who were blinded to clinical information, independently evaluated the examinations for the presence of CP and were asked to rank the importance of individual EUS features. There was moderately good interobserver agreement in the final diagnosis of CP (Kappa = 0.45).

Interobserver agreement was good for the individual criteria "ductal dilation" and "lobularity" but was poor for the other 7 criteria. The presence of stones was regarded as the most predictive feature of CP by all endosonographers, followed by visible side branches, cysts, lobularity, irregular main pancreatic duct, hyperechoic strands, main pancreatic duct dilation and main duct hyperechoic margins[32].

In our opinion, the early diagnosis of CP remains problematic due to lack of specificity and the presence of interobserver variability. The overall interpretation of the experienced endosonographer may be more valuable than a diagnosis based on a scoring system.

Only a few studies have evaluated the utility of biopsy in addition to EUS for the diagnosis of CP. One small study suggested that fine needle aspiration may improve the negative predictive value but not the specificity of EUS[33], however this study was limited by the small number of patients without chronic pancreatitis. Out of 37 patients, 31 had chronic pancreatitis. Only 4 patients had normal EUS findings, 3 without and one with chronic pancreatitis (negative predictive value of 75%). The negative predictive value was improved to 100% by FNA-cytology. In our opinion, it is difficult to draw conclusions based on such small numbers. Another study found that EUS-guided core biopsies with a Trucut needle was poor at diagnosing CP[34].

In conclusion, current data do not support a role of EUS-guided biopsies in the diagnosis of CP. In addition

to their questionable diagnostic value, pancreatic biopsies carry a potential risk of post-procedure pancreatitis.

CP makes the detection of pancreatic cancer more difficult. In a series of 282 patients with pancreatic mass (210 with adenocarcinoma), a lower sensitivity for EUS-FNA was observed in patients with CP (more than 4 EUS-criteria) than in those without CP (73.9% *vs* 91.3%). Patients with CP required more EUS-FNA passes to establish a diagnosis versus those without CP (5 *vs* 2)[35].

In summary, the diagnosis of CP remains challenging. EUS criteria have been established. Although these criteria are highly sensitive, they lack specificity in early stages. EUS is accurate in ruling out CP if no pancreatic abnormalities are found and in diagnosing CP if multiple criteria are present. However, a wide grey zone remains for patients with minimal to moderate findings.

CP decreases the sensitivity of EUS-FNA in the evaluation of pancreatic masses.

BILIARY PANCREATITIS AND CHOLEDOCHOLITHIASIS

In most patients with biliary pancreatitis, the causal gallstone has already passed. This makes it difficult to identify those patients in whom ERCP with sphincterotomy may be beneficial. In this context, EUS may provide a minimally invasive modality to diagnose or exclude choledocholithiasis. A review of five studies by Verma *et al* evaluating the efficacy of different modalities in diagnosing choledocholithiasis found an aggregated sensitivity of EUS of 0.93, a specificity of 0.96, a positive predictive value of 0.93, and a negative predictive value of 0.96. There was no statistical difference between MRCP and EUS[36]. In a study by Lui *et al*[37], 100 patients admitted for acute pancreatitis were evaluated with trans-abdominal ultrasound, EUS, and ERCP. EUS was found to be as sensitive as ERCP in the detection of choledocholithiasis, but with a lower complication rate.

Arguedas *et al* proposed a decision analysis model in evaluating biliary pancreatitis. Cost-effectiveness of strategies involving observation, intraoperative cholangiography, EUS, MRCP, and ERCP was evaluated. The results demonstrated that the choice of strategy is strongly influenced by the pretest probability of choledocholithiasis. If cost-minimization is the goal, observation with intraoperative cholangiography at the time of cholecystectomy is preferred in patients considered at "low risk" for choledocholithiasis. EUS is cost effective in patients at "intermediate risk" and ERCP is the preferable strategy in patients at "high-risk". There was no utility for MRCP in this model, as EUS was less costly[38]. Scheiman *et al*[39], also suggested that there is no role for MRCP for biliary pancreatitis in centers where EUS is available.

Sugiyama *et al* prospectively evaluated 35 patients with suspected acute biliary pancreatitis. All patients underwent trans-abdominal ultrasound, CT, EUS, and ERCP. The severity of pancreatitis was graded using APACHE Ⅱ scores. EUS and ERCP were significantly more sensitive in the detection of CBD stones than trans-abdominal ultrasound and CT. ERCP and EUS were equivalent in CBD stone detection. Based on the severity of the pancreatitis, 20 of 35 ERCP were determined to be potentially avoidable[38].

In summary, EUS is both sensitive and specific in the detection of common bile duct stones and has a considerably lower complication rate than ERCP. While patients with high likelihood of cholelithiasis should undergo ERCP directly, EUS may enable selective use of ERCP in those with intermediate likelihood[1,3,7,10,38,39].

CONCLUSION

EUS is helpful in the evaluating patients with AIP and in diagnosing CP. In patients with AIP, EUS enables the diagnosis of occult cholelithiasis, pancreas divisum, chronic pancreatitis or an occult neoplasm. While EUS may be more sensitive than ERCP in diagnosing CP, the specificity is limited in early stages. In biliary pancreatitis, EUS allows accurate detection of common bile duct stones and can be used to select patients who will benefit from ERCP.

Abstract

Autoimmune pancreatitis has emerged over the last 40 years from a proposed concept to a well established and recognized entity. As an efficient mimicker of pancreatic carcinoma, its early and appropriate recognition are crucial. With mounting understanding of its pathogenesis and natural history, significant advances have been made in the diagnosis of autoimmune pancreatitis. The characteristic laboratory features and imaging seen in autoimmune pancreatitis are reviewed along with some of the proposed diagnostic criteria and treatment algorithms.

Key words: Autoimmune pancreatitis; Chronic pancreatitis; Idiopathic pancreatitis; Sclerosing pancreatitis

INTRODUCTION

In a fashion similar to other solid organs, the pancreas has been linked with autoimmune disease in the form of "autoimmune pancreatitis". The concept was originally postulated by Sarles *et al*[1] over 40 years ago, when non-alcoholic pancreatitis was associated with hypergammaglobulinemia. However, only in the last 10 years has this clinical entity been firmly established in the list of diseases affecting the pancreas and thus appropriately gained significant attention. An efficient mimicker of pancreatic carcinoma on both clinical and radiologic grounds, its early and accurate diagnosis can have profound treatment and prognostic implications, distinguished by the rapid reversal of its characteristic lesions with corticosteroid therapy.

DEFINITION AND NOMENCLATURE

With mounting evidence suggesting an underlying autoimmune mechanism, the term autoimmune pancreatitis was originally introduced by Yoshida *et al*[2] in 1995. Characterized histologically by a predominant lymphoplasmacytic infiltrate and fibrosis that can lead to both endocrine and exocrine dysfunction, autoimmune pancreatitis likely accounts for a significant proportion of cases previously classified as idiopathic pancreatitis. Various disease descriptors have been previously proposed such as chronic sclerosing pancreatitis[3], lymphoplasmacytic sclerosing pancreatitis with cholangitis[4], sclerosing pancreatocholangitis[5], non-alcoholic duct-destructive chronic pancreatitis[6], chronic pancreatitis with irregular narrowing of the main pancreatic duct[7], and pseudotumorous pancreatitis[8]. Retrospectively, these various descriptors likely describe the entity that we now refer to as autoimmune pancreatitis, however focused on its specific radiologic or histologic findings. As will be discussed further, although autoimmune pancreatitis is now the preferred term, its clinical, biochemical, radiologic, and pathologic findings are heterogeneous.

DEMOGRAPHICS AND EPIDEMIOLOGY

Despite the increasing cases of autoimmune pancreatitis being reported around the world, its true prevalence and incidence have yet to be determined. Three case series have reported prevalence rates of 4% to 6% of all patients diagnosed with chronic pancreatitis[9,10]. The mean age of diagnosis is 55, this however can vary with cases presenting from 30 to 70 years of age[3,6,11,12]. A male predilection of 1.7:1-2:1 has been reported in three surgical series[12-14]. Considering its postulated autoimmune pathogenesis, it has been associated with Sjogren's syndrome[15,16], rheumatoid arthritis[14], primary sclerosing cholangitis[16,17], retroperitoneal fibrosis[18] and inflammatory bowel disease[19]. Although the prevalence of a concurrent autoimmune diagnosis has been reported in various series, they are likely underestimates as some diagnoses of autoimmune pancreatitis may precede the diagnosis of the concurrent autoimmune condition[9,10,20].

PATHOGENESIS

Although the precise etiology and pathogenesis of autoimmune pancreatitis remains unknown, mounting evidence supports an autoimmune cause. Similar to other autoimmune diseases, an association of the HLA haplotype DRB1*0405-DQB1*0401 with autoimmune pancreatitis in the Japanese population has been discovered[21]. Significant autoimmune markers of the disease include its association with other autoimmune diseases, a predominant lymphoplasmacytic infiltrate on histology, hypergammaglobulinemia, elevated IgG4 levels and the presence of autoantibodies. A number of autoantibodies including antinuclear antibody (ANA), antismooth muscle antibody (ASMA), rheumatoid factor, antilactoferrin antibody (ALF) and anticarbonic anhydrase Ⅱ antibody (CA-Ⅱ) have been frequently detected in patients with autoimmune pancreatitis[22]. Both CA-Ⅱ and ALF are found in the normal pancreas, with CA-Ⅱ located in duct cells and ALF being found in the acinar cells. However, they are also distributed in the cells of several other organs including the lactating breast, biliary ducts, distal renal tubules, and salivary, bronchial and gastric glands. Thus potentially explaining some of the extrapancreatic sequelae of autoimmune pancreatitis.

As in Sjogren's syndrome or primary sclerosing cholangitis, CD4+ T-cells inducing a Th1 type of immune response are predominantly involved in the development of autoimmune pancreatitis as effector cells over Th2 type CD4+ T-cells[22,23]. Further strengthening this discovery, an animal model of autoimmune pancreatitis, using neonatally thymectomized mice immunized with CA-Ⅱ or ALF found that CD4+ Th1 cells are mainly involved in the early development of murine autoimmune pancreatitis[24]. Pancreatic specimens from this mouse model revealed histologic features consistent with those seen in autoimmune pancreatitis in humans. Therefore, an autoimmune reaction against CA-Ⅱ or ALF *via* CD4+ Th1 T-cells has a role in the early development of autoimmune pancreatitis. However many questions remain regarding the underlying triggering event and precise mechanisms leading to autoimmune pancreatitis.

CLINICAL CHARACTERISTICS

The presenting symptoms are variable and most commonly include painless jaundice, weight loss and abdominal pain. Although common, abdominal pain tends to be mild and variable in duration, usually lasting weeks to months. Patients rarely present with acute attacks of pain, more typical of acute pancreatitis. Jaundice has been reported in up to 70%-80% of patients in some series and is usually due to an accompanying stricture in the distal common bile duct[25]. Considering the patient demographics and common presenting symptoms, it is clear why many patients are initially diagnosed with pancreatobiliary malignancies and prior to the recognition of autoimmune pancreatitis would undergo unnecessary invasive procedures.

In some series, up to 60% of patients with autoimmune pancreatitis have diabetes mellitus[26,27]. The precise pathogenesis is unclear however different theories have been proposed. The majority are felt to manifest as type 2 diabetics with a degree of impaired glucose tolerance, however a proportion have been found to have antibodies to islet cells and glutamic decarboxylase and thus can manifest as Type 1 diabetics. It has been reported that a proportion of patients with autoimmune pancreatitis associated diabetes mellitus improve following steroid therapy[28].

The presence of potential extrapancreatic target antigens in the lungs, breasts and kidneys can also lead to clinical manifestations. Breast, renal and pulmonary inflammatory masses have been detected in patients with autoimmune pancreatitis and found to be composed of a lymphoplasmacytic infiltrate containing numerous IgG4 positive plasma cells[29,30]. Cases of autoimmune pancreatitis associated with interstitial pneumonia and mild renal failure due to interstitial nephritis have also been reported[31-33].

DIAGNOSIS-DIAGNOSTIC IMAGING

Diagnostic imaging plays a critical role in the diagnosis of autoimmune pancreatitis. It is often the first investigative modality that raises the possibility of autoimmune pancreatitis, based on characteristic imaging features. As a result, both radiologists and non-radiologists need to be familiar with its unique features on ultrasound, computed tomography and endoscopic retrograde cholangio-pancreatography.

Ultrasound

Although abdominal ultrasonography is a commonly ordered initial radiologic investigation for painless jaundice, overlying bowel gas and obesity greatly limit its ability to accurately visualize the pancreas. Furthermore, ultrasound findings in patients with autoimmune pancreatitis are non-specific and include many features commonly seen in other types of acute and chronic pancreatitis. The role of contrast-enhanced ultrasonography is evolving and may prove to be an important modality in the differentiation of pancreatic lesions[34].

Computed tomography (CT)

In patients with diffuse pancreatic involvement, the findings on CT usually consist of a diffusely enlarged pancreas, commonly referred to as 'sausage-like' or 'bulky', which correlates with the pathologic finding of marked stromal edema on gross examination (Figure 1). Focal involvement typically appears as a mass, most commonly involving the head of the pancreas, with low attenuation or isoattenuation. Peri-pancreatic fat infiltration is uncommon. Pancreatic parenchymal calcification and intraductal stones, commonly seen in chronic pancreatitis, are also rarely observed in autoimmune pancreatitis. Mild peri-pancreatic lymphadenopathy and loss of parenchymal lobularity are commonly seen.

Another distinguishing feature of autoimmune pancreatitis is delayed enhancement of the pancreatic parenchyma. The pancreas tends to appear hypodense in comparison to the spleen on the arterial enhanced

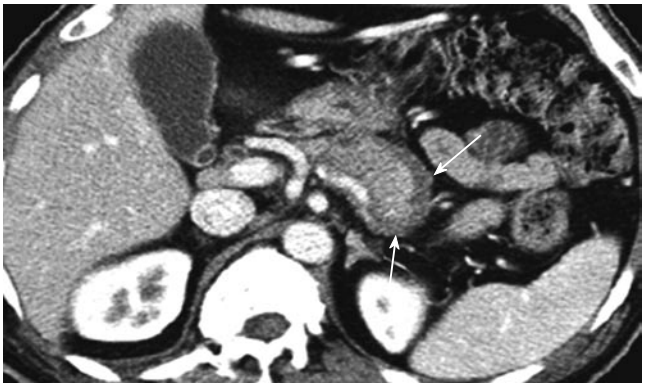

Figure 1 Contrast enhanced CT showing sausage-like swelling of the pancreatic tail along with a surrounding low attenuation rim (arrows).

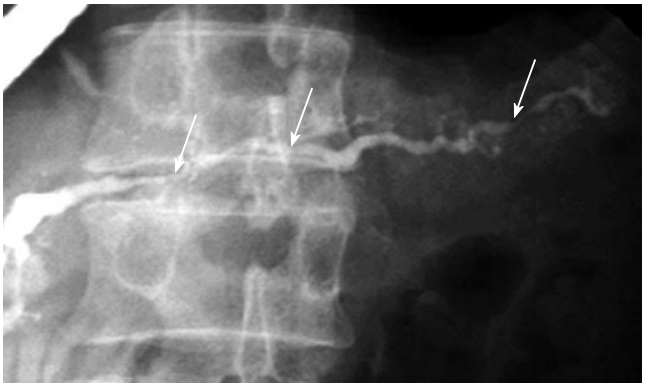

Figure 2 Direct pancreatography delineating a pancreatic duct with multiple segments of narrowing (arrows).

phase with increasing attenuation in the delayed phase images. It has been proposed that delayed enhancement is a reflection of the heterogeneous lymphoplasmacytic infiltrate and fibrosis observed on histologic examination of the pancreas[35]. Finally, a capsule-like low density rim can also be seen surrounding the pancreas on both arterial and delayed images. This may represent clear demarcation of the inflammatory process in autoimmune pancreatitis from the surrounding peripancreatic fat, due to the absence of peripancreatic fat infiltration.

Magnetic resonance cholangio-pancreatography (MRCP)

The role of MRCP continues to evolve, especially as a non-invasive modality in assessing pancreatobiliary ductal anatomy. Its role however in autoimmune pancreatitis remains limited, primarily because the lack of exogenous contrast and lower resolution compared to ERCP, greatly limit its ability to detect the characteristic pancreatic duct changes.

Endoscopic retrograde cholangio-pancreatography (ERCP)

The hallmark findings on direct pancreatography are focal, segmental, or diffuse narrowing of the main pancreatic duct (Figure 2)[36]. The pattern and degree of ductal narrowing is a direct result of ductal compression due to the heterogenous lymphoplasmacytic infiltrate and fibrosis affecting the gland. Although uncommon, the focal variant of autoimmune pancreatitis represents a diagnostic challenge because its findings are quite similar to those expected in pancreatic cancer. Usually associated with a mass in the head of the pancreas on CT, the focal type of autoimmune pancreatitis results in localized stenosis of the main pancreatic duct and upstream dilatation.

In the 'segmental' variant, multiple strictures affecting different sections of the pancreatic dust are visualized with intervening duct that appears non-dilated. In the 'diffuse' form, the entire pancreatic duct is narrowed. Rather than representing distinct variants of autoimmune pancreatitis, some reports have documented progression of the segmental form to a more diffuse appearance on ERCP without therapy[12]. Thus suggesting that the different patterns of ductal narrowing are primarily a result of the timing of ERCP and represent the spectrum of the disease rather than distinct entities[20,36].

Other potential ERCP findings in autoimmune pancreatitis include narrowing of the intrapancreatic portion of the common bile duct and irregular narrowing of extrahepatic bile ducts. Although uncommon, dilatation of the intrahepatic bile ducts has also been reported[36].

Endoscopic ultrasonography (EUS)

Due to its ability to accurately visualize the pancreas and perform fine needle aspiration, EUS is a crucial modality in the diagnosis of autoimmune pancreatitis. The absence of exogenous contrast makes it an important diagnostic test, even prior to CT, especially in women of child-bearing age. The findings seen in autoimmune pancreatitis closely resemble those found on CT, including a hypoechoic gland with focal or diffuse parenchymal swelling. Above all, the ability to perform tissue acquisition either by fine needle aspiration or core biopsy further strengthens the role of EUS in the diagnosis of this elusive entity.

DIAGNOSIS-PATHOLOGY

The hallmark histologic finding of autoimmune pancreatitis includes a dense lymphoplasmacytic infiltrate and fibrosis (Figure 3). The infiltrate is often heterogeneous in its distribution throughout the gland and its degree of cellularity. Although consisting predominantly of lymphocytes, the cellular infiltrate also contains neutrophils and eosinophils. Studies using immunohistochemistry have further defined that the lymphocyte population consists predominantly of CD4+ T lymphocytes with a smaller but detectable population of CD8+T cells and B cells[24].

Another important histologic finding is the presence of periductal inflammation, usually involving medium-sized and large interlobular ducts (Figure 4)[37]. Sometimes referred to as a 'collar' of inflammation, it consists predominantly of plasma cells and lymphocytes, sometimes forming germinal centers. The infiltrate is primarily subepithelial, with the epithelium only rarely being infiltrated by lymphocytes. It completely encompasses the duct leading to luminal narrowing by way of epithelial infolding and gives the lumen a star-like appearance[24]. Periphlebitis and perineural inflammation are also often

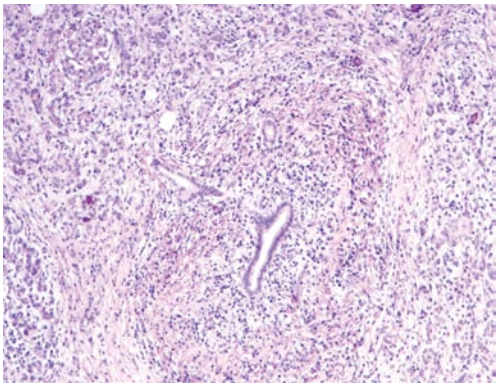

Figure 3 Diffuse pancreatic lymphoplasmacytic infiltrate with early fibrosis and atrophy.

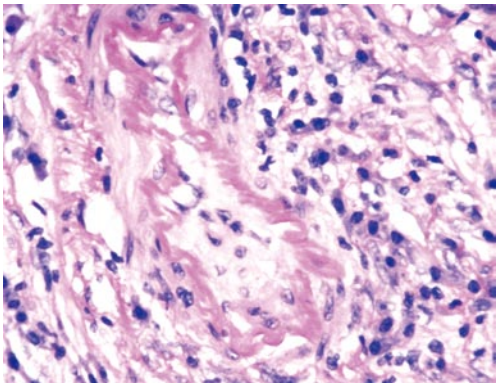

Figure 5 Medium sized artery with infiltration of the vessel wall by lymphocytes and plasma cells.

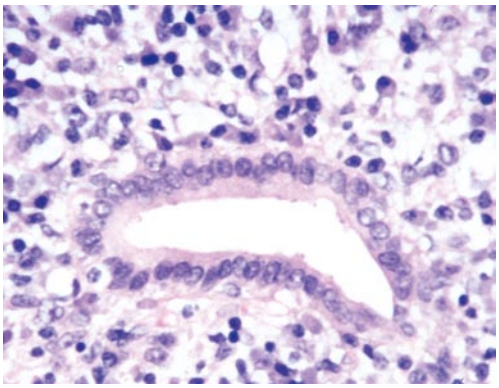

Figure 4 Small pancreatic duct surrounded by a cuff of lymphocytes and plasma cells that is extending into the atrophic pancreatic parenchyma.

Table 1 Diagnostic criteria for autoimmune pancreatitis proposed by the Japanese Pancreas Society

A Imaging criterion: Diffuse narrowing of the main pancreatic duct with an irregular wall (more than 1/3 the length of the entire pancreatic duct) and enlargement of the pancreas
B Laboratory criterion: Abnormally elevated levels of serum gamma-globulin and/or IgG, or the presence of autoantibodies
C Histopathologic criterion: Marked lymphoplasmacytic infiltration and dense fibrosis
For the diagnosis, criterion A must be present together with criterion B and/or C

observed (Figure 5)[12,30].

Finally, an important histologic observation in the pathologic diagnosis of autoimmune pancreatitis is the absence of ductal dilatation, calcifications and proteinaceous plugs, commonly found in chronic pancreatitis.

DIAGNOSTIC CRITERIA

Considering the difficulty in accurately differentiating autoimmune pancreatitis from other forms of chronic pancreatitis and pancreatic carcinoma, a number of diagnostic criteria have been proposed. The earliest was proposed by the Japanese Pancreas Society and is outlined in Table 1[38]. It is based on three criteria encompassing imaging, laboratory and histopathologic findings. The mandatory imaging findings include diffuse narrowing of the pancreatic duct involving at least one third of the entire length along with pancreatic enlargement. One of the two 'minor' laboratory or pathologic criteria also needs to be present for the diagnosis. Aparisi *et al*[39] proposed a different scoring system based on clinical presentation, laboratory parameters and morphologic findings. More recently, investigators have specifically included an elevation in the IgG4 level and response to steroids as supporting criteria for the diagnosis of autoimmune pancreatitis[11,40].

Kim *et al*[11] retrospectively applied the original diagnostic criteria of the Japanese Pancreas Society to a series of 28 patients diagnosed with autoimmune pancreatitis who had responded to steroid therapy. The original diagnosis required the presence of diffuse enlargement of the pancreas and diffuse or segmental irregular narrowing of the main pancreatic duct. Supporting criteria included elevated levels of IgG and/or IgG4, the presence of autoantibodies and histopathologic findings. Despite the absence of laboratory abnormalities or histopathologic findings in some patients, steroid therapy was initiated if the imaging criteria were met. The authors concluded that had they strictly applied the diagnostic criteria of the Japanese Pancreas Society, 9 of 28 patients would have not been diagnosed with autoimmune pancreatitis and appropriately treated. Seven of the 9 patients would have been missed because the extent of ductal narrowing was less than one third of the entire length of the main pancreatic duct. Another two patients had normal IgG levels, absence of autoantibodies and non-diagnostic pancreatic histopathology. As a result, the authors revised the diagnostic criteria by including the response to steroids and association with other autoimmune diseases as supporting criteria. They also abolished the need for more than one third of the pancreatic duct to be affected.

Although none of the proposed diagnostic criteria have been validated, they underscore the highly characteristic

imaging findings in autoimmune pancreatitis. Finally, the histopathologic findings which have previously been felt to represent the gold standard for the diagnosis can be absent on specimens due to the patchy distribution of the disease and have also been seen in patients with alcohol induced chronic pancreatitis[30].

TREATMENT AND PROGNOSIS

Corticosteroids are the first line therapy in the treatment of autoimmune pancreatitis, often providing dramatic and rapid results. The role of other immunosuppressive agents in this patient population remains largely undefined.

Prednisone is usually initiated at a dose of 0.4-0.6 mg/kg per day for a period of months. Although a detailed steroid schedule has not yet been fully defined, most patients are usually treated for a period of 2-3 mo, with a tapering schedule of 5 mg every 1-2 wk.

From a laboratory perspective, hypergammaglobulinemia and elevated IgG4 levels can resolve and previously identified autoantibodies can become undetectable[41]. Marked changes are also observed in the pretreatment findings of CT and ERCP[20]. The diffuse enlargement of the gland, characteristic pattern of enhancement and capsule-like low density rim seen on CT revert to normal. ERCP findings of focal, segmental or diffuse pancreatic duct narrowing also disappear. Narrowing of the distal common bile duct normalizes. Since almost all patients undergo ERCP prior to the initiation of steroid therapy, the finding of distal common bile duct narrowing is often treated with stent placement. The rapid reversal of biliary narrowing with steroid therapy usually allows for stent removal within 1-2 mo.

These radiologic changes closely parallel the clinical improvement that patients experience, specifically regarding the most common presenting symptoms of abdominal pain or painless jaundice. They are often observed within 2-4 wk of corticosteroid initiation and serve to further confirm the diagnosis of autoimmune pancreatitis.

In terms of prognosis, although the majority of patients achieve a sustained clinical remission with a tapering course of corticosteroid therapy, a subset may go on to require chronic maintenance dosing of 5-10 mg/d. The long term prognosis of autoimmune pancreatitis remains as yet undefined considering its recent discovery. Two different cohorts involving 23 patients followed for a mean of 56 mo and 17 patients followed for 16 mo, each had 1 patient relapse[9,35]. In both cases the patient was successfully treated with a second course of corticosteroids and maintained on low dose steroid therapy.

CONCLUSION

In the last 40 years autoimmune pancreatitis has gone from a proposed concept to a well-recognized clinical entity. Despite the fact that our understanding regarding its pathogenesis, presentation, diagnosis and treatment have evolved, many questions remain unanswered. Its relationship to other autoimmune diseases, precise pathogenesis, accurate diagnosis and long-term prognosis require further clarification.

Above all, as an efficient mimicker of pancreatic carcinoma, the accurate and timely diagnosis of autoimmune pancreatitis can have drastic consequences on therapy and prognosis. Thereby underlining the critical importance of its awareness among internists, gastroenterologists, radiologists, pathologists and surgeons.

Abstract

Sphincter of Oddi dysfunction (SOD) is a term used to describe a group of heterogenous pain syndromes caused by abnormalities in sphincter contractility. Biliary and pancreatic SOD are each sub-classified as type Ⅰ, Ⅱ or Ⅲ, according to the Milwaukee classification. SOD appears to carry an increased risk of acute pancreatitis as well as rates of post ERCP pancreatitis of over 30%. Various mechanisms have been postulated but the exact role of SOD in the pathophysiology of acute pancreatitis is unknown. There is also an association between SOD and chronic pancreatitis but it is still unclear if this is a cause or effect relationship. Management of SOD is aimed at sphincter ablation, usually by endoscopic sphincterotomy (ES). Patients with type Ⅰ SOD will benefit from ES in 55%-95% of cases. Sphincter of Oddi manometry is not necessary before ES in type Ⅰ SOD. For patients with types Ⅱ and Ⅲ the benefit of ES is lower. These patients should be more thoroughly evaluated before performing ES. Some researchers have found that manometry and ablation of both the biliary and pancreatic sphincters is required to adequately assess and treat SOD. In pancreatic SOD up to 88% of patients will benefit from sphincterotomy. Therefore, there have been calls from some quarters for the current classification system to be scrapped in favour of an overall system encompassing both biliary and pancreatic types. Future work should be aimed at understanding the mechanisms underlying the relationship between SOD and pancreatitis and identifying patient factors that will help predict benefit from endoscopic therapy.

Key words: Sphincter of Oddi dysfunction; Pancreatitis, Post-ERCP pancreatitis; Sphincter of Oddi manometry; Endoscopic sphincterotomy

McLoughlin MT, Mitchell RMS. Sphincter of Oddi dysfunction and pancreatitis. *World J Gastroenterol* 2007; 13(47):

INTRODUCTION

Sphincter of Oddi dysfunction (SOD) is the term used to describe a heterogenous group of clinical pain syndromes caused by abnormalities in sphincter contractility. The sphincter of Oddi (SO), a fibromuscular sheath encircling the distal common bile duct (CBD), pancreatic duct (PD) and common channel, controls the flow of bile and pancreatic secretions into the duodenum and prevents reflux of duodenal contents into the pancreaticobiliary system.

SOD describes SO dysmotility or stenosis leading to reduced transphincteric flow of bile or pancreatic juice[1]. SO stenosis is a structural abnormality where there is a physical alteration of the sphincter due to inflammation and fibrosis. SO dyskinesia results in a hypo- or hypertonic sphincter with altered motility causing an intermittent functional blockade of the sphincter[2]. As it is often difficult to distinguish SO stenosis from dyskinesia, the term Sphincter of Oddi dysfunction is used to cover both conditions.

Because of the anatomical position of the SO patients with SOD typically present with recurrent biliary or pancreatic type pain. The Rome Ⅱ diagnostic criteria for biliary pain are episodes of severe steady pain in the epigastrium and right upper quadrant, associated with all of the following: (1) Symptom episodes lasting at least 30 min with pain free episodes in between; (2) At least one attack of pain in the last 12 mo; (3) Pain that is steady and interrupts daily activities or requires consultation with a doctor; (4) No evidence of structural abnormalities to explain the symptoms.

Pancreatic pain is described as post-prandial, episodic, prolonged pain in the upper abdomen and/or back[3]. It is often presumed in the setting of acute recurrent pancreatitis in the absence of biliary stone disease or anatomical abnormalities. The true prevalence of SOD is not known but ongoing biliary type pain occurs in 10%-20% of patients who have had a cholecystectomy[4]. Sphincter ablation, usually by endoscopic sphincterotomy, is at the forefront in the management of SOD and one of the challenges of this condition is to identify which patients will benefit from it.

CLASSIFICATION OF SOD

The Milwaukee Classification, proposed by Hogan and Geenen[5,6], sub-classifies biliary and pancreatic SOD into three types on the basis of symptoms, laboratory tests and radiological imaging (Table 1). Abnormally high basal sphincter pressure identified during sphincter of Oddi manometry (SOM) confirms the presumed diagnosis. As biliary drainage time is difficult and somewhat impractical to measure and may increase the risk of an ERCP it is rarely performed in clinical practice. In any case, there may be little or no correlation between basal sphincter of Oddi pressures and drainage times[7]. Therefore, a contemporary modified version of the Milwaukee classification, which does not include duct drainage times, is generally used in practice[3]. Sub classification of SOD into types Ⅰ, Ⅱ and Ⅲ helps predict the underlying pathology and the likelihood of symptom relief after treatment. Type Ⅰ disease is thought to result from a fixed stenosis caused by chronic inflammation and fibrosis and has the highest response rate to therapy. An episodic dysmotility is the presumed underlying abnormality in the other types and often does not respond as well to treatment[8,9].

There are some potential problems with the Milwaukee classification. For example, the description of typical biliary or pancreatic pain may be interpreted differently between individuals and this may lead to inappropriate referral for SOM, particularly for patients with presumptive type Ⅲ SOD. Also, according to the Milwaukee criteria, LFTs should normalize between attacks but patients are often labeled with type Ⅱ SOD on the basis of pain and abnormal LFTs which do not normalize[10]. CBD diameter of at least 12 mm is one of the criteria in the diagnosis of SOD. Most patients being investigated for SOD have had their gallbladder removed and in the past it was accepted that it was normal for a post-cholecystectomy CBD to be 2-3 mm dilated. However, in a cohort of 59 patients, Majeed *et al*[11] found no difference between pre- and post-cholecystectomy CBD diameter. As the upper limit of normal for CBD diameter is 7 mm, a cut off of 12 mm potentially leaves a large number of patients misdiagnosed. Also, variations in basal pressure and response to sphincterotomy between the biliary and pancreatic portions of the SO have led to calls for this dual classification system to be scrapped in favor of a single, overall system.

Table 1 Milwaukee classification of sphincter of Oddi dysfunction

1 Biliary type:
Type Ⅰ:
Typical biliary type pain
Liver enzymes (AST, ALT or ALP) > 2 times normal limit documented on at least 2 occasions during episodes of pain
Dilated CBD > 12 mm in diameter
Prolonged biliary drainage time (> 45 min)
Type Ⅱ:
Biliary type pain and
One or two of the above criteria
Type Ⅲ:
Biliary type pain only
2 Pancreatic type SOD
Type Ⅰ:
Pancreatic type pain
Amylase and/or lipase > 2 times upper normal limit on at least 2 occasions during episodes of pain
Dilated pancreatic duct (head > 6 mm, body > 5 mm)
Prolonged pancreatic drainage time (> 9 min)
Type Ⅱ:
Pancreatic type pain, and
One or two of the above criteria
Type Ⅲ:
Pancreatic type pain only

SPHINCTER OF ODDI MANOMETRY

SOM remains the gold standard for the diagnosis of SOD. It is usually combined with a diagnostic ERCP examination and involves cannulating the ampulla with the manometry catheter. A triple lumen catheter allows continuous aspiration of PD fluid that may reduce the risk of post- procedural pancreatitis[12]. To determine which duct has been cannulated a small amount of contrast is injected or some fluid aspirated to determine its color. A catheter "pull-through" of the sphincter is performed to assess the pressure profile and to localize the point of peak basal pressure. Normal basal sphincter pressure is approximately 15 mmHg but ranges from 3 to 35 mmHg. It is generally accepted that a basal pressure greater than 40 mmHg (based on a threshold of 3 standard deviations above the median) is abnormal[13]. In patients with SO stenosis this recording is reproducible and does not respond to muscle relaxants[1]. In contrast, SO dyskinesia is characterized by a response to smooth muscle relaxants[5], an excess of retrograde contractions (> 50%), tachyoddia (rapid contraction frequency > 7/min) and a paradoxical contraction response of the SO following an intravenous dose of CCK[1,14].

In type I SOD SOM will be abnormal in 75%-95%[15]. However, the frequency of abnormal biliary manometry varies from 28% to 60% for type Ⅱ patients and from 7 to 55% in type Ⅲ patients[16]. Various factors may explain the differences in frequencies of SOD in published reports. For example, selection of patients with a typical biliary or pancreatic type pain rather than a non-specific pain will increase the yield of basal pressure abnormality. SOM measures a "snap shot" of sphincter pressure during the study period that may not always be reproducible. A study of 12 patients with previously normal SOM showed evidence of elevated SO pressures in 5 (42%) when re-tested after a median of 337 d[17]. Also, the pressure in the pancreatic and biliary portions of the SO can vary so assessment of only one sphincter component, rather than both, will reduce the frequency of SOD detection. Current data suggests a discordance rate of between 35% and 65%[16,18-22]. Therefore, both portions of the SO should be measured separately for a full assessment. This necessitates classifying each patient with respect to the pancreatic and biliary components of the SO and is one of the reasons some experts have called for a single overall classification system. When both sides of the sphincter are evaluated there is little difference between them in predicting

abnormal basal pressure[16].

Because SOM is technically difficult, invasive, has a variable diagnostic yield and has recognized complications, other indirect methods of evaluating SO function have been developed. These include the Morphine-Prostigmin provocative test (Nardi test; now obsolete), the ultrasound- or MRCP-secretin test, and quantitative hepatobiliary scintigraphy. However, current data suggests that non-invasive tests have a relatively low specificity and sensitivity[15], although there is some evidence that secretin stimulated MRCP may be useful in selecting patients with suspected type Ⅱ SOD who are most likely to benefit from sphincterotomy [23]. Therefore, despite the risk, and assuming careful patient selection, SOM remains the diagnostic tool of choice for most clinicians.

PANCREATITIS POST SOM

Acute pancreatitis is the main complication of SOM. Increased intraductal pressure, overfilling of the ductal system, difficult and repeated cannulation of the PD causing spasm and trauma have all been postulated as etiological factors, possibly by affecting pancreatic duct drainage[24]. This hypothesis is indirectly supported by the observation that PD stenting after biliary sphincterotomy[24] and needle knife sphincterotomy over a PD stent[25] have been found to reduce the incidence of pancreatitis in patients with SOD.

The rate of post-SOM pancreatitis in patients suspected of having SOD has been found to be as high as 31%[27-30]. Sherman *et al*[27] found a much lower rate of pancreatitis when an aspirating catheter was used (1 of 33 patients; 4%) compared with an infusion catheter (8 of 34 patients; 31%). Walters *et al*[31], however, found no difference in the incidence of pancreatitis when comparing the two types of manometry catheter (8% *vs* 13%). In a case series of 146 patients (207 SOM measurements), Rolny *et al*[28] reported a 6% incidence of pancreatitis when using the standard catheter. In addition, acute pancreatitis developed in 10 of 95 (11%) patients who had undergone pancreatic manometry alone, compared with 1 of 93 (1%) who had biliary manometry alone. Recommended methods of reducing the rate of pancreatitis from SOM include evaluating biliary SO alone in patients with suspected biliary disease[32], limiting SO perfusion to 1-2 min[33] and careful patient selection. For example, Scicchitano *et al*[29] found a significantly higher rate of pancreatitis when the indication for SOM was idiopathic acute recurrent pancreatitis (IARP) compared to unexplained abdominal pain (29% *vs* 6%). The incidence of pancreatitis was 50% in the patients with IARP and high SO basal pressure. Temporary prophylactic pancreatic duct stenting has been shown to reduce the incidence of pancreatitis in a variety of patient groups, including those undergoing SOM[25,26,34,35].

A retrospective review of 100 patients who had undergone SOM found an overall incidence of pancreatitis of 17%[30]. The incidence was significantly higher in patients who had undergone SOM and ERCP, compared to those who had only undergone SOM (26.1% *vs* 9.3%). Multiple regression analysis showed that sphincterotomy added no additional risk beyond that associated with ERCP. These results imply that other factors during ERCP, and not the manometry itself, predispose to pancreatitis. The authors recommended that ERCP should be performed at another session, possibly 24 h after SOM.

Results from other studies suggest that the risks of pancreatitis are intrinsic to the patient group undergoing the procedure and the therapy provided, rather than the SOM itself. Freeman *et al*[36] recorded complication rates for sphincterotomy in patients with suspected SOD and those in whom it was already confirmed. The complication rate was 21% for patients who underwent SOM and 25% when sphincterotomy was not preceded by SOM. Another study compared the pancreatitis rate from ERCP between patients with suspected SOD, some of whom also underwent SOM, and a control group of patients with biliary stones[37]. 27% of patients with suspected SOM developed post-procedural pancreatitis, compared with 3.2% of the control group ($P < 0.001$). However, there was no significant difference in the rate of acute pancreatitis in the first group between those who had SOM and those who did not (OR 0.72: 95% CI 0.08-9.2). Similarly, in a large trial of over 1000 patients who underwent ERCP with or without SOM, Cheng *et al*[38] found that SOM was not a risk factor for post-ERCP pancreatitis.

The variability in complication rates between studies is probably multifactorial and related to the timing and duration of the procedure, the number of passes with the manometry catheter and technique and skill of the operator. However, it is probable that, in skilled hands, SOM does not significantly increase the risks of post-ERCP pancreatitis and remains a useful tool in the diagnosis of SOD, particularly for types Ⅱ and Ⅲ.

SOD AND ACUTE PANCREATITIS

SOD may contribute to the risk of acute pancreatitis by causing abnormal biliary or pancreatic juice flow. In the Australian Bush opossum, which has a similar biliary and pancreatic anatomy to humans, the combination of pancreatic duct ligation and stimulation of pancreatic exocrine secretion with cholecystokinin/secretin uniformly causes acute pancreatitis[39]. In another group, reduced transphincteric flow was achieved by applying topical carbachol to the SO, causing PD pressures comparable with those opossums in which the PD was ligated. However, acute pancreatitis only occurred when carbachol application was combined with pancreatic secretory stimulation. Decompression of the PD negated the effects. Therefore, the combination of PD obstruction with increased exocrine secretion was needed to produce acute pancreatitis. Although it is a recognized complication of SOD, this study demonstrated that SOD might be a causative factor in the production of acute pancreatitis.

Kruszyna *et al*[40] carried out ERCP with pre- and post- sphincterotomy SOM in a group of 30 patients with mild acute biliary pancreatitis and compared results with a control group of 30 patients with no evidence of CBD stones or pancreatitis. The patients with pancreatitis had a significantly elevated CBD pressure, SO basal pressure and wave amplitude compared to controls.

There was a significant reduction in all parameters after sphincterotomy. They concluded that SO dysfunction, either primary or secondary to spasm caused by a gallstone migrating through the ampulla, may have a role in acute biliary pancreatitis.

Although there is very little direct evidence supporting the role of the SO in causing pancreatitis in humans, there is plenty of circumstantial evidence. Fazel *et al*[41] measured intrapancreatic ductal pressure blindly in 263 patients presenting with either recurrent abdominal pain, acute recurrent pancreatitis or chronic pancreatitis. Complete SOM was then performed and patients with SOD were found to have a significantly higher ductal pressure compared to those with normal SO motility. This difference was seen across all three groups ($P < 0.01$) and patients with acute and chronic pancreatitis did not have a significant elevation in intraductal pressure compared to individuals with abdominal pain only. The authors concluded that SOD leads to an increase in intrapancreatic ductal pressure but this rise in pressure is not the sole cause of pancreatitis.

Warshaw *et al*[42] showed that infusion of secretin caused PD dilatation of > 1 mm in 83% of patients with SO stenosis and 72% with accessory papilla stenosis, compared with controls. This dilatation response was abolished after surgical sphincteroplasty. A positive secretin test was associated with a good surgical outcome in 90% of cases. It has been shown that in patients undergoing surgery for idiopathic acute recurrent pancreatitis (IARP) the SO narrows at the opening of the PD, suggesting that this narrowing may play a role in its development[43].

An abnormality of SO function has also been implicated in the pathogenesis of acute pancreatitis attributed to other causes. An organophosphate insecticide is a recognized cause of acute pancreatitis in humans. It acts by irreversibly inhibiting cholinesterase resulting in delayed breakdown of synaptic acetylcholine[44], and has been shown to cause pancreatitis in animals[45], probably due to the combination of obstruction at the level of the SO and cholinergic stimulation of pancreatic secretions. Scorpion venom causes acetylcholine release, stimulating the pancreas and SO, and causes pancreatitis in a similar way to organophosphate poisoning[46].

Other rare causes of acute pancreatitis including hypercalcemia and hyperlipidemia may involve abnormalities of SO function. High extra-cellular calcium stimulates smooth muscle and stimulates pancreatic secretion in animal models and it is thought that abnormal calcium regulation of the SO may be an underlying factor in the pathophysiology[47]. A study of hypercholesterolemic rabbits showed a failure of SO relaxation again indirectly suggesting that SO dysfunction may contribute to the risk of pancreatitis[48]. Therefore, although its exact role is not known, the evidence, taken together, suggests that the SO at some level is an important factor in the development of acute pancreatitis, including pancreatitis that may be attributed to another aetiology.

SOD IN RECURRENT ACUTE PANCREATITIS

Clinical evaluation, blood testing and imaging will yield a cause of acute recurrent pancreatitis in 70%-90% of cases. In the remaining "idiopathic" acute recurrent pancreatitis (IARP) cases more extensive evaluation may be required, including assessment for SOD. Abnormal SOM in IARP ranges from 15%-72% with a mean of 30.5% (Table 2)[16,49-54]. The high incidence of abnormal SOM in IARP reflects the fact that a substantial proportion of these patients are likely to have SOD .

Table 2 Frequency of abnormal sphincter of Oddi manometry in idiopathic acute recurrent pancreatitis

Author	Year	Patient number, *n*	Abnormal SOM	Frequency (%)
Gregg *et al*[49]	1984	125	28	22
Toouli *et al*[50]	1985	28	14	50
Venu *et al*[51]	1989	116	17	15
Sherman *et al*[52]	1992	49	15	31
Eversman *et al*[16]	1999	47	34	72
Coyle *et al*[53]	2002	90	28	31
Kaw *et al*[54]	2002	126	41	33
Total		581	177	30.5

With the exception of a study by Eversman *et al*[16], the published studies measured sphincter pressure in only one duct, i.e., either pancreatic OR biliary, although in some cases it is not clear which duct was actually measured. Eversman *et al*, however, performed SOM of the biliary and pancreatic ducts in 593 patients, of whom 360 had intact sphincters. Of the 47 patients with idiopathic acute pancreatitis, 12 had increased pressure in the pancreatic portion of the SO, 3 had increased pressure in the biliary portion and 19 had it in both. The measurement of sphincter pressure in both ducts accounts for the much higher frequency of SOD in IARP that was found in this study. Choudari *et al*[55] also reported a higher frequency of basal sphincter abnormality of at least one duct in patients with chronic pancreatitis.

Of the 360 patients measured in the study by Eversman *et al*[16], 68 (18.9%) had abnormal pancreatic sphincter basal pressure alone, 41 (11.4%) had abnormal biliary basal sphincter pressure alone and in 113 (31.4%) the basal pressure was abnormal for both sphincters. Therefore, 219 (60.1%) of the patients had sphincter dysfunction. The authors concluded that assessment of both the pancreatic and biliary portions of the SO is necessary to accurately detect SOD. The frequency of SOD did not differ whether typed by biliary or pancreatic criteria (65% type Ⅱ and 59% type Ⅲ). As there was so little difference in the frequency of SOD according to the modified Geenen-Hogan criteria, the authors argued for an overall classification for SOD encompassing biliary and pancreatic types.

Guelrud *et al*[56] retrospectively reviewed ERCP studies from 64 children (> 1 year old) and adolescents with recurrent pancreatitis. SOM and sphincterotomy were performed in 9 patients, all of whom had SOD. Seven of these patients had a choledochal cyst and 2 had anomalous pancreaticobiliary union (APBU). After a mean follow up of 26.4 mo (range 18-38), 8 of these patients were symptom free and one had occasional pain but no further episodes of pancreatitis. They concluded that recurrent

pancreatitis and ABPU are associated with SOD in children and adolescents and that sphincterotomy was beneficial to these patients.

SOD AND CHRONIC PANCREATITIS

Early studies investigating the association of SOD and chronic pancreatitis were inconclusive. Some studies showed no difference in pancreatic sphincter pressures between patients with chronic pancreatitis and controls[57-61]. However, these studies involved patients with chronic pancreatitis due to alcohol and in two of the studies the controls were patients with unexplained abdominal pain[58] or suspected biliary dyskinesia[60]. Also, although one of these studies found no significant difference between SO basal pressure in patients with chronic pancreatitis and controls, the pancreatic duct pressure was significantly higher in the early stages of chronic pancreatitis than normal subjects[57]. Other trials have shown a correlation between elevated pancreatic sphincter pressures and chronic pancreatitis[19,62-64]. Many of these also used patients with chronic pancreatitis secondary to alcohol. However, in the only one of these studies that excluded alcoholic patients, basal pancreatic sphincter pressures were significantly higher in the early stages of chronic pancreatitis than controls[62]. Laugier[64] performed manometry of the SOD and main pancreatic duct before and after intravenous injection of secretin in chronic pancreatitis patients and controls. Secretin transiently increased pancreatic duct pressure in controls, but chronic pancreatitis patients had a persistently elevated pancreatic duct pressure and a manometric pattern of SOD. The secretin-induced elevation in ductal pressure was greater and more sustained in patients with chronic pancreatitis, particularly of recent onset (less than 4 years).

It has been shown that local installation of alcohol on the SO results in elevated SO pressures, suggesting a role in the pathogenesis of alcoholic pancreatitis[65]. Tarnasky *et al*[66] looked for evidence of chronic pancreatitis in patients undergoing manometry for investigation of unexplained upper abdominal pain (n = 104). Pancreatic ductography, EUS and pancreatic fluid bicarbonate concentration measurements were carried out. Patients with SOD were 4 times more likely to have evidence of chronic pancreatitis than those with normal sphincter pressure (P = 0.01). Of 68 patients with SOD, 20 (29%) had structural evidence of chronic pancreatitis and 20 of 23 patients (87%) with chronic pancreatitis had SOD. The authors concluded that SOD is associated with structural evidence of chronic pancreatitis in patients with unexplained pancreaticobiliary pain. Patients with chronic pancreatitis and SOD were significantly older than those with SOD but no chronic pancreatitis. This raises the possibility that SOD precedes the development of pancreatitis.

The available evidence certainly suggests a link between SOD and chronic pancreatitis. However, it is still not clear if this is a cause or effect relationship, i.e., does the generalized scarring associated with chronic pancreatitis also involve the sphincter or does the hypertensive sphincter cause elevated pressure and, hence, morphological changes? Further work is required to clarify this issue.

SPHINCTEROTOMY FOR SOD

Biliary type SOD

Management of SOD has traditionally been aimed at sphincter ablation by endoscopic sphincterotomy. Most data on sphincterotomy relates to biliary sphincter ablation alone and clinical improvement has been reported to occur in 55%-95% of patients[15] with the grade of SOD having a significant effect on outcome. Outcomes are generally measured using pain scores or quality of life measures[2], although a lack of standardization in characterizing the patients and assessing response make comparisons between trials problematic.

There are no randomized or controlled trials of therapy for type I SOD and the available evidence is derived from small retrospective trials. Rolny *et al*[67] carried out ERCP and SOM on 17 post-cholecystectomy patients with suspected type I SOD. All patients had a dilated CBD at ERCP and delayed contrast drainage and 11 had elevated SO pressure. Sphincterotomy resulted in symptom relief in all patients after a mean follow up of 28 mo. It was concluded that, in symptomatic post-cholecystectomy patients, the triad of abnormal LFTs, dilated CBD and delayed contrast drainage was sufficient to make a diagnosis of definitive SO abnormality and, as these patients invariably benefit from sphincterotomy, SOM was unnecessary.

Other studies have reported the effect of sphincterotomy for both type I and type Ⅱ patients. Thatcher *et al*[68] retrospectively reviewed 46 patients (31 with type I and 15 with type Ⅱ) who had undergone sphincterotomy for SOD. In the patients with type I SOD 87% had improved pain scores at 3 mo and 77% after a mean follow up of 12.5 mo. When evaluated along with the patients with type Ⅱ SOD, patients with a dilated bile duct and delayed contrast drainage at ERCP had a better response to therapy (P = 0.01) and reduced complication rate (P = 0.03) compared to those with normal ducts at ERCP. 29 patients underwent SOM but a favorable treatment outcome did not correlate with manometric assessment, particularly in patients with abnormal ducts. Therefore, patients suspected of having type I SOD benefited from sphincterotomy, irrespective of SOM results.

Lin *et al*[69] performed sphincterotomy on 24 patients based on clinical findings of post-cholecystectomy pain, biochemical abnormalities and/or dilated bile ducts. Enzyme abnormalities were a significant predictor of response to therapy (P = 0.018) whereas duct dilatation was not (P = 1.0).

These small studies suggest that endoscopic sphincterotomy without SOM is effective in suspected type I biliary SOD. However, patients with presumptive type Ⅱ SOD have, by definition, less concrete evidence for obstruction at the level of the sphincter so more extensive evaluation is necessary to predict those who would benefit from sphincterotomy.

Three randomized trials of endoscopic therapy for types Ⅱ and Ⅲ SOD have been reported. In one of these

47 patients with presumed type Ⅱ SOD were randomly assigned to endoscopic sphincterotomy (n = 23) or a sham procedure (n = 24) in a prospective double-blind study[6]. All patients had biliary type pain, clinical characteristics in keeping with biliary obstruction and had a previous cholecystectomy. Eleven patients in the treatment group had manometric evidence of elevated sphincter pressure and 10/11 described improved pain scores at 1 year. In contrast, only 3 out of 12 patients in the control group who had elevated pressure had an improved pain score over the same time period. Pain scores were unchanged in patients with normal sphincter pressures, irrespective of treatment. After one year sphincterotomy was performed in 12 symptomatic patients who had initially undergone the sham procedure, 7/12 with elevated sphincter pressure and 5/12 with normal pressure. A total of 40 patients were followed for 4 years and after that time 17 of the 18 patients (95%) with SOD verified by manometry had benefited from sphincterotomy. However, only 30%-40% of patients with an elevated sphincter pressure treated with sham sphincterotomy or with a normal pressure treated by sphincterotomy or sham benefited from therapy. The authors concluded that SOM predicted outcome from sphincterotomy and that sphincterotomy offers long-term pain relief in patients with verified SOD.

An Australian study of SOM in 81 post-cholecystectomy patients with biliary-type pain compared outcomes among a mixed group of patients with types Ⅰ (n = 9), Ⅰ-Ⅱ (n = 27), Ⅱ (n = 27) and Ⅲ (n = 18)[70]. The manometric records were categorized as SO stenosis, SO dyskinesia or normal, after which patients were randomized in each category to sphincterotomy or a sham procedure in a prospective double blind study. In the SO stenosis group symptoms improved in 11/13 patients treated with sphincterotomy compared to 5/13 who had a sham procedure (P = 0.041). Results from each treatment group did not differ for patients with SO dyskinesia and normal SOM. This trial provided further evidence that patients with presumed SO dysfunction, with subsequent manometrically diagnosed SOD, benefit from endoscopic sphincterotomy. The authors hypothesized a generalized motility disorder to account for the lack of benefit in patients with normotensive but dyskinetic sphincter function.

Sherman *et al*[71] reported results of a randomized trial comparing sphincterotomy, surgical biliary sphincteroplasty with pancreatic septoplasty (with or without cholecystectomy) to sham sphincterotomy for types Ⅱ and Ⅲ biliary patients with manometrically documented SOD (n = 52). After 3 years, 69% of patients undergoing endoscopic or surgical sphincterotomy had symptomatic improvement compared to 24% in the sham sphincterotomy group (P = 0.009). Type Ⅱ patients had an 81% response to sphincter ablation compared to 58% for type Ⅲ patients; double that of the sham sphincterotomy group.

These trials suggest that SOM is a useful guide in predicting benefit from sphincterotomy in type Ⅱ SOD. However, other (non-randomized) trials have suggested that manometric findings do not correlate with clinical outcome. For example, Botoman *et al*[72] included types Ⅱ (n = 35) and Ⅲ (n = 38) patients to assess response to sphincterotomy. There was no difference between the two groups with respect to sphincter hypertension (60% *vs* 55% respectively), symptomatic improvement at 3 years (60% *vs* 56%) or post-procedure pancreatitis rates (15% *vs* 16%). The authors suggested that current classifications are inadequate to define either incidence of SOD or response to sphincterotomy. In another trial SOM was performed in all but 3 patients from a total of 35 patients with suspected type Ⅱ SOD and 29 with type Ⅲ[73]. Sphincterotomy was performed in all patients with SO pressure greater than 40 mmHg, which included 62.5% of the type Ⅱ patients and 50% of the type Ⅲ patients. After 6 wk 70% of the patients with type Ⅱ SOD and 39% of the type Ⅲ SOD who had sphincterotomy reported benefit (P = 0.13, type Ⅱ *vs* type Ⅲ). None of the patients with normal manometry had symptomatic improvement. After long-term follow up (median 2.5 years) sustained improvement occurred in 60% of the type Ⅱ patients but only 8% of those with type Ⅲ (P < 0.01). The investigators felt that the current classification helps predict outcome after sphincterotomy but again acknowledged a lack of difference in the incidence of abnormal SO baseline pressure between type Ⅱ and type Ⅲ SOD.

Cicala *et al*[74] performed SOM and quantitative scintigraphy in 30 patients with suspected type Ⅰ or type Ⅱ SOD. Fourteen (6 type Ⅰ and 8 type Ⅱ) of the 22 patients were offered and underwent sphincterotomy. At long term follow up, all 14 patients were asymptomatic, biochemical abnormalities had resolved and hepatic hilum-duodenum transit time (HHDT) at scintigraphy had significantly decreased. The patients who had refused sphincterotomy had no change in symptoms or HHDT. Scintigraphy predicted favorable outcomes in 93% of cases compared to 57% for SOM. Two other studies found no correlation between response to sphincterotomy and sphincter pressure for either type Ⅰ or type Ⅱ patients[68,75].

The frequency of hypertension in either sphincter among patients with presumptive type Ⅲ SOD ranges from 25%-70%[76]. The previously cited trial by Sherman *et al*[71], which was published as an abstract, is the only randomized controlled trial that has dealt with outcomes post-sphincterotomy for patients with type Ⅲ SOD. 29 patients with presumed type Ⅲ SOD were randomized and after a 3-year follow up period symptoms had improved in 8/13 (62%) who had undergone endoscopic sphincterotomy, 3/10 (30%) who has sham sphincterotomy and 3/6 (50%) after surgery. A follow up study after dual sphincterotomy for biliary and pancreatic SOD, which included 166 patients with type Ⅲ SOD, found no significant difference in re-intervention rates between different classes of SOD (i.e., biliary *vs* pancreatic, type Ⅱ *vs* type Ⅲ)[77]. After a mean follow up of 44 mo, persistent symptoms prompted re-intervention in 28.3% of patients with type Ⅲ SOD, compared to 20.4% for combined type Ⅰ and Ⅱ (P = 0.105). Other studies report response rates between 8%-65% for type Ⅲ SOD[73,76].

It has been postulated that type Ⅲ SOD is part of a spectrum of functional GI disorders and many patients labeled with it may in fact have a diffuse gastrointestinal motility disturbance. Desautels *et al*[78], for example,

showed that patients with type Ⅲ SOD exhibit duodenal-specific visceral hyperalgesia and their symptoms are reproduced by duodenal distension. The challenge remains to identify which patients will most likely to benefit from a particular therapy. Varadarajulu *et al*[2] suggest that patients who present with discrete, self-limiting episodes of typical biliary or pancreatic type pain are the ones most likely to benefit from SOM and sphincterotomy. With the current evidence available it is reasonable to consider medical therapy as the first line of treatment for patients with suspected type Ⅲ SOD. ERCP with SOM should be considered in the event of failure of medical therapy with sphincterotomy if manometry is abnormal.

Pancreatic type SOD

Evidence that SOD may be a cause of IARP is supported by the resolution of pancreatitis after sphincterotomy, with up to 80% improvement in patients with IARP after biliary sphincterotomy[79]. Tarnasky *et al*[80] showed that biliary sphincterotomy reduced pancreatic basal pressure to within the normal range in 30% of patients immediately after the procedure and 20% after longer term follow up, presumably by ablation of the common channel sphincter, and hence a reduction in the length of the residual pancreatic portion. In a proportion of patients therefore, biliary sphincterotomy alone may resolve pancreatitis or pancreatic pain.

In the one controlled trial addressing response to therapy in patients with acute recurrent pancreatitis presumed to be secondary to SOD, Jacob *et al*[81] compared response to ERCP with or without stent insertion in patients with negative investigations including SOM. Stent insertion reduced the rate of recurrence of pancreatitis from 53% to 11% over a 3-year study period.

Kaw *et al*[54] assessed the relationship between microlithiasis and sphincter hypertension in 67 patients with IARP. After endoscopic biliary sphincterotomy, 88% of patients with type I SOD and 73% with type Ⅱ were asymptomatic, irrespective of microlithiasis or gallbladder status. In a study in which ERCP, SOM and endoscopic ultrasound (EUS) were carried out on 90 patients with acute recurrent pancreatitis, SOD was found to be the most common cause found ($n = 28$) [53]. Of the 22 of these patients who underwent biliary sphincterotomy 21 had reduced episodes of acute pancreatitis after 6 mo.

It has been suggested that inadequate pain relief after biliary sphincterotomy may be due to inadequate biliary sphincterotomy, recurrent biliary stenosis, chronic pancreatitis, other residual pancreaticobiliary disease or a non-pancreaticobiliary cause, e.g., irritable bowel syndrome or a persistent abnormality in pancreatic sphincter pressure[28,82,83]. In the latter case, dual biliary and pancreatic sphincterotomy may improve outcome. Eversman *et al*[84] reported long term outcome of biliary sphincterotomy alone in patients with SOD. Patients with SOD and an abnormal pancreatic sphincter pressure needed re-intervention more often than those with abnormal biliary sphincter pressure alone (39.4% *vs* 16.2%, $P < 0.05$) or dual sphincter hypertension (29%, $P < 0.05$). These results support the theory that an untreated pancreatic SOD may cause recurrent pain in patients who have undergone biliary sphincterotomy alone. A previously cited study by the same authors[16] showed that manometry of both pancreatic and biliary portions of the SO is necessary for complete evaluation for SOD. Other studies have drawn the same conclusions[22,85].

Guelrud *et al*[86] reported the response to four different therapeutic options in patients with normal pancreatography and elevated sphincter pressures (pancreatic type Ⅱ SOD). Symptomatic improvement occurred in 28% of patients treated by biliary sphincterotomy alone, in 54% who had biliary sphincterotomy combined with pancreatic orifice dilatation, in 77% who underwent dual sphincterotomies at two separate sessions and in 86% of patients who had dual sphincterotomies performed during a single session. Compared to biliary sphincterotomy alone, dual sphincterotomy had significantly better outcomes ($P < 0.0005$), irrespective of whether they were performed at a single or at separate sessions. The authors suggested that pancreatic sphincter ablation should be considered for patients with type Ⅱ SOD and an abnormal pancreatic basal sphincter pressure. Other studies have shown similar results. Soffer and Johlin[87] found symptomatic improvement following pancreatic sphincterotomy in 16 out of 25 (64%) patients unresponsive to biliary sphincterotomy. In a further trial, 43 patients who had not responded to biliary sphincterotomy were followed up for a median of 14 mo after pancreatic sphincterotomy. 39/43 patients (91%) showed clinical improvement with 31/43 having a complete response[88].

Another group of investigators followed-up 313 patients who had undergone endoscopic dual sphincterotomy for manometry documented SOD of at least one sphincter for a mean of 43.1 mo[77]. Hypertension was demonstrated in both sphincters in 57%, in the pancreatic sphincter alone in 35% and in the biliary sphincter alone in 26%. Immediate complications occurred in 15% of patients and re-intervention was required in 24.6% of patients at a median follow-up of 8 mo. Re-intervention rates were similar irrespective of ducts with abnormal basal sphincter pressure or previous cholecystectomy. Compared to biliary sphincterotomy alone in historical controls, dual sphincterotomy had a lower re-intervention rate in patients with pancreatic SOD alone (21.3% *vs* 39.4%, $P = 0.034$) and a comparable outcome in those with SOD of both ducts (26.6% *vs* 29%, $P = 0.412$) or isolated biliary SOD (25% *vs* 16.2%, $P = 0.285$). Immediate complication rates occurred in 47/313 patients (15%) with pancreatitis in 45/313 (14.4%). Severe pancreatitis occurred in 0.9% of patients. These complication rates are lower than those reported for biliary sphincterotomy in the prospective study by Freeman *et al*[36] when 21.7% of patients developed pancreatitis, of which 3.7% were severe. This may relate to differences in the quality of pancreatic drainage between the two trials. Fogel *et al*[26] also noted that biliary, as opposed to dual, sphincterotomy was more likely to induce pancreatitis in patients with suspected SOD. Therefore, dual sphincterotomy seems to be beneficial for patients with pancreatic SOD, but not in those with biliary SOD alone. It remains unclear

whether dual sphincterotomy should be performed at the initial procedure. Further randomized trials comparing single versus dual sphincterotomy in patients with SOD are necessary to determine the most appropriate sphincter therapy based on SOM findings. However, other factors should also be taken into account. In a recent trial which included patients with biliary types Ⅰ, Ⅱ and Ⅲ SOD, all 121 patients underwent biliary sphincterotomy[89] and 49 patients had pancreatic sphincterotomy at initial or subsequent ERCP if there was a history of abnormal pancreatic manometry in the setting of continuous pain, persistent pain after biliary sphincterotomy or a history of amylase elevation. There was no significant difference in patient response according to Milwaukee classification. (However, this may reflect the numbers of patients involved, with only 18 meeting the criteria for type Ⅰ SOD). Significant predictors of poor response were normal pancreatic manometry, delayed gastric emptying, daily opioid use and age < 40. Abnormal liver function tests and a dilated bile duct were not significant predictors of outcome. These findings support the argument that we cannot rely on the Milwaukee classification alone to predict response to treatment. The authors suggested that patient factors and pancreatic manometry may be more important predictors of outcome of dual sphincterotomy for SOD. These issues should be taken into account before embarking on therapy.

POST-ERCP PANCREATITIS IN SOD

Overall pancreatitis rates post- ERCP are usually quoted to be between 5%-15%[36,90]. Prospective studies have consistently shown that SOD confers increased risk of post-ERCP pancreatitis (PEP). Cheng *et al*[38] evaluated risk factors for ERCP-induced pancreatitis in 1115 patients who had undergone ERCP. Suspected SOD was a significant risk factor with an OR of 2.6. In a prospective study of 1223 ERCP procedures, Vandervoort *et al*[91] found that patients with manometrically proven SOD had a threefold risk of PEP (21.7% *vs* 7.2%). Freeman *et al*[92] found an overall pancreatitis rate of 6.7% in 1963 ERCP procedures with an odds ratio of 2.6 for suspected SOD. A meta-analysis of 15 prospective clinical trials found that patients with suspected SOD had a relative risk of developing pancreatitis of 4.09 (95% CI 3.37-4.96, $P < 0.001$)[93]. SOD is therefore an independent risk factor for post-ERCP acute pancreatitis and the decision to proceed to ERCP, with or without SOM and/or sphincterotomy, should be made with care.

Sphincterotomy for SOD increases the risk of PEP. One randomized control trial, albeit small ($n = 36$), found a post-sphincterotomy pancreatitis rate of 33% in patients with SOD in whom a PD stent was not placed[94]. Five prospective randomized trials have compared PEP rates between high risk patients with or without PD stent placement. Four of these included patients with SOD (Table 3)[25,35,94,95]. Of these four studies all showed a trend to reduction of PEP with PD stent placement, and two reached statistical significance. A meta-analysis of five prospective studies showed a 3-fold increased risk of post-ERCP pancreatitis if a pancreatic stent was not used (15.5% *vs* 5.8%, OR 3.2, 95% CI 1.6-6.4)[96].

Table 3 Role of pancreatic stent insertion in prevention of post- ERCP pancreatitis; results of randomized controlled trials that included patients with SOD

Author	Year	No. of patients	Pancreatitis rate (%)		
			Stent	No stent	
Smithline *et al*[95]	1993	93	14	18	$P = 0.299$
Tarnasky *et al*[25]	1998	80	7	26	$P = 0.03$
Patel *et al*[94]	1999	36	11	33	$P > 0.05$
Fazel *et al*[35]	2003	76	5	28	$P < 0.05$

At least three case control studies have also included patients with SOD. In two of these there was a significant reduction in PEP with a pancreatic stent[26,88] and in the other the reduction of pancreatitis rate from 66.7% to 14.4% did not quite reach significance ($P = 0.06$)[97]. Therefore, there is substantial evidence that pancreatic stent placement reduces the incidence of post-ERCP pancreatitis in high-risk groups such as SOD. However, failure to deploy the stent successfully may occur in up to 10% of patients[98], and failed pancreatic stent placement can increase the rate of PEP sixteen fold[97]. Therefore, pancreatic stent placement should not be attempted unless the likelihood of success is very high.

CONCLUSION

The relationship between SOD and pancreatitis is a complex one. An association between SOD and acute pancreatitis appears to be beyond doubt, not least because of the high frequency of abnormal SOM in IARP. SOD also carries a significantly increased risk of post-ERCP pancreatitis with rates of over 30%, although correct placement of a pancreatic stent at the time of the procedure appears to reduce this risk. However, although various mechanisms have been postulated, the exact role of SOD in the pathophysiology of pancreatitis is not known and it is unclear if SO dysfunction as a primary event or secondary to other factors is the principal mechanism. There is also evidence linking SOD with chronic pancreatitis but whether this is a cause or effect relationship is still unknown.

Sphincterotomy remains the management of choice for SOD. All patients with type Ⅰ SOD should have their sphincter ablated and, by general consensus, this group does not require manometry prior to the procedure. The question whether dual sphincterotomies should be carried out remains unanswered and further randomized trials are required to clarify this. For patients with type Ⅱ SOD grade A studies have found that SOM is a useful guide in predicting response to sphincterotomy, although some smaller studies showed that manometric findings do not correlate with clinical outcome. However, most experts agree that patients with suspected type Ⅱ SOD should have SOM before considering sphincterotomy.

The management of patients with type Ⅲ SOD is more difficult still with response rates to sphincterotomy ranging from 8% to 65%. In general, sphincter ablation is probably warranted if SOM is abnormal but medical

therapy should be tried before proceeding to manometry. Detailed history taking is paramount for these patients. The more the pain pattern differs from that set out in the Rome Ⅱ criteria, the less likely is the patient to benefit from treatment. Until there is a more adequate method of characterizing patients with type Ⅲ SOD it will not be possible to carry out a randomized trial of sphincterotomy against placebo. Ultimately, this will be the only way of proving the benefit or otherwise of sphincterotomy for patients with presumptive type Ⅲ SOD.

Recent evidence supports the need to measure both portions of the SO to maximize the detection rate of SOD. This dual classification has prompted a call for a single overall classification system from some quarters. A recently published trial[89] has also shown that other patient factors such as age, opioid use, delayed gastric emptying and pancreatic manometry are more important predictors of response to dual sphincterotomy than abnormal liver function tests and a dilated ductal system, on which the traditional classification system is heavily based. Further large prospective trials are required to identify other potential patient factors that may help predict response to therapy; such factors should be taken into account in any future overhaul of the current classification system.

Abstract

Although there is a great deal of information on celiac disease and associated involvement of other non-intestinal sites, data on concomitant changes in the structure and function of the pancreas is limited. The present review critically examines pancreatic endocrine changes that have been well documented in the literature, including insulin-dependent diabetes mellitus. Pancreatic exocrine alterations may also occur, and if severe, marked malnutrition with pancreatic failure and ductal calcification have been observed. Finally, other pancreatic disorders have been recorded with celiac disease.

Key words: Celiac disease; Gluten-sensitive enteropathy; Diabetes mellitus; Chronic pancreatitis; Pancreatic function

INTRODUCTION

Considerable information has already been published on both the intestinal and the extra-intestinal manifestations of celiac disease. Pancreatic changes may be caused by celiac disease or co-exist with celiac disease. Both endocrine and exocrine function of the pancreas may be substantially changed in celiac disease. As a result, superimposed or more severe clinical changes may appear and marked nutritional disturbances may result. Although data is very limited, there is increasing evidence that impaired endocrine and exocrine pancreatic function in celiac disease may be favorably influenced by gluten-free diet treatment.

PANCREATIC ENDOCRINE CHANGES

Over the past decade or so, a number of studies from Europe[1,2] and North America[3,4] have demonstrated that the prevalence of celiac disease in patients with type 1 diabetes is increased. This association is due, at least in part, to sharing of the human leukocyte antigen allele, DR3, and, by linkage disequilibrium, DQ2[5]. In addition to a common "autoimmune" basis, it is conceivable that some celiacs have developed diabetic changes secondary to severe pancreatic insufficiency with exocrine dysfunction. Earlier serological studies employed IgA antibody studies for celiac screening, particularly using IgA endomysial antibody (EMA) testing. This eventually became the "gold standard" for serological studies, until subsequent identification of tissue transglutaminase (TTG) as the tissue antigen for endomysial antibodies[6]. As a result, IgA TTG antibodies (using ELISA methodology) became a very attractive alternative for first line screening and also permitted development of a quantitative assay.

A recent TTG prospective study[7] in children and adolescents with type 1 diabetes evaluated TTG antibody titres in 125 males and 108 females followed in a pediatric diabetes center. Altogether, 26 patients, including 15 males and 11 females, had positive TTG titres and, of these, 19 were also positive for EMA. In those positive for both TTG and EMA, small intestinal biopsies were done. Histopathological abnormalities described in celiac disease were detected ranging from increased numbers of intraepithelial lymphocytes to severe crypt hyperplastic villous atrophy (Marsh 3 lesion)[7]. These studies also suggested that serial TTG serological measurements in insulin-dependent diabetics might play a role in monitoring their serological responses as well as the compliance to the gluten-free diet. In children and adolescents, close monitoring is critical as compliance in these age groups may be especially difficult to assess. While over 40% of the diabetics in this study were asymptomatic[7], prospective serological screening appeared to facilitate selection for biopsy evaluation.

Earlier detection of celiac disease has been urged in type 1 diabetes, even in children, because of the long-term risks of undiagnosed celiac disease. It has been suggested that the longer the duration of untreated celiac disease (also in dermatitis herpetiformis), the higher the risk of

enteropathy-associated T cell lymphoma[8]. Moreover, adherence to a gluten-free diet appears to reduce the risk of enteropathy-associated T cell lymphomas in celiac disease. Finally, the association of lymphoma, celiac disease and type 1 diabetes has also been documented in 4 cases[9].

Other long-term complications may occur including iron deficiency anemia, osteoporosis, infertility and growth retardation. These appear to be most significant when patients are poorly compliant with a gluten-free diet, or if diagnosis is delayed until later in life[10]. Finally, improved glucose control with a gluten-free diet has also been shown in type 1 diabetes with concomitant celiac disease[11]. In these studies with type 1 diabetes in celiac disease, pancreatic exocrine function was not evaluated.

PANCREATIC EXOCRINE CHANGES

Pancreatic exocrine function may also be substantially altered in celiac disease. Even though the precise prevalence of altered pancreatic function in celiac disease is not known, impaired pancreatic function may be a cause of impaired digestion and absorption resulting in malnutrition[12]. It has been estimated that over 20% of patients with celiac disease have defective exocrine pancreatic function[13]. This may be related to several factors. First, impaired secretion and/or release of pancreatic stimulating hormones from the diseased proximal small intestine may be important[14]. Immunohistochemical studies on small intestinal biopsies from untreated celiac disease have demonstrated significant alterations in enteric endocrine cells, including an absence of secretin cells[15].

Moreover, studies with test meals in celiacs have suggested impaired secretion of cholecystokinin-pancreozymin, resulting in reduced pancreatic exocrine cell stimulation[16]. Second, deficiencies of amino acids may result from impaired small intestinal amino acid uptake, leading to reduction in precursors of pancreatic enzyme synthesis[12,17]. Third, protein malnutrition may lead to structural changes in the pancreas, including atrophy of acinar cells and pancreatic fibrosis, resulting in impaired pancreatic exocrine function[12]. Pancreatic enzyme measurements were also found to be reduced with mucosal atrophy and could be inversely correlated with the degree of intestinal damage[18]. Earlier studies measuring xylose absorption were limited in ability to separate pancreatic and intestinal causes of steatorrhea, especially if the degree of impairment was mild[19]. Subsequent attempts to define altered intestinal permeability using large molecules (e.g., cellulobiose, mannitol)[20] or separate pancreatic insufficiency from intestinal dysfunction with noninvasive stable isotopes[21] have not become widely accepted.

Severe structural changes have also been documented. Pancreatic calcification, most often associated with chronic or persisting pancreatic inflammation, has been traditionally associated with excessive alcohol use.

Atrophy, fibrosis and altered pancreatic function have also been detected in experimental animals treated with diets deficient in protein, in adults with protein energy malnutrition, in children with kwashiorkor and in some early autopsy studies of patients with celiac disease[16,17,22-24]. In addition, pancreatic calcification has been reported with chronic protein malnutrition in the Indian subcontinent and in some African countries[25]. Finally, an adult patient with celiac disease and non-alcohol related pancreatitis with calcification has been described in North America[26]. Possible effects on pancreatic exocrine function in celiac disease poorly compliant to a gluten-free diet has not been evaluated.

MISCELLANEOUS DISORDERS

A number of other miscellaneous pancreatic disorders have been associated with celiac disease. Pancreatic mucinous adenomas have been associated with celiac disease in a patient with polycystic kidney disease[27]. In addition, pancreatic and ampullary carcinomas have been recorded in celiac disease[28,29], although the celiac disease has often only been recognized after pancreatoduodenectomy suggesting that subclinical celiac disease may be "unmasked" by major upper gastrointestinal surgery and should be considered in the differential diagnosis after pancreatoduodenectomy[22,29].

Celiac disease has been associated with chronic calcific pancreatitis in patients with pancreas divisum[30]. Diabetes-related autoantibodies may appear in children with celiac disease, including antibodies to insulin, immunoglobulin, islet cells and glucagon[31]. Early-onset vitamin B12 malabsorption in children with celiac disease has also been documented and related to impaired pancreatic exocrine secretion[32]. Finally, macroamylasemia has also been attributed to gluten-related amylase autoantibodies (particularly in childhood)[33].

Because of the possible deleterious effects of biliary tract lithiasis on pancreatic structure and function, gallbladder function in celiac disease may also be important and carefully examined in celiac disease. In some, slow emptying of the gallbladder has been documented, associated with impaired contraction response to fat[34,35]. Studies of enteric endocrine cells have demonstrated significant quantitative and qualitative changes in celiacs[15]. In addition, studies with test meals have suggested impaired secretion of cholecystokinin in patients with celiac disease, and, possibly, impaired gallbladder responsiveness to cholecystokinin[15,34]. In spite of these physiological alterations, there does not appear to be a significant predisposition to gallstones in celiac disease and consequently, secondary pancreatic damage. Only 9 of 350 celiac patients had a cholecystectomy for gallstone disease[14]; however, in a survey of elderly celiacs initially diagnosed after the age of 60 years, approximately 20% had developed gallstone disease[36,37].

CONCLUSION

In summary the endocrine and exocrine function of the pancreas may be impaired in celiac disease and their pathogenesis may be closely linked. Further studies are needed to explore the importance of detection of endocrine and exocrine pancreatic disorders in celiac disease, along with potential treatment options.

Abstract

Transplantation of pancreatic tissue, as either the intact whole pancreas or isolated pancreatic islets has become a clinical option to be considered in the treatment of patients with type 1 insulin-dependant diabetes mellitus. A successful whole pancreas or islet transplant offers the advantages of attaining normal or near normal blood glucose control and normal hemoglobin A1c levels without the risks of severe hypoglycemia associate with intensive insulin therapy. Both forms of transplants are also effective at eliminating the occurrence of significant hypoglycemic events (even with only partial islet function evident). Whereas whole pancreas transplantation has also been shown to be very effective at maintaining a euglycemic state over a sustained period of time, thus providing an opportunity for a recipient to benefit from improvement of their blood glucose control, it is associated with a significant risk of surgical and post-operative complications. Islet transplantation is attractive as a less invasive alternative to whole pancreas transplant and offers the future promise of immunosuppression-free transplantation through pre-transplant culture. Islet transplantation however, may not always achieve the sustained level of tight glucose control necessary for reducing the risk of secondary diabetic complications and exposes the patient to the adverse effects of immunosuppression. Although recent advances have led to an increased rate of obtaining insulin-independence following islet transplantation, further developments are needed to improve the long-term viability and function of the graft to maintain improved glucose control over time.

TRANSPLANTATION FOR THE TREATMENT OF TYPE 1 DIABETES

It has been clearly shown that patients with type 1 insulin-dependent diabetes mellitus (IDDM) benefit from improved blood glucose control. In 1993, the Diabetes Control and Complications Trial Research Group reported that patients with IDDM treated with intensive insulin therapy showed a reduced risk of developing retinopathy, albuminuria or microalbuminuria and clinical neuropathy when compared to patients who received conventional insulin therapy[1]. In this trial the intensive therapy group was shown to have achieved sustained lowered blood glucose concentrations over time as reflected by significantly lower glycosylated hemoglobin values compared to those of the conventional insulin therapy group. Although the intensive therapy group benefited from reduced long-term complications, the risk of severe hypoglycemia associated with tight glycemic control was three times greater than in the conventional therapy group.

Transplantation of pancreatic tissue, as either the intact whole pancreas or isolated pancreatic islets has become a clinical option to be considered in the treatment of patients with IDDM. Successful pancreatic transplantation offers the advantages of attaining normal or near normal blood glucose control without the risks of severe hypoglycemia associated with intensive insulin therapy. Pancreatic transplantation however, may not always achieve the sustained level of tight glucose control necessary for reducing the risk of secondary diabetic complications and exposes the patient to peri-operative or procedural risks, the adverse effects of immunosuppression and the risk of an eventual significant loss of graft function necessitating a return to exogenous insulin.

When either transplantation of a whole pancreas or pancreatic islets is being offered for the treatment of IDDM, the goals of the program should include: (1) A transplant procedure, which can be performed with overall low morbidity and mortality and subject the recipient to a minimal degree of side effects and complications of the post-procedural care; (2) Elimination of the need for insulin administration and close blood glucose monitoring; (3) Eliminate the occurrence of significant hypoglycemic events; (4) Creation of a euglycemic state, with preprandial and postprandial blood glucose concentrations and

hemoglobin A1c levels comparable to those in the non-diabetic population; (5) Achieving sustained effect of the transplant as to maintain normal glucose homeostasis over time.

WHOLE PANCREAS TRANSPLANTATION

Whole pancreas transplantation, first performed in 1966 in combination with a kidney in IDDM patients suffering from end-stage renal failure, demonstrated that a euglycemic state could be obtained without the need for exogenous insulin[2]. The early procedures however, were complicated by a high morbidity rate; early graft failure and poor patient survival and few transplants were performed[3]. Improvements in transplant techniques, immunosuppression therapies and post-transplant monitoring of graft function and rejection has resulted in a dramatic improvement in patient morbidity and graft survival. With the improved outcomes and demonstrated efficaciousness in controlling the diabetic glycemic state, whole pancreas transplantation is now recognized by the American Diabetes Association as an acceptable therapeutic alternative to continued insulin therapy in diabetic patients with imminent or established end-stage renal disease who had or plan to have a kidney transplant[4].

Pancreas transplantation may be considered as a group of three separate, clinical entities: simultaneous pancreas and kidney transplant (SPK), pancreas after kidney transplant (PAK) and pancreas transplant alone (PTA). Each form of transplant is characterized by its own indications, risks and outcomes.

Simultaneous pancreas kidney transplantation

Diabetes is a major cause of renal disease and is associated with approximately 40% of new cases of end-stage renal failure (ESRF) in the US, who will subsequently require renal dialysis or kidney transplantation[5]. When an IDDM patient develops ESRF and requires a kidney transplant; consideration is now commonly given to whether the patient would also benefit from receiving a pancreas transplant. SPK transplantation is the most common form of pancreas transplantation performed accounting for 60% of the total number of pancreas transplants performed each year in the US (approximately 900/year)[6-8]. The annual number of SPK transplants has remained stable over the last 10 years, however this may reflect the increasing interest in the option of PAK transplantation (living donor kidney transplantation) by the patient in ESRF with IDDM.

When SPK transplantation is performed, the patient undergoes only one operation and following the surgery may be managed on the same (or very similar) immunosuppressive drugs they would have received for a renal transplant alone. The combined procedure offers excellent patient and pancreatic graft survival, producing a sustained euglycemic state off of exogenous insulin or oral hyperglycemic agents[7,9]. The renal transplant provides an effective method of surveillance of both grafts for acute rejection (creatinine clearance, biopsy) and may in part explain the improved one-year and long-term pancreatic graft survival rates when compared to a pancreas transplant without a donor-matched kidney transplant. There also has been no evidence that the pancreas transplant may have a deleterious effect on the simultaneously transplanted kidney.

Pancreas after kidney transplantation

As the number of patients with ESRF increased in the past decade, the demand for renal transplantation outpaced the supply of cadaveric kidneys available. By 2000, the number of living donor kidney transplants performed in the US exceeded the number of cadaveric donor transplants. Whereas SPK transplantation is usually restricted to the use of cadaveric kidneys only, PAK transplantation offers the option of using a living donor kidney, and in doing so both expands the number of kidneys available for transplant and allows the diabetic patient the opportunity to benefit from early living donor kidney transplant (better long term outcome, avoidance of dialysis). With improved surgical technique, better immunosuppressive drugs and rejection monitoring, outcomes for solitary pancreas transplants have improved such that PAK transplantation is now routinely considered[6,7]. The kidney transplant recipient is required to demonstrate stable renal function and minimal post procedure complications to be acceptable for subsequent pancreas transplantation. The PAK transplant option does require the patient to undergo two major operations, however the post transplant immunosuppression and care are similar to kidney transplant alone.

Pancreas transplantation alone

PTA is offered in some transplant centers to IDDM patients who have difficult to manage diabetes and suffer from severe hypoglycemic episodes (often with hypoglycemic unawareness) with little or no evidence of renal disease. As with PAK transplantation, improvements in PTA graft survival has significantly improved in recent years, although the question of whether or not the procedure may have an adverse long term affect on the recipients renal function (calcineurin antagonist based immunosuppression) has not been resolved. The normalizing of blood glucose levels with the pancreas transplant may offer this patient group the possibility of long-term improvement in renal function. The American Diabetes Association's 2006 Position Statement on pancreas and islet transplantation recommends "In the absence of indications for kidney transplantation, pancreas-alone transplantation should only be considered a therapy in patients who exhibit these three criteria: (1) a history of frequent, acute and severe metabolic complications (hypoglycemia, marked hyperglycemia, ketoacidosis) requiring medical attention; (2) clinical and emotional problems with exogenous insulin therapy that are so severe as to be incapacitating; and (3) consistent failure of insulin-based management to prevent acute complications"[4]. Since 2001, PTA has accounted for approximately 12% of pancreas transplants performed annually in the US[6].

WHOLE PANCREAS TRANSPLANTATION SURGERY

Bladder verses enteric pancreatic drainage

In the early development of pancreas transplantation, the surgical procedure involved drainage of the exocrine pancreas secretions in to the bladder. This was best accomplished by transplanting (in continuity) a short segment of donor duodenum with the pancreas, which provides a conduit from the pancreas to the bladder through which the secretions could be drained. Use of the duodenum-to-bladder drainage reduced the rate of transplant exocrine secretion leaks and allowed monitoring for evidence of early graft rejection by the frequent measurement of amylase activity in the urine. Direct biopsy of the transplanted pancreas and duodenum by cystoscopic technique could also be performed[3]. However, the loss of bicarbonate-rich pancreatic secretions into the bladder is associated with a number of problems. Patients who have undergone bladder drainage of their pancreas transplant require daily oral bicarbonate and fluid replacement to offset the severe metabolic acidosis and at times significant fluid loss associated with the procedure. Other problems associated with bladder drainage include: reflux graft pancreatitis (bladder dysfunction associated with diabetic neurogenic bladder); cystitis; urethritis and stricture formation; recurrent bladder infections. For some patients (approximately 15% at three years from the time of transplantation) the complications were severe enough that surgical reversal of the bladder drained pancreas transplant, with re-direction of the secretions into the small bowel was necessary[3,9].

In the late nineties transplant centers began to perform primary enteric drainage of pancreatic secretions in order to avoid the complications of bladder drainage. Improvements in immunosuppression had led to a reduced number of episodes of acute graft rejection and increasing experience with direct percutaneous needle biopsy reduced the need for urinary amylase monitoring. Enteric drainage of pancreatic secretions prevented the obligatory loss of sodium bicarbonate and fluid and the subsequent hypovolemia, metabolic acidosis and the other complications associated with bladder drainage. Initially the procedure often involved anastomosis of the transplant duodenal segment to a Roux-en-Y limb of the recipient's mid-small bowel to reduce the likelihood of an anastomotic leak, however the surgery is now routinely performed directly to the small bowel. Enteric drainage of the pancreatic transplant secretions is now the more commonly performed procedure, used in 81% of SPK, 67% of PAK and 56% of PTA transplants performed in the US during 2000-2004 (when a SPK was performed, the donor-matched kidney may be followed for evidence of acute graft rejection which may be a better early marker than urinary amylase output)[6-10].

Systemic verses portal venous drainage

Vascular drainage of the pancreas transplant may be performed either into the systemic venous system (most commonly used is the external iliac vein) or into the portal venous system (using a vein of the small bowel mesentery). With systemic venous drainage the insulin secreted by the pancreas transplant avoids early hepatic extraction and results in an elevation of both basal and stimulated serum insulin concentrations. Portal venous drainage directs the insulin released by the pancreas transplant initially to the liver in a fashion similar to the release of insulin in a non-diabetic person. Although it is felt to be "more physiological", portal venous drainage of the pancreas transplant has not been shown to offer any advantage over systemic venous drainage in maintaining normal glucose homeostasis or lipid metabolism. It has been suggested that direct presentation of the pancreas transplant alloantigen to the liver may provide an immunologic benefit. However, registry data has not found evidence for improved graft survival when portal venous drainage has been performed. Systemic venous drainage remains the more commonly performed procedure, used in 77% of SPK, 73% of PAK and 56% of PTA transplants performed in the US during 2000-2004[6-9].

Surgical complications

The complexity of the whole pancreas transplant procedure, along with the likelihood of pre-existing disease secondary to their IDDM, exposes the recipient to a variety of significant operative and post-operative risks. The extent of the post-operative problems likely limited the widespread acceptance of pancreas transplantation in the early era of its development. Serious surgical complications following the procedure include: thrombosis of graft vessels, intra-abdominal hemorrhage, anastomotic leak (enteric or bladder), graft pancreatitis, pancreatic fistula formation and intra-abdominal sepsis, all of which may require re-laparotomy and the possibility of graft loss. In recent years, with improvements in donor and recipient selection criteria, surgical technique, immunosuppression protocols (reduced incidence of early, acute rejection) and prophylaxis regimes (anti-viral, anti-bacterial and antithrombosis), there has been a significant decrease in the overall incidence of serious complications and the rate of re-laparotomy[11,12].

Immunosuppression

Since 2000, in the US the most common primary protocol for maintenance immunosuppression for whole pancreas transplantation is Tacrolimus and Mycophenolate Mofetil (MMF), although other agents such as Cyclosporine, Sirolimus and Azathioprin in varying combinations are also being used in a small number of centers[7,8]. In addition, the majority of transplant centers continue to use corticosteroids, although there is an movement towards "steroid-free" immunosuppression protocols in an attempt to reduce their adverse effects (glucose control, dyslipidemia, bone loss) in the diabetic patient transplant population. The initial success with pancreatic islet transplantation in 2000 was obtained using an immunosuppression protocol of Sirolimus and Tacrolimus in combination and avoiding steroid entirely[13]. Sirolimus has proven to be difficult to use in some patients (mouth ulcers, hyperlipidemia)[14] and recent studies

have demonstrated poorer graft survival and inferior renal function when Sirolimus is used as a primary agent in combination with Tacrolimus when compared with the use of Tacrolimus and MMF in kidney and heart transplantation[15-17]. Induction immunosuppression is routinely used in whole pancreas transplantation, with > 75% of recipients receiving either: (1) a T-cell depleting polyclonal antibody (Thymoglobulin, ATGAM) or monoclonal antibody (OKT3, Campath), (2) a non-depleting monoclonal anti-CD25 antibody (Zenapax, Simulect), or (3) both[7,8].

Long-term use of immunosuppression is associated with a number of significant side effects and complications. The side effects most commonly seen with standard maintenance immunosuppression include: nephrotoxicity, hypertension, hyperlipidemia, microvascular disease, glucose intolerance, gastrointestinal problems, weight gain, skin changes/alopecia/hirsutism[18]. Immunosuppression-relate complications include: infections (viral, bacterial, fungal, parasitic) and malignancy (skin, lymphoproliferative, genitourinary). The risk of infection depends upon the degree of immune compromise created by the immunosuppressive regiment and the exposure to possible pathogens, either through re-activation of pre-existing infection (e.g., viral, tuberculosis) or introduction by the transplant process (e.g., surgical technique, transfer from donor)[19]. The risk of skin cancer for a patient on immunosuppression following renal transplantation is cumulative, ranging from 10% to 40% at 10 and 20 years respectively (ratio of squamous cell to basal cell carcinoma 2:1)[20]. The overall prevalence of post-transplant lymphoproliferative disease and leukemia varies from 1% to 2%[21].

OUTCOMES OF WHOLE PANCREAS TRANSPLANTATION

Patient and graft survival

Whole pancreas transplantation has proven to be a safe procedure with a 1 year and 3 year patient survival rates for all forms of pancreas transplant (SPK, PAK, PTA) in the US since 1998 at about 95% and 89% respectively (unadjusted patient survival rates, 2005 OPTN/SRTR Annual Report)[6] (Table 1). Transplantation of a pancreas simultaneously with a kidney may also increase long-term IDDM patient survival compared to kidney transplantation alone. Whereas the mortality risk is increased over the first 18 months for the SPK recipient (associated with an increased rate of complications such as infection when compared to kidney transplant alone), when the pancreas continues to function post transplant, recipient survival is superior to SPK recipients who have had their pancreas graft fail or diabetic patients who received only a cadaveric kidney transplant[22,23].

One and 3 year graft survival rates for SPK transplant in the US since 1998 for kidney are ⩾ 91% and ⩾ 83% and pancreas are ⩾ 82% and ⩾ 75% respectively. Pancreas graft survival rates for PAK and PTA over a similar period were slightly less that for SPK: for 1 year 72% to 81% and 74% to 83% respectively, and at 3 years 63% to 71% and 60% to 69% respectively (unadjusted graft survival rates, 2005 OPTN/SRTR Annual Report). Although the incidence of acute kidney graft rejection has been shown to be greater following SPK than for kidney transplant alone (15% *versus* 9%), patients following SPK transplantation as a group general demonstrate better kidney graft function. This advantage of SPK on renal function disappears however when the analyses are adjusted for donor and recipient variables[9].

Table 1 Unadjusted patient and graft survival following SPK, PAK or PTA by year of transplant at 1 and 3 years

			Year of transplant					
		Survival (%)	1998	1999	2000	2001	2002	2003
SPK	Patient	One year	93.9	94.8	95.1	94.1	94.8	95.5
		Three years	89.6	90.6	90.2	89.6	+	+
PAK	Patient	One year	94.5	94.4	96.0	95.2	95.7	95.5
		Three years	90.8	88.1	91.2	89.1	+	+
PTA	Patient	One year	96.8	97.3	99.1	97.5	97.6	94.5
		Three years	90.5	90.9	95.5	90.8	+	+

CONSEQUENCES OF WHOLE PANCREAS TRANSPLANTATION

Blood glucose control

Successful whole pancreas transplantation produces a normoglycemic state in the majority of recipients, usually within minutes of completion of the procedure without the need for exogenous insulin. Transient hypoglycemia may occur over the first 24 h requiring I.V. glucose support. Patients demonstrate normal fasting and post-prandial blood glucose concentrations and a lowering of hemoglobin A1c to normal levels. Where systemic venous drainage of the pancreas has been performed, fasting and meal-stimulated insulin concentrations are elevate, the likely result of the elimination of first-pass hepatic extraction. Portal venous drainage typically results in a more normal pattern of fasting and meal-stimulated insulin concentrations, with similar glucose control. Although insulin levels are elevated by systemic venous drainage, blood glucose homeostasis appears to be unaffected, demonstrating normal glucose utilization and hepatic glucose production. Whole pancreatic transplantation is also an effective treatment for patients who had a long history of severe, symptomatic hypoglycemia. The normal glucagon response to hypoglycemia is restored and hypoglycemic episodes are uncommon. Whole pancreas transplantation has been shown to be effective in providing recipients with long-term normal glycemic control off insulin (10 years or more). Reduced hemoglobin A1c levels are maintained and patients demonstrate fasting

blood glucose and glycemic control in response to a meal or glucose challenge similar to those of the non-diabetic population[9,24].

Secondary complications of IDDM

The microvascular, neurologic and macrovascular diseases associated with IDDM has been attributed to long-term poor glycemic control. Whereas the Diabetes Control and Complications Research Group reported that improved glucose control through intensive insulin therapy effectively delayed the onset, or slowed the progression of diabetic retinopathy, nephropathy and neuropathy, the risk of severe hypoglycemia was significant and only a small percentage of patients could sustain the required improvement in metabolic control. Whole pancreas transplantation has now been performed over a long enough period of time to allow study of the effect of sustained normal glycemic control in patients with IDDM.

Diabetic nephropathy

Whole pancreas transplantation does prevent de-novo diabetic changes, which would otherwise occur in a diabetic recipient of a kidney transplant[25]. There is also evidence that long-term successful pancreas transplantation may improve pre-existing histological changes secondary to diabetes in the native kidneys, although the effect is only observed after 5 or more years[26]. Whether native renal function benefits from PTA is uncertain, as the nephrotoxic effect of calcineurin inhibitor based immunosuppression therapy must be considered. Registry data has identified that from 2% to 8% of PTA recipients develop ESRF and require a kidney transplant by one year[9,27]. A recent report of case matched PTA with diabetic controls found however that although native renal function decreased significantly after PTA in patients with decreased creatinine clearance (CrCl $\leqslant$ 70 mL/min) at the time of transplantation, it was well tolerated among patients with a CrCl $\geqslant$ 70 mL/min[28]. Another study also found evidence for improvement of renal function after pancreas transplantation, documented by reduction of urinary excretion of protein with stable creatinine concentration and CrCl[29].

Diabetic retinopathy

The diabetic population undergoing pancreas transplantation typically has already developed some degree of retinal pathology and most have received laser therapy. Advanced retinal change does not seem to benefit from pancreatic transplantation as the damage has already occurred. Initial studies that examined the short-term effect of pancreas transplantation on diabetic retinopathy were unable to demonstrate any positive effect of corrected blood glucose control when compared to diabetic recipients of a kidney alone or SPK with a failed pancreas graft[30]. Studies which followed successful pancreas transplants for 5 or more years however, do show a benefit to the recipient with mild to moderate disease, with stabilization of established retinopathy, delay in the progression of new disease, improvement in visual acuity and a reduction in the use of laser therapy[9,31].

Diabetic neuropathy

Polyneuropathy is a common complication of both IDDM and ESRF and advanced motor, sensory and autonomic neuropathies are frequently seen in patients undergoing whole pancreas transplantation. Improvement of both motor and sensory neuropathies symptoms will occur following kidney transplantation alone, however correction of uremia secondary to diabetic nephropathy by kidney transplantation does not halt the progression of the underlying diabetic neuropathic process. Diabetic patients studied following pancreas transplantation with return to a normoglycemic state do show a significant early improvement in sensory and motor nerve conduction studies that continue to improve over time. However clinical neurological examination and testing for autonomic nerve dysfunction demonstrated little improvement, even when followed over a longer period of time[32-35].

Micro- and macrovascular disease

Diabetic microangiopathy, the result of chronic hyperglycemia and subsequent metabolic disturbances seen in IDDM, is the principle cause of many of the severe late complications of diabetes[36]. The progression of microvascular disease-related problems (e.g., nephropathy, retinopathy neuropathy) is reduced when tight glucose control has been obtained, either through intensive insulin therapy or following successful whole pancreas transplantation. Direct evidence for improvement of the microvasculature following pancreas transplantation can also be demonstrated. Skin blood flow characteristics (as measured by laser Doppler), a measure of the degree of microcirculation impairment, have been shown to improve (but not normalize) following pancreas transplantation when compared to non-diabetic controls[37]. The calcineurin-inhibitors, Cyclosporine and Tacrolimus, in addition to being nephrotoxic, have been shown to produce microangiopathy following transplantation and their use may negate any benefit a diabetic recipient might obtain from tight glucose control[38,39].

There is evidence that whole pancreas transplantation may reduce the risk of macrovascular disease. Carotid intima media thickness (determined by carotid ultrasound), a measure shown to correlate with the likelihood of cardiovascular events in IDDM (coronary artery disease, atherosclerotic vascular disease, mortality), is reduced following whole pancreas transplantation. The reduction of the carotid intima media thickness occurs early following transplantation and is independent of other causative factors such as smoking, age, serum lipid concentration and failure of a kidney transplant[40]. However, the typical recipient of a pancreas transplant has had long-standing IDDM and frequently has established vascular intimal disease and plaque formation and clinically significant vascular disease that may progress following transplantation[41].

Quality of life

Patients who have received a whole pancreas transplant consistently report an improvement in their quality of life (QOL), although pancreas transplantation is a complex

surgical procedure, requires life-long immunosuppression and careful follow-up, and is associated with a significant incidence of complications, including re-hospitalization. The improvement in QOL is maintained unless the pancreas recipient experienced graft loss. For patients with IDDM who are in ESRF, a significant improvement in their health may be expected following either correction of uremia or elimination of their diabetic state. In a prospective, longitudinal study of patients undergoing either SPK or kidney transplant alone (KTA), Gross *et al* found that the addition of a pancreas transplant increased the measure of QOL beyond the improvement seen with KTA and the pancreas recipients reported greater improvement in areas that are diabetes-specific[9,42-44].

Pancreatic islet transplantation

As discussed above, the Diabetes Control and Complications Trial Research Group reported that improved glycemic control through intensive insulin therapy delays the onset and slows the progression of diabetic complications. Improved glycemic control however, was hard to sustain and associated with intense insulin therapy was a significant increase in severe hypoglycemic episodes. Whole pancreas transplantation is capable of producing a sustained, euglycemic state, reducing the incidences of hypoglycemia and offering the possible benefit of reducing microvascular, macrovascular and neurologic complications. Pancreas transplantation however, is a major, complex surgical procedure associated with significant risk and cost that may limit its general acceptability, especially when a potential diabetic recipient has little evidence of renal impairment and does not need a kidney transplant.

Within the past 20 years, pancreatic islet transplantation has become a clinical reality and an option in the treatment of IDDM. Islet transplantation has a distinct advantage over whole pancreas transplantation in regards to reduced peri-procedure morbidity. The procedure avoids major surgery and the risk of associated post-operative complications, re-laparotomy and acute (vascularized) graft loss. Islet transplantation, with its ability to be cultured for a period of time prior to transplantation, also offers the future possibility of reducing the immunogenicity (both allo and auto) of the tissue such that little or no immunosuppression will be required.

Early efforts to treat IDDM patients with pancreatic islet transplantation were mostly unsuccessful. Although the first human pancreatic islet allografts were performed in 1974[45], it wasn't until 1991 that a pancreatic islet transplant recipient achieved sustained euglycemia off insulin (for 1 year)[46]. In 2000, the Edmonton group reported 7 consecutive islet transplant recipients achieving insulin independence. All recipients received islets from 2 pancreas donors (one received islets from 4 donors), and were maintained on a glucocorticoid-free immunosuppression protocol using Sirolimus and low-dose Tacrolimus[13]. The success of the Edmonton program has led to a general acceptance that islet transplantation is a clinically feasible therapy, which may be considered for the treatment of patients with IDDM, especially when accompanied by severe hypoglycemia. Since the report of success from Edmonton interest has grown in islet transplantation and now more than 40 centers in North America and many more worldwide are performing this procedure[47].

Patient selection

Pancreatic islet transplant, in general, has been restricted to patients with IDDM who suffer from hypoglycemic unawareness or metabolic instability, or have early evidence of secondary complications due to their diabetes. The patients require long-term, calcineurin-based immunosuppression and thus are subjected to the risks of these agents, such as nephrotoxicity, infection and malignancy. The patient may also become sensitized due to their alloimmune response to the transplant, potentially interfering with subsequent transplantation. Patients with evidence of significant diabetic renal impairment are excluded from islet transplantation until they either require or have undergone a kidney transplant. To improve the likelihood of attaining euglycemia off insulin, most transplant programs and clinical trials will restrict islet transplantation therapy to patients weighting less than 70 kg, a body mass index (BMI) < 27 and not requiring an excessive amount of daily insulin for glycemic control[47-51].

PANCREATIC ISLET TRANSPLANT PROCEDURE

Islet isolation and culture

One of the key elements attributed to the success of the Edmonton program (Edmonton Protocol) was the need to transplant high-quality, purified islets in sufficient numbers. This usually requires isolation of islets from two or more whole pancreata. Refinement of the islet isolation process, with the standardizing of pancreas digestion (the universal use of controlled pancreatic duct perfusion with collagenase and the Ricordi digestion chamber) and use of the COBE cell processor (continuous gradient purification system) for islet purification from exocrine tissue now allows many transplant centers a source of high-quality islets[52-54]. Although some centers transplant the isolated, purified pancreatic islets immediately, other centers maintained the islets in culture for a short period (up to 48 h) prior to transplantation. Holding islets in culture for a short period does not seem to have a detrimental affect on their viability and function and allows the transplant center the option of pre-conditioning the islet tissue (to reduce immunogenicity or improve post-transplant viability), or initiate immunosuppression treatment of the recipient prior to the transplant[55-57].

In the islet recipient, access to the portal vein is obtained by either percutaneous transhepatic portal venous catheterization or mini-laparotomy. The pancreatic islets are suspended in an albumin solution and infused by gravity, along with heparin through the portal vein to embolize in the liver. Prophylactic anticoagulation is continued for several days to reduce the likelihood of an instant blood-mediated inflammatory reaction (IBMIR) with subsequent clot formation and inflammatory

response that has been shown to lead to islet damage[58-60]. Islet recipients are routinely given exogenous insulin to maintain blood glucose levels in a physiologic range as hyperglycemia in the early post-transplant period has been shown to be detrimental to islet function and may interfere with islet engraftment[55,56,61].

Procedural complications

Pancreatic islet transplantation is a less invasive alternative to whole pancreas transplantation and has been shown to be associated with a much lower risk of serious complications. The majority of serious adverse events reported in 2006 by the Collaborative Islet Transplant Registry (CITR) were related to the infusion procedure: bleeding, hematoma and portal vein thrombosis (41.9%)[47]. Newer catheters and radiologic techniques for sealing the intra-hepatic tract used for portal vein infusion of the islets has resulted in a reduction in the incidence of post procedural bleeding[62]. Increased purity of the islet preparation with a subsequent decreased total islet volume infused into the liver may also reduce the likelihood of portal pressure elevation, a risk factor that has been associated with bleeding, in particular, with a second or subsequent islet transplant. The routine use of anticoagulation has likely limited the incidence of portal vein thrombosis, however has been shown to be a factor in the rate of procedural bleeds. Following transplantation, liver transaminases typically are elevated; however routinely return to the normal range within 4 wk[50]. The long-term consequences of intra-hepatic islet infusion are not yet known. The Edmonton group has reported changes consistent with fatty liver in 8 of their first 36 patients on magnetic resonance imaging following transplant.

Immunosuppression

Since 1999, in the US the majority of islet transplant programs (> 90%) use Sirolimus and Tacrolimus in combination as maintenance immunosuppression (Edmonton Protocol). All programs used one or more induction immunosuppression agents at the time of the first islet infusion, the most common being a non-depleting monoclonal anti-CD25 antibody. Complications related to immunosuppression therapy were the second most common severe event reported by CITR (29.6%). Whereas some studies have reported that islet transplant recipients may demonstrate evidence of deterioration of renal function (immunosuppression related) especially where creatinine clearance is already significantly impaired, others have reported no deleterious renal effect following islet transplant[14,47,51].

OUTCOMES OF PANCREATIC ISLET TRANSPLANTATION

Collaborative islet transplant registry

In a survey of all North American transplant programs by CITR, 31 active programs reported 593 islet infusion procedures in 319 recipients during the period 1999-2005[47]. CITR has information on 225 of the 319 allograft recipients (71%) and 425 of the 593 infusion procedures (72%) from 23 participating centers. Sixty-four of the recipients (28.4%) received one islet infusion, 122 (54%) received two, 38 (17%) received three, and one received a total of four islet infusions. Of the 225 recipients, 203 (89%) received an islet transplant alone, while 22 recipients (10%) had previously received a kidney transplant prior to the islet transplant. Insulin independence (off insulin for 14 days or more) was achieved by 69.7% of islet recipients at some point following their last transplant (within two years). Considering all participants, 46.6% remained insulin independent for at least one year following their last transplant and 33.3% were insulin independent at 2 years. Patients who had achieved insulin independence at any point, at one year had a basal C-peptide level (1.1 ng/mL, SD 0.65), and hemoglobin A1c (6%, SD 0.8) in the normal (or near normal) range. Severe hypoglycemic events were shown to be dramatically deceased following the first islet infusion. Greater than 85% of recipients had one or more severe hypoglycemic event prior to transplant, compared to less than 5% in the first year following the transplant.

International trial of the edmonton protocol for islet transplantation

In 2006, a study organized by the Immune Tolerance Network (initiated by the National Institutes of Health) among six North American and three European transplant centers to assess the feasibility and reproducibility of the Edmonton Protocol reported their results[14]. Each center was confined to use the islet isolation technique and immunosuppression protocol as described by the Edmonton group. In the period 2001-2003, 36 patients underwent 77 islet infusion procedures. Eleven of the recipients (31%) received one islet infusion, 9 (25%) received two and 16 (44%) received three infusions. Insulin independence was achieved by 21 patients (58%) at some point, 16 patients (44%) remained insulin independent for one year and 5 (14%) remained insulin-independent at 2 years following their last transplant (35 patients evaluated at 2 years). Although most patients had returned to requiring insulin by two years, C-peptide remained detectable in 70%, demonstrating persistence of islet function. Average hemoglobin A1c levels were in shown to be in the normal range for patients who remained insulin-independent at 2 years, and only slightly elevated above normal when partial graft function was demonstrated. All patients with residual islet function were completely protected from severe hypoglycemic episodes.

Secondary complications of IDDM

Successful islet transplantation, with correction of glycemic control has only been a clinical reality for a short period of time and there has been little published to-date on the effect of islet transplantation on the secondary complications (microvascular, neurologic and macrovascular diseases) associated with IDDM. Assessment of the long-term safety and effectiveness of islet transplantation for the treatment of IDDM will require the future report of more centers with longer periods of follow-up.

CONCLUSION

Both whole pancreas transplantation and pancreatic islet transplantation have been shown to be successful at creating a euglycemic state in a patient with IDDM with preprandial and postprandial blood glucose concentrations and hemoglobin A1c levels comparable to those in the non-diabetic population. Both forms of transplants are also effective at eliminating the occurrence of significant hypoglycemic events (even with only partial islet function evident). Whole pancreas transplantation has also been shown to be effective at maintaining a euglycemic state over a sustained period of time, and thus provides an opportunity for a recipient to benefit from improvement of their blood glucose control (halt or reverse secondary complications of IDDM). Islet transplantation is attractive as a less invasive alternative to whole pancreas transplantation and offers the future promise of immunosuppression-free transplantation through pre-transplant culture. Although recent advances have led to an increased rate of obtaining insulin-independence following islet transplantation, further developments are needed to improve the long-term viability and function of the graft to maintain improved glucose control over time.

Abstract

AIM: To establish the extent to which contrast enhancement with SonoVue in combination with quantitative evaluation of contrast-medium dynamics facilitates the detection of hepatic tumors.

METHODS: One hundred patients with histologically confirmed malignant or benign hepatic tumor (maximum size 5 cm) were analyzed. Contrast-enhanced ultrasound (bolus injection 2.5 mL SonoVue) was carried out with intermittent breath-holding technique using a multifrequency transducer (2.5-4 MHz). Native vascularization was analyzed with power Doppler. The contrast-enhanced dynamic ultrasound investigation was carried out with contrast harmonic imaging in true detection mode during the arterial, portal venous and late phases. Mechanical index was set at 0.15. Perfusion analysis was performed by post-processing of the raw data [time intensity curve (TIC) analysis]. The cut-off of the gray value differences between tumor and normal liver tissue was established using Receiver Operating Characteristic (ROC) analysis 64-line multi-slice computed tomography served as reference method in all cases. Magnetic resonance tomography was used additionally in 19 cases.

RESULTS: One hundred patients with 59 malignant (43 colon, 5 breast, 2 endocrine metastases, 7 hepatocellular carcinomas and 2 kidney cancers) and 41 benign (15 hemangiomas, 7 focal nodular hyperplasias, 5 complicated cysts, 2 abscesses and 12 circumscribed fatty changes) tumors were included. The late venous phase proved to be the most sensitive for classification of the tumor type. Fifty-eight of the 59 malignant tumors were classified as true positive, and one as false negative. This resulted in a sensitivity of 98.3%. Of the 41 benign tumors, 37 were classified as true negative and 4 as false negative, which corresponds to a specificity of 90.2%. Altogether, 95.0% of the diagnoses were classified as correct on the basis of the histological classification. No investigator-dependency (P = 0.23) was noted.

CONCLUSION: The results show the possibility of accurate prediction of malignancy of hepatic tumors with a positive prognostic value of 93.5% using advanced contrast-enhanced ultrasound. Contrast enhancement with SonoVue in combination with quantitative evaluation of contrast-medium dynamics is a valuable tool to discriminate hepatic tumors.

INTRODUCTION

Benign liver lesions have a prevalence of approximately 20% in the whole population, whereas tumor patients show hepatic metastases in 25%-50% at the time of diagnosis. The liver is the main region for the manifestation of distant metastases in oncological diseases. Therefore, reliable detection of hepatic metastases is a prerequisite for evaluating the prognosis and establishing a therapeutic procedure. To evaluate the prospects of resection or to plan interventional therapy, it is essential to establish the number and location of the lesions. Prior to this, the focal hepatic lesion must be accurately characterized. Since no

single diagnostic tool has been able to clarify this question with sufficient reliability up to now, histological analysis remains the gold standard. Characterization of focal hepatic lesions with imaging techniques is an important part of radiological diagnosis and is still the focus of scientific research because of technical innovations of existing methods[1-15]. Special attention has been paid to the validation of new methods, especially the further development of contrast-enhanced ultrasound techniques because ultrasound is the most common and best available imaging technique[1-3,5-14].

In a patient with a known primary malignancy, any focal liver lesion seen on non-enhanced ultrasound must be regarded as suspicious of metastasis. However many lesions (25%-50% of lesions ≤ 2 cm) will eventually prove to be benign; next to contrast-enhanced ultrasound, other imaging modalities or biopsies are used to further characterize the lesion. For lesions < 1 cm, the false-negative rate of non-enhanced ultrasound is as high as 80%. Therefore contrast-enhanced ultrasound should be carried out in addition to conventional ultrasound in most cancer patients for definitive liver staging[6-9].

This prospective two-center study investigated the possibility of evaluating the malignancy of liver lesions on the basis of contrast-enhanced harmonic imaging (CHI) and SonoVue, by comparing the dynamics of the contrast agent in tumor lesions with those in the surrounding tissue. The objective of this study was to examine to what extent the detection of liver tumors will be simplified after contrast application with SonoVue, in combination with quantitative measurement of contrast agent dynamics. Special attention was paid to the feasibility of assessing the malignancy of the tumor by quantitative measurement of the tumor tissue contrast compared to the surrounding healthy tissue.

MATERIALS AND METHODS

Study design

This prospective study was performed at two centers. The equipment (Logic 9; GE Healthcare, Milwaukee, WI, USA), transducers (4C probe), data acquisition (PACS connection) and display, as well as the procedure of ultrasound examination were set identically at both centers.

Only patients with histologically confirmed malignant or benign hepatic lesions were included in the study. Tumor sizes were differentiated as follows: < 3 cm, and 3-5 cm. The maximum number of lesions considered was five.

Exclusion criteria were: tumor lesion > 5 cm, and more than five lesions, strong allergic reactions, diseases of liver and kidney with confirmed elevation of laboratory parameters, acute heart failure, acute myocardial infarction, subcutaneous emphysema, meteorism, tachypnea, and aerobilia.

Operational sequence and follow-up

A biopsy was taken from the malignant liver tumors to establish the histological result (if necessary, surgical resection or radiofrequency ablation was performed). In case of hemangioma, constant results of ultrasound examinations over 2 years and additional MRI or multiphase CT with constant results over 2 years was required. All contrast-enhanced ultrasound investigations were conducted with a multi-frequency linear transducer (2.5-4 MHz, Logic 9; GE Healthcare). Transmitted energy was reduced to a magnitude of < 30% with a mechanical index (MI) of 0.15. In fundamental B-scan, an optimal depth adjustment with three focus zones was made. After B-scan and analysis of vascularization with power Doppler ultrasound, an intravenous bolus injection of 2.5 mL SonoVue (Altana, Bracco, Konstanz, Germany) was administered through a 20-18 Ga peripheral cubital cannula, followed by a bolus injection of 10 mL NaCl.

Using CHI, the microbubbles of the contrast medium were stimulated to vibrate and their energetic harmonic Doppler frequencies were employed for imaging. In the technique of pulse inversion harmonic imaging (PIHI) of CHI, emission frequencies are digitally encoded. Several pulses, each after a defined period of time, were produced. Then the received echos were subtracted from each other. The harmonic frequencies of contrast-enhanced echos in the flowing blood remained as image information. In the subtraction mode of the background information, the influx of contrast agent and its distribution were imaged, even with very low acoustic energy.

A low MI allowed the real-time evaluation of the contrast-agent enhancement. CHI suppressed the fundamental linear echoes from the liver tissue, whereas the non-linear echoes reflected from the microbubbles remained, which provided the ultrasound signal. The true agent detection mode was also used to process the fundamental non-linear signal generated by ultrasound contrast agents that were stronger than the harmonic signal, thereby increasing the specificity of the microbubble-to-tissue ratio. The combination of SonoVue with true agent detection mode using a low MI allowed dynamic enhancement of the blood supply of a liver nodule to be evaluated during the various phases of contrast-agent circulation. Perfusion curves described the ultrasound signal intensity over time after contrast bolus injection in a region of interest (ROI).

Modified ultrasound slices close to the tumor enabled a minimum depth of penetration to be maintained. One turn of the scanner head examined the whole liver during intermittent breath holding. Digital data from cine sequences allowed post-processing of the dynamic tumor blood flow and calculation of 3D data block images. Scanning was carried out during the arterial (< 30 s), portal venous (40-120 s) and late venous (> 120 s) phases in true agent detection mode. Parallel dynamic imaging in fundamental B-scan and recording of the dynamics of contrast agent in the subtraction mode of CHI were performed in the meantime, which greatly facilitated the localization of tumor lesions.

Color-coded Doppler sonography and power Doppler ultrasound were used to evaluate native vascularization. Color enhancement was adjusted to the lowest possible pulse repetition frequency (PRF, < 1000 Hz) and to the best possible, artifact-free color enhancement, in order to avoid artifacts. The complete data of the contrast-agent examination were recorded in up to 5 min. The length of

the specific cine loops in the three stages was a minimum of 20 s each.

Measurements were done in the arterial phase (to quantify arterial vascularization), in the portal venous phase (to asses contrast-agent accumulation, pooling), and up to 5 min in the late phase (to assess the wash-out effect).

Altogether, five measurements were performed in each patient in the ROIs: one measurement within the lesion (T1) and four in the surrounding liver parenchyma at 12, 3, 6 and 9 o'clock positions (G1, G2, G3 and G4), with ROIs not larger than 5 mm. A careful adjustment of the position of the ROIs was effected manually depending on inspiration or expiration. Time intensity curve (TIC) analyses were made off-line and then transferred into an spreadsheet table (Excel 2003; Microsoft, Redmond, WA, USA) for off-line analysis. In addition, digital raw data were recorded and saved.

The different dynamics of the depletion of contrast agent - in comparison to the depletion within normal liver tissue - was used to assess the malignancy of the tumors. For this purpose, the recorded gray scale parameters of the ROIs were averaged over the time of recording, and then the following gray scale differences were calculated:

arterial phase: Diffart = T1art - (G1art + G2art + G3art + G4art)/4

portal venous phase: Diffpv = T1pv - (G1pv + G2pv + G3pv + G4pv)/4

late venous phase: Difflv = T1sv - (G1sv + G2sv + G3sv + G4sv)/4

The malignancy of the tumor was then inferred from the absolute value of the differences. If the absolute value of Diffsv was smaller than -0.4 in the case of a malignant tumor, the assessment was rated as true positive, if the value was greater than -0.4, the assessment was rated as false negative. If the value was greater than -0.4 in the case of a benign tumor, the assessment was rated as true negative, otherwise as false positive. First, the critical value had been ascertained in a small preliminary study, which had shown characteristic contrast-agent dynamics in malignant liver tumors. The determination of the optimal scale value is shown in the section ROC analysis. Figure 1A-C presents an example of contrast-agent dynamics.

An increased wash-out of contrast agent molecules appeared to occur in the malignant tumor vessels rather than in normal hepatic vessels. This was probably caused by arteriovenous shunts within the lesion and additional tumor necrosis, which prevented accumulation of microbubbles in the malignant tumor. Therefore, the tumor was more hypoechoic, especially in the late phase, i.e., the gray value imaging was less distinct. This characteristic behavior could then be used for quantitative evaluation of gray value differences in the diagnosis of liver tumor malignancy.

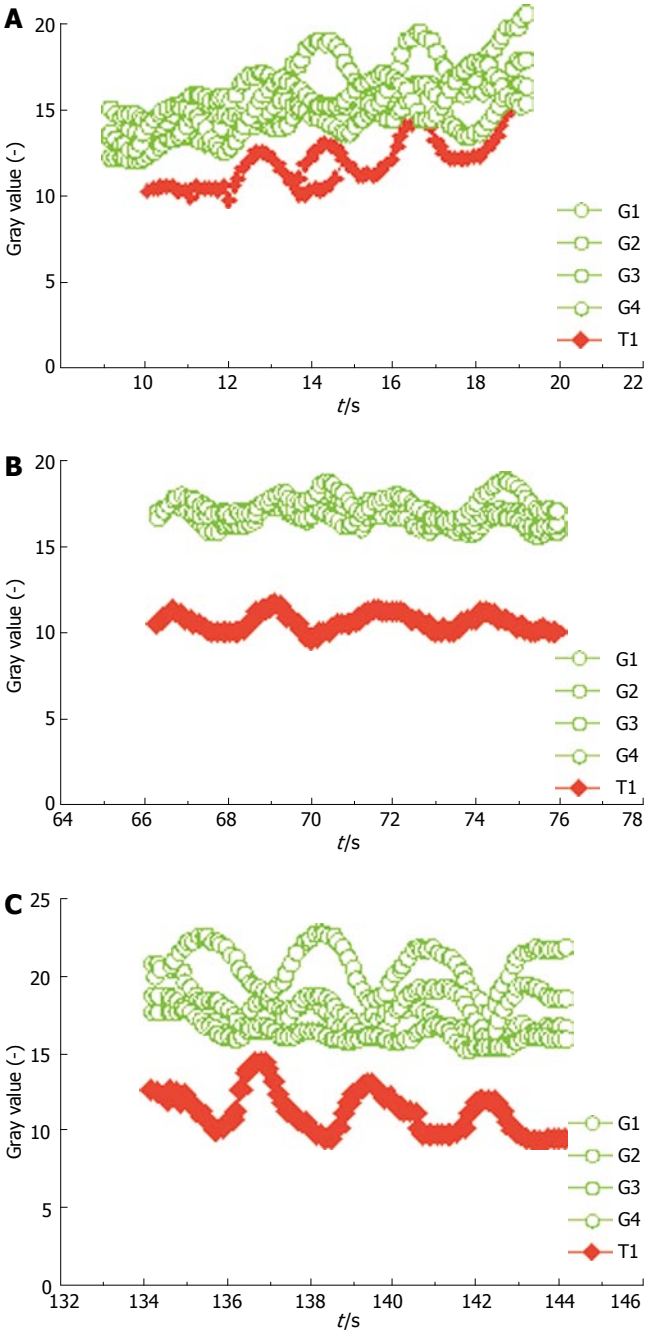

Figure 1 Gray value progression of the five ROIs over 10 s. **A**: For a patient with liver metastasis in the arterial phase; **B**: For the same patient in the portal-venous phase; **C**: For the same patient in the late venous phase. (red, gray-value progression in the tumor; green, gray-value progression in the surrounding healthy tissue).

Ethical concerns

The study data were collected within the framework of an external quality control as a registry complying with the principles of the Helsinki/Edinburgh Declaration of 2002. Before each contrast agent application, patients were informed in detail about possible risks such as allergic reactions. The consent of all patients was obtained prior to the study.

Statistical analysis

All results were presented as the mean ± SD. Specificity, sensitivity, positive and negative prognostic value, as well as diagnostic accuracy were calculated to evaluate their diagnostic significance. Since there were, as a rule, no clinical findings or the history of the patient was not available, the examiner could not establish a pretest probability. In this situation, the resulting sensitivity and specificity of the three diagnostic tests were calculated on

Table 1 Results based on contrast-enhanced CHI during the arterial phase

	Tumor present	Tumor not present	
Test positive	40	19	59
Test negative	19	22	41
	59	41	100

Table 2 Results based on contrast-enhanced CHI during the portal-venous phase

	Tumor present	Tumor not present	
Test positive	54	10	64
Test negative	5	31	36
	59	41	100

the basis of the following table[17]:

	Disease existent	Disease non-existent	
Test positive	a	b	a + b
Test negative	c	d	c + d
	a + c	b + d	

Where a is the number of patients with existing disease and a positive test result (true positive); b is the number of patients with no disease, but a positive test result (false positive); c is the number of patients with existing disease and a negative test result (false negative); d is the number of patients with no disease and a negative test result (true negative); a/(a + c): sensitivity: true positive results/ number of affected patients; d/(b + d): specificity: true negative results / number of healthy patients.

Using the Bayes formula it was possible to calculate the probability[17] that disease was present, on the basis of a positive result of the diagnostic test (positive prognostic value: pV).

$$pV = \frac{\text{true positive results}}{(\text{true positive results} + \text{false positive results})}$$

It was also possible to calculate the probability of no disease on the basis of a negative test result (negative prognostic value: nV).

$$pV = \frac{\text{true negative results}}{(\text{true negative results} + \text{false negative results})}$$

RESULTS

Patient characteristics

Altogether, 100 consecutive patients (43 women, 57 men, aged 25-83 years; mean 57 years) with suspicion of hepatic tumor were included in the study. Fifty-nine of these suffered from a malignant tumor (43 metastases of colon carcinoma, 5 metastases of breast cancer, 2 endocrine metastases, 7 HCC metastases, and 2 renal cell carcinoma), 41 patients had a benign tumor (9 hemangioma, 6 high-flow hemangioma, 7 nodular hyperplasia, 5 complicated cysts, 2 abscess, and 12 circumscribed fatty degeneration of the liver (focal hyposteatosis) with constant results over a minimum of 2 years. Maximum tumor size was 5 cm.

Table 3 Results based on contrast-enhanced CHI during the late phase

	Tumor present	Tumor not present	
Test positive	58	4	62
Test negative	1	37	38
	59	41	100

Table 4 Diagnostic value of quantitative CHI for detection of malignant hepatic tumors in different phases after intravenous application of ultrasound contrast agent

	Arterial phase	Portal-venous phase	Late venous phase
Specificity (%)	53.7	75.6	90.2
Sensitivity (%)	67.8	91.5	98.3
Positive prognostic value	67.8	84.4	93.5
Negative prognostic value	53.7	86.1	97.4

Analysis of contrast-agent dynamics

Arterial phase: Of the 59 patients with histologically confirmed malignant tumors, 40 were classified as true positive and 19 as false negative in the arterial phase. Of the 41 patients with histologically classified benign tumor, 22 were classified as true negative and 19 as false positive (Table 1, Figure 1A). In the arterial phase, a sensitivity of 67.8% with a specificity of 53.7 % (pV 67.8%, nV 53.7%) was achieved. Therefore, 62% of the test results were correct.

Portal venous phase: Of the 59 patients with histologically confirmed malignant tumor, 54 were classified as true positive and 5 as false negative in the portal venous phase. Of the 41 patients with histologically classified benign tumor, 31 were classified as true negative and 10 as false positive (Table 2, Figure 1B). This resulted in a sensitivity of 91.5% with a specificity of 75.6%, which gave a pV of 84.4% and nV of 86.1%. The correctly interpreted test evidence therefore amounted to 85.0%.

Late venous phase: Of 59 patients with histologically confirmed malignant tumor, 58 were classified as true positive and 1 as false negative in the late phase. Of 41 patients with histologically confirmed benign tumor, 37 were classified as true negative and 4 as false positive (Table 3, Figure 1C). This resulted in a sensitivity of 98.3% with a specificity of 90.2%, which gave a pV of 93.5% and nV of 97.4%. In the late venous phase, the correctly interpreted test evidence amounted to 95.0%.

A comparison of the diagnostic values of the three phases shows that the best accuracy was achieved in the late venous phase (Table 4).

Stability of diagnostic criteria

The sensitivity over the course of the study provided a sensitive indicator of the diagnostic value of this method in identifying malignant liver tumors in 100 patients (Figure 2). Only the late venous phase was analyzed since

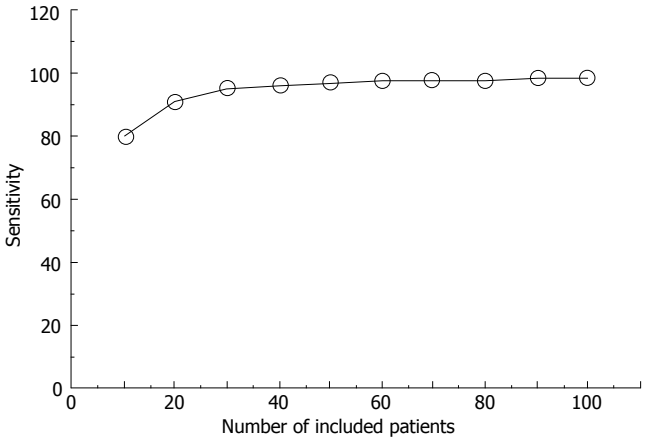

Figure 2 Sensitivity of the diagnostic test in relation to the number of patients examined. The sensitivity over the course of the study provides a sensitive indicator to the diagnostic value of this method in identifying malignant liver tumors in 100 patients.

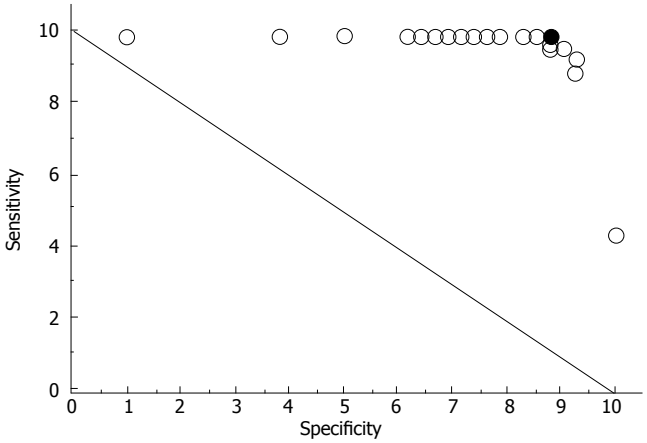

Figure 3 ROC diagram showing the specificity and sensitivity in the late venous phase for different limiting values (varying the cut-off values from +5 to -5). A greater distance from the diagonal line indicates that a diagnostic test had a higher reliability. The black point in the ROC diagram corresponds to the best sensitivity and specificity.

it showed the most sensitive results. Sensitivity over the course of the trial was cumulatively calculated after every 10 patients. This showed that sensitivity very clearly approached a stable final value. This meant that sensitivity would not have changed significantly if more patients were included. Therefore, a valid evaluation could be made. The other diagnostic parameters showed similar results.

ROC analysis

The test results depended on the cut-off value of the gray value differences that were chosen. By modifying the cut-off value by means of an ROC analysis, it was possible to attain the optimum selectivity by improving sensitivity and specificity[18]. Figure 5 shows the respective specificity and sensitivity for the late venous phase for different limiting values (varying the cut-off values from +5 to -5). Usually, the greater the distance from the points to the diagonal, the better the diagnostic test. It is evident that the point marked in red in the ROC diagram was the one with

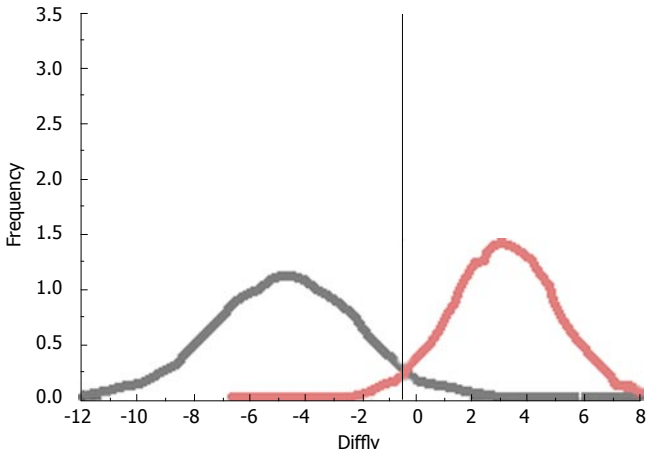

Figure 4 Distribution of the characteristic gray-value differences in the late venous phase for patients with benign (black) or malignant (red) hepatic tumor.

Table 5 Specificity and sensitivity for both testing centers

	Center 1 *n* = 50	Center 2 *n* = 50	Total *n* = 100
Specificity (%)	85.7	95.0	90.2
Sensitivity (%)	100	96.7	98.3
Negative prognostic value	100	95.0	97.4
Positive prognostic value	90.6	96.7	93.5

the most sensitivity and specificity. This optimum cut-off value was easy to calculate [cut-off valueopt = 0.5 × (specificity + sensitivity)/2] (Figure 3). The optimal cut-off value between the two groups of patients was readily established. The best selectivity for the two groups was at a cut-off value of -0.4 (Figure 4).

Center dependence

The diagnostic parameters were calculated and compared for the two centers (Table 5). Variations in the parameters were based on one single case in the whole study with a false-positive value in only one center, and a single case was still too small for a separate description. The quality of testing did not differ between the two centers: 47 out of 50 patients were classified correctly in center 1, and 48 out of 50 in center 2. There was therefore no center-dependence ($P = 0.229$) (Figure 5A-F).

DISCUSSION

All patients with suspected hepatic lesions, who were sent for further diagnostic workup to the two different centers, were consecutively included in the study. First, an ultrasound examination of the liver was undertaken using B-scan with a high-resolution multifrequency probe, resulting in a complete digital data set of the whole liver. Then, vascular ultrasound with power Doppler was performed to assess the vascularization of tumor lesions detected by the B-scan. After a bolus injection of 2.5 mL SonoVue, quantitative dynamic contrast-enhanced ultrasound was performed in low MI Technique for the arterial, portal-venous and late venous phase. As for

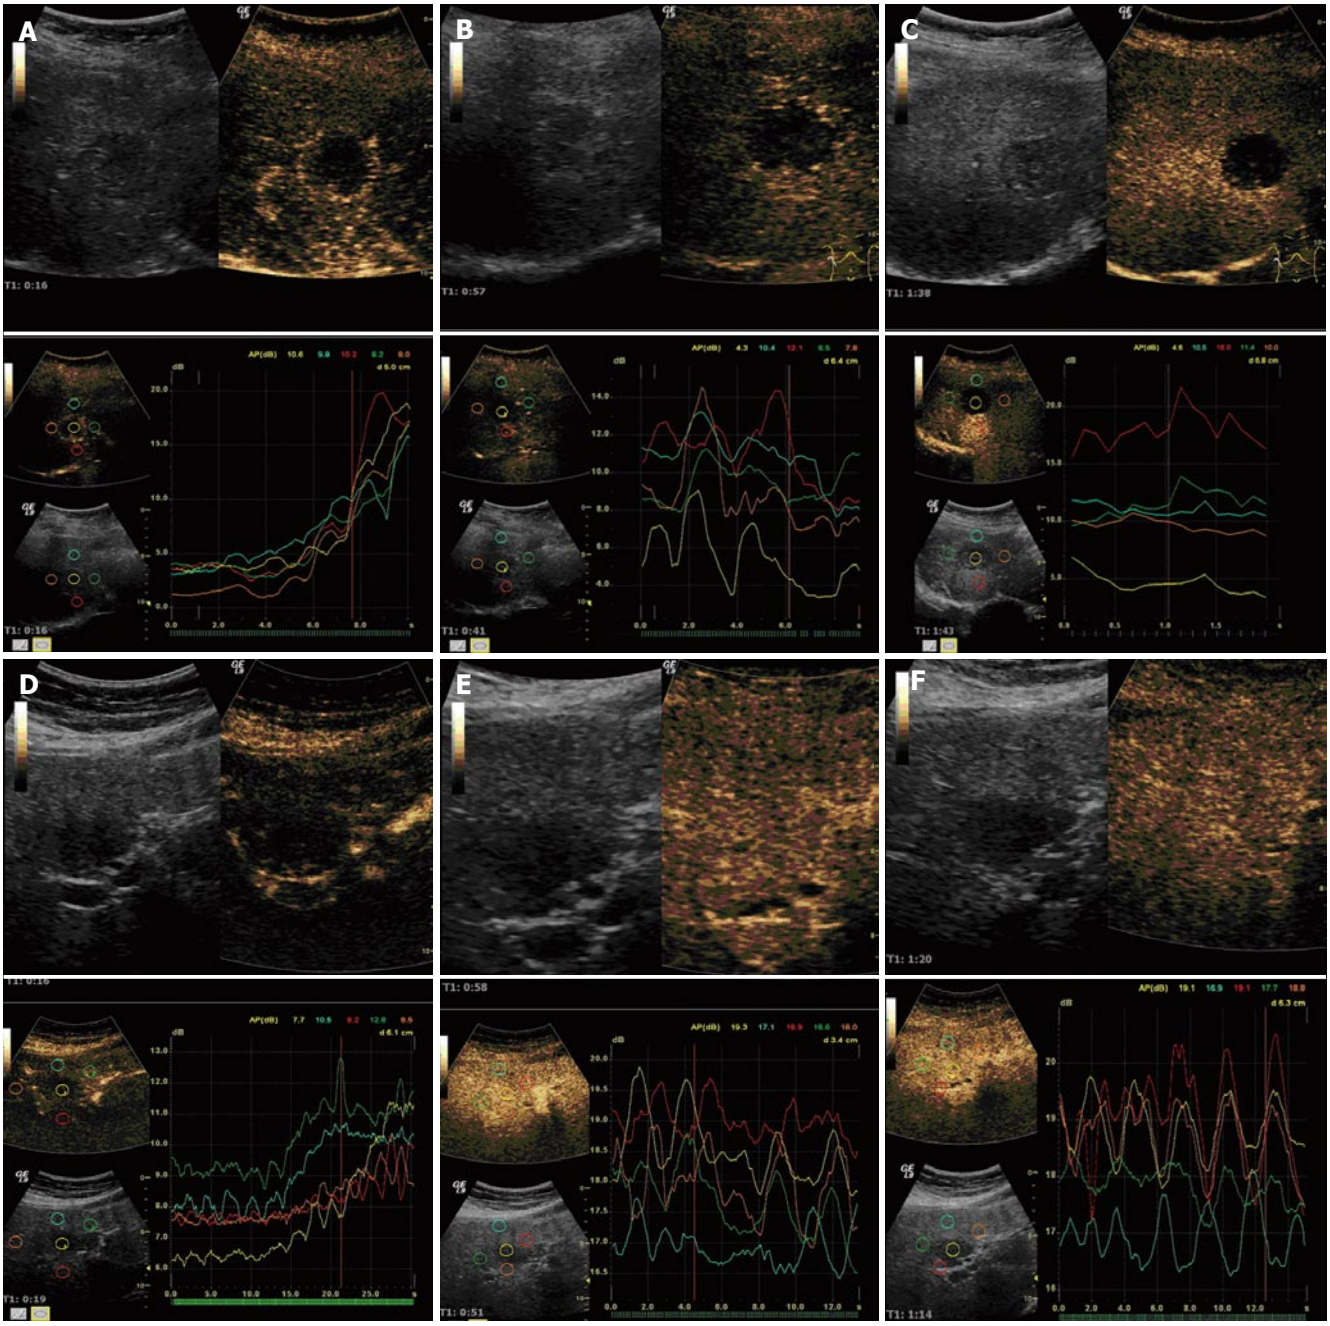

Figure 5 True agent detection mode of CHI with TIC analysis. **A**: Malignant lesion in the arterial phase. Arterial enhancement of the tumor margin - metastasis of beast cancer; **B**: Malignant lesion in the portal-venous phase. Lower enhancement of the tumor - metastasis of beast cancer; **C**: Malignant lesion in the late venous phase (> 100 s). Lower enhancement of the tumor - metastasis of beast cancer; **D**: Benign lesion in the arterial phase. Lower enhancement of the tumor-adenoma histological confirmed in the early arterial phase; **E**: Benign lesion in the portal-venous phase. Enhancement of the tumor - adenoma histological confirmed-similar to normal liver tissue; **F**: Benign lesion in the late venous phase. Enhancement of the tumor-adenoma histological confirmed - similar to normal liver tissue.

the Contrast Harmonic Imaging (CHI) technique, Pulse Inversion Harmonic Imaging (PIHI) with simultaneous data acquisition of the B-image and the contrast-enhanced perfusion image in True Agent Detection mode was used. Data were stored with dynamic and cine sequences up to a maximum of 60 s. Contrast -agent dynamics were represented in terms of the digital raw data of the gray values, exported into a spreadsheet table, and evaluated by an external institution without any knowledge of imaging and the clinical data. The histological result was only communicated after the end of the study, so that diagnostic criteria were analyzed without any previous knowledge. An information bias was therefore precluded (which is especially important for radiological imaging), which enabled the prognostic values to be calculated according to Bayes[18]. Diagnostic tests were therefore evaluated in the same way as in the specific clinical situation.

Conventional ultrasound methods are limited for depicting and characterizing focal liver lesions by a low contrast between the lesion and normal parenchyma. The use of specific contrast agents for ultrasound improves the diagnostic value of conventional ultrasound and enables a complete diagnosis of liver lesions. Solutions for a complete ultrasound diagnosis have been proposed

with the introduction of second-generation contrast agents and the use of low MI techniques, such as pulse inversion, which allows a continuous sweep with the same bubbles[1-3,5-10]. The support of gray-scale images is essential to delineate the lesions better and to check the perfect matching of contrast-enhanced and B-mode images. The availability of the true agent detection mode is able to overcome these limitations by higher signal sensitivity and simultaneous acquisition of gray scale and contrast-enhanced images.

SonoVue provides strong and persistent harmonic resonance at low MI ($\leqslant$ 0.2), with which minimal or no bubble destruction occurs. This allows for continuous real-time imaging of a lesion during its vascular phase. With real-time low-MI imaging, the dynamic enhancement pattern and the vascular morphology of a lesion is assessed during the arterial phase (10-20 s until 25-50 s after bolus injection) and portal-venous phase (30-45 s until 120 s after bolus injection). The delayed phase (> 120 s after bolus injection) is particularly useful for the detection of, as they show as non-enhancing defects. Characterization is also improved by the late phase, as the vast majority of benign lesions show contrast uptake in this phase[5,7,8]. Our results show that by means of CHI and subsequent quantitative gray-value analysis of contrast-agent dynamics in the late venous phase, it is possible to assess malignant liver tumors with a sensitivity of 98.3% with an nV of 97.4%.

High-resolution digital contrast-enhanced ultrasound techniques have considerably improved the assessment of malignant and benign tumor lesions in the liver[1-12]. Under optimal examination conditions that enable imaging of the entire liver, it is possible to attain a diagnostic reliability comparable to that of contrast-enhanced MRI with a liver-specific contrast agent, and an even higher diagnostic certainty of > 90%, compared with contrast-enhanced multi-detector-spiral CT[1,4,15]. Using ultrasound contrast agents, a signal amplification of up to 10 dB is feasible. This allows a better differentiation between regular liver tissue and malignant tissue within the liver, which has an increased contrast wash-out in the portal-venous and, especially, in the late phase. The perfusion curves in healthy liver tissue show a slow increase, which reaches a plateau at the portal-venous phase, followed by a very slow decrease. In most benign tumors, enhancement can also be detected in the late phase after contrast agent injection. In cases of malignancy, the decrease begins in the portal-venous phase in most cases after slow marginal arterial enhancement. Tumor lesions of HCC, liver adenoma, high-flow hemangioma and focal nodular hyperplasia can show an early arterial enhancement in the first 30 s in perfusion curves[4,6,8,12,13]. These lesions may be masked in the portal-venous phase. Therefore, the most important phase for tissue differentiation is the late phase, because malignant tissue shows a contrast-agent wash-out in the late phase, whereas regular tissue still has a slowly descending plateau. This is the explanation for the significant differences of the gray-value analysis of the contrast-enhanced TIC analysis in the late phase.

Using a continuously acquired contrast-enhanced dynamic CHI, the diagnostic accuracy in characterization of benign lesions, such as partially thrombosed or high flow hemangioma, focal nodular hyperplasia or local fatty and regenerative changes, is superior to that of B-scan or contrast-enhanced spiral CT[1,2,5,8,10].

The general problem for liver ultrasound still remains unchanged. The subdiaphragmatic liver segments Ⅳa and Ⅷ are difficult to visualize, which makes it very difficult to assess a lesion within these segments. Investigation of only part of the liver was possible owing to the high attenuation of ultrasound especially in the cranial and dorsal parts of the liver where the position of the liver was very high under the diaphragm or when patients had difficulty holding their breath. Secondly, fatty areas or cirrhosis of the liver, as well as lesions location deeper than 10 cm, diminish the penetration of contrast-specific imaging modes, which results in a decreased signal noise[1,5,8-10]. Another major problem for all imaging modalities such as contrast-enhanced CT or MRI remains the detection and characterization of lesions smaller than 5 mm[7].

SonoVue is a pure intravascular blood-pool contrast agent without a specific liver phase. The microbubbles help to visualize small parenchymal vessels. Malignant liver lesions such as metastases or HCC lesions are characterized by demarcation during the late phase. SonoVue late phase is based on visualization of parenchymal vessels. It is possible for very small HCC lesions, hemangiona or adenoma with vascular architecture comparable to that of the liver parenchyma to be missed in the detection study. Hypervascularization is a feature of HCC with a diameter > 2 cm. This may explain why the early phase of enhancement might not be effective for some very small HCC lesions. Early arterial enhancement can be found in 76%-96% of HCC lesions, and homogeneous enhancement in the late phase in 3%-30% of the patients[4,6,8,12,13].

The detection rate still remains examiner-dependent, even with low-MI contrast-agent techniques. In our study, we were able to demonstrate the feasibility of objective digital raw data analysis, which was not influenced by different examiners in our two-center approach. Therefore, dedicated software for computer-aided diagnosis can be developed, which allows the user an objective assessment of benign or malignant liver lesions based on digital raw data.

Contrast-enhanced ultrasound (CEUS) reveals typical patterns of contrast enhancement in the different lesion histotypes, and provides equivalent accuracy to CT and MRI in focal liver lesion characterization. CEUS should be considered in every patient with a known malignancy with proven or suspected liver metastases at baseline ultrasound during preoperative staging or postoperative follow-up.

Without dynamic evaluation of contrast enhancement, in approximately 10% of cases focal liver lesions remain indeterminate even after microbubble injection, and therefore Gadobenate-Dimeglumine (Gd-BOPTA) enhanced MRI should be employed, followed when necessary by ultrasound-guided biopsy. Standard cross-sectional imaging procedures including multislice CT or Gd-BOPTA-enhanced MRI should be referenced in every case not explorable by ultrasound, or in patients with no evidence of liver metastases at CEUS and with clinically

suspected liver metastases, such as in cases with increased serum levels of tumor markers.

Using dynamic CHI, the malignancy of hepatic tumors can be predicted with a positive prognostic value of 93.5%. CHI with SonoVue in combination with dynamic quantitative evaluation of contrast-agent dynamics is a valuable tool for discrimination.

COMMENTS

Background

Liver lesions are a common diagnostic problem in medical imaging. Contrast-enhanced ultrasound is a recently introduced new modality in lesion assessment. In our study the quantitative evaluation of raw ultrasound data was assessed compared with histology as a gold standard.

Innovations and breakthroughs

Based on this raw data evaluation, new computer-assisted algorithms can be created, which allow automated liver lesion diagnosis.

Applications

For contrast-enhanced ultrasound-based lesion evaluation, three phases (arterial, portal-venous, and late phase) are mandatory. Computer-based dynamic analysis of raw digital ultrasound data facilitates lesion characterization.

Peer review

In this study, the authors review their experience of CHI and its diagnostic value in patients with space-occupying liver lesions. They conclude that using dynamic CHI, the malignancy of hepatic tumors can be predicted with a pV of 93.5%. CHI with SonoVue in combination with dynamic quantitative evaluation of contrast-agent dynamics is a valuable tool for discrimination.

Abstract

AIM: To investigate the expression of coxsackievirus and adenovirus receptor (CAR) and adenovirus-mediated reporter gene transfer in five human colon cancer cell lines.

METHODS: Expression of CAR-specific mRNA and protein was analyzed by reverse transcriptase polymerase chain reaction and Western blotting, respectively. Adenovirus-based gene delivery was evaluated by infection of cells with adenoviral vector carrying the green fluorescent protein (GFP) gene.

RESULTS: All the colon cancer cell lines examined (HT29, LS180, SW480, SW948 and SW1116) expressed CAR full-length mRNA and an alternatively-spliced variant that lacks the transmembrane coding exon. All cell lines were detected as CAR-positive by Western blot analysis. Further, all cells we examined were efficiently infected with adenoviral vector-GFP.

CONCLUSION: The data indicated that the five colon cancer cell lines tested expressed adenovirus primary receptor and could be efficiently infected by adenoviral vectors. Therefore, these cell lines will be useful for adenovirus-based gene transfer and research.

Key words: Coxsackievirus and adenovirus receptor; Adenoviral infection; Gene therapy

INTRODUCTION

Colorectal cancer is the third most common cancer and among the three top fatal malignancies. In 2007, there were an estimated 153760 new cases and 52180 deaths from colorectal cancer, which corresponds to approximately 10% of all newly diagnosed cancers in the United States[1,2]. Gene therapy has been considered a potential innovative approach for the treatment of colorectal cancer[3,4]. To date, over 600 gene therapy clinical trials have been initiated in the US, 60% of which are cancer-related[5]. Currently, adenoviral vectors are the most frequently administered vectors[6]. This is because of their advantageous features such as a broad range of cell targets, the ability to be produced in high titers, and their accommodation of relatively large segments of DNA[7,8].

Adenovirus initiates infection as well as does adenovector-mediated gene transfer by attachment of the fiber knob to a cell surface receptor, the coxsackievirus and adenovirus receptor (CAR)[9]. CAR, the primary high-affinity receptor for adenovirus, is a 46-ku transmembrane glycoprotein and belongs to the immunoglobulin superfamily[10,11]. The human CAR gene, CXADR, encodes a 365-amino acid protein, and four pseudogenes have been reported on chromosomes 15, 18 and 21 (two copies)[12]. Alternatively spliced variants of CAR have also been identified[13]. Thoelen et al has described three splice variants (β-, δ- and δ-transcripts) of the CAR gene in addition to the normal α-transcript.

Expression of CAR has been studied in numerous cell lines including those of head and neck carcinoma[14], renal cell carcinoma[15], bladder cancer[16], ovarian cancer[17,18], cervical cancer[19], lung and pancreatic cancer[20], prostate cancer[21] and glioma[22]. In all these studies, high expression of CAR correlated with increased adenoviral infection efficiency; cells lacking or expressing low levels of CAR were resistant to adenovirus infection.

Since CAR expression has not been studied in colon cancer cell lines, we examined the expression of CAR at the mRNA and protein levels, along with its splice variants in five human colon cancer cell lines. Adenovirus-mediated reporter gene transfer was also evaluated.

MATERIALS AND METHODS

Cell lines

Five human colon cancer cell lines HT29, SW480, SW948, SW1116 and LS180, as well as the human embryonic kidney (HEK) cell line (CAR-positive) and Chinese hamster ovary (CHO) cells (CAR-negative) (ATCC numbers: HTB-38, CCL-228, CCL-237, CCL-233, CL-187, CRL-1573, CCL-61) were obtained from the National Cell Bank of Iran (NCBI). Cells were cultured in RPMI 1640, Dulbecco's Modified Eagle's Medium, Minimum Essential Medium, or L-15 medium. All cells were maintained with 100 U/mL penicillin, 100 μg/mL streptomycin and 100 mL/L fetal bovine serum (FBS). Cell lines were cultured either in 10-cm culture plates or in flasks at 37℃ and in 50 mL/L CO_2 in a humidified incubator.

RT-PCR

Total cellular RNA was extracted from each cell line by Biozol reagent (Bioflux, Japan). Two micrograms of total RNA were converted to cDNA by reverse transcription, using Moloney murine leukemia virus reverse transcriptase (Fermentas, Lithuania) and random primers (Roche, Germany) as described previously[23], with minor modifications. Since pseudogenes have been identified for the CAR gene, the CAR mRNA sequence was aligned with the pseudogenes (multiple alignment at http://bioinfo.genopole-toulouse.prd.fr/multalin/multalin.htm). CAR primers (CARf, 5'-CGTGCTCCTGTGCGGAGTAGT-3'; CARr, 5'-GACCCATCCTTGCTCTGTGCT-3') were designed in exons 1 and 7 with intervening introns of approximately 51 Kb, in a way that would align only with CAR mRNA and mismatched the pseudogenes in at least one nucleotide at the 3'-ends. Phosphoglucomutase-1 (PGM-1), human house keeping gene primers (PGMf, 5'-TCCGACTGAGCGGCACTGGGAGTGC-3'; PGMr, 5'-GCCCGCAGGTCCTCTTTCCCTCACA-3') or murine β-actin house keeping gene primers (actinf, 5'-GAACCCT AAGGCCAACCGTGA-3'; actinr, 5'-AGGAAGAGGAT GCGGCAGTGG-3') were used as internal controls.

The PCR protocol consisted of an initial denaturation for 5 min at 94℃; followed by 32 cycles of denaturation for 30 s at 94℃, annealing for 30 s at 62℃, and extension for 60 s at 72℃. The final cycle had a prolonged extension time of 7 min at 72℃. PCR products were analyzed by electrophoresis on a 1.5% agarose gel, stained with ethidium bromide and visualized under UV light. The length of the expected product was 1068 (α-transcript) or 806 (β-transcript) bp for the CAR gene and 382 and 374 bp for the PGM1 and β-actin genes, respectively.

Cloning

Amplification products of the CAR β-transcript were cloned using InsTAclone PCR Cloning Kit (Fermentas) following the manufacturer's instructions. In brief, PCR products were ligated into a pTZ57R/T vector and transformed by a heat shock method into competent *Escherichia coli*. Transformants were selected in LB medium containing ampicillin, X-gal and IPTG. The presence of the expected insert was confirmed by PCR and sequencing.

Immunoblotting

For immunoblotting analysis, cells were lysed for 1 h at 4℃ in lysis buffer containing 50 mmol/L Tris (pH 8.0), 150 mmol/L NaCl, 10 mL/L Nonidet-P40 (NP40), 0.1 mL/L SDS and one tablet of complete, mini, EDTA-free protease inhibitor cocktail (Roche, Germany) per 10 mL lysis buffer. After the removal of cell nuclei by centrifugation, protein concentrations were measured by the Bradford protein assay. Equal amounts of protein (15 μg) from each cell lysate were diluted with SDS loading buffer, heated for 5 min at 95℃ and electrophoresed on a 10% SDS-polyacrylamide gel. The separated proteins were then electrotransferred to a nitrocellulose membrane, which was blocked with 50 g/L non-fat dried milk in Tris buffered saline-Tween (TBST) buffer to block non-specific binding sites. The blot was then incubated with polyclonal rabbit anti-CAR primary antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA; 1/1000 dilution in TBST and 0.01 g/mL BSA) with gentle shaking for 1 h at room temperature. After extensive washing, polyclonal anti-rabbit horseradish peroxidase-conjugated secondary antibody (1/1000 dilution in TBST and 0.01 g/mL BSA) was applied for 1 h at room temperature with gentle shaking. Bands were visualized using an ECL kit (Amersham) according to the manufacturer's instructions.

Adenoviral vector

Adenoviral vector expressing the green fluorescent protein (GFP) gene driven by the cytomegalovirus promoter[24] was used to assess the colon cancer cell lines infected with adenoviral vector. Virus titer was determined by optical absorbance at A_{260} (1 A_{260} unit = 10^{12} particles/mL).

Adenovirus-mediated GFP gene transfer

To evaluate reporter gene transfer by the adenovirus vector, five colon cancer cell lines were plated in 24-well culture plates at a density of 5×10^4 cells/well and grown at 37℃ in a humidified incubator. After overnight incubation, cells were infected with Ad5-GFP at a multiplicity of infection (MOI) of 50 virus particles/cell. Two hours later, cells were washed twice with PBS and 600 μL fresh complete medium was added to every well. After 36 h, cells were evaluated for GFP expression by fluorescence microscopy.

RESULTS

CAR mRNA expression in colon cancer cell lines

We first examined the expression of CAR by RT-PCR. Integrity was evaluated by running RNA on 1% agarose gel and the quantity of RNA was measured spectrophotometrically. cDNA was then synthesized and CAR specific sequences amplified using CAR-specific primers (CARf, CARr). As shown in Figures 1A and 2, CARf and CARr primers generated a seven-exon-encompassing fragment with the expected length of 1068 bp in all the colon cancer cell lines. These primers could not amplify the pseudogenes (Figure 2, lane 1), and therefore the bands observed in lanes 2-6 were generated by just the amplification of cDNA. Any probable

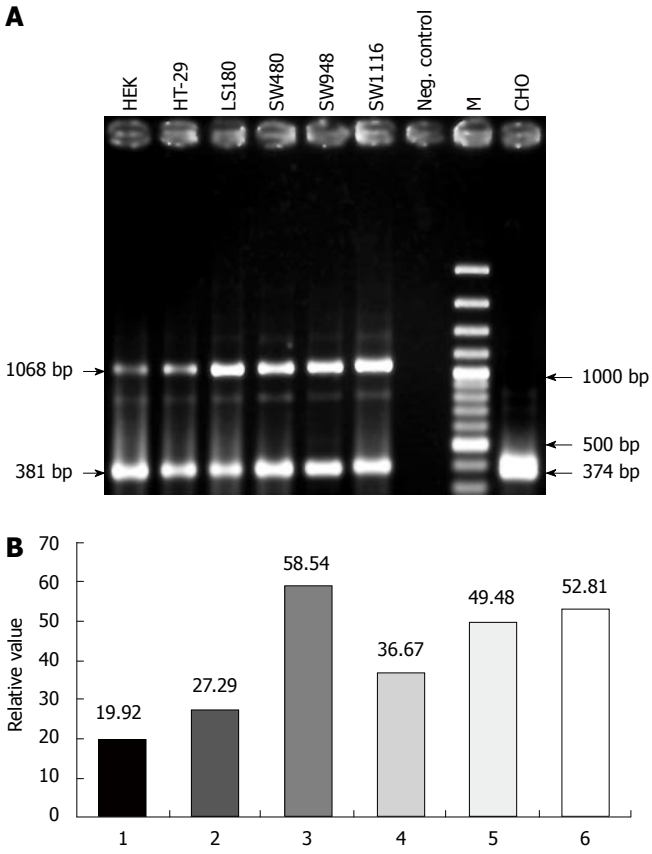

Figure 1 **A**: Multiplex RT-PCR of expression of coxsackievirus and adenovirus receptor, PGM and β-actin (internal controls); **B**: CAR mRNA level in different cell lines. 1-6 refer to HEK (positive control), HT-29 (colon), LS180 (colon), SW480 (colon), SW948 (colon) and SW1116 (colon) cells, respectively.

contamination of cDNA with genomic DNA could be disregarded.

CAR protein expression in colon cancer cell lines

We examined the expression of CAR by Western blotting. For immunoblotting, cell lines were cultured, harvested, lysed in appropriate lysis buffer and finally analyzed with anti-CAR antibodies. As shown in Figure 3, a band of about 46 ku was detected in HEK, HT-29, Ls-180, SW480, SW948 and SW1116 cell lines but was not observed in the negative control CHO cells.

Alternatively spliced variant of CAR

After electrophoresis and staining of RT-PCR products, an additional fragment of 806 bp was also observed (Figure 2). This shorter band produced by CAR-specific primers was cloned and sequenced, which revealed that this fragment was the result of an alternative splicing event between exons 4 and 7, lacking exons 5 and 6, of the CAR normal transcript, and was therefore the previously determined β-splice variant. All the colon cell lines studied expressed the β-splice variant although the band intensity of the splice variant was low when compared with the intensity of the normal transcript.

Detection of GFP gene expression in colon cancer cell lines

As shown in Figure 4, Ad5-GFP vector entered the cells and expression of the GFP gene indicated the efficient infection of these cells by the adenoviral vector.

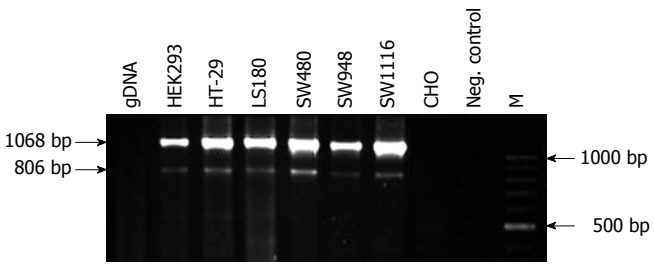

Figure 2 Expression of CAR in colon cancer cell lines. Two micrograms of total RNA prepared from several different human colon cancer cell lines were subjected to RT-PCR analysis. RT-PCR revealed β-transcript expression in addition to the normal CAR gene transcripts.

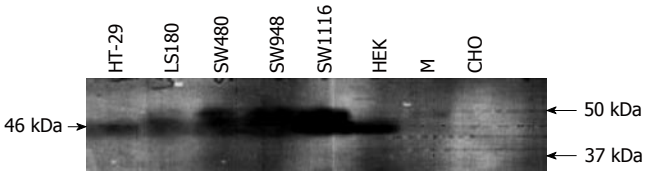

Figure 3 Western blot analysis of CAR protein in colon cancer cell lines. Total protein from five human colon cancer cell lines was separated by SDS-PAGE, transferred to nitrocellulose membranes, and reacted with the correct anti-CAR antibodies.

DISCUSSION

Gene therapy is a therapeutic modality for malignant cancers. For this, the recombinant adenovectors Ad2 and Ad5 derived from the human adenovirus subgroup C are attractive gene transfer vehicles for cancer gene therapy[25,26]. As therapeutic efficacy has been demonstrated to correlate with the ability of adenovirus to enter target cells, expression of CAR has been studied extensively.

Several tumor cell lines including those for ovary cancer[17], head and neck carcinoma[14], renal cell carcinoma[15], prostate[21] and bladder[16] cancer have shown relatively low CAR expression; although high expression of CAR mRNA has been reported in osteosarcoma cell lines[27]. In the present study, CAR expression was investigated in five colon cancer cell lines, and it was shown that CAR was expressed in all of them, although some variations in band intensity of RT-PCR products were observed among the different cell lines (Figure 1B). The mismatch between specific primers and CAR pseudogenes made us certain that only cDNA could act as the source of amplification in RT-PCR. The existence of CAR pseudogenes has apparently not been taken into account in previous studies that have investigated CAR expression[18,19,29].

Alternatively spliced products of the CAR gene have been identified; β-variant mRNA has been detected in multiple human tissues such as heart, brain, lung, liver, kidney and pancreas[10], and has also shown to be expressed in osteosarcoma cell lines[27], HeLa cells[28] and musculoskeletal tumors[29]. The β-transcript is predicted to encode a 252-amino-acid protein that can be released

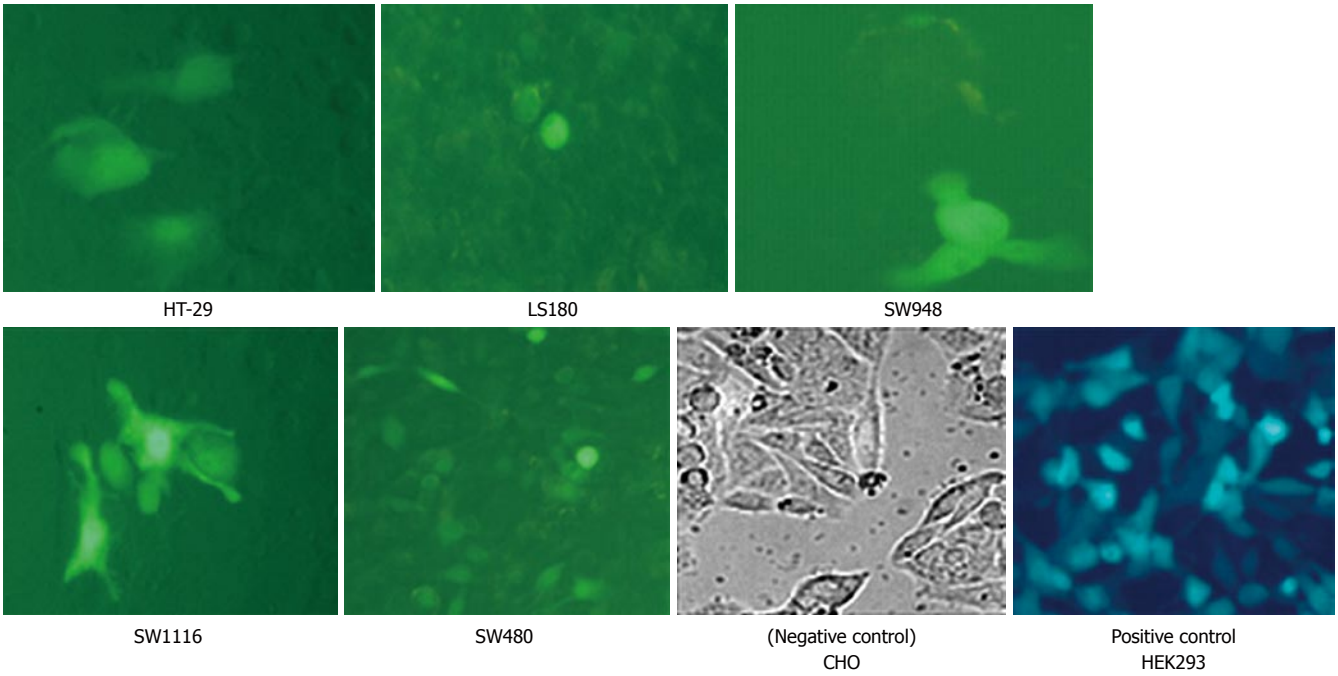

Figure 4 Sensitivity of colon cancer cells to adenovirus infection. Cells were plated in 24-well culture plates and infected with Ad5-GFP at an MOI of 50. After 36 h, cells were evaluated for GFP expression by fluorescence microscopy. GFP was expressed when recombinant adenoviruses infected the cells.

from cells to the culture medium because of the absence of a transmembrane domain[28]. CAR cytoplasmic and transmembrane domains are not necessary for virus attachment[30], so the anticipated β-variant protein might be as effective as the full-length variant in binding to adenovirus. In the present study, the β-transcript was demonstrated to be present in colon cell lines, in addition to the normal α-transcript.

To evaluate whether CAR mRNA expression correlated with CAR protein expression, Western blotting was carried out. CAR protein was shown to be present in the colon cell lines investigated; therefore, they could be considered as CAR-positive on the basis of CAR protein expression. In addition, no alternative protein band that could be attributed to the β-transcript-encoded protein was observed. Western blotting was carried out using a commercial polyclonal antibody against amino acids 1 to 300 of the original protein and cell lysates. Thus, the absence of any alternative signal (β-variant protein) could be explained as very low or undetectable intracellular level of this shorter variant and its secretion from the cell surface. However, β-variant protein is not detected in extracts of HeLa cells that express both β- and normal variants[28]. Therefore, the potential translation of CAR alternative transcript and its proposed regulatory role in antivirus defense mechanisms[28] remains to be confirmed.

Experiments with the Ad5 vector carrying the GFP reporter gene showed that the colon cancer cell lines studied were sensitive to adenovirus infection, and after 36 h GFP gene expression was easily detected by fluorescence microscopy.

In conclusion, the results of this study suggested that adenovirus-based gene delivery was efficiently applied to the five colon cancer cell lines. However, to clarify the efficiency of adenoviral-mediated gene transfer in colon tumors, further studies will be required to explore the expression of CAR.

COMMENTS

Background

Vectors based on human adenovirus serotypes 2 and 5 show increasing promise as gene delivery vehicles, and currently adenoviral vectors are the most commonly administered vectors for cancer gene therapy. Adenovirus initiates gene transfer by attachment to cell surface receptor, the coxsackievirus and adenovirus receptor (CAR).

Research frontiers

Reports show that the efficiency of adenoviral infection is dependent on the expression of CAR on target cells. However, adenovirus-mediated gene transfer is in practice hindered by the relatively low expression of CAR on tumor cells.

Innovations and breakthroughs

This is believed to be the first report to examine the expression of CAR in human colon cancer cell lines at the mRNA and protein level.

Applications

These results might be of potential value in adenovirus-based gene transfer and research in colon cancer cell lines.

Terminology

Gene therapy: to replace a malfunctioning mutated gene with a normal wild-type gene or to express a therapeutic gene in target cells. A prerequisite for efficient gene therapy is to determine a system for delivering the therapeutic gene to target cells. Adenovirus: non-enveloped, icosahedral, particles with double stranded DNA genome that in humans, is divided into six species (A-F) and 51 serotypes. CAR: primary cellular receptor for attachment of both coxsackie B virus and adenovirus subgroup C to target cells.

Peer review

This manuscript by Yassan Abdolazimi and co-authors is presented in a clear style.

Experimental details are provided accordingly. Relevant controls were included in the study. The authors' findings are discussed with the relevant literature.

Abstract

AIM: To investigate the change in eukaryotic gene expression profile in Caco-2 cells after infection with strains of *Escherichia coli* and commensal probiotic bacteria.

METHODS: A 19 200 gene/expressed sequence tag gene chip was used to examine expression of genes after infection of Caco-2 cells with strains of normal flora *E. coli*, *Lactobacillus plantarum*, and a combination of the two.

RESULTS: The cDNA microarray revealed up-regulation of 155 and down-regulation of 177 genes by *E. coli*. *L. plantarum* up-regulated 45 and down-regulated 36 genes. During mixed infection, 27 genes were up-regulated and 59 were down-regulated, with nullification of stimulatory/inhibitory effects on most of the genes. Expression of several new genes was noted in this group.

CONCLUSION: The commensal bacterial strains used in this study induced the expression of a large number of genes in colonocyte-like cultured cells and changed the expression of several genes involved in important cellular processes such as regulation of transcription, protein biosynthesis, metabolism, cell adhesion, ubiquitination, and apoptosis. Such changes induced by the presence of probiotic bacteria may shape the physiologic and pathologic responses they trigger in the host.

Key words: *Lactobacillus*; *Escherichia coli*; Gene expression; Probiotic; cDNA microarray

INTRODUCTION

There has been an upsurge in clinical trials involving probiotics in gastrointestinal diseases. Although promising, these trials with specific probiotic bacteria have shown variable results, with limited elucidation of the underlying pathophysiology. In real life, these strains never act on the host cells in isolation and over 800 bacterial strains in the adult human colon are engaged in constant cross talk with intestinal epithelial cells. No detailed study so far has attempted to examine the effect of individual probiotic bacteria on host gastrointestinal cells, and the changes during co-infection with other enteric bacteria.

However, a lot of emphasis has recently been given to the normal bacterial flora in the intestine, including many *Lactobacillus* strains that are considered as probiotics with health-promoting effects on the host. A myriad of effects have been shown by these bacteria, spanning from bacterial killing *via* secretion of bacteriocins[1], to inhibition of attachment and invasion by pathogenic bacteria[2], and modulation of host inflammatory responses[3]. These commensal strains have been shown to modulate the expression of genes involved in important physiologic functions such as postnatal intestinal maturation, cell growth, proliferation, nutrient absorption, mucosal barrier function, and angiogenesis[4-6]. Multiple laboratory studies have shown beneficial effects of *Lactobacillus* strains against single pathogenic bacterial strains in *in vitro* and *in vivo* systems[7,8]. During the last few years, there has been an exponential increase of clinical trial reports and reviews in the literature pertaining to the utility of probiotics in gastrointestinal and allergic diseases[9-21]. Many small studies utilizing *Lactobacillus* and *Bifidobacteria* have shown beneficial effects such as better weight gain and improved

feeding tolerance[22] in neonates, and efficacy against neonatal necrotizing enterocolitis (NEC)[23-25] and sepsis[24]. Other reports have demonstrated no effect in NEC[26], and in some cases, deterioration of specific conditions with probiotic therapy[25]. Results of clinical trials done by our group have shown a wide range (0%-60%) of colonization rates in newborn infants when three different probiotic strains were used[27]. These mixed and non-reproducible results have raised more questions than providing answers, and have strongly suggested complex interactions among bacterial strains and epithelial cells in the human intestine[7,28-30].

At this time, our understanding of the response of eukaryotic cells (e.g., intestinal cells) is limited to nutrients and local factors[31], and virulence mechanisms involving individual microorganisms. Although contrasting signal transduction mechanisms in bacterial and eukaryotic gene transcription have been described[32], reports on cross talk between bacteria and epithelial cells have focused on single bacterial strains[33]. As a result, the physiologic and pathologic changes in the host cells as a response to multiple bacteria have not been addressed. Since the mammalian gut is colonized with multiple bacterial strains very quickly after birth, it is conceivable that the ultimate effect of probiotic treatment will depend greatly on the presence of other bacteria in the host intestine at that time.

In the current study, we examined the difference between gene expression in intestinal cells in response to infection with a single bacterial strain, compared to that during mixed infection. Caco-2 cells were utilized to discern the effect of *Lactobacillus* plantarum (the most common *Lactobacillus* species in humans)[34], *Escherichia coli* (a common Gram-negative enteric strain) and the combination of the two strains. A high-density cDNA glass microarray and standard techniques were employed to identify bacteria-induced gene expression in this eukaryotic system.

MATERIALS AND METHODS

Caco-2 cell culture model

Caco-2 cells, obtained from American Type Culture Collection (ATCC HTB-37), were used at passage 10-12. This human colon-adenocarcinoma-derived cell line has been used extensively for physiologic and enteric bacterial pathogenesis studies[35]. The cells were cultured in a humidified atmosphere containing 5% CO_2 at 37℃ in Dulbecco's Modified Eagle's Medium (DMEM; Gibco, Grand Island, NY, USA with 10% fetal calf serum (Sigma, St. Louis, MO, USA), 2 mmol/L glutamine, 1.0 mmol/L sodium pyruvate, 0.1% non-essential amino acids, 100 U/mL penicillin and 100 μg/mL streptomycin. All experiments were performed without serum or antibiotics in 8-10-d-old cells after they reached confluence.

Bacterial strains

E. coli strain 6-1 was isolated from a healthy infant, and has been used previously in *in vitro* and *in vivo* studies in our laboratory[36]. This strain does not possess any known virulence genes[37]. We used a human strain of *L. plantarum* (ATCC 202195), the species most commonly isolated from humans[34].

Defined bacterial treatment of epithelial cells

Cells were washed in PBS and re-fed with experimental DMEM without serum or antibiotics before the experiments. Following previously described methods in which a maximal effect of *Lactobacillus* was seen, Caco-2 cells were infected with *E. coli* and/or *L. plantarum* at 1:10 multiplicity of infection, and incubated for 2 h[38].

cDNA microarray

For examination of Caco-2 cell gene expression under our experimental conditions, we used a high-density glass microarray H19K (University Health Network Microarray Centre, Toronto, www.microarrays.ca/home.html) that had 19 200 genes/expressed sequence tags (ESTs). These included fully characterized, partially characterized and some uncharacterized human gene elements. Each gene/EST was printed in duplicate in this array. The genes in the array represented constitutively expressed genes/ESTs and the manufacturer did not include genes that are transiently expressed, such as cytokines and chemokines. In our experiments, we used dye swapping procedures and bioinformatics tools considered as standard techniques that have been reported in similar studies in the past[39].

Sample preparation

Total RNA was extracted from Caco-2 cells grown in 75-cm^2 tissue culture flasks using the TRIZOL method (Invitrogen, Carlsbad, CA, USA), following manufacturer's instructions. RNA samples were treated with RNAse-free DNAse to remove contaminating genomic DNA, examined by 260/280 nm UV absorption ratio (> 1.8) followed by assessment of integrity by running in a 1.2% agarose gel and ethidium bromide staining.

Preparation of fluorescent-labeled cDNA[40], hybridization[41] and signal detection

Total mRNA (10 μg) was reversely transcribed using 20 mmol/L dNTP mix including amino-allyl dUTP (AA-dUTP; Sigma) and 400 U SuperScript Ⅱ Reverse Transcriptase (Invitrogen, Carlsbad, CA, USA). The resulting aa-cDNA, cleaned with a QIAquick column (Qiagen, Valencia, CA, USA), was coupled with Cy3 or Cy5 dye (Amersham Biosciences, Piscataway, NJ, USA) in the presence of sodium bicarbonate for 1 h in the dark. After adding 10 μL 4 mol/L hydroxylamine and 125 μL buffer PB (Qiagen supplied) to each, the control and treatment samples were combined and cleaned using another QIAquick column. The elute was transferred to a Microcon YM 30 centrifugal filter device (Amicon Millipore, Bedford, MA, USA), and after adding 20 μL cot-1 human DNA (Gibco-BRL), the whole volume was concentrated to 5 μL. Ten microliters of 1 μg/μL poly (A) RNA (Sigma), 1 μL 10 μg/μL tRNA (Gibco-BRL), 4 μL water and 5 μL hybridization buffer (50% formamide, 5 × SSC (3 mol/L sodium chloride, 0.3 mol/L sodium citrate and 0.1% SDS) were added. The array was pretreated at 42℃ for 1 h with hybridization buffer. After overnight

Table 1 Common genes induced by bacterial treatment (Seventeen genes were influenced by both *E. coli* and *L. plantarum* and four genes by both *E. coli* and combination treatment)

hybridization at 42℃, the slides were washed in 50 mL 2 × SSC and 0.1% SDS at 55℃ for 5 min, once in 0.1 × SSC and 0.1% SDS for 5 min at room temperature (RT), and for 5 min with 0.1 × SSC at RT, air-dried and scanned with 555 nm and 647 nm lasers in a Scan Array 5000 (GSI Lumonics, Novi, MI, USA). Images of the fluorescence intensity for each dye were analyzed using Imagene 4.2 software (Biodiscovery, CA, USA).

RNA from each experimental condition and control Caco-2 cells were hybridized on the same microarray. To eliminate the color bias, duplicate reactions were carried out in which the dyes (Cy3, Cy5) for the control and experimental samples were swapped.

Data interpretation

Individual gene intensity data files for each experimental condition were compared with the control values using the GeneSight 2.1 program (Biodiscovery). After correction for the local background, normalization using all the spots, removal of the outliers, averaging of the replicates and transforming to base 2, each gene was assigned a relative expression value when compared with the control. A twofold or larger difference in the relative gene expression was considered significant.

The data discussed in this publication have been deposited in NCBIs Gene Expression Omnibus (GEO, http://www.ncbi.nlm.nih.gov/geo/) and are accessible through GEO Series accession number GSE5874.

Real-time quantitative PCR

We randomly selected eight genes (BMF, CD248, PPM1E, FXYD3, OAS2, FY, CERK and HPSE) from our pool of expressed genes/ESTs that are well characterized in the literature and appear to have some biologic significance. ESTs were not included. Real-time quantitative PCR (Bio-Rad iQ SYBR Green Supermix and iCicler) was done using GAPDH for normalization. The levels of expression detected by microarray were compared with PCR results. The primers used to amplify specific gene segments are presented in Table 1. The relative gene expression was calculated using the comparative $\Delta\Delta C_T$ method. Each sample was tested twice in triplicate.

RESULTS

Gene expression after bacterial infection

After 2 h treatment, *E. coli*, *L. plantarum* and their combination changed the expression (by twofold) of 332,

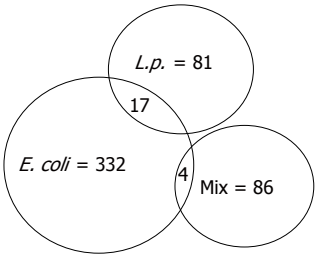

Figure 1 Schematic representation of the genes influenced by each treatment, and the overlapping (common) genes among treatments. The relative gene expression after treatment was > 2-fold compared with the control.

81 and 86 genes, respectively, compared to uninfected control Caco-2 cells (Figure 1). After infection with *E. coli*, 155 genes were up-regulated and 177 were down-regulated (Table 1 and Supplementary Table 1). *L. plantarum* induced up-regulation of 45 genes and 36 genes were down-regulated (Table 1 and Supplementary Table 2). The combination treatment up-regulated 27 genes and down-regulated 59 (Table 1 and Supplementary Table 3) [Note: The supplementary tables above can be accessed at: http://panigrahipeds.googlepages.com/suppl-tables.pdf; Raw data of all 19 200 genes during each treatment can be accessed from the NCBI/GEO data base (GSE5874) at: http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?token=nzyxdkkuwukuytk&acc=GSE5874]. Mixed infection nullified the previously demonstrated stimulatory and inhibitory effects of *E. coli* on 152 and 177 genes and of *L. plantarum* on 38 and 26 genes, respectively. Stimulation of 23 and inhibition of 59 genes were noted after mixed infection that was not influenced by either bacterium alone.

There were 21 genes influenced by two different treatment conditions (Table 1). Seventeen genes were affected by *E. coli* and *L. plantarum*, and four by *E. coli* and the combination of bacteria. Genes nos. 1-7 were up-regulated by both *E. coli* and *L. plantarum*; and genes nos. 8-17 were down-regulated by both bacteria. For each of the 17 genes in this group, the effects of the individual bacteria were brought to baseline by the combination treatment. In contrast, for three genes BMF, CD248 and PPM1E (nos. 18, 19 and 20 in Table 1), the stimulatory effect of *E. coli* was maintained after mixed infection with *L. plantarum*. For one gene (no. 21, CARD8), the 3.26-fold down-regulation by *E. coli* was reversed in the mixed infection, with demonstration of a four fold increase.

Apart from the specific up- and down-regulation of genes by either *E. coli* or *L. plantarum*, and reversal of *E. coli*-induced effects when *L. plantarum* was used as a co-infectant, several genes of physiologic importance were noted in our system. Table 2 describes 58 genes under 10 specific categories that were expressed during mixed infection. While the function of a small number of genes was not very well defined, most of the genes could be grouped into important cellular functions. These include genes involved in transcription regulation, RNA processing, protein biosynthesis, and other important processes such as ubiquitination, cell adhesion, proliferation and apoptosis.

Confirmation of selected gene expression by real-time quantitative PCR

Eight genes were randomly tested by quantitative real-time PCR to verify the expression detected by microarray (Table 3). For each of these genes, RT-PCR confirmed their expression after the three bacterial treatments in the same direction (stimulation or inhibition) as in the microarray experiments (Figure 2).

DISCUSSION

The infant gut is essentially sterile at birth and is first colonized with Enterobacteriaceae, which change the redox potential in the intestine and allow more microaerophilic and anaerobic species to colonize[42,43]. The latter group, which is comprised primarily of *Bifidobacteria* and *Lactobacillus* organisms[44], are considered as normal flora that coexist in the human colon, as new species are introduced to ultimately provide a stable flora in the human gut[45], in which over 800 bacterial species coexist in harmony[46]. In such a healthy state, the intestinal mucosa serves as the first line of defense against infections by providing an important mechanical and immunologic barrier between the host's internal milieu and the gut environment. These intestinal epithelial cells generate and transmit signals between bacteria and deeper layers in the intestine[47]. In the event of specific infections, epithelial cells express and secrete proinflammatory and chemoattractant cytokines[48] that further transmit signals to the underlying cells in the reticuloendothelial system[47]. The virulence factors and the host responses to these factors in various diseases have been studied in a fair amount of detail (*E. coli*, *Vibrio cholerae*, *Salmonella* and *Pseudomonas*) using tissue culture and *in vivo* models, and specific genes and gene functions have been described[49-52]. These experiments have utilized single bacterial strains.

In an attempt to mimic the natural gut environment, communication systems among bacteria have also been studied relatively well. Chemical signals produced and detected by bacteria can be directed at other bacteria and self. This phenomenon, called as quorum sensing, is important for the microorganism's adaptation to the local environment[53]. This fundamental prokaryotic behavior (among bacteria) is known to affect the symbiotic or antagonistic environment created within the gut milieu. However, the effect of single versus multiple bacterial species on eukaryotic cells has not been addressed in the literature.

The stimulus for us to conduct the current study came from our observation that a large number of probiotic trials have been conducted and reported in the recent past, with almost no basis for selection of the strain, and more importantly, with no data on changes in physiologic or pathologic parameters in the host, other than analysis of the primary and secondary clinical endpoints. Although a live bacterial supplement was used in all of these reported studies, there was also a serious lack of data on the colonizing ability of the probiotic strain and changes in the colonization by other bacteria in the host gut. Since the newborn gut is colonized with a paucity of bacteria (an average 2.5 species in preterm infants)[37,54] that expands to a limited but heterogenous flora by 10 d of age[55], we designed the current simple system to examine the effects of *L. plantarum*, a common human probiotic strain, and *E. coli*, the most common colonizing strain in the neonatal

Negative value indicates reduction in gene expression.

period, on gut cells. We took advantage of a microarray chip that allowed us to examine 19 200 human genes in this simulated microbial gut environment. In this *in vitro* model, single and combined bacteria were allowed to interact with cultured cells, and our results were analyzed under high-stringency conditions to identify specific genes expressed during defined bacteria-gut cell interactions.

In our system, we observed a change (up- or down-regulation) in the expression of 333, 81 and 86 genes upon infection with *E. coli*, *L. plantarum* and the combined

Table 3 Primers used for RT-PCR

Gene symbol	Gene ID (NCBI)	Gene name	Gene role	Primer	Primer sequence 5′-3′

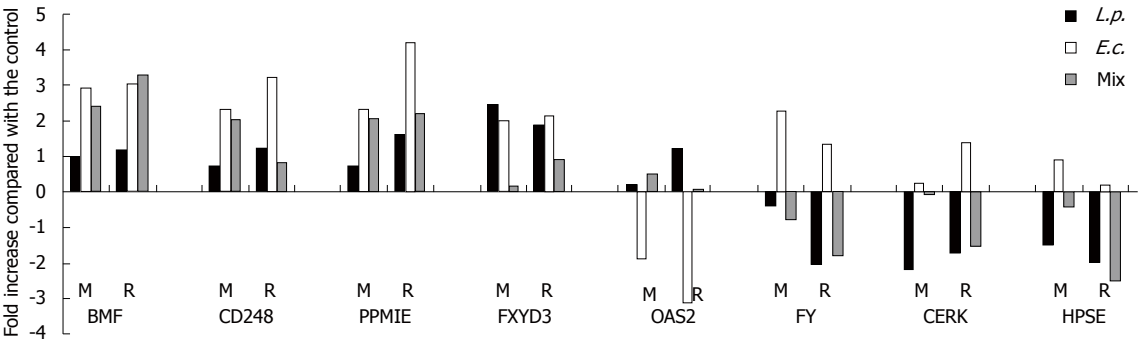

Figure 2 Effect of different bacterial treatments on expression of eight genes assessed by microarray (M) and RT-PCR (R).

treatment, respectively. Our real-time PCR experiments confirmed the modifications demonstrated in the microarray experiments, albeit at a lower level, a phenomenon also reported in other studies[50]. The numbers of unique genes presented in this study are in the range reported in previous studies in which Gram-negative enteric pathogens modified the expression of 0.5%-13% of the genes in epithelial cells[50,56-58], and commensal bacteria induced differential expression of 0.35%-6.2% of examined genes in mouse colonocytes[59]. Our strain of *E. coli* modified 1.73%, and *L. plantarum* modified 0.43% of genes. The slightly lower number of genes identified in our 19200 array may have been due to the use of a non-pathogenic strain of *E. coli*, a commensal *Lactobacillus*, and an array that included only constitutively expressed genes. Genes expected to be expressed after a bacterial insult such as pro-inflammatory cytokines were not spotted on this array. Additionally, a slightly low number might have resulted from our conservative choice of a twofold increase in expression as being significant in our analysis.

There are several comparisons that can be made between our results and those of others using a similar approach but with single bacterial infection. For example, from the six genes up-regulated by enteropathogenic *E. coli* in HeLa cells[49], we found only one (zyxin, a cytoskeletal protein) to be in common with our microarray results. There was a similar increase (1.72-fold) in expression of this gene when our *E. coli* strain 6-1 was used to infect Caco-2 cells. Two previous studies with commensal flora have reported that bacterial reconstitution of germ-free mice increased the expression of the colon-specific serum amyloid A1 gene[60,61]. In our model, serum amyloid A2 gene expression was increased by 2.22-fold. From the 12 genes down-regulated by non-pathogenic bacterial reconstitution of germ-free mice, reported by Fukushima *et al*[59] in colonic epithelial cells, three were in common with our microarray; selenoprotein P, 3-hydroxy-3 methylglutaryl-coenzyme A synthase and metallothionein. All three were also down-regulated in our combination treatment model. The authors also showed a down-regulation of solute carrier family 20 - member 1. Our results were very similar to this observation in that we also noted a decrease in the expression of other members of the solute carrier families, i.e., family 2, 9, 12, 20, 24, 25 and 35. Fukushima *et al*[59] have shown overexpression of heat shock protein (60 kDa) in germ-free mice compared to specific pathogen-free rodents that had received treatment with normal mouse flora. We observed a similar phenomenon in our system in which down-regulation of heat shock proteins 75, 105 and

an ortholog of mouse heat shock protein 70 kDa were noted after combined bacterial treatment. We observed cytochrome c oxidase subunits Ⅳ isoform 1, Va, Ⅵb, Ⅵc, Ⅶa, Ⅶb, Ⅶc and Ⅷ to be up-regulated after *L. plantarum* treatment, similar to that described by Hooper *et al*, who demonstrated up-regulation of cytochrome *c* oxidase subunit 1 by *Bacteroides*, another species also considered as commensal flora. Hooper and colleagues have also shown up-regulation of calmodulin after treatment with *Bacteroides*[61]. Similar increases in expression were noted for calmodulin 1, 2 and 3, calmodulin-dependent protein kinase and phosphodiesterase in our system.

We observed modulation of multiple genes known to have an impact on cellular and physiologic processes in the eukaryotic system (Table 2). These genes ranged from basic transcriptional regulators to those involved in protein synthesis, cellular metabolism, cell proliferation and apoptosis. During mixed infection, we observed down-regulation of three genes involved in ubiquitination. Ubiquitin-conjugating enzyme E2N, ubiquitin-carrier protein E2-EPF and ubiquitin A-52 residue ribosomal protein fusion product 1 were reduced 2.02, 2.05 and 2.29-fold, respectively. In a recent study that investigated anti-inflammatory properties of *Lactobacillus casei*, expression of several genes involved in ubiquitination was reduced, including E2N, a gene (common to our system) that was reported to be decreased 2.88-fold[62]. The authors concluded I-κB stabilization *via* reduced ubiquitination and downstream modulation of inflammatory response driven by NF-κB in *Shigella*-infected Caco-2 cells. We used a non-pathogenic commensal strain of *E. coli* in our experiments, and while the aim of the current study was not to assess or examine the effects of *L. plantarum* during bacterial infection or inflammation, our results strongly suggest that *Lactobacillus* strains do indeed affect common physiologic pathways in gut cells, which may ultimately shape the host response in health and disease.

In our study, it was important and intriguing to note that the three experimental infections induced quite unique gene-expression profiles. Even the mixed infection with *E. coli* and *L. plantarum* had a very small overlap with the expression profiles of the strains when they were used alone. This illustrates how colonization can change the gene expression of host cells as they are exposed to more than one species of bacteria. In real life, the gut cells are exposed to a multitude of bacterial strains, and hence, it may be of limited value to study the effect of infection or colonization by single bacterial species in a clean tissue culture environment, and use the results as the basis for designing treatment or preventive strategies. Using neonatal models of gut colonization, we have previously shown that bacterial ecology (combination of Gram-negative and Gram-positive organisms), rather than individual virulent bacterial strains, plays a more important role in diseases such as NEC[36]. The results of our current study are in line with previous observations, and now provide an additional line of support and offer a possible explanation for the varied results of recent probiotic trials. On a broader scale, this report provides an insight into the complex host response that can be expected at mucosal sites such as the gastrointestinal tract. Based on the results obtained from tissue culture with only two bacteria in the system, it can be speculated that our findings are only the tip of the iceberg, and the real *in vivo* picture in mammals will be even more complex. While it is becoming increasing clear that specific *Lactobacillus* species posses unique health-promoting characteristics[29], knowledge gained from the current study further indicates that a "one strain fits all" approach may not always succeed in the treatment or prevention of specific diseases. A more global approach needs to be taken with proper emphasis on the microbial ecology, while addressing the pathogenesis of unique bacterial diseases in the mammalian intestine at different ages and stages of development.

In the context of *in vivo* or clinical trial environment, it should be noted that our current model and results do not represent a universal phenomenon, nor provide a comprehensive picture of the human intestine. For example, genes expressed will probably be different if other probiotic strains such as *Bifidobacteria* and *L. casei* were used in our system. Similarly, combinations of other aerobic and anaerobic Gram-negative and Gram-positive strains may induce different sets of genes. We can utilize other microarray systems with cytokine and signaling-molecule genes (not spotted in the current 19 200 gene array), when our aim would be to identify modifications in inflammatory mediators. The relative concentrations of each bacterium in the system may also change the gene-expression profile. In the current study, we selected a 1:10 ratio of *E. coli* to *Lactobacillus* infecting dose to simulate the human intestinal microflora, in which anaerobic and microaerophilic organisms form the dominant flora[63]. Since enteric bacteria such as *E. coli* are sometimes present at < 0.1% of the total bacterial population, with a predominance by obligate anaerobes[64], it is not unexpected to observe a different gene-expression profile when a 10-100-fold higher proportion of *Lactobacilli* are used in the system. Nevertheless, such manipulations and experiments can be done, and despite some limitations, assessment of mRNA-expression profiles by cDNA array analysis can be utilized as a useful technique for expanding our understanding of the colonocyte-bacteria interaction[50].

While it may appear difficult to analyze complex microflora (400-800 species) and their interactions with gut cells in the mature intestine, this is now made feasible with the availability of new techniques. Fluorescent *in situ* hybridization utilizing bacterial rRNA can identify and quantify major genera of bacteria, even if they are non-culturable in stools[65,66]. Bacterial microarray chips developed during the last year can identify thousands of bacterial species in stools in one experiment[67,68]. Denaturing gradient gel electrophoresis can be utilized to monitor changes in microflora pattern[69,70] over time and after administration of probiotic supplements. Live colonocytes can be isolated from stool samples and used to examine the expression of genes and proteins during different experimental and/or disease states[71,72]. At this juncture, there is a need for the scientific community to engage in careful evaluation of probiotic strains in *in vitro* and *in vivo* systems prior to initiation of clinical trials. With the new non-invasive tools at hand, such preclinical

endeavors, coupled with concurrent examination of changes in the gut flora and host responses during clinical trials, hold great promise in discerning the difference between "snake oil" and "magic bullets" when it comes to the role of probiotic therapy in human medicine.

Abstract

AIM: To investigate the link between chronic biliary inflammation and carcinogenesis using hamster gallbladder epithelial cells.

METHODS: Gallbladder epithelial cells were isolated from hamsters and cultured with a mixture of inflammatory cytokines including interleukin-1β, interferon-γ, and tumor necrosis factor-α. Inducible nitric oxide synthase (iNOS) expression, nitric oxide (NO) generation, and DNA damage were evaluated.

RESULTS: NO generation was increased significantly following cytokine stimulation, and suppressed by an iNOS inhibitor. iNOS mRNA expression was demonstrated in the gallbladder epithelial cells during exposure to inflammatory cytokines. Furthermore, NO-dependent DNA damage, estimated by the comet assay, was significantly increased by cytokines, and decreased to control levels by an iNOS inhibitor.

CONCLUSION: Cytokine stimulation induced iNOS expression and NO generation in normal hamster gallbladder epithelial cells, which was sufficient to cause DNA damage. These results indicate that NO-mediated genotoxicity induced by inflammatory cytokines through activation of iNOS may be involved in the process of biliary carcinogenesis in response to chronic inflammation of the biliary tree.

Key words: Biliary carcinoma; Inflammation; Inflammatory cytokine; Nitric oxide; Inducible nitric oxide synthase; DNA damage; Gallbladder epithelial cell; Hamster

INTRODUCTION

It is well known that chronic local inflammation increases the risk for cancer development in several organs, such as colon, lung, pancreas, and esophagus[1,2]. Similarly, biliary carcinoma develops under chronic inflammatory conditions involving the biliary epithelium in the setting of gallstone disease, congenital choledochal cyst, pancreaticobiliary maljunction, or primary sclerosing cholangitis[3,4]. Moreover, recent reports have described the occurrence of secondary biliary carcinomas in patients with persistent reflux cholangitis after bilioenterostomy, transduodenal sphincteroplasty, or endoscopic sphincterotomy for both benign and malignant diseases of the liver, bile duct, and pancreas[5-7]. However, the molecular mechanisms of biliary carcinogenesis as a consequence of chronic biliary inflammation remain unclear. We have previously demonstrated that persistent reflux cholangitis after bilioenterostomy accelerates biliary carcinogenesis through activation of biliary epithelial cell kinetics in hamsters[8-10]. Furthermore, more severe cholangitis is associated with a high occurrence of biliary carcinoma. However, the molecular mechanisms by which chronic biliary inflammation increases the risk of biliary carcinogenesis are obscure, similar to the clinical occurrence in humans. Meanwhile, we have established a method for culturing biliary epithelial cells from the hamster using a collagen gel technique[11].

Chemically reactive oxidants, radicals, and electrophilic mediators, such as hydrogen peroxide and oxyradicals, nitric oxide, malondialdehyde, 4-hydroxynonenal, or eicosanoids, are produced during inflammation, and these chemical mediators are known to induce a variety of biological reactions[2]. Recently, attention has been focused on nitric oxide (NO) as an endogenous mutagen, an angiogenesis factor, and an inhibitor of apoptosis[12]. NO is a free radical that is synthesized from L-arginine by the family of nitric oxide synthases (NOSs). Three

isoforms of the NOSs have been isolated: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS)[13,14]. Although nNOS and eNOS are present constitutively, iNOS is induced in inflamed tissues and generates relatively large amounts of NO, compared with nNOS and eNOS[13-15]. Cytokine and/or lipopolysaccharide stimulation is known to induce iNOS expression in macrophages, hepatocytes, and many other cell types including certain epithelial cells[16-19]. Moreover, iNOS expression and generation of NO in inflamed tissues have been postulated to potentiate epithelial cells to malignant transformation through the ability of NO to promote mutagenic changes in DNA through DNA oxidization and protein nitrosylation[20,21].

In this study, we investigated the role of iNOS activation, NO generation, and DNA damage as the link between chronic inflammation and biliary carcinogenesis, by utilizing normal hamster gallbladder epithelial cells cultured with inflammatory cytokines.

MATERIALS AND METHODS

Animals

Five-week-old female Syrian golden hamsters (Shizuoka Laboratory Animal Center, Shizuoka, Japan) were used. The animals were kept under standard laboratory conditions in the Laboratory Animal Center for Biochemical Research at Nagasaki University Graduate School of Biochemical Sciences. All experiments were performed following the Guidelines for Animal Experimentation of Nagasaki University.

Isolation and culture of biliary epithelial cells from hamsters

Biliary epithelial cells were isolated from the biliary tree of hamsters as previously described[11]. After laparotomy, inferior vena cava was paracentesed with a 22G needle, and the liver was perfused in situ with 100 mL Ca^{2+} - and Mg^{2+} - free phosphate-buffered saline (CMF-PBS) containing 10 mmol/L 2-[4-(2-Hydroxyethyl)-1-piperazinyl] ethanesulfonic acid (HEPES) at pH7.4, and 1 mmol/L ethylene glucol-bis (E-aminoethylether) N, N, N', N'-tetraacetic acid (EGTA) for 10 min at 37℃. The vena cava was clamped above the diaphragm, and the perfusing solution was drained *via* the incised portal vein, followed by perfusion with 100 mL Hanks' balanced salt solution (GIBCO, Grand Island, NY) containing 50 mmol/L HEPES and 0.04% collagenase (Nittazeratin, Osaka, Japan) for 10 min at 37℃. After perfusion with the collagenase solution, the liver, gall bladder, and extrahepatic bile duct were removed en bloc. The biliary tree was isolated and separated into the intrahepatic and extrahepatic bile ducts and the gall bladder in CMF-PBS containing 0.1 mmol/L EGTA. The biliary fragments were minced.

The biliary fragments were embedded on collagen gel plated (Collagen Gel Culture kit; Nittazeratin, Osaka, Japan) 60-mm petri dishes with 2 mL of an ice-cold mixture of collagen solution composed of 0.3% acid solution collagen (Cellmatrix Type I -A), 10 × HamF12, and 0.8 N NaOH at 8:1:1 dilution. After incubation at 37℃ with 5% CO_2 and 95% humidity for 20-30 min, collagen gels were overlaid with 5 mL of culture medium composed of Dulbecco's modified Eagle medium/HamF12 medium (DMEM/HamF12, GIBCO) and 10% fetal bovine serum (GIBCO). After incubation of biliary fragments for 7-10 d, the epithelial cells extended widely on the surface of the gel, while the mesenchymal cells progressed toward the inside of the gel. The biliary epithelial cells were isolated from the peripheral region of cellular sheets (Figure 1).

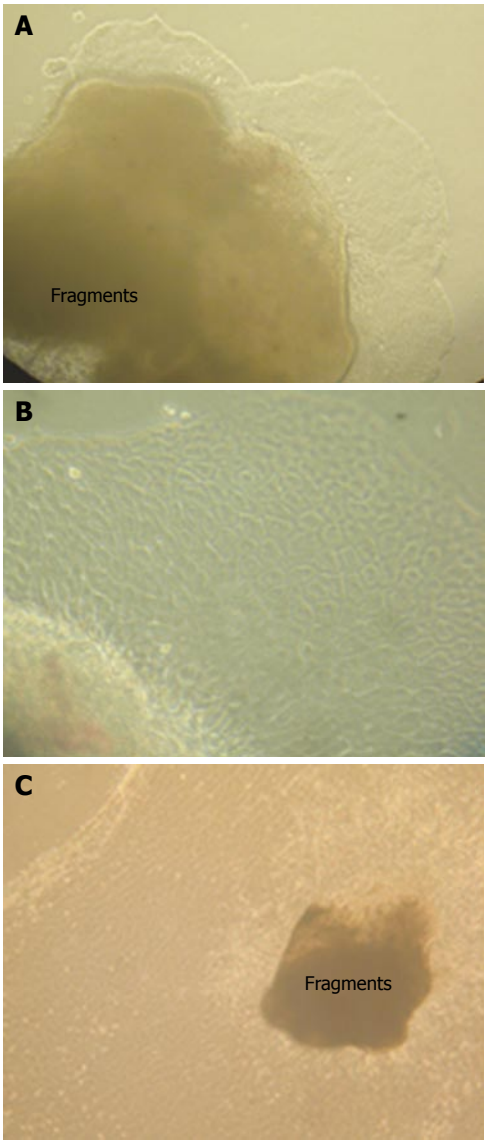

Figure 1 Isolation of hamster biliary epithelial cells. **A**: Phase contrast microscopy revealing a small amount of hamster gallbladder epithelial cells growing on the collagen gels 24 h after culture (× 100); **B**: High magnification of hamster gallbladder epithelial cells demonstrating cuboidal cells around the biliary fragments (× 400); **C**: Phase contrast microscopy showing widely extended gallbladder epithelial cells on the surface of the gel 7 d after culture (× 40).

Addition of inflammatory cytokines

Gallbladder epithelial cells isolated from hamsters were used in this study because of its higher cellular activity compared to other biliary epithelial cells. Resuspended gallbladder epithelial cells (1×10^5 cells/mL) were plated on collagen-coated plates. After incubation for 24 h, the epithelial cells were prepared for three different

experimental protocols: incubation with culture medium alone (control group), incubation with a cytokine mixture known to increase iNOS expression in other cell types[18,22] consisting of human recombinant interleukin (IL) 1-β (0.5 ng/mL), interferon (IFN)-γ (5 ng/mL), and tumor necrosis factor (TNF)-α (250 ng/mL) (CM group), or incubation with the same cytokine mixture and an iNOS inhibitor L-N (G)-monomethyl arginine (L-NMMA, 0.03 mmol/L) (CM + L-NMMA group). These human recombinant cytokines and L-NMMA were obtained from the Sigma Chemical Co. (St. Louis, MO). Gallbladder epithelial cells in each group were incubated at 37℃ for 24 h, and then processed for the following analyses.

Measurement of NO_2^- and NO_3^- in the medium

To determine the amount of NO produced by gallbladder epithelial cells, nitrite (NO_2^-) and nitrate (NO_3^-) levels were measured in the culture media by high performance liquid chromatography with a NOx analyzer (ENO-10; Eicom, Kyoto)[23].

RT-PCR

iNOS mRNA was amplified using a nested RT-PCR method[24]. The sequences of primers (Invitrogen Life Technologies, Carlsbad, CA) used in this study are shown in Table 1[24-26].

Total RNA was extracted from gallbladder epithelial cells using a RNA extraction kit (ISOGEN; Nippon Gene, Tokyo). Reverse transcription and PCR amplification were performed with a RNA PCR kit Ver.3.0 (Takara Shuzo, Tokyo, Japan). After reverse transcription, the first amplification was performed using 1 μmol/L of the cDNA, together with PCR primers NOS-590F and NOS-893R. The PCR conditions were one cycle of denaturing at 95℃ for 2 min, followed by a touch-down protocol consisting of 18 cycles of 15 s at 95℃, 30 s at 60℃, and 1 min at 72℃, then 25 cycles of 15 s at 95℃, 30 s at 42℃ minus 1℃ per cycle, 1 min at 72℃, and a final extension at 72℃ for 10 min[24]. Next, 1 μL of the cDNA from this amplification was reamplified using the PCR primers specific for iNOS (NOS40F and NOS40R)[24]. The PCR conditions were an initial denaturation at 95℃ for 2 min, followed by a touch-down protocol consisting of 13 cycles of 15 s at 95℃, 30 s at 70℃ minus 1℃ per cycle, 1 min at 72℃, then 30 cycles of 15 s at 95℃, 30 s at 57℃, 1 min at 72℃, and a final extension at 72℃ for 10 min[24]. As a control, amplification of mRNA for glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was performed[24,26], and the PCR conditions were the same as those described for the first nested PCR amplification. The amplification products were resolved by electrophoresis on 3% (w/v) agarose gels containing 0.1 μg/mL ethidium bromide and photographed under UV trans-illumination.

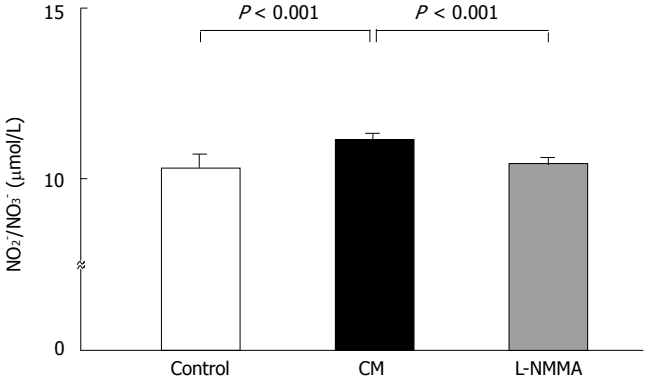

Figure 2 High performance liquid chromatography showing significantly elevated NO_2^- + NO_3^- levels in the CM group compared with the control group, similar NO generation in the CM + L-NMMA group and control group, being significantly lower than that in the CM group.

Comet assay (single cell gel electrophoresis assay)

Comet assay was performed as described previously[27,28]. The gallbladder epithelial cells in each group were resuspended at 1×10^5 cells/mL in ice cold CMF-PBS and combined with molten LMAgarose (Trevigen, Gaitherburg, MD) at a ratio of 1:10 (v/v). The sample was immediately pipetted onto a frosted microscope slide (CometSlide; Trevigen, Gaitherburg, MD). The slides were placed flat at 4℃ in the dark for 10 min, immersed in prechilled lysis solution (Trevigen, Gaitherburg, MD), and left at 4℃ for 30 min to remove cellular proteins, leaving DNA as nucleoids. The slides were then immersed in an alkaline solution (pH > 13, 0.3 mol/L NaOH and 0.001 mol/L EDTA) for 30 min to denature the DNA and hydrolyze sites of damage. The samples were electrophoresed for 10 min and stained with SYBR green I (Trevigen, Gaitherburg, MD) according to the manufacturers instructions. At least 75 cells on each slide, randomly selected by fluorescence microscopy, were analyzed using National Institutes of Health image (Netscape Navigator) with the comet analysis macro (comet 1.4 macro)[29].

Statistical analysis

Values for NO_2^- + NO_3^- levels and proportion of DNA damage were expressed as mean ± SE. For statistical analysis, ANOVA was used to compare non-repeated measurements between groups, followed by Bonferroni correction for paired comparison. $P < 0.05$ was considered statistically significant.

RESULTS

Generation of NO_2^- and NO_3^-

The amount of NO measured by high performance liquid chromatography in each group is shown in Figure 2. The concentration of NO_2^- + NO_3^- in the media was

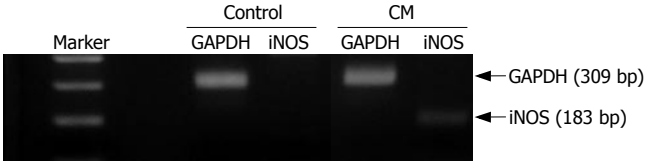

Figure 3 iNOS mRNA expression in gallbladder epithelial cells in the CM group and no iNOS mRNA expression in the control group.

10.35 ± 0.47 μmol/L in the control group (n = 26), 11.06 ± 0.18 μmol/L in the CM group (n = 26), and 10.46 ± 0.18 μmol/L in the CM + L-NMMA group (n = 27). NO generation was significantly higher in the CM group than in the control group ($P < 0.001$). Meanwhile, NO generation in the CM + L-NMMA group and control group was similar, and significantly lower than that in the CM group ($P < 0.001$).

RT-PCR

RT-PCR/touch down amplification of iNOS mRNA in gallbladder epithelial cells is shown in Figure 3. iNOS mRNA (183 bp) expression was demonstrated in the CM, while none of the control cells expressed iNOS mRNA.

Comet assay

Representative fluorescent micrograph images evaluated by single cell gel electrophoresis using comet assay are shown in Figure 4A. In contrast to the intact spherical nuclei observed in the control group, the cells treated with cytokine mixture demonstrated a comet tail indicative of DNA damage. In the CM + L-NMMA group, the cells also exhibited intact spherical nuclei. The ratio of DNA exhibiting comet tails evaluated by using NIH image was 2.14% ± 0.59% in the control group, 5.14% ± 0.69% in the CM group, and 1.70% ± 0.62% in the CM + L-NMMA group (Figure 4B). The level of DNA damage in the CM group was significantly higher than that in the control group ($P < 0.001$), and decreased to the control level after the addition of L-NMMA.

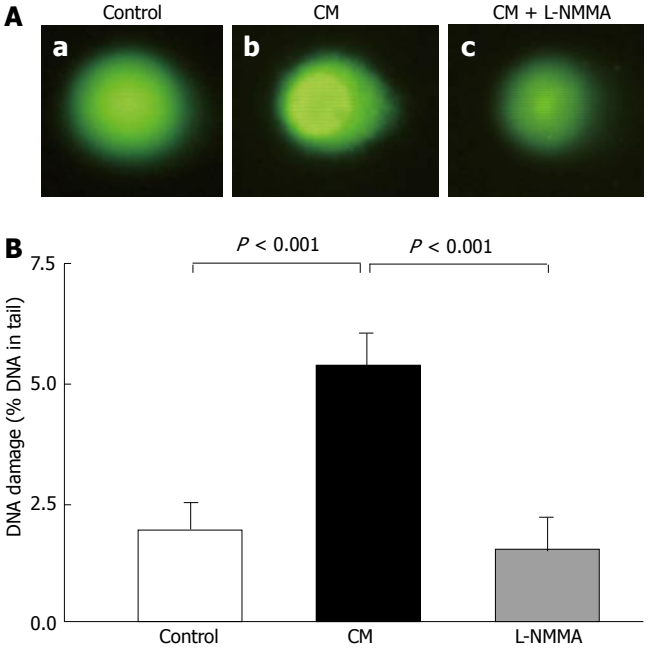

Figure 4 NO-dependent DNA damage evaluated by comet assay. **A**: Fluorescence microscopy showing the apparent comet tail in gallbladder cells stimulated by the cytokine mixture and intact spherical nuclei of the cells in the control group and CM + L-NMMA group; **B**: Analysis of the proportion of DNA migrated to comet tails using NIH image showing a significantly higher level of DNA damage in the CM group than in the control group, which decreased to the control level after the addition of L-NMMA.

DISCUSSION

The induction of iNOS expression and NO production has previously been described in a variety of precancerous or cancerous lesions, in which the NO level of production is in proportion to the degree of malignancy[30,31]. Recently, Jaiswal *et al*[27,32] reported that human cholangiocarcinomas exhibit intensive immunohistochemical staining for iNOS and that cholangiocarcinoma cell lines stimulated by inflammatory cytokines and cholangiocyte cell lines transfected with iNOS produce large amounts of NO due to iNOS expression, which result in both oxidative DNA damage and inhibition of the excision DNA repair process. In the present study, we used primary epithelial cells isolated from the gallbladder because these normal epithelial cells should be suitable for estimating the involvement of iNOS and NO in biliary carcinogenesis, especially in the initiation of biliary carcinoma in response to chronic inflammation.

Following stimulation with a mixture of inflammatory cytokines of IL-1β, IFN-γ, and TNF-α, NO generation was significantly increased in the gallbladder epithelial cells. Furthermore, the production of NO in the presence of inflammatory cytokines was completely suppressed by the addition of an iNOS inhibitor, L-NMMA. Moreover, the expression of iNOS mRNA in the gallbladder epithelial cells was clearly demonstrated in the presence of cytokine-stimulation using nested RT-PCR, but not in the absence of stimulatory cytokines. These findings indicate that inflammatory cytokines promote iNOS expression and NO generation in normal epithelial cells of hamster gallbladder.

NO has the ability to directly oxidize DNA, causing mutagenic changes[20,21]. Although NO also contributes to intracellular communication, inhibition of apoptosis, and enhancement of vascular dilatation, permeability, and neovascularization[33,34], DNA damage may be an essential and initial process involved in the malignant transformation of a wide variety of epithelial cells, and DNA damage in the individual cell can be detected using the highly sensitive comet assay[27,28,32]. In this assay, damaged single- and double-stranded DNA within the nucleus are allowed to migrate toward the anode, by an alkaline hydrolysis process during electrophoresis, resulting in the appearance of a "comet tail". In our study, the comet assay clearly demonstrated that the proportion of DNA moving to the comet tail, i.e., indicating DNA damage, was significantly higher in the cytokine mixture group than in the control group, and that the increased DNA damage was completely inhibited by L-NMMA. These data indicate that inflammatory cytokines stimulate iNOS-mediated DNA damage in normal gallbladder

epithelial cells. Although almost all DNA oxidative breaks can be excised by multiple excision DNA repair processes before mutations occur[35], DNA damage can lead to p53-mediated cell growth arrest and apoptosis, and the accumulation of p53 protein can repress the transcription of iNOS[36]. Furthermore, a recent report has shown that the tumor suppressant organization of normal p53 protein is inhibited in the presence of large amounts of NO in inflamed tissues[37]. In consideration of these facts, the results of our study suggest that NO-mediated oxidative DNA damage produced by inflammatory cytokines through iNOS expression is involved in an initiation process linking chronic biliary inflammation to malignant transformation.

Inflammatory cytokines released in the inflamed tissues initiate the induction of iNOS, resulting in increased NO production. As demonstrated in our study, iNOS-mediated NO production is sufficient to induce DNA damage in normal biliary epithelial cells. In association with persistency of biliary inflammation, the accumulation of NO-mediated genotoxicity may initiate the malignant transformation of epithelial cells lining the biliary tree. Our hamster models of both *in vivo* and *in vitro* tumorigenesis will enhance the understanding of the mechanisms of inflammation-related biliary carcinogenesis.

ACKNOWLEDGMENTS

The authors would like to thank Dr. S Maeda, Department of Pharmacology 1, Nagasaki University Graduate School of Biomedical Sciences, for technical assistance and advice in measuring NO.

COMMENTS

Background

It is well known that biliary carcinoma develops under chronic inflammatory conditions involving the biliary epithelium. We have previously demonstrated that persistent reflux cholangitis after bilioenterostomy accelerates biliary carcinogenesis through activation of biliary epithelial cell kinetics in hamsters. However, the cellular mechanisms of biliary carcinogenesis in response to inflammation remain unclear.

Research frontiers

In the present study, we used primary epithelial cells isolated from the gallbladder of hamsters. These normal epithelial cells should be suitable for estimating the involvement of iNOS and NO in biliary carcinogenesis, especially in initiation of biliary carcinoma in response to chronic inflammation.

Innovations and breakthroughs

In normal hamster gallbladder epithelial cells, cytokine stimulation induced iNOS expression and NO generation which was sufficient to cause DNA damage. The results suggest that NO-mediated oxidative DNA damage produced by inflammatory cytokines through iNOS expression is involved in an initiation process linking chronic biliary inflammation to malignant transformation.

Applications

Our hamster models of both *in vivo* and *in vitro* tumorigenesis will enhance the understanding of the mechanisms of inflammation-related biliary carcinogenesis.

Peer review

The authors investigated the role of inducible nitric oxide (iNOS) in DNA damage using cultured gallbladder epithelial cells. They speculated that the DNA damage would be related to biliary carcinogenesis. The data were interesting.

Abstract

AIM: To characterize the correlation between severity of hepatopulmonary syndrome (HPS) and degree of hepatic dysfunction, and to explore how intestinal endotoxemia (IETM) affects the development of HPS in cirrhotic rats.

METHODS: Male Wister rats were fed with a diet containing maize flour, lard, cholesterol, and alcohol and injected subcutaneously with CCl_4 oil solution every two days for 8 wk to induce typical cirrhosis and development of HPS. The animals were also given a nitric oxide (NO) production inhibitor, N^{ω}-nitro-L-arginine methyl ester (L-NAME) intraperitoneally, and an iNOS inhibitor, aminoguanidine hydrochloride (AG) via gavage daily from the end of the 4th wk to the end of the 6th or 8th wk, or a HO-1 inhibitor, zinc protoporphyrin (ZnPP) intraperitoneally 12 h prior to killing. Blood, liver and lung tissues were sampled.

RESULTS: Histological deterioration of the lung paralleled to that of the liver in the cirrhotic rats. The number of pulmonary capillaries was progressively increased from 6.1 ± 1.1 (count/filed) at the 4th wk to 14.5 ± 2.4 (count/filed) at the 8th wk in the cirrhotic rats. Increased pulmonary capillaries were associated with increased blood levels of lipopolysaccharide (LPS) (0.31 ± 0.08 EU/mL *vs* control 0.09 ± 0.03 EU/mL), alanine transferase (ALT, 219.1 ± 17.4 U/L *vs* control 5.9 ± 2.2 U/L) and portal vein pressure. Compared with normal control animals, the number of total cells in bronchoalveolar lavage fluid (BALF) of the cirrhotic rats at the 8th wk was not changed, but the number of macrophages and the ratio of macrophages to total cells were increased by nearly 2-fold, protein expression of inducible nitric oxide synthase (iNOS) and endothelial nitric oxide synthase (eNOS) started to increase significantly at the 4th wk, and reached its peak at the 8th wk in the lung of cirrhotic rats. The increase of iNOS expression appeared to be quicker than that of eNOS. NO_2^-/NO_3^- was also increased, which was correlated to the increase of iNOS (r = 0.7699, P < 0.0001) and eNOS (r = 0.5829, P < 0.002). mRNA expression of eNOS and iNOS was highly consistent with their protein expression.

CONCLUSION: Progression and severity of HPS as indicated by both increased pulmonary capillaries and histological changes are closely associated with LPS levels and progression of hepatic dysfunction as indicated by increased levels of ALT and portal vein pressure. Intestinal endotoxemia plays a central role in the development of HPS in the cirrhotic rat model by inducing NO and/or CO.

Key words: Endotoxin; Alcohol; Nitric oxide synthase; Hemeoxygenase-1; Capillary; Macrophage; Cirrhosis; Hepatopulmonary syndrome

Zhang HY, Han DW, Su AR, Zhang LT, Zhao ZF, Ji JQ, Li BH, Ji C. Intestinal endotoxemia plays a central role in development of hepatopulmonary syndrome in a cirrhotic rat model induced by multiple pathogenic factors. *World J Gastroenterol* 2007; 13(47): 6385-6395

http://www.wjgnet.com/1007-9327/13/6385.asp

INTRODUCTION

Hepatopulmonary syndrome (HPS) develops when arterial oxygenation deficiency occurs due to intrapulmonary vascular dilatations that are often associated with severe hepatic disease[1]. Recent studies support that the presence

of HPS significantly increases the mortality of cirrhotic patients, particularly those with decompensated liver disease[2,3].

The pathogenesis and precise mechanism of pulmonary vascular abnormalities in HPS are the fields of active investigation. So far, studies have been focused on characterizing the increased pulmonary production of vasodilator substances, most notably nitric oxide (NO). Pulmonary NO overproduction in human HPS, as assessed by exhaled NO levels, has also been reported[4,5]. It was reported that HPS patients showed short term improvements in oxygenation after acute administration of L-NAME (a specific nitric oxide synthase inhibitor) or methylene blue (an inhibitor of cyclic guanosine monophosphate generation)[6-8], indicating that pulmonary NO and cyclic guanosine monophosphate production can lead to changes in pulmonary vascular tone, thus affecting oxygenation. However, the role of pulmonary NO in lung oxygenation is still controversial. Inhalation of L-NAME could not acutely improve intrapulmonary vasodilatation[9], and sequential inhibition of the nitric oxide-cyclic guanosine monophosphate pathway by curcumin (diferuloylmethane), terlipressin and methylene blue could not improve the intrapulmonary shunt, and both hypoxaemia and orthodeoxia were substantially worsened after treatment with the above three durgs[10], strongly suggesting that factors other than nitric oxide synthase (NOS)-derived NO effects on vascular tone contribute to HPS. It has also been shown that the levels of COHb indicative of CO production are increased in cirrhotic patients who develop HPS compared to the cirrhotic patients who do not develop HPS and correlate with gas exchange abnormalities, suggesting that CO may also contribute to human HPS[11].

The sequelae of endotoxemia are often fatal. The lung appears to be an organ sensitive to endotoxemia and many distant-focus infections can be detected as a result of pulmonary dysfunction[12,13]. Patients with hepatic cirrhosis have an elevated plasma level of lipopolysacchride (LPS)[14], which is a leading causative factor for cirrhotic complications, such as hepatorenal syndrome[15-18] and hepatic encephalopathy[19].

We have previously developed a rat model characteristic of cirrhosis and HPS that can be non-invasively induced by multiple pathogenic factors including high fat diet, alcohol, cholesterol, corn flour and CCl_4[20]. A significantly increased level of LPS in plasma is closely related to the deceased blood oxygen content and intrapulmonary vascular dilatation in the rat model, suggesting that intestinal endotoxemia (IETM) and its accompanying cytokines, such as TNF-α, play a role in the pathogenesis of HPS.

This study was to further characterize the relation between severity of HPS and degree of hepatic dysfunction, and to explore how IETM affects the development of HPS in cirrhotic rats. The results show that the severity of HPS parallels to the levels of blood LPS and progression of hepatic dysfunction and IETM plays a central role in the development of HPS in cirrhotic rats.

MATERIALS AND METHODS

Animals and reagents

Male Wister rats, weighing 220-250 g, were obtained from the Animal Center of Shanxi Medical University. All animals received human care during the study. The study was approved by the Ethical and Research Committee of the Shanxi Medical University. Experiments were performed following the institutional guideline for animal research. Cirrhosis and HPS were induced in the rats as previously described[20]. In brief, male Wister rats were fed with a complex diet containing maize flour, lard, cholesterol, and alcohol for 8 wk, and injected subcutaneously with CCl_4 oil solution every two days over the experimental period to induce typical cirrhosis and development of HPS. The animals were also given a NO production inhibitor, N^{ω}-nitro-L-arginine methyl ester (L-NAME) intraperitoneally, 5 mg/kg per day, or an inducible nitric oxide synthase (iNOS) inhibitor, aminoguanidine hydrochloride (AG) *via* gavage, 100 mg/kg per day from the end of the 4th wk to the end of the 6th or 8th wk, or 50 μmol/kg hemeoxygenase-1 (HO-1) inhibitor, zinc protoporphyrin (ZnPP) intraperitoneally 12 h prior to killing. The animals were randomized into four groups: (1) normal control group (fed with standard diet), (2) 4-wk group (fed with the complex diet for 4 wk), (3) 6-wk group (fed with the complex diet for 6 wk), and (4) 8-wk group (fed with the complex diet for 8 wk). Blood, liver and lung tissues were sampled from the rats.

Limulus amebocyte lysate (LAL) reagent, for determination of LPS in plasma, was provided by Shanghai Yi Hua Scientific, Inc (Shanghai, China). Tumor necrosis factor α (TNF-α) radioimmunoassay kit was provided by Radioimmunity Institute of PLA General Hospital (Beijing, China). Detecting kit for NO_2^-/NO_3^- was provided by Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Polyclone anti- endothelial nitric oxide synthase (eNOS) and anti- inducible nitric oxide synthase (iNOS) were purchased from Beijing Zhongshan Biotic Reagent Company (Beijing, China). Immunohistochemistry kit for hemeoxygenase-1 (HO-1) was obtained from Wuhan Boshide Bioengeering Institue (Wuhan, China). TRIzol reagent was bought from the Life Technologies Company (California, USA). Reverse transcriptase polymerase chain reaction (RT-PCR) primers for β-actin, eNOS, and iNOS were synthesized by Shanghai Jiebeist Gene Company, LTD (Shanghai, China). NO inhibitor L-NAME, specific iNOS inhibitor AG, and HO-1 inhibitor ZnPP were obtained from Sigma Chemical Co (St. Louis, MO).

Measurement of LPS, TNF-α, alanine transferase, malondialdehyde *in plasma, NO_2^-/NO_3^- and COHb in pulmonary homogenate and portal vein pressure*

The contents of LPS, TNF-α, alanine transferase (ALT), malondialdehyde (MDA) in plasma, NO_2^-/NO_3^- (indirectly reflecting NO) and COHb (indirectly reflecting CO) in pulmonary homogenate were measured with the different kits following their manufacturers'instructions. The method described by MacPhail *et al*[21] was modified for

measurement of portal vein pressure (PVP) in which 18-gauge over-the-needle catheter was inserted into portal vein and connected to a water manometer.

Histology and calculation of capillaries

Samples from the liver and lung were collected and fixed immediately in 100 g/L phosphate-buffered formaldehyde overnight. After paraffin embedding, serial 4-μm thick sections were prepared and stained with hematoxylin and eosin (HE). Images (× 100) of liver and lung sections were captured with Olympus microscope equipped with a digital camera. The number of capillaries was counted in 6 fields per slide per group (n = 6) with the Image-Pro plus full automatism analysis system.

Number of cells in bronchoalveolar lavage fluid

Bronchoalveolar lavage was performed with 0.9% sterile NaCl. The number of total cells and macrophages in bronchoalveolar lavage fluid (BALF) was counted respectively with a hemocytometer and the ratio of macrophages to total cells was calculated.

Dynamic study of eNOS, iNOS and HO-1 protein expression in lung architecture

Samples from the right lobe of lung were collected into 100 g/L phosphate-buffered formaldehyde and fixed overnight. Serial 4-μm thick sections were prepared after the samples were dehydrated in graded ethanol solutions, cleared in chloroform, and embedded in paraplast. Expression of eNOS, iNOS and HO-1 was analyzed with immunohistochemical staining and quantified with the Image-Pro plus full automatism analysis system in a blind fashion.

Dynamic study of eNOS and iNOS mRNA expression in lung

RT-PCR was employed to detect the mRNA expression of eNOS and iNOS genes in lung. The primer sequences used are as follows: eNOS (435 bp)[22]: 5'-CTGCTGCCCG AGATATCTTC-3', 5'-AAGTAAGTGAGAGCCTGGCG CA-3'; iNOS (388 bp)[23]: 5'-AGCATCACCCCTGTGTTC CACCC-3', 5'-TGGGGCAGTCTCCATTGCCA-3'; β-actin (630 bp, as control)[24]: 5'-GATGGTGGGTAT GGGTCAGAAGGAC-3', 5'-GCTCATTGCCGATAG TGA TGA CT-3'.

Total RNA was extracted from 50-100 mg snap-frozen left lung tissue following TRIzol protocol. Following precipitation, the RNA was resuspended in RNase-free buffer, the concentration was determined by measuring the ultra-violet light absorbance at 260 nm and 280 nm and the purity of RNA was estimated from the ratio of A_{260}/A_{280}.

Single-stranded complementary DNA (cDNA) was synthesized from the total RNA. Two μg RNA was mixed with 0.5 μg oligo (dT), pre-incubated in 15 μL of diethylpyrocarbonate (DEPC) at 70℃ for 5 min, and rapidly chilled on ice. Five μL of M-MLV 5 × reaction buffer, 1.25 μL of dNTP (10 mmol/L, each), 25 units of rRNasin ribonuclease inhibitor, 200 units of M-MLV RT and DEPC-treated water were added into the annealed primer/template to a final volume of 25 μL. The reaction solution was incubated at 42℃ for 60 min and terminated by placing it on ice after denaturation at 85℃ for 5 min. The resulting cDNA was used as a template for subsequent PCR.

The PCR mixture contained 5 μL of 10 × Taq buffer, 1 μL of dNTP (10 mmol/L, each), 1 μL of gene specific primers, 2.0 units of Taq DNA polymerase and 1 μL of cDNA in a total volume of 50 μL. Thirty-five cycles of amplification were performed with an initial incubation at 94℃ for 3 min and a final extension at 72℃ for 7 min, each cycle consisted of denaturation at 94℃ for 1 min, annealing at 64℃ for 1 min and extension at 72℃ for 1 min. The quantities of cDNA producing equal amounts of β-actin-PCR-product were used in PCR with the primers for iNOS and eNOS. Following RT-PCR, 10 μL samples of amplified products was resolved by electrophoresis on 1.2% agarose gel and stained with ethidium bromide. The level of each PCR product was semi-quantitatively evaluated using a digital camera and an image analysis system (Alpha Innotech Co., USA), and normalized to β-actin.

Statistical analysis

Data were evaluated by analysis of variance, multiple comparisons between groups were performed with SPSS software. All values are reported as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

Comparison of histological features of both liver and lung

Pulmonary pathological changes were consistent with hepatic pathological changes towards the same direction, namely, pulmonary pathological changes became progressively exacerbated as liver injury progressed. In normal liver architecture, sinusoids and cord located in order around central veins (Figure 1A). Derangement of hepatic cord and central lobular necrosis with infiltration of inflammatory cells, cytoplasm rarefaction in liver cells with balloon-like alteration and steatosis, and increased fiber amount in interlobular area were found in the 4th wk group (Figure 1B). Furthermore, more typical balloon-like alteration and steatosis, fiber network formation, further aggravated infiltration of inflammatory cells were observed in the 6th wk group (Figure 1C). False lobule formation, secondary degeneration and necrosis in liver cells with infiltration of inflammatory cells were demonstrated in the 8th wk group (Figure 1D). Thin alveoli wall with disseminated pulmonary phagocytes was observed in the normal control group (Figure 2A). Thick alveoli wall with infiltration of phagocytes and neutrophils was observed in the 4th wk group (Figure 2B). Dilated capillaries and increased capillary density in further wider septum, and partially decreased air space in their size with infiltration of phagocytes and neutrophils were found in the 6th wk group (Figure 2C). Obviously dilated capillaries and increased number of capillaries, massive enlarged phagocytes within wider septa and air spaces with focal narrower air spaces were found in the 8th wk group (Figure 2D).

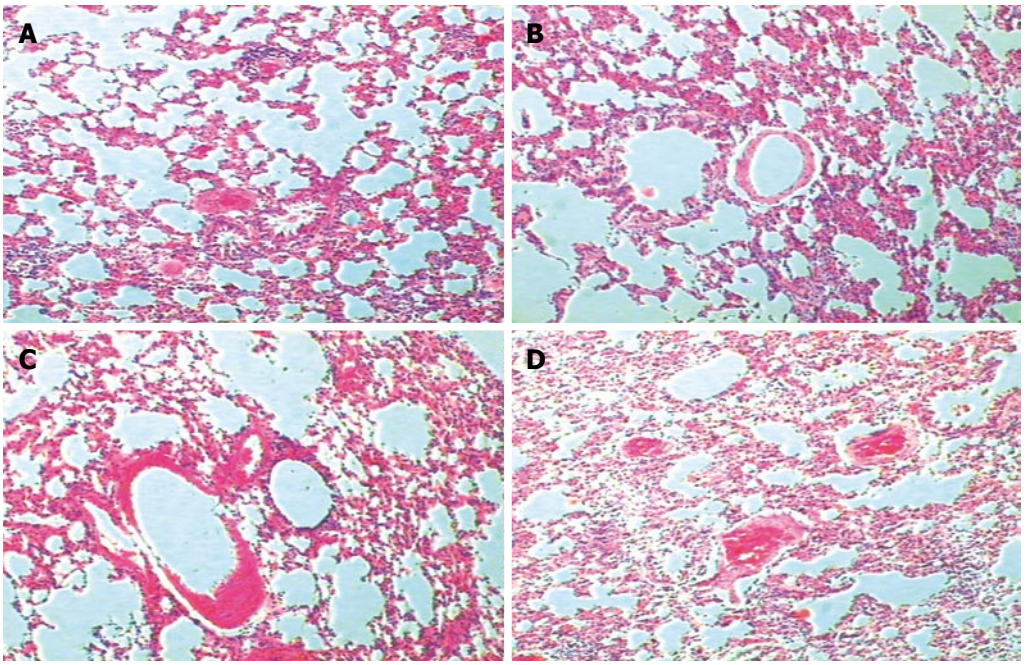

Figure 2 Lung histology of HPS (HE, × 200) in normal control group (**A**), 4th wk group (**B**), 6th wk group (**C**) and 8th wk group (**D**).

Changes in pathological parameters

The levels of LPS, TNF-α, ALT and MDA in plasma were progressively increased over the period of 8 wk. PVP was significantly elevated in the 4th wk and persisted up to the 8th wk (Table 1).

We have previously reported that the pulmonary capillaries are dilated in the lung of cirrhotic rats based on Tc99MAA labeling and scanning[20]. To know if proliferation of capillaries also occurs during the development of HPS, we counted the number of capillaries. The number of pulmonary capillaries was progressively increased in cirrhotic rats (Figure 3), which was positively related to the increased levels of LPS, TNF-α, ALT and MDA in plasma as well as to the NO and CO in pulmonary homogenate (Table 2).

The number of cells in bronchoalveolar lavage fluids could reflect the function of lung. Compared with normal control animals, the total number of cells was not changed. However, the number of macrophages and the ratio of macrophages to total number of cells were significantly increased in BALF of cirrhotic rats at the 8th wk, strongly suggesting that macrophages could play a role in the pathogenesis of HPS (Table 3).

Levels of NO_2^-/NO_3^-, eNOS and iNOS in lung

Immunohistochemistry displayed that eNOS protein expression in pulmonary architecture started to increase significantly at the 4th wk and reached its peak at the 8th wk (Table 4). The change in iNOS protein expression was similar to that of eNOS, but significant differences were detected between the 4th and 6th wk as well as between the 6th and 8th wk, showing a progressive ascending. NO_2^-/NO_3^- was nearly increased by 3.5-fold at the 4th wk, by 5-fold at the 6th wk, and by more than 7-fold at the 8th wk.

6th wk	0.68 ± 0.07[a]	1.23 ± 0.03[a,c]
8th wk	0.75 ± 0.08[a,e]	1.46 ± 0.05[a,e]

[a]$P < 0.05$ *vs* normal group; [c]$P < 0.05$ *vs* 4th wk group; [e]$P < 0.05$ *vs* 6th wk group.

The increased NO_2^-/NO_3^- was more relevant to the expression of iNOS ($r = 0.7699$; $P < 0.01$) than to that of eNOS ($r = 0.5829$, $P < 0.002$).

The expression of eNOS and iNOS was distributed differently in the lung tissue stained with immunohistochemistry. In normal lung, eNOS was expressed in pulmonary capillary endothelium. In contrast, eNOS was expressed not only in the endothelium but also in type Ⅰ and Ⅱ epithelial cells and macrophages, and the expression was progressively increased in the lung of cirrhotic rats over the experimental period (Figure 4). iNOS was located mainly in macrophages and type Ⅱ epithelial cells during the development of HPS.

At mRNA levels, the expression of eNOS and iNOS in the lung was highly consistent with their protein expression (Table 5, Figure 5). Plasma endotoxin was significantly correlated with the expression of eNOS and iNOS over the 8 wk period (Table 6), suggesting that IETM might induce the expression of eNOS and/or iNOS in the development of HPS.

Effects of NOS or HO-1 inhibitors on expression of HO-1 or NOS in lung

The level of COHb and expression of HO-1 in the lung of cirrhotic rats began to increase at the 4th wk and reached their peak at the 8th wk (Table 7). The location of

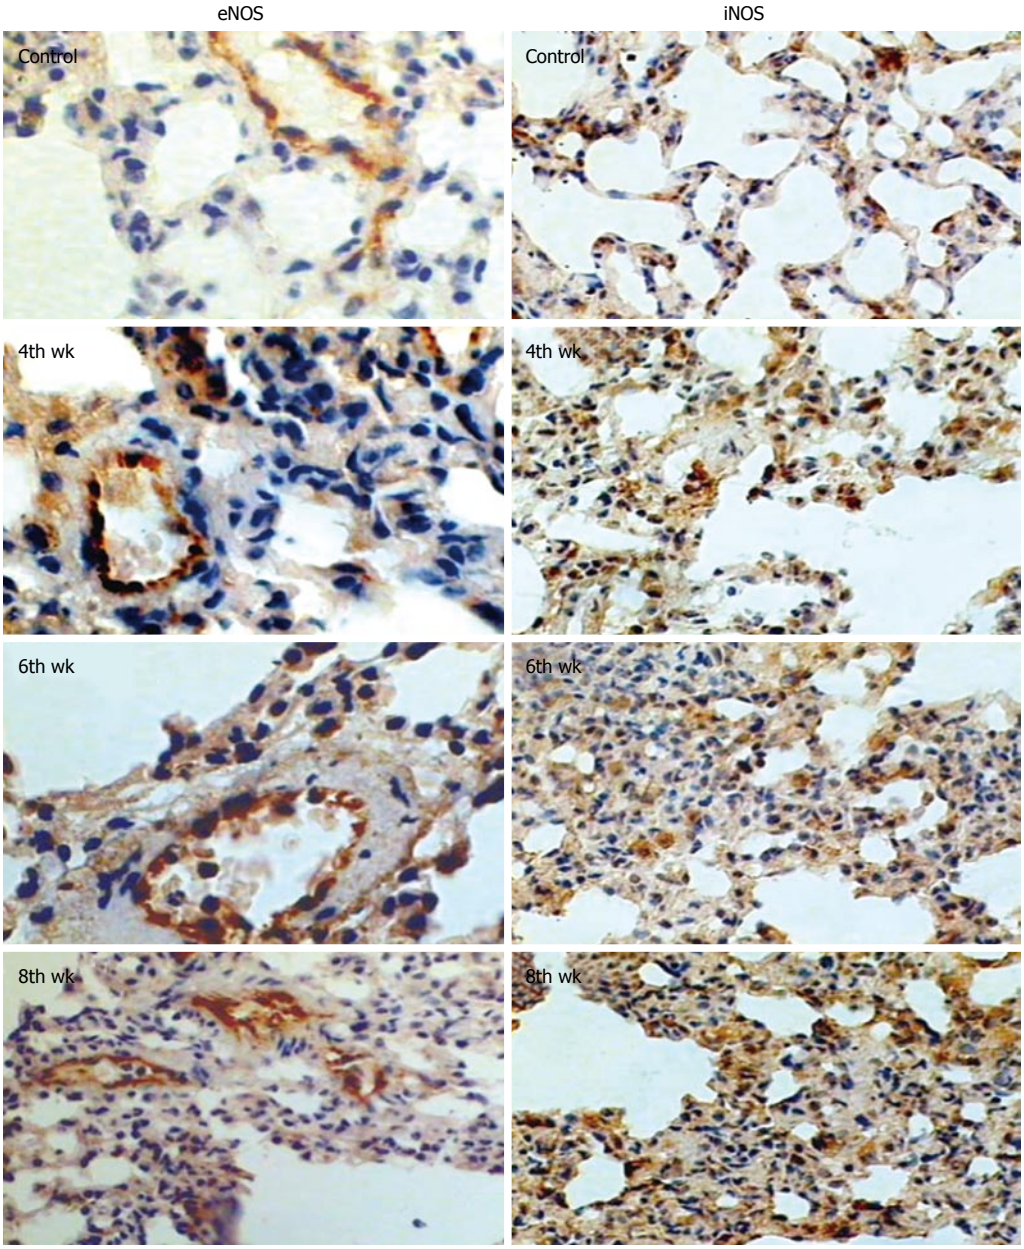

Figure 4 Immunohistochemistry of NOS expressions in the lung of rats with their eNOS and iNOS stained brown (× 200).

HO-1 was mainly found in pulmonary type Ⅱ epithelial cells, macrophages, and capillary endothelium (Figure 6). The levels of plasma LPS and TNF-α were closely correlated with COHb and expression of HO-1 (Table 8).

The expression of HO-1 in cirrhotic rats was decreased by 3-fold at the 6th wk when the non-specific inhibitor (L-NAME) of NOS was administrated and by 5-fold when the specific inhibitor (AG) of iNOS was administrated (Table 9). Similar effects were also detected at the 8th wk. Inhibition of HO-1 expression specifically by ZnPP in cirrhotic rats decreased significantly the expression of eNOS and iNOS (Table 10), indicating that both CO and NO were involved in the development of HPS.

DISCUSSION

In this study, dynamic alterations in plasma endotoxin were found to be closely associated with the expression

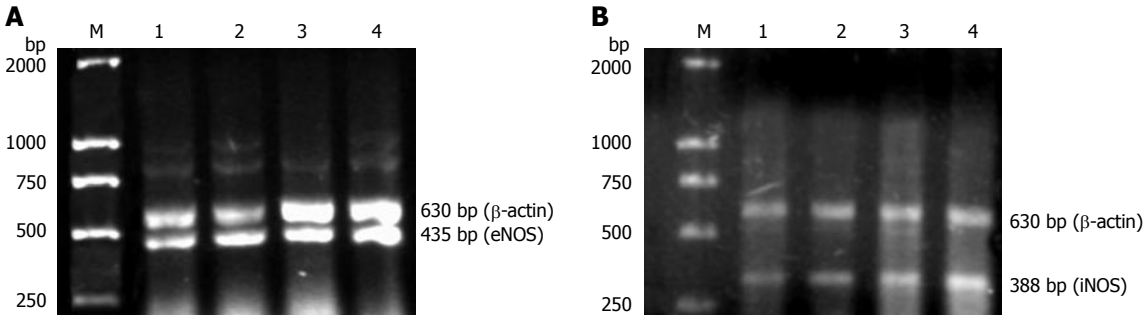

Figure 5 Expression of eNOS mRNA (**A**) and iNOS mRNA (**B**) in rat lung. M: DNA size marker; 1: control; 2: 4th wk group; 3: 6th wk group; 4: 8th wk group.

of eNOS, iNOS, HO-1, the number of capillaries, the histological changes characteristic of HPS in cirrhotic rats, demonstrating that the function of lung and liver is simultaneously deteriorated, both CO and NO are involved in pulmonary vascular abnormalities, pulmonary macrophages play a role in HPS of hepatic cirrhosis rats.

Whether the presence and severity of HPS are associated with the severity of underlying liver disease remains unclear. It was reported that HPS occurs more common in advanced cirrhosis[25-29]. HPS can also occur in acute[30] and chronic noncirrhotic hepatitis[31,32]. In patients with hypoxic hepatitis, intrapulmonary vasodilatation indicative of HPS frequently occurs and can be reversed

after normalization of hepatic dysfunction[33], indicating that HPS is interrelated with underlying liver disease. In contrast, other studies reported that HPS occurs both in extrahepatic portal venous obstruction[34] and in hepatic venous outflow obstruction without hepatic cirrhosis[35], suggesting that severe liver dysfunction and cirrhosis are not absolutely associated with the development of HPS. In the present study, the characteristic histological changes in both liver and lung during the development of HPS were observed in cirrhotic rats, indicating that there is a paralleling deterioration of lung and liver function, which supports our hypothesis that hepatic pathological alteration is a substantial basis for the development of HPS in cirrhotic rats.

Oxygenation of red blood cells occurs in the alveolar-capillary network where the pulmonary capillary bed and alveoli come together in the alveolar wall achieving optimal gas exchange. Because the diameter of pulmonary capillaries (about 6 μm) is slightly smaller than that of red blood cells (8 μm), red blood cells must flow through in a single file and change their shape as they pass through the pulmonary capillaries. This shape change ensures a minimal distance between oxygen in alveoli and hemoglobin in red cells. Passive changes in the diameters of pulmonary capillaries are caused by alterations in pre- and post-capillary resistance. Injection of micro-opaque gelatin into pulmonary arteries of autopsy specimens from patients with cirrhosis has documented the presence of pre-capillary pulmonary vascular dilatations and direct arteriovenous communications[36]. The resulting consequence is the distending of pulmonary capillaries with increased blood leading to incomplete penetration of oxygen through dilated vessels that abut upon alveoli and true anatomic shunts in which deoxygenated blood is directly shunted into arterial blood bypassing gas exchange units. Therefore, it is believed that hypoxemia occurs as a result of one (or the combination of several) of the following mechanisms: (1) ventilation-perfusion mismatching (reflecting excess perfusion for a given ventilation), (2) diffusion-perfusion impairment (due to an increased oxygen diffusion distance from alveoli to hemoglobin across the dilated vessels), and (3) true intrapulmonary anatomical shunts[37-42]. It was reported that vascular abnormalities in HPS are associated with the increased number of dilated pre-capillaries, capillaries and pre-capillary arteriovenous communications[43]. In experimental HPS, the increased number of pulmonary vascular capillaries can be observed under electron microscope[44], but no detailed analysis is available. Lung perfusion imaging with Tc99MAA can show broadened pulmonary capillaries in rats with HPS[20]. Furthermore, in the present study, a number of progressively increased pulmonary capillaries were found as cirrhosis progresses in rats, confirming the probability of remodeling, angiogenesis or vasculogenesis proposed by Gomez *et al*[9]. The increased number of pulmonary capillaries is positively correlated with both dynamically increased levels of LPS, TNF-α, and MDA in plasma, further demonstrating that LPS plays a central role in the development of HPS in cirrhotic rats[20]. The increased number of pulmonary capillaries is also positively correlated with dynamically increased ALT. Moreover, a clinical syndrome similar to HPS has been observed in congenital disorders without liver injury in which either hepatic venous blood flow does not reach the lung [45] or portal venous blood reaches the inferior vena cava without passing through the liver[46], indicating that factors either produced or metabolized in the liver can modulate the pulmonary vasculature and play a key role in maintaining the normal pulmonary vascular integrity. In addition, liver transplantation can reverse the ventilation-perfusion mismatch seen in HPS and restore normoxaemia[47]. These findings further support our notion that hepatic pathological alteration is a substantial basis for the development of HPS.

The role of NO in cirrhotic hyperdynamic circulation and induction of iNOS in endothelial cells by cytokines and endotoxin has been suggested as the mechanism[48], which soon appears as a very likely candidate for HPS[49]. However, the involvement of NOS isoform in increased NO production in the lung is controversial[50-53]. In the present study, the expression of eNOS and iNOS started to increase at the 4th wk and was closely related to the increased plasma LPS. Interestingly, the expression of iNOS not eNOS was significantly increased at the 6th wk compared to that at the 4th wk and the increased levels of nitric and nitrate in pulmonary homogenate exhibited a more significant linear correlation with iNOS than with eNOS, suggesting that iNOS may be more important in the development of HPS. In addition, a significantly increased quantity of macrophages in bronchoalveolar lavage fluid was observed during HPS in cirrhotic rats. These results demonstrate that the elevated NO results preferably from iNOS of pulmonary macrophages and, to a lesser extent, from eNOS in the lung of cirrhotic rats. Pulmonary macrophages may be a leading contributor to the development of HPS. Meanwhile, COHb in homogenate and HO-1 expression in the lung were increased over the 8 wk period of experiment. The increased COHb and HO-1 were positively correlated with the increased plasma LPS and TNF-α level. Since increased HO-1 expression in intravascular macrophages and carbon monoxide overproduction are also reported in a model of common bile duct ligation in rats[52], it would be interesting to investigate the interplay of NOS/NO pathway and HO-1/CO pathway in pulmonary vascular abnormalities in cirrhotic rats. For this purpose, L-NAME (a non-selective inhibitor of NOS), AG (a selective inhibitor of iNOS), or ZnPP (a selective inhibitor of HO-1) were administrated in cirrhotic rats. Interestingly, we observed a mutual inhibition, i.e., L-NAME or AG inhibited HO-1 expression, whereas ZnPP inhibited eNOS and iNOS expression. Histologically, AG inhibitor likely inhibited the enlargement of diameters of the dilated pulmonary capillaries at the 6th wk but there was no obvious change in the number of capillaries (data not show). Therefore, CO may be another important mediator in the development of HPS, HO-1/CO and NOS/NO pathways may be interrelated in pathogenesis of intrapulmonary vascular abnormalities in cirrhotic rats.

The underlying mechanisms are required to be further investigated.

Hypoxia is very important in inducing expression of the vascular endothelial growth factor (VEGF)[54], which specifically regulates endothelial cell growth and differentiation and also acts as a survival factor for endothelial cells[55]. It is generally believed that hypoxia is a consequence of intrapulmonary vascular dilatation in the presence of IETM. Since hypoxia induces NO generation[56-58] and NO induces expression of VEGF[59-62], it is conceivable that blood vessel remodeling and angiogenesis or vasculogenesis occurs during the development of HPS in cirrhotic rats. However, it is worth mentioning that CO may also be a contributing factor in regulating the expression of VEGF since CO levels are correlated with the number of capillaries.

In summary, IETM plays a central role in the development of HPS under conditions of hepatic cirrhosis[63,64]. Therefore, strategies against LPS should be made for preventing the development of HPS.

COMMENTS

Background

Hepatopulmonary syndrome (HPS) develops when arterial oxygenation deficiency occurs due to intrapulmonary vascular dilatation often associated with severe hepatic disease. Recent studies support that the presence of HPS significantly increases mortality in cirrhosis patients, particularly in those with decompensated liver disease. The pathogenesis of HPS remains to be elucidated. Some complications of cirrhosis, including hepatorenal syndrome, hepatic encephalopathy and HPS are closely associated with intestinal endotoxemia (IETM) in both experimental and clinical investigations. We further explored the pathogenesis of HPS on the basis of the preceding research in a cirrhotic rat model induced by multiple pathogenic factors.

Research frontiers

One of the characteristics of hepatopulmonary syndrome is intrapulmonary vascular dilation which severely affects pulmonary gas exchange leading to hypoxia and increased mortality of cirrhotic patients. The present study focused on clarifying the pathogenesis of HPS, particularly the mechanism of intrapulmonary vasodilation. Clinically, many studies have been performed on evaluating the prevalence, etiology, clinical features, early diagnosis, treatment and prognosis of this syndrome worldwide.

Innovations and breakthroughs

In this study, we further characterized the relation between severity of HPS and degree of hepatic dysfunction, and explored how IETM affects the development of HPS in cirrhotic rats. Our results indicate that the severity of HPS is directly associated with the level of blood LPS and progression of hepatic dysfunction, and IETM plays a central role in the development of HPS.

Applications

All of our findings in the present study further confirm that IETM plays a central role in the development of HPS under conditions of hepatic cirrhosis. Therefore, the strategy against LPS is certainly effective both in preventing the development of HPS and in its treatment.

Terminology

Angiogenesis: a natural process in the body that involves the growth of new blood vessels. It can occur in many diseases, such as coronary artery disease, peripheral artery disease and stroke when blood supply and oxygen are insufficient in tissues. It denotes the formation of new blood vessels from pre-existing ones. Vasculogenesis: the process of blood vessel formation occurring by a *de novo* production of endothelial cells. Microvasculature remodeling: alterations in a blood vessel network resulting from arteriogenesis and angiogenesis. Briefly, arteriogenesis is an increased arterial diameter while angiogenesis is an increased number of capillaries either by sprouting from or splitting existing capillaries. External events stimulate these two types of vessel growth through a combination of mechanical and chemical pathways.

Peer review

This manuscript is very interesting. The topic is original for a basic science study and the structure of material and methods is outstanding. Results are clearly explored and discussion widely covers the topic even for humans.

Abstract

AIM: To examine the mechanism of inactivation of the p16 gene in gallbladder cancer, and to investigate p16 alterations and their correlation with clinicopathological features.

METHODS: Specimens were collected surgically from 51 patients with gallbladder cancer. We evaluated the status of protein expression, loss of heterozygosity (LOH), homozygous deletion and promoter hypermethylation using immunohistochemistry, microsatellite analysis, quantitative real-time polymerase chain reaction (PCR) and methylation-specific PCR, respectively. In addition, mutations were examined by direct DNA sequencing.

RESULTS: Homozygous deletions of the p16 gene exon2, LOH at 9p21-22, p16 promoter hypermethylation, and loss of p16 protein expression were detected in 26.0% (13/50), 56.9% (29/51), 72.5% (37/51) and 62.7% (32/51), respectively. No mutations were found. LOH at 9p21 correlated with the loss of p16 protein expression ($P < 0.05$). Homozygous deletion of the p16 gene, a combination LOH and promoter hypermethylation, and multiple LOH at 9p21 were significantly correlated with the loss of p16 protein expression ($P < 0.05$). LOH at 9p21 and promoter hypermethylation of the p16 gene were detected in 15.4% (2/13) and 92.3% (12/13) of the tumors with homozygous deletion of the p16 gene, respectively. P16 alterations were not associated with clinicopathological features.

CONCLUSION: Our results suggest that LOH and homozygous deletion may be two distinct pathways in the inactivation of the p16 gene. Homozygous deletion, a combination of LOH and promoter hypermethylation, and multiple LOH are major mechanisms of p16 inactivation in gallbladder cancer.

Key words: Gallbladder cancer; Homozygous deletion; Loss of heterozygosity; p16; Quantitative real time PCR

INTRODUCTION

Gallbladder carcinoma is a highly malignant neoplasm with a poor prognosis, and most patients are diagnosed at an already advanced stage[1-3]. Gallbladder carcinoma is a relatively common cancer and is the sixth highest cause of cancer death in Japanese women.

Several genes have been implicated in the tumorigenesis of gallbladder cancers, including *K-ras*, cerbβ2, p53[4,5], $p16^{INK4a}$/CDKN2, and the fragile histidine triad (FHIT)[6]. Genetic alterations in the 9p21 chromosomal region have been linked to malignant progression.

The p16 gene, located on chromosome 9p21, encodes a critical negative regulator of cell cycle progression and is inactivated in various cancers. The p16 gene is an important tumor suppressor gene, which interacts strongly with cyclin-dependent kinases 4 and 6, and inhibits their ability to interact with cyclin D[7]. p16 induces cell cycle arrest at G1 and G2/M checkpoints, which blocks cells from phosphorylating retinoblastoma protein 1, and prevents cells from exiting the G1 phase of the cell cycle[8]. p16 can act as a negative regulator of normal cell proliferation. Inactivation of the p16 gene plays an important role in tumorigenesis. p16 inactivation by loss of heterozygosity (LOH) and point mutations has been reported in biliary tract cancers[9] and intrahepatic cholangiocarcinoma[10].

Aberrant promoter methylation is an important mechanism in silencing cancer-related genes during the process of carcinogenesis. Epigenetic inactivation of tumor suppressor genes has been commonly reported in various tumors[11]. Promoter hypermethylation, as

well as gene deletions and point mutations, has been shown to be a major mechanism of p16 inactivation[12,13]. Hypermethylation of the CpG islands of the p16 gene promoter region has been reported in various types of tumor.

The main modes of p16 gene inactivation in gallbladder carcinoma are known to include LOH, mutation and hypermethylation[12,14]. Homozygous deletion of the p16 gene has not previously been investigated in gallbladder cancer. Therefore, we sought to comprehensively study genetic and epigenetic alterations of p16, including homozygous deletion of the p16 gene, and the relationship between these abnormalities and clinicopathological features.

MATERIALS AND METHODS

Tissue specimens

Paraffin-embedded tissue samples were obtained from 51 patients who underwent surgical resection at Juntendo University School of Medicine, Japan, between April 1996 and April 2005. Gallbladder carcinoma patients consisted of 25 women and 26 men, ranging in age from 36 to 94 (mean, 65.1) years. Their tumors consisted of 46 adenocarcinomas and five adenosquamous carcinomas. The adenocarcinomas included 39 well-to-moderately differentiated and seven poorly differentiated tumors. Most of the patients had advanced gallbladder carcinoma, with invasion of the subserosa (n = 22, 43.1%) and serosa (n = 18, 35.3%), while the other 11 patients (19.6%) had early gallbladder carcinoma (mucosa or muscularis propria invasion). All histological slides were reviewed by M.T. and H.T. and were classified based on the WHO classification of gallbladder carcinoma. Medical records were available for all patients.

Immunohistochemical analysis

Immunohistochemistry was performed using anti-p16 (F-12; 1:500 dilution; Santa Cruz Biochemistry, Santa Cruz, CA, USA) and an automated slide staining system (NexES IHC; Ventana, AZ, USA), according to the manufacturer's instructions. P16 immunostaining was performed within 2 weeks of sectioning, because reactivity decreased over time after preparation. Normal lymphocytes and intrahepatic bile ducts were positive controls for p16. The percentage of positive nuclei was scored as follows: -, 0%-10%, + 1%-25%, ++, 25%-50%, and +++, > 50% positive cells. Scores of +, ++ and +++ were considered to represent positive immunostaining, while - was deemed to be negative.

DNA extraction

Formalin-fixed, paraffin-embedded tissue blocks were used. Serial 10-μm sections were cut from each block and stained with hematoxylin and eosin to locate the tumor and non-neoplastic tissue before DNA extraction. Sections were cut, deparaffinized, and microdissected with an 18-gauge needle. The microdissected tissues were digested overnight at 55℃ in buffer (1% Tween 20, 10 mmol/L Tris-HCl, pH 8, 1 mmol/L EDTA, and 100 μg/mL proteinase K). The lysates were heated at 95℃ for 10 min and stored at 4℃ until analyzed by polymerase chain reaction (PCR).

Methylation assay

DNA methylation was investigated using an EZ DNA methylation kit (Zymo Research, CA, USA), according to the manufacturer's protocol. Microdissected genomic DNA (1 ng) was denatured with M-dilution buffer at 37℃ for 15 min, followed by incubation with CT conversion reagent at 50℃ for 16 h in the dark. After treatment, the DNA was purified using M-binding buffer, incubated with M-desulphonation buffer at room temperature for 15 min, washed with wash buffer, and finally resuspended in M-elution buffer.

Primers for the p16 gene were 5'-TTATTAGAGGG TGGGGTGGATTGT-3' (sense) and 5'-CCACCTAAAT CAACCTCCAACCA-3' (antisense) for the unmethylated reactions, and 5'-TTATTAGAGGGTGGGGCGGATCG C-3' (sense) and 5'-GACCCCGAACCGCGACCGTAA-3' (antisense) for the methylated reactions, as described previously[15]. PCR reactions were started by denaturation at 95℃ for 5 min, followed by 40-45 cycles of 94℃ for 30 s, 65℃ (for methylated p16) or 60℃ (for unmethylated p16) for 45 s, and 72℃ for 60 s, with a final extension at 72℃ for 10 min. PCR products were analyzed by electrophoresis on a 3% agarose gel, and visualized by ethidium bromide staining. DNA from the Raji cell line was used as a positive control. Distilled water was used as a negative control.

LOH analysis

Paired normal and tumor DNA samples were amplified by hot-start PCR, using locus-specific flanking primer pairs for five fluorescently labeled microsatellite markers, D9S171-FAM, D9S1748-FAM, D9S942-NEX, D9S974-NED, and D9S1749-NED (Figure 1). Primer sequences were obtained from the NCBI UniSTS database (http://www.ncbi.nlm.nih.gov/). Markers mapping to the chromosome 9p21-22 region were used. D9S1748, D9S942 and D9S974 are within a coding sequence of the p16 gene. D9S1749 is telomeric to p16 and D9S171 is centromeric to p16. PCR was performed with an initial denaturation at 95℃ for 15 min, followed by 36 cycles of denaturation at 95℃ for 30 s, annealing at 58℃ (D9S171, D9S1748, D9S942, D9S974) or 55℃ (D9S1749) for 45 s, and extension at 72℃ for 60 s, and final extension at 72℃ for 10 min. After PCR, samples were diluted at 1:7 in formamide, heated to 95℃ for 2 min, chilled on ice, and analyzed with Genescan software on an ABI PRISM 310 genetic analyzer (PE-Applied Biosystems, Foster City, CA, USA). Allelic ratios in both normal and tumor samples were calculated and compared. The area under each peak, representing each allele in the microsatellite pair, was obtained. LOH was defined as a > 50% reduction in the tumor peak compared to that of the corresponding normal tissue. Additional bands that were not seen on normal DNA, but were observed in tumor samples, were considered evidence of microsatellite instability (MSI).

Detection of homozygous deletion of p16 exon2

Homozygous gene deletion and gene dosage of p16 exon2

in gallbladder cancer were determined using a TaqMan-based real-time PCR method. Briefly, p16 gene exon2 and the GAPDH gene were amplified in a monoplex assay. The primer sequences for detecting p16 exon2 were 5'-AGCTTCCTTTCCGTCATGC-3' (sensze) and 5'-TCATGACCTGCCAGAGAGAA-3' (antisense). The primer sequences for detecting the GAPDH gene were 5'-GCATCCTGGGCTACACTGAG-3' (sense) and 5'-AG GTGGAGGAGTGGGTGTC-3' (antisense). The probe sequence for p16 gene exon2 was FAM-TGGCTCTG, and the probe sequence for the GAPDH gene was FAM-CTCCTCTG (the three FAM-labeled probes were manufactured by Roche Applied Science, Mannheim, Germany). The real-time PCR was performed in a 25 μL final volume containing 12.5 μL of Premix Ex Taq (Perfect Real Time; Takara, Kyoto, Japan), 50 ng DNA template, 10 μmol/L of each primer, 10 μmol/L Universal Library Probe, 0.5 μL ROX reference dye (50 ×), and 5.75 μL distilled water. The thermal cycling conditions on the ABI PRISM 7500 instrument were set to 10 s at 95℃, followed by 40 cycles of 5 s at 95℃, alternating with 34 s at 60℃. DNA from lymphocytes isolated from a paraffin block was used as a positive control. All reactions were done in triplicate. Normalized gene dosage ratios were interpreted as follows: 0-0.3, homozygous deletion; 0.31-0.69, under-representation (of the test gene, relative to the reference gene); 0.7-1.49, retention of copy number; and > 1.5 over-representation.

Table 1 The primer sequence of the p16 genes

Exon	Primer sequence	Size (bp)	Anneling temperature (℃)
Exon1α	F: 5'-GAGAGGGGGAGAGCAGGCAG-3' R: 5'-GCAAACTTCGTCCTCCAGAGT-3'	250	58
Exon2-1	F: 5'-AGCTTCCTTTCCGTCATGC-3' R: 5'-GCAGCACCACCAGCGTG-3'	203	56
Exon2-2	F: 5'-AGCCCAACTGCGCCGAC-3' R: 5'-CCAGGTCCACGGGCAGA-3'	147	58
Exon2-3	F: 5'-TGGACGTGCGCGATGC-3' R: 5'-GGAAGCTCTCAGGGTACAAATT C-3'	189	56
Exon3	F: 5'-CCGGTAGGGACGGCAAGAGA-3' R: 5'-CTGTAGGACCCTCGGTGACTGAT GA-3'	169	58

Mutation analysis

Mutation analysis was performed for the p16 gene (exons 1α, 2 and 3). Primer sequences and PCR conditions were as described previously[16,17] (Table 1). Amplification was performed using a Perkin Elmer GeneAmp 9600 Thermal cycler. After visualizing the PCR products in a 3% agarose gel, an aliquot (5 μL) of the PCR product was treated at 37℃ for 15 min with 1 μL ExoSAP-IT (GE Healthcare Biosciences, Piscataway, NJ, USA), followed by inactivation at 80℃ for 15 min. Part of this mix (6 μL) was directly sequenced using a BigDye Terminator v1.1 Cycle Sequencing kit (Applied Biosystems Japan, Chiba) on an automated sequencer (ABI PRISM 3100 Genetic analyzer; Perkin-Elmer, Japan).

Statistical analysis

Frequency distributions were analyzed by the χ^2 test. Correlations were examined between alterations of p16 and p16 expression, or between alterations of p16 and clinicopathological parameters. $P < 0.05$ was deemed statistically significant.

RESULTS

Immunohistochemical analysis

Loss of p16 protein expression occurred in 62.7% (32/51) of gallbladder cancer patients. Staining for p16 was weak in 13.7% (7/51) of patients, moderate in 17.6% (9/51), and strong in only 9.8% (5/51) of patients (Figure 1). There was no significant difference in p16 protein expression according to patient age, gender, tumor stage, T factor, N factor or histology (Table 2).

p16 status

LOH at 9p21-22 was detected in at least one marker in 56.9% (29/51) of patients. LOH occurred in 11.8%, 27.5%, 11.8%, 13.7% and 39.2% of patients who were positive for the markers D9S171, D9S1748, D9S942, D9S974 and D9S1749, respectively. Approximately 29.4% of the cases presented with LOH in a single marker, 11.8% with LOH in two markers, and 15.7% with LOH in three or more markers. LOH at the three markers D9S1748,

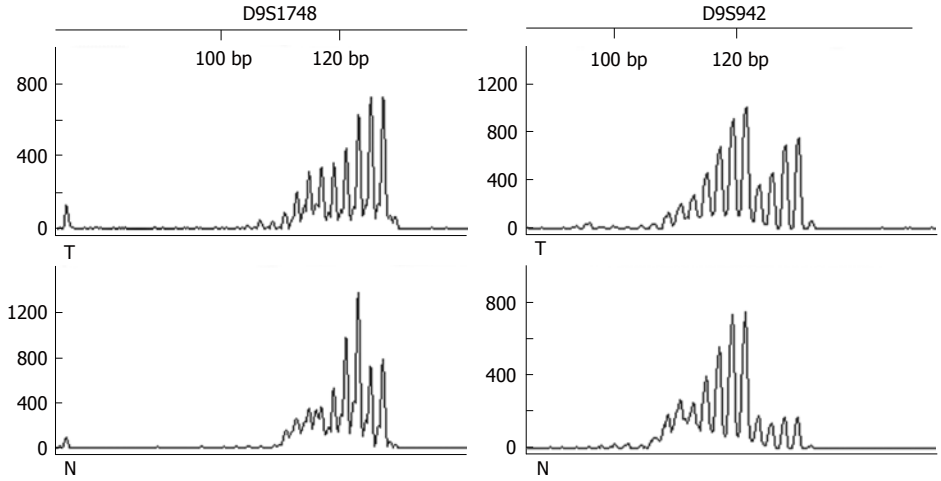

Figure 2 Representative example of the results of microsatellite analysis showing LOH at D9S1748 and LOH at D9S942 (right, case 25; left, case 45). The scales on the top and left side of each figure represent the size (bp) and the intensity, respectively. N: Normal; T: Tumor.

D9S942 and D9S974 within a coding sequence of the p16 gene was 37.3% in total. Representative examples of LOH at D9S942 and D91748 are shown in Figure 2.

Gene dosage of p16 exon 2 was successfully measured in 50 of 51 cases. Homozygous deletion of p16 exon2 was detected in 13 of 50 (26%) tumors. Overall the p16 gene was altered by homozygous deletion and LOH in 56.9% (29/51) of the tumors, indicating that alterations at this locus are involved in the vast majority of the tumors. In our analysis, LOH at 9p21-22 and homozygous deletion of p16 exon 2 were not associated with demographic variables such as age, gender, tumor histology and stage, T factor or N factor (Table 2).

p16 methylation status

Hypermethylation of the p16 gene was observed in 72.5% (37/51) of the patients (Figure 3). The relationship between p16 hypermethylation and various clinicopathological features was analyzed statistically. There was no significant correlation with the clinicopathological parameters assessed, including age, gender, tumor stage, T factor or N factor (Table 2). P16 methylation was found in 37 of 51 gallbladder cancer patients (72.5%), and loss of p16 protein expression was detected in 20 of the 37 tumors (54.1%) showing p16 hypermethylation. Our data showed that P16 protein expression was not significantly correlated with p16 hypermethylation.

p16 mutations

In tumors without homozygous deletions, exons 1α, 2 and 3 were amplified. In five cases, which were non-informative for the markers investigated, constitutive DNA was not available. No mutations were detected in exons 1α, 2 or 3.

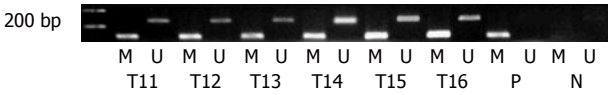

Figure 3 Methylation status of the $p16^{INK4a}$ gene by methylation-specific PCR. PCR products amplified by unmethylated (U) and methylated (M) specific primers. P: Positive control; N: Negative control. Methyaltion band is at 150 bp and unmethylated band is at 234 bp.

Table 3 Association between p16 protein expression and 9p21-22

Association between p16 protein expression and alterations of p16

We investigated the association between p16 protein expression and P16 alterations. LOH at 9p21-22 was not associated with the loss of p16 expression. However, LOH at three genes (D9S1748, D9S942 and D9S974) within a coding sequence of p16 was correlated with the loss of p16 expression ($P < 0.05$) (Tables 3 and 4). Furthermore, homozygous deletion of the p16 gene, a combination of LOH at 9p21 and promoter hypermethylation of the p16 gene, multiple LOH at 9p21 correlated with the loss of p16 protein expression ($P < 0.05$) (Table 5). Loss of p16 protein expression was detected in nine of 13 tumors with homozygous deletion. LOH at 9p21 was detected in only two of 13 cases with homozygous deletion, while promoter hypermethylation of the p16 gene was detected in 12 of 13 cases with homozygous deletion.

DISCUSSION

We examined the mechanisms of p16 inactivation and the relationship between p16 alterations and clinicopathological features in gallbladder cancer. p16 alterations have been evaluated individually in previous studies, but our study is believed to be the first attempt to evaluate homozygous deletion of the p16 gene. We sought to carry out a comprehensive study of p16 gene status, investigating gene dosage, allelic status, hypermethylation, mutation, protein expression, and clinicopathological features in gallbladder cancer.

Loss of p16 protein expression has been examined in various types of cancer, including gallbladder cancer. We examined p16 protein expression by immunohistochemistry in 51 cases of gallbladder cancer. Loss of p16 protein expression has been reported to range between 24 and 76% in gallbladder cancer[14,18-20,23]. In our study, the loss of p16 expression was detected in 32 of 51 (62.7%) patients with gallbladder cancer. In addition, the loss of p16 expression has been correlated with tumor progression or with decreased survival among patients with carcinoma of the lung, pancreas and esophagus, and malignant melanoma[21,22,24]. The correlation between p16 expression and clinicopathological factors is controversial. Ma *et al*[15] have reported that decreased expression of p16 is correlated with pathological grade and tumor progression in gallbladder carcinoma. However, Shi *et al*[16] have reported that loss of p16 protein expression is not significantly associated with any clinicopathological factors or survival. Quan *et al*[20] have reported that the loss of p16 expression is not associated with pathological grade. We also failed to find any association between the loss of p16 expression and clinicopathological parameters.

The mechanisms of inactivation of the p16 gene are homozygous deletion, LOH, promoter hypermethylation, rearrangement, and intragenic mutation.

Homozygous deletions are important for complete inactivation of tumor suppressor genes[13]. Previous investigators have evaluated homozygous deletion of the p16 gene in a small series of biliary tract and gallbladder cancer cell lines. Ku *et al*[25] have reported that homozygous deletion of the p16 gene was detected in three of six (50%) gallbladder cell lines. Yoshida *et al*[9] have reported that homozygous deletion of the p16 gene was detected in one of two gallbladder cell lines and in two biliary tract cell lines. Caca *et al*[26] have reported that homozygous deletion of the p16 gene was detected in eight of nine (88.8%) biliary tract cell lines, but homozygous deletion of the p16 gene was not detected in 21 biliary tract cancers. Homozygous deletion of the p16 gene has not previously been examined in gallbladder cancer. Our study is believed to be the first report to evaluate homozygous deletion of the p16 gene. We employed quantitative real-time PCR to evaluate homozygous deletion. In our series, homozygous deletion of the p16 gene was detected in 13 of 50

cases (26%). Previous studies have demonstrated that homozygous deletion of tumor suppressor genes plays an important role in the development and progression of some malignancies. However, in our series, homozygous deletion of the p16 gene was not associated with clinicopathological features.

Loss of p16 expression is correlated with homozygous deletion of the p16 gene in gallbladder cancer and other malignancies. Eight of nine biliary tract cell lines with homozygous deletion of the p16 gene showed loss of p16 expression, as reported by Caca *et al*[26]. In our series, loss of p16 expression correlated with homozygous deletion of the p16 gene in nine of 13 tumors. In four cases, homozygous deletion of the p16 gene did not correlate with p16 protein expression. Four tumors with homozygous deletion of the p16 gene displayed moderate to strong positive staining in immunohistochemistry. These tumors showed diffuse positive staining in some areas and partial or complete loss of p16 staining in other areas. The areas which showed loss of p16 expression were not captured during microdissection, and consequently the tumors were scored as having homozygous deletion. Previous reports have shown that the loss of p16 protein expression does not always correlate with homozygous deletion of the p16 gene[27,28].

Promoter hypermethylation of p16 leads to inactivation of the gene in various cancers. In gallbladder cancer, the frequency of p16 promoter hypermethylation ranges from 24% to 56%[12,29-31]. In our study, p16 hypermethylation was found in 72.5% (37/51) of the tumors. The frequency in our study was comparatively higher than that in previous studies. Previous studies have revealed that the frequency of p16 promoter hypermethylation is not associated with tumor progression and clinicopathological characteristics[30,31]. Similarly, we found that p16 hypermethylation was not associated with any clinicopathological features. Some investigators have demonstrated that p16 hypermethylation is correlated with the loss of p16 expression in intraductal carcinoma of the liver, lung cancer, hepatocellular carcinoma and esophageal cancer[32-35]. In the present study, 20 of 30 (66.6%) cases with p16 promoter hypermethylation showed a loss of p16 expression. However, there was no correlation between promoter hypermethylation and the loss of p16 expression.

We failed to detect any p16 mutations in the present study. Previous studies have shown a frequency of p16 mutation of 0%-80% in gallbladder and biliary tract cancer and cell lines[9,12,14,25]. Ueki *et al* have reported that 13 of 53 (24.5%) cases of gallbladder cancer showed non-silent p16 gene mutations. Kim *et al* have reported that p16 mutations were detected in four of 13 (30.7%) patients with gallbladder cancer. Yoshida *et al* have reported that eight of 10 cases of gallbladder cancer showed p16 point mutations. These studies did not examine homozygous deletion of the p16 gene. Ku *et al* have reported that homozygous deletion of the p16 gene was found in three of six biliary tract cell lines, but no p16 mutation was found in the remaining three biliary tract cell lines, which did not show homozygous deletion. Caca *et al*[26] have reported that p16 mutations were not found in three biliary tract cell lines and 21 biliary tract cancers, which did not show homozygous deletion of the p16 gene. In the present study, a p16 mutation was not found in any of the cases analyzed. These results suggest that the p16 mutation is associated with homozygous deletion of the p16 gene.

LOH at 9p21 has been detected in different types of tumors and cell lines[36,37]. The frequency of LOH at 9p21 in gallbladder carcinoma ranges from 38 to 60%[5,38,39]. Previous studies have demonstrated that LOH at 9p21 correlates with the loss of p16 expression in various types of cancer[22,40]. We also investigated the association between p16 protein expression and LOH at 9p21-22 in gallbladder cancer. Although an association between LOH at 9p21-22 and p16 protein expression was not found in our study, LOH at three genes (D9S1748, D9S942 and D9S974) which are located within a coding sequence of p16, correlated with loss of p16 protein expression. The mode of p16 silencing may be explained by a modification of Knudson's two-hit model[41]. In cases which show the loss of p16 protein expression, LOH or promoter hypermethylation may have occurred in only one allele, and other mechanisms may also have been involved in other alleles.

In conclusion, we investigated comprehensively the mechanisms of inactivation of the p16 gene in gallbladder cancer, and the association between p16 alterations and clinicopathologic features. Although the mutation of p16 is a rare event in gallbladder cancer, homozygous deletion, LOH and promoter hypermethylation were frequent events. LOH at 9p21 correlated with loss of p16 protein expression. In addition, homozygous deletion of the p16 gene, combination of LOH and promoter hypermethylation, and multiple LOH at 9p21 significantly correlated with loss of p16 protein expression ($P < 0.05$). LOH at 9p21 was detected in only two of 13 cases with homozygous deletion, while promoter hypermethylation of the p16 gene was detected in 12 of 13 cases with homozygous deletion. Promoter hypermethylation of the p16 gene may have occurred as an earlier event, followed by homozygous deletion as a later event in cases of homozygous deletion. LOH and homozygous deletion may be two distinct pathways for inactivating the p16 gene in gallbladder cancer.

Our results suggest that multiple alterations of the p16 gene imply multiple mechanisms for the inactivation of the p16 gene in gallbladder cancer. The mechanisms may be important for the diagnosis and treatment of this disease.

Abstract

AIM: To assess the importance of preoperative diagnosis and presentation of left-sided gallbladder using ultrasound (US), CT and angiography.

METHODS: Retrospective review of 1482 patients who underwent enhanced CT scanning was performed. Left-sided gallbladder was diagnosed if a right-sided ligamentum teres was present. The image presentations on US, CT and angiography were also reviewed.

RESULTS: Left-sided gallbladder was diagnosed in nine patients. The associated abnormalities on CT imaging included portal vein anomalies, absence of umbilical portion of the portal vein in the left lobe of the liver, club-shaped portal vein in the right lobe of the liver, and difficulty in identifying segment Ⅳ. Angiography in six of nine patients demonstrated abnormal portal venous system (trifurcation type in four of six patients). The main hepatic arteries followed the portal veins in all six patients. The segment Ⅳ artery was identified in four of six patients using angiography, although segment Ⅳ was difficult to define on CT imaging. Hepatectomy was performed in three patients with concomitant liver tumor and the diagnosis of left-sided gallbladder was confirmed intraoperatively.

CONCLUSION: Left-sided gallbladder is an important clinical entity in hepatectomy due to its associated portal venous and biliary anomalies. It should be considered in US, CT and angiography images that demonstrate no definite segment Ⅳ, absence of umbilical portion of the portal vein in the left lobe, and club-shaped right anterior portal vein.

Key words: Left-sided gallbladder; Angiography; Computed tomography; Ultrasound

INTRODUCTION

Left-sided gallbladder is defined as a gallbladder located to the left side of the ligamentum teres. This anomaly can be divided into three anatomic abnormalities: a situs inversus, an ectopic left-sided gallbladder, and a right-sided ligamentum teres[1-4]. Left-sided gallbladder with right-sided ligamentum teres has been a rare anomaly since Hochstetter's first description in 1886. Its characteristic description is a "gallbladder lying over the left side of the ligamentum teres"[1,4,5]. The associated anomalies with left-sided gallbladder include portal vein anomalies, biliary system anomalies, and segment Ⅳ atrophy[5-9]. The complex anomalies associated with left-sided gallbladder are important during hepatectomy, particularly in living donor liver transplantation. Preoperative survey of the anomalies of the portal triad is important in minimizing the incidence of postoperative biliary and vascular complications. Unknowingly, ligation of the left branch of the portal vein and bile duct that contribute to three-quarters of the liver hemodynamics will cause hepatic failure, biliary congestion and leakage[7,8,10-12]. This series reports nine cases of left-sided gallbladder with right-sided ligamentum teres. Its associated anomalies and significance during hepatectomy are identified and discussed.

MATERIALS AND METHODS

We reviewed 1528 enhanced CT scans performed

Table 1 Patient profiles and imaging results

Patient number	Clinical status and history	Club-shaped form portal vein (ultrasound finding[1])	Left lateral segment of liver (computed tomography finding[2])	Segment Ⅳ artery (angiogram finding)	Portal vein configuration (angio-portogram finding)
1	HCV, HCC, right hepatectomy	Over right lobe liver	Hypertrophic	From RHA	Trifurcation type
2	HCC, HBV and HCV	Not clear	Normal size	Not obvious	Other type
3	Right lobe HCC	Over right lobe liver	Mild hypertrophic	From RHA	Trifurcation type
4	Right lobe HCC, HBV	Over right lobe liver	Normal size	> From RHA	Trifurcation type
5	Hysterectomy, abdominal pain	Not clear	Normal size	NA	Not available
6	Liver tumor, HBV	Not clear	Mild hypertrophic	NA	Not available
7	Multiple HCC	Over right lobe liver	Normal size	NA	Not available
8	HCC, left lateral partial segmentectomy	Not clear	Normal size	From LHA	Trifurcation type
9	HCC, left lateral segmentectomy	NA	Normal size	Not obvious	Other type

[1]No umbilical portion over left lobe liver in all patients whose US results were available; [2]Club-shaped form portal vein over right side of the liver, no umbilical portion over left lobe of the liver. No defined segment Ⅳ in any patients. HBV: Hepatitis B carrier; HCV: Hepatitis C carrier; NA: Not available; RHA: Right hepatic artery.

for survey of liver tumors, other abdominal tumors, retroperitoneal tumors and abdominal pain at Chang Gung Memorial Hospital, Kaohsiung, Taiwan from 1999 to 2004. Forty-six patients were excluded because the gallbladder position or fossa could not be determined from previous hepatectomy or cholecystectomy. Of the remaining 1482 patients, nine were diagnosed to have left-sided gallbladder due to the presence of a right-sided ligament teres on enhanced CT. Among these patients, one underwent right hepatectomy and cholecystectomy for segment Ⅳ hepatocellular carcinoma (HCC). The other two patients underwent left lateral segmentectomy and partial hepatectomy for left lateral segment HCC, respectively.

RESULTS

Nine patients from a screening population of 1482 patients (0.6%) were diagnosed with left-sided gallbladder with enhanced CT. Ultrasound (US) was performed in eight of the nine patients, and angiography was done because of liver tumors in six patients. The clinical status and imaging findings are listed in Table 1. US demonstrated no umbilical portion of the portal vein over the left lobe of the liver in eight patients, of whom, four had an abnormal club-shaped portal vein over the right side of the liver (Figure 1A), whereas the other four patients did not clearly show a dilated portion of the portal vein on the right side of the liver. Enhanced CT demonstrated absence of the umbilical portion of the portal vein over the left lobe of the liver, and an abnormal umbilical portion of the portal vein over the right lobe of the liver, as in the US findings. Segment Ⅳ of the liver was difficult to define on CT imaging in all nine patients (Figure 1B). Angiography was performed in six of the nine patients. In four patients, the portal veins ramified to the right and left portal tributaries, and the left tributary of the portal vein diverged into lateral and medial portions. The medial portion veered to the ventral side and formed the umbilical portion, which finally joined the ligamentum teres (trifurcation type) (Figure 1C). The other two patients had the portal veins ramified to the right, and small left portal tributaries. In these patients, the right portal vein formed the umbilical portion with some tributaries, and finally joined the ligamentum teres. The type of portal vein ramification could not be defined from conventional descriptions in these two patients (Figure 2). The main hepatic arteries ran alongside with the main portal venous tributaries in all six patients, of whom four had well-defined segment Ⅳ artery (Figure 3). One patient underwent right hepatectomy and cholecystectomy due to HCC over the right lobe of the liver. Another two patients receive left lateral segmentectomy. In these cases, the left-sided gallbladder was well-demonstrated intraoperatively (Figure 1D).

DISCUSSION

Left-sided gallbladder with right-sided ligamentum teres is rarely reported. However, with advances in diagnostic imaging modalities, such as US, CT, MRI and angiography, left-sided gallbladder is increasingly being reported to be associated with right-sided ligamentum teres, accompanied by abnormal intrahepatic portal venous branching. An initial impression of left-sided gallbladder is made when the ligamentum teres is deviated to the right side, and a right-sided umbilical portion of the portal vein is present with difficulty in defining segment Ⅳ anatomy[5,6,8]. Our survey of nine cases is the largest report to date, and revealed an incidence of 0.6% of this anomaly, which is consistent with the previously reported incidence of 0.1%-1.2%[5,7,8,13,14].

There are several explanations for the development of left-sided gallbladder without situs inversus. First, the normal gallbladder bud may migrate to the left lobe instead of the right, and lies on the left side of the ligamentum teres[15]. In this situation, the portal vein, biliary tree and hepatic artery should be in the normal location and classified into ectopic gallbladder. Second, the gallbladder may develop directly from the left hepatic duct, and is accompanied by failure in development of the normal structure on the right side[7,15]. Our literature review

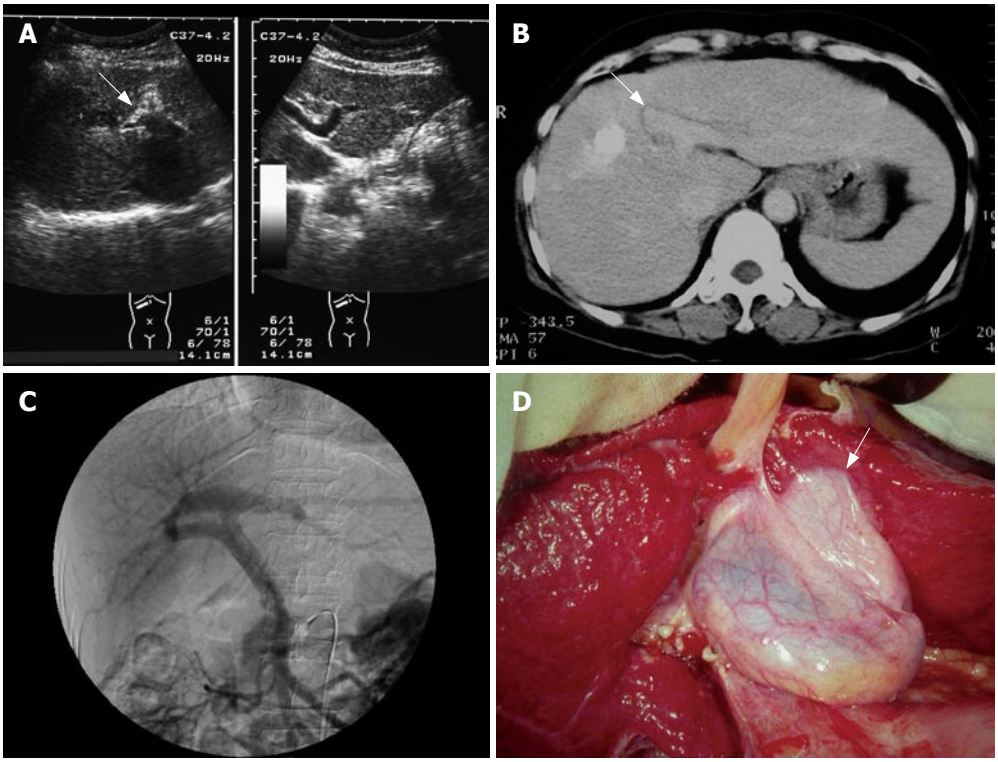

Figure 1 A 50-year-old woman with chronic hepatitis C. Right trisegmentectomy and cholecy-stectomy were performed due to the right lobe liver tumor. **A**: US demonstrated a club-shaped portal vein (arrow) over the right lobe of the liver and no umbilical portion over the left lobe of the liver; **B**: Enhanced CT demonstrated enlarged left lateral segment and a club-shaped portal vein (arrow) over the right side of the liver; **C**: Angiography demonstrated trifurcation type of the portal vein; **D**: Intraoperative photography demonstrated gallbladder over left side of ligamentum teres and adhesions on the left lateral segment (arrow).

Figure 2 A 55-year-old man with HCC, chronic hepatitis B and C. Angio-portography demonstrated bifurcation with a small branch of the left portal vein (black arrow), segmental Ⅳ branch of the portal vein (white arrow), and a club-shaped form of the right portal vein with many branches.

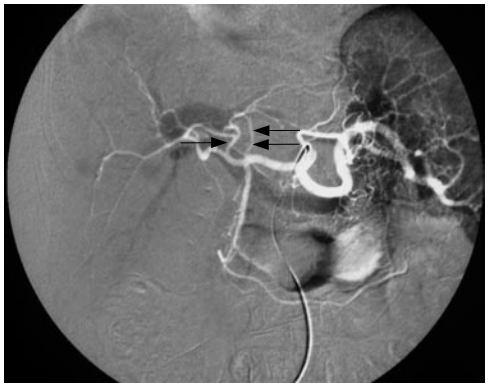

Figure 3 A 59-year-old woman with HCC in the segment Ⅵ of the liver and chronic hepatitis C. Angio-portography with substrate on arterial phase. The hepatic arteries (white vessels) followed the portal veins (black vessels). The segmental Ⅳ artery (arrow) was demonstrated. Right anterior side liver parenchyma was supplied from the segmental Ⅳ artery. The left hepatic artery (double arrows) originated from the common hepatic artery near the orifice of the gastroduodenal artery.

showed[5-7,11,15,16] only one case of left-sided gallbladder in which the cystic duct originated from the left hepatic duct[16]. The proposal of left-sided gallbladder development due to a second gallbladder originating directly from the left hepatic duct was not favored in those cases. Third, the left umbilical vein disappears and right umbilical vein partly remains. The peripheral (or placental) and central portions of the latter develop into the ligamentum teres and ligamentum venosum, respectively (Matsumoto's hypothesis)[13,17]. According to this hypothesis, the right umbilical portion should lie to the right of the gallbladder bed, but the gallbladder bed lay astride the ligamentum teres, as reported in four previous cases[7,18]. Nevertheless, this explanation also does not fit with our cases. Fourth, the gallbladder is on the left side of the ligamentum teres simply because the latter deviated to the right[5,7,16]. Maetini *et al*[7] have stated that there are three types of portal vein anomalies with the umbilical portion supplying the right anterior portion. In type A, the umbilical portion is to the right of the Cantlie line, whereas the umbilical portion lies on and to the left of the Cantlie line in types B and type C, respectively (Figure 4). They have also found that in the cases of left-sided gallbladder, the right posterior segmental duct joins the common duct distal to the bifurcation, and the aberrant right anterior segmental duct lies in the groove for the ligamentum teres, at which it forms a reverse U-shaped segment similar to the portal vein (Figure 5). They believe that the gallbladder on the left side of the ligamentum teres is there simply because the latter deviated to the right. As the right lobe of the liver becomes atrophied, we propose that the ligamentum teres moves from the left (type C) to the right (type A).

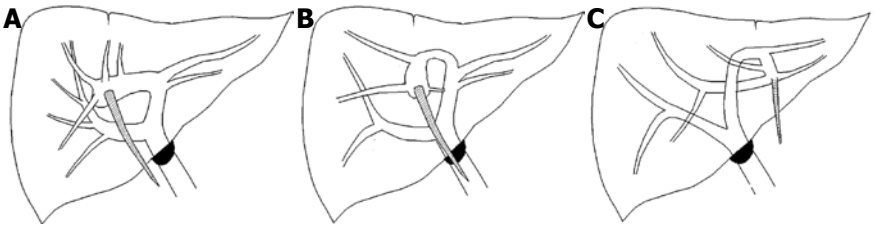

Figure 4 Maetini *et al* have described three types of portal vein anomalies with the umbilical portion supplying the right anterior portion. In type **A**, the umbilical portion is over the right side of the Cantlie line. In type **B**, the umbilical portion lies on the Cantlie line. In type **C**, the umbilical portion arises from the left portal vein with anterior segmental branches. As the ligamentum teres moves from the type C to the type A, the gallbladder moves to the left of the ligamentum teres.

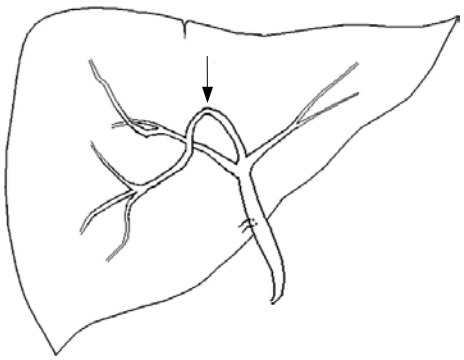

Figure 5 The right anterior segmental bile duct ran downward and ventrally formed a reverse U-shape (arrow), which followed the right anterior portal vein and lay in the groove for the ligamentum teres in left-sided gallbladder. Maetani *et al* believe that the gallbladder on the left side of the ligamentum teres is simply because the latter deviated to the right.

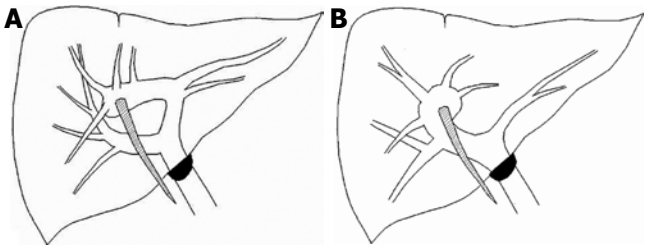

Figure 6 **A**: The trifurcation type of portal vein anomaly in a left-sided gallbladder; **B**: Bifurcation type of portal vein anomaly in a left-sided gallbladder. The abnormal intrahepatic portal venous branches could not be determined into these two types was divided into the other type.

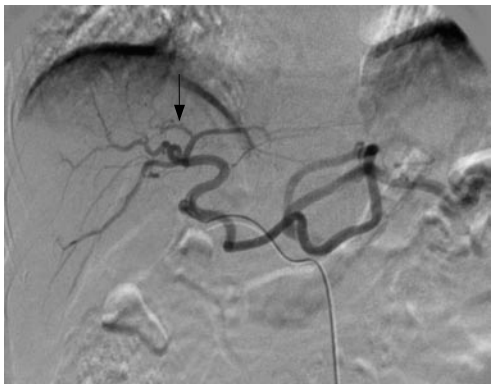

Figure 7 A 64-year-old man with HCC. The segmental Ⅳ artery (arrow) from the left hepatic artery is demonstrated.

The gallbladder moves to the left of the ligamentum teres, and the umbilical portion occupies the right side of liver.

Left-sided gallbladders have previously been reported to be associated with portal vein anomalies, biliary system anomalies, and segment Ⅳ atrophy. The associated portal vein anomalies are significant in hepatectomy, split liver transplantation, or living donor liver hepatectomy in transplantation, and can be classified into three types: the trifurcation type, bifurcation type and the other type, in which portal vein ramification cannot be defined from conventional descriptions (Figure 6)[5,19]. Intrahepatic arteries in left-sided gallbladders have not previously been described in detail[2,5]. In principle, the hepatic arteries follow the portal venous tributaries but the hepatic arterial variations and dissociation between the intrahepatic bile duct and portal vein have been reported[5,11,20,21]. In our six patients, in general, the hepatic arteries followed the portal venous tributaries (Figure 3). Angiography demonstrated the segment Ⅳ hepatic artery (Figures 3 and 7) in four of six patients, although segment Ⅳ was difficult to define on CT imaging. Segment Ⅳ atrophy is unlikely and we believe that the segment is embedded in the right lobe of the liver, and the true right lobe of the liver is relatively hypoplastic. Hypoplasia of the right lobe of the liver contributes to the ligamentum teres and umbilical portion being deviated to the right and therefore, causing a left-sided gallbladder. The dividing line between segment Ⅳ and the right lobe of the liver was not visualized, while segment Ⅳ was embedded in the right lobe of the liver. Although biliary tree anatomy was not evaluated in our patients, the bile duct and arterial branches appear to follow the portal venous tributaries of left-sided gallbladders[5,7,8,11]. If segment Ⅳ is embedded in the right lobe of the liver, the segment Ⅳ bile duct originated from left main intrahepatic duct ran downward and ventrally formed a reverse U-shaped right anterior segmental bile duct because of the intrahepatic duct following the portal vein. The segment Ⅳ bile duct can reasonably explain the formation of a reverse U-shaped right anterior segmental duct that joins the left hepatic duct and lies in the groove for the ligamentum teres, as reported by Maetani *et al* and Newcombe *et al*[7,22,23].

A left-sided gallbladder is an important entity during liver resection, particularly in left hepatectomy for tumors, complicated hepatolithiasis, and in liver transplantation[7,8,24]. Our experience of one patient who underwent hepatectomy for liver tumor in the segment Ⅳ with diagnosis of left-sided gallbladder and trifurcation type of portal vein anomaly aided in planning for resection (Figure 1A-D). As a result, an extended right instead of a left hepatectomy was performed. If this anomaly had not been recognized preoperatively, left hepatectomy could have been performed, and the portal vein supplying three-quarters of the liver may have been ligated, leading to

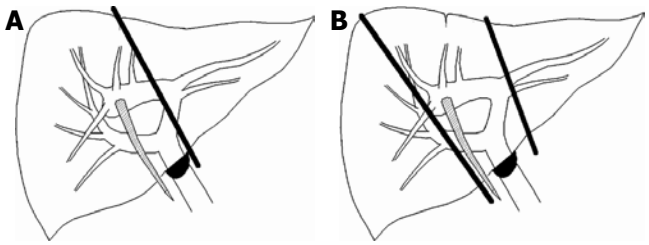

Figure 8 Trifurcation type of portal vein anomaly. **A**: If left hepatectomy is performed, the portal veins draining three-quarters of the liver parenchyma will be ligated. Hepatic necrosis may occur over right anterior portion of the liver parenchyma and contribute to hepatic failure; **B**: Left lateral segmentectomy or right hepatectomy is safe in this type portal vein anomaly.

hepatic failure, biliary congestion or bile leakage[7,8,11,12]. In two other patients, a tumor was located over the lateral segment; left hepatectomy was considered risky and only a left lateral segmental or partial hepatectomy was acceptable in both cases (Figure 8). All patients were discharged uneventfully post-hepatectomy.

Prior knowledge of a left-sided gallbladder is also important in living donor liver transplantation. In right lobe living donor liver transplantation, right lobe graft harvesting encounters double right portal veins in a patient with a left-sided gallbladder. Hepatic venoplasty or vein graft interposition for the reconstruction of the portal veins must be performed, thereby contributing to the complexity of surgery. In left lobe living donor liver transplantation, left-sided gallbladders with trifurcation-type portal vein anomaly are more technically demanding because only the left lateral segment can be used, and separation of the right anterior portal and left portal vein is mandatory[12,25-27]. The volume of the left lateral segment instead of the whole lateral lobe is calculated to determine left liver volume suitable for donation. In some cases, there is no common trunk of the left portal veins, which leads to difficulty in portal vein reconstruction and the possibility of portal vein thrombosis[8].

Anatomical variations associated with left-sided gallbladders are also important in split liver transplantation[12,25-27]. There are two ways of splitting the liver parenchyma suitable for transplantation: (1) dividing the right and left lobes of the liver into anatomical right or left lobes; and (2) separating the liver between the left medial segment and left lateral segment. During division of the right and left lobes of the liver, the portal venous pedicle is separated at the hepatic hilar region, with the left portal vein free and the right portal vein continuous with the main portal vein, or the double right portal veins free and the left portal vein continuous with the main portal vein. Hepatic venoplasty or vein graft interpositions are necessary to reconstruct these anomalous vessels. When separating the liver between the left medial and left lateral segments, the portal venous pedicle is usually divided at the hepatic hilar region, with the left portal vein free and the right portal vein continuous with the main portal vein. This conventional approach can preserve the right lobe, but the volume of left lateral segment may not be sufficient for donation from donors with a left-sided gallbladder. Preoperative evaluation of the left lateral segment volume is, therefore, critical in donors with a left-sided gallbladder.

Right anterior hepatic duct joining the left hepatic duct is a common variation in left-sided gallbladders. Its angle is too acute for possible dilatation in the treatment of the postoperative residual hepatolithiasis, with eventual stenting through the T-tube tract. Percutaneous transhepatic cholangioscopic lithotomy via the left intrahepatic duct should be considered and can provide a more favorable anatomy[24,28,29]. Left-sided gallbladders are overlapped by both the ligamentum teres and falciform ligaments, as well as by the left lobe of the liver. Although laparoscopic cholecystectomy can be performed with the standard port sites with a falciform lift, more medial positioning of the gallbladder-retracting port, and placement of the right-hand operating port to the left of the midline is suggested for laparoscopic removal of left-sided gallbladders[6,30,31].

In conclusion, left-sided gallbladders are a rare anomaly. Judicious preoperative planning is important to identify associated anomalies necessary for the safe conduct of laparoscopic cholecystectomy, hepatectomy, split liver transplantation, or living donor liver hepatectomy in transplantation. If a left-sided gallbladder is found on enhanced CT imaging, further study such as angiography, CT angiography or MRI studies can provide more detailed vascular and even biliary anomalies for preoperative planning. Although left-sided gallbladders with segment Ⅳ atrophy have been reported[5,6,8], we propose that segment Ⅳ is not atrophic but embedded in the hypoplastic right lobe. However, not all cases in our study were defined by CT and angiography.

COMMENTS

Background

Left-sided gallbladders with right-sided ligamentum teres are a rare anomaly associated portal vein anomalies, biliary system anomalies, and the absence of segment Ⅳ. The associated anomalies are important entities during liver resection, complicated hepatolithiasis, and in liver transplantation. Preoperative diagnosis of left-sided gallbladders with associated anomalies is indispensable to minimize the incidence of operative complications.

Research frontiers

Although preoperative diagnosis of left-sided gallbladders is important, there are only a few reported case series of left-sided gallbladders. We assessed the imaging presentation on US, CT and angiography of left-sided gallbladders, which was diagnosed if a right-sided ligamentum teres was present on CT.

Innovations and breakthroughs

This study of nine cases is the largest reported to date with detailed imaging presentation by US, CT and angiography. The etiology of left-sided gallbladders was investigated with the imaging presentations of hepatic vein anomalies, hepatic artery anomalies, biliary anomalies and the absence of segment Ⅳ of the liver.

Applications

Awareness of the special imaging presentations of left-sided gallbladders on US, CT and angiography is important to make an accurate diagnosis. Identification of the associated anomalies will prevent dangerous maneuvers in hepatectomy, split liver transplantation, or living donor liver hepatectomy in transplantation.

Terminology

A left-sided gallbladder is defined as a gallbladder located to the left side of the ligamentum teres. The anomalies associated with left-sided gallbladders, including

portal vein anomalies, biliary system anomalies, and segment Ⅳ atrophy, were reported. Segment Ⅳ is one of three hepatic segments that constitute the left lobe of the liver. It lies between the falciform ligament and the vertical plane of the right hepatic vein, and is demarcated on the diaphragmatic surface of the liver by a line extrapolated from the fossa for the gallbladder to the inferior vena cava; the medial segment is supplied by medial branches of the umbilical part of the left branch of the portal vein.

Peer review

The authors assessed the importance of preoperative diagnosis and presentation of left-sided gallbladders using US, CT and angiography. They concluded that left-sided gallbladders are an important clinical entity in hepatectomy, because of their associated portal venous and biliary anomalies. It should be considered in US, CT and angiography images that demonstrate no definite segment Ⅳ, absence of umbilical portion of the portal vein in the left lobe, and club-shaped right anterior portal vein.

Abstract

AIM: Consecutive monitoring of intragastric pH using the Bravo® capsule.

METHODS: We put threads through a Bravo® capsule and then affixed it to the gastric wall by endoscopic hemoclipping in seven subjects. Study data were uploaded to a computer *via* Datalink every 48 h. In this way, repeated monitoring of intragastric pH was undertaken.

RESULTS: All subjects were able to monitor gastric pH over a 1-wk period, and five for > 2 wk. No complications were encountered during the monitoring. After pH monitoring, we safely retrieved the capsule endoscopically.

CONCLUSION: Clipping a Bravo® capsule onto the gastric wall enabled long-term intragastric pH monitoring. This is a methodological report of pH monitoring over a period of > 2 wk.

Key words: Gastric pH; Ambulatory monitoring; Bravo system

INTRODUCTION

The Bravo® pH monitoring system is a catheter-less system. It has been reported to be useful clinically because it enables monitoring without pain while the subject undertakes daily activities[1-5]. The Bravo® capsule is attached to the esophageal mucosa by suction *via* the delivery system, and it is usually eliminated spontaneously within 1 wk[2]. According to manufacturer Medtronic, the average life of a capsule's battery is 14 d, and consecutive pH monitoring is theoretically possible until the capsule battery goes flat. We used these characteristics of the Bravo® capsule to develop a new method for long-term monitoring of intragastric pH[6].

MATERIALS AND METHODS

Subjects and materials

The subjects of this study were seven *Helicobacter pylori*-negative volunteers. The Bravo® pH monitoring system (Medtronic, Shoreview, MI, USA), nylon threads, flexible overtube® (Sumitomo Bakelite, Tokyo, Japan), and stainless steel hemoclips (HX-200L-135; Olympus Optical, Tokyo, Japan) were prepared.

Preparation for Bravo® capsule

First, we removed the Bravo® capsule from its delivery system and we tied two nylon threads to the capsule and made each thread into a 2-cm diameter ring. Next, we confirmed a connection between the capsule and the receiver. The capsule was then calibrated in buffer solutions.

Placement of the Bravo® capsule

Endoscopic examinations with sedation were conducted on the subjects and results revealed the absence of any abnormal lesions. The flexible overtube was back-loaded onto the endoscope prior to the procedure. We carefully inserted the flexible overtube® with the tip of the endoscope inside the stomach. The Bravo® capsule was then passed through the tube into the stomach. Using hemoclips, the threads attached to the capsule were fixed on the greater curvature of the upper corpus (Figure 1).

Schedule

We administered antacids to determine whether the Bravo® capsule precisely monitored changes in intragastric pH. The subject was administered 150 mg ranitidine hydrochloride orally twice daily at 8:00 and 20:00 h. No limitation of meals and activities was imposed but meal times were set at 7:00, 12:00 and 19:00 h. Alcohol and tobacco were prohibited.

Analysis of pH data

Study data were uploaded to a computer *via* Datalink

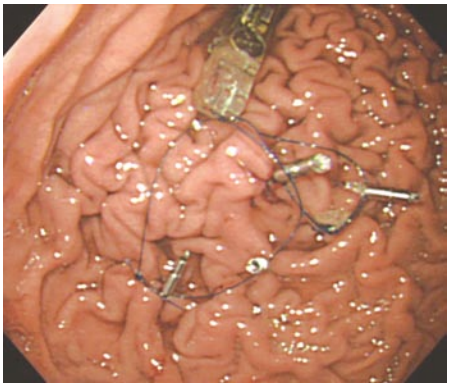

Figure 1 Bravo® capsule in the stomach. The Bravo® capsule was placed onto the gastric wall in the greater curvature of the upper corpus. Threads attached to the capsule were fixed by hemoclips.

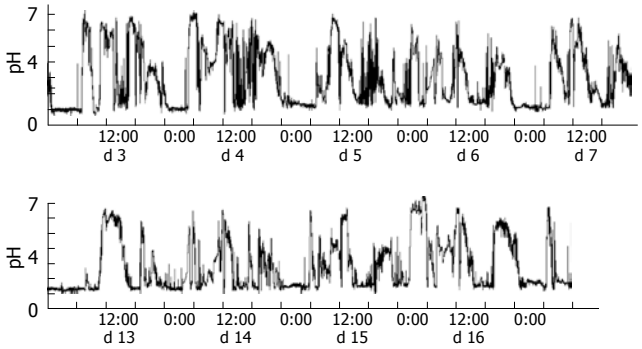

Figure 2 Intragastric pH graph monitored by the Bravo® pH capsule. The upper graph shows d 3-7 of pH monitoring, and the lower graph shows d 13-16 after placement of the Bravo® capsule in one subject.

(Medtronic) every 48 h and analyzed using basic computer software (EXCEL; Microsoft, Redmond, WA, USA). After monitoring was completed, the fixed Bravo® capsules were removed endoscopically. We cut the threads tied to the capsule using scissors forceps (FS-3L-1; Olympus Optical), and put the capsule in the Roth Retrieval Net TM (United States Endoscopy Group, Mentor, OH, USA). Then, we retrieved the capsule by pulling it into an attachment mounted on the tip of the fiberscope.

Ethics

This study was approved by our hospital ethics committee and informed consent for participation in the study was obtained from all subjects.

RESULTS

Placement of the Bravo® capsules took less than 5 min. No complications or side effects were observed during pH monitoring. All subjects were able to perform normal daily activities. Two of the seven subjects ended gastric pH monitoring because their capsule batteries went flat (at d 7 and 13). The other five succeeded in pH monitoring for 16 consecutive days. During this study, the average rate of captured data per day was 97.7%. A selection of the pH monitoring data is shown in Figure 2.

Gastric acid secretion was suppressed, beginning on the first day of ranitidine intake. However, during the medication period, the percentage time with pH < 4 increased and the median pH decreased. At the time of re-administration, the effect of the drug developed more slowly than at the first time it was given.

Retrieval of the Bravo® capsules took less than 5 min. No capsule suffered any damage.

DISCUSSION

Using the standard vacuum method, it is more difficult to attach the Bravo® capsule to a large lumen such as the stomach, than to the esophagus. It took us 15 min to place the capsule using the conventional method. The capsule was then eliminated on the fifth day. In previous studies of the Bravo® system, intragastric pH monitoring was carried out for just 48 h[7-9]. Since an endoscopic procedure and administration of premedication can influence gastric acid secretion[10], a longer period for pH monitoring would be helpful for diagnosis[11-13]. In our study, we were able to monitor gastric pH for at least 1 wk.

We had some difficulty in passing threads through the capsule beforehand, but we needed only about 5 min to affix the capsule under endoscopic guidance[7]. The Bravo® system has been reported to be safe[2,14,15], although there is a report of esophageal perforation during attachment of the capsule[16]. We used a flexible overtube® so that the capsule could pass safely through the cervical esophagus, a physiologic stricture. However, complications with the flexible overtube® have been reported[17], and so care must be taken when inserting it.

In addition, the precision of long-term pH monitoring using an antimony electrode fixed in stomach may create problems. However, in our study, pH rhythm was reflected by the effects of meals and medication, but the precision itself was not influenced. Some studies have suggested that the effects of histamine H2-receptor antagonists are attenuated during continuous treatment; an effect expressed as tolerance or tachyphylaxis[18-21]. Tachyphylaxis of ranitidine was observed in our study. The rates of captured data per day in the esophagus and stomach have been reported as 97.7% to 99.3%[7,14] and 98.3%[7], respectively. In our study, the rate was high and did not decrease over the 16-d period.

After monitoring for 16 d, we endoscopically retrieved the fixed capsules from the stomach. The Bravo® capsule attached to the esophagus by suction was eliminated spontaneously through the gastrointestinal tract. However, we confirmed that a capsule fixed to the stomach for a long period did not suffer any damage.

H2-receptor antagonists and proton-pump inhibitors rapidly and potently suppress gastric acid secretion and are widely used for treatment of acid-related diseases[22-27]. However, they have some clinical weaknesses, tachyphylaxis and nocturnal gastric acid breakthrough[28-30], which have not been resolved. One reason has been the availability of only intermittent pH monitoring, but not long-term continuous monitoring. Our method is useful clinically not only for the diagnosis of acid-related diseases, but also for the elucidation of their problems.

In conclusion, we present a newly developed method for easy and simple long-term monitoring of intragastric pH using the Bravo® pH monitoring system.

ACKNOWLEDGMENTS

We thank Mrs. E Shouji (Department of Gastroenterology and Hematology, Hokkaido University Graduate School of Medicine) and Mr. T Iwasaki (Medical Care Support Division, Hokkaido University Hospital) for endoscopic support.

COMMENTS

Background

The Bravo® capsule is usually attached to esophageal mucosa by suction *via* the delivery system and eliminated spontaneously within 1 wk. However, consecutive pH monitoring is theoretically possible until the capsule battery goes flat.

Research frontiers

It has been reported that an endoscopic procedure and administration of premedication can influence gastric acid secretion when using the Bravo® pH monitoring system. In previous studies of the Bravo® system using its conventional vacuum method of attachment, it was only possible to carry out intragastric pH monitoring for 48 h.

Innovations and breakthroughs

Clipping of a Bravo® capsule onto the gastric wall enabled intragastric pH monitoring for > 2 wk. The methodology is easy and simple.

Applications

Our method is clinically useful, not only for diagnosis of acid-related diseases, but also for the elucidation of tolerance of H2-receptor antagonists and nocturnal gastric acid breakthrough of proton-pump inhibitors.

Terminology

Bravo® pH monitoring system is a catheter-less pH monitoring system.

Peer review

The authors have reported a modified method for long-term monitoring of intragastric pH using the Bravo capsule fixed on the gastric wall by endoscopic hemoclipping. The contents of the manuscript are reasonable, and this may be a useful method for the elucidation of tolerance to H2-receptor antagonists and nocturnal gastric acid breakthrough of proton-pump inhibitors, as the authors state.

Abstract

AIM: To study the association between irritable bowel syndrome (IBS) variants (constipation, diarrhea, or both) and personality traits in non-psychiatric patients.

METHODS: IBS was diagnosed using the Rome Ⅱ diagnostic criteria after exclusion of organic bowel pathology. The entry of each patient was confirmed following a psychiatric interview. Personality traits and the score of each factor were evaluated using the NEO Five Factor Inventory.

RESULTS: One hundred and fifty patients were studied. The mean age (± SD) was 33.4 (± 11.0) year (62% female). Subjects scored higher in neuroticism (26.25 ± 7.80 *vs* 22.92 ± 9.54, $P < 0.0005$), openness (26.25 ± 5.22 *vs* 27.94 ± 4.87, $P < 0.0005$) and conscientiousness (32.90 ± 7.80 *vs* 31.62 ± 5.64, $P < 0.01$) compared to our general population derived from universities of Iran. Our studied population consisted of 71 patients with Diarrhea dominant-IBS, 33 with Constipation dominant-IBS and 46 with Altering type-IBS. Scores of conscientiousness and neuroticism were significantly higher in C-IBS compared to D-IBS and A-IBS (35.79 ± 5.65 *vs* 31.95 ± 6.80, $P = 0.035$ and 31.97 ± 9.87, $P = 0.043$, respectively). Conscientiousness was the highest dimension of personality in each of the variants. Patients with C-IBS had almost similar personality profiles, composed of higher scores for neuroticism and conscientiousness, with low levels of agreeableness, openness and extraversion that were close to those of the general population.

CONCLUSION: Differences were observed between IBS patients and the general population, as well as between IBS subtypes, in terms of personality factors. Patients with constipation-predominant IBS showed similar personality profiles. Patients with each subtype of IBS may benefit from psychological interventions, which can be focused considering the characteristics of each subtype.

Key words: Irritable bowel syndrome; Personality; Conscientiousness; Neuroticism; Openness; Constipation-predominant

INTRODUCTION

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder with a wide variety of presentations that include abdominal pain, bloating, disturbed defecation (constipation and/or diarrhea) or alternating bowel habits, and the absence of any detectable organic pathological process[1]. Symptom-based criteria along with limited medical evaluation are used for diagnosis. Treatment is challenging because of the heterogeneity of the presenting symptoms, together with the unclear pathophysiology of the disorder. To date, treatment strategies are focused on specific symptoms, potential underlying disorders in stress responsiveness, and predisposing psychological features.

Regardless of the unclear etiology of the syndrome, it is commonly accepted as being a disorder closely influenced by affective factors. IBS seems to be influenced by psychosocial stressors and psychiatric comorbidity. The incidence of mood and anxiety disorders has been well studied in IBS patients. The high rates of psychiatric co-morbidity in IBS patients indicate that the affective symptoms may be specific and integral to the syndrome, rather than be a specific syndrome related to a chronic intestinal disease[2]. This has resulted in recommendations on how to best detect and integrate treatments to achieve better outcomes for these patients[3], and has led to significant improvements. Patients and physicians might benefit from detailed identification and psychotherapeutic intervention in patients with comorbid psychiatric disorders (as opposed to psychodynamic personality dysfunction).

However, the underlying personality structure might be misinterpreted at the present time because of the

poor quality and dubious results of early research done in the area of personality factors as they relate to IBS[4]. The five-factor model of personality defines personality traits in terms of five basic dimensions: extraversion, which incorporates talkativeness, assertiveness and activity level; agreeableness, which includes kindness, trust and warmth; conscientiousness, which includes organization, thoroughness and reliability; neuroticism versus emotional stability, which includes nervousness, moodiness and temperamentality; and openness to experience, which incorporates imagination, curiosity and creativity. This model has been widely accepted because the structure of traits in it is consistent among highly diverse cultures with various languages, and between men and women, and older and younger adults[5].

Patients are often subclassified by their predominant bowel habits, that is, constipation-predominant, diarrhea-predominant, or alternating diarrhea and constipation. Patients with IBS share basic pathophysiological features, regardless of bowel habits; however, differences in perception, autonomic function, and symptom characteristics between constipation-predominant and diarrhea-predominant patients have been described[6-8]. Psychological treatment has been reported to be more effective for diarrhea- than constipation-predominant patients[9]. The association between psychological features and specific symptoms of IBS has been minimally explored. We hypothesized that personality traits are also associated with the dominant symptom of IBS. We sought to assess the distribution of personality traits in IBS patients in our cohort as a first step, and then define any relationship with dominant symptoms.

MATERIALS AND METHODS

Continuous patients attending our university outpatient clinics with a diagnosis of IBS were included. Diagnosis was established after a stool examination, clinical evaluation and endoscopy (in some cases) by a gastroenterologist using the ROME Ⅱ criteria for IBS. All patients were clinically investigated to identify the presence of "alarm factors". Patients were excluded if an organic cause of the condition were possible, or if there were a history of serious somatic disease. All patients gave informed written consent. Demographic information, severity and course of illness, abdominal pain severity over previous weeks, bowel habits and gastrointestinal symptoms were obtained. Patients described whether their symptoms arose with stress and if/how they disrupted their daily activities. Patients were divided into three groups: constipation-predominant (C-IBS), diarrhea-predominant (D-IBS) and altering diarrhea or constipation (A-IBS), according to their self-explanation of recent symptoms.

Patients were referred to the first author, who was blinded to characteristics of IBS, for psychiatric and psychosomatic assessments. A history or current symptoms of any DSM-IV psychiatric diagnosis[11] on axis Ⅰ or seizure disorders led to exclusion from the study.

Personality dimensions in non- psychiatric IBS patients were evaluated by the NEO Five-Factor Inventory (NEO-FFI), a 60-item questionnaire which usually requires 10-15 min to complete. This questionnaire is rated on a five-point scale to yield scores in five major domains of personality and requires a sixth-grade reading level. Scores of five personality factors measured by NEO have previously been described in a survey of an Iranian population of all universities[10].

Table 1 Mean (SD) scores of five personality factors measured by FFI in patients with irritable bowel syndrome compared to the Iranian general population

	IBS patients	General population	*P*
Openness	26.25 (5.22)	27.94 (4.87)	< 0.0005
Conscientiousness	32.90 (7.80)	31.62 (5.64)	< 0.0005
Extraversion	27.06 (6.09)	26.89 (6.15)	0.733
Agreeableness	28.97 (6.74)	32.90 (7.00)	0.344
Neuroticism	26.25 (7.80)	22.92 (9.54)	< 0.0005

Statistical analysis

Data were analyzed using the SPSS Statistical package ver.13 (SPSS, Chicago, IL, USA). Means ± SD were used to describe continuous variables and proportions for categorical data. Conditions were met for using two-tailed Student's t test and Chi-square test, which were applied when appropriate. Within- and between-group comparisons were performed using ANOVA. The Bonferroni inequality test was used to affirm that significance was not reached by chance alone. Overall significance was set at 0.05.

RESULTS

One hundred and fifty patients age, mean ± SD was 33.4 ± 11.0 year (62% female), with IBS by ROME Ⅱ criteria were enrolled in the study. Bowel problems that were provoked by distress in > 80% of patients interrupted daily activities in up to 70%.

NEO-FFI showed a significantly higher level of neuroticism and conscientiousness and a lower level of openness in the non-psychiatric IBS patients. Table 1 shows mean scores for five personality factors in our patients compared to the Iranian general population (by NEO FFI)[12]. Women with IBS had significantly higher levels of neuroticism, conscientiousness and extraversion compared to men (P = 0.032, 0.003 and 0.037 in that order) (Figure 1).

Our study population consisted of 71 patients with D-IBS, 33 with C-IBS and 46 with A-IBS. Patient occupation, educational level and marriage status had similar patterns among the groups. Symptoms reported by patients with C-IBS and A-IBS were more related to stressors (P = 0.004).

The score for conscientiousness was significantly higher in C-IBS (35.79 ± 5.65) than D-IBS (31.95 ± 6.80) and A-IBS (31.97 ± 9.87) (P = 0.035 and 0.043). Neuroticism had a higher score in C-IBS compared to the other groups (P = 0.044). Conscientiousness was the highest dimension of personality in each of the variants: 42% of C-IBS, 55% of D-IBS and 47% of A-IBS patients.

Personality profiles were somewhat capricious in

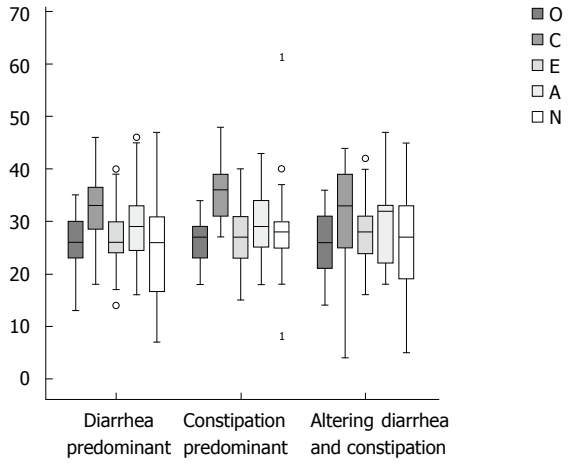

Figure 1 Scores of personality factors in irritable bowel syndrome patients, defined by dominant symptom. Box plots show distribution of the scores, defining means, minimum, maximum, range, interquartile range and cases out of 95% confidence intervals(as[1]). O: Openness to Experience; C: Conscientiousness; E: Extraversion; A: Agreeableness; N: Neuroticism.

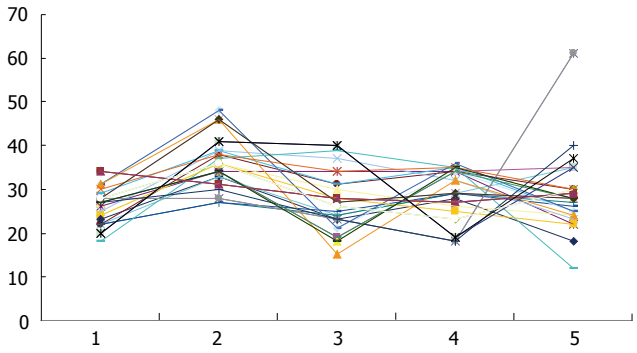

Figure 2 Personality profiles in patients with C-IBS. 1: Openness to Experience; 2: Conscientiousness; 3: Extraversion; 4: Agreeableness; 5: Neuroticism.

patients with A-IBS and D-IBS. Whereas, patients with C-IBS had mostly similar personality profiles (Figure 2), which showed higher scores for neuroticism and conscientiousness, a low level of agreeableness, along with openness and extraversion close to those of the general population.

DISCUSSION

The present study was designed to investigate personality characteristics of non-psychiatric IBS patients considering their IBS subtype. Emotional states and personality traits may affect the physiology of the gut[13], and play a role in how symptoms are experienced and interpreted, and can thus influence treatment[14,15]. This can be an important issue when considering a management strategy to achieve a better outcome for an IBS patient. The prevalence of IBS has been reported to be 18.4% in the general Iranian population[16].

The five-factor model provides a dimensional account of the structure of normal personality traits, dividing personality into five broad dimensions. There has been little research examining the biological correlates of the dimensions and very little in known about the personality structure in IBS patients. Neuroticism and aggression are reported to be higher in patients with functional gastrointestinal disease without psychiatric comorbidity, and personality traits are believed to influence pain reporting[17]. A low level of neuroticism and little concealed aggressiveness is reported to predict treatment outcome with antidepressants in non-psychiatric patients, which are most prominent in women. These personality dimensions are better predictors of outcome than serotonergic sensitivity[18].

Differences between male and female patients with IBS have been reported; the significant differences found here in the traits of neuroticism, extraversion and conscientiousness were consistent with other studies that suggest women consistently score higher than men on self-reported trait anxiety[19,20]. The data for non-psychiatric individuals drawn from a pool prepared for standardization of the Iranian version of NEO PI-R are among the limitations of the present study. For a more appropriate comparison, the control individuals in future studies might be beneficially selected from the member of patients' family.

Studies on personality dimensions according to subtypes of IBS are limited. Similar personality dimensions (by the Minnesota Multiphasic Personality Inventory) have been reported in subgroups of IBS patients with predominant constipation and for those with predominant diarrhea[21].

In the current study, C-IBS patients scored higher on neuroticism and conscientiousness. Neuroticism is a personality trait characterized by overstated reactivity to physiological changes. According to Costa and McCrae[5], people with elevated scores on the neuroticism dimension are emotionally unstable with overwhelmingly negative emotions. Neuroticism is related to emotional intelligence, which involves emotional regulation, motivation, and interpersonal skills. Hans Eysneck theorized that neuroticism is a function of activity in the limbic system, and research suggests that people who score high on neuroticism have a more reactive sympathetic nervous system, and are more sensitive to environmental stimulation[22]. Centrally targeted medications, such as anxiolytics and low-dose tricyclic antidepressants, which involve inhibitory effects on the sensitivity of emotional motor system[23] are widely used for C-IBS patients[24] as they can balance the neuroticism dimension of such patients.

Individuals with high self-consciousness are not at ease with others, are sensitive to ridicule, and prone to feelings of inferiority. This is compatible with a lack of success in completing the "anal stage" of Freud's theory of psychosexual development, which is supposed to result in an obsession with perfection and control. Such patients may benefit from selective serotonin re-uptake inhibitors which increase the extracellular level of the neurotransmitter serotonin.

Personality disorders can be conceptualized as extreme variants of the normal personality dimensions[25]. Excluding such disorders, we sought the personality make up that can introduce vulnerable profiles for IBS in a cross-sectional manner. Research has focused on incorporating various forms of psychotherapy in the hope of alleviating symptoms. Psychological interventions

have been aimed at individuals and at groups and include insight-oriented psychotherapy, hypnotherapy, behavior therapy and group psychotherapy. Such interventions try to address various unconscious conflicts in the subject and thereby help them re-establish a sense of emotional stability[26], modify maladaptive behavior and seek new solutions to problems[27], incorporate multi-component cognitive-behavioral therapy treatment programs[28], and have reported significant improvement in symptoms. It is felt that the profession of counseling psychology, which looks to develop wellness, strength and resources within individuals, has the potential to make a unique contribution to the prevention and alleviation of IBS[29]. Presently, the effectiveness of psychological treatments in IBS is being reviewed[30] in the light of conflicting evidence that supports the use of psychological treatment, an inadequate methodology for randomized controlled trials in this area, and the limited evidence of how to improve the global health of IBS patients with drug therapy[31]. The present study presents added evidence of the differences between subgroups of IBS. As such, this may help to focus management plans in each subgroup to obtain better outcomes.

COMMENTS

Background

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder that is commonly accepted as a disorder closely related to psychological factors. Patients might benefit from detailed identification and psychotherapeutic interventions.

Research frontiers

Mood and anxiety disorders are well studied in IBS patients but information about any underlying personality structure is lacking. Additionally, differences in subtypes of IBS (according to dominant symptom) have been described in perception, autonomic function, and symptom characteristics, which are recommended for evaluation in IBS patients according to their presenting symptoms. This report elucidates personality characteristics of IBS patients according to their dominant symptom using a well-designed personality questionnaire.

Innovations and breakthroughs

IBS patients scored higher on neuroticism, openness and conscientiousness compared to the general Iranian population. Conscientiousness was the highest dimension of personality in each of the variants. The scores for conscientiousness and neuroticism were significantly higher in C-IBS compared to D-IBS and A-IBS. An analogous personality profile was noted in patients with C-IBS composed of the higher scores of neuroticism and conscientiousness, a low level of agreeableness, and with openness and extraversion similar to those of the general population.

Applications

Overstated personality dimensions of IBS patients (especially the constipation-dominant subtype) can be balanced by the use of well-known medications, like anxiolytics, low-dose tricyclic antidepressants and selective serotonin re-uptake inhibitors. Given the added evidence of the differences between subtypes of IBS and vulnerable personality profiles, future studies on drug or psychotherapy may achieve more reliable outcomes.

Terminology

IBS is a gastrointestinal disorder that has a wide variety of presentations that include abdominal pain, bloating, disturbed defecation (constipation and/or diarrhea or alternating bowel habits) and the absence of any detectable organic pathological process. NEO-FFI is a questionnaire with a five-point scale to yield scores in five major domains of personality: openness to experience, conscientiousness, extraversion, agreeableness and neuroticism

Peer review

The results and conclusions of the paper are reliable. The presentation is adequate and easy to read. There are no ethics problems. This is a good manuscript with an interesting approach to the subject.

Abstract

AIM: To investigate the population-based prevalence of fatty liver disease (FLD) and its risk factors in Guangdong Province, China.

METHODS: A cross-sectional survey with multiple-stage stratified cluster and random sampling of inhabitants over 7-year-old was performed in 6 urban and rural areas of Guangdong Province, China. Questionnaires, designed by co-working of epidemiologists and hepatologists, included demographic characteristics, current medication use, medical history and health-relevant behaviors, i.e., alcohol consumption, smoking habits, dietary habits and physical activities. Anthropometric measurements, biochemical tests and abdominal ultrasonography were carried out.

RESULTS: Among the 3543 subjects, 609 (17.2%) were diagnosed having FLD (18.0% males, 16.7% females, $P > 0.05$). Among them, the prevalence of confirmed alcoholic liver disease (ALD), suspected ALD and nonalcoholic fatty liver disease (NAFLD) were 0.4%, 1.8%, and 15.0%, respectively. The prevalence rate (23.0%) was significantly higher in urban areas than (12.9%) in rural areas. After adjustment for age, gender and residency, the standardized prevalence of FLD in adults was 14.5%. Among them, confirmed ALD, suspected ALD and NAFLD were 0.5%, 2.3%, and 11.7%, respectively, in adults and 1.3% (all NAFLD) in children at the age of 7-18 years. The overall prevalence of FLD increased with age in both genders to the peak of 27.4% in the group of subjects at the age of 60-70 years. The prevalence rate was significantly higher in men than in women under the age of 50 years (22.4% *vs* 7.1%, $P < 0.001$). However, the opposite phenomenon was found over the age of 50 years (20.6% *vs* 27.6%, $P < 0.05$). Multivariate and logistic regression analysis indicated that male gender, urban residency, low education, high blood pressure, body mass index, waist circumference, waist to hip ratio, serum triglyceride and glucose levels were the risk factors for FLD.

CONCLUSION: FLD, especially NAFLD, is prevalent in South China. There are many risk factors for FLD.

Key words: Fatty liver disease; Prevalence; Epidemiology; Risk factors

INTRODUCTION

Fatty liver disease (FLD), defined as lipid accumulation exceeding the normal range of 5% of liver wet weight, is a chronic disorder, which includes alcoholic liver disease (ALD) and nonalcoholic fatty liver disease (NAFLD). FLD encompasses a morphological spectrum consisting of hepatic steatosis and steatohepatitis which can progress to cirrhosis and hepatocellular carcinoma[1]. In the past, excess alcohol consumption accounted for most cases of FLD, but recently nonalcoholic causes of fatty liver have attracted considerable attention. In addition to alcohol consumption, factors such as insulin resistance (IR), oxidative stress, mitochondrial dysfunction, immune deregulation, and adipokines play an important role in the pathogenesis of FLD[2,3].

FLD has become a common problem in both developed and developing countries. According to the

Office for National Statistics in the United Kingdom, liver disease mainly FLD ranks the fifth most common cause of death after heart disease, stroke, pulmonary disease and cancer[4]. In recent years, due to alterations in life style and dietary habits, the incidence of FLD has increased dramatically in China. It is thus of importance to assess the epidemiological features of FLD in this country in order to facilitate its prevention and treatment. Although some epidemiological studies concerning FLD have been reported in China, most of them were based on clinical settings or on health check-up groups, which do not represent population data. So far only one population-based study from Shanghai, an eastern city of China, has been published in English[5]. The data from rural areas and other parts of this country are still lacking.

In this study, we investigated the prevalence of FLD in population of South China and identified its major risk factors. Since the random sampling method and high response rate limited the selection and responder biases, our results reflect the population-based data in both urban and rural areas.

MATERIALS AND METHODS

Study design

Guangdong Province with a population of about 85 millions (mainly Han nationality people) is located in an economically advanced region in South China. Its capital city, Guangzhou, has 8-million residents. The heterogeneity of economy, geography, and culture in different areas inside the province influences the life styles of the people.

Between April and November of 2005, a cross-sectional survey with multiple-stage stratified cluster and random sampling was performed on the basis of a previous analysis of the population distribution in this province[6,7]. In order to represent the data in general population, sampling clusters were randomly drawn from urban and rural areas all over the province. Six areas with 4365 residents over 7 years of age were selected, i.e., 2 communities from downtown of Guangzhou city (Yuanzhongyuan community of the Liwan district and the Xinyi community of the Baiyun district, with a total of 1436 urban residents) and four units within the province, i.e., a village in central area of the province (Huadu county, 822 rural residents), a village in southern area (Huizhou county, 1037 rural residents), a village in western area (Zhanjiang county, 351 rural residents) and a community in northern area (Shaoguan city, 719 urban residents).

Of the 4365 potential participants, 3903 agreed to take part in this investigation with a responder rate of 89.6%. Among them, 3543 subjects (90.6%, 1311 males and 2232 females, at the age of 7-100 years) provided their complete information, accounting for approximately 44.3/100 000 of the total population of Guangdong Province[7]. Interview, physical examination, laboratory assessment and ultrasonographic examination were performed for each subject on the same day at a mobile examination center. The study was approved and supported by Guangzhou Health Bureau. Written consent was obtained from each participant.

Interview and physical examination

A face-to-face interview was carried out by specially trained post-graduate students of Guangzhou Medical College and supervised by experienced investigators. Standard questionnaires, designed by co-working of epidemiologists and hepatologists, included the following items: demographic characteristics, current medication use, medical history and health-relevant behaviors, i.e., alcohol consumption, smoking habits, dietary habits and physical activities. Physical examination covered body height, weight, blood pressure, waist circumference (WC), waist-to-hip ratio (WHR) and routine anthropometric parameters in healthy check-up.

Biochemical tests

Intravenous blood samples were collected from fasting subjects by routine methods. Fasting serum glucose levels and lipid profiles were measured with an automatic chemistry- immuno-analyzer (Olympus Corporation, Tokyo, Japan). Serum asparatate aminotransferase (AST), and alanine aminotransferase (ALT), serum bilirubin (BIL) and albumin levels were measured by standard laboratory methods. Tests for the serum makers of hepatitis A virus (HAV), hepatitis B virus (HBV) and hepatitis C virus (HCV) were also carried out.

Ultrasonography

Real-time ultrasonography (US) of the upper abdominal organs was performed for each subject by 2 experienced physicians using a scanner equipped with a 3.5 mmHz transducer (Siemens Adama, German). The physicians performing the US were unaware of the clinical and laboratory results.

Diagnostic criteria

FLD, NAFLD and ALD were diagnosed according to the guidelines for diagnosis and treatment of nonalcoholoic and alcoholoic fatty liver diseases issued by Fatty Liver and Alcoholic Liver Disease Study Group of the Chinese Liver Disease Association[8,9], which were adapted from the American Gastroenterological Association[10]. Briefly, the diagnosis of FLD, NAFLD and ALD was based on the combination of medical history, clinical symptoms, laboratory and US findings. Viral hepatitis and other chronic liver diseases needed to be ruled out. Liver biopsy was taken when the diagnosis was suspected. In this epidemiological study, only 12 subjects underwent biopsy. In most cases FLD was diagnosed and staged by US findings. ALD was diagnosed when a subject fulfilling the FLD criteria drank more than 40 g (male) or 20 g (female) alcohol per day over 5 years. Suspected ALD was defined when the alcohol consumption was 20-40 g (male) or 10-20 g (female). NAFLD was diagnosed when the alcohol consumption was less than these amounts.

The US diagnostic patterns of FLD were based on the presence of a 'bright' liver (brightness and posterior attenuation) with stronger echoes in the hepatic parenchyma than in the renal parenchyma, vessel blurring and narrowing of the lumen of hepatic veins in the absence of findings suggestive of other chronic liver

FLD: Fatty liver disease; ALD: Alcoholic liver disease; NAFLD: Non-alcoholic fatty liver disease.

diseases. The degree of FLD evaluated by US reflected the degree of steatosis. A liver displaying increased but homogenous dot reflection, blurred but still discernible vascular profiles and weak portal vein echogenicity was defined as early-stage. A medium-stage FLD was characterized by disappearance of the portal vascular wall and slightly increased liver volume. Patients with nebulous optical appearance in the liver, little portal vein echogenicity in more than 1/3-1/2 of the liver area and increased liver volume were considered to be in the advanced stage[11-13].

Obesity was categorized according to the body mass index (BMI) criteria for Asians issued by the Regional Office for Western Pacific Region of the World Health Organization[14]. Subjects with BMI ⩾ 25 were considered as obese, BMI ⩾ 23 but < 25 as overweight, BMI ⩾ 18.5 but < 23 as normal, BMI < 18.5 as underweight. Central (or abdominal) obesity was estimated by waist circumference (WC) and waist-to-hip ratio (WHR). A WHR value ⩾ 0.9 (male) or ⩾ 0.8 (female) was considered as central obesity. Dyslipidemia was considered when having one of following serum lipid profiles: total cholesterol (TC) ⩾ 5.72 mmol/L, triglycerides (TG) ⩾ 1.70 mmol/L, high-density lipoprotein cholesterol (HDL-C) < 0.91 mmol/L, and low-density lipoprotein cholesterol (LDL-C) ⩾ 3.64 mmol/L. Subjects with their fasting serum glucose (FSG) value of ⩾ 7.0 mmol/L and/or with a history of diabetes were considered to have diabetes mellitus. Hypertension was defined as systolic or diastolic blood pressure above 140 mmHg or 90 mmHg, respectively. Smokers in this study were defined as those smoking more than one cigarette each day for at least one year or more than 20 packages of cigarettes in total. Alcohol drinkers were defined as those drinking more than 2 times each month for more than 5 years. Heavy tastes meant the habits of preferring salted and spiced foods. Extraverted character meant the active personal characters of subjects. The definitions of urban and rural areas were in accordance with the publication of the Fifth Chinese National Population Census in 2000[7].

Statistical analysis

Data were examined with the SPSS 13.0 for Windows. $P < 0.05$ was considered statistically significant. Exposure ratio comparison and multivariate regression analyses were performed to evaluate the risk factors.

RESULTS

Age and gender-specific prevalence of FLD

Data are shown in Tables 1 and 2. Of the 3543 subjects, 609 (17.2%) were diagnosed having FLD, among them 367 (10.4%), 218 (6.1%) and 24 (0.7%) fell into early, medium and advanced degrees by US staging. The overall prevalence of FLD increased to the peak of 27.4% in the group at the age of 60- years and then decreased in both genders ($P < 0.01$). There was no prevalent difference between males and females (18.0% *vs* 16.7%, $P > 0.05$). However, FLD was more common in males than in females under 50 years of age. An opposite trend was noted over 50 years of age ($P < 0.05$). The prevalence of FLD in children at the age of 7-18 years (5/379, 1.3%) differed significantly from that in adults (604/3164, 19.1%, $P < 0.001$). The overall prevalence of ALD, suspected ALD and NAFLD was 0.4%, 1.8% and 15%, respectively, accounting for 2.3%, 10.7% and 87.0% of the 609 FLD subjects, respectively. In subgroup comparison, the prevalence of confirmed ALD and suspected ALD was significantly higher in males (0.9% and 4.0%) than in females (0.1% and 0.5%, $P < 0.001$). Nevertheless, the prevalence of NAFLD was lower in males than in females (13.0% *vs* 16.1%, $P < 0.05$).

Prevalence of FLD in urban and rural areas

The prevalence of FLD was significantly lower in rural areas than in urban areas (12.9% *vs* 23.0%, $P < 0.001$), mainly due to the difference in NAFLD (11.1% *vs* 20.3%, $P < 0.001$). A slight difference was observed in rural areas between ALD and suspected ALD subjects compared with urban areas, but it was not significant ($P > 0.05$) (Table 3).

Prevalence of FLD and serum lipid profiles

High serum levels of TG, TC, LDL-C and FSG were all positively associated with FLD ($P < 0.01$), but HDL-C did not reach significance ($P > 0.05$) (Table 4). The prevalence of FLD in dyslipidemia subjects was 3.65 (95% CI = 2.87-4.65) folds higher than that in normal controls. High TG levels were the most prominent factor for dyslipidemia

Table 4 Serum levels and lipid profiles in FLD patients and controls (mean ± SE)

	n	TG (mmol/L)	TC (mmol/L)	HDL-C (mmol/L)	LDL-C (mmol/L)	FSG (mmol/L)
FLD	609	2.81 ± 2.55	5.52 ± 1.11	1.72 ± 1.25	3.06 ± 0.91	6.01 ± 2.68
Controls	2934	1.63 ± 1.59	5.19 ± 1.07	1.67 ± 0.57	2.90 ± 0.81	4.95 ± 1.56
P		< 0.001	< 0.01	> 0.05	< 0.01	< 0.01

FLD: Fatty liver disease; TC: Total cholesterol; TG: Triglycerides; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol.

Table 5 Exposure ratios of variables in adult FLD patients compared with controls

n	Male	Urban	Primary school and below	Extraverted character	Alcohol drinkers	Smokers
Total 3164	*n* (%)	*n* (%)	*n* (%)	*n* (%)	*n* (%)	*n* (%)
FLD 604	232 (38.4[1])	344 (57.0)	245 (40.6)	214 (35.4[a])	141 (23.3)	160 (26.5[a])
Controls 2560	869 (33.9)	1140 (44.5)	783 (30.6)	787 (30.7)	457 (17.9)	553 (21.6)
χ^2	4.295	30.282	22.112	4.966	9.619	6.665
n	Heavy tastes	Overweight	Obesity	Hypertension	WHR	WC
Total 3164	*n* (%)	*n* (%)	*n* (%)	*n* (%)	*n* (%)	*n* (%)
FLD 604	208 (34.4)	478 (79.4)	120 (19.9)	287 (47.6)	531 (87.9)	432 (71.5)
Controls 2560	689 (26.9)	650 (25.5)	79 (3.1)	658 (25.7)	1469 (57.8)	558 (21.8)
χ^2	13.616	616.708	235.812	110.141	189.387	560.357

[a]$P < 0.05$ *vs* controls and all the others; $P < 0.01$ *vs* controls. FLD: Fatty liver disease; WC: Waist circumference; WHR: Waist-to-hip ratio.

with an odd ratio (OR) of 4.49 (95% CI = 3.56-5.66). The OR of high TC was 1.95 (95% CI = 1.56-2.44). The OR of elevated FSG and combined dyslipidemia was 4.93 (95% CI = 3.55-6.84) and 6.64 (95% CI = 4.83-9.12), respectively.

Adjusted prevalence of FLD

After adjustment for gender, age and residence area according to the demographic characteristics of the Fifth Chinese Census[7], the age-, gender- and residency- specific standardized prevalence of FLD was 14.5%. Confirmed ALD, suspected ALD and NAFLD were 0.5%, 2.3% and 11.7% respectively in adults (over 18 years of age). The overall prevalence of FLD was 11.3% and confirmed ALD, suspected ALD and NAFLD were 0.4%, 1.8% and 9.1% respectively, in all people over 7 years of age.

Exposure ratio and logistic regression analysis

The exposure ratio (%) analysis of anthropometric and clinical parameters in adults (above 18 years of age, $n = 3164$) with and without FLD was carried out to screen for the relevant factors for FLD (Table 5). The ratios of all variables for FLD and controls were significantly different ($P < 0.01$). In order to identify the risk factors, we further performed a multivariate regression logistic analysis with probability for entry 0.05 and removal 0.1 (Table 6). Male gender, urban inhabitation, hypertension, high BMI, WC, WHR, serum TG, and FSG were found to be independent risk factors for FLD, and education was a protective factor for FLD. Alcoholic consumption and heavy tastes in food were marginally but not significantly related to FLD. Smoking and extraverted character were excluded from the risk factors for FLD ($P > 0.05$).

Table 6 Multivariate regression logistic analysis for FLD ($n = 3543$)

Variables	β	SE	χ^2	*P*	OR	OR 95%CI

DISCUSSION

FLD is a common disease. NAFLD has been increasingly recognized as the most common liver disease in Western countries. So far no accurate incidence is available. The prevalent data obtained from clinical series and autopsy studies suggest that 20%-30% of individuals in the Western world have FLD. In general population, the prevalence of NAFLD ranges 3%-24% in the world[15-17], 20%-25% in Italy[18], 30% in Israel[19], 16% in Korea[20], 14% in Japan[21] and 15% (18% for FLD) in Shanghai, China[25]. The discrepancy among the studies is probably due to the methods of sample selection, modalities used for diagnosis and diversity of life styles and dietary habits in different areas. Since China is a developing country, it is not surprising that the standardized prevalence of FLD (14.5%) and NAFLD (11.7%) is lower in China than in developed countries. The urban prevalence is lower in Guangdong Province than in Shanghai city[5]. It seems that the rapid modernization of Shanghai has brought about its inhabitants more metabolic problems than that of Guangdong Province. Our results in adults and children are comparatively close to those in Japan, probably because the inhabitants in South China share the similar dietary habits (sea food preference) with Japanese[21]. In this study, only 24 cases (0.7% in general population) had advanced stage of FLD diagnosed by US, accounting for 3.9% of the 609 FLD cases. Although US is reasonably accurate as compared with biopsy, it cannot provide precise information about the histological features associated with disease progression especially inflammation[15]. The results in this study roughly reflect the lower severity of FLD in this area.

There are conflicting results regarding the relation of NAFLD to age and gender[15-18]. Bedogni *et al*[18] found that the prevalence of NAFLD increases with age in both genders and then significantly decreases over 66 years of age[18]. However, it was reported that hepatic triglyceride is correlated with age only in white women[16]. The variations between studies can be attributed to the differences in social, cultural and environmental backgrounds among the target subjects. In this study, the highest prevalence of FLD (mainly NAFLD) was observed in the sixth decade of life. The prevalence of FLD in males increased stably with age, and steadily from 50-60 years of age in females. The peak prevalence was observed in females (31.4%) at the age of 60 years, which was 20 years later than that in males (23.8%), which might be due to the menopausal status and lack of physical exercise in this period of time.

In developed countries, alcoholism, obesity and diabetes are the most common causes for FLD. Alcohol drinking plays a role in FLD[22,23]. In this study, only 0.5% adults in Guangdong Province suffered from ALD, reflecting the low alcohol consumption in South China. For this reason, multivariate analyses failed to demonstrate the role of alcohol drinking in FLD (P = 0.078). NAFLD is a manifestation of metabolic syndrome in liver, including obesity, type 2 diabetes, hypertension and dyslipidemia[15,24-28]. Metabolic syndrome, a common disorder in Western countries, has become a severe problem in China due to alterations in life styles and dietary habits. In this study, the prevalence of FLD increased with BMI and HWR, an index for central obesity. These findings are consistent with the reported data[5,19,29,30]. Our results indicate that dyslipidemia, especially high serum level of TG is a major risk factor for FLD, which also agrees with the results in most studies that the role of TG is more important than TC in the pathogenesis of metabolic syndrome and NAFLD[18,23]. When the serum level of TC in this area is relatively low, it fails to reach the significant level as a risk factor for FLD. The education background is related to the prevalence of FLD, probably because the people with a higher education level have paid more attention to their health and they are more likely to adjust their diet habits and exercise for the prevention of obesity.

There are several methodological limitations in this study. First, although participants were randomly selected, the enrollment of a greater proportion of females and elderly subjects in the study may bring about bias to the results. Second, the large number of immigrant population in Guangdong Province, especially in cities may have also confounded the study. In order to limit these biases, the prevalence rate was standardized for age, gender and residency areas. Multivariate regression analyses were performed to strengthen the reliability of our findings. Third, although histology remains the gold standard for the pathological diagnosis of FLD[31,32], imaging modalities like ultrasonography with a reasonably high sensitivity can identify FLD[32-35]. In this study, the diagnosis of fatty liver was based on ultrasonography. For the ethical reason, it is impossible to perform biopsy in an epidemiological study. In addition, the influence of exercise was not taken into account in this study.

In summary, FLD, especially NAFLD, is common in South China and many risk factors are related to the pathogenesis of this metabolic syndrome.

COMMENTS

Background

Fatty liver disease (FLD) has become a common problem in both developed and developing countries. In recent years, due to alterations in life style and dietary habits, the incidence of FLD has increased dramatically in China. It is thus of importance to assess the epidemiological features of FLD in this country in order to facilitate its prevention and treatment. Although some epidemiological studies concerning FLD have been reported in China, most of them were based on clinical settings or on health check-up groups, which do not represent the population data. So far only one population-based study from Shanghai, an eastern city of China, has been published in English. The data from rural areas and other parts of this country are still lacking.

Research frontiers

FLD encompasses a morphological spectrum consisting of hepatic steatosis and steatohepatitis which can progress to cirrhosis and hepatocellular carcinoma. In the past, excess alcohol consumption accounted for most cases of FLD, but recently nonalcoholic causes for fatty liver have attracted considerable attention. In addition to alcohol consumption, factors such as insulin resistance (IR), oxidative stress, mitochondrial dysfunction, immune deregulation, and adipokines play an important role in the pathogenesis of FLD. Although FLD has been reported worldwide, it is difficult to determine the true prevalence because of problems in interpreting data from various studies due to referral bias, population heterogeneity, study design, imaging modalities, and liver biopsies. These studies on the FLD epidemiology have improved the detailed knowledge about the prevalence of FLD and the metabolic risk factors associated regional (e.g., urban *vs* rural) and ethnic differences, as they may provide clues to pathogenesis and individual risk factors for liver disease and metabolic complications. Further studies are also required to confirm the impact of fatty liver on chronic liver diseases.

Innovations and breakthroughs

The incidence of FLD is likely to rise steadily in China in urban areas owing to the westernization of the diet, excessive food intake, increased elderly population, changes in life style and lack of exercise. Because the majority of people live in rural areas of China, it is necessary to investigate the prevalence of FLD in China. In this study, since the random sampling method and high response rate limited the selection and responder biases, our results reflect the population-based data and the major risk factors for FLD in both urban and rural areas. This study assessed the prevalence of and risk factors for NAFLD in China.

Applications

With regards to increasing obesity, FLD, especially NAFLD, is believed to be the most common form of chronic liver diseases, which can progress to cirrhosis. Because there is no proven management for NAFLD, identification of important risk factors for this condition will provide valuable information on both risk stratification and development of risk-reduction strategies.

Terminology

Fatty liver disease (FLD), defined as lipid accumulation exceeding the normal range of 5% of liver wet weight, is a kind of chronic disorders, including alcoholic liver disease (ALD) and nonalcoholic fatty liver diseases (NAFLD). Briefly, the diagnosis of FLD, NAFLD and ALD is based on the combination of medical history, clinical symptoms, laboratory and imaging modalities (ultrasonography, computed tomography scans, and magnetic resonance imaging). Viral hepatitis and other chronic liver diseases need to be ruled out. ALD is diagnosed when a subject fulfilling the FLD criteria drinks more than 40 g (male) or 20 g (female) alcohol per day over 5 years. NAFLD is diagnosed when alcohol consumption is less than 40 g (male) or 20 g (female).

Peer review

This is an interesting, well written and generally well designed study. Although it does not identify fundamentally new or unexpected findings with respect to the incidence of FLD, the data highlighting the nonalcohol - related incidence of FLD

in developing areas are important.

Abstract

AIM: To study the effectiveness and mechanisms of anti- human vascular endothelial growth factor (hVEGF) hairpin ribozyme on angiogenesis, oncogenicity and tumor growth in a hepatocarcinoma cell line and a xenografted model.

METHODS: The artificial anti-hVEGF hairpin ribozyme was transfected into hepatocarcinoma cell line SMMC-7721 and, subsequently, polymerase chain reaction (PCR) and reverse transcription polymerase chain reaction (RT-PCR) were performed to confirm the ribozyme gene integration and transcription. To determine the effects of ribozyme ,VEGF expression was detected by semiquantitative RT-PCR and enzyme liked immunosorbent assay (ELISA). MTT assay was carried out to measure the cell proliferation. Furthermore,the transfected and control cells were inoculated into nude mice respectively, the growth of cells in nude mice and angiogenesis were observed.

RESULTS: VEGF expression was down-regulated sharply by ribozyme in transfected SMMC-7721 cells and xenografted tumor. Compared to the control group, the transfected cells grew slower in cell cultures and xenografts, and the xenograft formation was delayed as well. In addition, the microvessel density of the xenografted tumor was obviously declined in the transfected group. As demonstrated by microscopy,reduction of VEGF production induced by ribozyme resulted in a significantly higher cell differentiation and less proliferation vigor in xenografted tumor.

CONCLUSION: Anti-hVEGF hairpin ribozyme can effectively inhibit VEGF expression and growth of hepatocarcinoma *in vitro* and *in vivo*. VEGF is functionally related to cell proliferation, differentiation and tumorigenesis in hepatocarcinoma.

INTRODUCTION

Rapidly growing tumors routinely outstrip their supply of oxygen and nutrients, and induction of new blood vessels is critical to sustain neoplastic proliferation[1-4]. A number of growth factors have been identified as potential positive regulators of angiogenesis. Among them, vascular endothelial growth factor (VEGF) appears to have a central role in the angiogenic process. VEGF not only is the target of many proangiogenic factors but also regulates molecules that are implicated in endothelial proliferation. It has been suggested that VEGF may be a proximate angiogenic factor through which others act. In fact, over-expression of VEGF is the characteristic of most malignant tumors including hepatocarcinoma[5-9], which is regulated in response to hypoxia[7,10-12] and highly related to microvessel density of cancer, grade of malignance and metastasis[13-15]. It now appears that VEGF also has autocrine functions acting as a survival factor for tumor cells protecting themselves from stresses such as hypoxia, chemotherapy and radiotherapy[16]. Consequently, anti-

VEGF therapies are being actively investigated as potential anti-cancer treatment modalities, either as alternatives or adjuncts to conventional chemo or radiation therapy. Clinical trials using anti-VEGF mAbs such as bevacizumab have validated the efficacy of this therapeutic approach but have also revealed adverse effects.

Hepatocellular carcinoma (HCC) is one of the most common and aggressive cancers worldwide, being the third cause for cancer-related deaths. As a malignant solid tumor, HCC is characterized by fast infiltrating growth, early metastasis, high-grade malignancy, and poor therapeutic efficacy[17]. It is a highly vascular tumor dependenting on neovascularization and a rapidly developing malignancy[18]. The VEGF level in HCC tissues is significantly higher than that in distal cancerous tissues[6]. The abnormal expression levels of VEGF in sera of HCC patients are directly correlated with the metastasis and recurrence of tumors[5,19,20]. Since HCC is insensitive to conventional chemotherapeutics and its prognosis is poor, it is important to explore an antiangiogenesis method for HCC characterized by a high vascularity. Up to now, many strategies for gene therapy have been developed. Ribozymes are a group of catalytically active nucleic acids capable of site-specific cleavage of target mRNAs, thus decreasing mRNA expression and inhibiting the function of target gene[21]. Both hairpin and hammerhead ribozymes are the most commonly used gene therapy models. In contrast to hammerhead ribozyme, the hairpin ribozyme reaction requires an environment closer to human physiology. The hairpin ribozyme uses a catalytic mechanism that does not require metals for cleavage or ligation of substrate RNA. In this regard, it is presently unique among RNA catalysts. The hairpin ribozyme has been approved for its use in gene therapy.

The role of VEGF in HCC proliferation, differentiation and tumorigenesis is unclear. The present study was to study the effectiveness and mechanisms of hairpin ribozyme targeting human VEGF (hVEGF) mRNA on exon 3 on VEGF expression, angiogenesis, oncogenicity and tumor growth in HCC cell cultures and xenografts.

MATERIALS AND METHODS

Cell line and cell cultures

Human hapatocarcinima cell line SMMC-7721 was maintained in our laboratory. Cells were incubated with RPMI 1640 medium (GIBCO BRL, Carlsbad, CA, USA) supplemented with 10% heat-inactivated calf serum (Sijiqing, Hangzhou, China), 100 U/mL penicillin G sodium and 100 μg/mL streptomycin sulfate in a humidified atmosphere containing 50 mL/L CO_2 at 37℃.

Synthesis of anti-human VEGF hairpin ribozyme and recombinant plasmids

The secondary structure of ribozyme was obtained by the ribozyme- aided design software, and the primers of hairpin ribozyme were synthesized (Shengong, Shanghai, China) based on the third exon of hVEGF as previously described[22]. The sequences of specific primers of ribozyme used are as follows: forward: 5'-GATCCCTGATAAGAATCCAACCAGAGAAACACACGTTGTGGTATATTACCTGGTAG-3' and reverse: 5'-AATTCTACCAGGTAATATACCACAACGTGTGTTTCTCTGGTTGGATTCTTATCAGG-3'. Ribozyme was synthesized in a 50 μL reaction system, which was mixed with 1 μL (25 μmol/L) primers, 5 μL NaCl buffer and 43 μL ddH_2O. Since the gene of anti- hVEGF hairpin ribozyme only has a 50 bp product, after incubation at 94℃ for 2 min followed by annealing of the two primers at room temperature, ribozyme was acquired.

After plasmid pcDNA3.1+ (Invitrogen, San Diego, CA) was digested with restriction endonucleases BamHI and EcoRI (TakaRa, Japan), the purified products of anti-hVEGF hairpin ribozyme were subcloned into them, thus, the recombinant eukaryotic expression plasmid pcDNA3.1+/ribozyme (abbreviated as pcDNA3.1+/RZ) was constructed.

Preparation and identification of SMMC-7721/RZ transgenic cells

SMMC-7721 cells were seeded in 6-well plates at 2 × 10^5 cells per well and cultured as described above. The recombinant eukaryotic expression plasmid pcDNA3.1+/RZ was transfected into SMMC-7721 cells by LipofetamineTM2000 (Invitrogen, San Diego, CA) following the manufacturer's instructions, and positive clones were selected with G418, then SMMC-7721/RZ transgenic cells were obtained. At the same time, two control groups were established: the SMMC-7721 cell control (abbreviated as SMMC-7721 cell) and the SMMC-7721 cells transfected with blank vector of pcDNA3.1+ control (abbreviated as SMMC-7721/pcDNA3.1+ cells).

Integration and transcription of the objective gene in SMMC-7721/RZ transgenic cells were identified by polymerase chain reaction (PCR) and reverse transcription polymerase chain reaction (RT-PCR). Genomic DNA was extracted from cells in 3 groups using genomic DNA (Shengong, Shanghai, China). PCR was performed to detect the integration of ribozyme gene in SMMC-7721/RZ transgenic cells. The ribozyme primers (forward: 5'-GGACTTTCCTACTTGGCAGTACATC-3', reverse: 5'-CCACAACGTGTGTTTCTCTGGTTGG-3') were used in this study. Genomic DNA template was amplified with an initial denaturation at 94℃ for 2 min, then 30 cycles at 94℃ for 50 s, at 58℃ for 50 s and at 72℃ for 45 s, followed by at 72℃ for 10 min. To evaluate transcription of the ribozyme gene in SMMC-7721/RZ transgenic cells, RT-PCR was performed. Total RNA was extracted from cells using UNIQ column total RNA extraction kits (Shengong, Shanghai, China). First strand cDNA was synthesized from 2 μg of total RNA with an oligo (dT)18-primer in 20 μL of first strand reaction mix at 37℃ for 1 h. Thirty cycles of PCR were done. First strand cDNA was employed as template and the sequences of specific primers of ribozyme are as follows: forward: 5'-TAGAGAACCCACTGCTTACTGGCT-3', and reverse: 5'-CCACAACGTGTGTTTCTCTGGTTGG-3'.

RT-PCR and ELISA for VEGF expression

SMMC-7721/RZ cells were seeded in 24-well plates at

1×10^5 cells per well. The SMMC-7721 cell control and the SMMC-7721/pcDNA3.1+ cell control were established. Cells were cultured for 72 h, and then the supernatant was harvested. Total RNA was isolated from cells, and then RT-PCR was performed to detect the transcription level of VEGF mRNA in cells. Data were presented and normalized to β-actin. The sequences of PCR primers of VEGF and β-actin are as follows: VEGF (forward: 5'-TGGTAGAGTTCATGGATGTCTATCA-3', reverse: 5'-GCATGGTGATGTTGGACTCCTCA-3'), β-actin (forward: 5'-TGCGTGACATTAAGGAGAAG -3', reverse: 5'-CTGCATCCTGTCGGCAATG-3'). The expression of VEGF protein in supernatant was detected by ELISA assay following the manufacturer's instructions (Jingmei, Shanghai, China).

Cell proliferation detection by MTT assay

SMMC-7721/RZ cells were seeded in 96-well plates at 1×10^4 cells per well. Three control groups were established as follows: non-cell control group, SMMC-7721 cell control group and SMMC-7721/pcDNA3.1+ cell control group. Cells were cultured for 24, 48, 72, 96 h respectively, and viability was assessed using 3-(4, 5- dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide (MTT) (SIGMA, St. Louis. USA) at a final concentration of 0.5 mg/mL. Cells were incubated for 2 h, the medium was aspirated, and the cells were dissolved in acidic isopropanol (90% isopropanol, 0.5% sodium dodecyl sulfate, 40 mmol/L HCl). Optical density was read on a microplate reader at 570 nm using the isopropanol as blank. The inhibitory rate (IR) was calculated as follows: IR (%) = (1-absorbance of the treated wells)/(absorbance of the control wells) × 100%.

Human hepatocarcinoma xenograft experiments

Female athymic BLAB/c nude mice, 4-5 wk of age, were purchased from Shanghai Experimental Animal Company, Chinese Academy of Sciences (Shanghai, China) and housed in a pathogen-free facility. *In vivo* studies approved by the Fourth Affiliated Hospital of Soochow University Animal Care Committee, were conducted in accordance with the institutional and China guidelines. Subconfluent SMMC-7721/RZ transgenic cells or SMMC-7721/pcDNA3.1+ cells were suspended in PBS and injected subcutaneously into the right flanks (2×10^6/0.1 mL) of 5 nude mice in each treatment group. Tumor size was measured every other day using an external caliper. Tumor volumes (V) were determined following the equation: $V = (L \times W^2) \times 0.5$, where L is the length and W is the width of tumor. The standard for tumor formation was the diameter of tumors > 0.5 cm. When the experiment was terminated at the 5th wk after tumor formation, the mice were sacrificed. The tumors were isolated, photographed, snap frozen in liquid nitrogen and stored at -80℃, or fixed in formalin for subsequent multiple assays.

Histologic and immunohistochemical assay

Tumor tissues were formalin-fixed and paraffin-embedded. After deparaffinized and rehydrated, the slides were stained with hematoxylin and eosin (HE) in succession, and finally mounted and visualized under microscope. The number of karyokinesis and pathologic karyokinesis was calculated in each visual field, and ten visual fields were selected randomly in each section.

Immunostaining was performed on 5-μm thick sections. Serial sections of paraffin-embedded tumor tissue were dewaxed and hydrated. After antigen retrieval, its endogenous peroxidase activity was blocked with 3% hydrogen peroxide solution for 5-10 min. The sections were washed in distilled water, and soaked in pH 7.4 phosphate-buffered saline (PBS) for 5 min. Nonspecific binding was blocked by incubation with 3% normal goat serum for 10 min. The sections were incubated with primary antibody, rabbit anti-human VEGF polyclonal antibody or rat anti-murine cell determinant (CD34) monoclonal antibody (Santa Cruz Biotechnology, Santa Cruz), at a dilution of 1:100 for 1-2 h at 37℃. Anti-CD34 was used as a pan-endothelial marker for microvessel density (MVD) analysis. After washed with PBS, the sections were incubated for 30 min at 37℃ with biotinylated secondary antibody and then with horseradish peroxidase (HRP)-conjugated streptavidin for 30 min at 37℃. The color was developed with a Vector DAB substrate kit for 1 min and 30 s and counterstained with hematoxylin. All sections were analyzed by conventional light microscopy and digital photography.

MVD was evaluated according to the CD34 endothelial cell immunostaining. For the microvessel counting, positivelystained CD34 was counted in ten visual fields of each slide. Any endothelial cluster positive for CD34 (brown yellow staining) was considered a single countable microvessel.

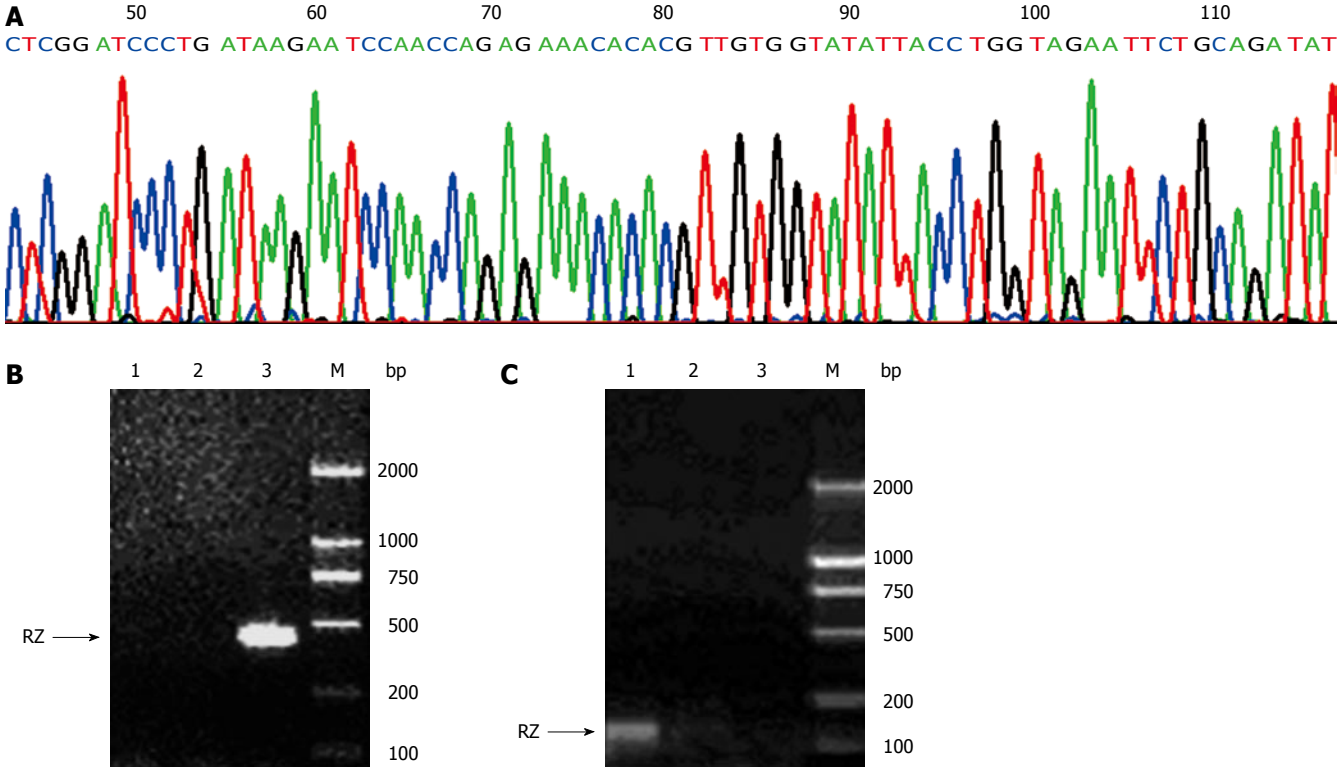
Statistical analysis

All statistical analyses were carried out by the Statistical Package for the Social Sciences (SPSS) software, Version 10.0 for Windows. All values such as tumor volume and weight, karyokinesis and microvessel, were expressed as mean ± SD. Chi-square test was used for rate contrast. $P < 0.05$ was considered statistically significant.

RESULTS

Construction and identification of recombinant eukaryotic expression plasmid pcDNA3.1+/RZ

When products from annealing of the two specific primers of ribozyme were run on agarose gels and visualized with ethidium bromide staining, an amplicon of 50 bp of anti-hVEGF hairpin ribozyme (including cohesive terminal of BamHI and EcoRI) was shown. After cleaved by BamHI and EcoRI, the recombinant eukaryotic expression plasmid pcDNA3.1+/RZ generated an amplicon of 50 bp, revealing that anti-hVEGF hairpin ribozyme was successfully subcloned into pcDNA3.1+. Recombinant plasmids harboring ribozyme sequences in the pcDNA3.1+ backbone were checked by restriction enzyme analysis and sequencing. As shown in Figure 1A, the sequence of the gene subcloned into pcDNA3.1+ was identical to that of the synthetic gene designed according to Genebank, indicating that the recombinant eukaryotic



Figrue 1 Construction and identification of recombinant eukaryotic expression plasmid pcDNA3.1+/RZ. **A**: Sequencing result of the anti-hVEGF hairpin ribozyme gene subcloned into pcDNA3.1+; **B**: Integration of the ribozyme gene detected by PCR (1: SMMC-7721 cells; 2: SMMC-7721/pcDNA3.1+cells; 3: SMMC-7721/RZ cells; M: DL2000 marker); **C**: Transcription of the ribozyme gene detected by RT-PCR (1: SMMC-7721/RZ cells; 2: SMMC-772 cells; 3: SMMC-7721/ pcDNA3.1+ cells; M: DL2000 marker).

expression plasmid pcDNA3.1+/RZ was successfully constructed.

Integration and transcription of anti-hVEGF hairpin ribozyme in SMMC-7721/RZ cells

The forward and reverse primers were designed based on the sequence of pcDNA3.1+ and anti-hVEGF hairpin ribozyme. PCR amplification of ribozyme in genomic DNA of SMMC-7721/RZ cells generated an amplicon of 400 bp (Figure 1B). Using the primers designed based on the sequence of pcDNA3.1+ transcriptional start site and ribozyme, RT-PCR showed that PCR amplification of ribozyme in cDNA of SMMC-7721/RZ cells generated an amplicon of 140 bp (Figure 1C). In contrast, these amplicons were not found in SMMC-7721 cells and SMMC-7721/pcDNA3.1+ cells, demonstrating that the gene of anti-hVEGF hairpin ribozyme transfected into SMMC-7721 cells could be integrated with SMMC-7721 cell genome and transcripted into corresponding mRNA efficiently.

VEGF transcription and expression

As the ultimate goal we sought to achieve was the reduction of VEGF secretion into extracellular compartment by SMMC-7721 cells, we investigated if transfection of ribozyme has a direct effect on VEGF secretion by SMMC-7721 cells. As demonstrated in Figure 2A, VEGF protein expression level detected by ELISA in transgenic SMMC-7721/RZ group was 363.64 ± 19.68 ng/L, which was significantly lower than that in SMMC-7721 cell group (1358.69 ± 49.81 ng/L) and SMMC-7721/pcDNA3.1+ group (1369.57 ± 32.61 ng/L) ($P < 0.01$). There was no significant difference between SMMC-7721 cell group and SMMC-7721/pcDNA3.1+ group ($P > 0.05$). These results indicate that ribozyme inhibited VEGF expression (more than 73%) in HCC cells *in vitro*.

To determine whether the inhibitory effect of ribozyme on VEGF expression is at the transcriptional level, VEGF mRNA expression in tumor cells was detected by RT-PCR. The products were run on 1% agarose gels and visualized with ethidium bromide staining. SMMC-7721/RZ cells and two control group cells generated an amplicon of 195 bp. By normalizing to β-actin, the level of VEGF mRNA expression in SMMC-7721/RZ cells was remarkably lower than that in two control groups (Figure 2B), suggesting that ribozyme could reduce VEGF expression by inhibiting its transcription.

Proliferation of transgenic cells

As shown in Figure 2C-D, after cells were cultured for 24, 48, 72 and 96 h, the proliferation rate for SMMC-7721/RZ cells was significantly lower than that for SMMC-7721 cells and SMMC-7721/pcDNA3.1+ cells ($P < 0.01$). On the third day, ribozyme-mediated growth inhibition rate reached 78.6%. There was no significant difference in proliferation of SMMC-7721 cells and SMMC-7721/pcDNA3.1+ cells ($P > 0.05$). The results reveal that ribozyme inhibited proliferation of HCC cells *in vitro*.

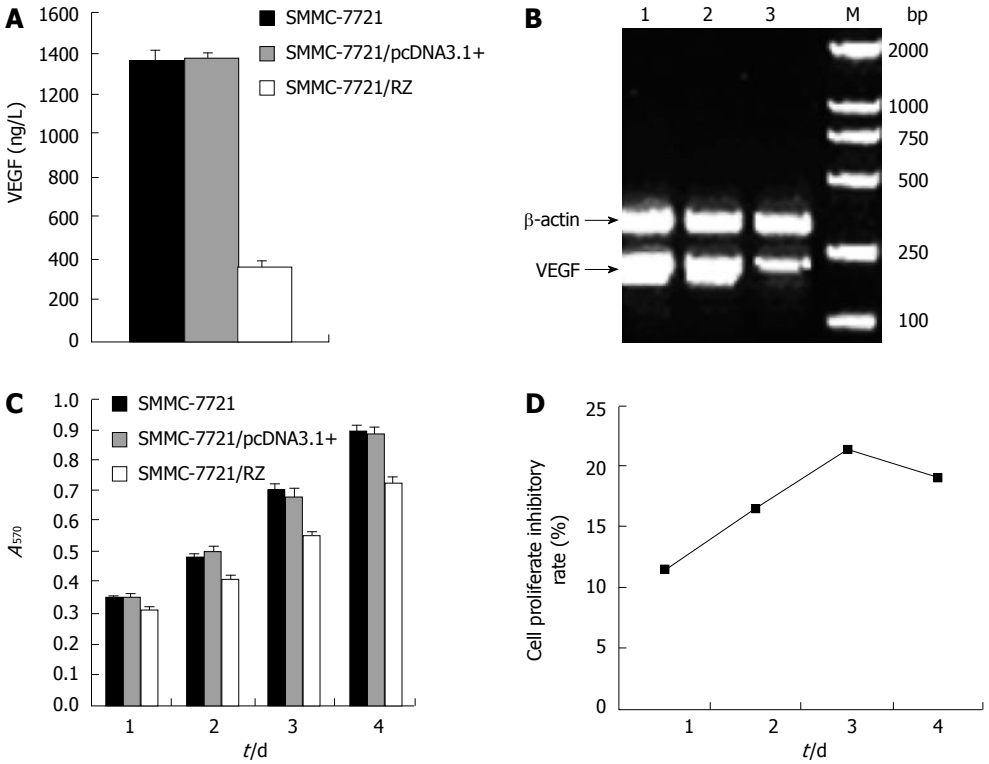


Figure 2 Effects of anti-hVEGF hairpin ribozyme on expression of VEGF and proliferation of SMMC-7721 cells *in vitro*. **A**: ELISA validation of VEGF expression; **B**: RT-PCR validation of VEGF mRNA transcription in SMMC-7721 group(1), SMMC-7721/pcDNA3.1+ group(2) and SMMC-7721/RZ group(3), (M: DL2000 marker); **C**: Influence of ribozyme on SMMC-7721 cell proliferation; **D**: Influence of ribozyme on inhibitory rate for proliferation of SMMC-7721 cells.

Formation and growth of xenografted tumor

To determine the impact of anti-hVEGF hairpin ribozyme on tumorigenicity *in vivo*, control and ribozyme-transduced cells were transplanted subcutaneously into BLAB/c nude mice. Histology and immunohistochemistry displayed different levels of VEGF expression and angiogenesis on sections of xenografted and control tumor tissues. As expected, tumors appeared on d 14 (± 6.3) and d 7 (± 2.6) in SMMC-7721/RZ group and SMMC-7721/pcDNA3.1+ group, respectively ($P < 0.01$). The ribozyme transgenic cells resulted in tumor formation with lower levels of VEGF expression and angiogenesis and delayed tumor formation on 17.2 ± 13.7 d compared with 8.6 ± 3.3 d in control cells ($P < 0.01$). Formation of large, red (vascular) tumors was observed in SMMC-7721/pcDNA3.1+ cells of all mice. However, formation of small white (avascular) tumors was found after inoculation with SMMC-7721/RZ cells. The tumor volume and weight at the time of sacrifice in SMMC-7721/RZ group (0.19 ± 0.0085 cm^3, 0.26 ± 0.076 g) were significantly lower than those in SMMC-7721/pcDNA3.1+ group (0.59 ± 0.019 cm^3, 0.74 ± 0.050 g, $P < 0.01$). The inhibitory effects of anti-hVEGF hairpin ribozyme on HCC xenograft growth in nude mice were comparable and significant ($P < 0.01$).

Histologic and immunohistochemical findings

As shown in Figure 3A, different shape and size of tumor cells were found in SMMC-7721/pcDNA3.1+ group. Their nuclei were large with a disproportional ratio of karyoplasm. Nuclear chromatin was condensed. Several basophilia chromatospherites were seen. Normal karyokinesis (8.26 ± 0.55/visual field) and pathologic karyokinesis (8.52 ± 0.17/visual field) were frequently observed. In contrast, the shape and size of tumor cells in SMMC-7721/RZ group were coincident. Nuclear chromatin was puff. Normal karyokinesis (3.18 ± 0.23/visual field) and pathologic karyokinesis (3.3 ± 0.37/visual field) were significantly less than those in SMMC-7721/pcDNA3.1+ group ($P < 0.01$).

Immunohistochemical staining showed VEGF as light brown particles. VEGF chromatosis was distinctly less or/and weaker in SMMC-7721/RZ group than in SMMC-7721/pcDNA3.1+ group (Figure 3B).

The control mice displayed well vascularized tumors. Tumor blood vessels and their wall were abundant in the control group. In SMMC-7721/RZ group, however, tumor blood vessels were seldom seen with vessel wall frame collapsed. As shown in Figure 3C, a significant difference in the relative intensity of immunostaining for anti-CD34 antibody (an endothelial marker) was observed between the SMMC-7721/RZ group and the control group, indicating that vascularization was decreased in SMMC-7721/RZ group after transfection of anti-hVEGF hairpin ribozyme. MVD in the sections was significantly lower in SMMC-7721/RZ group (3.82 ± 0.88) than in the control group (7.02 ± 0.14, $P < 0.01$).

DISCUSSION

It was reported that ribozyme is used to inhibit cellular targets[23-25]. Among them is the ribozyme-based therapeutics for cancer which might be devised to inhibit tumor growth or to prevent its metastasis. Compared to other gene technologies, the superiorities of ribozyme are as follows: (1) ribozyme has dual effects of cleavage and blockade, (2) it cannot be easily hydrolyzed by nucleic acid enzymes because it can bind to target RNA to

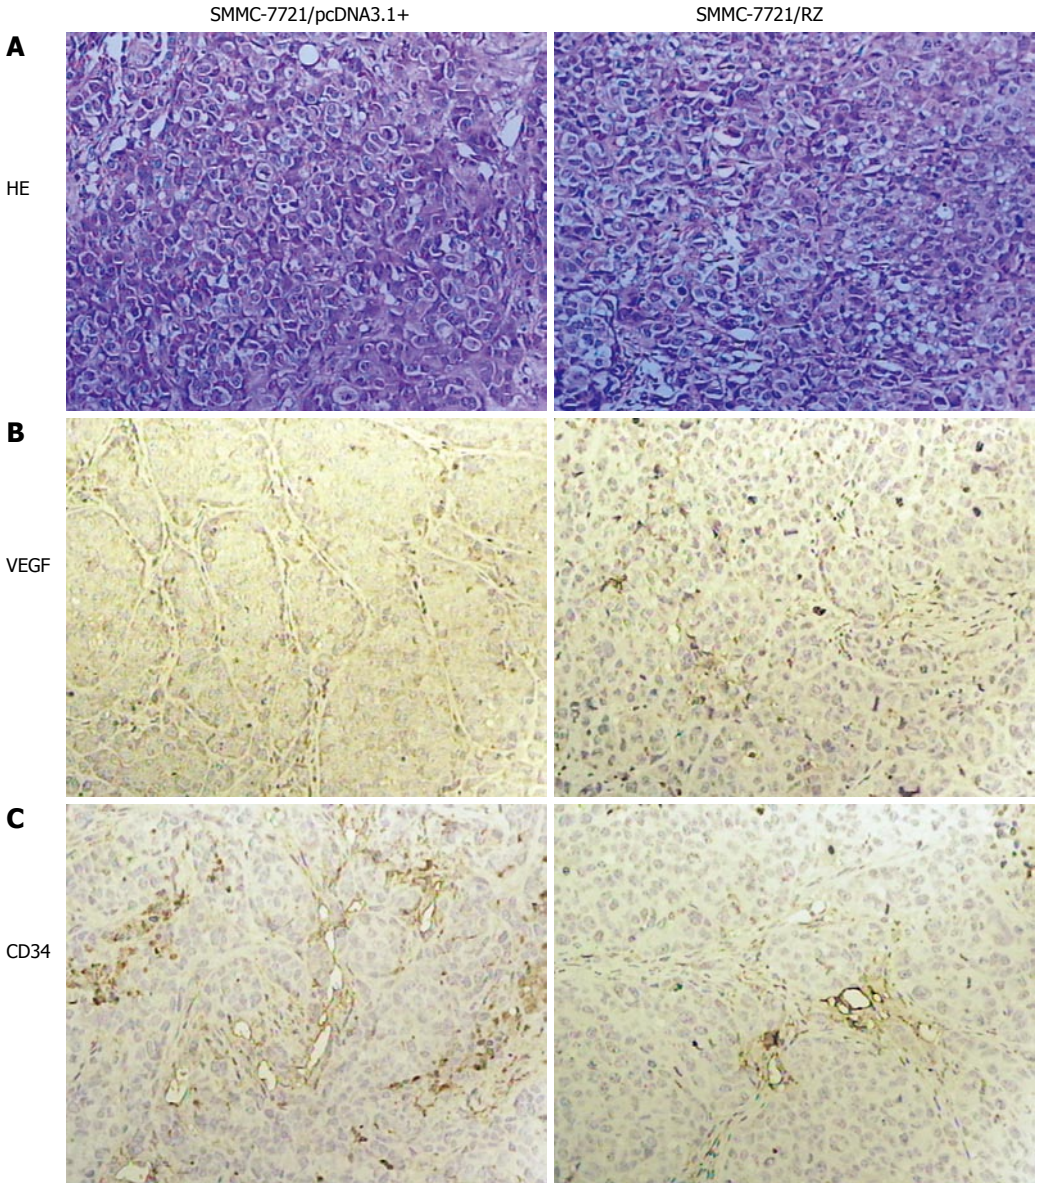

Figure 3 HE staining of tumor tissue (**A**), immunohistochemical staining of VEGF antibody (**B**) and CD34 antibody (**C**) for assay of their positive particles.

form a stable helix structure, (3) ribozyme molecule can destruct multiple target RNAs and be used repeatedly[26]. Biochemical characterization has shown that hairpin ribozyme is one of the most efficient ribozymes.

In order to devise effective anti-hVEGF hairpin ribozymes, we performed a sequence analysis of hVEGF mRNA and studied its secondary structure. We took into account the ideal site of hairpin ribozyme cleavage and its substrates in exon 3 of a GUC since this site is more easy for hairpin ribozyme to approach and less affected by the secondary structure. A fragment of the ribozyme gene and its sequence were verified by digestion of pcDNA3.1+/RZ with BamHI and EcoRI and sequencing. Our results show that the recombinant eukaryotic expression vector pcDNA3.1+/RZ could be successfully constructed. Stable integration and transcription of the ribozyme gene in SMMC-7721 cells were confirmed by PCR and RT-PCR. When introduced into hepatocarcinoma cell line SMMC-7721, anti-hVEGF hairpin ribozyme suppressed not only VEGF mRNA transcription but also VEGF protein expression. VEGF protein expression was inhibited by approximately 73% in SMMC-7721 cells transfected by ribozyme. These results reveal that the constructed ribozyme can selectively inhibit VEGF gene expression in human hepatocarcinoma cells. Ciafre *et al*[27] have developed an anti-VEGF hammerhead ribozyme targeting the 5' part of human VEGF mRNA. Transfection of U87 human glioblastoma cells with plasmid vectors encoding for this ribozyme resulted in a strong (-56%) reduction of VEGF secretion in the extracellular medium. We believe that our ribozyme has a better biological activity in selectively inhibiting VEGF expression. The successful use of ribozymes as therapeutic agent depends upon many factors, e.g., category of ribozymes (hairpin and hammerhead ribozymes), relative amount of active ribozymes in cells, their co-localization with target RNAs, structural features of transcripts influencing accessibility to specific target sites, catalytic efficiency, interaction of target RNAs with proteins, and intracellular stability of targeted RNAs and ribozymes.

Little is known about the role of VEGF in HCC cell proliferation, differentiation and tumorigenesis. One of the more intriguing aspects of our results is that after cells were cultured for 24, 48, 72 and 96 h, the proliferation

rate for SMMC-7721/RZ cells was significantly lower than that for SMMC-7721 cells and blank vector cells, and the inhibitory rate of ribozyme for the growth of SMMC-7721 cells was 21.4% on the third day. Apoptosis peak was detected by flow cytometry in SMMC-7721/RZ cells, the rate of apoptosis was 11.0% (data not shown), suggesting that the expression of anti-hVEGF hairpin ribozyme can significantly reduce VEGF secretion by transfected cells and inhibit cell growth and apoptosis in hepatocarcinoma cells. In other words, VEGF signaling can prolong the survival of HCC cells that may be independent of angiogenesis. Since Masood *et al*[28] reported that the expression of Flt-1 and KDR, the receptors of VEGF, is high in AIDS-Kaposi sarcoma cells and primary tumor tissues. Similar results have been observed in several tumors, by researchers in succession[29-31]. To inhibit VEGF expression or to block VEGF binding to its receptor results in growth inhibition of tumor cell lines, such as melanoma and ovarian carcinoma cell lines expressing VEGF receptors. In sharp contrast, cell lines not expressing VEGFRs show no response[28]. VEGF addition causes phosphorylation of mitogen-activated protein kinase as well as VEGF receptor, and induces proliferation and migration of lung cancer cells[32]. Our results are consistent with those previously observed. These findings suggest that tumor cells secrete VEGF which not only induces angiogenesis but also acts as an autocrine growth factor for carcinoma cells defined by the expression of VEGF receptors[33]. Our data suggest that HCC cells express specific VEGF receptors which respond to autocrine VEGF, thus activating signaling pathways that impede apoptosis and promote cell proliferation.

Because results on cell lines often represent a distorted and incomplete picture of the *in situ* physiopathology of cancer where the tumor microenvironment and neovascularization play a critical role in tumor growth and progression, we expanded our study to matched primary tumors using xenograft models. Oncogenicity is a critical index to judge malignant proliferation. The transfected SMMC-7721 cells were transplanted into nude mice. VEGF expression and microvascularization were distinctly decreased in SMMC-7721/RZ cell group when compared with SMMC-7721/pcDNA3.1+ cell group. Furthermore, tumor formation was delayed and its growth was significantly slowed down by ribozyme. Furthermore, reduced VEGF production induced by ribozyme resulted in higher cell differentiation, less cyto-heteromorphism and proliferation in the ribozyme transfected group, as demonstrated by microscopy, suggesting that VEGF is functionally related to cell differentiation directly or indirectly by regulating expression of certain genes. Our data reveal that VEGF plays a basic role in the induction of tumorigenicity, and underlines the importance of inhibiting its production. Moreover, Xu *et al*[34] found that down-regulation of VEGF gene by introducing anti-VEGF hairpin ribozyme gene into leukemia cell line K562 can alter the gene expression profiles. Among the 4096 gene clones on the microarray, 191 were detected to have the marked changes with 104 down-regulated and 87 up-regulated, showing that they are functionally related to cell cycle progression, gene replication, metabolism, cell apoptosis, cell signal transduction, and oncogenes[34]. All these findings indicate that VEGF is a key molecule for tumor progression, although it is unclear how VEGF expression regulates various genes.

In human hepatocarcinoma tumor xenograft experiment, although there was a significant difference in *P* value between the control and ribozyme groups, tumor formation was observed in the ribozyme group. To further decrease tumor formation, in combined with anti-VEGF ribozyme, it is necessary to explore ribozymes targeting other genes, which contribute to hepatocarcinoma tumorigenesis such as N- ras, C-myc and IGF-Ⅱ.

In conclusion, VEGF promotes tumorigenesis and angiogenesis, and anti-hVEGF hairpin ribozyme can efficiently inhibit the VEGF expression and growth of hepatocarcinoma *in vitro* and *in vivo*. In VEGFRs-expressing tumors such as HCC, VEGF inhibition may be attributed to inhibition of tumor angiogenesis and direct effects on tumor cell proliferation/survival. Anti-hVEGF hairpin ribozyme may be a candidate for HCC gene therapy. However, its clinical application needs further study.

COMMENTS

Background

Angiogenesis, known as the development and proliferation of new blood vessels, is vital for the growth of tumors. Vascular endothelial growth factor (VEGF) is an essential cytokine in the regulation of angiogenesis. Little is known about the role of VEGF in hepatocellular carcinoma (HCC) proliferation, differentiation and tumorigenesis. The present study was to study the effectiveness and mechanisms of anti-human VEGF (hVEGF) hairpin ribozyme on VEGF expression, oncogenicity and tumor growth in hepatocarcinoma cell line and xenografted model.

Research frontiers

HCC is a highly vascular tumor depending on neovascularization and insensitive conventional chemotherapeutics. It is important to explore antiangiogenesis methods for HCC. Hairpin ribozyme has been used in gene therapy.

Innovations and breakthroughs

To our knowledge, this is the first report that anti-hVEGF hairpin ribozyme can effectively inhibit VEGF expression and growth of hepatocarcinoma *in vitro* and *in vivo*. VEGF inhibition can inhibit tumor angiogenesis and tumor growth that may be dependent and independent of angiogenesis in HCC. Our results also suggest that VEGF is functionally related to cell proliferation, differentiation and tumorigenesis.

Applications

Anti-hVEGF hairpin ribozyme can be used as a therapeutic agent for hepatocarcinoma.

Terminology

Ribozymes: a group of catalytically active nucleic acids capable of site-specific cleavage of target mRNAs, thus decreasing mRNA expression and inhibiting the function of target gene.

Peer review

In this paper, the role of anti-VEGF hairpin ribozyme in antitumor and antigangiogenic activities is described. The experiments were well designed. The data support that VEGF plays its role through angiogenesis and other pathways directly leading to carcinoma.

Abstract

Pancreatic cancer is an aggressive malignancy, relatively resistant to chemotherapy and radiotherapy, which usually presents late. Disease specific mortality approaches unity despite advances in adjuvant therapy. We present the first reported case of complete pathological response following neoadjuvant therapy in a locally advanced pancreatic adenocarcinoma.

Key words: Chemotherapy; Pancreatic cancer; Pathology

INTRODUCTION

Pancreatic cancer is an aggressive intra-abdominal malignancy and approximately 3000 new cases are diagnosed each year in the United Kingdom, most of them usually present with advanced pancreatic cancer and only 10%-20% of patients are resectable at presentation. Surgery with complete resection of the primary lesion offers the only chance of long term survivorship and cure in this cohort of patients. For locally advanced pancreatic cancer, several chemotherapeutic and combined modality regimens have been described, generally with conflicting results, poor response rates, high toxicity, not changing the natural history of the disease. Several novel and new regimens are being tried in the neoadjuvant setting in patients with locally advanced pancreatic cancer at presentation in the hope of down-staging the disease and rendering it resectable. We present the first case of complete pathological response following down-staging chemotherapy.

CASE REPORT

A 69-year-old man presented with nausea, anorexia and weight loss. On investigation, he was diagnosed to have locally advanced adenocarcinoma of the pancreas encasing the superior mesenteric artery and vein with enlarged peri-pancreatic and aortocaval nodes (Figure 1). Final staging after endoscopic ultrasound was T4N1M0. The patient had a past medical history of aortic stenosis and atrial fibrillation for which he took diltiazem daily. Shortly after diagnosis he developed obstructive jaundice which was relieved by an endobiliary stent, which failed to achieve adequate drainage, following which he underwent a double bypass in the form of a gastrojejunostomy and hepatojejunostomy.

After a CT guided biopsy which confirmed invasive adenocarcinoma of the pancreas, he commenced chemotherapy with gemcitabine in combination with oxaliplatin. Upon completion of two cycles of chemotherapy, gemcitabine was replaced with capecitabine due to drug interaction causing breathlessness and he underwent 9 cycles of chemotherapy on the new regime. During chemotherapy surveillance cross-sectional imaging suggested stable disease with normal serum CA19-9 levels. After a 4-wk break he further had 6 cycles of the above combination chemotherapy.

Eighteen months from the initial diagnosis surveillance scans demonstrated good local response to the combination chemotherapy without any distant metastatic disease and he was referred for consolidation radiotherapy, of which he had a total of 25 fractions, which he tolerated well and CT scans suggested further reduction in the disease which now looked resectable (Figure 2).

Based on the remarkable response the patient underwent surgery with curative intent in the form of pancreatoduodenectomy approximately 2 years after his initial diagnosis from which he made an uneventful recovery. Histopathology review of the resected specimen showed a complete response with no evidence of the original invasive adenocarcinoma. A follow-up CT scan at 4 mo as shown did not demonstrate any evidence of recurrent disease.

Figure 1 Initial CT scan showing the inoperable mass in the pancreatic head.

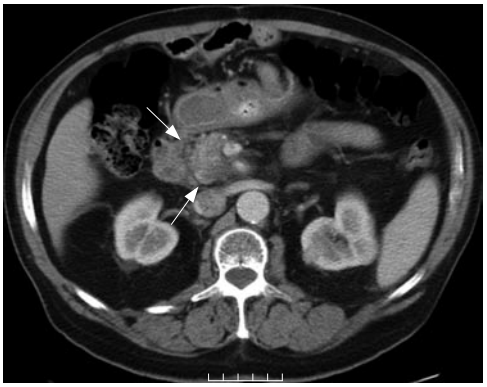

Figure 2 CT scan after completion of chemotherapy showing the operable disease.

DISCUSSION

Pancreatic cancer remains a formidable challenge to clinicians and carries a tumour specific mortality of nearly 100%[1]. Complete resection offers the only hope of cure but is applicable to the minority of patients that present with resectable disease. Approximately 10%-20% of patients present with locally advanced pancreatic cancer without evidence of distant metastatic spread at the time of diagnosis. Prior to the use of neoadjuvant therapy these patients were denied surgery with curative intent and had very short survival times after diagnosis.

Several neoadjuvant regimens have been described to try and downstage locally advanced pancreatic cancer and chemoradiation here is considered as an induction therapy to reduce tumour volume, lymph node disease and extent of vascular involvement[2-5]. In locally advanced pancreatic cancer, complete remissions have not yet been described[6]. Neoadjuvant therapy has its own intrinsic advantages in that it theoretically increases vulnerability of cancer cells because of intact vasculature, better tumour cell oxygenation and probability of sterilizing cells at the resection margin. It also affords a test of the biology of the disease in that patients with progressive disease on chemotherapy can be spared an exploratory laparotomy and trial dissection and managed along the palliative pathway. The risk of pancreatic fistula also seems to be decreased in previously irradiated field[7].

Several regimens have been described and utilized in the neoadjuvant setting for locally advanced pancreatic cancer in an attempt to induce regression of the disease and render it resectable with conflicting results[8]. 5-FU based regimens were originally described but had poor response rates and eventually gave way to gemcitabine based regimens[9]. Combined modality treatments using gemcitabine in combination with other agents like capecitabine, oxaliplatin, bevacizumab and irenotecan have shown promise with prolonged progession-free intervals and better response rates[10-12]. In these settings gemcitobine is used as a radiation sensitizer and combination with external beam radiotherapy remains a popular regimen[13].

Complete pathological response remains an elusive goal in this subset of patients who may then be offered a pancreatoduodenectomy with the aim of long term surviviorship or cure, who if untreated have a very short life expectancy. The future of combined modality therapy for locally advanced pancreatic cancer will focus on the development of newer biological agents that target specific alterations in the cancer cells including vascular endothelial growth factor, epidermal growth factor and matrix metallo protineases[14,15].

In conclusion, complete pathological response following down-staging chemotherapy is possible in patients with locally advanced pancreatic cancer and may offer the patient a chance at long term survival or cure.

Abstract

This report describes a rare case of metastatic hepatocellular carcinoma (HCC) presenting a huge mass in the left external auditory canal (EAC). The patient was a 55-year-old man with hepatitis B virus-related HCC. He presented to our department with a three-month history of increasing left otalgia, and hearing loss with recent fresh aural bleeding. Histopathologic examination indicated that the tumor was secondary to HCC. Although external irradiation was not effective, the tumor was treated with surgical debulking and high dose rate 192 Ir remote afterloading system (RALS) for postoperative intracavitary irradiation. A review of the literature revealed only five other cases of HCC metastasis to the temporal bone, all of which mainly metastasized in the internal acoustic meatus. The present case is the first report of HCC metastasis to the EAC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a very highly invasive tumor that metastasizes hematogenously and lymphogenously to distant sites. Most frequently affected sites are the lungs, regional lymph nodes, bones, and adrenal glands[1]. However, external auditory canal (EAC) metastases from HCC are extremely rare. A review of the literature revealed only five other cases of HCC metastasis to the temporal bone, all of which mainly metastasized in the internal acoustic meatus[2-4]. To the best of our knowledge, the present patient is the first case of HCC metastasis to the EAC.

We report here a rare case of bleeding due to EAC metastasis from HCC. The patient was treated with surgical debulking and high dose rate ^{192}Ir remote afterloading system (RALS) for postoperative intracavitary irradiation.

CASE REPORT

A 55-year-old man presented to our department with a three-month history of increasing left otalgia, and hearing loss with recent fresh aural bleeding, in April 2006. He denied any vertigo, and had no evidence of facial palsy. His past medical history revealed that hepatitis B virus-related HCC was diagnosed two years ago. Owing to the tumor's inoperability and the presence of lung metastases, the patient began systemic chemotherapy with 5-fluorouracil and cisplatin, which was maintained for two years.

Physical examination did not find the left tympanic membrane, because the EAC was completely occupied by a tumor. Right-sided otoscopy was normal. Vestibular examination was unremarkable. There was no lymphadenopathy, and the remainder of the head and neck and neurologic examinations was unremarkable.

Magnetic resonance imaging showed a well-enhanced tumor lesion within the left EAC. T1- and T2- weighted images revealed that the EAC lesion exhibited a mixture of hypointensity and hyperintensity (Figure 1A). CT imaging showed tumor formation on the posterior wall of the EAC, and a shallow bony erosion (Figure 1B).

A biopsy was performed, and pathologic examination

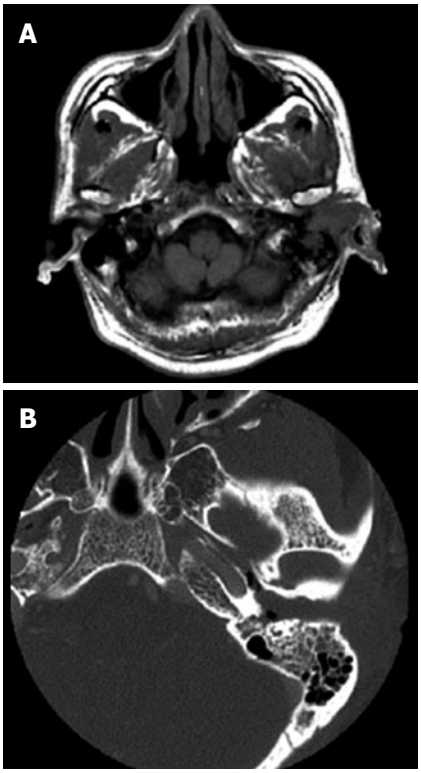

Figure 1 Axial T1-weighted magnetic resonance image of the head showing a huge mass in the left EAC with extension of the lesion into the mastoid (**A**), and axial CT of the temporal bone demonstrating the mass occupying the left EAC (**B**).

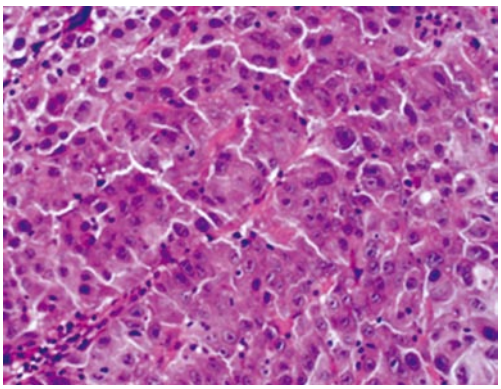

Figure 2 Microscopically, the lesion in the external auditory canal is composed of proliferating atypical epithelial cells forming a solid and thick trabecular arrangement with necrosis, and a fibrous stroma (hematoxylin/eosin stain, x 400).

Figure 3 Angiography showing hypervascularity in the left external auditory canal supplied by the posterior auricular artery (the arrow indicates the tumor stain).

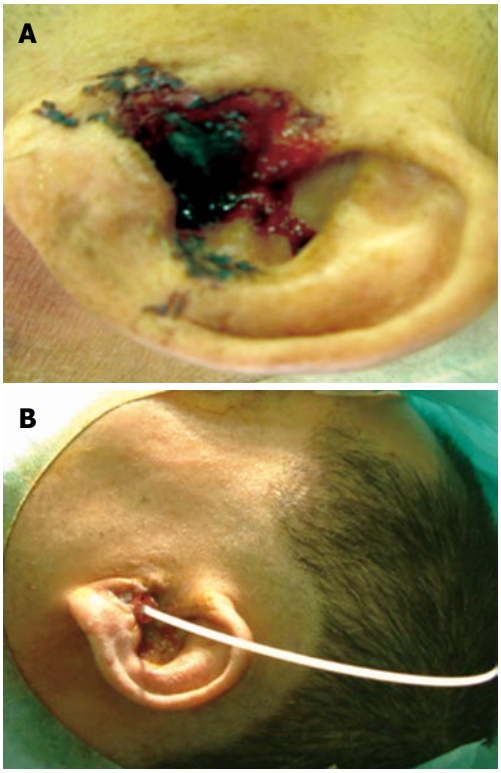

Figure 4 Metastatic hepatocellular carcinoma protruding from the left external auditory canal (**A**) and inserted and fixed catheter for the ^{192}Ir remote afterloader system in the left external auditory canal after debulking surgery (**B**).

taken through the EAC suggested metastasis of HCC with histopathologic features similar to the primary lesion (Figure 2). The biopsy of the mass produced much bleeding, which was stopped with local pressure.

First, the patient received external irradiation (total dose, 30 Gy) to treat the EAC lesion. Despite the external irradiation therapy, the tumor increased in size, and was continuously bleeding. Therefore, it was decided to change the treatment from external irradiation to surgical debulking and ^{192}Ir RALS. We planned to proceed with the debulking surgery for the progressive disease followed by transcatheter arterial embolization by means of superselective catherization.

Angiography was performed to delineate blood supply to the mass, and to embolize any feeding vessels. The external carotid artery was cannulated via the femoral artery, using the Seldinger technique. Evidence of vascular blush in the region of the left EAC was observed, and the posterior auricular artery was identified for embolization (Figure 3).

Following angiography, surgical debulking was performed under general anesthesia and a 6-Fr catheter for the ^{192}Ir remote afterloader system was inserted into the left EAC (Figure 4A and B). A total dose of 15 Gy (10 Gy/Fr/wk) was given over a one-week period. When the irradiation treatment was completed in May 2006, otoscopy revealed tumor remission. Neither radiation-induced dermatitis nor otitis media with effusion was observed. Although the patient remained clinically free of disease in his left EAC (Figure 5), he died of progressive liver failure and lung metastases from HCC 9 mo after the treatment.

DISCUSSION

HCC is the most common malignant tumor of the

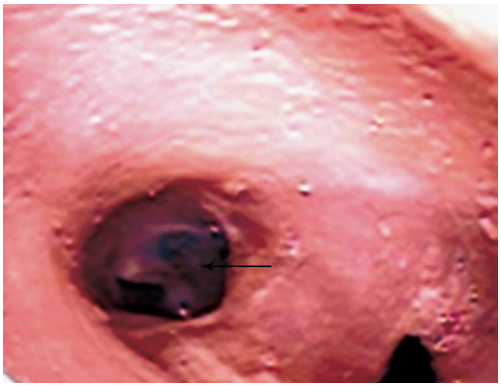

Figure 5 Fiberscopy of the external auditory canal 6 mo after treatment showing no evidence of residual tumor (the arrow indicates the left tympanic membrane).

liver. Intrahepatic metastases occur early in the disease, and more than half of these tumors metastasize to extrahepatic sites[5]. Autopsy and surgical series have suggested the presence of metastases from HCC in the lungs (18.1%-49.2%), lymph nodes (26.5%-41.7%), bones (4.2%-16.3%), and adrenal glands (8.4%-15.4%)[6-8]. However, reports on metastases from distant primary malignancies to different sites in the ear including EAC, are uncommon. The temporal bones are among the more common sites of the ear to develop metastases from distant malignancies[9]. Gloria-Cruz *et al*[4] reviewed the autopsy records of 864 cases, and reported that 47 of 212 patients (22%) with primary non-disseminated neoplasms had metastatic diseases involving the temporal bones. The primary site of the majority of metastases to the temporal bones is the breast (21%), followed by the lungs (12%), kidneys, and prostate, and only three patients (6%) showed histologic features consistent with HCC[4]. No other study has reported HCC metastasis to the EAC. To the best of our knowledge, the present patient is the first case of HCC metastasis to the EAC.

To treat metastatic tumors including HCC of the EAC, curative surgical resection is sometimes impossible, radiation therapy and chemotherapy can be considered as palliative therapies. Although external irradiation was performed in the present case, it was not effective, and the tumor was continuously bleeding. Therefore, we attempted surgical debulking and ^{192}Ir RALS as postoperative irradiation. As a result, fiberscopy after treatment confirmed the effectiveness and safety of this combined procedure. In general, side effects of conventional external irradiation to the auditory canal include many complications such as external canal stenosis, otitis media with effusion, cholesteatoma, sensorineural hearing loss, vestibular impairment, facial nerve paralysis, and osteoradionecrosis. However, none of these complications was observed in this case.

^{192}Ir RALS is the best choice of treatment to ensure decreased doses to other important organs such as the tympanic membrane, temporal bone, and carotid artery while providing a curable dose to a target volume in EAC tumors[10]. In addition, this treatment can be performed in a short period, without any invasive procedure, and may become a choice of modality for its efficacy and less severe side effects.

In conclusion, a rare patient with EAC metastasis from HCC can be treated with surgical debulking and high dose rate ^{192}Ir RALS for postoperative intracavitary irradiation. This combined treatment can be used as a palliative modality for such patients.

Abstract

We report a case of decompensated porto-pulmonary hypertension closely associated with the development of intra-portocaval shunt thrombosis. A woman with Laennec's cirrhosis was hospitalized because of severe dyspnea and edema. She underwent surgical portocaval anastomosis ten years ago. Imaging studies showed massive intra-shunt thrombosis, portal hypertension, ascites, pleuro-pericardial effusions and enlargement of right cardiac cavities. Cardiac catheterization allowed to rule out coronary and left-sided heart abnormalities and led to the diagnosis of pre-capillary pulmonary hypertension. Antithrombotic treatment with low molecular weight heparin was instituted. The management also included ACE inhibitors, spironolactone, low-salt diet and lactulose. The patient was discharged and three months later we observed the disappearance of edema, ascites and pleuro-pericardial effusions, a marked body weight reduction and improved dyspnea and liver function tests. A possible link between the development of intra-shunt thrombosis and clinical decompensation in our patient was hypothesized. In fact, it has been demonstrated that the increased portal pressure, caused by occlusion of portosystemic shunt, reduces renal plasma flow and increases systemic endothelin-1 concentration. In our patient the disappearance of edematous state and improved dyspnea observed after recanalization of the shunt strongly support this hypothesis.

INTRODUCTION

Porto-pulmonary hypertension (PPHT) refers to the development of pulmonary arterial hypertension in the setting of portal hypertension with or without chronic liver disease and is defined by a mean pulmonary artery pressure > 25 mmHg in the presence of normal pulmo-capillary wedge pressure (< 15 mmHg)[1,2]. The pathogenesis of PPHT is under investigation, although histopathologic features are similar to those found in primary pulmonary hypertension[3]. A current study supports the hypothesis that pulmonary vasculature may be exposed to either cytokines or excess circulating vasoconstrictors, such as endothelin-1 (ET-1) produced by the diseased liver[4]. Although the vast majority of patients with PPHT are asymptomatic, dyspnea is the most frequent presenting symptom[5].

CASE REPORT

A 39-year-old obese woman with Laennec's cirrhosis (Child-Pugh B) was admitted to our hospital in January 2003 because of the recent onset of dyspnea (NYHA IV), dependent edema and abdominal pain. In 1991, she underwent surgical side to side portocaval shunt for refractory ascites and since then she has never complained of dyspnea or edema. Physical examination showed platypnea, arterial blood gas analysis showed hypoxaemia (pO2: 63 mmHg) with orthodeoxia (pO2: 49 mmHg). On admission, liver function tests were as follows: total bilirubin: 84.5 μmol/L, AST: 1.14 μkat/L, ALT: 0.55 μkat/L, GGT: 87 U/L, alkaline phosphatase: 4.2 nkat/L, serum albumin: 28 g/L, ammonia (as NH3): 88 μmol/L, prothrombin time 60%. Hepatic ultrasonography with Doppler imaging showed massive intra-shunt thrombosis, portal hypertension (18 mmHg) and mild ascites. No gastroesophageal varices were found by digestive endoscopy. D-dimer level was 1.4 mg/L and antithrombin activity was 43%. The presence of both peripheral venous thrombosis and recurrent microembolism was ruled out by Doppler ultrasonography and ventilation-perfusion lung scan. Computerized tomography confirmed recent intra-shunt thrombosis and showed also pleuro-pericardial effusions and ascites. Markers of autoimmunity were negative.

Right atrial and ventricular enlargement with severe

Table 1 Hemodinamic parameters during cardiac catheterization

Aortic pressure (mmHg)	103-76 (mean 85)
Right atrial pressure (mmHg)	11 (mean)
Right ventricular pressure (mmHg)	70-18 (mean 35)
Pulmonary arterial pressure (mmHg)	70-30 (mean 43)
Pulmonary capillary wedge pressure (mmHg)	10
Cardiac output (l/min)	5.43
Cardiac index (l/min per m^2)	2.83
Total pulmonary resistance (dyn•s/cm^5)	632
Pulmonary vascular resistance (dyn•s/cm^5)	488
Systemic vascular resistance (dyn•s/cm^5)	1088

tricuspidal regurgitation was also detected by echocardiography. Systolic pulmonary arterial pressure, as measured by Doppler analysis, was 50 mmHg. Cardiac catheterization showed no coronary and left-sided heart abnormalities. Hemodynamic parameters (Table 1) led to the diagnosis of moderate precapillary pulmonary hypertension. Antithrombotic treatment with low molecular weight heparin was instituted. The treatment also included ACE inhibitors, spironolactone, insulin, low-salt diet (2 gr pd) and lactulose. This management decreased the retention of sodium and water in the kidney from 12 mEq/d on admission to 186 mEq/d after 3 d of treatment, and improved edema, as demonstrated by natriuresis. The patient was discharged one month later with the above-mentioned prescription and, after three months of follow-up, physical examination showed the disappearance of edema, marked weight reduction (20 kg) and improved dyspnea (NYHA II). Liver function tests were as follows: total bilirubin: 15.3 μmol/L, AST: 0.56 μkat/L, ALT: 0.47 μkat/L, GGT: 36 U/L, alkaline phosphatase: 1.85 nkat/L, serum albumin: 30 g/L, ammonia (as NH3): 76 μmol/L, prothrombin time 67%. Abdominal ultrasonography showed recanalization of porto-caval shunt, disappearance of ascites and right pleural effusions. No pericardial effusions were found by ecocardiography. Antithrombin activity was 56%, D-dimer 0.2 mg/L. Orthotopic liver transplantation was excluded because of the high intra-operative mortality in patients with portopulmonary hypertension and the conflicting results reported in this condition[6]. Therefore, the patient was referred to a specialized center in order to start an appropriate vasodilatory therapy, which appears to be the only feasible treatment.

DISCUSSION

This case report suggests a possible link between the development of intra-shunt thrombosis and clinical decompensation in our patient. In fact, a recent study showed that increased portal pressure caused by occlusion of porto-systemic shunt reduces renal plasma flow, leading to renal sodium and water retention, and increases systemic ET-1 concentration[4]. In our patient, disappearance of edema and improved dyspnea, observed after recanalization of the shunt, strongly support this hypothesis, although further experience with similar cases is needed.

Abstract

Malignant fibrous histiocytoma (MFH) is a pleomorphic mesenchynal sarcoma. It is uncommonly arises primarily from the intra-peritoneal cavity. Primary peritoneal MFH with tumor bleeding and rupture is rare. We describe the imaging features of a 70-year-old patient presenting with ruptured hemorrhagic peritoneal MFH at subhepatic area, accompanied by massive hemoperitoneum, mimicking a ruptured pedunculated hepatocellular carcinoma. Computed tomography (CT) revealed a large heterogeneous enhanced subhepatic mass with adjacent liver, gallbladder and colon invasion. Tumor hemorrhage and rupture complicated with peritoneal seeding and massive bloody ascites were also detected. Angiography showed a hypervascular tumor fed by enlarged right hepatic arteries, cystic artery and omental branches of gastroepiploic artery. The patient underwent laparotomy for tumor resection, but the tumor recurred one month after operation. To our knowledge, the CT appearance of ruptured intraperitoneal MFH complicated by hemoperitoneum has not been previously described.

INTRODUCTION

Massive hemoperitoneum is an emergent life-threatening condition requiring prompt management. Tumor-associated hemoperitoneum is commonly related to hypervascular intra-abdominal visceral organ tumor rupture, but rarely related to hemorrhage of the hypervascular tumor of primary peritoneal origin. Malignant fibrous histiocytoma (MFH) is the most common sarcoma at late adult life. About 5%-10% of MFH lesions arise from the peritoneal cavity[1], and may develop various degrees of tumor bleeding[1-3]. Herein, we present a case of spontaneously bleeding peritoneal MFH located in the subhepatic area with direct liver invasion presenting as massive hemoperitoneum, mimicking a ruptured pedunculated hepatocellular carcinoma.

CASE REPORT

A 70-year-old man was admitted to the emergency department because of intensifying abdominal pain of a 10-days' duration with aggravation in the recent two days before admission. The patient also complained of body weight loss. Physical examination revealed a pallid face, orthopnea and a distended abdomen with a palpable tender mass in the right upper to middle quadrant of the abdomen. Pulse rate and blood pressure were normal. Mild anemia (hemoglobin of 130 g/L), leukocytosis (white blood cell count 16.83 × 10^9/L) and elevated C-reactive protein (247 mg/L) were also noted. Other laboratory data were unremarkable. Serological tests were negative for hepatitis B and positive for hepatitis C. The serum levels of tumor markers of alpha-fetoprotein, CEA and CA19-9 were within normal limits.

Abdominal sonography revealed a large mixed hyperechoic and hypoechoic mass at the hepatic right lower region with massive ascites. Abdominal paracentesis revealed bloody ascites, with an erythrocyte count of 100 000/mm^3. Computed tomography (CT) depicted a large ill-defined hemorrhagic mass (approximately 7.5 cm × 8.6 cm × 12.4 cm in size) with heterogeneous enhancement involving segments V and VI of liver with large extra-hepatic components in the peritoneal cavity accompanied with massive bloody ascites (Figure 1). The subhepatic mass also compressed and invaded the gallbladder and adjacent hepatic flexure of colon. Enlarged omental arteries were found surrounding the subhepatic mass (Figure 1). Tumor rupture with irregular tumor margin and peritoneal seeding were also present.

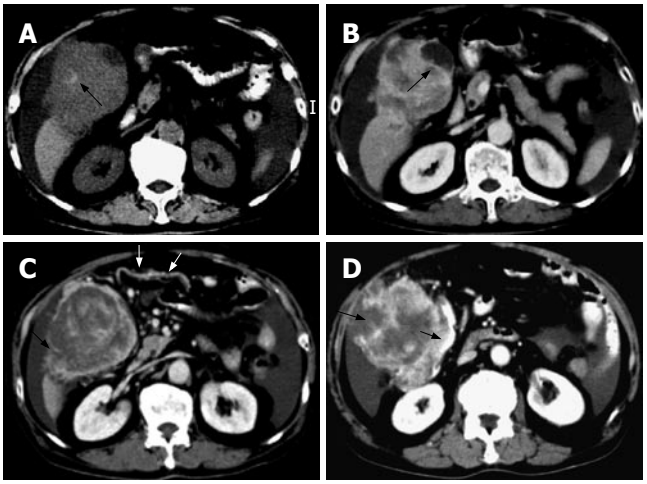

Figure 1 A 70-year-old man with hemorrhagic peritoneal malignant fibrous histiocytoma located subhepatically and presenting as massive hemoperitoneum. **A**: Pre-enhanced computed tomography shows a high-density intra-lesional hemorrhage (black arrow) within the subhepatic tumor involving the anterior aspect of segment V and VI of liver. Ascites are also noted; **B**: Post-enhanced CT shows heterogeneous enhancement of the subhepatic mass directly invading the gallbladder (black arrow); **C**: Post-enhanced CT study at a lower level shows enlarged omental branches (white arrows) of the gastroepiploic artery supplying the subhepatic tumor. A cleavage plane (black arrow) between the subhepatic mass and the liver tip parenchyma was identified, suggestive of an extra-hepatic origin of the mass; **D**: Post-enhanced CT study at the lower tumor level reveals the large subhepatic mass directly invades the adjacent hepatic flexure of colon (thick black arrow). Tumor rupture with irregular tumor margin (thin black arrow) is also evident.

A presumptive diagnosis of pedunculated hepatocellular carcinoma rupture was made. Therefore, emergent angiography was performed and disclosed a large hypervascular tumor located at the right subhepatic region, supplied by enlarged right inferior hepatic arteries, cystic artery, and omental branches of gastroepiploic artery (Figure 2). Transarterial embolization with gelfoam pieces was performed to achieve hemostasis for these engorged feeding arteries.

Six days later, the patient underwent laparotomy for radical tumor excision. Intraoperative examination revealed a large bleeding peritoneal subhepatic tumor rupture with contiguous omentum, liver, gallbladder and colon invasion. Peritoneal seeding and 3 L bloody ascites were also found. Pathology of the excised specimen revealed a storiform-pleomorphic malignant fibrous histiocytoma with marked hemorrhage and necrosis.

One month after the operation, the patient was readmitted to the emergency department due to massive upper gastrointestinal bleeding. CT revealed multiple hepatic and peritoneal metastases with duodenal involvement. Panendoscopy confirmed the duodenal invasion by the recurrent tumor causing internal bleeding. Despite intensive fluid supplementation and blood transfusion therapy, the patient died of hypovolemic shock 3 d later.

DISCUSSION

MFH is a pleomorphic sarcoma initially described by O'Brien and Stout[4]. It is the most common sarcoma in late adulthood, with a peak incidence in the fifth and sixth decades. Men are affected twice as frequently as women. MFH is microscopically characterized by areas of spindle cells arranged in a storiform pattern, and pleomorphic areas with haphazardly arranged sheets of fibroblasts and histiocytes. This neoplasm has a variety of histologic subtypes, including storiform-pleomorphic, myxoid, giant cell, inflammatory and angiomatoid. MFH generally affects the extremities and retroperitoneum. Uncommon locations include the head and neck region, dura mater, brain, lung, heart, aorta, pancreas, liver, spleen, breast, intestine and mesentery[1,5,6]. The propensity of MFH for invasion of contiguous organs and local recurrence result in its poor prognosis.

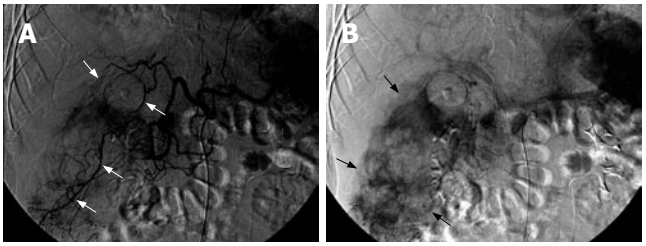

Figure 2 **A**: Arterial phase image of the celiac arteriogram shows hypertrophied right inferior hepatic arteries, cystic artery and omental branches of gastroepiploic artery (white arrows) supplying the hypervascular subhepatic mass; **B**: Venous phase shows prominent tumor stains in the peripheral portion of the huge subhepatic mass (black arrows).

The radiographic features of MFH are non-specific. On CT, FMH usually presents as a poorly demarcated or a well circumscribed mass, and exhibits peripheral solid enhanced component with intralesional hypodense areas of myxoid change, hemorrhage or necrosis. Although the vascularity of MFH is variable, the majority of lesions are moderately hypervascular with tumor supply derived from multiple surrounding vessels[1,7]. Because of the rich vascularity of the lesion, preoperative transarterial embolization may be considered to shrink the tumor and minimize intraoperative hemorrhage.

MFH can develop variable degrees of tumor hemorrhage either spontaneously or as a result of response to chemotherapy[1,8]. Approximately 5% MFHs will develop apparent intra-tumoral hemorrhage spontaneously, especially when MFH arises from the peritoneum or omentum[1]. The intratumoral hemorrhage can be so extensive as to obscure the underlying neoplasms and create a large cyst-like space that might be mistaken as a hematoma, abscess or cystic tumor. Previous reports described that intra-peritoneal MFHs situated at the mesovarium and gastrocolic ligament with marked intra-tumoral hemorrhage manifested as large cystic tumors, causing diagnostic confusion[2-3]. Nevertheless, these intra-peritoneal MFH lesions with extensive tumor hemorrhage were still confined to the tumor mass itself, rather than complicated with extra-tumoral bleeding into the peritoneal cavity. However, in the present case, the subhepatic peritoneal MFH not only experienced intra-tumoral hemorrhage but also developed tumor rupture with extra-tumoral bleeding into the peritoneal cavity, mimicking a ruptured hepatocellular carcinoma. Three previous cases of MFH causing extra-tumoral massive bleeding had

been reported, all involving metastatic MFH lesions at the alimentary tract causing gastrointestinal bleeding[9-11]. A case of post-irradiation induced dermal MFH with spontaneous tumor hemorrhage, causing massive skin bleeding had also been reported[12]. Another case of primary aortic MFH presenting as aortic dissection was described as well[13]. However, to the best of our knowledge, intra-peritoneal MFH bleeding complicated with massive hemoperitoneum causing acute abdominal emergency has not been previously reported.

Tumor-associated hemoperitoneum is frequently related to rupture of underlying intra-abdominal hypervascular tumors. Hepatocellular carcinoma (HCC) rupture is the most common cause of tumor-associated hemoperitoneum in male patients of all ages in Asia and Africa, especially patients with large and peripherally located tumors. Compared to the incidence of intraperitoneal visceral organ tumor rupture causing hemoperitoneum, the occurrence of primary peritoneum-origin tumor bleeding presenting with hemoperitoneum is rare. A review of the literature found only one similar case report which described a hypervascular peritoneal hemangiopericytoma with spontaneous tumor bleeding causing a small amount of hemoperitoneum[14]. By contrast, in our present case, large amounts of bloody ascites were found, indicating that the MFH had tumor rupture with active tumor bleeding rather than minimal tumor bleeding only.

In the present case, CT showed that the vast majority of subhepatic tumor was situated in the extra-hepatic peritoneal cavity and the center of the mass was outside of the liver parenchyma. These findings suggest that the subhepatic mass may be a tumor of extra-hepatic origin rather than arising from the liver parenchyma. Furthermore, the subhepatic tumor was large enough not only to compress but also to directly invade the liver and gallbladder. However, the subhepatic tumor and the compressed liver tip parenchyma still exhibited negative "beak sign" on CT study, seen as an obtuse angle between the subhepatic mass and the compressed liver tip surface with partially preserved dull edges of the liver. These findings suggest that the subhepatic mass did not arise from the liver. Moreover, a cleavage plane between the subhepatic mass and the compressed lower-most liver tip parenchyma was also identified as negative "embedded organ sign" on CT scan, indicating the subhepatic mass was compressing the liver, but did not arise from the liver. In addition, CT also revealed enlarged omental arteries supplying the subhepatic mass, presenting as "prominent feeding artery sign". This suggests the subhepatic mass may be a tumor of peritoneal omentum origin. Angiography also confirmed the subhepatic tumor was mainly supplied by multiple enlarged omental arteries, whereas the hepatic artery only accounted for a minority of tumor feeding. Advanced HCC with omentum invasion can develop extra-hepatic collateral vessels from the omental branches of the gastroepiploic artery, but HCC usually still preserves its dominant feeding arteries from the hepatic artery rather than from the extra-hepatic omental artery. The more prominent blood supply from the omental arteries than the hepatic artery in the present case is an unusual phenomenon in HCC. Careful analysis of the CT imaging features of this case indicate that a subhepatically located bleeding peritoneal tumor with liver invasion should be taken into account as a possible cause of peri-hepatic tumor complicated with hemopertitoneum. Since MFH is the most common sarcoma in the elderly, primary peritoneal MFH, although rare, should be included among the causes of tumor-related hemoperitoneum. However, the radiographic features of MFH are indistinguishable from those of other peritoneal malignant neoplasms, such as leiomyosarcoma, gastrointestinal stromal tumor, fibrosarcoma or angiosarcoma.

In conclusion, MFH arising from the peritoneal subhepatic region is rare, but the potential exists for a hemorrhagic peritoneal sarcoma to directly invade adjacent organs, mimicking an exophytic hepatic tumor rupture. The possibility of MFH should be carefully considered when a patient presents with a hemorrhagic subhepatic tumor and no prior documented hepatitis episode and liver cirrhosis.

Abstract

Eosinophilic enteritis, a relatively rare entity, usually involves gastric antrum or proximal small bowel. Our case is rarer in its involvement of the distal small bowel and presents unusually as intussusception. The disease if diagnosed in the initial stages responds well to medical treatment but if associated with complications or misdiagnosed, surgical modality is the treatment of choice. In our case, the patient presented with acute intestinal obstruction due to intussusception and emergency laparotomy with ileoileal anastomosis was done. Histopathology confirmed the diagnosis as eosinophilic enteritis. This case with such a presentation is discussed here.

Key words: Eosinophilic enteritis; Intussusception; Intestinal obstruction; Eosinophils; Ileoileal

Kshirsagar AY, Jagtap SV, Kanojiya RP, Langade YB, Shinde SL, Shekhar N. Eosinophilic enteritis presenting as a rare cause for ileo-ileal intussusception. *World J Gastroenterol* 2007; 13(47): 6444-6445

http://www.wjgnet.com/1007-9327/13/6444.asp

INTRODUCTION

Eosinophilic enteritis is a rare, poorly understood condition presenting with a bizarre spectrum of unexplained symptoms mimicking any other acute abdominal conditions. Diagnosis initially is based on exclusion of other abdominal conditions though ultimately histopathology is definitive. The majority of patients respond to medical treatment but if associated with complications like obstruction, perforation, intussusception *etc.*, surgical intervention is necessary. We present a case of eosinophilic enteritis of the distal ileum with intussusception.

CASE REPORT

A 40-year-old man was admitted to the emergency department of our hospital for severe colicky upper abdominal pain and vomiting. He had a history of mild colicky abdominal pain a month ago but no history of food sensitization, allergic disease, asthma, parasitic infestations or any abdominal surgery. Physical examination revealed generalized distention with tenderness all over the abdomen. Per rectal examination was unremarkable. Blood investigations revealed 117 g/L hemoglobin, 8700/mm^3 white blood cells with 67% neutrophils, 36% lymphocytes and 3% eosinophils. The rest of haematological investigations were within normal limits. Abdominal radiograph revealed multiple air-fluid levels suggestive of small bowel obstruction. Ultrasonography revealed intussusception of the distal small bowel. Emergency laparotomy revealed ileo-ileal intussusception with gangrenous changes, about 15 cm proximal to the ileo-caecal junction. Resection with ileo-ileal anastomosis was done.

Histopathology revealed the surrounding mucosa and submucosa. Muscular layers were heavily infiltrated by eosinophils (50-60/Hpf) along with polymorphonuclear cells, lymphocytes and few plasma cells. Intestinal wall was thickened with areas of necrosis suggestive of eosinophilic enteritis with gangrene. No evidence of malignancy was found. The patient was asymptomatic, his follow-up serum immunoglobulin E levels were within normal limits, and repeated peripheral smears did not show eosinophilia(Figures 1-3).

DISCUSSION

Eosinophilic gastroenteritis is one of the rare conditions and its etiology is poorly understood. It usually involves the gastric antrum and proximal small bowel, but rarely involves the distal gut. In about 85% of cases it is associated with eosinophilia. Classification of eosinophilic enteritis is based upon the presence of eosinophilia

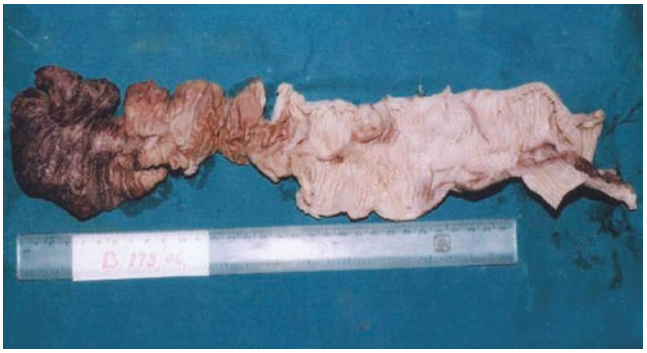

Figure 1 Ileo-ileal intussusception with a 10-cm ileal segment showing blackish brown discoloration.

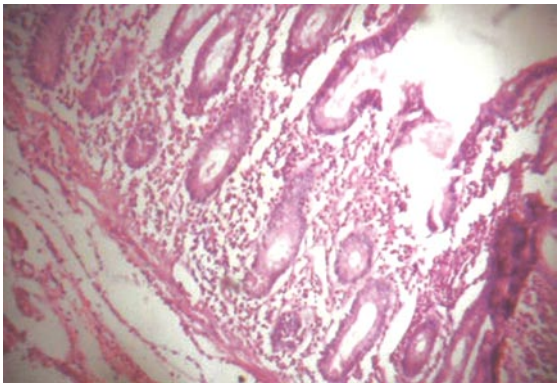

Figure 2 Microphotograph of ileum showing severe infiltration by eosinophils in all coats (HE, × 40).

or eosinopenia[1]. Clinical features depend upon the most prominent layer of visceral wall involvement by eosinophils, i.e., mucosal, muscular or serosal[2-6]. Involvement of muscularis results in obstructive symptoms and serosal involvement produces ascites. Evaluation of immunoglobulin E levels may help to detect an allergic cause. Despite all clinical factors, definitive diagnosis can only be made by histopathology confirming eosinophilic involvement of the affected area. In cases of intussusception, malignancy should always be ruled out[7].

At present, laparoscopic full thickness biopsy can be definitive in suspected cases[8]. Corticosteroid therapy is the mainstay of medical treatment. Long term follow-up is required as there are always chances of recurrence[9].

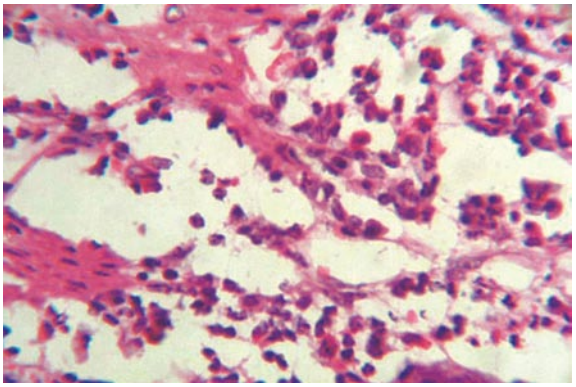

Figure 3 Microphotograph of ileum muscle coat showing severe eosinophilic infiltration (HE, × 100).

ACKNOWLEDGMENTS

The authors thank Dr. HR Tata, Head of the Department of Surgery and Medical Director, for allowing us to publish the data and Mrs. MC Deshingkar for her secretariat support in preparing this paper.

Abstract

Endoclip migration into the common bile duct following laparoscopic cholecystectomy (LC) is an extremely rare complication. Migrated endoclip into the common bile duct can cause obstruction, serve as a nidus for stone formation, and cause cholangitis. We report a case of obstructive jaundice and acute biliary pancreatitis due to choledocholithiasis caused by a migrated endoclip 6 mo after LC. The patient underwent early endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy and stone extraction.

Key words: Laparoscopic cholecystectomy; Endoclip migration; Biliary pancreatitis; Endoscopic retrograde cholangiopancreatography

Dolay K, Alis H, Soylu A, Altaca G, Aygun E. Migrated endoclip and stone formation after cholecystectomy: A new danger of acute pancreatitis. *World J Gastroenterol* 2007; 13(47): 6446-6448

INTRODUCTION

Laparoscopic cholecytectomy (LC) has become the standard approach in the treatment of benign gallbladder disease. The widespread use of LC does not increase the total incidence of postoperative complications[1]. Endoclip migration into the common bile duct was first reported by Raul *et al*[2] in 1992 as an extremely rare complication. To our knowledge, this is the first case of a migrated clip eventually resulting in acute biliary pancreatitis after LC, although choledocholithiasis due to endoclip migration into the common bile duct has been reported[1].

CASE REPORT

A 56-year-old woman with mild right upper quadrant pain for 2 d was admitted to our hospital for acute onset of severe upper abdominal pain radiating to the back accompanied with vomiting for 12 h. On physical examination, she had no fever, the sclera was icteric, and there was tenderness on the right upper quadrant of the abdomen and the epigastric area with no rigidity and rebound pain. Her amylase and lipase levels were 2066 U/L and 1980 U/L, respectively. Her liver function tests were as follows: 5 mg/dL direct bilirubin, 303 IU/L gamma glutamyl transpeptidase, 135 IU/L alkaline phosphatase, 127 mg/dL glucose, 12 g/dL blood urea nitrogen, 170 IU/L lactate dehydrogenase, 8.6 mg/dL calcium, 3.8 g/dL albumin, 66 mmHg arterial Po_2, 6800/μL white blood cells, 35% hematocrit , and 12 g/dL hemoglobin. She underwent selective noncomplicated LC 6 mo prior to this episode of acute pancreatitis.

Plain abdominal X-rays showed three endoclips in the right upper quadrant, two of them were close to each other and one was located inferiomedially to the others. Abdominal ultrasonography (US) revealed that the common bile duct was dilated to 12 mm in diameter and the pancreas was swollen. The distal common bile duct could not be evaluated adequately by US.

The patient was diagnosed as mild biliary acute pancreatitis based on the modified Imrie criteria. After medical treatment was started, ERCP performed on the second day of admittance, demonstrated a stone (12 mm in diameter) and an imbedded surgical clip at the distal part of common bile duct which was dilated to 13 mm in diameter (Figure 1A). A sphincterotomy of 15mm was performed. The extraction balloon catheter was easily burst when the stone was extracted. The stone was removed *via* a Dormia basket catheter (Figure 2A and B).

Her symptoms improved on the first day after ERCP and the serum amylase level decreased to 250 IU/L. Her amylase levels and other biochemical parameters were normal on d 2 after ERCP and she was discharged from the hospital without any complications. There was no clinical or biochemical abnormality attributable to the biliary system or pancreas during the 1-year follow-up period after ERCP.

DISCUSSION

Although the long term behavior of metal endoclips placed during LC is not clear, it is a well known-phenomenon

Figure 1 ERCP demonstrating a stone (12 mm in diameter) and an imbedded surgical clip at the distal part of the common bile duct.

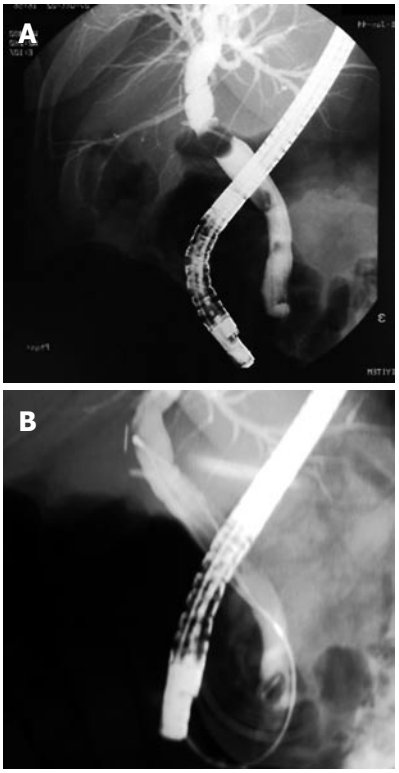

Figure 2 Placement of balloon catheter (**A**) and (**B**) Dormia basket catheter to extract the stone above the common bile duct after endoscopic sphincterotomy.

that the remained foreign materials in abdominal cavity tend to migrate towards the organs with lumens. Since stone formation within the common bile duct due to silk suture material after open cholecystectomy (OC) was first described in 1987, various foreign bodies causing nidus formation in bile ducts have been reported[3,4]. Ban *et al*[3] have divided biliary tract foreign bodies into three categories: operative residuals, penetrating missiles, and ingested items.

The first cases of choledocholithiasis due to endoclip migration into the common bile duct after OC and LC were reported by Walker *et al*[5] in 1979 and by Raoul *et al*[2] in 1992, respectively.

The true pathogenesis of migration of endoclips into the common bile duct is unclear. According to the first hypothesis, cystic duct remains patent due to ineffective clipping resulting in bilioma with bile leakage[2,6-8]. This bilioma leads to necrosis in the stump of the cystic duct by inducing chronic inflammation. The liberated clip in the necrotized cystic duct stump migrates into the common bile duct by eroding it mechanically. Presentation of the bile leakage might be subclinical, self-limited or clinically overt, which may explain why migrations occur in the early postoperative period with bile leakage.

According to the second hypothesis, the clip migrates into the ductal system by eroding the bile duct due to the local inflammation around the endoclip[6,9-12]. Short cystic duct or cystic artery, clip placement close to the common bile duct, manipulations after clipping (uncontrolled aspiration and irrigation, retraction of porta hepatis, *etc.*), local suppurative complications and ischemia on the ductal wall (excessive dissection) are risk factors for clip migration.

There have been rare reports concerning the migration of clips into the common bile duct resulting in complications other than stone formation, such as cholangitis, obstruction and stenosis of the common bile duct[6,11,13]. Cetta *et al*[14] reported a case of transient acute pancreatitis in the absence of associated stones 15 d after LC, probably due to spontaneous passage of an endoclip through the common bile duct. The case presented here is unique since stone formation and eventually acute pancreatitis occurred due to clip migration. It was reported that the time of endoclips to migrate into the bile ducts after LC is between 11 d and 6 years[2,6,7,15,16].

Absorbable clips and ultrasonic dissection without clipping in LC can prevent occurrence of clip migration and its complications[13,17]. However, these methods have not yet been used commonly by surgeons probably due to the complication and high costs of their applications. Bile duct stones associated with migration of clips after LC are usually extracted during ERCP[2,8,14]. However, when ERCP fails or in cases with additional pathology, open surgery or percutaneous transhepatic cholangioscopy can be performed[8,18].

The role of early ERCP and endoscopic sphincterotomy (ES) in the treatment of acute biliary pancreatitis is still controversial[19]. At present, early endoscopic intervention is suggested in patients with acute biliary pancreatitis when criteria for severity are met and/or there are coexistent cholangitis, jaundice, dilated common bile duct, smoldering or deteriorating clinical course[19]. In this case, we preferred early ERCP due to the presence of jaundice and dilated common bile duct.

In conclusion, endoclips after LC may migrate into the common bile duct leading to stone formation, obstruction, cholangitis, stenosis and even pancreatitis. Care should be taken during clip application, and clips should be completely squeezed by the clip applicator and unnecessary manipulations after clipping should be avoided.

Jiang Y. Number of monthly hits to *WJG* articles linked to PubMed surpasses 70 000. *World J Gastroenterol* 2007; 13(47): 6449

http://www.wjgnet.com/1007-9327/13/6449.asp

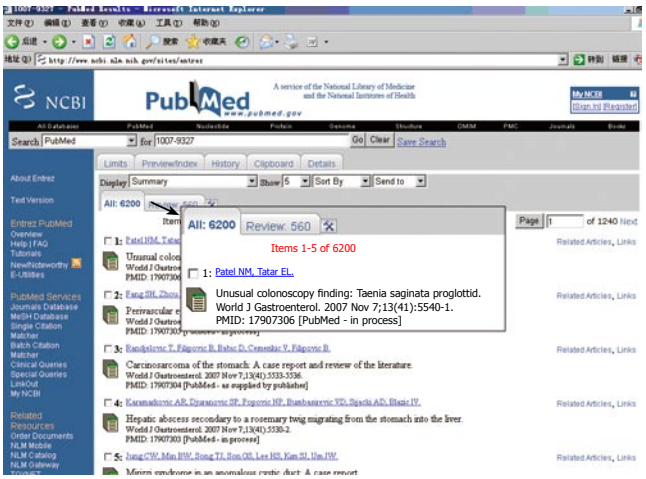

Figure 1 All 6200 articles published on *WJG* from 1998 to 2007 have been indexed by PubMed.

The latest data from LinkOut Team NCBI/US NLM show that the number of hits to *World Journal of Gastroenterology (WJG)* articles linked to LinkOut of PubMed reached 2 254 327 during the period of April, 2004, to September, 2007; further, the number was 72 532 for the month of September, 2007, which was 7344 hits higher than that of the same period in 2006.

The MEDLINE database, as one of most important components of PubMed, a web searching system managed by NCBI of America, provides statistical data for life science related journals. All 6200 articles published on *WJG* from 1998 to 2007 are covered by PubMed (Figure 1).

The data from PubMed also show that the average monthly hits to *WJG* articles linked on PubMed has been increasing every year since *WJG* started being covered by PubMed in Apr, 2004. Since that time, the total number of hits has been 344 499 in 2004, 47 110 in 2005, 66 305 in 2006, and 67 760 in 2007, with a milestone being reached in 2006 when *WJG* was recovered by SCI.

The above data clearly indicate that the quality of articles published in *WJG* has been increasing, and attracting more widespread attention at the same time.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Electronic journal (list all authors)

Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.
EDITORIAL and LETTERS TO THE EDITOR are free of charge.

Abstract

More than 170 million people worldwide have chronic hepatitis C. Acute hepatitis C is rarely diagnosed because it is commonly asymptomatic. Most infected patients are unaware of their condition until the symptoms of chronic infection manifest. Treatment of acute hepatitis C is something of a paradox because spontaneous resolution is possible and many patients do not have symptoms. However, several factors provide a rationale for treating patients who have acute hepatitis C. Compared with acute hepatitis C, chronic hepatitis C is associated with a worse prognosis, the need for more intensive treatment, longer treatment duration, and a decrease in successful treatment outcomes. Conversely, early intervention is associated with improved viral eradication, using a regimen that is better tolerated, less expensive, more convenient, and of shorter duration than the currently approved combination therapies for chronic hepatitis C.

Key words: Acute hepatitis C; Therapy; Pegylated interferon

Kamal SM. Acute hepatitis C: Prospects and challenges. *World J Gastroenterol* 2007; 13(48): 6455-6457

http://www.wjgnet.com/1007-9327/13/6455.asp

The good news is that the annual incidence of acute hepatitis C has fallen in recent years, primarily because of effective blood and blood product screening efforts and increased education on the dangers of needle sharing. The bad news is that there are no approved therapies for treating patients with acute hepatitis C and most patients infected with the hepatitis C virus (HCV) are unaware of their exposure and remain asymptomatic during the initial stages of the infection, making diagnosis difficult and often surprising for the patient. However, there is a subset of patients - mainly healthcare workers - who have documented exposure as a result of a needle stick accident. These patients are subsequently monitored within surveillance programs to establish a documented conversion from HCV RNA-negative to HCV RNA-positive status[1]. While HCV accounts for only a minority of cases of acute hepatitis, it is the primary cause of chronic hepatitis and liver disease. With more than 170 million chronic hepatitis C patients worldwide[2] and an alarming increase in the related morbidity and mortality projected for the next decade[3], an improvement in our ability to diagnose and treat patients with acute hepatitis C would have a major impact on the prevalence of chronic hepatitis and its associated complications worldwide.

Because most acute hepatitis C patients remain undiagnosed and there is a relatively high rate of spontaneous resolution of HCV infection, little is known about the epidemiology of acute hepatitis C. Robust epidemiological data is available only for those patients who progress to chronic infection, develop symptoms, and/or seek treatment. However, what we do know about the epidemiology of acute hepatitis C is that intravenous drug and surgical/accidental exposure have been identified as the most common route of HCV transmission in most studies conducted in Western populations (Figure 1). Indeed, intravenous drug use accounted for about 25% to 54% of acute cases of hepatitis C in studies conducted in the US and throughout Europe[4-7]. In the United States alone, almost half of all HCV-positive patients aged 20 to 59 years report a history of injection drug use[8]. Transfusion-related acute hepatitis C is relatively rare; however, blood transfusion prior to 1992 remains a significant risk factor for hepatitis C infection throughout the world[8]. Sexual contact is another important route of transmission (risk factor 4% to 25%)[4-6]. Individuals with 20 or more lifetime sexual partners are at significant risk for hepatitis C in Western Countries; those participating in high risk sexual behavior are particularly susceptible because of an association with herpes simplex-type 2 infection[2,8]. In other geographic areas, social and cultural differences combine to produce a very different set of risk factors for hepatitis C. In Egypt and other African nations, illicit drug use is almost non-existent and infection mainly occurs *via* blood transfusion, or through nosocomial exposure (surgery or during circumcision)[9]. Intrafamilial exposure is also a primary route of transmission in rural Egypt[10].

Unfortunately, there is no universally agreed-upon diagnostic criteria for acute hepatitis C; a series of clinical features generally leads us to suspect acute HCV infection[11]. These 'characteristics' include an acute increase in alanine aminotransferase levels to more than

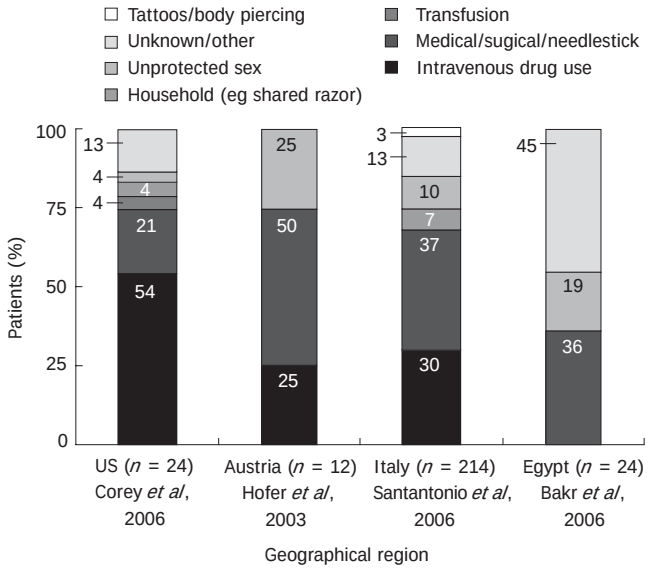

Figure 1 Acute hepatitis C sources of infection by geographic region.

10 times the upper limit of normal (with or without an increase in bilirubin) and an exposure to HCV during the previous 2-12 wk coupled with subsequent detectable HCV RNA. The few patients with acute hepatitis C who display symptoms may complain of constitutional problems or jaundice[12]; however, even among these symptomatic patients, jaundice is not always evident and slight fatigue may be the only indication that infection has taken place[13].

In many patients, HCV infection is self-limiting and spontaneously resolves before proceeding beyond the acute phase. However, establishing just how many cases resolve before reaching the chronic status has proved difficult because so few cases are actually detected. Estimates of spontaneous resolution range from 10% to 60%[1,14]; conversely, 43% to 86% of cases are thought to result in chronic infection[13]. Although these estimates vary widely, a general rule of thumb is that 20% to 26% of patients with acute hepatitis C experience spontaneous resolution[11,15]. Spontaneous resolution is most likely during the first 3-4 mo after infection; after 6 mo, it rarely occurs. So, we generally consider the first 6 mo after infection as "acute hepatitis C" and anything thereafter, "chronic hepatitis C".

Several clinical features - including the presence of symptoms and the patient's sex, immune status, and age - can serve as useful predictors of spontaneous resolution in patients with acute hepatitis C. Robust and multispecific $CD4^+$ and $CD8^+$ T cell responses are closely associated with recovery, suggesting that patients with strong immune systems have a better chance of controlling the infection[1,11]. Additionally, patients less than 40 years of age are more likely to undergo spontaneous resolution. Interestingly, infants with HCV infection have a 75%-100% chance of spontaneous resolution[11]. Conversely, patients with weakened immune systems, such as those with HIV or solid organ transplant recipients, experience more frequent progression to chronic infection[11]. Finally, self-limiting disease is also significantly more common in women than men (40% *vs* 19%, $P < 0.01$) possibly due to the facilitation of HCV clearance by an estrogen-dependent mechanism[15].

There are no currently approved treatments for acute hepatitis C; however, recently published clinical trials can be used as a basis for establishing successful management strategies. Monotherapy with standard interferon (IFN) alfa-2b or pegylated IFN (PEG-IFN) alfa-2b for 24 wk have both been shown to be effective treatments. For example, an induction regimen of IFN alfa-2b (5 MU daily for 4 wk and then 3 times weekly for 20 wk) yielded a sustained virologic response (SVR) rate of 98% in one study[16]. Similarly, 89%-95% of patients receiving PEG-IFN alfa-2b monotherapy (1.5 μg/kg per wk for 12 to 24 wk) successfully achieved viral eradication[17,18]. With both regimens, an 8-12 wk observation period between exposure to HCV and initiation of therapy is important to allow for the possibility of spontaneous resolution.

In conclusion, acute hepatitis C is a rarely encountered clinical entity. Although it is usually asymptomatic and often resolves spontaneously, it also represents an important window in the time course of this infection during which medical intervention is greeted with a high degree of success. Efforts to increase awareness, improve diagnosis, and facilitate treatment of acute hepatitis C will have far reaching implications for the management of chronic hepatitis C, where current disease management and health outcome strategies are less effective.

Abstract

Despite advances in preoperative evaluation and postoperative care, intervention, especially surgery, for relief of obstructive jaundice still carries high morbidity and mortality rates, mainly due to sepsis and renal dysfunction. The key event in the pathophysiology of obstructive jaundice-associated complications is endotoxemia of gut origin because of intestinal barrier failure. This breakage of the gut barrier in obstructive jaundice is multi-factorial, involving disruption of the immunologic, biological and mechanical barrier. Experimental and clinical studies have shown that obstructive jaundice results in increased intestinal permeability. The mechanisms implicated in this phenomenon remain unresolved, but growing research interest during the last decade has shed light in our knowledge in the field. This review summarizes the current concepts in the pathophysiology of obstructive jaundice-induced gut barrier dysfunction, analyzing pivotal factors, such as altered intestinal tight junctions expression, oxidative stress and imbalance of enterocyte proliferation and apoptosis. Clinicians handling patients with obstructive jaundice should not neglect protecting the intestinal barrier function before, during and after intervention for the relief of this condition, which may improve their patients' outcome.

Key words: Obstructive jaundice; Intestinal barrier; Intestinal permeability; Endotoxemia; Bacterial translocation; Tight junctions; Occludin; Claudin-4; Apoptosis; Oxidative stress

INTRODUCTION

When mechanical biliary obstruction is diagnosed, surgical, endoscopic or radiologic intervention is usually recommended. However, despite advances in preoperative evaluation and postoperative care, intervention, especially surgery, for relief of obstructive jaundice still carries high morbidity and mortality rates, mainly due to sepsis and renal dysfunction[1-3]. The concept of preoperative biliary drainage to reduce the postoperative morbidity and mortality in patients with malignant obstructive jaundice has not proved its efficacy leading to a longstanding controversy on this issue. Studies assessing the impact of endoscopic or radiologic drainage procedures prior to surgery in jaundiced patients showed high rates of complications, highlighting the role of the factor "intervention" in general in this patient population[4]. Recently, a randomized controlled multicenter clinical trial was designed to seek evidence whether or not preoperative biliary drainage should be performed in patients with obstructive jaundice due to a periampullary tumor[4].

The reasons for the high morbidity and mortality encountered in the post operative period have been attributed to impaired immune function and the high incidence of systemic endotoxemia[5-8]. In obstructive jaundice, increased intestinal permeability has been postulated to be a key factor contributing to bacterial and endotoxin translocation to mesenteric lymph nodes, portal circulation and liver[9,10]. A suppressed clearance capacity of Kupffer cells, the main hepatic macrophage population, attributed to accumulation of bile acids into liver, permits the "spillover" of endotoxin from portal into systemic circulation, with consecutive release of proinflammatory cytokines, potentially leading to the development of the so called "gut derived sepsis". Improved knowledge and understanding of the underlying pathophysiological mechanisms explaining the failure of the gut barrier in jaundiced patients may render us with better tools for prevention, treatment and patient selection.

THE GUT BARRIER STRUCTURAL AND FUNCTIONAL COMPONENTS

Nowadays, it is accepted that the gastrointestinal tract is not only a passive organ of nutrient absorption, but it

additionally displays important endocrine, immunologic, metabolic and barrier functions. The intestinal tract contains the body's largest interface between a person and his or her external environment. The complexity of its function is obvious when thinking that at the same time the intestine has to serve two opposite functions; the selective permeability of needed nutrients from the intestinal lumen into the circulation and into the internal milieu in general, and, on the other hand, the prevention of the penetration of harmful entities including microorganisms, luminal antigens, and luminal proinflammatory factors. The latter function is known as barrier function. Gut barrier function is dependent on the immune barrier, composed of locally acting factors such as, the secretory IgA, intra-mucosal lymphocytes, Payer's nodules, mesenteric lymph nodes and of the systemic host defense represented mainly by the reticuloendothelial system, the biological barrier, which is made up of normal intestinal flora responsible for colonization resistance, and the mechanical barrier, consisting of the closed-lining intestinal epithelial cells and by the capillary endothelial cells. All these components of gut barrier integrity can be affected by biliary obstruction and the absence of bile within the intestinal lumen.

THE EFFECT OF BILE ON THE GUT BARRIER

The presence of bile and bile acids in the intestinal lumen is associated with a number of positive effects, contributing to a normal gut barrier function.

Bile and the immune barrier

Experimental studies have shown that bile affects homing and distribution of T-lymphocytes in the gut-associated lymphatic tissue (GALT) and its absence results in decreased numbers of $CD4^+$ and $CD8^+$ T-lymphocytes and mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expressing cells in the lamina propria[11]. In addition, bile affects the size and number of B-lymphocytes in Peyer's patches. In experimental animals, the ligation of the common bile duct induced efficient apoptosis in Peyer's patch B-lymphocytes through a Toll-like receptors-2 dependent elevation of Fas expression and/or increase in sensitivity to Fas mediated apoptosis[12]. Bilirubin has been shown to impair bactericidal activity of neutrophils attenuating bacterial clearance mechanisms[13]. Bile also contains immunoglobulin A, which enhances mucosal defense either by maintaining mucosal integrity, or by binding to bacteria and viruses[14]. Circulating polymeric immunoglobulin A (IgA) binds to the secretory component (SC) on the surface of rat hepatocytes and is internalized and transported by vesicles to the canalicular membrane where the IgA-SC complex is secreted into bile. Secretion of IgA is sensitive to bile flow and the biliary secretory pathways for IgA and SC are dissociated after brief periods of cholestasis[15]. There is also evidence that specific or nonspecific antibodies contained in bile inhibit adhesion of enteric bacteria on the intestinal mucosa or inhibit bacterial endocytosis by enterocytes, thus preventing bacterial translocation[16].

Bile and the biological barrier

Bile acids have been reported to inhibit the growth of certain bacteria such as Bacteroides, Clostridia, Lactobacillus and Streptococci[17-20]. Absence of bile salts results in a disturbed intestinal bacterial balance with overgrowth of gram negative bacteria[19,21]. Bile salts have a detergent-like activity, which can make bacterial membranes permeable and can eventually lead to membrane collapse and cell damage[22]. Alternatively, bile salts are thought to prevent intestinal endotoxin and bacterial translocation by binding directly intraluminal endotoxin and bacteria, and creating poorly absorbed detergent-like complexes[23].

Bile and the mechanical barrier

In addition, bile exerts trophic effects on the intestinal mucosa, increasing villous density and inducing hypertrophy of the intestinal wall components[21,24]. *In vitro* experiments have shown that bile acids promote intestinal epithelial cell proliferation through a c-myc-dependent mechanism and protect against apoptotic cell death through activation of NF-κB[25,26]. These data support an important beneficial role of bile salts in regulation of mucosal growth and repair. Recent studies have also shown that bile is crucial for the maintenance of the integrity of enterocyte tight junctions, regulating the expression of the essential tight junction-associated proteins occludin and ZO-1, thus preserving the intestinal paracellular barrier[27,28].

INTESTINAL PERMEABILITY IN THE JAUNDICED PATIENT

Increased intestinal permeability has been postulated to be a key factor contributing to bacterial and endotoxin translocation and the pathogenesis of septic and renal complications in patients with extrahepatic biliary obstruction[29]. Beyond several experimental studies that have repeatedly demonstrated increased intestinal permeability in obstructive jaundice, this phenomenon has been confirmed in the clinical setting as well[5,29-31]. Increased intestinal permeability was evidenced in jaundiced patients either directly by the lactulose/mannitol permeability test[29,31], or indirectly by measurements of endotoxin concentrations in portal and systemic circulation[32], determination of anti-endotoxin core antibodies[31] and by multiple sampling during laparotomy in jaundiced patients, demonstrating growth of translocating bacteria of primarily enteric origin in extraintestinal sites[33]. Clinical data also demonstrate that surgical biliary decompression in obstructive jaundice exaggerates the pathophysiological disturbances and significantly increases intestinal permeability in the immediate post operative period as compared to non-surgically treated patients[5]. This probably reflects that the magnitude of an additional "trauma" in jaundiced patients is of importance and this should be considered in order not to further aggravate the patient's condition and host defense and potentially increase morbidity and mortality.

MECHANISMS OF INCREASED GUT PERMEABILITY IN OBSTRUCTIVE JAUNDICE

Intestinal permeability is determined by interactions among several barrier components including the unstirred water layer, mucosal surface hydrophobicity, the surface mucous coat, epithelial factors (especially tight junctions) and endothelial factors[34]. Each of these components has different permeability properties. However, among these factors, the intestinal epithelium consisted of the epithelial cells which are linked close to the apical surface by the tight junctions seem to be the most important in determining intestinal permeability[35]. Up to now, the mechanism of increased intestinal permeability in obstructive jaundice remains an enigma, but in the last few years experimental studies have shed light on our knowledge in the field.

In several studies, obstructive jaundice does not seem to induce dramatic morphologic changes in the intestinal mucosa on routine light microscopy[10,36], while in others non-specific findings, such as subepithelial edema, lifting of the villus and sporadic mucosal denudation with exposure of lamina propria have been documented[9,19,37]. However, ultrastructural studies on intestinal mucosa revealed certain kinds of cell disruption, represented by alterations of cellular and mitochondrial membrane[37]. In general, most studies had demonstrated that obstructive jaundice increases intestinal permeability though epithelial continuity is retained and the mechanism for this was not evident.

Tight junctions

The key event in the pathophysiology of obstructive jaundice-associated complications is gut derived endotoxemia[7]. According to its size, this molecule as well as other bacterial byproducts, could have permeated the intestinal mucosa through the paracellular pathway[38]. Therefore, our research group investigated for the first time the expression of occludin, a bona fide integral component of the tight junction, in the intestinal epithelium of jaundiced rats. The results of this study showed that intestinal mucosal barrier dysfunction in obstructive jaundice is associated with regional loss of occludin expression in the intestinal epithelium, observed mainly at the upper part of the villi[28]. Our immunohistochemical observations were confirmed by immunoblotting by other investigators, who additionally showed that obstructive jaundice leads to decreased mucosal expression of the TJ-associated protein ZO-1 as well[27]. Those researchers applying *in vitro* experiments with enterocytic monolayers incubated in the presence or absence of graded concentrations of bile showed that the alterations of intestinal tight junctions were bile mediated, while this finding was also supported *in vivo* because gavaging mice with rat bile significantly ameliorated the deleterious effects of obstructive jaundice on intestinal permeability. Also, in a current study it was shown that intestinal electrophysiological parameters in jaundiced animals, which substantially depend on intestinal TJs' integrity, were improved after oral supplementation with bile salts[39]. Further investigaton into the role of intestinal TJs alterations on gut barrier failure in obstructive jaundice demonstrated an up-regulation of claudin-4 expression in the upper part of the villi. Claudins are the only known variable elements in TJs and different expression, combination and mixing ratios of various members of the claudin family are essential in regulation of barrier properties of TJs[40]. There is evidence that the functional role of claudin-4 in the intestinal epithelium may be associated with loosening of intercellular junctions and opening of the paracellular route[41]; therefore, its overexpression is compatible with increased intestinal permeability. The key role of claudin-4 and occludin in obstructive jaundice-associated intestinal permeability alterations is further evidenced by improvement of gut mucosal barrier after restoration of their expression by regulatory peptides administration[28,42]. Apart from the role of bile deprivation, another explanation of altered intestinal occludin and claudin-4 expression in obstructive jaundice is through endotoxin-mediated mechanisms. The excessive presence of endotoxin in portal and systemic circulation stimulates a systemic inflammatory response, characterized by the release of cytokines and other proinflammatory mediators such as tumor necrosis factor-alpha (TNF-α), interleukin-1, interleukin-6, interferon-gamma (INF-γ), nitric oxide and oxygen free radicals[43]. These substances may produce injurious effects on TJs structure and function compromising intestinal epithelial barrier function[44-47]. Specifically, it has been demonstrated that TNF-α as well as INF-γ downregulate the human occludin promoter[48]. Given that increased levels of both TNF-α and INF-γ have been demonstrated in obstructive jaundice[43,49], it is tempting to speculate that these cytokines may account for occludin down-regulation. Furthermore, endotoxin reduces splachnic blood flow and disrupts intestinal microcirculation resulting in hypoxia of enterocytes and energy depletion[50]. Studies in epithelial cells monolayers have shown that adenosine triphosphate depletion induces the structural perturbation of the TJ leading to loss of the permeability barrier[51]. An additional contributory factor might be increased bacterial adherence to the enterocyte. Obstructive jaundice results in intestinal bacterial overgrowth, mainly represented by *E. coli* over growth[28]. Absence of bile deprives the gut from about 90% of secretory IgA, which normally prevents bacterial adherence to the intestinal mucosa[16]. Overgrowth of *E. coli* and lack of biliary IgA may lead to increased attachment of this bacterial strain to the intestinal mucosa. *In vitro* studies have shown that attachment of the enteropathogenic *E. coli* in intestinal epithelial cells monolayers dissociates occludin from the tight junctions, thus disrupting the paracellular barrier[52].

Cell proliferation and apoptosis

Absence of bile from the intestinal lumen is known to induce intestinal mucosal atrophy[21,53]. Epithelial homeostasis is highly dependent on the balance between cell proliferation and death, and knowledge of both factors is essential when elucidating how obstructive jaundice regulates intestinal cell turnover and mucosal cellularity. Experimental studies provided evidence of increased apoptosis of enterocytes in intestinal crypts

in parallel with decreased mitotic activity[10,54]. These cellular events occurring in intestinal crypts, where the mucosal proliferation zone exists, may explain the induction of mucosal atrophy observed in cases of biliary obstruction[54].

The responsible mechanisms of increased intestinal apoptosis could reflect primary immunologic events following BDL (apoptosis has been shown to be induced by a variety of triggers, including proinflammatory cytokines such as TNF-α, IL-1 and IL-6, or by cytotoxic T lymphocytes that act through either granzyme B or Fas receptor pathways) or a direct action of bacterial toxins[43].

It is well known that bile salts exert a potent trophic effect on the intestinal epithelium. This action is based on their mitogenic effect on the enterocytes. *In vitro* studies have shown that intestinal cells exposed to physiological concentrations of the bile salt taurodeoxycholate, within 24 h are beginning to enter into S-phase of the cell cycle, while after 6 d of exposure to bile salts, cell growth is stimulated by almost 70% relative to cells grown in the absence of bile salts[26]. The proliferative effect of taurodeoxycholate is at least partly mediated by regulation of the transcription of the proto-oncogene c-myc, which has been shown to play an important regulatory role during intestinal epithelial proliferation[26].

The significant contribution of the imbalance between cell proliferation and apoptotic death in the phenomenon of gut barrier failure in obstructive jaundice is further evidenced by the improvement of gut barrier function and the reduction of gut derived endotoxemia when factors that restore intestinal homeostasis were administered. The enhancement of intestinal permeability by glutamine may be explained by its proliferative and antiapoptotic effect on the intestinal mucosa[55-57]. Administration of intestinal trefoil agents such as Growth hormone and Insulin-like growth factor I , which act on intestinal mucosal growth, development and metabolism, significantly improved intestinal barrier function and reduced portal and systemic endotoxemia in obstructive jaundice, exerting, beyond their trophic effect, a potent antiapoptotic action on the intestinal mucosa leading to preservation of mucosal homeostasis[10]. In addition, gut regulatory peptides Bombesin and Neurotensin which have been shown to prevent gut barrier dysfunction in obstructive jaundice, exerted also a combined mitogenic and antiapoptotic effect on the intestinal mucosa[54].

Oxidative stress

Altered intestinal tight junction expression and increased intestinal apoptosis are accompanied by significant alterations of the intestinal oxidative state, which represent an additional important factor in promoting intestinal injury in obstructive jaundice[21,54,58]. Studies with experimental animals showed that obstructive jaundice induces intestinal oxidative stress evidenced, not only by increased lipid peroxidation and glutathione oxidation, but also by a general imbalance between protein or non protein thiols and protein or non protein disulfides (symmetric or mixed)[21,54,59]. Specifically, in the intestine we observed increased levels of the high oxidative stress markers of thiol redox state oxidized glutathione (GSSG), non-protein mixed disulfides (NPSSR) and protein symmetric disulfides (PSSP), accompanied by the decrease of the low oxidative stress markers glutathione (GSH), GSH:GSSG ratio and protein thiols (PSH). Our findings of increased intestinal oxidative stress in obstructive jaundice were also confirmed in the clinical setting[58]. The potential mechanisms of high intestinal oxidative stress in obstructive jaundice have been extensively reviewed previously[58,60]. Briefly, increased levels of bile acids, systemic endotoxemia and the subsequent inflammatory response[61], up-regulation of inducible nitric oxide synthase expression[62,63], increased neutrophil chemotaxis and superoxide anion generation[64] and decreased systemic levels of the antioxidant vitamin E[65], contribute to the promotion of the oxidative process in obstructive jaundice.

A question raised is whether intestinal cellular and oxidative alterations could be interrelated. It has been shown that reactive oxygen species may promote cell growth arrest, *via* a mitogen-activated protein kinases dependent pathway that alters the status of growth regulatory proteins, and apoptotic cell death, *via* a cytochrome c-mediated activation of the caspase family[66]. Thus, oxidative stress may promote intestinal apoptosis and inhibition of cell proliferation, leading to mucosal atrophy in obstructive jaundice. In addition, given that oxidative stress disrupts the TJ structural complex by modulating the assembly, localization, expression and function of their molecular components[46], this factor may underlie the altered intestinal TJ expression and increased permeability in obstructive jaundice. The interrelation of oxidative stress with intestinal cellular alterations in extrahepatic cholestasis is also supported by the fact that the oral administration of the antioxidant GSH preserves the intestinal mucosal redox state and prevents intestinal histological and electrophysiological changes[39]. In line with this observation, in a recent work[59], we demonstrated that administration of different antioxidant substances (N-acetyl-cysteine, allopurinol, α-tocopherol) in ten days' cholestatic rats, induces a significant antioxidant action in the intestine, mediated by a certain influence profile on the thiol redox state by each substance, leading to improvement of intestinal barrier function and prevention of endotoxemia. In addition, administration of gut regulatory peptides bombesin and neurotensin in experimentally jaundiced rats, induces a potent antioxidant effect on the intestine, preventing all the mentioned intestinal cellular alterations (apoptosis, inhibition of cell proliferation, altered TJ expression) and improving intestinal mucosal barrier function[28,42,54]. Taken together all these data suggest that intestinal oxidative stress and the thiol redox state are important factors in the promotion of the deleterious effects of obstructive jaundice on the anatomical and functional integrity of the intestinal mucosa.

The pathophysiology of obstructive jaundice-induced gut barrier failure, endotoxemia and systemic complications, is schematically presented in Figure 1.

CONCLUSION

Clinicians handling patients with obstructive jaundice

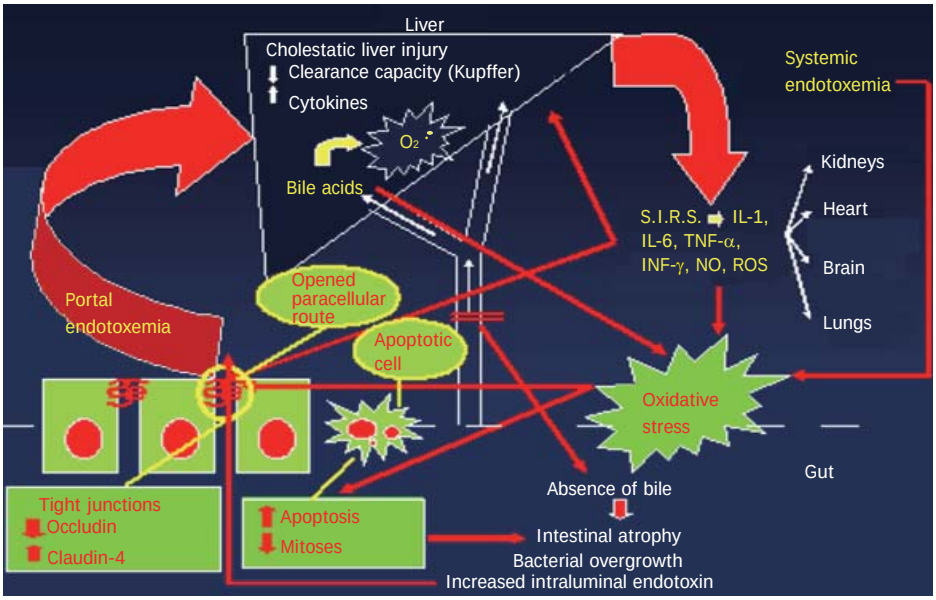

Figure 1 Pathophysiology of obstructive jaundice-induced gut barrier failure, endotoxemia and systemic complications. Absence of intraluminal bile deprives the gut from its bacteriostatic, endotoxin-neutralizing and mucosal-trophic effect leading to increased intestinal bacterial and endotoxin load and mucosal atrophy. These alterations promote bacterial and endotoxin translocation into portal circulation and subsequently, through a decreased clearance capacity of Kupffer cells because of cholestasis, into systemic circulation. Systemic endotoxemia activates a systemic inflammatory response, which is associated with dysfunction of remote organs, while it further aggravates intestinal barrier dysfunction and cholestatic liver injury. Endotoxemia, cytokinemia and increased bile acids concentrations represent important promoters of reactive oxygen species formation in diverse organs, encompassing the intestine. Increased intestinal oxidative stress in obstructive jaundice, contributes to induction of apoptosis and inhibition of cell proliferation in intestinal crypts, leading to mucosal atrophy. In parallel, intestinal oxidative stress, endotoxemia, systemic release of inflammatory mediators and absence of intraluminal bile, disrupts the integrity of enterocytes' tight junctions by altering the expression of their molecular components. As a consequence the intestinal paracellular route opens, contributing to further escape of endotoxin from the intestinal lumen into portal circulation, thus leading to a vicious cycle.

should not neglect protecting the intestinal barrier function before, during and after intervention for the relief of this condition, because failure of the intestinal barrier with consequent endotoxemia and the systemic inflammatory response may lead to serious and even life threatening complications. In this context, minimization of the additional surgical trauma, antibiotic prophylaxis, adequate fluid replacement to prevent visceral-microcirculatory disturbances, enteral nutrition to improve microcirculation, prevent mucosal atrophy and provide important nutrients for enterocytes and lactulose administration to reduce the incidence of endotoxemia are well demonstrated strategies. Growing research interest in this field has shed enough light in the pathophysiology of intestinal failure in obstructive jaundice demonstrating that the breakage of gut barrier is multi-factorial, involving disruption of the immunologic, biological and mechanical barrier. Altered intestinal tight junctions expression, oxidative stress and imbalance of cell proliferation and apoptosis may play a key role in gut permeability alterations in cases of biliary obstruction. Future studies focused on the pharmacological modulation of these factors may lead to a better control of intestinal permeability not only in obstructive jaundice, but also in diverse clinical states which may be complicated by gut-derived sepsis.

Abstract

Cholangiocarcinomas are malignant epithelial liver tumors arising from the intra- and extra-hepatic bile ducts. Little is known about the molecular development of this disease, and very few effective treatment options are available. Thus, prognosis is poor. Genetic and epigenetic changes play an integral role in the neoplastic transformation of human cells to their malignant counterparts. This review summarizes some of the more prevalent genetic alterations (by microRNA expression) and epigenetic changes (hypermethylation of specific gene promoters) that are thought to contribute to the carcinogenic process in cholangiocarcinoma.

Key words: Promoter regions; CpG islands; Tumor suppressor; Oncogene; Inflammation

INTRODUCTION

Neoplastic transformation of normal cells into their malignant counterparts often requires a series of genetic changes. These changes can range from "simple" mutations in the genes themselves that ultimately lead to loss-of-function or gain-of-function changes in key genes that are responsible for the control of apoptosis and cell cycle progression respectively, to more complex changes in non-protein factors (e.g. RNA and DNA) that regulate the control of specific gene expression[1-4]. These more complex changes can be classified as either genetic or epigenetic changes[1,3,4]. For the purpose of this review, we will define and limit the "complex" genetic changes as being any changes that occur in non-coding RNAs and epigenetic changes in the modification of the promoter regions of the genes themselves (e.g. hyper- and hypomethylation)[3-6].

Non-coding RNAs

Non-coding RNAs have recently been recognized as gene-specific regulators and therefore are similar in function to transcription factors. These RNAs can regulate every stage of gene expression, including transcription, mRNA stability and translation[5,7]. A role for these RNAs in the neoplastic transformation of cells is emerging[4]. A major sub-type of non-coding RNA is the microRNAs, which are small RNA molecules encoded in the genomes of plants and animals[5]. These highly conserved, about 21-mer RNAs regulate the expression of specific target genes by binding to the 3'-untranslated regions of mRNAs[7]. Each microRNA is thought to regulate multiple genes and since hundreds of microRNA molecules are predicted[6], the relative importance of these molecules in the control of gene expression is potentially massive. Several research groups have provided evidence that microRNAs may act as key regulators of processes as diverse as early development[8], cell proliferation and cell death[9], apoptosis and fat metabolism[10], and cell differentiation[11,12]. In addition, recent studies suggest a possible link between microRNAs and various cancers, including chronic lymphocytic leukemia[13], colonic adenocarcinoma[14], Burkitt's Lymphoma[15] and cholangiocarcinoma[16-18].

Epigenetic changes

Epigenetic gene silencing refers to non-mutational gene inactivation that can be passed from parental cells to daughter cells[1]. The addition of methyl groups to cytosine residues in CpG dinucleotides in DNA is a biochemical modification that meets this requirement, referred to as hypermethylation[1]. Genes carrying epimutations

cause morphological phenotypes to be transmitted from generation to generation, not based on any alteration in the coding sequence of the relevant genes, but instead caused by CpG (or CpNpG) hypermethylation of their promoter sequences[2]. Methylation patterns in mammalian cells are regulated by DNA methyltransferases[19], which transfer a methyl group to the cytosine portion of the CpG dinucleotide[19]. This allows for the binding of methyl-specific DNA-binding proteins such as MeCP1 or MeCP2 to regulatory elements, which in turn represses transcription[20]. These binding proteins can then attract histone deacetylases, which then remodel chromatin into highly repressed states[20]. Hypermethylation has been shown to play an important role in the progression of tumor growth in almost all types of cancer[21].

Recent data suggest that both genetic and epigenetic changes are required for transformation, promotion and progression of cholangiocarcinoma[16,17,22-26], a deadly cancer of the cells lining the intra- and extra-hepatic biliary tract[27,28]. This type of cancer is increasing in its incidence worldwide, with no effective treatment options[29,30]. Therefore, understanding the molecular events associated with the neoplastic transformation of cholangiocytes to cholangiocarcinoma may aid in the development of improved therapeutic strategies. This review will summarize our current understanding of the most prevalent genetic and epigenetic changes associated with cholangiocarcinoma.

THE REGULATION OF TUMOR SUPPRESSOR GENES AND CELL CYCLE INHIBITORS

Methylation

The hypermethylation and inactivation of a number of cell cycle inhibitors have been shown to occur in cholangiocarcinomas. The most well-characterized of these epigenetic changes is in the $p16^{INK4a}$ gene, which has been described in up to 83% of cholangiocarcinomas[23,26]. This gene is responsible for binding to the cyclin dependent kinase 4 (CDK4) and inhibits its ability to interact with cyclin D1[31]. In the absence of $p16^{INK4a}$ activity, such as after promoter methylation, CDK4 binds to cyclin D1, which subsequently leads to unchecked entry into the S phase of the cell cycle[31]. There also appears to be increased incidence of hypermethylation of the related $p14^{ARF}$ occurring in 25% of cholangiocarcinoma samples studied[25]. The $p14^{ARF}$ gene normally prevents p53 degradation and hence cell-cycle arrest[32], which constitutes another checkpoint that may be lost in cholangiocarcinoma[33]. In addition to the above-mentioned genes, many other cell cycle entry inhibitors have been shown to be hypermethylated. These include $p16^{INK4b}$ (50% of tumors studied)[26] and 14-3-3 sigma (59.5% of tumors studied)[34].

In addition, the expression of many tumor suppressor genes is repressed in cholangiocarcinomas[24]. The most striking of which is Semaphorin3B, which was found to be methylated in 100% of the cholangiocarcinoma cases studied[24]. RassF1A[26] and p73[26] are also hypermethylated and suppressed in 65.3% and 36.1% of cholangiocarcinoma cases studied respectively.

Taken together, the epigenetic silencing of a vast array of tumor suppressor genes and inhibitors of cell cycle progression obviously plays an important role in the initiation and progression of cholangiocarcinoma. Inactivation of these genes allows cells to avoid apoptosis and to proliferate unchecked.

microRNA

To date, the data concerning microRNA regulation of cell cycle and/or apoptotic genes is sparse. Recently Meng *et al* showed that miR-141 was highly overexpressed in malignant cholangiocytes[16]. Using a bioinformatics approach, a predicted target of miR-141 was the CLOCK gene, which regulates circadian rhythms and can act as a tumor suppressor[16]. Inhibiting miR-141 effectively increased CLOCK protein expression in cholangiocarcinoma cells[16]. Another microRNA species that was found to be overexpressed in malignant cholangiocytes was miR-200b[16]. The target gene for this was predicted to be the protein tyrosine phosphatase non-receptor type 12 (PTPN12), the dysregulation of which may contribute to tumor cell survival and oncogenesis[16]. Similarly, the expression of miR-21 was overexpressed in cholangiocarcinoma, which effectively blocks the expression of the tumor suppressor gene PTEN[16].

Conversely, other microRNA species have been identified as being downregulated in cholangiocarcinoma compared to non-malignant cholangiocytes. miR-29b expression was suppressed in the cholangiocarcinoma cell line KMCH as well as in approximately 33% of human cholangiocarcinoma samples[18]. Enforced miR-29b overexpression in cholangiocarcinoma cells effectively reduced the expression of Mcl-1, an anti-apoptotic protein of the Bcl-2 family[18] and sensitized cholangiocarcinoma cells to tumor necrosis factor-related apoptosis-inducing ligand cytotoxicity, suggesting that the suppression of miR-29b expression found in cholangiocarcinoma allows the overexpression of Mcl-1 and can ultimately lead to the resistance of cholangiocarcinoma to cell death[18]. Another microRNA that is downregulated in cholangiocarcinoma is miR-370[17]. Interestingly, the expression of this particular microRNA has been shown to be under tight epigenetic regulation by hypermethylation[17]. One of the targets for miR-370 is the oncogene mitogen-activated protein kinase kinase kinase 8 (MAP3K8)[17], thus MAP3K8 is upregulated in cholangiocarcinoma cell lines as well as in tumor cell xenografts *in vivo*[17].

THE REGULATION OF GENES INVOLVED IN DNA REPAIR

Methylation

Inherited mutations that affect DNA repair genes are strongly associated with high cancer risks in humans. A number of the DNA repair genes have been shown to be hypermethylated in cholangiocarcinoma. Hypermethylation of the hMLH1 mismatch repair gene promoter has been shown to occur in up to 23.6%

of cholangiocarcinomas[26], which has previously been revealed to lead to microsatellite instability in other tumor types[35]. Another gene, O6-methylguanine-DNA methyltransferase (MGMT), is silenced in up to 33% of cholangiocarcinoma tumors studied[26]. This gene is an important suicide enzyme involved in the defense against O6-alkylating endogenous metabolites and environmental carcinogens. Interestingly, transcriptional repression of MGMT was associated with the accumulation of GC-AT transitional mutations in the p53 gene and, to a lesser extent, the k-*ras* gene in cholangiocarcinoma[26,36]. Lastly, the glutathione S-transferase P1 (GSTP1) gene, which inactivates electrophilic carcinogens by conjugation with glutathione is hypermethylated in cholangiocarcinoma, occurring in 6% to 34% of cases studied[26,34]. Taken together, the hypermethylation of genes responsible for DNA repair appears to be an important step in the carcinogenic process of cholangiocarcinoma.

microRNA

To our knowledge, and to date, no genes involved in DNA repair have been identified as targets of transcriptional control by microRNA in cholangiocarcinoma.

THE REGULATION OF GENES INVOLVED IN INFLAMMATION

Methylation

Chronic inflammation, such as those seen in various cholestatic liver diseases, is a recognized risk factor for the development of cholangiocarcinoma[27,28]. Therefore, it follows that certain mediators of the inflammatory process may be integral in the carcinogenic processes associated with neoplastic transformation of cholangiocytes[37-39]. Indeed, sustained overexpression of the cytokine interleukin-6 (IL-6) has been demonstrated to have an integral role in cholangiocarcinoma biology[38,39]. This aberrant overexpression of IL-6 has recently been shown to be as a consequence of the epigenetic silencing of the suppressor of cytokine signaling 3 (SOCS-3)[40]. SOCS-3 promoter methylation was observed in a subset of cholangiocarcinoma samples as well as in a number cholangiocarcinoma cell lines[40]. Enforced overexpression of SOCS-3 in these cell lines effectively reduced the IL-6-mediated signal transduction cascade[40]. Therefore the loss of this negative regulator of IL-6 in cholangiocarcinoma may contribute to the inflated expression and activity of inflammatory molecules seen in cholangiocarcinoma.

A downstream consequence of aberrant IL-6 expression may be the further hypermethylation of the promoter regions of a number of critical target genes in cholangiocarcinoma. IL-6 has been shown to regulate the enzyme activity of one of the DNA methyltransferases responsible for the hypermethylation of promoter regions[41]. In cholangiocarcinoma cells, IL-6 overexpression resulted in the altered promoter methylation of a number of genes including the epidermal growth factor receptor (EGFR)[42]. EGFR promoter methylation was decreased and gene and protein expression increased by IL-6[42], suggesting that the epigenetic regulation of gene expression by the inflated IL-6 expression seen in cholangiocarcinoma can contribute to tumor progression by altering the expression of growth regulatory pathways, such as those involving EGFR[42].

microRNA

In addition to changes in promoter methylation, aberrant IL-6 expression in cholangiocarcinoma also has implications on microRNA expression and function. Enforced IL-6 overexpression in human cholangiocarcinoma cell lines significantly increased the expression of several members of the let-7 family of microRNAs[22]. Expression of let-7a contributes to the survival effects that are attributed to IL-6 over-expression[22]. A putative target of let-7a microRNA is the gene neurofibromatosis 2 (NF2)[22], which is a negative regulator of Stat-3[43]. Thus, overexpression of IL-6 in cholangiocarcinoma and subsequent upregulation of let-7a decreased the expression of NF2, thereby removing the negative regulation of Stat-3[22]. Constitutive activation of Stat-3 has been implicated in a number of cancers and is thought to be responsible for the IL-6-mediated survival signaling[22].

THE REGULATION OF GENES INVOLVED IN CELL ADHESION AND INVASION

Methylation

E-Cadherin is a calcium-dependent cell adhesion molecule that suppresses metastatic processes and tumor cell invasion[44-46]. In cholangiocarcinoma, methylation of the E-cadherin promoter occurred in up to 48% of all samples studied[25,26,34,47]. Downregulation of this gene by epigenetic changes has been reported in a number of other cancers[44,45], and re-expression can be induced by treatment with a demethylating agent in cholangiocarcinoma[48].

microRNA

To our knowledge, no genes that are involved in cell adhesion or the metastatic process associated with cholangiocarcinoma biology have been shown to be regulated by microRNAs.

CONCLUSION

In conclusion, from the epigenetic changes summarized in this review, it is obvious that epigenetic silencing as well as genetic regulation by microRNAs play a very important role in the neoplastic transformation of cholangiocytes to their malignant counterparts. A summary of the changes in specific promoter hypermethylation and microRNA can be found in Tables 1 and 2 respectively. We acknowledge that this summary is far from complete and that more target genes are being described regularly. Further analysis and characterization of these genetic and epigenetic changes, as well as the potential interplay between hypermethylation and microRNA expression will aid in the identification of therapeutic targets for the design of treatment strategies to combat this deadly malignancy.

Table 1 Summary of genes subject to epigenetic silencing during the course of cholangiocarcinoma tumor progression

Gene	Incidence of methylation in CCH (%)	Function	Reference
$p16^{INK4a}$	14-50	Cell cycle regulator	[26,34,47]
$p14^{ARF}$	38	Cell cycle regulator	[26]
$p15^{INK4b}$	12-50	Cell cycle regulator	[26,47]
14-3-3 sigma	59.50	Cell cycle regulator	[34]
Semaphorin3B	100	Tumor suppressor	[24]
p73	36	Tumor suppressor	[26]
RassF1A	26-65	Tumor suppressor	[26,47]
hMLH1	25	DNA mismatch repair	[26]
MGMT	11-33	Methyl transferase	[26,34]
GSTP1	6-34	Inactivation of carcinogens	[26,34]
SOCS-3	ND	Inhibits inflammation	[40]
EGFR	ND	Growth factor	[42]
E-cadherin	43	Cell adhesion	[25,26,34,47]

ND: Not determined.

Table 2 MicroRNAs known to be changed in cholangiocarcinoma

MicroRNA	Target gene	Function	Direction changed in CCH	Reference
miR-141	CLOCK	Circadian rhythm	Increased	[16]
miR-200b	PTPN12	Tumor suppressor	Increased	[16]
miR-21	PTEN	Tumor suppressor	Increased	[16]
miR-29b	Mcl-1	Anti-apoptotic gene	Decreased	[18]
miR-370	MAP3K8	Oncogene	Decreased	[17]
let-7a	NF2	Negative regulator of inflammation	Increased	[22]

Abstract

Intrahepatic cholangiocarcinomas (ICC) are neoplasms that originate from cholangiocytes and can occur at any level of the biliary tree. Surgical resection is the current therapy of choice for this highly aggressive cancer. However, the 5-year survival still is poor, with high recurrence rates. Due to the intrahepatic growth a significant proportion of patients present with advanced disease and are not candidates for curative surgery or transplantation. The existing palliative options are of limited benefit and there is a great necessity for novel therapeutic options. In this article we review the role of the phosphoinositide 3-kinase(PI3K)/ AKT and extracellular regulated kinase (ERK) signaling pathways in ICC and present new data on the prognostic value of these protein kinases. Finally, we discuss future upcoming therapeutic options based on targeting these signaling pathways.

Key words: Extra cellular regulated kinases; Cholangiocarcinoma; Prognosis; Oncology; Immunohistochemistry

INTRODUCTION

Cholangiocarcinomas (CCC) are rare malignant tumors arising from the biliary tract. According to their anatomic location they can be categorized as either intrahepatic or extrahepatic. Although intrahepatic cholangiocarcinoma (ICC) is less frequent than extrahepatic carcinoma, within malignant liver tumors it ranks second after hepatocellular carcinoma. The incidence of cholangiocarcinoma differs considerably in different geographic regions, with the incidence highest in Southeast Asia[1]. In western countries ICC accounts for about 10% of primary liver malignancies with increasing incidence. Established risk factors for development of cholangiocarcinoma are liver fluke infestation especially with opisthorchis viverini, primary sclerosing cholangitis, hepatolithiasis, anomalous biliary-pancreatic malformation, choledochal cysts, thorotrast exposure, liver cirrhosis and hepatitis C infection[2]. However, most cholangiocarcinomas arise in the absence of known underlying risk factors.

The prognosis of ICC is very poor. Due to its intrahepatic localization, symptoms occur late in the course of the disease and patients often present with an advanced tumor. Most patients exhibit a median survival of less than 9 mo after diagnosis. To date, complete resection has been the only curative therapy. Recent trends are to advocate accurate preoperative staging with an aggressive surgical approach to achieve complete tumor resection[2,3]. In the majority of patients ICC presents at an advanced stage or patients have associated co-morbidity that preclude surgery. This patient group needs adequate palliation such as chemotherapy. Biliary decompression, which can be achieved by surgery, radiology or endoscopy, is an additional palliative treatment option. However, since ICC rarely cause biliary congestion, these additional palliative options are rarely used.

The importance of an optimal preoperative assessment of resectability and the lack of potent optional (adjuvant) therapeutic approaches, emphasize the necessity of novel prognostic and predictive parameters. This review focuses on the relevance of two central biological signaling pathways - namely the AKT and ERK1/2 pathway - in ICC. The development of phospho-specific antibodies for immunohistochemistry allows the evaluation of signaling activity of these pathways in pathological specimens. Phosphorylation of proteins either on specific tyrosine or serine residues is a posttranslational event modulating the activity of many key signaling molecules in the cell including AKT and ERK1/2[4]. We recently demonstrated AKT and ERK phosphorylation as an independent prognostic parameter in breast cancer and colorectal cancer, respectively[5,6]. Others found an association of AKT

and ERK1/2 with decreased survival in various human malignomas including breast cancer, colorectal cancer, pancreatic cancer, malignant melanoma, leukemia and mucoepidermoid cancer[5,7-10]. This review describes the biological background of AKT and ERK in ICC, presents our own new data, analyses the potential prognostic relevance and discusses upcoming therapeutic options.

GENERAL BIOLOGY OF THE AKT AND ERK SIGNALING PATHWAYS

AKT/PKB (Protein kinase B)

AKT is a central player in the regulation of metabolism, cell survival, motility, cell cycle progression and transcription. AKT is a serine/threonine kinase and its activation is induced by phosphorylation mediated by Phosphoinositide (PI) 3-kinase (PI3K) in association with tyrosine kinase receptors. The AKT family comprises three mammalian isoforms, PKBα, PKBβ and PKBγ (AKT1, AKT2 and AKT3, respectively), which are products from different genes and share a conserved structure. AKT includes three functional domains: an N-terminal pleckstrin homology (PH) domain, a central kinase domain, and a C-terminal regulatory domain. PI3K is localized upstream of the AKT kinase and is essential for the activation of AKT. PI3K and thereby AKT are activated upon (1) autophosphorylation of receptor tyrosine kinases induced by ligands (such as growth factors), (2) activation of cytokine receptors, (3) stimulation of G-Protein coupled receptors, or (4) activation of integrin signaling[11,12]. Upon PI3K mediated generation of the second messenger PtdIns (3,4,5) P_3 AKT is translocated from the cytoplasm to the plasma membrane. Once recruited to the membrane, AKT is activated by a phosphoinositide-dependent kinase 1 and 2 (PDK1, PDK2) dependent multistep process that results in the phosphorylation of both Threonine 308 and Serine 473 residues necessary for full AKT activation. Due to the great number of downstream substrates AKT kinase modulates a variety of central cellular processes as summarized in Figure 1.

ERK (extracellular regulated kinases)

ERK1/2 - also referred to as p44 and p42 MAP kinases - are ubiquitously expressed kinases and represent one component of the three mitogen activated protein kinases (MAPK) cascades that are activated by an enormous array of stimuli. The MAPK pathways phosphorylate and activate numerous proteins, including transcription factors, cytoskeletal proteins, kinases and other enzymes. Each of the three MAPK pathways contains a three-tiered kinase cascade comprising a MAP kinase kinase kinase (synonyms: MAPKKK, MAP3K, MEKK or MKKK), a MAP kinase kinase (synonyms: MPKK, MAP2K, MEK or MKK) and the MAPK. This review focuses on ERK1 and ERK2 that form a part of the MAPK module containing Raf MAPKKKs (A-Raf- B-Raf, C-Raf/Raf1) and the MEK1/MEK2 MAPKKs. All MAPKs are activated by dual phosphorylation of the conserved threonine and tyrosine residues. ERK1 and ERK2 are induced by stimuli such as tyrosine receptor kinases or G-protein coupled receptors. This leads to activation of Ras, which then triggers a complex network including the activation of Raf isoforms. ERK1/2 exhibit a variety of substrates including several key transcription factors (Figure 1). Depending upon the intensity and duration of stimulation ERK1/2 can result in proliferation of differentiation[13].

TARGETS OF THE AKT AND ERK PATHWAY

Both AKT and ERK mediate their effect *via* several substrates, which may be localized in the nuclei or in the cytoplasm. AKT can potentially phosphorylate over 9000 substrates in mammalian cells including typical cytoplasmic as well as nuclear proteins. Thus, AKT activity not surprisingly can be detected in both the nucleus and the cytoplasm[14]. When interpreting immunohistochemically stained tissue slides, it is important to keep the subcellular localization of activated AKT or ERK in mind. Moreover it seems as if both kinases show different subcellular localizations in various human carcinomas. In a colon cancer study, we showed pAKT immuno-localization in the nucleus and cytoplasm[6], in contrast to our results in ICC with a restricted immunoreactivity in the cytoplasm.

Cytosolic substrates for ERK include several pathway components involved in ERK negative feedback regulation. Multiple residues on SOS (son of sevenless homolog) are phosphorylated by ERK following growth factor stimulation. SOS phosphorylation destabilizes the SOS-Grb2 complex, eliminating SOS recruitment to the plasma membrane and interfering with Ras activation of the ERK pathway. It has also been proposed that negative feedback by ERK occurs through direct phosphorylation of the epidermal growth factor EGF receptor at Thr669[15].

ERK1 and ERK2 regulate transcription indirectly by phosphorylating the 90 kDa ribosomal protein S6 kinases (RSKs), a family of broadly expressed Ser/Thr kinases activated in response to mitogenic stimuli, including growth factors and tumor-promoting phorbol esters[16]. Active RSKs appear to play a major role in transcriptional regulation, translocating to the nucleus and phosphorylating such factors as the product of proto-oncogene *c-fos* at Ser362, serum response factor (SRF) at Ser103, and cyclic AMP response element-binding protein (CREB) at Ser133[17,18]. Recent studies revealed a spatial control of ERK signaling by Sef (similar expression of FGF), a recently identified inhibitor, whose action mechanisms are not fully defined. Sef acts as a molecular switch for ERK signaling by specifically inhibiting nuclear translocation of ERK without inhibiting its activity in the cytoplasm[19]. Further studies are necessary to elucidate the regulatory mechanisms of Sef.

Upon phosphorylation, nuclear translocation of ERK1 and ERK2 is critical for both gene expression and DNA replication induced by growth factors. Probably the best-characterized transcription factor substrates of ERKs are ternary complex factors (TCFs) including Elk-1, which is directly phosphorylated by ERK1 and ERK2 at multiple sites[20]. Upon complex formation with SRF, phosphorylated TCFs transcriptionally activate the numerous mitogen-inducible genes regulated by serum response elements

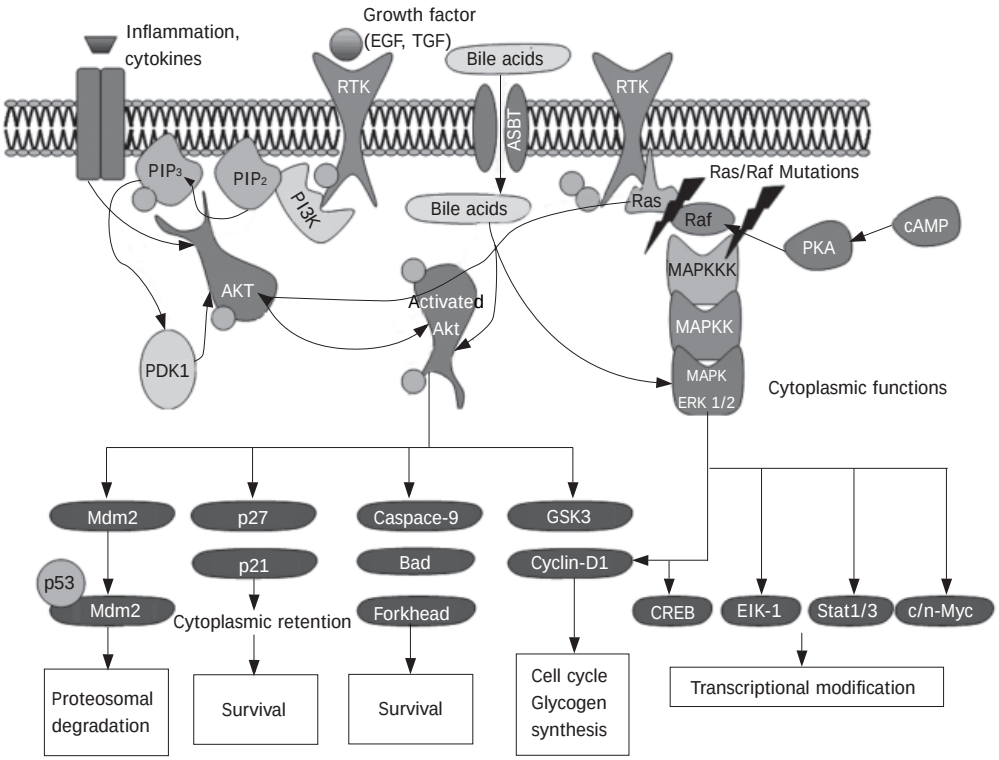

Figure 1 Overview of the AKT and ERK signaling pathway.

(SREs)[21]. Another direct target of ERK, at least *in vitro*, is the product of proto-oncogene c-*myc*, a short-lived transcription factor involved in multiple aspects of growth control[22].

AKT may mediate its functions both in the cytoplasm and in the nucleus. AKT phosphorylates a great variety of substrates involved in the regulation of key cellular functions including cell growth and survival, glucose metabolism and protein translation. Most of the well-known targets are located in the cytoplasm but it is noteworthy that many of the substrates of AKT are proteins that function in the nucleus. Some relevant cytoplasmic targets of AKT are GSK3 (glycogen synthase kinase), IRS-1 (insulin receptor substrate-1), PDE-3B (phosphodiesterase-3B), BAD, human caspase 9, Forkhead and NF-B transcription factors, BRCA1, MDM2 (murine double minute), mTOR (mammalian target of rapamycin), eNOS (endothelial nitric oxide synthase), Raf protein kinase and $p21^{Cip/Waf1}$. Several of these targets such as MDM2 translocate to the nucleus upon activation *via* AKT [23-28]. Similar to ERK1/2, immunohistochemical analysis of pAKT in various human cancers shows both cytoplasmic and nuclear immunoreactivity. *In vitro* studies showed that AKT is activated by membrane localization and later translocated to the cytosol and nucleus[29]. The function of nuclear activated AKT is not yet fully understood. Among the nuclear substrates there are fatty acid synthase[30], estrogen and androgen hormone receptors[31,32] and transcriptional factors of the FOXO family[33]. All these factors are supposed to increase cell survival.

SPECIAL ASPECTS OF AKT AND ERK IN CHOLANGIOCARCINOMA

Both the AKT and ERK pathways can be activated *via* several growth factors/survival factors, stimulation of G-protein-coupled receptors, or activation of integrin signaling. Due to the great array of activators relevant to different human cancers, we will focus on those activators that are likely to be specific for ICC.

Activation by growth factors

Both the AKT and the ERK pathway are inducible *via* growth factor stimulation. It is known that a subset of ICC exhibit overexpression of the EGF and HER-2 receptor[34]. Indeed, in our study group 21.3% (13/61) of ICC showed strong EGFR overexpression, which was confirmed by others[35]. Due to the relatively large subset of ICC with EGF or HER-2 expression activation of these ligands might be relevant for the progression of ICC.

Activation by cytokine receptors

A well-known risk factor for the development of cholangiocarcinoma is chronic inflammation. Chronically inflamed biliary epithelium is exposed to cytokines and chemokines. Indeed, cholangiocarcinoma cells constitutively secrete Interleukin 6 (IL-6), which is supposed to be a pivotal cytokine for cholangiocarcinogenesis[36-38]. A recent paper found ERK1/2 and AKT in cholangiocarcinoma cell lines to be activated *via* the cytokine receptor C-X-C motif chemokine receptor 4 (CXCR4) *via* the CXC chemokine ligand 12 (CXCL12). Thus, inflammation signals mediated by cytokine receptors are capable of inducing the ERK and AKT pathway[39].

Activation by oncogenes

It is crucial to know that AKT and ERK can be induced by mutation of oncogenes such as *Ras* and *Braf*. *Ras* is frequently mutated in many tumors, and is associated with constitutive activation of the ERK1/2 MAPKs. A

recent study showed that in contrast to hepatocellular carcinoma (HCC), *K-ras* and *Braf* mutations are a frequent event in cholangiocarcinoma[40]. In fact 22% of the cholangiocarcinoma analysed exhibited a *K-ras* mutation and 45% a *B-Raf* mutation, respectively.

Since Ras and Braf proteins are members of the Ras/Raf/MAPKKK/MAPKK/MAPK pathway, activating mutations of *K-ras* and *B-raf* should result in increased activation of MAPK. Indeed it was shown, that tumors harboring a *B-raf* mutation exhibited stronger ERK1/2 immunostaining[40]. *K-ras* mutations are a frequent event in colorectal cancer and we recently demonstrated a consecutive activation of the ERK pathway in cancers with mutated *K-ras*[6]. These data indicate that frequent disruption of alterations in the Ras/Raf/MAPKKK/MAPKK/MAPK pathway, either by *Ras* or *Braf* mutations, may play a central role in cholangiocellular carcinogenesis.

Activation by bile acids

Cholangiocytes are exposed to high concentrations of bile acids. It is known that bile acids after cellular uptake by apical sodium bile acid cotransporter (ASBT), are capable of altering the AKT and ERK signaling pathways[41]. Moreover, the EGFR-pathway appears to be activated by extracellular bile acids *via* its ligand transforming growth factor TGF-alpha in cholangiocytes[42] and the human cholangiocarcinoma cell line[43]. The EGFR pathway, once activated initiates several signaling cascades, including the AKT and ERK pathways.

ERK AND AKT PATHWAYS AND PROGNOSIS

Little is known about the prognostic relevance of the ERK and AKT pathways in intrahepatic cholangiocarcinoma. In fact, there is only one study that was based on a small cohort of 24 samples that does not discriminate between extra- and intrahepatic cholangiocarcinoma[44]. Thus, we aimed to elucidate the clinical impact of activated AKT and ERK pathways in a large and homogenous cohort of solely intrahepatic cholangiocarcinoma.

We would like to present new data derived from a large study of 62 intrahepatic cholangiocarcinomas. Between 1998 and 2006 a total of 62 patients with a mean age of 58 ± 11.5 years were available for this study. The study comprised consecutive patients who underwent surgery for liver resection. Patients solely undergoing an explorative laparatomy without subsequent resection or with hilar cholangiocarcinoma, gallbladder carcinoma or mixed hepato/-CCC were excluded from the study. The diagnosis of ICC was based on histology by examination of the resected liver specimen.

IMMUNOHISTOCHEMISTRY (IHC)

Phospho-AKT and Phospho-ERK

Immunostaining with pAKT (1/2/3) serine 473 was carried out with a monoclonal anti-phospho-AKT antibody (Cell Signaling Technology, Beverly, Massachusetts, USA). Subsequent to antibody retrieval, the primary antibodies were incubated for 30 min at 1:20 dilution. Antibody detection was performed with peroxidase-conjugated streptavidin and diaminobenzidine as chromogen. Tumors were classified according to their cytoplasmic staining intensity: negative (0), moderate (1) and strong (2).

Monoclonal phospho-p44/42 MAPK antibody (threonine 202/ tyrosine 204; Cell Signaling Technology, Beverly, Massachusetts, USA) was used at a 1:100 dilution. Tumor cells with strong specific immunostaining, independent of the amount of stained cells, were scored as strongly positive (2+). Tumors exhibiting a detectable but faint immunostaining were scored as weak (1+), whereas tumors with a minimal, hardly detectable or missing staining pattern were classified as negative (0).

EGFR

Immunostaining with EGFR was carried out with a monoclonal anti-EGFR antibody (Zymed Laboratories Inc, CA, USA). The primary antibodies were incubated for 30 min at 1:100 dilution. Antibody demonstration was achieved using the commercially available anti-mouse IgG detection kit (EnVision, DakoCytomation, Carpenteria, CA, USA). Classification was performed following the guidelines of PharmDx^{Tm} (DakoCytomation). Tumor samples lacking immunostaining were classified as negative (0), whereas the remaining were classified into 1+, 2+ or 3+ depending on the level of immunoreactivity.

Ki67 Immunostaining, TUNEL

The growth fraction was determined as previously described[45]. *In situ* DNA fragmentation was established using the terminal desoxyribonucleotide transferase (TdT)-mediated dUTP nick end labelling technique (TUNEL) as previously described[45].

Statistical analysis

Immunostainings were assessed by two of the authors in a blind-trial fashion without knowledge of the clinical outcome. Interobserver agreement[46] of pERK and pAKT was substantial (kappa = 0.78 and 0.63). Relationships between ordinal parameters were investigated using two tailed χ^2 analysis (or Fisher's exact test where patient numbers were small). Overall survival (OS) curves were estimated using the Kaplan-Meier method, and any differences in the survival curves were compared by the log-rank test.

IHC of pAKT, pERK and EGFR

Immunostaining for pAKT was localized to the cytoplasm of tumor cells. Twenty two patients (37.3%) were classified as negative, 24 (40.7%) as moderately positive and 13 (22%) as strongly positive. Immunostaining of pERK exhibited a specific nuclear and cytoplasmatic staining pattern. Representative pAKT and pERK immunostainings are shown in Figure 2. In all, 26 (41.9%) tumors lacked pERK immunostaining, 19 (30.6%) tumors exhibited a moderate staining intensity and 17 (27.4%) tumors were classified as strongly positive. Immunostaining of EGFR was localized to the membrane of the tumor cells. Due to the lack of paraffin material, two cases were excluded from EGFR-

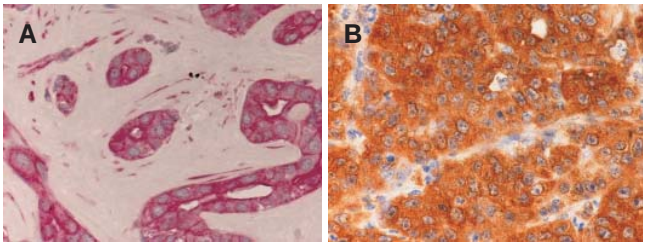

Figure 2 Light micrograph displaying strong phospho-ERK1/2 (**A**) and strong phospho-AKT (**B**) expression as analyzed by immunohistochemistry in intrahepatic cholangiocarcinoma (x 400).

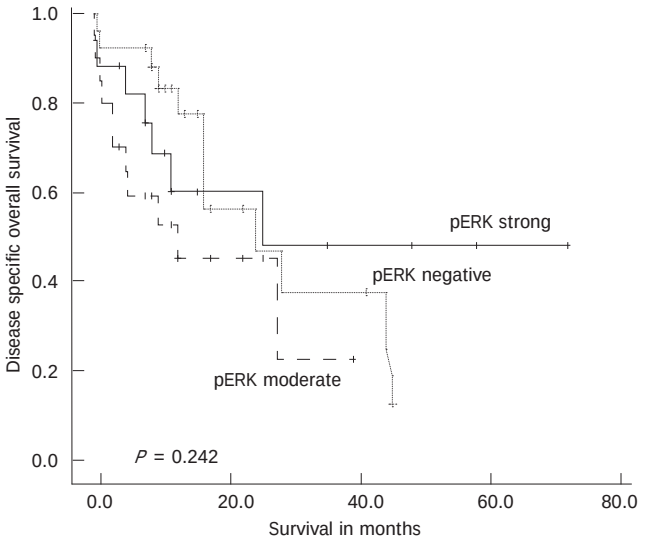

Figure 3 Kaplan-Meier survival plot for disease specific overall survival in the complete series of 62 intrahepatic cholangiocarcinoma in relation to pERK immunostaining intensity. Log-rank test: $P = 0.242$.

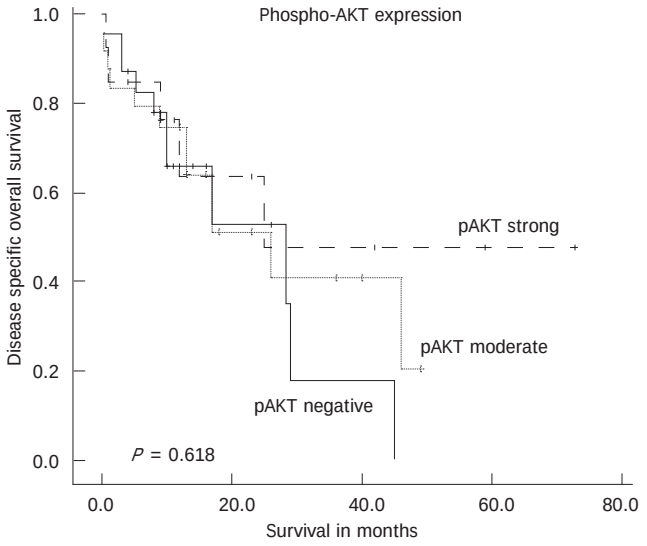

Figure 4 Kaplan-Meier survival plot for disease specific overall survival in the complete series of 59 intrahepatic cholangiocarcinoma in relation to pAKT immunostaining intensity. Log-rank test: $P = 0.618$.

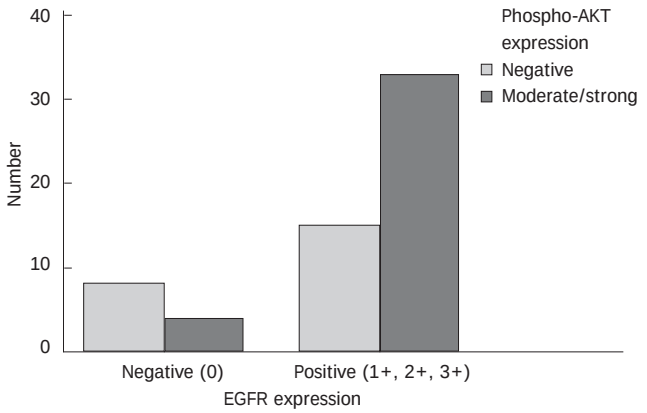

Figure 5 Intrahepatic cholangiocarcinoma with positive EGFR expression exhibit significantly more frequent AKT activation (χ^2 analysis: $P = 0.028$).

IHC. In all, 12 (19.7 %) tumors were classified as negative, 19 (31.1 %) as 1+, 17 (28.9%) as 2+ and 13 (21.3%) as 3+. χ^2 analysis revealed that EGFR-positive tumors (1+, 2+, 3+) had a statistically significant association with AKT activation ($P = 0.028$; Figure 5) but not with ERK activation. Kaplan-Meier survival analysis did not reveal a prognostic relevance of pAKT, pERK (Figures 3 and 4) or EGFR expression nor were any of the parameters associated with apoptosis or growth fraction (data not shown).

CONCLUSION

The ERK and AKT pathways are of central relevance and can induce growth factor independent growth, insensitivity to apoptotic signals, ability to invade and alter response to chemotherapeutic drugs. The fact that mutations of the Ras/Raf/MAPKKK/MAPKK/MAPK pathway occur in more than 60% of cholangiocarcinomas indicates the importance of these pathways for the carcinogenesis of cholangiocarcinomas and highlights new strategies in the treatment of this disease[47]. Moreover, the finding of a relatively large subset of ICC presenting overexpression of growth factors such as EGFR and HER-2/neu support the notion, that these growth factors play a relevant role in the progression of ICC. Our results support the notion that the AKT but not the ERK1/2 pathway is induced by EGFR overexpression, since we found a coexpression of pAKT and EGFR in ICC. However, neither ERK1/2 nor AKT activation influenced patient survival in this large series of ICC. Thus, both kinases may not serve as potential prognostic markers in this highly aggressive disease. Our results are in contrast to a previous study suggesting AKT as a favourable prognostic parameter in cholangiocarcinoma[44]. This study by Javle *et al* did not discriminate between intrahepatic and extrahepatic cholangiocarcinoma and is based on a small cohort with 24 patients; thus, the data derived should be interpreted with caution. The main advantage of the present study is the large number of patients ($n = 62$) in combination with a high homogeneity of this series composed of consecutively resected ICC.

Both the AKT and ERK pathways are topics of preclinical and clinical trials. A promising candidate is the multikinase inhibitor Sorafenib, which inhibits several

kinases including the Raf kinase, an upstream activator of the ERK pathway[48,49]. A recent study published the results of a phase Ⅱ study of sorafenib in patients with advanced hepatocellular carcinoma. It was demonstrated that HCC patients with higher pERK baseline levels had a longer time to progression following treatment with sorafenib thus pointing towards the possible relevance of activated pERK as an useful biomarker in HCC[48,49]. With regard to carcinomas of the biliary system the results of a phase Ⅱ study of sorafenib in patients with unresectable or metastastic gallbladder carcinoma or cholangiocarcinoma have been presented in Abstract form[50]. Sorafenib as a single agent did not result in a clinically significant objective response rate in patients with gallbladder and cholangiocarcinoma, but demonstrated an impact on survival that may be comparable to commonly used chemotherapy regimens. These promising data point towards novel therapeutic options utilizing multikinase inhibitors such as Sorafenib. In addition, the inhibition of upstream activators of the AKT and ERK pathways such as EGFR and HER-2 might also constitute novel therapeutic approaches. The results in a small number of patients showed that cetuximab, a monoclonal antibody against EGFR, is well tolerated and provides good palliative effects in advanced cholangiocarcinoma[51].

Despite the widely acknowledged potential of AKT inhibitors as anticancer therapy, few have made it to clinical trials. Wortmannin and LY294002 may have limited clinical utility owing to their lack of specificity, associated adverse effects, poor pharmacology, and poor solubility[52,53]. *In vivo* use of LY294002 in mice has been associated with many adverse effects, including death[54]. Furthermore, in mice, Wortmannin induces liver and bone marrow toxicity, and LY294002 can induce dermatitis and inhibit growth. Therefore, although Wortmannin and LY294002 inhibit the PI-3K/AKT pathway, their drawbacks raise doubts about their suitability as leading candidates for additional drug development.

Currently studies aimed at testing the clinical relevance of AKT inhibitors such as VQD-002, [Triciribine (TCN-P)] which is a tricyclic nucleoside that inhibits activated AKT, are being conducted. For example, the MD Anderson Cancer Center, Houston, TX (USA), and the H. Lee Moffitt Cancer Center, Tampa, FL (USA) have an ongoing Phase Ⅰ/Ⅱa clinical trial with VQD-002 in ovarian, pancreatic, breast, and colorectal cancer patients with tumors that over-express AKT (http://www.vioquestpharm.com/content/VQ0A002_about.html). Regarding the MAPK pathway, oral MEK inhibitors such as CI-1040 are currently being tested in a multicenter phase Ⅱ study in patients with advanced non-small-cell lung, breast, colon, and pancreatic cancer[55].

In addition to the above-mentioned kinases, another potential therapeutic target is worth mentioning. Against the background of NSAIDs, recent studies have evaluated selective COX-inhibitors for their effect on cell growth and invasion of cholangiocarcinoma cells *in vitro* and in nude mice[56-60]. Treatment with COX-2 inhibitors resulted in induced apoptosis and inhibited proliferation. In a recent study we demonstrated the independent prognostic value of immunohistochemical COX-2 protein expression in resected ICC[45], thereby offering a further potential additional adjuvant therapeutic approach with COX-2 inhibitors facilitating an optimised therapeutic strategy. Moreover COX-2 may serve as a target for chemoprevention in high-risk patients.

Significant progress has been made in understanding this disease, and patients are being diagnosed earlier at specialized centers. Moreover, an optimized preoperative assessment of resectability as well as an aggressive intraoperative approach to achieve complete tumor resection might increase long-term survival[3]. However, a significant proportion of patients present with advanced disease and are not candidates for curative surgery. The palliative options, mainly consisting of chemotherapy, are of limited benefit, as cholangiocarcinomas respond poorly to existing therapies. Therefore, further clinical and preclinical trials are necessary in order to develop novel therapeutic options based on new tumor targets such as AKT, ERK and EGFR. Although the activation of these pathways did not show an impact on survival in ICC - at least in this study - in contrast to many other human carcinomas, an interruption of these pathways or associated signaling molecules by specific inhibitors might, nevertheless, have favorable effects on long-term survival for this highly aggressive cancer.

Abstract

The features of JAK-STAT signaling in liver cells are discussed in the current review. The role of this signaling cascade in carcinogenesis is accentuated. The possible involvement of this pathway and alteration of its elements are compared for normal cholangiocytes, cholangiocarcinoma predisposition and development. Prolactin and interleukin-6 are described in detail as the best studied examples. In addition, the non-classical nuclear translocation of cytokine receptors is discussed in terms of its possible implication to cholangiocarcinoma development.

Key words: Cholangiocarcinoma; Janus tyrosine Kinases; Signal Transducers and Activators of Transcription; Prolactin; Interleukin-6; Cytokine receptors; Receptor tyrosine kinases

INTRODUCTION

The signaling pathway of Janus tyrosine Kinases-Signal Transducers and Activators of Transcription (JAK-STAT) is activated by a variety of hormones (prolactin, growth hormone, leptin, erythropoietin), as well as cytokines, and growth factors *via* their receptors. JAK-STAT signaling participates in the regulation of cell proliferation, differentiation, survival, motility, and apoptosis in different organs including liver[1]. During the last decades, the data on cytokine/growth factor receptors expression and functions in different liver cell types (hepatocytes, cholangiocytes, Kupffer and stellate cells) have rapidly grown. It highlights the importance of JAK-STAT signaling in normal liver physiology and pathology. Moreover, deregulation of this pathway is closely associated with tumorigenesis.

Cholangiocarcinoma is a malignancy of the biliary epithelium with the worst prognosis among other liver tumors. It is relatively rare, but it frequently progressively increases. Molecular cholangiocarcinoma markers are mainly nonspecific and require further investigation. The main risk factors for cholangiocarcinoma development are hyperplasia of bile duct epithelia induced by bile duct obstruction, hepatolithiasis, inflammation, fibrosis, and some other factors[2-4]. Though the role of the JAK-STAT cascade is poorly deciphered both in normal cholangiocytes and in cholangiocarcinoma cells, a number of papers have been published recently where the role of prolactin (Prl), growth hormone (GH) and interleukin-6 (IL-6) and expression of corresponding receptors in cholangiocytes has been shown[5-7]. Expression of these receptors undergoes essential changes under hyperplasia of bile duct epithelia induced by bile duct obstruction, thus the role of the JAK-STAT pathway should attract further investigations in this area.

PRINCIPLES OF JAK-STAT SIGNALING

The main site for JAK-STAT signaling initiation is the cellular membrane; however, internalization pathways have been recently shown to be also important for the generation of comprehensive biological effect and sustaining signal transduction. Among other intracellular targets of receptor-JAK-STAT the cascade nucleus plays a key role[8-10]. Mitochondrial targeting of some cytokine receptors (GH receptor) has also been described[11].

The initial steps of signaling cascade activation by hormone (cytokine) are still intensively studied, but for many of them an interaction between signaling molecules and preformed receptor dimers leads to rotation of intercellular parts of receptor and subsequent activation of receptor-associated JAKs[12] followed by STAT docking on receptor and its phosphorylation, dimerization, and nuclear translocation (Figure 1).

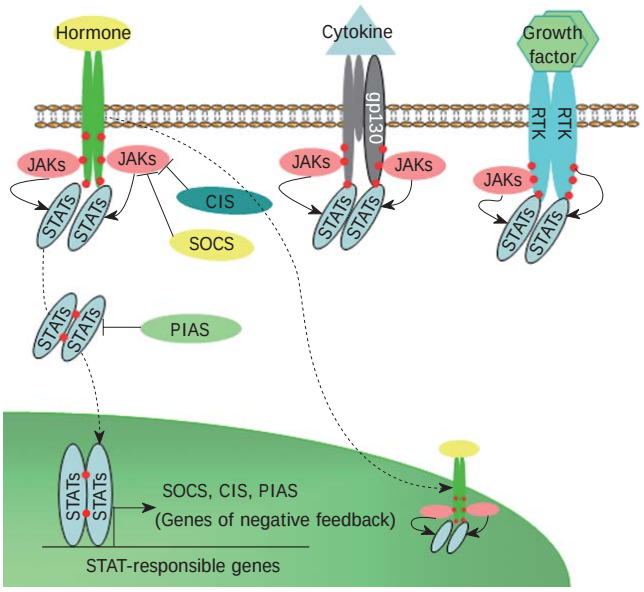

Figure 1 Schematic representation of JAK-STAT signaling induced by hormones, cytokines, and growth factors. RTK: Receptors tyrosine kinases; JAK: Jannus kinase; STA: Signal transducer and activator of transcription; SOCS: Suppressor of cytokine signaling; CIS: Cytokine induced suppressor; PIAS: Protein inhibitors of activated STATs. Solid arrows - phosphorylation; Dashed arrows - nuclear translocation; Blunt arrows - inhibition; Red circles - phosphorylated tyrosines.

Different JAKs (JAK1, JAK2, JAK3, and Tyk2) and STATs (STAT1, STAT2, STAT3, STAT4, STAT5a, STAT5b, and STAT6) participate in JAK-STAT signal transduction. STAT3 and STAT5 are expressed in many cell types, activated by various hormones, cytokines and growth factors and play a role in different biological responses, whereas other STAT proteins (STAT1, 2, 4 and 6) are revealed mainly in specific cell types and participate predominantly in host defense mechanisms[13,14]. Phosphorylated STAT dimers can bind to STAT-responsive elements in the promoters of various genes, resulting in modulation of their transcription. STATs often act on gene transcription in cooperation or competition with NF-κB, AP-1, and a glucocorticoid receptor due to close co-localization of correspondent binding sites[15-17] accomplishing a crosstalk with other signaling cascades.

Suppressors of cytokine signaling (SOCS) proteins are able to inhibit JAK-STAT signaling. SOCS1 and SOCS3 are the most potent and broadly distributed suppressors with similar inhibition effects on gp130 related, Prl, and GH signaling. Promoter regions of SOCS1 and SOCS3 genes possess functional STAT binding elements and activation of JAK-STAT signaling induces rapid up-regulation of SOCS proteins by STAT-dependent pathways. In accordance with negative feedback mechanism JAK-STAT signaling is inhibited by SOCS proteins association with catalytic domains of JAKs as well as by SOCS binding to phosphorylated tyrosine residues of cytokine, GH, Prl, leptin, and erythropoietin (Epo) receptors which act as docking sites for downstream signaling[18-20]. STAT activation can also be inhibited by direct interaction with protein inhibitors of activated STAT proteins (PIAS)[21].

In some cases activation of STATs occurs independently of JAKs and is involved in receptor tyrosine kinase signaling. This activation is induced by direct interaction with receptor tyrosine kinases or by subsequent downstream signaling with implication of other kinases such as Src. For example, STAT3 is activated in response to stimulation by EGF, HGF, CSF-1, PDGF and other growth factors; and their corresponding receptor tyrosine kinases (ErbB1, ErbB-2, c-met, CSF-1, PDGF receptors, and others) possess a common STAT3 docking motif in their cytoplasmic domains. STAT5a phosphorylation is induced by EGF[13,22,23].

JAK-STAT SIGNALING AND CARCINOGENESIS

Altered activation of JAK-STAT signaling has been shown in multiple solid tumors and leukemia[24-26]. In different experimental models tumorigenesis is associated with increased expression and/or activity of JAK1, 2[27,28] or STAT3, 5[29]. A constitutively active mutant of STAT3 has been shown to transform rat fibroblasts[30], and the increased expression of wild type STAT5 in the lymphoid lineage induced T cell leukemia in mice[31]. A constitutively active mutant of JAK2 has been identified in patients with polycythaemia vera[32]. Moreover, increased levels of correspondent ligands can be associated with JAK-STAT induced carcinogenesis: in animal models of prostate and mammary gland hyperplasia with local overexpression of Prl[33,34]; in humans hyperprolactinemia is considered as a risk factor for breast and, probably, prostate cancer[35,36]; overexpression of GH in transgenic mice leads to increased frequency of mammary adenocarcinoma[37]. A particular and essential role for neoplasia progression of autocrine production of Prl has been revealed[34,38]. Only autocrine, but not exocrine GH, is suggested to promote neoplasia[39-41].

The role of the JAK-STAT cascade is not limited to induction of carcinogenesis: for example, the predominant role of TYK2 and STAT1 in many types of cancer is antitumorigenic *via* regulation of apoptosis[42]. Moreover, in some models JAK1 and 2 also play an antitumorigenic role[43]. Prl induced activation of JAK2 prevents breast cancer cells mesenchymal transition and acts as an invasion suppressor[44,45]. Reduced phosphorylation of STAT5 in breast cancer highlights patients with a worse prognosis of disease development[46].

CHOLANGIOCARCINOMA DEVELOPMENT AND JAK-STAT SIGNALING

A number of signaling molecules acting via the JAK-STAT pathway participate in regulation of bile duct cell functions. Among them, Prl and IL-6 (activation of complete JAK-STAT cascade), and EGF, HGF (activation of STAT *via* receptor tyrosine kinases) have their receptors in human and animal cholangiocarcinoma tissues and cell lines. Other JAK-STAT signaling molecules involved in the development of other cancer types have not been yet investigated.

Since the development of cholangiocarcinoma is closely related with obstructive, fibrotic, cirrhotic, and inflammation

changes of biliary epithelium leading to its hyperplasia or dysplasia, it is reasonable to compare the peculiarity of JAK-STAT signaling induced by different ligands in normal cholangiocytes, bile duct cells proliferating under conditions of different hepatic pathologies considered as a predisposition to cholangiocarcinoma development, and in cholangiocarcinoma cells.

HORMONAL INDUCTION OF JAK-STAT SIGNALING AND CHOLANGIOCARCINOMA DEVELOPMENT

Prolactin signaling

Prl is a multifunctional pituitary hormone that also works as a locally produced cytokine. Prl regulates differentiation, proliferation, water-salt balance in different cell types including many ductal structures (such as ductal systems of mammary, lacrimal, submaxillary, prostate glands, pancreas, and kidney) and possesses high immunomodulatory activity[47,48]. Prl participates in the stimulation of rat bile duct cell proliferation and cholangiocyte regulation of bile water salt balance[49,50].

Prl receptor (PrlR) exists in several isoforms with a tissue specific ratio of expression. Long and short rat PrlR isoforms are the result of alternative splicing of cytoplasmic domain exons of a single gene. Several intermediate PrlR isoforms with varying cytoplasmic domains have been found in human normal and tumor tissues. The short PrlR isoform has been suggested to negatively regulate activity of the long isoform by heterodimerization. JAK-STAT pathway with predominant usage of JAK2 and STAT5 proteins is the main signaling pathway activated by Prl. STAT1 and STAT3 proteins may also be involved in Prl signaling with nuclear translocation of their homo- and heterodimers. SOCS1, 2, and 3 attenuate Prl signaling[47,48,51-53].

Prolactin JAK-STAT signaling and their alterations under conditions of cholangiocarcinoma predisposition and development

Systemic Prl levels are elevated under different liver pathologies associated with increased cholangiocarcinoma incidents[54-56], while local Prl production by the cholangiocarcinoma cell line (RS-1) is observed only in a few samples (Ostroukhova & Smirnova, unpublished observations).

Normal animal and human bile duct cells express PrlR messenger RNA and protein at a relatively low level. Contrary to hepatocytes where short PrlR isoform predominates, normal rat bile duct cells express a predominantly long receptor isoform that is similar for such Prl target tissues, such as the uterus, pituitary, and mammary gland[7,57].

Hyperplasia of bile duct epithelia in rats induced by bile duct obstruction or normally occurring in immature animals as a risk factor of cholangiocarcinoma development is characterized by sharp elevation of cholangiocyte PrlR expression in both males and females. Similarly, obstructive human liver diseases with jaundice development and

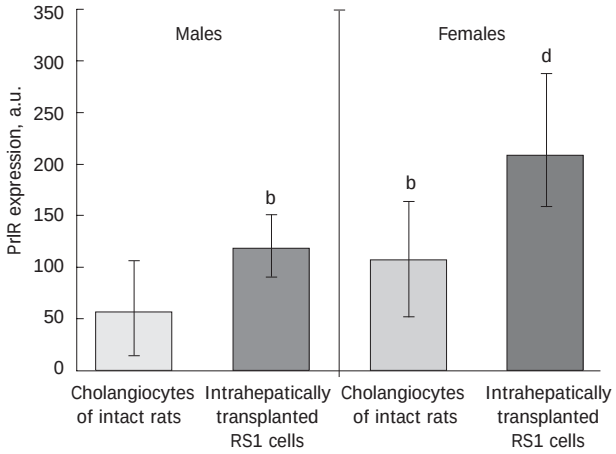

Figure 2 Increasing of prolactin receptor expression in rat liver transplanted RS-1 cholangiocarcinoma cell line. a.u, arbitrary units of intensity of PrlR expression. Medians, upper and lower quartiles. $^{b}P < 0.001$, *vs* intact males, $^{d}P < 0.001$, *vs* intact females.

enrichment of bile ducts are accompanied by a pronounced increase in cholangiocyte PrlR expression as compared with mild cholestasis without jaundice with limited affect on bile duct cell proliferating activity[57]. Obstructive conditions induce both dramatic elevation of the long receptor isoform and an increase in short isoform expression in bile duct cells. The level and isoform ratio of cholangiocyte PrlR in normal and obstructive conditions are only slightly dependent on gonadal hormones and independent of Prl[7,49,57].

Human cholangiocarcinoma samples are characterized by high PrlR expression significantly exceeding PrlR expression in cholangiocytes and hepatocytes under conditions of non-tumor liver diseases (Ostroukhova & Smirnova, unpublished observations). Intrahepatic transplantation of RS1 cholangiocarcinoma cells induces significant elevation of tumor cell PrlR expression (Figure 2) as compared both with subcutaneous tumor transplants and cholangiocytes of normal animals[58].

In cholangiocarcinoma cells the isoforms ratio is similar to the ratio observed in cholangiocytes proliferating under obstructive conditions. Surprisingly, relatively high levels of PrlR in transplantable cholangiocarcinoma have been revealed not only in female recipients, but also in male counterparts under conditions of relatively low levels of both Prl and estrogens[58]. Thus, it seems possible that the main regulators of PrlR expression in cholangiocarcinoma differ from sex hormones and may be connected with tumor derived autocrine/paracrine factors. Such unusual regulation may be an early event of cholangiocyte dysplasia since sharp elevation of PrlR expression in both males and females primarily occurs in bile duct cells proliferating in response to bile duct obstruction[7,49].

Prolactin - estrogen cross-talk and cholangiocarcinoma development

Prl as a female sex hormone acts in close connection with estrogens. In addition to systemic positive regulation of Prl production by estrogens and vise versa, a cross-talk between these hormones has been shown at the level of target tissues.

Prl stimulates both alpha and beta mRNA estrogen receptor expression in some tissues and putative STAT5α and STAT5β response elements have been identified in their promoters[59].

Estradiol *via* estrogen receptor (ER) alpha activates transcriptional expression of human PrlR through promoter Ⅲ that functions in different tissues including liver. Estrogens increase and tamoxifen reduces expression of Prl receptor mRNA in breast tumors and some other tissues[60-62]. Estrogens participate in regulation of downstream Prl signaling using different mechanisms. Estrogens can attenuate JAK-STAT signaling by Prl. Estrogens *via* ER α up-regulate SOCS2 expression thus diminishing JAK-STAT signaling. ER alpha activation could diminish PrlR signaling *via* direct interaction with STAT5α which leads to reduced STAT5α nuclear translocation. On the contrary, nongenomic action of estrogens that requires a ligand-binding domain of the membrane estrogen receptor alpha leads to rapid induction of STAT3 and STAT5 phosphorylation, their nuclear translocation, and transcriptional activity[61,63-66].

All these facts are very important taking into account that both PrlR and ERs are sharply increased in human cholangiocarcinoma samples and cell lines. While normal cholangiocytes express extremely low ERs, cholangiocarcinoma cells are characterized by intensive cytoplasmic and nuclear expression of ERα and ERβ as well as increased ERα/ERβ ratio that is typical for other cancer types. Besides, these estrogens potentiate and tamoxifen attenuates proliferation of human cholangiocarcinoma cell lines *in vitro*[4,6]. As in the case of PrlR, high level of ER expression in cholangiocarcinoma have been revealed not only in females, but also in males[67]. Based on both cytoplasmic and nuclear ER localization in cholangiocarcinoma cells it seems possible that estrogen regulation of Prl induced tumor JAK-STAT signaling is both nuclear and nongenomic and its bottom-line effects should be investigated carefully. It is interesting that in spite of high sensitivity of cholangiocarcinoma cells to both types of female sex hormones cholangiocarcinoma development is more frequent in men (1.5-1) than in women[68]. It may be due to attenuation of Prl tumor signaling by estrogens in the case of relatively high levels of both hormones in women. In any case combined therapy with tamoxifen and bromocriptine may be perspective clinical strategy for treatment of cholangiocarcinoma.

Cross-talk of Prl with EGF signaling leading to ErbB1 and ErbB2 phosphorylation has also been found, e.g. in breast cancer cells[69]. Since both Prl receptor and ERbB1 and ErbB2 are present in cholangiocarcinoma cells it may be relevant also to cholangiocarcinoma Prl signaling.

Growth hormone (GH) JAK-STAT signaling

As in the case of Prl, JAK-STAT signaling activated by GH mainly includes JAK2 activation and STAT5 phosphorylation, though STAT1 and 3 activation are sometimes also implicated. GH induces the expression of several negative regulators of GH signaling: SOCS1, 2, and 3, CIS[70,71].

GH receptor is present in normal rat cholangiocytes and isolated cholangiocytes respond to GH stimulation by IGF-1 secretion that in turn promotes cholangiocyt proliferation. GH receptor expression is increased in rat cholangiocytes after common bile duct ligation[72]. Contrary, in total liver of mice under the same conditions and humans with obstructive cholestasis and cirrhosis, changes of GH receptor expression and IGF-1 production are opposite[73]. GH signaling in cholangiocarcinoma cells has not been yet investigated.

Leptin JAK-STAT signaling

Leptin receptor is homologous to gp130 and can activate JAK2, mainly STAT3, but also STAT5, STAT6, STAT1 proteins[74-77]. SOCS3 is a negative regulator of leptin JAK-STAT signaling[18,78,79].

Autocrine/paracrine leptin production and leptin mRNA have been shown in different types of cancer cell lines *in vitro* and in some tumors *in vivo*. Serum leptin level also increases in patients with some cancer types[76,80]. Leptin is considered an agent responsible for overcoming the antiproliferative effect of antiestrogen therapy in different cancer types. Leptin receptors have been found in different cancer types and cell lines and leptin signaling is associated with suppression of tumor cell apoptosis[13,78].

Leptin expression has been detected in liver stellate cells and its local production is increased under obstructive cholestasis conditions. Leptin acts as a direct hepatic stellate cell survival agent[81-83]. Serum leptin is also elevated after common bile duct ligation and CCl_4 induced liver fibrosis that are both risk factors for cholangiocarcinoma development[84]. The leptin receptor has been found in bile duct cells of one type of mammalian species[85]. The role of leptin induction of JAK-STAT signaling needs to be investigated in cholangiocarcinoma development, and known STAT3 activation during cholangiocarcinoma progression (see below) may be partly due to leptin signaling.

Erythropoietin (Epo) JAK-STAT signaling

Epo is produced mainly by the fetal liver and the adult kidney. Epo interaction with Epo receptor activates JAK2 and STAT5[86,87]. Due to its erythropoietic functions, Epo has been widely used for prevention and treatment of cancer-associated anemia. However, Epo proangiogenic activity can compromise its beneficial effects in cancer patients.

Expression of Epo and Epo receptors has been found in a number of nonhematopoietic tissues as well as in different types of primary tumors and tumor cell lines suggesting the generation of autocrine-paracrine growth stimulatory Epo-Epo receptor loop in cancer cells. Experimental blockade of Epo signaling results in inhibition of different tumor growth and angiogenesis with concomitant elevation of apoptotic death of tumor and vascular endothelial cells[87-90].

Epo and/or Epo receptor expression have been found in liver stromal cells and some primary hepatic tumors, and tumor cell lines as well as in Kupffer cells during regeneration[87,89-93]. Still, we have not found any data on Epo expression and signaling in human cholangiocarcinoma

and its animal models. Based on the frequency of Epo and Epo receptor expression in different types of tumor cells, a key role of the fetal liver in Epo production, a role of hepatic progenitor cells, enriched in fetal liver, in liver cancer development as well as possibility of bone marrow derived liver stem cells to differentiate into biliary cells[90,94-97] it is easy to assume that the same situation occurs in cholangiocarcinoma development. Several facts support this assumption. In an earlier study the elevation of liver Epo production after bile duct ligation has been shown[98]. Data on the possibility of tissue specific estrogen modulation of local Epo expression together with elevation of estrogen receptor expression in human cholangiocarcinoma are also of great interest in this connection[6,86,99,100].

CYTOKINE INDUCTION OF JAK-STAT SIGNALING AND CHOLANGIOCARCINOMA DEVELOPMENT

Interleukine-6 (IL-6) induced JAK-STAT signaling

IL-6 and other cytokines of this family have their own receptors, but need a common receptor subunit gp130 for signal transduction. Binding of IL-6 to its receptor leads to dimerization of gp130, resulting in activation of gp130-associated JAK kinases (JAK1, JAK2, and TYK2) and subsequent activation of STAT3 proteins forming homodimers or rarely heterodimers with STAT1. There is reciprocal negative regulation of JAK-STAT3 and MAPK signaling by IL-6[15,101,102]. SOCS3 activated by STAT3 suppresses IL-6 signaling[15,18-20].

Alterations of local and systemic IL-6 level under conditions of cholangiocarcinoma predisposition and development

Autocrine/paracrine production of IL-6 by normal liver bile duct cells as well as by cultured human intrahepatic biliary epithelial cells is very low. Bile duct obstruction triggers pronounced elevation of IL-6 mRNA and protein production by bile duct cells, which can be mediated by inflammatory conditions[103-105]. A pronounced autocrine/paracrine secretion of IL-6 by different human intrahepatic cholangiocarcinoma cell lines has been observed *in vitro*[106,107]. Obstructive changes as well as cholangiocarcinoma development are also associated with elevation of systemic plasma IL-6 level[108].

Alterations of IL-6 signaling under conditions of cholangiocarcinoma predisposition and development

In vitro normal bile duct cells express both IL-6 receptor and gp130 messenger RNA and protein, but their expression level is further increased in cholangiocarcinoma cells. Appearance of autocrine IL-6 production and high level of its receptors lead to autocrine/paracrine loop of IL-6 signaling during cholangiocarcinoma progression[5,109].

IL-6 target genes in cholangiocarcinoma progression

IL-6 enhances cell survival and proliferation of human malignant cholangiocytes by up-regulation of myeloid cell leukemia-1 (mcl-1) mRNA and protein expression which is a key member of the antiapoptotic Bcl-2 protein family[107,110]. Disruption of IL-6 signaling at different levels diminishes Mcl-1 promoter activity, its mRNA and protein level in human cholangiocarcinoma cell lines.

Sustained IL-6/JAK-STAT signaling and enhanced Mcl-1 expressions in cholangiocarcinoma are associated with at least partial epigenetic SOCS3 silencing. In human cholangiocarcinoma tissues and cell lines unusual inverse correlation exists between phosphorylated STAT-3 and SOCS3 protein expression. SOCS3 negative cholangiocarcinoma (as well as cholangiocarcinoma lines) samples are characterized by extensive methylation of SOCS3 promoter as compared with nontumor tissue. Treatment with demethylating agent restores IL-6 induction of SOCS3 leading to termination of phosphorylated STAT3 response, reduction of cholangiocarcinoma cells level of Mcl-1, and sensitization of cholangiocarcinoma cells to Tumor necrosis factor Related Apoptosis Inducing Ligand (TRAIL)-mediated apoptosis[111,112].

GROWTH FACTOR INDUCTION OF STAT SIGNALING AND CHOLANGIOCARCINOMA DEVELOPMENT

HGF induced STAT signaling

HGF is a growth factor acting *via* receptor tyrosine kinase c-Met and inducing matrix dissociation, motility of epithelial cells, and enhancing invasiveness of tumor cells. In the 5'-flanking region of human HGF gene cis-acting STAT element has been found. Interruption of STAT3 signaling by dominant-negative STAT3 reduces HGF promoter activity[113,114].

Interaction of HGF with its receptor c-Met leads to receptor dimerization and phosphorylation of intracellular receptor domain which forms the docking sites for interaction with multiple downstream signaling molecules including STAT3. STAT3 activation has been shown to be necessary for full biological responses of HGF and HGF induced proliferation[115-117]. In hepatocytes and some other cell types HGF activates the STAT3 signaling pathway, moreover, not only STAT3 but also STAT1α/STAT1β and STAT5 interact with c-Met[118,119]. STAT3 phosphorylation induced by HGF/c-Met signaling is limited by consequent positive HGF action on SOCS3 expression in some cell types. SOCS3 has been observed to act as a negative regulator of HGF-induced cell migration[120-122].

Alterations of local and systemic HGF level

In situ hybridization studies have demonstrated that there is a close paracrine ligand-receptor relationship between HGF expressed in mesenchymal cells and c-Met expressed in the adjacent epithelial cells. HGF production is stimulated by various cytokines including IL-6-type cytokines. Both HGF and c-met mRNAs and protein products are overexpressed in cholestatic animal liver and human hepatolithiasis specimens[123-125]. Serum HGF level is elevated in cholangiocarcinoma patients[126]. Cholangiocarcinoma cell lines do not secrete HGF, but

their co-cultivation with neutrophils induces a high level of HGF secretion by these mesenchymal cells and may enhance invasiveness of tumor cells[127].

Alterations of HGF signaling

c-Met is expressed in cultured mouse biliary epithelial cells and liver bile ducts[123,128]. c-Met activation and elevation of c-met mRNA and protein expression have been shown in mouse chemically induced cholangiocarcinoma, different cholangiocarcinoma cell lines, and human cholangiocarcinoma patients. c-Met overexpression is more prominent in induced cholangiocarcinoma in rats and human cholangiocarcinoma cell lines as compared to normal and hyperplastic intrahepatic biliary epithelium[3,5,126,129-131]. The presence of HGF-c-Met-STAT3 positive autocrine/paracrine loop in cholangiocarcinoma may confer increased survival, growth, and invasiveness during cholangiocarcinoma progression. The malignancy of cholangiocarcinoma cells containing activated STAT3 may be at least partly due to stimulation of HGF expression in adjacent mesenchymal cells and c-met overexpression in tumor cells.

ERbB2 induced JAK-STAT and STAT signaling

ErbB2 also known as HER-2 or HER-2/neu is a member of ErbB receptor tyrosine kinase family acting mainly as the most common partner for heteromerization for other members of this receptor family (ErbB1, ErbB3 and ERbB2) among which EGF is the main ligand for ErbB1 (EGFR). ErbB receptors may be constitutively associated with JAK kinases. Direct association between ErbB2 and other ErbB receptors with STAT3 has also been found. Src kinases are the other molecules for ErbB receptor mediated STAT signaling and potential upstream regulators of JAK kinases. Ligand induced receptor dimerization leads to recruitment of Src kinase that induces JAK and STAT3 phosphorylation, dimerization and nuclear translocation[132,133]. Neuregulin induced heterodimers of ErbB2 and ErbB4 may activate STAT5[23]. Expression of SOCS1, 3, 4, 5 is elevated by EGF treatment[134-136]. Tumor cell types that over express ErbB2 preferentially activate prosurvival STAT signaling. In different tumors an autocrine loop between cytokines and ErbB receptors induces constitutive STAT3 activation[133,137].

In human non-neoplastic hepatic tissue ErbB2 mRNA and protein products have been found only in large mature bile ducts or have not been revealed at all[138-140]. Human gallstone disease and common bile duct ligation in rats are accompanied by appearance or elevation of ErbB2 expression in cholangiocytes as compared with normal liver but its expression was lower than in cases of cholangiocarcinoma[138,141,142]. ErbB2 overexpression has been revealed in different human biliary tract cancer cell lines, xenobiotic induced rodent cholangiocarcinoma, as well as in human cholangiocarcinoma tissue samples. Overexpression of both ErbB1 (EGFR) and ErbB2 may serve as a base for enhancement of EGF signaling in cholangiocarcinoma. Altered ERbB2 expression occurs early in cholangiocarcinogenesis and may play an important role in its progression[129,130,139,143,144].

PERSPECTIVE THERAPEUTIC ADDRESSING OF THE JAK-STAT PATHWAY

As illustrated above, signaling of most hormones, cytokines and growth factors involved in cholangiocyte regulation seems to be enhanced under the progression of cholangiocarcinoma. It is associated, not only with increment of their systemic levels, but also (probably mainly) due to their local hepatic secretion and increment of the expression of their receptors. Taking together these observations we can suggest that local manipulation of JAK-STAT activation can be a very perspective therapeutic approach for managing of cholangiocarcinoma at different stages of its progression. Recent advances in development of hormonal and cytokine antagonists (recombinant proteins for Prl and GH and peptide for IL-6[145-147]) give us an efficient tool for this treatment. Since synthetic specific inhibitors of JAK and other tyrosine kinases are intensively developed, we could suggest their efficient application for managing of cholangiocarinoma in addition to antagonists.

For the moment, the most specific and efficient way to inhibit the components of the JAK-STAT pathway is local expression (tissue-specific) of dominant negative analogues of JAKs and STATs. Evidently, their application is now limited to laboratory investigations and needs further development of genetic therapy. Nevertheless, it is a potent tool for precise pre-clinical investigations of JAK-STAT inhibition in cholangiocarcinoma. Thus, in the next chapter we focus on a detailed description of the main players of the JAK-STAT pathway in cholangiocarcinoma.

JAK-STAT SIGNALING UNDER CONDITIONS OF CHOLANGIOCARCINOMA PREDISPOSITION AND DEVELOPMENT

Presented data indicate that a number of receptors associated with JAK-STAT signaling are expressed in normal cholangiocytes, their expression increases under conditions of cholangiocarcinoma predisposition and is additionally elevated in cholangiocarcinoma cells (Table 1). Preferably used components of JAK-STAT signaling for such receptors are shown in Table 2. Thus, STAT5 and STAT3 proteins are the main downstream components for hormones, growth factors, and cytokines using JAK-STAT signaling in normal, proliferating, and malignant cholangiocytes and both STAT3 and STAT5 are implicated in promotion of cell survival in a variety of other normal and cancer tissues. SOCS3 is the primary negative regulator of cholangiocyte JAK-STAT signaling (Table 2). Among all these components, only STAT3 and SOCS3 have been investigated in cholangiocarcinoma cells.

STAT3

STAT3 plays an important role in transduction of survival signals downstream of both JAKs and receptor tyrosine kinases. Aberrant and frequently constitutive activation of STAT3 has been described in a variety of human cancers. Activation of STAT3 in tumors is associated also with tumor escape from immune attack[151,152].

Table 1 Cholangiocyte receptors associated with the JAK-STAT signaling pathways: alterations of expression during cholangiocarcinoma predisposition and development

Receptor type	Norma	Direction of alteration		References
		Cholangiocarcinoma predisposition	Cholangiocarcinoma development

ErbB-2	No, JAK3, TYK2	STAT3 > STAT5, STAT6	SOCS3, SOCS1, SOCS4, SOCS5	[23,132-136,149,150]
c-Met	No	STAT3 > STAT5, STAT1	SOCS3	[115-122]

In normal liver phosphorylated STAT3 localizes in epithelial cells lining large bile ducts and peribiliary glands[104]. STAT3 was constitutively phosphorylated in tested cholangiocarcinoma cell lines but not in nonmalignant cholangiocytes. Mcl-1 promotor has STAT3 binding site. STAT3 site-directed mutagenesis decreases Mcl-1 promotor activity[111].

SOCS3

STATs activation is negatively regulated by SOCS proteins. SOCSs are generally considered as a kind of tumor suppressor gene. In some hepatocarcinoma cell lines aberrant methylation in STAT-binding sites of the SOCS3 gene has been associated with loss of SOCS3 function and enhancement of tumor cell growth and migration[153]. Epigenetic inactivation of tumor suppressor genes by hypermethylation is relevant to cholangiocarcinoma development[154]. Known sustained STAT3 activation during cholangiocarcinoma progression may be partly due to SOCS3 epigenetic silencing due to hypermethylation of its promoter in human cholangiocarcinoma tissues and cell lines. Inverse correlation has been observed between phosphorylated STAT3 and SOCS3 protein expression in cholangiocarcinoma specimens. In cholangiocarcinoma samples failing to express SOCS3, extensive methylation of SOCS3 promoter has been shown in comparison with paired nontumor tissue. Methylation of SOCS3 promoter is also identified in two cholangiocarcinoma cell lines. Treatment with demethylating agent leads to restoration of SOCS3 expression, subsequent termination of STAT activation, and reduction of cellular levels of Mcl-1[112].

Cholangiocarcinoma markers and STAT-responsible genes

Based on the data on molecular alterations in human cholangiocarcinoma reviewed by Sirica, 2005, we have tried to analyze whether cholangiocarcinoma marker genes have putative STAT response elements in their promoters. As shown in Table 3 a number of genes involved in cholangiocarcinoma growth signaling, cell cycle regulation, and apoptosis inhibition possess candidate STAT3-, STAT5-, and STAT-1-binding sites in their promoters. Prl and IL-6 induced STAT5 and STAT3 activation is essential for up-regulation of their transcription activity in different tumor types and leads mainly to tumor progression[2,16,86,107,110-112,155,156].

We can assume that cholangiocarcinoma markers (presented in Table 3) including growth factors, members of pro-inflammatory signaling pathway, CDK inhibitors, cyclins, members of the antiapoptotic Bcl-2 protein family including Mcl-1, Bcl-2, Bcl-XL, may serve as final potential molecular targets of JAK-STAT cholangiocarcinoma signaling induced by Prl, IL-6, HGF, EGF and some other molecules acting *via* JAK-STAT signaling. These promoters STAT-binding sites may be involved in overexpression of these markers in cholangiocarcinoma cells.

It is important to note that down-regulation of CDK inhibitors ($p21^{waf1/cip1}$, $p27^{kip1}$) is a characteristic feature of cholangiocarcinoma development while activated STATs up-regulate them in some other tissues (Table 3), thus the role of JAK-STAT signaling cannot be restricted to progression cholangiocarcinoma.

PRIMARY NUCLEAR JAK-STAT SIGNALING AND CHOLANGIOCARCINOMA DEVELOPMENT

Internalization pathways have also been demonstrated for signaling molecules associated with the JAK-STAT pathway. Nuclear accumulation of such molecules, ligand dependent nuclear translocation of corresponding receptors, nuclear localization of JAKs, and primary nuclear activation of STAT proteins have been revealed in different cell types and experimental systems. While

[1]Altered genes and direction of changes of their expression are adopted from[2].

membrane JAK-STAT signaling is the main signaling pathway in normal conditions, the importance of the primary nuclear pathway of JAK-STAT signaling rises under conditions of cell proliferation including preneoplastic and neoplastic proliferation. Appearance of components of JAK-STAT signaling in the nucleus or the enrichment of their nuclear pool seems to be associated with their participation in the regulation of proliferative processes and may be related to cholangiocarcinoma progression.

Ligands (such as Prl, GH, leptin, IL-1, IL-5, IFN-γ, TGF-α) and receptors acting *via* the JAK-STAT pathway or associated with STAT signaling by other mechanisms have been found in the nuclear compartment of different cell types mainly under conditions of high proliferative status and cancer development[8,10,166-169].

Nuclear translocation of Prl bound to Prl receptors has been revealed after Prl stimulation of Nb2 Prl-dependent lymphoma cells and the human breast cancer cell line T47D. Another mechanism suggests that Prl enters the nucleus in complex with cyclophilin B. In the nucleus this complex interacts with STAT5 and potentiates its activity facilitating STAT5 DNA binding. Prl/cyclophilin B complex directly interacts with the STAT5 N-terminus and appears to induce dissociation of PIAS3 from its complex with STAT5[170,171].

Both GH and GH receptor are subject to rapid nuclear translocation. Rat growth hormone binding protein (GHBP) that is a product of alternative splicing of GH receptor gene with an intact extracellular domain and without transmembrane and intracellular domains replaced by short carboxyterminal sequences, is also localized in cell nuclei in *in vitro* and *in vivo* experiments upon GH stimulation. Nuclear localized GHBP acts as a potent enhancer of STAT5 mediated transcription presumably by binding to PIAS proteins and thereby enhances the action of both GH and other members of the cytokine receptor superfamily[9,172].

Receptor tyrosine kinases associated with the JAK-STAT pathway or STAT signaling have also been found in the nuclear compartment. Nuclear EGF receptor (ErbB1) has been detected in highly proliferative tissues, such as regenerating liver, specimens of primary tumor, and cancer cell lines. Expression of nuclear ErbB1 correlates positively with increased level of cyclin D1 and negatively with overall survival in breast cancer patients. Nuclear ErbB1 co-localizes and interacts with importins α1β1, carriers that are critical for macromolecule nuclear import[8,168,169,173-176]. ErbB1 might act as a transcription factor to activate genes required for high proliferating activity. After EGF stimulation and ErbB1 nuclear translocation EGF-ErbB1 complex associates with cyclin D1 promoter element designated AT-rich sequence (RTRS)[177].

The ability of nucleus translocation is also inherent for other receptors of the ErbB family (ErbB2, ErbB3, and ErbB4). Rat p185neu, ErbB2, and ErbB3 receptors exist in the nucleus as full length molecules, while ErbB4 may undergo γ-secretase-mediated cleavage and with nuclear translocation of C-terminal 80-kDa fragment that represents a soluble cytoplasmic domain with an active tyrosine kinase region[10,178]. Nuclear ErbB2 associates with a specific nucleotide sequence (named HER-2-associated sequence - HAS) of the COX-2 gene promoter and is able to activate its transcription[168,173,175-178].

The hypothesis of a primary nuclear JAK-STAT signaling pathway is supported by data on constitutive expression of JAK1 and JAK2 in the cell nucleus. JAK1 and JAK2 molecules have been shown to contain nuclear localization sequences and both kinases have been revealed in nuclei of rat hepatocytes, pancreatic islet cells, CHO and some other cell types both without activation by upstream signaling and in active phosphorylated forms. GH treatment of cells stimulates phosphorylation of nuclear JAK2 without apparent changes of its subcellular localization. Active nuclear JAK2 phosphorylates transcription factor - nuclear factor 1-C2 (NF1-C2) in mammary epithelial cells[8,179,180]. Since both JAK1 and JAK2 are expressed constitutively in the nucleus and a number of cytokine receptors undergo nuclear translocation the realization of primary nuclear JAK-STAT signaling pathway seems very possible.

Primary nuclear STAT activation has also been observed. Nuclear ErbB1 has been shown recently to interact with STAT3 in the nucleus leading to transcriptional activation of inducible iNOS gene in breast carcinoma cells and this pathway may be associated with a high malignancy of other types of tumor cells with high level of nuclear ErbB1 and

STAT3[10]. C-terminal 80-kDa fragment of ErbB4 with nuclear traffic activity may associate with STAT5a in the nucleus and transactivate gene expression[178,181]. Intracellular ErbB4 domain possesses a nuclear localization sequence essential for its nuclear accumulation. In cotransfection experiments nuclear translocation of intracellular ErbB4 domain has been shown to be required for nuclear translocation of STAT5a and ErbB4 function as a nuclear chaperone for STAT5a transcription factor as has been suggested[182].

Thus, primary nuclear JAK-STAT signaling may become important at certain stages of the cell cycle or be critical for some populations of rapidly dividing or neoplastic cells.

Is a direct nuclear JAK-STAT pathway related to cholangiocarcinoma development? Intensive nuclear Prl receptor accumulation has been revealed in our laboratory in rat bile duct cells only after normal cholangiocyte transition to active proliferation during postnatal ontogenesis or after common bile duct ligation and is accompanied by elevation of total receptor content both in males and females[7]. Similarly, we have found nuclear localized Prl receptors with sharp elevation of their expression in samples of human cholangiocarcinoma tissues (Figure 3) as well as in liver transplanted rat cholangiocarcinoma cell line RS-1.

Both total content and nuclear expression of Prl receptors in transplanted RS-1 rat cholangiocarcinoma cells show moderate sex dependence with female predominance (Table 4). The intrahepatic RS1 cholangiocarcinoma transplant induces nuclear accumulation of Prl receptors not only in malignant cholangiocytes but also in adjacent and distant hepatocytes and increases total Prl receptor immunoreactivity in these cells[7,58].

We were unable to reveal prominent nuclear Prl receptor expression in hepatoma H27 cells after intrahepatic transplantation. Thus, nuclear accumulation of Prl receptors as well as their overexpression in intrahepatically transplanted RS1 cholangiocarcinoma cells and in hepatocytes of tumor bearing animals can serve as a specific marker of cholangiocarcinoma. Since we have used monoclonal antibodies U5 to the extracellular domain of rat Prl receptor, it was revealed that nuclear accumulation may be due to both full length Prl receptor or Prl binding protein as have been found for GH binding protein[9,172]. Appearance of Prl receptors in the nucleus is associated with Prl participation in the regulation of the proliferation process. This is confirmed by the data indicating that in Prl-dependent Nb2 lymphoma cells the cell cycle progression stops at the early G1 phase in the absence of Prl. Treatment of such cells with Prl leads to its transport to the nucleus followed by cell cycle progression[8,183].

In this respect unusual nuclear localization of prostaglandin E2 receptor EP1 that belongs to the G-protein coupled receptor superfamily detected in human cholangiocarcinoma cell lines seems very interesting[109].

Presented data show that primary nuclear JAK-STAT signaling may be relevant to cholangiocarcinoma progression and unusual nuclear localization of components of the JAK-STAT cascade may be considered as a predisposition to cholangiocarcinoma development.

CONCLUSION

While the role of GH, Prl and interleukins in normal cholangiocytes and pathophysiological states has been studied during the last decade, to date, the role of the JAK-STAT pathway in cholangiocarcinoma progression has not really been investigated and its importance is underestimated. Nevertheless, the summarized data provide a generalized view of the implication of the central cytokine signaling in tumor development of

epithelial bile duct cells. A more detailed study of JAK-STAT involvement in cholangiocyte proliferative diseases can open the door for newer therapeutic strategies serving a real alternative to surgery.

Moreover, an engagement of the new model of cancer (cholangiocarcinoma) to studies of JAK-STAT signaling can give us an exhaustive understanding of its role in cancer development at different stages, which is not yet completely clarified (promotive role in neoplasia development[33] and inhibitory role in metastasis progression[45]). Moreover, it can help us to decipher new mechanisms of activation of the components of the JAK-STAT pathway like receptor and/or ligand nuclear localization.

ACKNOWLEDGMENTS

We thank Dr. Vera Ruda for critical reading of the manuscript.

Abstract

AIM: To evaluate the prevalence and predictive factors of osteoporosis in patients with gastric adenocarcinoma after gastrectomy.

METHODS: The study included 133 patients diagnosed with gastric adenocarcinoma but who did not undergo prior diagnostic work-up for osteoporosis. Bone mineral density (BMD) was measured by dual-energy X-ray absorptiometry (DXA) and vertebral deformity was assessed by plain X-rays. We evaluated the effects of age, sex, body mass index (BMI), anemia, back pain, vertebral deformity, tumor staging, reconstruction type, and past medical history to determine predictive factors of osteoporosis in these patients.

RESULTS: The prevalence of osteoporosis in the lumbar spine was 38.3% (male, 28.9%; female, 54.0%), and 15.0% in the femoral neck (male, 10.8%; female, 22.0%). The vertebral deformity rate was 46.6% (male, 43.4%; female, 52.0%). Age, BMI and hemoglobin correlated with BMD ($P < 0.01$). In males, anemia and age > 64 years were independent predictive factors of osteoporosis in multivariate analysis. In females, back pain was an independent factor for osteoporosis.

CONCLUSION: The results of this study revealed that prevalence of osteoporosis and vertebral bone deformity rate were high in gastric cancer patients, regardless of post-gastrectomy duration and operation type. Early diagnosis and a proper management plan must be established in these patients.

Key words: Gastric adenocarcinoma; Gastrectomy; Bone mineral density; Osteoporosis; Vertebral deformity; Anemia; Back pain

INTRODUCTION

Gastric cancer is one of the most common cancers in the world. Although decreasing in prevalence, it is still the second most common cause of cancer death in the world. The incidence is still very high in East Asia[1]. Although the overall prognosis of gastric cancer is poor, the 5-year survival rate for those who receive operative treatment is 55.6% in Korea. Due to early diagnosis and aggressive surgical intervention, the survival rate is > 90% in cases of early gastric cancer in Korea[2]. However, many surviving patients suffer from the sequelae caused by the surgical procedure. Recently, a 63-year-old woman, who underwent gastrectomy for gastric malignancy, spontaneously developed multiple fractures. It was speculated that the synergistic effects of gastrectomy and other osteoporosis risk factors led to multiple fractures[3]. Weight loss, malnutrition, anemia and osteoporosis are common after gastrectomy[4]. Following gastric resection, reduced cortical and trabecular bone mass have been reported, however, the mechanism remains unclear[5,6].

The american Gastroenterological Association (AGA) has recommended dual-energy X-ray absorptiometry (DXA) in patients who are alive at least 10 years after gastrectomy[6], based on many reports of post-gastrectomy bone disease[7-20]. Most studies have dealt with patients with peptic ulcer disease, and those focusing on gastric cancer patients are rare. Recently, most gastrectomies have been done in patients with gastric malignancy. However, the age at operation and operation type might differ between peptic ulcer and gastric cancer. The duration after gastrectomy to onset of osteoporosis may also be different. Among the population aged > 50 years old, gastric cancer detection and operation have recently increased in Korea[2].

In this study, we evaluated the prevalence of osteoporosis and vertebral bone deformity rate in patients

with gastric adenocarcinoma after gastrectomy. We evaluated the impact of tumor staging, operation type, and other risk factors of osteoporosis. We also evaluated the association between clinical manifestations and osteoporosis for early diagnosis of osteoporosis in gastric cancer patients.

MATERIALS AND METHODS

One hundred and thirty-three patients with gastric cancer seen between January and December 2006 at the Korea Cancer Center Hospital were included in this study. The criteria for entry in this study were gastric cancer patients: (1) diagnosed with adenocarcinoma; (2) treated with curative gastrectomy and followed up without recurrence; (3) aged > 50 years; (4) never previously diagnosed with osteoporosis, and who had not taken any medication, such as estrogen, bisphosphonate, corticosteroid, and vitamin D; (5) with no other disease that affected bone mineral density (BMD) (like alcoholism, renal failure, chronic liver disease, and immobility); and (6) who could take care of themselves and had an average level of physical activity. Patients' characteristics are described in Table 1. Eighty-four enrolled patients were men and 55 were women, ranging in age from 50 to 80 years (median, 63.9 years).

The authors interviewed all patients closely regarding the known risk factors of osteoporosis, such as family history of osteoporosis, previous fracture, type 2 diabetes, and other chronic diseases and medication states. Anthropometric data (height, weight and BMI), operation record (tumor stage, gastrectomy and reconstruction type), and pathology report were also closely reviewed.

BMD of the lumbar spine (L1-4), and four sites in the proximal femur (femoral neck, Ward's triangle, greater trochanter, and total hip) were measured by DXA (GE Prodigy; Lunar Radiation, Madison, WI, USA). The results of BMD were expressed as absolute values (g/cm^2), T scores (compared with young adults) and Z scores (compared with age-matched controls) were according to Korean reference values provided by the GE-Lunar database. Osteoporosis was defined as a T score of < -2.5 and osteopenia as a T score of -1.0 to -2.5 SD[21]. Lateral radiographs of the thoraco-lumbar spine (T-L spine) were evaluated to assess vertebral bone deformity. Vertebral bone deformity was defined when Genant semi-quantitative grading was higher than grade 1[22]. Low BMI was defined as < 18.5 kg/m^2. Anemia was defined as hemoglobin < 11 g/dL in women and < 13 g/dL in men. High serum alkaline phosphatase (sALP) was defined as > 127 U/L (normal limit; < 126 U/L). Serum albumin, AST/ALT and blood urea nitrogen (BUN)/creatinine were used to rule out severe malnutrition, and liver and renal disease.

Statistical analysis

Numbers and values were expressed as means ± SD. Mean quantitative values were compared by Student's *t* test. Differences in proportions among the groups were analyzed by the χ^2 test. Variables relevant to osteoporosis were assessed by univariate analysis: age (< 64 *vs* ≥ 64 years); sex (male *vs* female); low BMI (< 18.5 kg/m^2); tumor stage; gastrectomy and reconstruction type (subtotal gastrectomy with Billroth Ⅰ and Billroth Ⅱ reconstruction *vs* total gastrectomy with Roux-en-Y reconstruction); serum ALP level (< 127 *vs* ≥ 127 U/L); hemoglobin level (male, < 13 *vs* ≥ 13 g/dL; female, < 11 *vs* ≥ 11 g/dL); family history of osteoporosis; previous fracture; type 2 diabetes; bone pain; and vertebral deformity. Variables significant by univariate analysis ($P < 0.05$) were included in a multivariate regression analysis. Data analysis was performed with SPSS version 13.0 (Chicago, IL, USA). $P < 0.05$ was considered as statistically significant.

RESULTS

DXA and vertebral deformity

BMD distribution was different between male and female patients; therefore, we listed BMD according to sex in Table 2. The Z score of L1-4 BMD was decreased -0.55 ± 1.55 in male and -0.72 ± 1.49 in female patients. However, the Z score of the femur neck was 0.44 ± 0.97 in male and 0.74 ± 1.14 in female patients. The L1-4 BMD Z score was significantly decreased compared with the femur neck BMD Z score ($P < 0.01$).

Fifty-one (38.3%) patients had osteoporosis and 42 (31.6%) had osteopenia in lumbar spine BMD, while 20 (15.0%) patients had osteoporosis and 42 (31.6%) had osteopenia in femur neck BMD (Figure 1). The osteoporosis rate was 28.9% in male and 54.0% in female patients in lumbar spine BMD. Osteoporosis rate was 10.8% in male and 22.0% in female patients in femur neck BMD. The BMI change after gastrectomy (-2.0 ± 2.4, male *vs* -2.9 ± 2.4 female), anemia rate (24% male *vs* 58% female), and TNM stage differed between male and female patients (Table 1). Vertebral bone deformity rate was 43.4% in male and 52.0% in female patients.

There was no difference in osteoporosis rate at the lumbar spine (39.7% *vs* 37.3%) and that of femur neck (17.2% *vs* 13.3%) between early and advanced gastric cancer. There was no difference in BMD and osteoporosis rate among patients who underwent partial gastrectomy with Billroth Ⅰ (40.4%) or Billroth Ⅱ reconstruction (38.9%), and total gastrectomy with Roux-en Y reconstruction (34.4%) (Figure 2).

Factors for osteoporosis in gastric adenocarcinoma

With the exception of sex, three variables were correlated with lumbar spine BMD. The correlation coefficients of age, BMI and hemoglobin were -0.391, 0.415 and 0.274, respectively ($P < 0.01$). In multiple regression analysis, BMI and hemoglobin level were correlated with BMD in male patients ($P < 0.05$). Age was not a significant factor ($P = 0.13$). On the contrary, BMI and age were significant factors in female patients ($P < 0.01$).

In univariate analysis, six variables were related to osteoporosis (Table 3). Of these factors, age > 64 years, female sex, BMI < 18.5 kg/m^2, anemia, back pain, and vertebral deformity were significant predictors of osteoporosis. Multivariate analysis disclosed three independent predictors after stratification by sex: serum hemoglobin level ≤ 13 *vs* > 13 g/dL (odds ratio, 4.887; 95% CI, 1.404-17.011; $P = 0.011$), age > 64 *vs* < 64 years

Table 1 Patient characteristics (mean ± SD)

Variables			All patients (n = 133)	Male (n = 83)	Female (n = 50)	P

(odds ratio, 3.923; 95% CI, 1.202-12.805; P = 0.018) in male patients, and back pain (odds ratio, 10.272; 95% CI, 2.297-45.942; P = 0.001) in female patients (Table 4).

DISCUSSION

In the present study, we examined BMD in gastric adenocarcinoma patients who underwent curative surgery and analyzed the factors that were related to osteoporosis. Hemoglobin level in men and back pain in women were independent risk factors of osteoporosis by multivariate analysis.

The overall prevalence of osteoporosis in gastric adenocarcinoma patients aged > 50 years was 39.6%. The osteoporosis rate of lumbar spine BMD was 29.8% in male and 54.5% in female patients. However, the osteoporosis rate of femur neck BMD was 11.9% in male and 26.3% in female patients. This difference might be explained by the fact that the Z score of lumbar spine BMD was significantly lower than that of femur neck BMD. It is consistent with other studies that trabecular bone was more affected than cortical bone after gastrectomy[7,8]. In other DXA-based studies in post-gastrectomy patients, the prevalence of spinal osteoporosis was 22%-37% and the prevalence of femoral neck osteoporosis was 10%-61%[9-11]. In the present study, 24 patients (18.0%) reported osteoporotic fracture with severe pain, such as Colles', ankle and severe vertebral fractures. Sixty-one (45.9%) patients complained of back pain and 62 (46.6%) showed vertebral bone deformity. Thirty-three (24.8%) patients complained of persistent back pain with vertebral deformity. Although it is not clear whether vertebral deformity with back pain directly indicates vertebral fracture, Zittel *et al* have reported that the overall vertebral fracture rate after gastrectomy was 31% by CT[12]. Recently, Gallacher *et al* have reported that vertebral deformity was found in 47% of osteoporosis patients and 23% of normal subjects[23]. In our study, we found vertebral deformity in 64.7% of osteoporosis patients and 22.5% of those with normal BMD.

The prevalence of osteoporosis was high in females, as previously reported[5,11,13]. However, this was mainly due to the effect of sex[24]. When we compared the Z scores of each sex, there was no difference in the decreased proportion of BMD, as in previous reports[14]. With the same age, women showed a greater osteoporosis rate than men. Except for estrogen deficiency, a high rate of anemia and low BMI might play some role in osteoporosis. Tovey

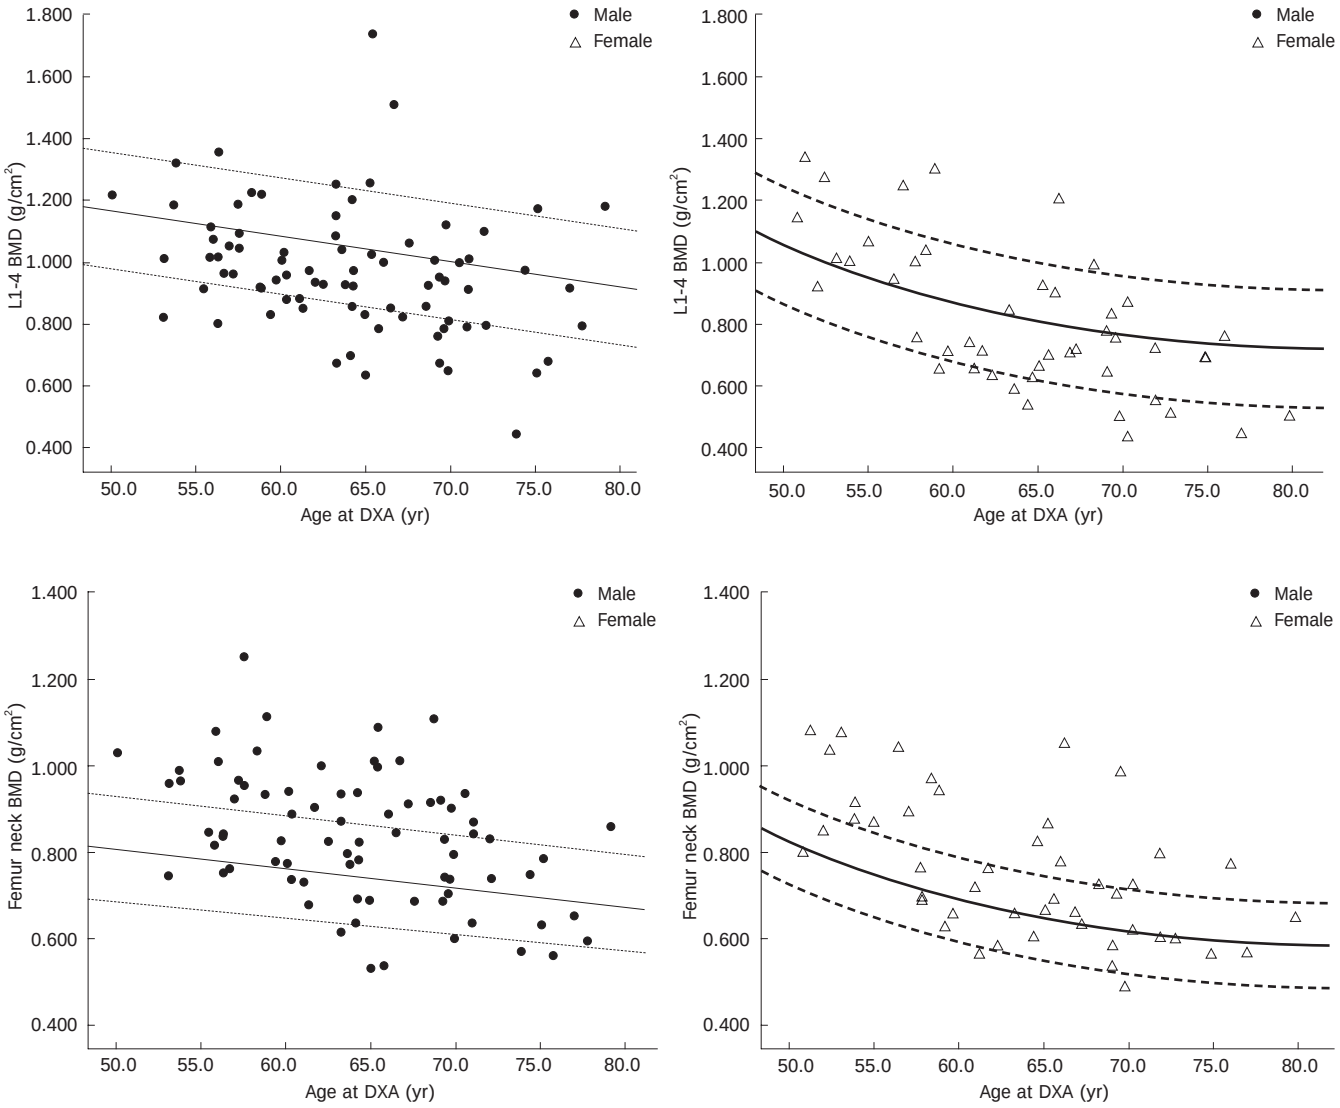

Figure 1 BMD of lumbar spine and femur neck. Solid line represents Z score = 0. Dashed line represents Z score = -1.0.

et al have also reported that iron deficiency anemia and osteoporosis are higher in female than in male patients throughout follow up after gastrectomy[5].

In the present study, there was no difference between BMD or osteoporosis rates between early and advanced gastric cancer. There was no difference in osteoporosis rates according to TNM stage. In addition, there was no difference in BMD and osteoporosis rate among patients undergoing Billroth Ⅰ, Billroth Ⅱ and Roux-en-Y reconstruction. Although some studies have shown that Billroth Ⅱ reconstruction patients have lower BMD compared to those undergoing Billroth Ⅰ reconstruction[15,16], our results showed no difference in osteoporosis rate in relation to surgical reconstruction type, as in previous studies[12,17]. These results indicate that gastrectomy itself affects BMD rather than the reconstruction method. The osteoporosis rate in gastrectomy patients cannot be predicted by reconstruction type, at least in surviving patients.

Anemia was a significant predictor for osteoporosis, at least in male patients. In multiple regression analysis, hemoglobin level was correlated with BMD in male patients ($P < 0.05$). In multivariate analysis, anemia was an independent predictor of osteoporosis (odds ratio, 4.887; $P = 0.011$). After gastrectomy and reconstruction, gastrointestinal physiology might be altered, and some nutrients might bypass the normal intestinal surface[6]. The main sites affected after gastrectomy are the duodenum and proximal jejunum, which are the main sites of calcium and iron absorption. In this study, we could not find an association between anemia and osteoporosis in females, as the rates were too high. The other factors such as age and BMI played a more important role in female patients. In females, 19 (86.4%) out of 22 patients who complained of back pain had osteoporosis. It is well known that new vertebral fractures are associated with substantial increases in back pain and functional limitation in older women[25].

This study had some limitations. We excluded patients who had been diagnosed as having previous osteoporosis. Therefore, selection bias might exist in many older patients and those who survived for long periods after gastrectomy. Although the postoperative duration or change in BMI did not show any impact on BMD or osteoporosis rate in our study, as in previous studies[17,18], some have reported

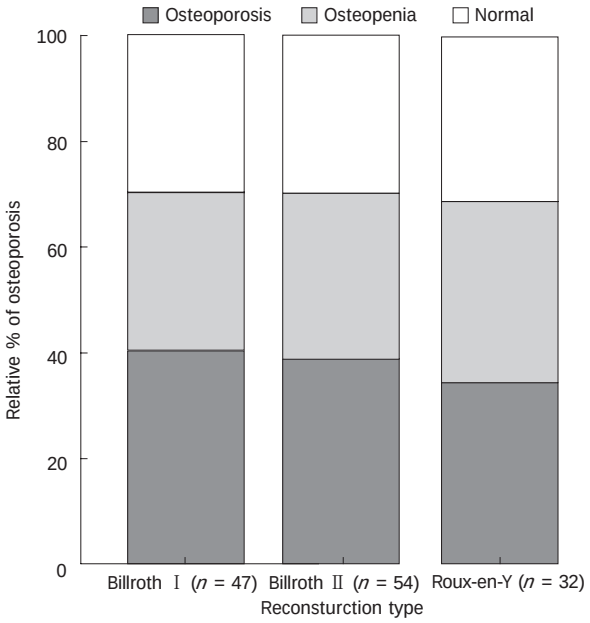

Figure 2 There was no difference in relative percentage of osteoporosis, osteopenia and normal BMD according to type of reconstruction in post-gastrectomy patients.

a negative correlation between BMD and the time interval after gastrectomy[14,19]. The other limitation was that 18 (13.5%) patients showed increased sALP ⩾ 127 U/L. In these cases, we could not rule out osteomalacia. Others have reported that 10%-20% of patients after gastrectomy might have osteomalacia[20,26].

In summary, we demonstrated high prevalence of osteoporosis and vertebral bone deformity in gastric cancer patients who underwent gastrectomy. Many also complained of back pain and a previous history of fractures. Considering the fact that gastric cancer patients after gastrectomy have many risk factors for osteoporosis fracture[27], early diagnosis and treatment are necessary. Anemia might be an important predictive factor of osteoporosis in the clinical setting. Although some early results suggest that post-gastrectomy osteoporosis is resistant to treatment[5], effective results have recently been reported with the development of many anti-osteoporosis drugs[28].

COMMENTS

Background

Post-gastrectomy bone disease may arise secondary to total or partial gastrectomy. The exact nature of the bone defect is unknown, although both osteoporosis and osteomalacia have been found. The incidence of osteoporosis is between 32% and 42%. These patients are associated with an increased risk of fracture. There is no difference in risk for post-gastrectomy bone disease between those undergoing a Billroth I and Ⅱ procedure.

Research frontiers

Recent studies have confirmed normal intestinal absorption of vitamin D in post-gastrectomy patients, although patients with post-gastrectomy steatorrhea have abnormal vitamin D absorption. Post-gastrectomy patients may alter their diet, and reduced serum 25-hydroxy-vitamin D level may in part reflect reduced dietary intake of vitamin D. Serum calcium and phosphate levels are most often normal post-gastrectomy, although calcium levels may be normal as a result of mobilization of calcium from bone. sALP, vitamin D metabolites and parathyroid hormone levels are variable post-gastrectomy. Patients who are at least 10 years post-gastrectomy (especially postmenopausal women, men aged > 50 years, and patients with low-trauma fractures), should undergo DXA testing.

Innovations and breakthroughs

This study confirms previous observations that the prevalence of osteoporosis is high in patients following gastrectomy. As noted previously, there is no difference in BMD and osteoporosis rate among patients undergoing Billroth Ⅰ, Billroth Ⅱ and Roux-en-Y reconstruction. A number of variables have been assessed in an attempt to identify factors that predispose to reduced BMD post-gastrectomy. The authors identified that hemoglobin level and age in men and back pain in women were independent risk factors of osteoporosis, by multivariate analysis. Increased time from surgery did not correlate with lower BMD.

Peer review

This is an interesting paper from South Korea. The data presented are clear and concise and have been described clearly in the text.

Abstract

AIM: To investigate the effect of arsenic trioxide (As_2O_3) on expression of vascular endothelial growth factor receptor-1 (VEGFR-1, Flt-1) and VEGFR-2 (KDR) in human gastric tumor cells and proliferation of vascular endothelial cells.

METHODS: The solid tumor model was formed in nude mice with the gastric cancer cell line SGC-7901. The animals were treated with As_2O_3. Microvessel density (MVD) and expression of Flt-1 and KDR were detected by immunofluorescence laser confocal microscopy. SGC-7901 cells were treated respectively by exogenous recombinant human $VEGF_{165}$ or $VEGF_{165}$ + As_2O_3. Cell viability was measured by MTT assay. Cell viability of ECV304 cells was measured by MTT assay, and cell cycle and apoptosis were analyzed using flow cytometry.

RESULTS: The tumor growth inhibition was 30.33% and 50.85%, respectively, in mice treated with As_2O_3 2.5 and 5 mg/kg. MVD was significantly lower in arsenic-treated mice than in the control group. The fluorescence intensity levels of Flt-1 and KDR were significantly less in the arsenic-treated mice than in the control group. $VEGF_{165}$ may accelerate growth of SGC7901 cells, but As_2O_3 may disturb the stimulating effect of $VEGF_{165}$. ECV304 cell growth was suppressed by 76.51%, 71.09% and 61.49% after 48 h treatment with As_2O_3 at 0.5, 2.5 and 5 μmol/L, respectively. Early apoptosis in the As_2O_3-treated mice was 2.88-5.1 times higher than that in the controls, and late apoptosis was 1.17-1.67 times higher than that in the controls.

CONCLUSION: Our results showed that As_2O_3 delays tumor growth, inhibits MVD, down-regulates Flt-1 and KDR expression, and disturbs the stimulating effect of $VEGF_{165}$ on the growth of SGC7901 cells. These results suggest that As_2O_3 might delay growth of gastric tumors through inhibiting the paracrine and autocrine pathways of VEGF/VEGFRs.

INTRODUCTION

Angiogenesis is recognized as playing a role in the pathophysiology of many human malignancies. It is an important factor in the progression and enlargement of solid neoplasms and is closely related to invasion and metastases[1-3]. Angiogenesis is influenced by a number of positive and negative regulatory factors, such as cytokines, extracellular matrix, and other cellular constituents including pericytes[4]. Among the factors contributing to angiogenesis, vascular endothelial growth factor (VEGF) is recognized as one of the most important molecules in the formation of new blood vessels. VEGF is a potent and specific mitogen for endothelial cells that activate the angiogenic switch *in vivo* and enhance vascular permeability. A variety of malignant human tumors are known to secrete VEGF, which has been correlated with the onset of angiogenesis in tumors[5-7]. Over-expression of VEGF is suggested to participate in the carcinogenic process[8]. VEGF binds to two distinct receptors on endothelial cells: VEGFR-1 (fms-like tyrosine kinase receptor 1, Flt-1) and VEGFR-2 (kinase insert domain containing receptor human homologue/fetal liver kinase 1

murine homologue, KDR/Flk-1)[9,10]. KDR is responsible for mitogenic signaling, and plays an important role in vasculogenesis and blood island formation, and Flt-1 regulates the assembly of endothelial cells and tissue factor production in endothelial cells[8]. Thus, it is suggested that inhibition of VEGF/VEGFR pathways may interrupt VEGF-induced angiogenesis. Recently, a few studies have demonstrated co-expression of VEGF and its receptors in tumor cells, which suggests that a VEGF autocrine pathway exists in tumor cells[11-14].

Arsenic is a common natural substance. Arsenic trioxide (As_2O_3) has shown substantial efficacy in treating both newly diagnosed and relapsed patients with acute promyelocytic leukemia (APL)[15]. Recent studies have shown that a wide variety of malignancies, including both hematological cancer and solid tumors derived from several tissue types, may be susceptible to therapy with As_2O_3[16-19]. These successes have prompted investigations to elucidate the mechanisms of action underlying these clinical responses. Emerging data suggest that arsenic induces apoptosis and inhibits tumor growth[15,16,20]. It has recently been reported that arsenic may inhibit angiogenesis[21-23]. We have recently shown *in vivo* and *in vitro* that As_2O_3 can inhibit VEGF expression and suppress angiogenesis and gastric tumor growth[24].

In the present work, we investigated further the effect of As_2O_3 on the expression of VEGF receptors Flt-1 and KDR in human gastric tumor cells and the proliferation of vascular endothelial cells. Our study demonstrated that As_2O_3 delayed tumor growth by inhibiting the paracrine and autocrine pathway of VEGF/VEGFRs.

MATERIALS AND METHODS

Animals and cells

Male Balb/c mice, 5-wk-old and weighing 19-21 g (from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China) were used in this study. The mice were kept in a laminar-filtered airflow cabinet under pathogen-free conditions with a constant temperature of 22℃ ± 2℃, relative humidity of 55% ± 5%, and 12-h dark/light cycles. All experiments were carried out according to the guidelines of the Laboratory Protocol of Animal Handling, Fourth Military Medical University. Human gastric cancer cell line SGC-7901 and ECV304, a cell line derived from human umbilical vessel endothelial cells, were purchased from the Animal Laboratory Centre, Fourth Military University.

Tumor xenografts in nude mice

SGC-7901 cells were cultured in RPMI 1640 medium supplemented with 100 mL/L fetal bovine serum (FBS) at 37℃ in a 5 mL/L CO_2 incubator. Thirty mice received subcutaneous injection in the right flank with 200 μL cell suspension containing 2×10^7 SGC-7901 cells. After 10 d, when established tumors of 0.2 cm-0.3 cm diameter were detected, drug administration was started.

Drug treatment

The animals were randomly divided into three groups of 10 animals each. Arsenious acid [H_3AsO_3 ($As_2O_3 + 3H_2O_2 \Leftrightarrow H_3AsO_3$); Yida Pharmaceutical, Harbin, China] diluted with saline solution was injected intraperitoneally every day to the two treatment groups (2.5 and 5 mg/kg in 0.2 mL) and the same volume of saline solution was injected into the control group. After 10 d of treatment, three groups of mice were sacrificed and the tumor masses were removed. After the weight of tumor masses was measured, they were fixed in 40 g/L paraformaldehyde, and the frozen sections were prepared with a cryomicrotome (HM505E, Microm, Germany) for immunofluorescence analysis.

Tumor inhibition and regression

Tumor growth inhibition (TGI) was calculated by measuring tumor volumes before treatment, and 6 and 11 d after treatment. Tumor volume (cm^3) was calculated using the formula: tumor volume = $1/2ab$, where a is the long axis, and b the short axis. TGI (%) = $(1 - Vt/Vc) \times 100\%$, where Vt is the mean tumor volume of the arsenic-treated group, and Vc the mean tumor volume of the control group.

Microvessel density (MVD)

For identification of microvascular structure, frozen sections were cut and stained with rat anti-mouse CD31 (Biolegend, USA) and secondary antibody (goat anti-rat IgG conjugated TRITC). MVD was determined by confocal microscopy of tumor tissue sections. A single microvessel was defined as any immunofluorescent endothelial cell that was distinguished from adjacent tumor cells and other connective tissue elements. The microvessels were carefully counted in 20 fields (×400). The mean ± SE was expressed as the number of microvessels identified within the area.

Immunofluorescence for Flt-1 and KDR

The frozen sections were kept at room temperature for 30 min, incubated in distilled water and PBS for 5 min each, permeabilized in 1 g/L Triton-X-100 for 10 min, washed with PBS, blocked with 100 mL/L sheep serum (Sigma, USA) at 37℃ for 20 min, incubated with the primary antibody (Flt-1 and KDR rabbit polyclonal antibodies; Lab Vision, Fremont, CA, USA) at 4℃ overnight, washed with PBS, incubated with the secondary antibody (sheep anti-rabbit IgG conjugated FITC, diluted 1:100; Sigma) for 1h at 37℃, washed with PBS, and then examined by a TCS SP2 laser confocal microscope (Leica, Wetzlar, Germany).

For each group, several field images of Flt-1 or KDR were observed under confocal microscopy. The fluorescence intensity of each cell in the confocal fluorescence images was measured using the Leica Confocal analysis system, and the mean fluorescence intensity in a group of cells was then calculated.

Cell viability assay

ECV304 cells were seeded in a 96-well plate (2×10^3 cells/well). After 48 h seeding, cells were treated with As_2O_3 (0.5, 2.5 and 5 μmol/L) for 2 d, in three parallel wells each, and untreated cells served as a control. By 48 h, 20 μL

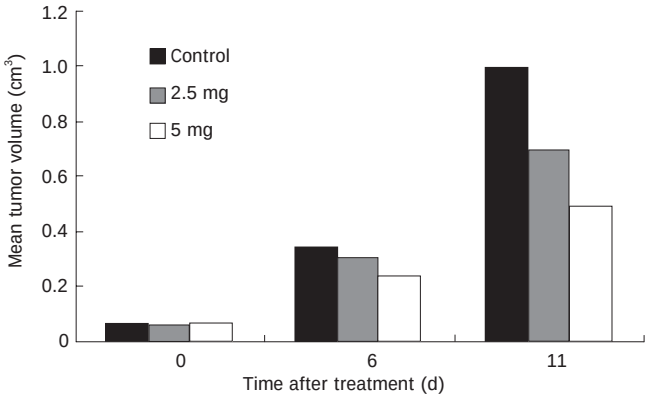

Figure 1 Arsenic trioxide inhibition gastric tumor xenografts growth.

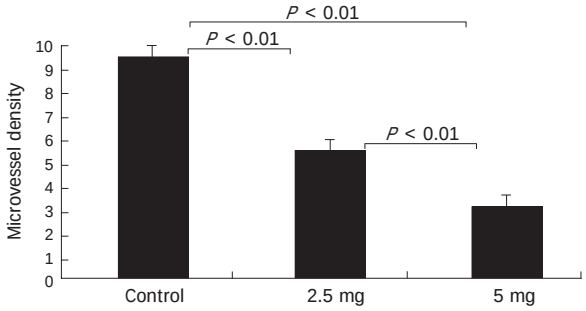

Figure 2 Effect of arsenic trioxide on tumor angiogenesis. Microvessel density (MVD) was measured with counting the fluorescence staining cell in high power field (400). Data are given as mean and SE.

MTT (15 mg/mL) was added to each well and incubated for a further 4 h. The medium was removed and 150 μL DMSO was added to each well. A_{492} was measured using a microculture reader. The percentage of viable cells was calculated as follows: (A of experimental group/A of control group) × 100%.

SGC-7901 cells were seeded in a 96-well plate (2×10^3 cells/well). After sedimentation, exogenous recombinant human $VEGF_{165}$ (2.5, 5, 15 and 20 ng/mL) or $VEGF_{165}$ (2.5, 5, 15 and 20 ng/mL) + 2.5 μmol/L As_2O_3 or $VEGF_{165}$ (2.5, 5, 15 and 20 ng/mL) + 5 μmol/L As_2O_3 were added to the medium, in three parallel wells each, and cultured for a further 48 h. For control wells, an equal volume of medium was added. The methods for the MTT assay and calculation of the percentage of viable cells were the same as above.

Flow cytometry by annexin V-FITC conjugated with propidium iodide (PI) staining

ECV304 cells were seeded in a 24-well plate (1×10^6 cells/well). After 48 h seeding, cells were treated with As_2O_3 (0.5, 2.5 and 5 μmol/L) for 2 d, and untreated cells served as controls. By 48 h, the cells were washed twice with cold PBS and then resuspended in a binding buffer at a concentration of 1×10^6 cells/mL, and the 100 μL solution (1×10^5 cells) was transferred to 5-mL culture tubes. Five microliters of annexin V-FITC and 10 μL PI (μg/mL) were added to each 100-μL solution, and the cells were gently vortexed and incubated for 15 min at room temperature in the dark. The samples, to which 400 μL PBS was added, were analyzed by FACScalibur flow cytometer (BD Biosciences, USA). Early apoptosis was estimated by the relative amount of $FITC^+PI^-$ cells.

Flow cytometry by PI staining

ECV304 cells were treated with As_2O_3 0.5, 2.5 or 5 μmol/L. By 48 h, the harvested cells were fixed with 1 mL of 750 mL/L cold ethanol at 4℃ overnight, and then washed with PBS. The cells were incubated with RNAse and PI for 30 min in the dark. Cell cycle of samples was analyzed using FACSCalibur flow cytometry.

Statistical analysis

The data were represented as mean ± SD. Data were analyzed with SPSS 10.0 statistical software (SPSS, Chicago, IL, USA). Multiple statistical comparisons were performed using ANOVA in a multivariate linear model. The Student-Newman-Kewls test was used to assess differences between the treatment and control group. $P < 0.05$ was considered statistically significant.

RESULTS

As_2O_3 inhibition of growth of human gastric tumor xenografts

All 30 nude mice developed tumors 10 d after implantation of SGC-7901 cells. When drug administration was started, there was no significant difference in the tumor volume of the three groups (control group, 67 ± 45 mm^3; 2.5 mg/kg As_2O_3 group, 63 ± 36 mm^3; 5 mg/kg group, 66 ± 48 mm^3, $P > 0.05$). Tumor volume in the three groups from 0, 6 and 11 d after treatment is shown in Figure 1. There were significant differences in the tumor volumes in the arsenic-treated groups (2.5 mg/kg, 696 ± 125 mm^3 and 5 mg/kg, 491 ± 116 mm^3) and control group (999 ± 338 mm^3, $P < 0.05$). On the other hand, the tumor volume in the 5 mg/kg As_2O_3 group was significantly less than that in the 2.5 mg/kg group ($P < 0.05$). TGI was 30.33% (2.5 mg/kg group) and 50.85% (5 mg/kg group) after arsenic treatment.

As_2O_3 inhibition of tumor angiogenesis

Sections of tumors were stained for CD31 immuno-fluorescence to detect the number of endothelial cells (ECs) as a measure of tumor angiogenesis. MVD was significantly lower in the 2.5 mg/kg As_2O_3 group (9.32 ± 0.33 *vs* 5.36 ± 0.32, $P < 0.01$) and 5 mg/kg group (9.32 ± 0.33 *vs* 3.05 ± 0.24, $P < 0.01$) than in the control group. MVD was significantly lower in the 5 mg/kg group than in the 2.5 mg/kg group. These result demonstrated the decreased capillary density of the tumor after treatment with As_2O_3 (Figure 2).

Effect of As_2O_3 on Flt-1 and KDR expression in tumor xenografts

Expression of Flt-1 and KDR was confirmed by the presence of fluorescence-stained cytoplasm in the tumor cells. Stronger immunoreactivity to Flt-1 (Figure 3A) and KDR (Figure 4A) was found in all the SGC-7901 tumor xenografts of the

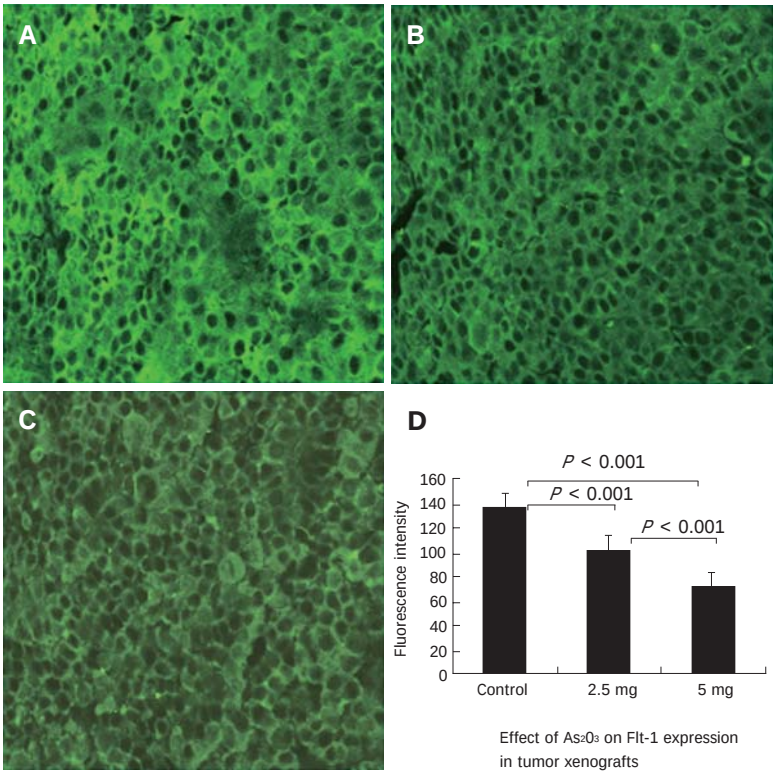

Figure 3 Effective inhibition of expression of Flt-1 (VEGFR-1) in the xenograft tumors by treatment with arsenic trioxide. Flt-1 expression was determined by Immunofluorescence staining and laser confocal microscope. Original magnification × 400. **A**: Control group; **B**: 2.5 mg/kg group; **C**: 5 mg/kg group; **D**: Quantitative analysis of fluorescence intensity in the three groups of tumors was measured using the Leica Confocal analysis system. Data are given as mean and SE.

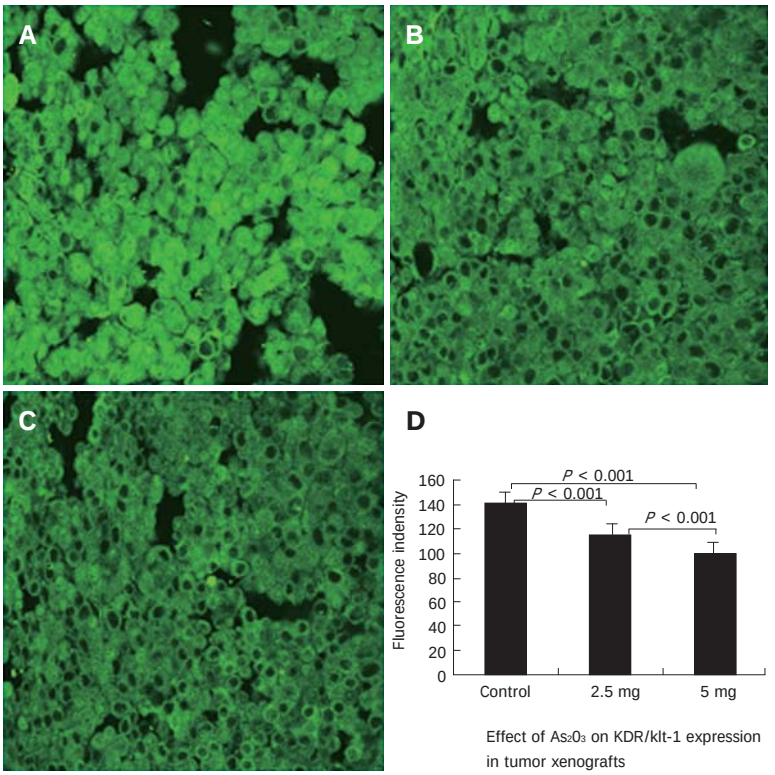

Figure 4 Effective inhibition of expression of KDR (VEGFR-2) in the xenograft tumors by treatment with arsenic trioxide. KDR expression was determined by Immunofluorescence staining and laser confocal microscopy. Original magnification × 400. **A**: Control group; **B**: 2.5 mg/kg group; **C**: 5 mg/kg group; **D**: Quantitative analysis of fluorescence intensity in the three groups of tumors was measured using the Leica Confocal analysis system. Data are given as mean and SE.

control group. The weaker fluorescence intensity was observed in tumor cells of the mice treated with 2.5 mg/kg (Figures 3 and 4B) and 5 mg/kg (Figures 3 and 4C) As_2O_3. The expression of Flt-1 and KDR in tumor cells was significantly less in the arsenic-treated groups than in the control group ($P < 0.001$). Expression of Flt-1 and KDR in the 5 mg/kg As_2O_3 group was less than that in the 2.5 mg/kg group (Table 1).

Effect of As_2O_3 on VEGF-stimulated growth of SGC7901 tumor cells

SGC7901 cells were incubated with varying concentrations of $VEGF_{165}$ or $VEGF_{165}$ + 2.5 μmol/L As_2O_3 and varying concentrations of $VEGF_{165}$ + 5 μmol/L As_2O_3. Its effects were measured using the MTT assay (Table 2). The results showed that $VEGF_{165}$ may have accelerated the growth of SGC7901 cells,

Table 1 Effect of As_2O_3 on Flt-1 and KDR/Flk-1 expression in tumor xenografts (fluorescence intensity) (n = 10, mean ± SD)

Group	Flt-1	KDR/Flk-1
Control	137.41 ± 3.36	141.62 ± 1.66
2.5 mg/kg	103.53 ± 2.23[b]	114.99 ± 2.19[b]
5 mg/kg	72.17 ± 0.87[b,d]	101.11 ± 1.89[b,d]

[b]P < 0.001, treatment groups *vs* control group; [d]P < 0.001, 5 mg/kg group *vs* 2.5 mg group.

Table 2 Effect of As_2O_3 on VEGF-stimulated growth of tumor cells (%)

	As_2O_3 (ng/mL)				
	2.5	5	10	15	20
$VEGF_{165}$	105.79	106.62	100.97	107.59	109.38
$VEGF_{165}$ + 2.5 μmol/L As_2O_3	84.24	97.95	97.59	100.48	94.94
$VEGF_{165}$ + 5 μmol/L As_2O_3	76.87	68.55	83.74	85.06	84.94

but As_2O_3 may have disturbed the stimulatory effect of $VEGF_{165}$.

Effect of As_2O_3 on proliferation of vascular endothelial cells

Cell viability was determined by the MTT assay (Figure 5). As_2O_3 inhibited the growth of ECV304 cells in a dose-dependent manner. Cell growth was suppressed by 76.51%, 71.09% and 61.49% after 48 h treatment with As_2O_3 at 0.5, 2.5 and 5 μmol/L, respectively.

Cell cycle and apoptosis of vascular endothelial cells induced by As_2O_3

Flow cytometry with only PI staining showed that the percentage of cells treated with As_2O_3 was higher in the sub-G1 period, lower in the sub-S period, and lower in the G2/G1 period when compared to the controls. Apoptotic cells were respectively 14.84% and 18.9% in the 2.5 and 5 μmol/L As_2O_3 groups (Table 3 and Figure 6). Early apoptotic cells, detected by flow cytometry with annexin V conjugated with PI staining, reached, respectively, 4.18, 5.36 and 7.4% in the 0.5, 2.5 and 5 μmol/L As_2O_3 groups (Figure 7). Early apoptosis in As_2O_3-treated groups was 2.88-5.1 times higher than that of the controls, and late apoptosis was 1.17-1.67 times than that of the controls.

DISCUSSION

Angiogenesis is critical for supporting the rapid growth of tumors. Angiogenesis inhibition is a promising therapeutic approach for the treatment of cancer. As_2O_3 has been demonstrated to induce complete remission in patients with APL without severe toxicity. More recently, *in vitro* studies have shown As_2O_3 apoptosis in other leukemia and solid tumor cells. As a novel anticancer agent, a few *in vivo* investigations of its efficacy on solid tumors have been carried out[19,21]. In this study, we observed the effect of As_2O_3 on growth and angiogenesis in a gastric cancer

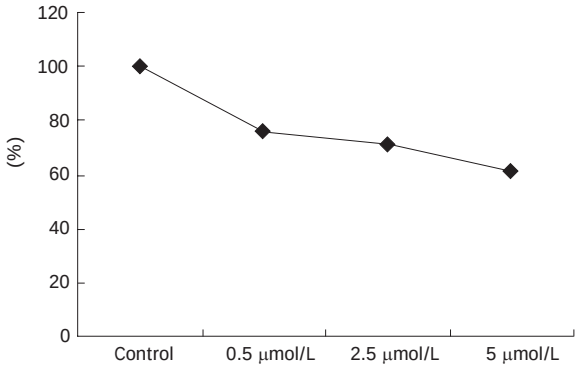

Figure 5 Effect of As_2O_3 on growth of ECV304 cells. The cell viability was analyzed by MTT assay.

Table 3 Effect of As_2O_3 on cell cycle of ECV304 cells (%)

Groups	G1	G2/G1	S	Apoptosis
Control	94.24	2.05	5.76	0
0.5 μmol/L As_2O_3	96.17	1.81	2.59	0
2.5 μmol/L As_2O_3	96.15	1.91	t0	14.84
5 μmol/L As_2O_3	96.96	1.84	0	18.90

SGC7901 xenograft model. MVD was measured in tumor tissue by the amount of labeled CD31. The results revealed that a 10 d treatment with As_2O_3 resulted in tumor growth inhibition and MVD decrease. TGI was respectively 29.08% and 52.17% in mice treated with 2.5 and 5 mg/kg As_2O_3. MVD was significantly lower in tumor tissues in arsenic-treated mice than in the control groups. The results demonstrated that As_2O_3 inhibited gastric cancer growth *in vivo* and suppressed the formation of new blood vessels in cancer tissues. Anti-angiogenesis may be one of the mechanisms by which As_2O_3 inhibits gastric cancer growth.

ECs are the primary structured units of blood vessels. In recent years, ECs have been the target cell of some angiogenesis inhibitors that have been undergoing clinical trials. These inhibitors can selectively affect diverse EC functions that are related to angiogenesis, including activation, proliferation, migration, invasion and survival[25,26]. It has been reported that particles of realgar (As_2S_2) with an average diameter of 100-150 nm can induce EVCV-304 cell apoptosis[27]. We studied the effect of As_2O_3 on growth and proliferation of ECV304 cells. In our study, the MTT assay showed that As_2O_3 inhibited the growth of ECV304 cells in a dose-dependent manner. Flow cytometry assays with only PI staining showed that the percentage of the cells treated with As_2O_3 were higher in the sub-G1 period, lower in the sub-S period, and lower in the G2/G1 period when compared to the controls; and 14.84% and 18.9% of the cells treated with As_2O_3 at 2.5 and 5 μmol/L, respectively, were apoptotic. Early apoptosis in the As_2O_3 treated groups was 2.88-5.1 times higher than that in the controls, and late apoptosis was 1.17-1.67 times higher than that in the controls. These results showed that As_2O_3 inhibited the viability of ECV304 cells and arrested the cells in G1 phase, blocked or delayed their entry into S phase, disturbed DNA synthesis, and induced apoptosis in

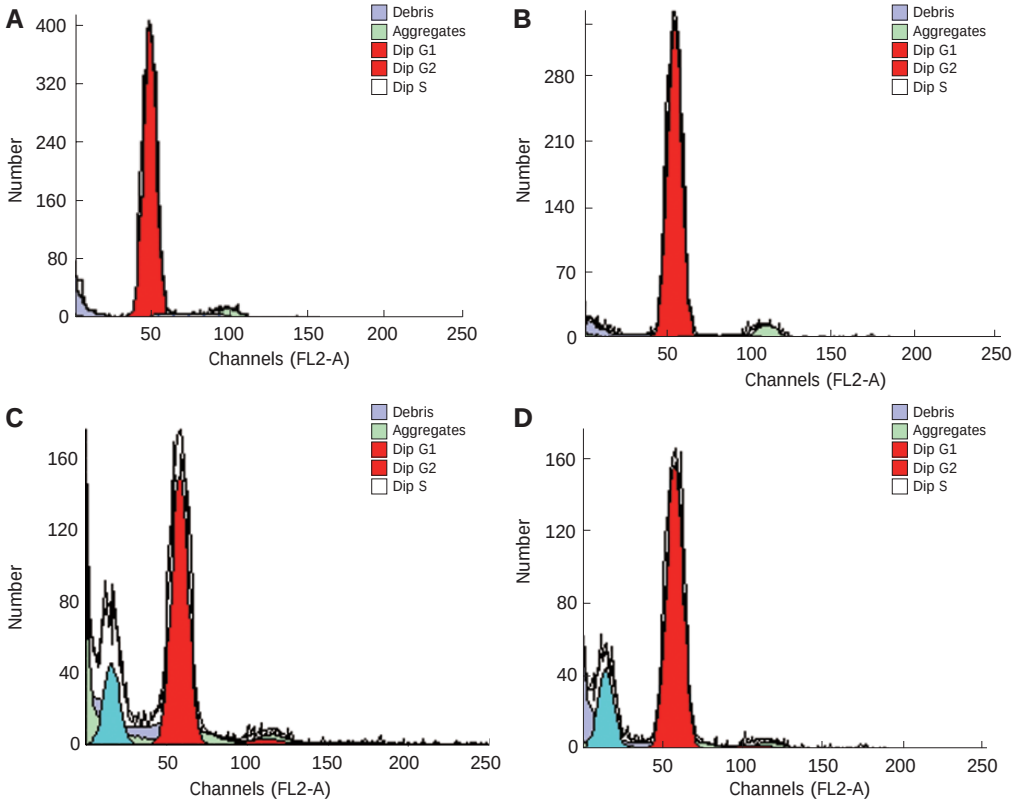

Figure 6 Effect of As_2O_3 on cell cycle of ECV304 cells. **A**: Control; **B**: 0.5 μmol/L As_2O_3; **C**: 2.5 μmol/L As_2O_3; **D**: 5 μmol/L As_2O_3.

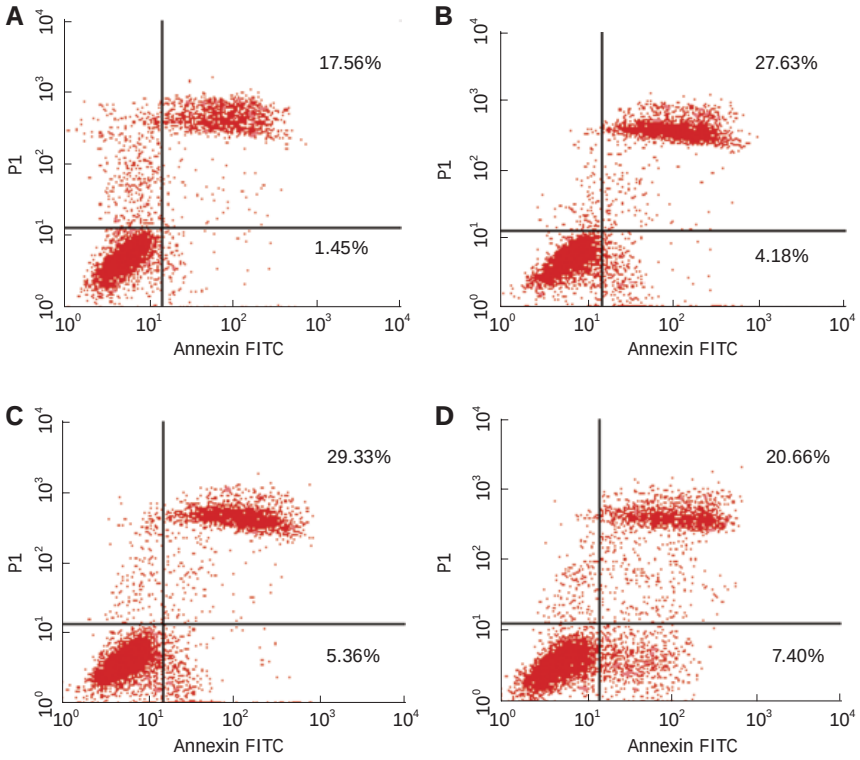

Figure 7 Induction of apoptosis in ECV304 with As_2O_3. Dual-stained with Annexin-V-FITC and PI and analyzed by flow cytometry. There was a dose-dependent increase in early apoptotic cells, as shown in the fourth quadrants plots. **A**: Control; **B**: 0.5 μmol/L As_2O_3; **C**: 2.5 μmol/L As_2O_3; **D**: 5 μmol/L As_2O_3.

the G1 phase.

Tumor angiogenesis appears to be achieved by the overexpression of angiogenic agents within solid tumors that stimulate host vascular EC mitogenesis and possibly chemotaxis. In recent years, it has been widely shown that activity of VEGF is a key feature during tumor growth and angiogenesis[28-30]. In the course of occurrence and development of gastric cancer, angiogenesis plays a crucial role in which VEGF is believed to be the most important factor in neovascularization[31]. Some studies have shown that the serum level of VEGF is not only related to prognosis of gastric cancer, but also to treatment efficacy[32].

Both types of specific receptors for VEGF, Flt-1

and KDR, are commonly distributed in ECs. VEGF acts by binding to the receptors on ECs, and prompts EC proliferation. VEGF and its receptors are the most important pathways in tumor angiogenesis. Inhibition of VEGF/VEGFR pathways may suppress angiogenesis and tumor growth. However, the expression of VEGFR is not EC-specific, and recent emerging evidence has shown that VEGFRs are expressed in several types of non-endothelial cells, especially in tumor cells, which indicates that there is an autocrine pathway of VEGF in tumor cells. A report by Zhang *et al*[8] has shown that eight gastric cancer lines (RF-1, RF-48, NCI-87, NCI-SNU-1, NCI-SNU-5, NCI-SNU-16, AGS-1 and KATO-Ⅲ) express VEGF, and six of these express both Flt-1 and KDR, and exogenous VEGF can stimulate the growth of KDR-positive tumor cells. These results suggest that VEGF acts not only as a paracrine factor on ECs, but also as an autocrine factor on tumor cells. VEGFR may play an important role in paracrine and autocrine pathways of VEGF, and VEGFR inhibitors can inhibit tumor angiogenesis and growth[8,9].

Our recent study[24] has demonstrated that As_2O_3 can inhibit expression of VEGF in gastric cancer. In the present study, we examined further the effect of As_2O_3 on VEGFR expression *in vivo*, and intended to confirm the anticancer activity of arsenic, which may block the paracrine and autocrine VEGF/VEGFR pathways, thereby delaying new tumor blood vessel formation and tumor cell growth. Our results showed that all of the Flt-1 and KDR expressed in the SGC-7901 tumor xenografts, and their expression in tumor cell control were higher than that in arsenic-treated mice. The fluorescence intensity levels of Flt-1 and KDR in tumor cells were significantly reduced in the arsenic-treated groups ($P < 0.001$). The fluorescence intensity levels of Flt-1 and KDR in the 5 mg/kg group were less than those in the 2.5 mg/kg group ($P < 0.001$). These results suggest that As_2O_3 can result in significant down-regulation of Flt-1 and KDR in a dose-dependent manner. The results of further experiments *in vitro* showed that exogenous $VEGF_{165}$ could stimulate the growth of SGC7901 cells, and As_2O_3 may have disturbed the stimulatory effect of $VEGF_{165}$. It indicates that the autocrine pathway of VEGF through VEGFRs is possible in gastric carcinoma, and As_2O_3 inhibits expression of Flt-1 and KDR in endothelial and tumor cells. As_2O_3 may block new blood vessel formation through the paracrine pathway and affect growth of tumor cells through the autocrine pathway of VEGF/VEGFRs, and delay tumor growth.

In conclusion, the results of our present study showed that As_2O_3 delayed growth of human gastric tumor xenografts in nude mice, decreased MVD in tumor tissues, inhibited proliferation of vascular ECs and induced their apoptosis, which resulted in down-regulation of Flt-1 and KDR expression in tumor tissues in a dose-dependent manner. Further results indicate that exogenous $VEGF_{165}$ can stimulate the growth of SGC7901 cells, and As_2O_3 may disturb the stimulatory effect of $VEGF_{165}$. These results suggest that As_2O_3 might delay growth of gastric tumor through inhibiting the paracrine and autocrine pathway of VEGF/VEGFRs.

COMMENTS

Background

Angiogenesis is an important factor in the progression and enlargement of solid neoplasms and is in close relation to invasion and metastases. Inhibition of angiogenesis may lead to control of tumor growth and metastasis, therefore, antiangiogenesis is a promising therapeutic approach for treatment of cancer. VEGF is recognized as one of the most important molecules in the formation of new blood vessels. VEGF binds to two distinct receptors on ECs: Flt-1(VEGFR-1) and KDR (VEGFR-2). Thus, it is suggested that inhibition of VEGF/VEGFR pathways may interrupt VEGF-induced angiogenesis.

Research frontiers

As_2O_3 shows substantial efficacy in treating both newly diagnosed and relapsed patients with APL. Recent studies have shown that a wide variety of malignancies, including both hematological cancer and solid tumors derived from several tissue types, may be susceptible to therapy with As_2O_3. These successes have prompted investigations to elucidate the mechanisms of action underlying these clinical responses. Emerging data suggest that arsenic induces apoptosis, and inhibits tumor growth and angiogenesis. We have recently shown *in vivo* and *in vitro* that As_2O_3 can inhibit VEGF expression and suppress angiogenesis and gastric tumor growth. In the present work, we investigated further the effect of As_2O_3 on expression of VEGF receptors Flt-1 and KDR in human gastric tumor cells and proliferation of vascular ECs.

Innovations and breakthroughs

Our results showed that As_2O_3 delayed growth of human gastric tumor xenografts in nude mice and decreased MVD in tumor tissues, inhibited proliferation of vascular ECs and induced their apoptosis, which resulted in down-regulation of Flt-1 and KDR/Flk-1 expression in tumor tissues in a dose-dependent manner. $VEGF_{165}$ could stimulate the growth of SGC7901 cells, and As_2O_3 may have disturbed the stimulatory effect of $VEGF_{165}$. These results suggest that As_2O_3 might delay growth of gastric tumor through inhibiting the paracrine and autocrine pathway of VEGF/VEGFRs.

Applications

The studies suggest that As_2O_3 might delay growth of gastric tumor through inhibiting the paracrine and autocrine pathway of VEGF/VEGFRs. One of the mechanisms by which As_2O_3 inhibits tumors growth is anti-angiogenesis through inhibiting VEGF/VEGFRs. Our results suggest that As_2O_3 might be used to treat tumors.

Terminology

VEGF is recognized as one of the most important factors in the formation of new blood vessels. As_2O_3 is a common natural substance.

Peer review

This is an excellent paper in terms of scientific rigor, and it is well-written. The experiments were well-designed and well-executed.

Abstract

AIM: To investigate the inhibitory effect and possible mechanism of action of schisandrin B in SC-B on gastric cancer cells *in vitro*.

METHODS: SC-B consisted of schisandrin B, aloe-emodin, and *Astragalus* polysaccharides. Exponentially growing human gastric cancer SGC-7901 cells were divided into six treatment groups: (1) control group (RPMI 1640 medium); (2) negative control group (2% DMSO); (3) positive control group (50 mg/L 5-Fluorouracil, 5-FU); (4) low-dose group (LSC, final concentration of schisandrin B, 25 mg/L); (5) moderate-dose group (MSC, final concentration of schisandrin B, 50 mg/L); (6) high-dose group (HSC, final concentration of schisandrin B, 100 mg/L). Follow-up was done at 12-48 h. An MTT (Methylthiazolyldiphenyl-tetrazolium bromide) assay was used to examine the inhibitory effect of SC-B on gastric cancer cells. The mitosis index was assessed using an inverted microscope. Flow cytometry was used to visualize the cell cycle. An RT-PCR (Reverse transcription-Polymerase chain reaction) -based assay was used to detect mRNA expression for cyclin D1 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH).

RESULTS: The MTT assay showed that the number of living cells in the LSC, MSC and HSC groups was significantly smaller than that in the DMSO-treated group ($P < 0.05$) at 12-48 h. The inhibitory rate (IR) of the LSC group was 41.15% ± 3.86%, 59.24% ± 5.34% and 69.93% ± 7.81% at 12, 24 and 48 h, respectively. The IR of the MSC group was 42.82% ± 4.94%, 62.68% ± 7.58% and 71.79% ± 8.12% at 12, 24 and 48 h, respectively. The IR of the HSC group was 37.50% ± 3.21%, 40.34% ± 2.98% and 61.99% ± 4.88% at 12, 24 and 48 h, respectively. These results suggested that a moderate dosage had the most obvious inhibitory efficacy at 48 h. Compared to the DMSO group, the mitosis index of the LSC, MSC, HSC groups was greatly decreased ($P < 0.05$) at all time points. Any dose of SC-B suppressed mitosis within 12-48 h. Compared to the DMSO group, the percentage of cells in the G_0/G_1 phase of the MSC group was greatly increased, and that of the S + G_2M phase was greatly decreased, while the percentage of cell inhibition (PCI) in the MSC group was greatly increased ($P < 0.05$). This suggested that SC-B could exclusively arrest cells in the G_0/G_1 phase. Cyclin D1 mRNA expression was lower in the MSC group than that in the DMSO group ($P < 0.05$).

CONCLUSION: SC-B can inhibit the proliferation and aberrant mitosis of human gastric cancer SCG-7901 cells *in vitro*. This inhibitory effect may be due to the down-regulation of cyclin D1 mRNA expression, which causes cell cycle arrest of gastric cancer cells.

INTRODUCTION

Gastric cancer is one of the most prevalent tumors. In China, its incidence and death rate are above those for all other tumors[1]. Therefore, the development of drugs for the treatment of gastric cancer is of great importance. Traditional Chinese medicines and their effective components have certain antitumor effects. This study investigated the inhibitory effect and mechanism of action of SC-B (consisting of schisandrin B, aloe-emodin and Astragalus polysaccharides) on the SGC-7901 cell line *in vitro*.

MATERIALS AND METHODS

Reagents

Schisandrin B and aloe-emodin were purchased from the National Institute for the Control of Pharmaceutical and Biological Products. Astragalus polysaccharides (UV > 70%) were from East Plant Health Protection. MTT, trypsin (1:250), fetal bovine serum and DMSO were from Sigma (St.

Louis, MO, USA). RPMI 1640 medium and Trizol reagent were from Gibco/BRL (Gaithersburg, MD, USA). Oligo-dT primers, reverse transcriptase (AMV) and Taq polymerase were all from Promega (Madison, WI, USA).

Cell line and cell culture

Human gastric cancer cells (SGC-7901) were purchased from the Department of Cellular and Molecular Biology, Shanghai Institute of Biochemistry and Cell Biology, Academia Sinica. Cells were cultured in MEM containing 10% heated-inactivated fetal calf serum and PNS (100 U/mL penicillin and 10 mL/L streptomycin), at 37℃, in a humidified atmosphere of 95% O_2/5% CO_2. Cells were sub-cultured every 2 or 3 d.

Grouping

Cells were classified into the following groups: control group (treated with RPMI 1640 medium); negative control group (treated with DMSO; final concentration, 2%); positive control group (treated with 5-FU; final concentration, 50 mg/L), low-dose group (LSC, containing 25 mg/L schisandrin B); moderate-dose group (MSC, containing 50 mg/L schisandrin B); and high-dose group (HSC, containing 100 mg/L schisandrin B). Note that SC-B consisted of schisandrin B, aloe-emolin and Astragalus polysaccharides at a ratio of 2:1:1.

MTT experiment

Exponentially growing SGC-7901 cells were digested by 0.25% trypsin for 1-2 min, and washed three times with PBS. RPMI 1640 medium containing 10% newborn bovine serum was added to obtain a cell density of 5×10^8 cells/L. Final cell suspensions (100 μL) were placed in 96-well plates in an incubator containing 5% CO_2, and incubated at 37℃ for 24 h. Then, 100 μL RPMI 1640 medium containing different concentrations of schisandrin B was added to each plate. The effects of schisandrin B were assessed using six replicates for each concentration of schisandrin B. Cells were cultured for 12, 24 and 48 h. The culture medium was changed every 24 h. Four hours before the end of the culture, 20 μL 5 g/L MTT was added to the wells. Optical density (OD) values for each well were measured at 490 nm using an enzyme-linked immunosorbent assay meter. Inhibitory rate (IR) was calculated according to the formula: IR = [1 - (mean of treated group)/(mean of control group)] × 100%.

Mitosis index

Cellular mitosis was observed using an inverted microscope, and the proportion of mitotic cells in 1000 cells was calculated after SC-B was added to the plates. The drug concentrations and incubation times were the same as those used in the MTT experiment.

Cell cycle analysis

Exponentially growing SGC-7901 cells were used for this experiment, and the cell density was adjusted to 3×10^8 cells/L by adding RPMI 1640 medium containing 10% newborn bovine serum, to obtain a 2 mL final volume in each six-well plate. Six-well plates were placed at 37℃ in an incubator containing 5% CO_2 for 24 h. The culture medium was changed 24 h later. Once the 2 mL final cell suspensions (containing SC-B with a final concentration of schisandrin B of 50 mg/L) were added, the cells were left to incubate for 48 h. Finally, samples were processed to obtain simple cell suspensions (target cell number was > 5×10^9 cells/L), which were fixed with 70% cold ethanol for 24 h, after centrifugation for 5 min at 200 × *g*. The cells were further centrifuged for 15 min at 200 × *g*, and then resuspended in 0.5 mL PBS. Then, they were digested by Rnase-A (final concentration, 50 mg/L) for 30 min at 37°C, and stained with propidium iodide (final concentration, 65 mg/L) for 30 min. Finally, cell suspensions were analyzed for the cell cycle using a nylon monofilament mesh screen with 44-μm openings and flow cytometry. The percentage of cell inhibition (PCI) was calculated according to the formula: PCI = [(Percentage of S + G_2M in DMSO group - Percentage of S + G_2M in treatment group) / Percentage of S+G_2M in DMSO group] × 100%.

Detection of Cyclin D1 mRNA

The methods for cell culture, including drug concentrations and incubation times were the same as those for the cell cycle analysis.

Total mRNA extraction

Cells in each six-well plate were homogenized in 1 mL Trizol and 0.2 mL chloroform, and the mixture was placed on ice for 5 min. After sedimentation by centrifugation at 12000 × *g* at 4℃, RNA was precipitated by combining the aqueous phase with an equal volume of isopropanol. The precipitate was recovered by centrifugation (12000 × *g* at 4℃), washed once with 75% ethanol, and solubilized in diethylpyrocarbonate (DEPC)-treated water. RNA concentrations were measured with a UV spectrometer. RNA/DNA (A_{260}/A_{280}) ratio had to be > 1.8.

Reverse transcription (RT)

Each RT reaction consisted of 1 μg extracted RNA, 1 μL 10 × RT buffer, 4 μL dNTPs (10 mmol/L), 0.5 μL oligo-dT primers, 1 μL AMV, and 0.25 μL RNase inhibitor, and DEPC-treated water was added to obtain a final reaction volume of 10 μL. RT was initially performed at 95℃ for 3 min, and placed on ice. Other reactants were added to the reaction system, and the mixture was further incubated at 42℃ for 70 min, and held at 95℃ for 3 min. Samples were frozen for later use.

Polymerase chain reaction (PCR)

Each PCR reaction included 10 μL 5 × PCR Buffer, 1.6 μL dNTPs, 0.5 μL of a 25 μmol/L solution of each primer, 0.25 μL Taq DNA polymerase, 10 μL RT products, and DEPC-treated water. The total reaction volume was 40 μL. PCR reaction conditions are shown in Table 1. The amplified products were visualized by electrophoresis on a 1.5% agarose gel, stained with 1 mg/L ethidium bromide, and illuminated and analyzed with a UVP gel imaging system (BIO-PRO, Carlsbad, CA, USA).

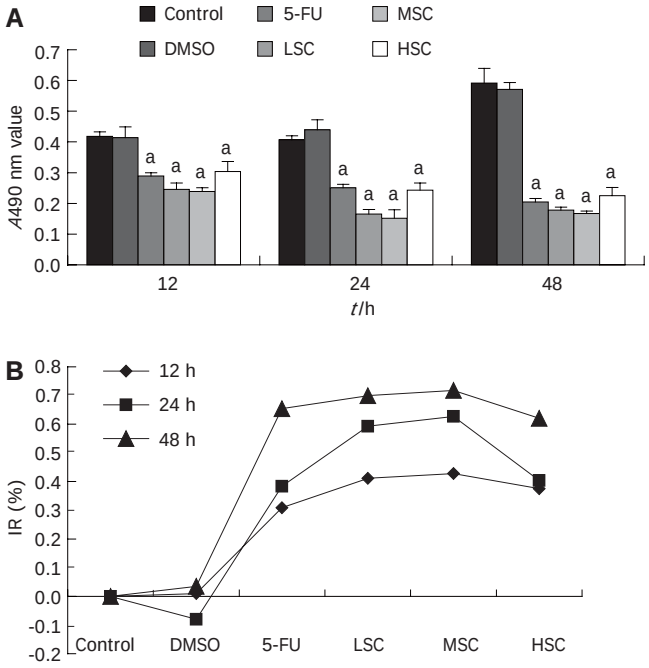

Figure 1 Effect of SC-B on gastric cancer SGC-7901 cell proliferation. Gastric cancer SGC-7901 cells were treated with SC-B (final concentration of schisandrin B was 25 mg/L, 50 mg/L and 100 mg/L for the LSC, MSC, and HSC groups, respectively) at the indicated times. **A**: Optical density values at 490 nm for each group were measured; **B**: Inhibitory rates (IR) of the 3 dosages are shown at different time points. $^aP < 0.05$ *vs* DMSO group.

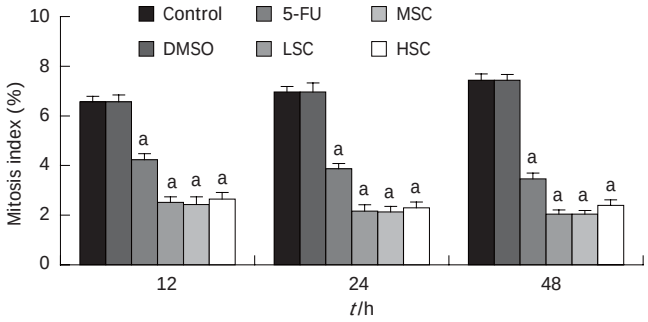

Figure 2 Influence of SC-B on the mitosis index of SGC-7901 cells. Gastric cancer SGC-7901 cells were treated with SC-B (final concentration of schisandrin B was 25 mg/L, 50 mg/L, and 100 mg/L for the LSC, MSC, and MSC groups, respectively) at the indicated times; $^aP < 0.05$ *vs* DMSO group.

Statistical analysis

Data were processed using SPSS10.0 software. One-way ANOVA analysis was used to examine the differences between the groups.

RESULTS

Effect of SC-B on gastric cancer SGC-7901 cells

Our results showed that the living cell numbers in the LSC, MSC, HSC groups were significantly smaller than that in the DMSO group ($P < 0.05$), as measured by the MTT assay, at 12, 24 and 48 h. The IR of the LSC group was 41.15% ± 3.86%, 59.24% ± 5.34%, and 69.93% ± 7.81% at 12, 24 and 48 h, respectively. The IR of the MSC group was 42.82% ± 4.94%, 62.68% ± 7.58% and 71.79% ± 8.12% at 12, 24 and 48 h, respectively. The IR of the HSC group was 37.50% ± 3.21%, 40.34% ± 2.98% and 61.99% ± 4.88% at 12, 24 and 48 h, respectively. These results suggested that a moderate dosage of SC-B had the most obvious inhibitory effect at 48 h (Figure 1).

Influence of SC-B on the mitosis of gastric cancer SGC-7901 cells

Compared to the DMSO group, the mitosis index of the LSC, MSC, HSC groups was greatly decreased ($P < 0.05$) at different time points. This suggested that SC-B could suppress mitosis of SGC-7901 cells treated with the three doses within 12 to 48 h (Figure 2).

Influence of SC-B on the cell cycle of gastric cancer SGC-7901 cells

Compared to the DMSO group, in the MSC group, the number of cells in the G_0/G_1 phase was greatly increased (62.59% ± 2.42% *vs* 56.76% ± 2.56%), but the number in the S + G_2M phase was greatly decreased (37.42% ± 2.42% *vs* 43.25% ± 2.56%). The PCI of the MSC group was greatly increased compared to the DMSO group (20.42% ± 3.11% *vs* 7.29% ± 2.83%, $P < 0.05$). This suggested that SC-B could exclusively arrest cells in the G_0/G_1 phase (Figures 3 and 4).

Influence of SC-B on cyclin D1 mRNA expression of gastric cancer SGC-7901 cells

GAPDH mRNA was used as the standard for PCR (320 bp). The ratio of cyclin D1 mRNA to GAPDH mRNA was used to quantify the expression level of cyclin D1 mRNA (573 bp). The results showed that cyclin D1 mRNA expression in the MSC group was lower than that in the DMSO group ($P < 0.05$) (Figure 5).

DISCUSSION

Schisandrin B, extracted from the fruit of *Schisandra chinensis* Baill, has been reported to have antitumor

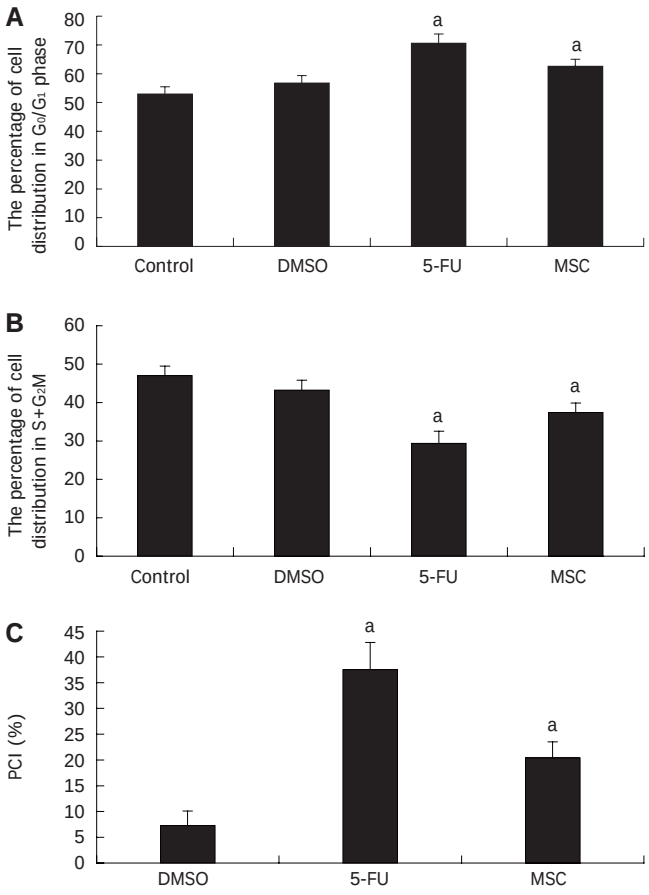

Figure 3 Effect of SC-B on the cell cycle of gastric cancer SGC-7901 cells. Gastric cancer SGC-7901 cells were treated with SC-B (final concentration of schisandrin B, 50 mg/L) for 48 h. **A**: Percentage of cell distribution in the G_0/G_1 phase; **B**: Percentage of cell distribution in the S+G_2M phase; **C**: Percentage of cell inhibition (PCI). $^aP < 0.05$ *vs* DMSO group.

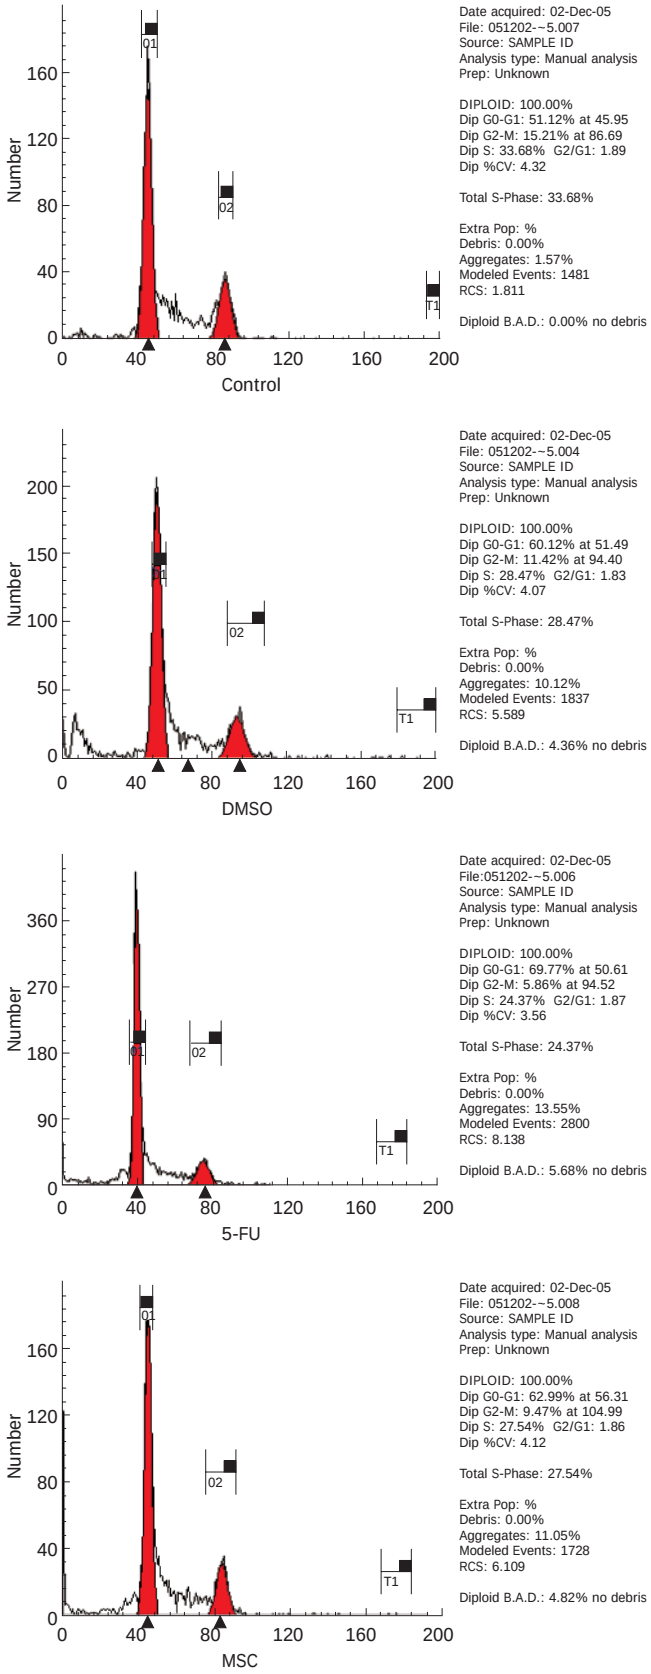

Figure 4 Flow cytometry results showing the influence of SC-B on the cell cycle of gastric cancer SGC-7901 cells.

effects. For example, schisandrin B can inhibit the proliferation of human hepatoma SMMC-7721 cells and induce apoptosis, involving the caspase-3-dependent and caspase-9-independent pathways, accompanied by down-regulation of Hsp70 protein expression at an early stage[2]. Schisandrin B enhances doxorubicin-induced apoptosis of SMMC7721 cells and MCF-7, a human breast cancer cell line, but not normal cells. This enhancement is associated with the activation of caspase 9[3]. Schisandrin B inhibits DNA synthesis in ascitic hepatoma cells[4]. Aloe-emodin is purified from *Aloe vera* leaves. Aloe-emodin modulates protein kinase C isozymes, inhibits proliferation, and induces apoptosis in U-373MG glioma cells[5]. The aloe-emodin-induced increase in the amount of proforms and fragments of nucleophosmin in the cytoplasm may be one of the important events for aloe-emodin-induced H460 cell apoptosis[6]. All this information supports the hypothesis that aloe-emodin represents a novel antitumor chemotherapeutic drug. *Astragalus mongholicus* polysaccharides have been isolated from one of the Chinese herbs, and are known to have various immunomodulatory activities[7]. We have previously shown that schisandrin B and aloe-emodin clearly inhibit the multiplication of human SGC-7901 cells within 12 to 48 h, and we have found that the most effective concentration ratio of schisandrin, aloe-emodin and *Astragalus* polysaccharides in SC-B is 2:1:1. The inhibitory effect of SC-B is significantly higher than that of schisandrin, aloe-emodin and *Astragalus* polysaccharides on their own[8].

This study investigated the inhibitory effect and

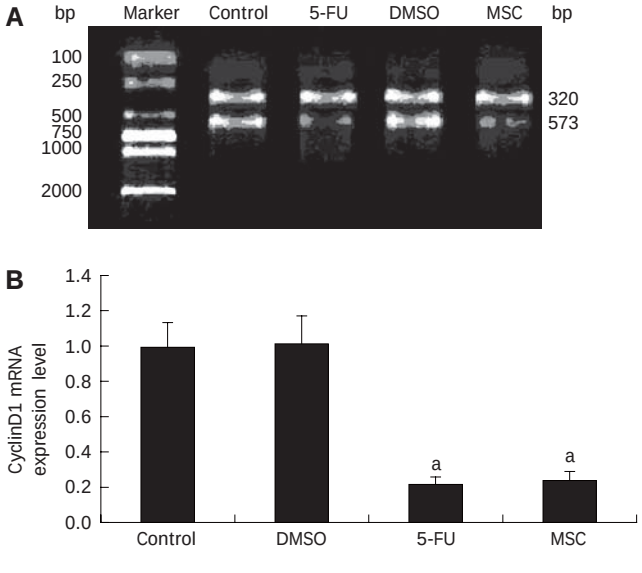

Figure 5 Influence of SC-B on cyclinD1 mRNA expression in gastric cancer SGC-7901 cells. Gastric cancer SGC-7901 cells were treated with SC-B (final concentration of schisandrin B, 50 mg/L) for 48 h. **A**: Electrophoretic bands of cyclinD1 mRNA and GAPDH; **B**: Half-quantitative results of the expression level of cyclinD1 mRNA, $^aP < 0.05$ *vs* DMSO group.

mechanism of SC-B on the SGC-7901 gastric cancer cell line *in vitro*. We showed that SC-B (25-100 mg/L) clearly inhibited the multiplication and mitosis of human gastric cancer SGC-7901 cells within 12-48 h, but a dose of 50 mg/L SC-B had the strongest inhibitory effect at 48 h. Therefore, when we further investigated the possible mechanisms of SC-B, we decided to use the moderate concentration (50 mg/L) and the 48-h time point.

The cell cycle consists of the G_1 phase (growth and preparation of the chromosomes for replication), S phase (synthesis of DNA), G_2 phase (preparation for mitosis), and M phase (mitosis). A eukaryotic cell cannot divide into two, and the resulting two cells cannot divide into four, unless two processes are alternated. These include the doubling of the DNA genome in the S phase (synthesis phase), and the halving of this genome during mitosis (M phase). The period between M and S is called the G_1 phase, and the period between S and M is the G_2 phase. Sometimes, a cell leaves the cell cycle temporarily or permanently. It exits the cycle at G_1, and enters a stage designated G_0. G_0 represents the absence of signals for mitosis, and an active repression of the genes needed for mitosis. Cancer cells cannot enter G_0, and are destined to repeat the cell cycle indefinitely[9]. If some mechanism can prevent S phase cancer cells from entering the M phase, then the infinite growth of cancer cells could be controlled. In our study, exponentially growing cells were used to analyze the changes in the cell cycle. We showed that SC-B (50 mg/L) exclusively arrested cells in the G_0/G_1 phase compared to the DMSO group. The number of cells in the G_0/G_1 phase in the MSC group was greatly increased ($P < 0.05$ *vs* DMSO group), which suggests that SC-B (50 mg/L) can prevent G_1 phase cancer cells from entering the M phase.

Quality controls of the cell cycle are cell-cycle checkpoints. Some key checkpoints are: G_1 checkpoint (to assess DNA damage before the cells enter S phase); S checkpoint (to monitor the presence of the Okazaki fragments on the lagging strand during DNA replication); G_2 checkpoint (during S phase, and after DNA replication); and M checkpoint (to detect any failure of spindle fibers to attach to the kinetochores, and arrest the cell in metaphase)[10-14]. Checkpoints can become activated due to DNA damage, exogenous stress signals, defects during DNA replication, or failure of the chromosomes to attach to the mitotic spindle[15]. Whether the cell cycle starts to allow the cells to proliferate depends on the G_1 checkpoint, which determines if the cells enter the S phase. The cell cycle is controlled by proteins in the cytoplasm. One of the main players in animal cells is cyclin D1. This is one of the important regulative factors that can induce cells from G_1 to enter the S phase. Increased amounts of cyclin D1 bind to cyclin-dependent kinases 4/6, which is the signal to prepare the chromosomes for replication[16,17]. RT-PCR was used to measure cyclin D1 mRNA expression in this study. The results showed that cyclin D1 mRNA expression was significantly reduced in the MSC group (50 mg/L) compared to the DMSO group ($P < 0.05$). This suggested that SC-B suppressed the multiplication and aberrant mitosis of human gastric cancer SGC-7901 cells by reducing cyclin D1 mRNA expression, which caused the cell cycle to arrest by inhibiting the G_1 checkpoint (i.e. by preventing gastric cancer cells from G_1 entering the S phase).

COMMENTS

Background

Gastric cancer is one of the most prevalent malignant tumors, and is classified as one of the first and most severe form of cancer harming people's health. Therefore, the exploitation of drugs to treat gastric cancer is of great significance. Traditional Chinese medicines and their effective components have certain antitumor effects.

Research frontiers

Schisandrin B, a dibenzocyclooctadiene derivative was isolated from the fruit of Schisandra chinensis. Many studies showed that schisandrin B has anticancer effects. Now, studies on the application of Schisandrin B in the preparation of anticancer medications, particularly for the treatment of multidrug resistant (MDR) cancer are hot research topics. Schisandrin B effectively reverses MDR cancer in combination with other anticancer chemotherapeutic agents.

Innovations and breakthroughs

Many other researches have revealed that Schisandrin B has anticancer effects, but Schisandrin B is cytotoxic to human cancer cells, which restricts its application in cancer chemotherapy. In this study, we successfully prepared SC-B for human use by mixing schisandrin B with aloe-emodin and Astragalus polysaccharides. The anticancer effect of SC-B was greatly increased compared with that of Schisandrin B on its own. In this study, we observed the influence of SC-B on living cell numbers, mitosis index, cell cycle, and $CyclinD_1$ expression in SGC-7901 cells. The results suggested that SC-B could suppress the multiplication and aberrant mitosis of human gastric cancer SGC-7901 cells by reducing $CyclinD_1$ mRNA expression, causing cell-cycle arrest by inhibiting the G_1 checkpoint.

Applications

SC-B could be applied in the treatment of gastric cancer, and might provide a potential therapeutic anticancer drug.

Terminology

Schisandrin B: Schisandrin B is a dibenzocyclooctadiene derivative isolated from the fruit of *Schisandra chinensis and Schisandra chinensis,* a woody vine which

bears numerous clusters of tiny, bright red berries; Cell cycle: The cell cycle or cell-division cycle refers to the series of events that take place in a eukaryotic cell from its formation and the moment it replicates itself; Cyclins: Cyclins are a family of proteins involved in the progression of cells through the cell cycle. The main players in animal cells are: G1 cyclin (cyclin D), S-phase cyclin (cyclins E and A), and mitotic cyclins (cyclins B and A).

Peer review

This is a good descriptive report on the potential chemotherapeutic effects of schisandrin B in gastric cancer, *in vitro*.

Abstract

AIM: To investigate the anti-neoplastic effects of MK615, an extract from the Japanese apricot (*Prunus mume*), against colon cancer cells.

METHODS: Three colon cancer cell lines, SW480, COLO, and WiDr, were cultured with MK615. Growth inhibition was evaluated by cell proliferation assay and killing activity was determined by lactate dehydrogenase assay. Induction of apoptosis was evaluated by annexin V flow cytometry. Morphological changes were studied by light and electron microscopy, and immunofluorescence staining with Atg8.

RESULTS: MK615 inhibited growth and lysed SW480, COLO and WiDr cells in a dose-dependent manner. Annexin V flow cytometry showed that MK615 induced apoptosis after 6 h incubation, at which point the occurrence of apoptotic cells was 68.0%, 65.7% and 64.7% for SW480, COLO, and WiDr cells, respectively. Light and electron microscopy, and immunofluorescence staining with Atg8 revealed that MK615 induced massive cytoplasmic vacuoles (autophagosomes) in all three cell lines.

CONCLUSION: MK615 has an anti-neoplastic effect against colon cancer cells. The effect may be exerted by induction of apoptosis and autophagy.

Key words: Colon cancer; Japanese apricot; *Prunus mume*; Autophagy; Apoptosis; MK615

INTRODUCTION

Japanese apricot, *Prunus mume* Sieb. et Zucc. (known as *ume* in Japanese), has for centuries been a traditional Japanese medicine, and is a familiar and commonly consumed food. *Prunus mume* is a species of Asian plum of the family Rosaceae. It is often called a plum, but it is more closely related to the apricot (ume in Japanese). MK615, an extract of compounds from Japanese apricot, has been shown to possess an anti-proliferative effect against some cancer cell lines[1,2]. Although MK615 induces apoptosis of breast cancer cells and some other human cancer cells, morphological studies have revealed the appearance of abundant cytoplasmic vacuoles early after MK615 exposure, which are not relevant to apoptosis[2]. The precise role of these vacuoles has not been elucidated.

Even though effective chemotherapeutic agents and regimens have been developed, colorectal cancer is still associated with high rates of morbidity and mortality worldwide[3,4]. Furthermore, the side effects of chemotherapeutic agents often hamper the quality of life of patients with colorectal cancer. There is a need, therefore, to develop new, effective and less toxic chemotherapeutic agents against colorectal cancer.

In the present study, we investigated the antineoplastic effects of MK615 against colon cancer cell lines *in vitro*. We found that MK615 strongly induced autophagy in colon cancer cells and exerted antineoplastic effects.

MATERIALS AND METHODS

MK615, derived from the fruit of the Japanese apricot[1], was provided by the Japan Apricot Co. (Gunma, Japan). The preparation involved the extraction of apricot juice using a press. This was then heated and concentrated. The concentrate was dissolved in diethylether, which was then completely removed from the extract by rotary evaporation. The dried hydrophobic extract, MK615, was dissolved in dimethyl sulfoxide (DMSO; Wako Pure Chemical Industry, Osaka, Japan) at several concentrations.

The MK615/DMSO solution was applied to cell cultures at a concentration of 10 μL/mL of culture medium. DMSO alone was added as a negative control.

Cells

Three human colon cancer cell lines, SW480, COLO, and WiDr, were purchased from the American Type Culture Collection (Manassas, VA, USA). These three were selected because of the differences in sex, race, and the productivity of proteins, such as carcinoembryonic antigen (CEA). Cells were maintained in Dulbecco's Modified Eagle's Medium (DMEM) containing 10% fetal calf serum (FCS) in a 5% CO_2 incubator.

Cell proliferation assay

The cells were plated at 1×10^4/well in 96-well plates in DMEM containing 10% (v/v) FCS. The cells were then cultured with or without MK615 at concentrations of 150, 300 or 600 μg/mL. For negative control wells, cells were cultured with 1% DMSO alone. After 48 h, 15 μL MTT (3-(4,5-dimethylthiazol-2-yl)-5-(3carboxymethoxyphenyl)-2-(4-sulphophenyl)-2H-tetrazolium, inner salt) (5 g/L) was added to each well, and the cells were incubated for 4 h. Then, 100 μL solubilization solution/stop mix was added following the manufacturer's instructions (Promega, Madison, WI, USA), and the plates were left to stand for 60 min. Absorbances at 570 nm and 630 nm were measured with an ELISA reader. Actual counts were calculated by subtracting the absorbance at 570 nm from that at 630 nm. Each assay was performed in triplicate and the average absorbance was calculated. The data presented here were calculated using the ratio of absorbance at each drug concentration to the absorbance in the absence of drugs.

Lactate dehydrogenase (LDH) assay

LDH assay was performed using the CytoTox 96 Non-Radioactive Cytotoxicity Assay (Promega). Briefly, cells were plated at 5×10^3/well in 96-well plates in DMEM containing 10% (v/v) FCS, then cultured with or without MK615 at 150, 300 or 600 μg/mL. For the negative control wells, cells were cultured with 1% DMSO alone. The medium was removed and 100 μL CytoTox-ONE Reagent was added. Cells were then incubated at 22℃ for 10 min and 50 μL stop solution added. The plates were shaken for 10 s and the absorbances at 560 nm and 590 nm measured with an ELISA reader. To obtain the maximum LDH release, 10 μL lysis solution (10 ×) was added to the positive control wells 45 min prior to harvest. After 48 h, a 50 μL supernatant was transferred to a fresh 96-well plate, and incubated for 30 min with 50 μL substrate mix at room temperature. Then, 50 μL stop solution was added, and the absorbance at 490 nm measured with an ELISA reader. Each assay was performed in triplicate and the average absorbance calculated. The data presented here were calculated using the formula: percentage cytotoxicity = 100 × (experimental - culture medium background) /(maximum LDH release - culture medium and lysis solution background).

Flow cytometry

Cells were cultured with MK615 at a concentration of 300 μg/mL for 6 h, then harvested by trypsinization and washed twice with PBS. Annexin V binding assay was performed using the Annexin V-FITC Apoptosis Detection kit (Becton-Dickinson, NJ) according to the supplier's instructions. At least 1×10^6 cells were incubated with FITC-conjugated annexin V at room temperature for 15 min. Cells were then analyzed on a FACScalibur flowcytometer (Becton-Dickinson).

Light microscopy

Cells were cultured with MK615 at a concentration of 300 μg/mL for 6 h, then collected by trypsinization. Collected cells were mounted on glass slides by the spin-down procedure (50 rpm, 3 min) and stained with Diff Quick staining solution (International Reagents, Kobe, Japan). Morphological changes were assessed by light microscopy of Diff Quick specimens.

Electron microscopy

Cells were cultured with MK615 at concentrations of 150, 300 or 600 μg/mL for 6 h, then fixed with 2% paraformaldehyde/2% glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.4), followed by 1% osmium tetroxide. After dehydration, thin sections were stained with uranyl acetate and lead citrate for observation using a JEM 100 CX electron microscope (JEOL, Peabody, NY, USA).

Immunofluorescence staining

Cells were cultured with MK615 at a concentration of 300 μg/mL for 6 h, then fixed in 4% paraformaldehyde and permeabilized with 0.1% Triton X-100. They were then washed three times in PBS containing 0.01% Triton X-100 and 10% FBS, followed by incubation with anti-autophagy cleaved-APG8b (MAPILC3B) antibody (ABGENT, CA, USA), or 4', 6-diamino-2-phenylindole (DAPI) nucleic acid stain (Lonza, Basel, Switzerland).

Statistical analysis

Statistical analysis for the cell proliferation assay and LDH assay was performed by Student's *t* test, comparing the counts at 0 μg/mL MK615 with those at each concentration of MK615. The percentage inhibition was calculated using the ratio of absorbance at each concentration of MK615 relative to the absorbance with no drug added.

RESULTS

The anti-proliferative effects of MK615 against colon cancer cells were evaluated by cell proliferation assay (Figure 1). The percentage inhibition rates of SW480 at 150, 300 and 600 μg/mL MK615 were 31.9%, 58.5% and 54.2%, respectively, and those of COLO and WiDr were 38.9%, 70.4% and 72.4%, and 12.1%, 54.5% and 58.3%, respectively. The inhibition induced by MK615 at all concentrations was significantly higher than that in the absence of MK615, and was dose-dependent in the COLO and WiDr cell lines.

We examined the ability of MK615 to kill colon cancer cells using a LDH-releasing assay (Figure 2). The percentage specific lysis of SW480 at 0, 150, 300 and 600 μg/mL

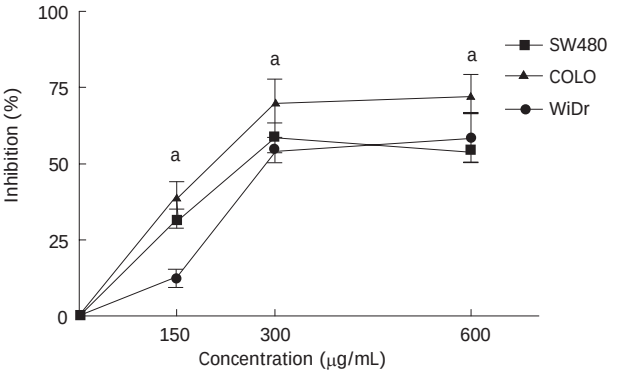

Figure 1 Dose-dependent inhibition of colon cancer cell growth by MK615. Growth inhibition was evaluated by MTT assay. The percentage inhibition (Y axis) was calculated using the ratio of absorbance at each drug concentration relative to absorbance in absence of the drugs. $^{a}P < 0.05$.

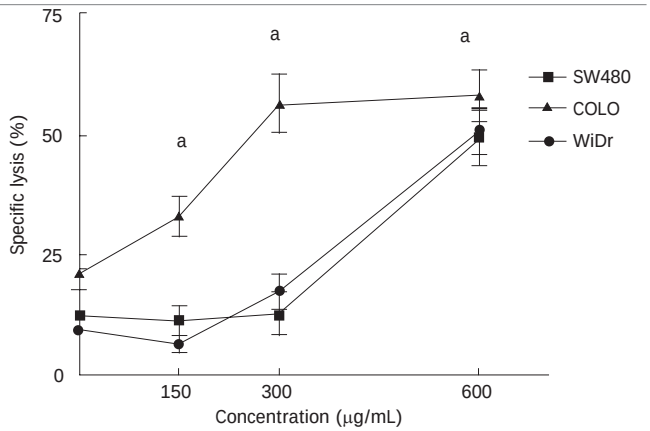

Figure 2 Dose-dependent lysis of colon cancer cells by MK615. Cells were challenged with 150, 300 or 600 μg/mL MK615. All three colon cancer cell lines were lysed effectively in a dose-dependent manner. $^{a}P < 0.05$.

MK615 was 12.5%, 11.3%, 12.8% and 49.6%, respectively. The respective values for COLO and WiDr were 21.4%, 33.1%, 56.6 and 58.3%, and 9.4%, 6.4%, 17.4% and 50.7%. The percentage specific lysis at all concentrations was significantly higher than that for the controls in all three cell lines.

The antiproliferative effect of MK615 is partly attributed to the induction of apoptosis[2]. As shown in Figure 3, MK615 treatment induced apoptosis in all three colon cancer cell lines. After incubation with 300 μg/mL MK615 for 6 h, the frequencies of apoptotic cells in SW480, COLO and WiDr cells were 68.0%, 65.7% and 64.7%, respectively.

It has also been reported that MK615 treatment induces the formation of cytoplasmic vacuoles in breast cancer cells[2]. Similarly, in the present study with colon cancer cells, abundant cytoplasmic vacuoles were observed in all three cell lines after 6 h incubation with MK615 at 300 μg/mL (Figure 4). Electron microscopy revealed that the cytoplasmic vacuoles were typical autophagosomes. Although some cells showed typical features of apoptosis (Figure 5A), there were abundant autophagosomes showing a membrane structure within which cytoplasmic structures were entrapped (Figure 5B-F). In some cells, degeneration of mitochondria was observed (Figure 5).

Immunofluorescence staining with Atg8 (LC3) showed positive labeling in all three cell lines after treatment with MK615 (Figure 6). Nuclei were stained blue with DAPI (Figure 6 A, C and E), and Atg8 (LC3) produced peripheral red staining (Figure 6 B, D and F).

DISCUSSION

In the present study, we showed that MK615 inhibited the growth of three colon cancer cell lines, SW480, COLO, and WiDr, and induced massive autophagy. Apoptosis is a well known form of programmed cell death (PCD), and is widely accepted as the main mechanism of cancer cell death[5-8]. Currently, apoptosis is classified as a type I PCD, whereas autophagy is classified as type II PCD[9-13]. Autophagy differs in several ways from type I PCD. Autophagy is a form of caspase-independent cell death, displays no DNA-laddering, and is typically characterized by the formation of cytoplasmic vacuoles. In recent years, the importance of autophagy has been stressed in various biological fields, including cancer[14-16]. Autophagy is an evolutionarily conserved pathway that delivers and recycles cytoplasmic components, such as mitochondria and Golgi apparatus. Thus, starvation is a typical trigger that can induce autophagy. Some studies have indicated that cancer cells show less autophagy than normal cells[17,18], which suggests that induction of autophagy is an attractive mode of anti-cancer therapy.

Autophagy can be induced by various agents, such as tamoxifen[19], γ-irradiation[20,21], and rapamycin[22,23], but few studies have investigated the induction of autophagy by natural substances. A previous study has found that soybean B-group triterpenoid saponins induce macroautophagy in human colon cancer cells[24].

Atg8 is a 117-amino-acid protein essential for the early phase of autophagy[25]. LC3 is a mammalian homologue of Atg8 and is the only established marker of autophagy in mammalian cells[26]. Conditions such as nutrient starvation initiate the formation of a double-membrane structure, which elongates to form a cytoplasmic vesicle, the autophagosome. Finally, autophagosomes fused with lysosomes generate single-membrane autophagolysosomes, resulting in the degradation of their content. Atg8 (LC3) binds to the membrane of the autophagosome and plays a crucial role in the process of autophagy[27,28]. In the present study, MK615 induced the expression of Atg8 (LC3) in all the colon cancer cell lines within 6 h of incubation. Expression of Atg8 (LC3) was exclusively localized in the cytoplasm. These findings indicated that MK615 induced massive autophagy in colon cancer cells *in vitro*.

Precise elucidation of the mechanism responsible for the antineoplastic effect of MK615 will require further study, as it remains unclear whether autophagy suppresses tumorigenesis or provides cancer cells with a rescue mechanism under unfavorable conditions. Kondo *et al* have reported that manipulation of autophagy may have different effects in different types of cancer cells. If cancer cells show defective autophagy, induction of autophagy

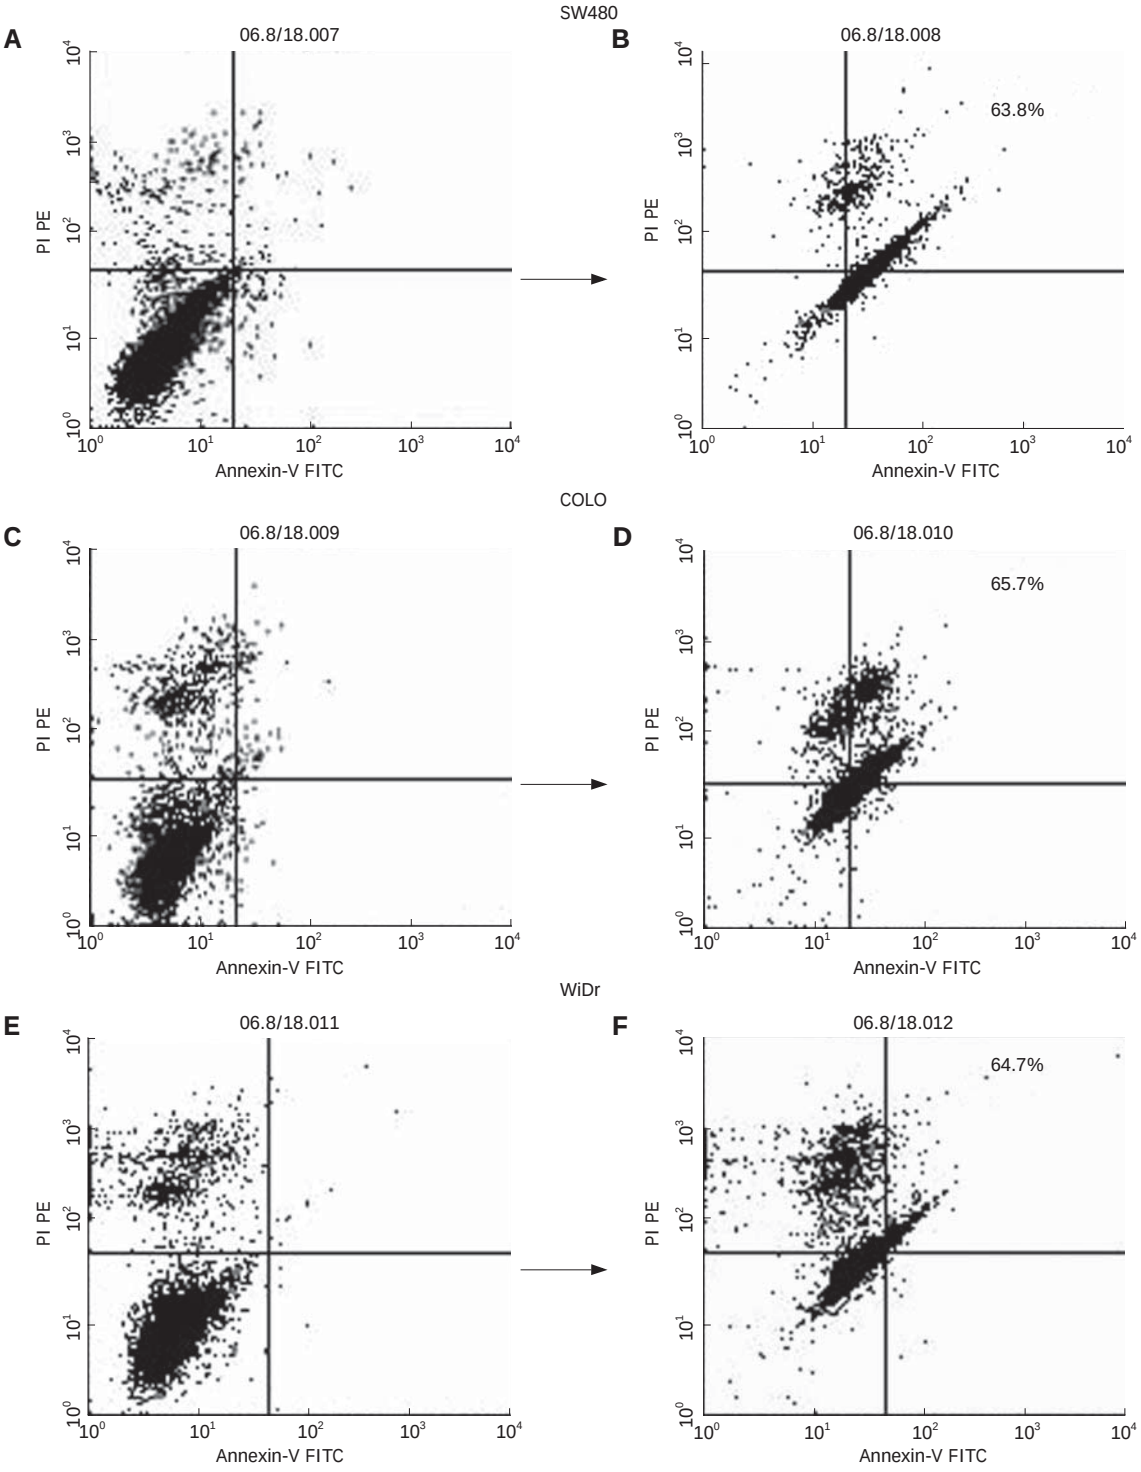

Figure 3 MK615-induced apoptosis in colon cancer cell lines. SW480, COLO and WiDr cells were cultured without (**A**, **C** and **E**) and with (**B**, **D** and **F**) MK615 at 300 mL, and harvested after 6 h incubation.

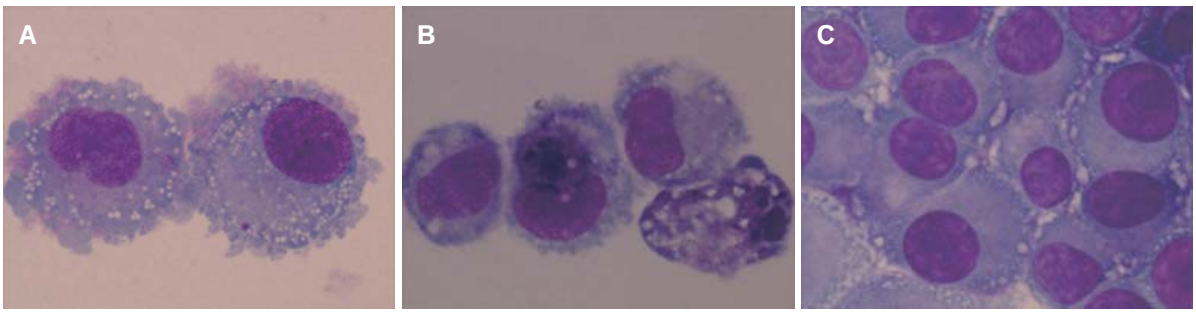

Figure 4 Massive induction of cytoplasmic vacuoles by MK615. MK615 (300 μg/mL) induced cytoplasmic vacuoles in SW480 (**A**), COLO (**B**) and WiDr (**C**) after 6 h incubation.

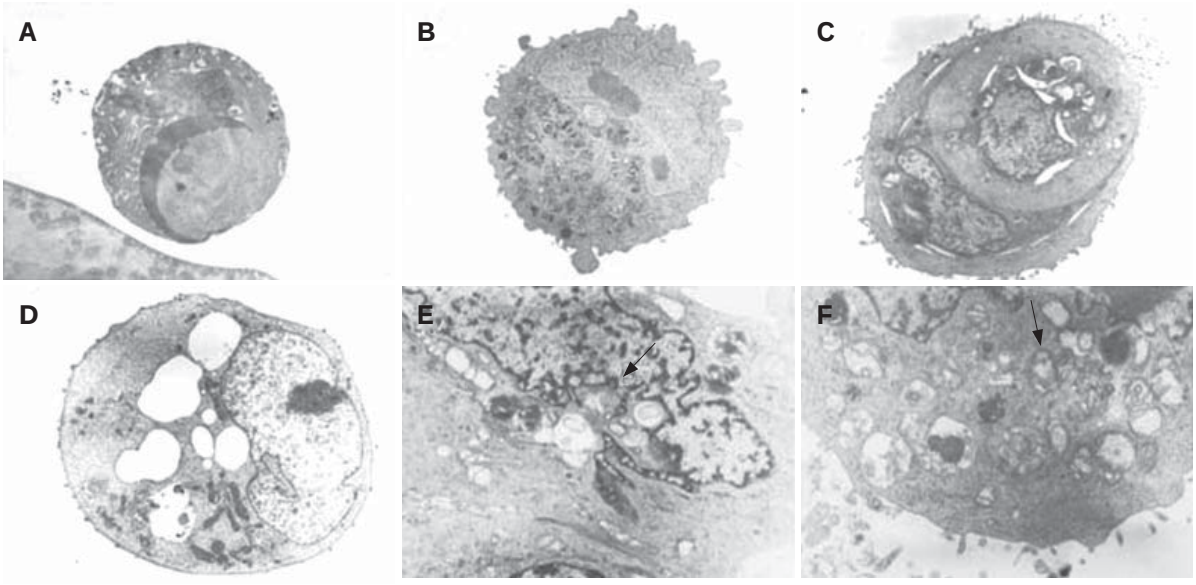

Figure 5 Electron micrographs of autophagy induced by MK615. **A**: MK615 induced typical features of apoptosis in SW480 cells; **B-F**: Autophagy induced by MK615. Cytoplasmic vacuoles (autophagosomes) induced by MK615 in SW480 **B** and **C**, COLO **D** and **E** and WiDr (**F**) cells. Degenerated mitochondria are evident (arrows in **E** and **F**).

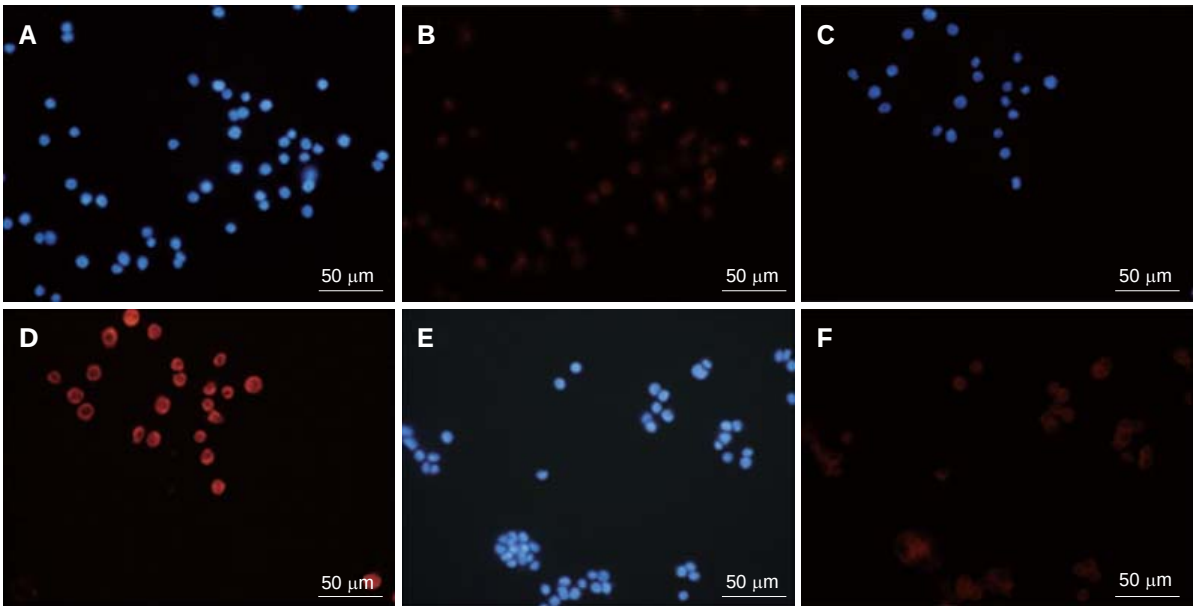

Figure 6 Immunofluorescence staining with Atg8 (LC3). SW480 (**A**), COLO (**B**) and WiDr (**C**) cells were cultured with MK615 at 300 μg/mL for 6 h. Nuclei were stained with DAPI (**A**, **C** and **E**), and Atg8 (LC3) was localized in the cytoplasm (**B**, **D** and **F**; note the central blank area in the cells).

may lead to the inhibition of cancer growth, whereas if cancer cells show protective autophagy in response to chemotherapy, this may decrease their sensitivity to anti-cancer treatment[29].

Importantly, Boya *et al* have reported that when cells are inhibited at the final step of autophagy, which is the fusion of autophagosome and lysosome, cells die during type I PCD (apoptosis); on the other hand, when cells complete the whole process of autophagy, they survive. Thus, the inhibition of autophagy causes cells to undergo apoptosis, which suggests that there is cross-talk between type I and type II PCD[30]. Indeed, the results of annexin-V flow cytometry indicated that MK615 induced apoptosis after 6 h of incubation.

In conclusion, we demonstrated that an extract of compounds from Japanese apricot (*ume*), MK615, exhibits anti-proliferative effects against colon cancer cells *in vitro*, and induced massive autophagy in these cells. Although further study is needed, the natural compounds in MK615 appear to exert antineoplastic effects through induction of autophagy-related PCD in colon cancer cells.

ACKNOWLEDGMENTS

The authors thank Dr. Keiichiro Yamaguchi for his excellent assistance with electron microscopy.

COMMENTS

Background

Japanese apricot, *Prunus mume* Sieb. et Zucc (*ume* in Japanese), has for centuries been a traditional Japanese medicine, and is a familiar and commonly consumed food. Some components of Japanese apricot have been shown to inhibit cancer cell growth.

Research frontiers

MK615 is an extract of compounds from Japanese apricot, and has been shown to possess an anti-proliferative effect against some cancer cell lines. Autophagy is a form of PCD and has been shown to regulate cancer-cell growth. However, there are not many substances that can stably induce autophagy in cancer cells.

Innovations and breakthroughs

In this report, we clearly described that MK615 inhibited the growth of colon cancer cells by aggressively inducing autophagy.

Applications

The side effects of chemotherapeutic agents often reduce the quality of life of patients with colorectal cancer. MK615 appears to be an effective and less toxic chemotherapeutic agent against colorectal cancer.

Terminology

Autophagy is classified as type Ⅱ PCD, and differs from type Ⅰ PCD (apoptosis). Autophagy is a form of caspase-independent cell death, displays no DNA-laddering, and is typically characterized by formation of cytoplasmic vacuoles. In recent years, the importance of autophagy has been stressed in various biological fields, including cancer.

Peer review

In this *in vitro* study, the authors investigated the antineoplastic effects of MK615, an extract from Japanese apricot (*ume* in Japanese), against colon cancer cells. They concluded that MK615 had an antineoplastic effect against colon cancer cells, and the effect may have been exerted by induction of apoptosis and autophagy.

Abstract

AIM: To assess the prevalence of extrahepatic manifestations in Bulgarian patients with chronic hepatitis C virus (HCV) infection and identify the clinical and biological manifestations associated with cryoglobulinemia.

METHODS: The medical records of 136 chronically infected HCV patients were reviewed to assess the prevalence of extrahepatic manifestations. Association between cryoglobulin-positivity and other manifestations were identified using χ^2 and Fisher's exact test. Risk factors for the presence of extrahepatic manifestations were assessed by logistic regression analysis.

RESULTS: Seventy six percent (104/136) of the patients had at least one extrahepatic manifestation. Clinical manifestations included fatigue (59.6%), kidney impairment (25.0%), type 2 diabetes (22.8%), paresthesia (19.9%), arthralgia (18.4%), palpable purpura (17.6%), lymphadenopathy (16.2%), pulmonary fibrosis (15.4%), thyroid dysfunction (14.7%), Raynaud's phenomenon (11.8%), B-cell lymphoma (8.8%), sicca syndrome (6.6%), and lichen planus (5.9%). The biological manifestations included cryoglobulin production (37.5%), thrombocytopenia (31.6%), and autoantibodies: anti-nuclear (18.4%), anti-smooth muscle (16.9%), anti-neutrophil cytoplasm (13.2%) and anti-cardiolipin (8.8%). All extrahepatic manifestations showed an association with cryoglobulin-positivity, with the exception of thyroid dysfunction, sicca syndrome, and lichen planus. Risks factors for the presence of extrahepatic manifestations (univariate analysis) were: age $\geqslant$ 60 years, female gender, virus transmission by blood transfusions, longstanding infection ($\geqslant$ 20 years), and extensive liver fibrosis. The most significant risks factors (multivariate analysis) were longstanding infection and extensive liver fibrosis.

CONCLUSION: We observed a high prevalence of extrahepatic manifestations in patients with chronic HCV infection. Most of these manifestations were associated with impaired lymphoproliferation and cryoglobulin production. Longstanding infection and extensive liver fibrosis were significant risk factors for the presence of extrahepatic manifestations in HCV patients.

Key words: Hepatitis C; Liver cirrhosis; Extrahepatic manifestations

INTRODUCTION

Hepatitis C virus (HCV) is associated with a wide spectrum of clinical and biological extrahepatic manifestations[1-3]. In chronically infected patients, the virus can trigger an impairment in lymphoproliferation with cryoglobulin production[3]. Mixed cryoglobulinemia with its complications (skin, neurological, renal, and rheumatologic) is the most significant extrahepatic manifestation of HCV

infection[4,5]. Mixed cryoglobulinemia can evolve into B-cell lymphoma in up to 10% of the patien[6,7].

Various non-organ specific auto-antibodies, present in low titers, are noted during the course of chronic HCV infection[8,9], but they do not influence the clinical profile of the disease[10]. Chronic HCV infection has been linked to two skin disorders, porphyria cutanea tarda and lichen planus, particularly with the involvement of the oral cavity[11,12]. Other possible HCV-associated diseases are type 2 diabetes mellitus[13], thrombocytopenia[14] and pulmonary fibrosis[15]. The sicca syndrome, although different from the typical Sjogren's syndrome, also appears to be associated with hepatitis C virus infection[16,17].

It is unclear whether HCV plays a pathogenic role in the development of thyroid dysfunction[18]. It is possible, that this extrahepatic manifestation of HCV is related to treatment with interferon rather than the virus[19].

The most common risk factors associated with extrahepatic manifestations of HCV infection are older age, female sex, and extensive liver fibrosis[8]. Several reports from different parts of the world suggest that hepatitis C virus affects not only the liver, but other tissues, organs and systems as well. Lymphoproliferative disorders, triggered by the virus, are the most significant extrahepatic manifestations in South-Eastern Europe, where Bulgaria is located.

The aim of the present study was to determine the prevalence of various extrahepatic manifestations of chronic HCV infection in our country, to analyze which extrahepatic manifestations are associated with impaired lymphoproliferation and cryoglobulin production, and to identify which patients are at greater risk of developing extrahepatic manifestations.

In our clinical practice, several patients present with extrahepatic manifestations even in the absence of a clearly defined clinical picture of hepatic illness. It is important to recognize these manifestations in order to make an early diagnosis and to initiate therapy in a timely manner.

MATERIALS AND METHODS

Patients

We included 136 Bulgarian patients who were referred to the Department of Internal Diseases and Gastroenterology of the University Hospital Alexandrovska during the period from 1996 to 2004. The main reason for patient referral was elevated liver enzymes. The diagnosis of HCV infection was made by the presence of anti-HCV antibodies (third generation ELISA) and a positive test for HCV-RNA (Cobas Amplicor HCV Monitor Test, v. 2.0, Roche Diagnostics). HCV genotypes were identified by direct sequence analysis (Immunogenetics, Belgium) in 60 patients[20]. HBsAg and HIV positive patients were not included in the study. Liver biopsy was performed in all patients. The data was collected before the patients were started on any specific treatment.

Methods

Patient records were reviewed to assess the presence of the following clinical manifestations: fatigue, arthralgia, Raynaud's phenomenon, palpable purpura, paresthesia, renal impairment (proteinuria, creatinine above the upper normal limit, and hypertension), sicca syndrome (mouth and eyes), thyroid dysfunction (TSH level below or above the normal range of 0.31-5.00 mU/L), lichen planus (skin and oral lesions), type 2 diabetes mellitus (hyperglycemia, treated by hypoglycemic drugs), pulmonary fibrosis (X-ray examination), lymphadenopathy, and lymphoma. The enlargement of peripheral lymph nodes was detected by palpation. The enlargement of mediastinal lymph nodes was detected by X-ray examination, and abdominal lymphadenopathy was detected by abdominal ultrasonography. Chest X-ray and abdominal ultrasonography were obligatory exams carried out routinely in all patients admitted to the hospital. Lymph node enlargement was confirmed by computerized tomography. The diagnosis of lymphoma was based on morphologic evaluation of lymph node tissue in the patients with co-existing peripheral lymphadenopathy, and by bone marrow biopsy. Histological analysis of the enlarged mediastinal and/or abdominal lymph nodes was not performed because patients refused to provide informed consent for invasive diagnostic surgical procedures.

Biological data obtained from for each patient included the presence or absence of cryoglobulins, thrombocytopenia, and auto-antibodies: anti-nuclear (ANA), anti-smooth muscle (ASMA), anti-neutrophil cytoplasm (ANCA), and anti-cardiolipin (ACL). The platelet count was obtained from the patients' files. Thrombocytopenia was defined as platelet count $\leqslant 110.10^9$/L. Cryoglobulins were detected by the Winfield method[21]. Twenty milliliters of venous blood was obtained from each patient in a pre-warmed (37℃) syringe, allowed to clot at 37℃ and the serum was separated by centrifugation. The supernatant was incubated at 4℃ for 8 d and examined daily for cryoprecipitate. Indirect immunofluorescence was used for the detection of ANA, ASMA, and ANCA (IFA/ Binding Site). A positive test for ANA and ASMA was defined as a titer $\geqslant$ 1/40, and for ANCA $\geqslant$ 1/20. Anticardiolipin antibodies (ACL-IgG and ACL-IgM) were detected by ELISA (Orgentec).

The following demographic and epidemiologic data was collected: age (less or $\geqslant$ 60 years), sex, the suspected duration of the infection (less or $\geqslant$ 20 years), an alcohol intake (less or $\geqslant$ 50 g/d), and the mode of infection. Questions regarding the most relevant identifiable HCV risks factors were asked, including transfusion of blood and blood products, intravenous drug use, surgical procedures, dental manipulation associated with bleeding, and needle stick injury in health workers. In patients with a past history of transfusions of blood and blood products, it was assumed that HCV infection was caused by contaminated blood and blood products.

The histological abnormalities in liver biopsy specimens, obtained blindly (Hepafix 1.4 mm, B. Braun, Germany), were scored according to the METAVIR system[22]. Each liver biopsy sample was assessed for the stage of fibrosis and grade of histological activity. Liver fibrosis was staged on a scale of 0 - 4, where 0 = no fibrosis, 1 - portal fibrosis without septa, 2 = few septa,

Table 1 Prevalence of clinical and biological extrahepatic manifestations in 136 patients with chronic HCV infection

Clinical manifestations	*n* (%)
Fatigue	81 (59.6)
Renal involvement	34 (25.0)
Type 2 diabetes mellitus	31 (22.8)
Paresthesia	27 (19.9)
Arthralgia	25 (18.4)
Purpura	24 (17.6)
Pulmonary fibrosis	21 (15.4)
Thyroid dysfunction	20 (14.7)
Raynaud's phenomenon	16 (11.8)
B-cell lymphoma	12 (8.8)
Sicca-syndrome (xerostomia)	9 (6.6)
Lichen planus	8 (5.9)
Biological manifestations	
Cryoglobulinemia	51 (37.5)

ASMA	23 (16.9)
ANCA	18 (13.2)
Anticardiolipin antibodies	12 (8.8)
Overall	
At least 1 extrahepatic manifestation	104 (76.5)

ANA: Anti-nuclear antibodies; ASMA: Anti-smooth muscle antibodies; ANCA: Anti-neutrophil cytoplasm antibodies.

3 = numerous septa without cirrhosis, and 4 = cirrhosis. Necroinflammatory activity was graded on a scale of A0-A3, where A0 = no histological activity, A1 = mild activity, A2 = moderate activity, and A3 = severe activity.

Statistical analysis

Quantitative data was expressed as mean ± SD. Univariate analysis used the χ^2- square or Fisher's exact test for comparison of qualitative values. An assessment of the characteristics of HCV infection (demographic, epidemiologic, histologic), associated with the presence of extrahepatic manifestations, was performed using univariate and multivariate logistic regression analysis. Statistical significance was assessed at $P < 0.05$. Adjusted odds ratio (OR) and 95% confidence intervals (CI) were derived from the coefficient of the final multivariate logistic model. The analysis was performed with SPSS v.12.0 statistical software.

RESULTS

A total of 136 patients with chronic HCV infection were included in the study, comprising of sixty-two (45.6%) males and seventy-four (54.4%) females. The mean age of the patients was 50.16 ± 16.08 years (range 20-80 years). Forty-six patients (33.8%) were ⩾ 60 years of age. Thirty-four patients (25.0%) had a history of alcohol intake (⩾ 50 g/d). The suspected duration of infection was ⩾ 20 years in 70 patients (51.5%) and < 20 years in 66 patients (48.5%). Genotyping was performed in sixty patients, fifty-two (87%) had genotype 1, 4 (6.5%) genotype 3, and 4 (6.5%) had mixed genotypes. Metavir scores for inflammatory activity were: A0 in 5 patients (3.7%), A1 48 (35.3%), A2 46 (33.8%), and A3 37 patients (27.2%). Metavir scores for fibrosis were: F0 in 12 patients (8.8%), F1 16 (11.8%), F2 25 (18.4%), F3 27 (19.9%), and F4 in 56 patients (41.1%). Twenty patients (14.7%) were intravenous drug users. Thirty-seven patients (27.2%) were possibly infected during surgical procedures. History of dental manipulation with bleeding was detected in 18 patients (13.2%). Needle stick injury was found in 11 health workers (8.1%). Fifty of the 136 patients (36.8%) had previously been transfused with blood or blood products. Thirty-eight of these 50 patients were women, who received blood transfusions during childbirth, and in 33 of these patients the duration of infection was ⩾ 20 years. Nineteen of these 38 women were ⩾ 60 years of age at the time of presentation. Twenty of these patients had Metavir stage F4, and 10 (10/38) were Metavir F3.

The overall prevalence of individual extrahepatic manifestations is shown in Table 1. At least one extrahepatic manifestation was identified in 104 patients (76.5%). The clinical manifestations, in descending order of prevalence were: fatigue (59.6%), kidney impairment (25.0%), type 2 diabetes mellitus (22.8%), paresthesia (19.9%), arthralgia (18.4%), palpable purpura predominantly of the lower extremities (17.6%), lymphadenopathy (16.2%), pulmonary fibrosis (15.4%), thyroid dysfunction (14.7%), Raynaud's phenomenon (11.8%), B-cell non-Hodgkin's lymphoma (8.8%), sicca-syndrome (6.6%), and lichen planus (5.9%). All patients with sicca-syndrome had xerostomia, but none had xerophtalmia. Three patients had skin lesions of lichen planus and five had oral lesions. The biological manifestations, in descending order of prevalence were: cryoglobulin (37.5%), thrombocytopenia (31.6%), ANA (18.4%), ASMA (16.9%), ANCA (13.2%), anti-cardiolipin antibodies (8.8%). The ANA, ASMA and ANCA were present in low titers (⩽ 1/160). None of the patients in the study had clearly defined clinical features of autoimmune liver disease.

The relationship between the presence of cryoglobulins and other extrahepatic manifestations is shown in Table 2. Cryoglobulin-positivity was related to the following clinical manifestations: fatigue, purpura, Raynaud's phenomenon, kidney impairment, type 2 diabetes mellitus, arthralgia, paresthesia, pulmonary fibrosis, lymphadenopathy, and B-cell lymphoma. Cryoglobulin-positivity was also associated with the following biological manifestations: thrombocytopenia, and positive ANA, ASMA, ANCA, and anti-cardiolipin autoantibodies. Three female patients (⩾ 60 years at the time of the study) with advanced liver fibrosis and history of blood transfusions during childbirth, first became cryoglobulin positive and subsequently developed lymphadenooathy over two, three, and five years respectively. Histological analysis of the removed lymph nodes showed low-grade non Hodgkin B-cell lymphoma. The present study did not show any association between the presence of cryoglobulins and thyroid dysfunction, sicca syndrome, and lichen planus (Table 2).

The demographic, epidemiological and liver histological features associated with the extrahepatic manifestations were analyzed by univariate and multivariate logistic regression analysis. The results are shown in Table 3. Using univariate logistic regression analysis there was a positive correlation

Table 2 Relationship between cryoglobulin-positivity and the presence (%) of extrahepatic manifestations in patients with chronic HCV infection

Extrahepatic manifestations	Cryoglobulin-positive patients (n = 51)	Cryoglobulin-negative patients (n = 85)	P	Odds ratio (95% confidence interval)
Fatigue	92.2	40.0	0.000	17.6 (5.8-53.4)

ANA: Anti-nuclear antibodies; ASMA: Anti-smooth muscle antibodies; ANCA: Anti-neutrophil cytoplasm antibodies; ACL: Anti-cardiolipin.

Table 3 Univariate and multivariate logistic regression analysis of factors associated with the presence of extrahepatic manifestations in patients with chronic HCV infection

Factors	Patients with the factor (%) in the presence of extrahepatic manifestations (n = 104)	Patients with the factor (%) in the absence of extrahepatic manifestations (n = 32)	Uni-variate analysis	Multi-variate analysis	Odds ratio (95% confidence interval)
Female sex	59.6	37.5	0.042		
Age ⩾ 60 yr	43.3	3.1	0.000		
Duration of infection ⩾ 20 yr	66.3	3.1	0.000	0.001	36.3 (4.6-284.9)
Transfusion of blood and blood products	43.3	15.6	0.006		
Metavir A3	30.8	15.6			
Metavir F4	52.9	3.1	0.000	0.011	15.4 (1.8-125.9)
Alcohol ⩾ 50 g/d	24.0	28.1			

between the presence of extrahepatic manifestations and female sex, older age (⩾ 60 years), duration of the infection (⩾ 20 years), transfusion of blood and blood products, and extensive liver fibrosis (Metavir F4). Univariate analysis did not show any correlation between extrahepatic manifestations and the mode of transmission: intravenous drug use (8.7% *vs* 34.4% for the patients without extrahepatic manifestations), surgical procedures (27.9% *vs* 25.5%), dental manipulation with bleeding (12.5% *vs* 15.6%), and needle stick injury in health workers (7.7% *vs* 9.4%). Univariate logistic regression analysis did not show an association between extrahepatic manifestations and high grade of inflammatory activity in the liver (Metavir A3) and alcohol intake of ⩾ 50 g/d (Table 3). Multivariate logistic regression analysis showed that the most significant association was between extrahepatic manifestations and long duration of infection and advanced liver fibrosis (Table 3).

DISCUSSION

The present study on 136 patients with chronic HCV infection, showed a high prevalence of extrahepatic clinical and biological manifestations. At least one manifestation was present in 76.5% of the patients. These results are similar to those reported in a large prospective French study, in which 74% of 1614 patients with chronic HCV infection had at least one extrahepatic clinical symptom[23]. By univariate analysis (Table 3) five risks factors were found to be related with clinical and biological extrahepatic manifestations in our patients: female sex, age ⩾ 60 years, transfusion of blood and blood products, duration of the infection ⩾ 20 years, and extensive liver fibrosis. By multivariate analysis (Table 3) the most significant risks factors were the longstanding infection and extensive liver fibrosis.

Fatigue was the most frequent non-specific clinical symptom in chronic HCV infection[2]. About 60% patients in this study considered fatigue as the initial or worst symptom of their disease (Table 1). In a prospective study of 1614 individuals with chronic HCV infection, fatigue was present in 53% of patients[24]. It is not known what causes fatigue in chronic HCV infection. The elevated fatigue score[25] is probably related to an increase in serum leptin levels which may interact with serotonin neurotransmission[26]. Fatigue can be considered a part of

the clinical picture of HCV-associated cryoglobulinemia, since this symptom was seen more frequently in cryoglobulin-positive than in cryoglobulin-negative patients (92.2% *vs* 40.0%, OR 17.6, 95% CI 5.8-53.4).

Hepatitis C virus escapes immune elimination in chronically infected patients[5]. In such patients, CD81-mediated activation of B cells triggers mono-oligoclonal B-lymphocyte expansion and the appearance of various HCV-related autoimmune disorders, including the syndrome of mixed cryoglobulinemia[6,27]. A recent meta-analysis showed that 44% patients with chronic HCV infection had circulating immune complexes with cryoprecipitating properties[28]. In the present study, cryoglobulins were isolated in 51 of the 136 (37.5%) patients, but we were not able to define the type of cryoglobulin in all the cases. However, there was considerable evidence to suggest that HCV was associated with type Ⅱ mixed cryoglobulinemia, with clinical features of vasculitis which mainly affects the small sized blood vessels of the skin, joints, nerves, and kidneys[5,29]. Skin is the most frequently involved target organ[30]. In previous studies, palpable purpura was observed in 10% to 21% patients with clinically manifested cryoglobulinemic syndrome[11], and in 7% of all HCV infected patients[8]. We observed palpable purpura, predominantly over the lower extremities, in 24 of the 136 patients (17.6%), with much higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (41.2% *vs* 3.5%, OR 19.1, 95% CI 5.3-68.8). Symptoms related to Raynaud' s phenomenon were observed in 16 of the 136 patients (11.8 %), with higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (25.5% *vs* 3.5%, OR 9.3, 95% CI 2.5-34.7). Pruritus, Raynaud's phenomenon, and palpable purpura of the lower extremities are the main skin manifestations of chronic HCV infection, which is consistent with the findings of previous studies[11,31,32]. However, considering the high frequency of cryoglobulins in HCV patients, severe symptomatic mixed cryoglobulinemia with the clinical presentation of diffuse vasculitis was rare, seen in only 1% of cryoglobulin-positive patients[23]. Polyarteritis nodosa-type of clinical presentation was not observed in the present study.

Previous studies have shown that arthralgia is present in 44.7% patients with HCV-associated mixed cryoglobulinemia[33] and in 19% of all HCV infected patients[8]. The clinical picture may mimic rheumatoid arthritis, especially since rheumatoid factor was present in 71% of cases[34], but there was no joint destruction, and antibodies to cyclic citrullinated peptides, which are highly specific for rheumatoid arthritis, were absent[35]. In the present study, arthralgia was present in 18.4% patients, with higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (33.3% *vs* 9.9%, OR 4.8, 95% CI 1.8-12.2). None of the patients in the present study met the diagnostic criteria for rheumatoid arthritis.

Peripheral nervous system involvement is a characteristic feature of the more severe forms of clinically apparent HCV-cryoglobulinemia[3]. Peripheral neuropathy, manifested by paresthesia, was noted in 17% of all HCV patients[23] and in 37% to 80% of the patients with HCV-associated mixed cryoglobulinemia[36,37]. We observed paresthesia in 19.9% of all HCV infected patients, with a higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (41.2% *vs* 7.1%, OR 9.2, 95% CI 3.3-25.0). Sensory nerves are mainly affected in patients with HCV-associated mixed cryoglobulinemia[38]. Neuropathological data shows axonal degeneration, differential fascicular loss of axons, signs of demyelinization, and small-vessel vasculitis with mononuclear cell infiltrates in the perivascular areas[38,39].

Chronic HCV infection can trigger the immune complex syndrome of cryoglobulin deposition and type-1 membranoproliferative glomerulonephritis[40]. Diffuse membranoproliferative glomerulonephritis is found in 83% of cryoglobulinemic renal disease[41]. Misiani *et al*[42] found a high prevalence of HCV antibodies (66%) and HCV RNA (81%) in the serum of patients with cryoglobulinemic glomerulonephritis. Only 2% of the controls (patients with noncryoglobulinemic glomerulopathies) had HCV antibodies[42]. In Japan, the virus was found in 60% patients with membranoproliferative glomerulonephritis[43]. Clinically obvious renal disease was present in 20% to 30% of cryoglobulin-positive patients with HCV infection[7,23,44]. In 55% of these patients, the findings include mild proteinuria, mild microscopic hematuria and mild renal insuffiency[45,46]. Arterial hypertension is present in 80% patients[45,47]. In the present study, 34 of the 136 HCV patents (25%) had mild proteinuria, hypertension and serum creatinine levels above the upper limit of normal. These symptoms are related to HCV-cryoglobulinemia, since their prevalence was higher in cryoglobulin-positive than in cryoglobulin-negative patients (45.1% *vs* 12.4%, OR 5.5, 95% CI 2.3-12.7). Renal abnormalities during the course of HCV infection are usually diagnosed in most patients between the fifth and sixth decades of life, and occur slightly more frequently in women than men[45,48]. Risk factors for the development of severe renal failure at follow-up of these patients include age, serum creatinine level, and proteinuria at the onset of renal disease[41]. Cryoglobulin-related nephropathy has been reported to progress to chronic renal failure requiring dialysis in 10% patients[44], but the overall survival at 10 years was 80%[41].

Case-control studies show an increase in the prevalence of type 2 diabetes mellitus (14.5% to 24%) in patients with chronic HCV infection[13,49,50]. These findings have been confirmed in a representative sample of the general population in the USA[51]. Reports from diverse geographic regions have shown a 2- to 10- fold increase in the prevalence of diabetes in patients with HCV infection compared to liver disease controls[51-53]. The highest prevalence (up to 50%) was noted in patients with HCV-associated liver cirrhosis[54-56]. Our findings are consistent with these studies. We found type 2 diabetes in 31 of the 136 HCV patients (22.8%), which is higher than the prevalence (8.0%) in the general population of our country. Antonelli *et al*[57] found a higher prevalence (14.4%) of type 2 diabetes in HCV patients with mixed cryoglobulinemia compared to HCV-negative age-matched controls (6.9%) and the general population in northern Italy (2.5%-3.3%). We also found a higher prevalence of type 2 diabetes in cryoglobulin-positive than in cryoglobulin-negative patients (35.3% *vs* 15.3%, OR 3.0,

95% CI 1.3-6.8). Given the biology of HCV, which is both hepatotropic and lymphotropic, an immune-mediated mechanism may explain the raised prevalence of type 2 diabetes in HCV-patients with mixed cryoglobulinemia[57]. Recent studies suggest that insulin resistance mediated by proinflammatory cytokines, rather than a deficit in insulin secretion, is the primary pathogenic mechanism involved in the development of type 2 diabetes in HCV infection[58].

Soresi *et al*[59] detected abdominal lymphadenopathy in 22% patients with HCV infection and persistently normal transaminases, and in 38% of those with high alanine aminotransferase values. Multiple logistic regression analysis showed a significant relationship between abdominal lymphadenopathy and histological abnormalities of the liver, presence of HCV RNA in the serum and gamma-globulin levels[59]. Lymphadenopathy in chronic HCV infection indicates a possible interaction between viral antigens and the immune system[60]. This interaction may be complicated by autoimmunity, cryoglobulinemia and B cell malignancy[60]. In the present study, lymphadenopathy was seen in 22 of the 136 HCV patients (16.2%), with a higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (35.3% *vs* 4.7%, OR 11.0, 95% CI 3.4-35.1). Epidemiological studies have confirmed a link between HCV infection and B-cell non Hodgkin's lymphoma[61-63]. In a recent meta-analysis, the prevalence of HCV infection in patients with B-cell non Hodgkin's lymphoma was approximately 15%, which is much higher than the prevalence of HCV in the general population[64]. Clonal B cell proliferation was observed in patients with a longer duration of HCV infection, type Ⅱ cryoglobulin, and vasculitis[5,65,66]. Over 90% patients who developed non-Hodgkin lymphoma had type Ⅱ cryoglobulins[64]. About 10% patients with HCV mixed cryoglobulinemia evolved into lymphoma[6]. In a series of 231 Italian patients with mixed cryoglobulinemia, 20 developed B-cell lymphoma after a mean of 8.8 years[7]. The overall risk of non-Hodgkin lymphoma in patients with cryoglobulinemic syndrome was 35 times higher than that in the general population[64]. Our findings are in agreement with the results reported from Italy[67]. In the present study, B-cell non Hodgkin's lymphoma was diagnosed in 12 of the 136 HCV patients (8.8%) with higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (17.6% *vs* 3.5%, OR 5.8, 95% CI 1.5-22.7). The exact prevalence of HCV associated lymphoma in our country may be much higher, since patients with abdominal and/or mediastinal lymphadenopathy (without enlargement of peripheral lymph nodes) did not provide consent for invasive diagnostic surgical procedures. The appearance of cryoglobulins, peripheral lymphadenopathy and low-grade B-cell lymphoma in 3 women during follow-up suggested that benign lymphoproliferation, triggered by the virus, can evolve into malignant B cell lymphoma. It is possible that genetic and environmental factors[68] play a role in the higher prevalence of HCV-associated lymphoma in South-East Europe, including our country, compared to Northern Europe[69]. Based on the available evidence it appears that HCV is an important risk factor for B-cell malignancy in areas with a high prevalence of HCV infection[5], which in our country is 1.3%.

Ueda *et al*[70] noted a higher prevalence of anti-HCV antibodies in Japanese patients with idiopathic pulmonary fibrosis compared to the general population. The prevalence of idiopathic pulmonary fibrosis in anti-HCV positive patients was 9.4%[71]. HCV patients with mixed cryoglobulinemia have been found to have asymptomatic interstitial lung fibrosis diagnosed by chest X-ray and high-resolution computed tomography[15]. Pulmonary fibrosis in HCV-related cryoglobulinemia is perhaps triggered by local deposition of circulating HCV-containing immune complexes[72]. In the present study 21 of the 136 HCV patients (15.4%) showed pulmonary fibrosis on routine X-ray examination; the frequency of pulmonary fibrosis was higher in cryoglobulin-positive than in the cryoglobulin-negative patients (25.5% *vs* 9.4%, OR 3.2, 95% CI 1.2-8.6). These findings need further confirmation with the use of more sophisticated radiological techniques.

Serum autoantibodies are commonly seen in patients with chronic HCV infection. In a study by Lenzi *et al*[9] the overall prevalence of non-organ specific autoantibodies was significantly higher in anti-HCV positive patients compared to healthy subjects, and HBsAg positive controls (25% *vs* 6% and 7% respectively). Several studies have evaluated the prevalence of ANA and ASMA, with figures ranging from 4.4% to 41%[8,10,34] and 7% to 66% respectively[23,34,73]. In the present study, positive ANA and ASMA tests were seen in 18.4% and 16.9% patients respectively. The anti-ANA and ASMA antibodies were found in low titers ($\leqslant$ 1/160), and were detected predominantly in the cryoglobulin-positive patients (Table 2). However, none of the patients had a clearly defined clinical picture of autoimmune liver disease. Recent data suggests that the HCV core particles concentrated in the cryoprecipitate play a role in the interaction between the cryoglobulins, endothelial cells and neutrophil granulocytes[74]. The main antigens in HCV patients with a positive ANCA test are proteinase 3 and dihydrolipoamine dehydrogenase[75]. A positive ANCA has been found in 10% patients with HCV-associated mixed cryoglobulinemia[76]. In the present study, ANCA was present in 18 of the 136 patients (13.2%), with higher prevalence in cryoglobulin-positive than cryoglobulin-negative patients (25.5% *vs* 5.9%, OR 5.4, 95% CI 1.9-16.4). HCV patients with ANCA had a higher prevalence of skin involvement, anemia, abnormal liver function tests and elevated alpha feto-protein levels[75]. Anticardiolipin antibodies have been observed in 3.3% to 22% of HCV patients[77-79]. These antibodies were found more frequently in patients with HCV-associated cryoglobulinemia[80]. Our findings are consistent with previously reported data. In the present study, 12 of the 136 patients (8.8%) had anticardiolipin antibodies, with higher prevalence in cryoglobulin-positive than in cryoglobulin-negative patients (17.6% *vs* 3.5%, OR 5.8, 95% CI 1.5-22.7). According to a recent study, these antibodies do not have any clinical significance in HCV patients, since they are anti-β2-glicoprotein I independent[78]. The auto-antibodies seen in patients with HCV infection appear to resemble those seen in chronic viral infections - the autoantibody titers are low, frequently found during the clinical course

of cryoglobulinemia, but do not produce a typical autoimmune disease[29,80].

The prevalence of thrombocytopenia is higher in patients with chronic HCV infection than in the general population[14]. In a series of 368 patients with chronic HCV infection, Nagamine *et al*[81] detected 151 cases (41%) of thrombocytopenia. Our findings also suggest a high prevalence of thrombocytopenia in patients with chronic HCV infection (31.6%). This can be explained by the large number of patients with cirrhosis in the present study. Platelet sequestration and destruction in the spleen[82,83], along with low thrombopoetin production[83,84] play an important role in the pathogenesis of thrombocytopenia. However, a direct viral infection of the megakariocytes[85] and autoimmune mechanisms[86,87] cannot be ruled out. The higher prevalence of thrombocytopenia in cryoglobulin-positive than in cryoglobulin-negative patients (58.8% *vs* 15.3%, OR 7.9, 95% CI 3.5-17.8) in the present study may reflect the role of immune dysregulation in causing both abnormalities.

In previous studies, thyroid specific antibodies were observed in 22.1% patients with chronic HCV infection, but the presence of thyroid dysfunction was not different compared to age and gender matched controls[18]. Thyroid dysfunction was seen in 14.7% of our 136 untreated HCV patients, and there was no association with the presence of cryoglobulins. However, up to 12.6% HCV patients developed thyroid dysfunction during or after IFN therapy[88-90], with a significant association with female gender[91].

Lymphocytic infiltration of the salivary glands has been described in 57% patients with chronic HCV infection compared to 5% in deceased controls[16]. A direct role of the virus is suggested by studies on mice expressing HCV envelope proteins E1 and E2 in the liver and salivary glands[92]. Sialadenitis developed in 84% HCV infected mice compared to 2% in control littermates and 0% in HCV core transgenic animals[92]. Up to 10% patients with chronic HCV infection may develop symptoms of xerostomia and xerophthalmia[8], whereas less than 5% of patients with confirmed Sjogren syndrome are carriers of HCV[17]. In the present study, xerostomia was seen in 6.6% patients, but none had xerophthalmia. Our results show a much higher prevalence of xerostomia in cryoglobulin-positive patients, however there was no difference compared to those without cryoglobulins (Table 2). In a French study, the classic Sjogren syndrome (xerostomia, xerophthalmia, histological stages Ⅲ and Ⅳ in the Chilshom scale, and anti-SSA or anti-SSB antibodies) was observed only in 1% of patients with chronic HCV infection[32].

Clinical studies, predominantly from the Mediterranean area and Japan, suggest that lichen planus, mainly the oral form, is associated with HCV infection[93-95]. The overall prevalence of anti-HCV antibodies in Spanish patients with lichen planus was 29.2%[12]. Nagao *et al*[93] found serum anti-HCV antibodies in 28 (62%) and serum HCV RNA in 27 (60%) of 45 Japanese patients with oral lichen planus. However, these results have not been confirmed by reports from other regions[32,96]. The geographical differences could be related to immunogenetic factors since the allele HLA-DR6 is expressed in a significant proportion of Italian patients with oral lichen planus and HCV infection[95]. The frequency of lichen planus in our HCV patients (5.9%) is similar to that reported by Pawlotsky *et al*[32] in France (5%). We found oral lesions of lichen planus in 5 patients and skin lesions in 3 patients. In the present study, we did not find any association between cryoglobulinemia and the presence of lichen planus (Table 2). Pilli *et al*[97] detected HCV-specific T cells with phenotypic and functional characteristics of terminally differentiated effector cells at the site of the oral lesions. These findings and the detection of HCV RNA strands in the lichen tissue[98] suggests a possible role for HCV-specific T-cell responses in the pathogenesis of lichen planus associated with HCV infection[99].

Our study has demonstrated a high prevalence of extrahepatic manifestations in Bulgarian patients with chronic HCV infection. Most of these manifestations are the consequence of impaired lymphoproliferation and show an association with cryoglobulin production. Clinical features such as fatigue, palpable purpura, Raynaud's phenomenon, arthralgia, paresthesia, kidney impairment, type 2 diabetes, pulmonary fibrosis, lymphadenopathy, B cell lymphoma, thrombocytopenia and non-organ specific autoantibodies can be regarded as a part of the clinical spectrum of HCV-associated cryoglobulinemia. On the other hand, thyroid dysfunction, sicca-syndrome and lichen planus are also seen in patients with chronic HCV infection, but were not associated with the presence of cryoglobulins in the present study. Extrahepatic manifestations were observed more frequently in older women with longstanding infection, advanced liver fibrosis and HCV infection acquired through transfusion of blood and blood products during childbirth. These findings suggest that the dose of the virus and the route of transmission may be important factors associated with extrahepatic manifestations. The long duration of HCV infection and extensive liver fibrosis were the most frequent findings associated with extrahepatic manifestations, but the pathogenesis of such an association is unclear[1,23]. Progression of liver fibrosis and the development of systemic-portal venous anastomosis allows the passage of antigens directly into the systemic circulation, thus bypassing the liver filter and resulting in chronic interaction with the immune system[23]. Some of the immunological defects are the consequence of HCV interaction with dendritic cells and a shift from Th1 to Th2 cytokine profile[100,101].

Patients with chronic HCV infection have a high prevalence of extrahepatic manifestations. These manifestations are found more frequently in the patients with a long duration of infection and liver cirrhosis, even in the absence of a clearly defined clinical picture of hepatic illness. Most of these manifestations are associated with impaired lymphoproliferation and cryoglobulin production, triggered by hepatitis C virus. The benign lymphoproliferation, associated with cryoglobulinemia, can evolve into malignant B cell lymphoma. Physicians should be aware of the extrahepatic signs and symptoms of HCV infection. HCV should be tested in all patients with these manifestations. This may lead to early diagnosis and successful treatment of chronic HCV infection.

COMMENTS

Background

Hepatitis C virus (HCV) affects not only the liver, but other tissues, organs, and systems as well. In our practice, several patients with chronic HCV infection present with extrahepatic manifestations, even in the absence of a clearly defined clinical picture of hepatic illness. Lymphoproliferative disorders, triggered by the virus, are frequently seen in South-Eastern Europe, where Bulgaria is located.

Research frontiers

The aim of the present study was to assess the prevalence of different extrahepatic manifestations in Bulgarian patients with chronic HCV infection, to identify extrahepatic manifestations associated with impaired lymphoproliferation and cryoglobulin production, and to determine which patients are at greater risk of developing extrahepatic manifestations of chronic HCV infection.

Innovations and breakthroughs

We observed a high prevalence of extrahepatic manifestations (76.5%) in patients with chronic HCV infection. Patients with longstanding infection and cirrhosis had a higher risk of developing such manifestations. In the present study, most of the extrahepatic manifestations were associated with impaired lymphoproliferation and cryoglobulin production, with the exception of sicca syndrome, thyroid dysfunction and lichen planus. The presence of B-cell non Hodgkin's lymphoma was observed in 8.8% patients, with a higher prevalence in cryoglobulin-positive compared with cryoglobulin-negative patients (17.6% *vs* 3.5%, OR 5.8, 95% CI 1.5-22.7).

Applications

Physicians should be aware of the extrahepatic signs and symptoms of HCV infection. HCV should be tested in patients who have any of these manifestations. This may lead to early diagnosis and successful treatment of chronic HCV infection. The treatment of lymphoproliferative disorders, including B-cell non Hodgkin's lymphoma poses a challenge, and requires new therapeutic strategies.

Terminology

Hepatitis C virus (HCV) escapes immune elimination. HCV interacts with hepatocytes and B lymphocytes through a common (CD81) receptor. CD81-mediated activation of B cells in chronically infected patients can trigger clonal B-lymphocyte proliferation with cryoglobulin' production, and evolution of disease into B-cell non Hodgkin's lymphoma. HCV can interact, with or without immune mediated mechanisms, with different tissues, organs, and systems.

Peer review

The authors assessed the prevalence of extrahepatic manifestations in Bulgarian patients with chronic HCV infection and identified the clinical and biological manifestations associated with cryoglobulinemia.

Abstract

AIM: To investigate the effects of ZK1916784, a low calcemic analog of calcitriol on intestinal inflammation.

METHODS: Acute and chronic colitis was induced by dextran sodium sulfate (DSS) according to standard procedures. Mice were treated intraperitoneally with ZK1916784 or placebo and colonic inflammation was evaluated. Cytokine production by mesenterial lymph node (MLN) cells was measured by ELISA. Immunohistochemistry was performed to detect intestinal dendritic cells (DCs) within the colonic tissue, and the effect of the calcitriol analog on DCs was investigated.

RESULTS: Treatment with ZK191784 resulted in significant amelioration of disease with a reduced histological score in acute and chronic intestinal inflammation. In animals with acute DSS colitis, down-regulation of colonic inflammation was associated with a dramatic reduction in the secretion of the proinflammatory cytokine interferon (IFN)-γ and a significant increase in intereleukin (IL)-10 by MLN cells. Similarly, in chronic colitis, IL-10 expression in colonic tissue increased 1.4-fold when mice were treated with ZK191784, whereas expression of the Th1-specific transcription factor T-beta decreased by 81.6%. Lower numbers of infiltrating activated $CD11c^+$ DCs were found in the colon in ZK191784-treated mice with acute DSS colitis, and secretion of proinflammatory cytokines by primary mucosal DCs was inhibited in the presence of the calcitriol analog.

CONCLUSION: The calcitriol analog ZK191784 demonstrated significant anti-inflammatory properties in experimental colitis that were at least partially mediated by the immunosuppressive effects of the derivate on mucosal DCs.

Key words: Dextran sodium sulfate colitis; Calcitriol; Colonic inflammation; Dendritic cells

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic immune-mediated disease of the gastrointestinal tract of still unknown etiology, most commonly involving inflammation of the terminal ileum and colon. The disease is characterized by deregulated immune responses, and in particular, $CD4^+$ T cells that produce large amounts of proinflammatory cytokines [such as interleukin (IL)-2, interferon (IFN)-γ and tumor necrosis factor (TNF-α)] have been shown to play a central role[1]. Besides genetic factors that are thought to predispose individuals to develop IBD[2], the environment seems to contribute to the disease[3,4]. There is reason to believe that vitamin D may be an environmental factor that affects IBD, as vitamin D deficiency has been linked to ulcerative colitis and Crohn's disease even when the disease is in remission[5,6]. Additionally, vitamin D deficiency has been shown to accelerate the development of IBD symptoms among IL-10 knockout mice that develop spontaneous enterocolitis[7]. Also, calcitriol treatment reduces the ability of IL-10 knockout mice to produce and to respond to

TNF-α[8], and it has recently been shown that application of a calcitriol analog reduces intestinal inflammation in a 2,4,6-trinitrobenzene sulfonic acid colitis model[9].

Calcitriol is the activated form of vitamin D3 that binds to a nuclear receptor protein. In the $CD4^+CD45RB^{high}$ transfer model of colitis, in which T- and B-cell deficient recipient mice develop IBD symptoms when injected with $CD4^+CD45RB^{high}$ T cells, lymphocytes from vitamin D receptor (VDR) knockout mice increase colitis severity in recipient mice compared to similar cells from wild-type animals[10]. Also, VDR knockout mice develop a more severe colitis in response to dextran sodium sulfate (DSS) treatment than wild-type mice, which can be decreased in severity by dietary or rectally administered calcitriol[11]. To underline the importance of calcitriol in IBD, the VDR gene has been mapped to a region on chromosome 12 that has been shown to be linked to susceptibility for Crohn's disease, which suggests an influence of calcitriol on the intestinal immune system[12].

The immunoregulatory effects of the cellular receptor for calcitriol are complex and not yet finally understood. However, as the VDR was discovered in resting and activated lymphocytes[13], it has been suggested that calcitriol might be involved in immunoregulation. In particular, $CD4^+$ T cells that are known to play a major role in chronic colitis express VDR, and are among the identified targets of activated vitamin D[14,15]. Indeed, calcitriol is able to inhibit T-cell proliferation and secretion of different proinflammatory cytokines *in vitro*[13,16], and to suppress the development of several experimental models of chronic inflammatory diseases, such as rheumatoid arthritis, experimental autoimmune encephalomyelitis and diabetes *in vivo*[7,10,17-19]. Also, the presence of calcitriol significantly inhibits cell proliferation of T lymphocytes obtained from patients with ulcerative colitis[20,21]. In mice treated with calcitriol, increased production of TGF-β1 and IL-4 was observed[22], cytokines that are associated with the inhibition of T cell effector function in a murine model of colitis[23]. Furthermore, calcitriol has been found to inhibit dendritic-cell (DC) maturation, which leads to reduced alloreactive capacity[24] and enhanced generation of regulatory $CD4^+CD25^+$ T cells[25].

Calcitriol selectively regulates the immune response without compromising host ability to fight infection[17], which makes it an attractive target compared to standard immunosuppressive medication in patients with IBD. However, calcitriol has clear dose-limiting hypercalcemic effects that interfere with its systemic clinical use due to strong influence on calcium homeostasis and the risk of associated side effects. Recently, ZK191784, a new low-calcemic calcitriol derivative, has been identified that inhibits lymphocyte proliferation and suppresses secretion of proinflammatory cytokines by monocytes[26]. The compound has shown immunosuppressive activity in a murine contact hypersensitivity model when given systemically at concentrations that do not cause hypercalcemic effects, thereby suggesting a possible therapeutic application as an immunosuppressive agent[26].

The aim of our study was to investigate whether this modified calcitriol analog might have potential therapeutic value in the treatment of acute and chronic intestinal inflammation, using the DSS model of colitis.

MATERIALS AND METHODS

Mice

Female Balb/c mice were obtained from Charles River (Germany) and were used for the experiments at 6-8 wk of age and 20-22 g body weight. Animals obtained food and water *ad libitum*. The local Institutional Review Board approved the animal studies.

Reagents and antibodies

The calcitriol analog ZK191784 was synthesized as previously described[26], dissolved in ethanol at a concentration of 1×10^{-2} mol/L and kept at -20℃ until use. The following antibodies were used in the study (all purchased from BD Pharmingen, Heidelberg, Germany): anti-CD3, anti-CD11c, anti-CD28, anti-CD16/CD32, anti-MHC-Ⅱ, anti-CD40, anti-CD80, and anti-CD86.

Induction and treatment of DSS colitis

DSS (molecular mass 40 000) was purchased from ICN (Eschwege, Germany). Acute colitis was induced by feeding 3% DSS over 7 d[27]. Treatment with ZK191784 (100 μg/kg per day orally) or vehicle was either started on day -3 before DSS administration and maintained through to d 7 ("pretreatment"), or started on the first day of DSS application through d 7 ("treatment"). Mice were sacrificed on d 8. For induction of chronic colitis, mice received four cycles of DSS treatment. Each cycle was followed by a period of 10 d water without DSS. Treatment was performed before the first and before the third cycle of DSS for 7 d each (100 μg/kg per day orally). The animals were killed on d 8 after completion of the fourth cycle.

Histological examination

From the distal third of the colon, 1 cm of tissue was harvested from each animal, embedded in paraffin, stained with hematoxylin/eosin after sectioning, and used for histological analysis. To quantify the tissue damage, a scoring system was used as described previously[27]. Thereby, three sections, each obtained at a distance of 100 μm were evaluated. Mice were scored individually, each score representing the mean of three sections. Two independent investigators, blinded to the treatment group, performed histological examination. The total histological score represented the sum of the epithelium and infiltration score, and ranged from 0 to 8[27].

Cytokine ELISA of mesenterial lymph node (MLN) cells

MLN cells (pooled from each group of mice) were collected in cold cell-culture medium [RPMI-1640, 10% fetal calf serum (FCS), 100 U/mL penicillin and 100 μg/mL streptomycin; GIBCO-BRL, Eggenstein, Germany] and β-mercaptoethanol (3×10^{-5} mol/L; Sigma). Tissues were mechanically disrupted and the cell suspensions were filtered through a cell strainer (70 μm). Tissue-culture plates were coated in part with anti-CD3 (2.5 μg/well), and 2×10^5 cells/well were incubated in 200 μL

complete medium containing 10 U/mL IL-2 (Proleukin; Chiron) and in part with soluble anti-CD28 (1 μg/mL) for 24 h. Cytokine levels were measured in the supernatant by ELISA (all from Endogene, Woburne, MA, USA), according to the manufacturer's instructions.

Quantitative RT-PCR (light cycler)

RNA was extracted from colonic tissue using the RNeasy kit (Qiagen, Hilden, Germany) and transcribed (Promega, Mannheim, Germany). Quantification of cytokine mRNA was performed using a light cycler (Roche, Molecular Systems, Mannheim, Germany). The following primer pair was used for amplification of T-beta: 5'-AGGCTGCCTGCAGTGCTTC-3'and 5'-CTCGC CTGGTGAAATGTGC-3', annealing temperature at 62℃, and 3 mmol/L $MgCl_2$. For IL-10 amplification, the following primer pair was used: 5'-TCCTTAATGCAG GACTTTAAGGGTTACTTG-3'and 5'-GACACCTTG GTCTTGGAGCTTATTAAAATC-3', annealing temperature 62℃, and 3 mmol/L $MgCl_2$. For standardization, β-actin was amplified using the following primer pair: 5'-TGGAATCCTGTGGCATCCATGAAAC-3' and 5'-TAAAACGCAGCTCAGTAACAGTCCG-3'.

Generation of bone-marrow-derived DCs and isolation of $CD11c^+$ primary DCs

Bone-marrow-derived DCs (BM-DCs) were generated as described previously[28]. Briefly, bone marrow was flushed from femurs and tibiae of mice, and cells cultured for 10 d with PRMI (RPMI, 10% FCS, 1% penicillin/streptomycin, 1% l-glutamine, and 0.1% 2-mercaptoethanol) containing 200 U/mL granulocyte-macrophage colony-stimulating factor (GM-CSF) (Peprotech/Tebu, Germany). Subsequently, BM-DCs were incubated with different concentrations of ZK191784 (10, 100 and 1000 nmol/L) and stimulated overnight with 1 μg/mL LPS (Sigma, Germany). Supernatants were harvested for ELISA and BM-DCs were used for fluorescence-activated cell sorting (FACS) analysis.

For isolation of $CD11c^+$ DCs, spleen and MLNs were excised from ZK191784- or vehicle-treated animals (100 μg/kg per day orally, for 5 d), injected with 100 U/mL collagenase Ⅳ in RPMI (Worthington Biochemicals, Lakewood, NJ, USA) and incubated for 30 min at 37℃. After incubation, organs were mechanically dissociated. In the case of the spleen, red blood cells were removed by ACK lysis. $CD11c^+$ DCs were positively selected from single-cell suspensions from the spleen and MLNs using CD11c microbeads and a magnetic cell separation column, according to the manufacturer's instructions (Miltenyi Biotec, Bergisch Gladbach, Germany). The resulting DC preparations were > 95% CD11c-positive. Isolated DCs were stimulated overnight with 5 μg/mL phosphothioate-stabilized CpG-ODN with the following sequence: ODN1668 5'-TCCATGACGTTCCTGATG CT-3' (Metabion, Martinsried, Germany). Supernatants were harvested for ELISA and cells were used for FACS analysis.

FACS analysis and immunohistochemistry

Cells were analyzed by FACS using two-color staining. Briefly, isolated lymphocytes were incubated with 20 μg/mL of anti-CD16/CD32 mAb and 10% FCS to block Fc receptors, and stained with both fluorescein isothiocyanate (FITC)- and phycoerythrin (PE)-conjugated mAbs. The cells were washed and analyzed by flow cytometry using an EPICS-XL MCL Coulter. For immunohistochemistry, intestinal tissue samples were snap-frozen in liquid nitrogen embedded in optimal cutting temperature medium and 5- to 10-μm cryostat sections were cut. Incubation with primary antibodies was followed by incubation with biotinylated polyclonal anti-rat IgG or anti-hamster IgG (both Dianova, Germany) mAbs as secondary antibodies. Tissue was stained using the avidin/biotin complex immunoperoxidase kit according to the manufacturer's instructions (Vector Laboratories) and developed with 3-amino-9-ethylcarbazol. Sections were counterstained with hematoxylin/eosin.

Statistical analysis

Statistical analysis was performed using the Mann-Whitney *U* test for unpaired samples (histological score, cytokine levels) and Student's *t* test (cytokine levels of primary DCs and BM-DCs). Differences were considered statistically significant at $P < 0.05$ (labeled). For graphical analysis of the data, box plots were used. The box stretches from the lower hinge to the upper hinge and contains the middle half of the scores in the distribution. The median is shown as a line across the box, and the largest value below the upper hinge and the smallest value above the lower inner fence are drawn additionally, indicating the distribution.

RESULTS

Treatment with ZK191784 ameliorates acute and chronic DSS-induced colitis

As shown previously, vitamin D deficiency leads to severe colitis in IL-10 knockout mice[7]. However, limitations are involved in the study of cytokine-deficient animals, as intestinal inflammation in these mice may not represent a normal immune response, due to the lack of important regulatory cytokines. Therefore, we decided to investigate the effects of ZK191784 in the DSS models of acute and chronic colitis, as results in both models are not impaired by cytokine deficiency.

Administration of ZK191784 to mice before and during induction of acute colitis ameliorated colitis, as demonstrated by a significant reduction in the histological score by 25% compared to control mice (Figure 1A: control, 7.2 ± 0.44 *vs* ZK191784, 5.4 ± 1 34; $P < 0.05$), and reflected by a less severe inflammatory infiltrate and reduced epithelial damage, as seen in histological sections of the intestine (Figure 1C). Whether animals were pretreated with the calcitriol analog before induction of colitis or whether application of ZK191784 was started at the time of colitis induction made no difference in the ameliorating effect of the compound. Also, when animals were treated sequentially with the calcitriol analog during induction of chronic colitis, intestinal inflammation improved as well by 27.1% (Figure 1B: control, 7. 2 ± 1. 2 *vs* ZK191784, 5.25 ± 1. 9; $P < 0.05$). As demonstrated previously[26], the calcitriol compound did not increase serum levels of calcium in a significant manner, as compared to serum calcium levels in control animals (data not shown).

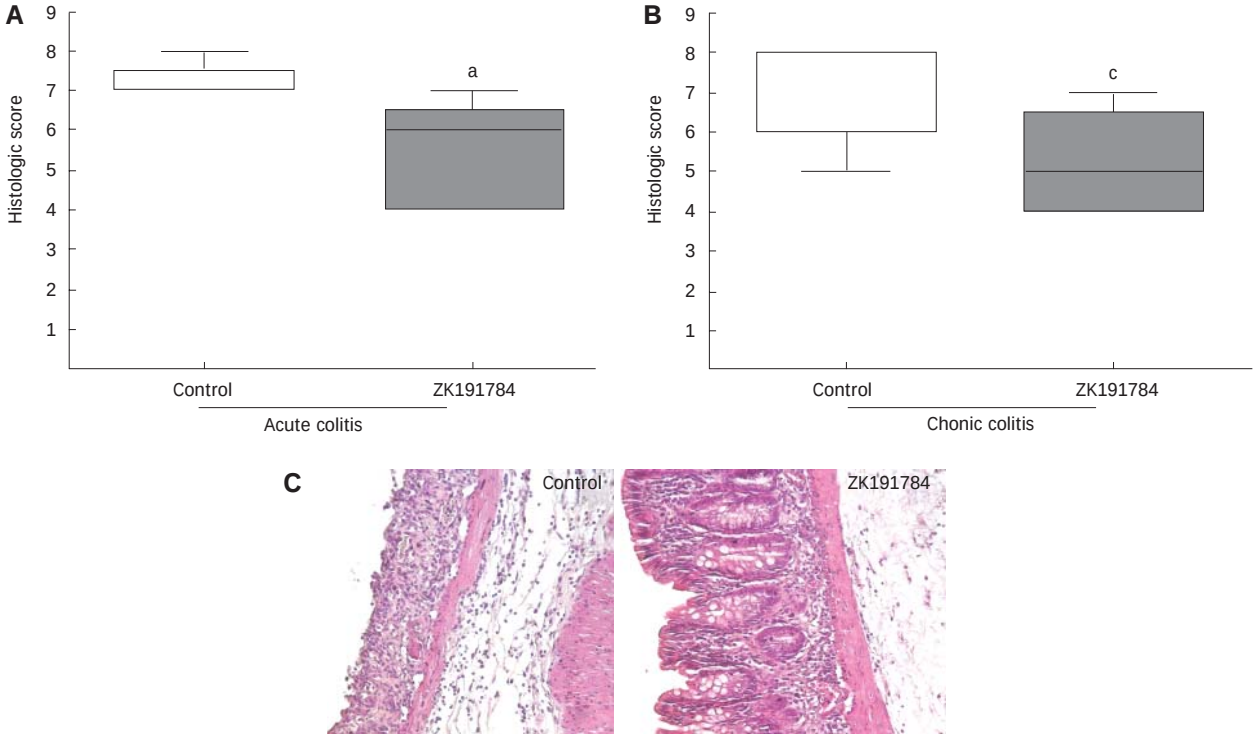

Figure 1 Treatment with ZK191784 ameliorates intestinal inflammation in acute and chronic DSS colitis. **A**: Acute DSS colitis was induced by administration of 3% DSS for 7 d. [a]$P < 0.05$, $n = 5$ mice per group. Data presented are representative of three independent experiments; **B**: Administration of ZK191785 was started after the first and the third cycle of DSS administration for induction of chronic colitis. [c]$P < 0.05$, $n = 8$ or 9 mice per group. Data show one of two independent experiments. Data are displayed as box plots in which the box contains the middle half of the scores in the distribution, the median is shown as a line across the box, and the largest value below the upper hinge and the smallest value above the lower inner fence are indicate the distribution; **C**: Representative colonic hematoxylin/eosin sections from animals with acute DSS colitis treated with ZK191784 or vehicle (× 100).

Treatment with ZK191784 suppresses the secretion of proinflammatory cytokines by MLN cells

In order to further characterize the differences in colitis severity between ZK191784-treated and control animals, we compared the cytokine secretion in both groups. Therefore, MLNs of diseased animals were harvested at the end of the experiment, and levels of pro- and anti-inflammatory cytokines within the supernatant of MLN cells were measured. The secretion of the proinflammatory cytokines IFN-γ (Figure 2A) and IL-6 (data not shown) by isolated cells was dramatically suppressed by treatment with ZK191784 in acute colitis compared with control mice (IFN-γ, -62.7%; IL-6, -47.4%, $P < 0.05$), whereas IL-10 secretion increased significantly by 2.3-fold (Figure 2B). Similarly, in chronic colitis, spontaneous IFN-γ secretion was suppressed by ZK191784 (control, 46.5 ± 8.4 pg/mL; ZK191784, 4.2 ± 1.2 pg/mL, $P < 0.05$). However, in chronic colitis we were not able to detect a significant difference in the secretion of IL-6 or IL-10 by MLN cells derived from ZK191784- or vehicle-treated animals (data not shown).

Th1 cytokines play a proinflammatory role in chronic DSS-induced colitis[29]. Therefore, we evaluated the effects of ZK191784 administration on expression of the Th1-specific transcription factor T-beta in the colonic tissue, using real-time PCR. As shown, the levels of T-beta expression were significantly reduced to 18% compared with those in the control group ($P < 0.0001$, Figure 2C). Additionally, even if we were not able to detect a significant difference in the secretion of the anti-inflammatory cytokine IL-10, the mRNA-levels of these cytokines increased slightly by 1.4-fold in ZK191784-treated animals ($P = 0.00025$, Figure 2D).

Treatment with ZK191784 prevents infiltration of intestinal lamina propria with activated CD11c$^+$ DC in animals with acute colitis

Vitamin D3 is known to interact with antigen-presenting cells and to prevent their activation[30], therefore, we were interested to see whether administration of the calcitriol compound ZK191784 influenced the activation of intestinal DCs within the inflamed colonic mucosa. As shown in Figure 3, immunohistochemical analysis for CD11c$^+$ DCs within the colonic lamina propria revealed a dramatic decrease in cell numbers in intestinal tissue derived from mice treated with ZK191784, as compared to that from control mice. Additionally, when staining for the activation marker CD80 was performed, almost no positive cells were found in the colonic mucosa of calcitriol-treated animals, whereas as expected, in control animals, large numbers of infiltrating CD80$^+$ cells were detected. No changes were observed concerning the numbers of CD3$^+$ T cells (data not shown).

ZK191784 inhibits the production of proinflammatory cytokines and the expression of costimulatory molecules by in vitro-derived DCs

So far, our results indicated that the positive effects of ZK191784 could be mediated by an influence of the compound on antigen-presenting DCs. It has previously

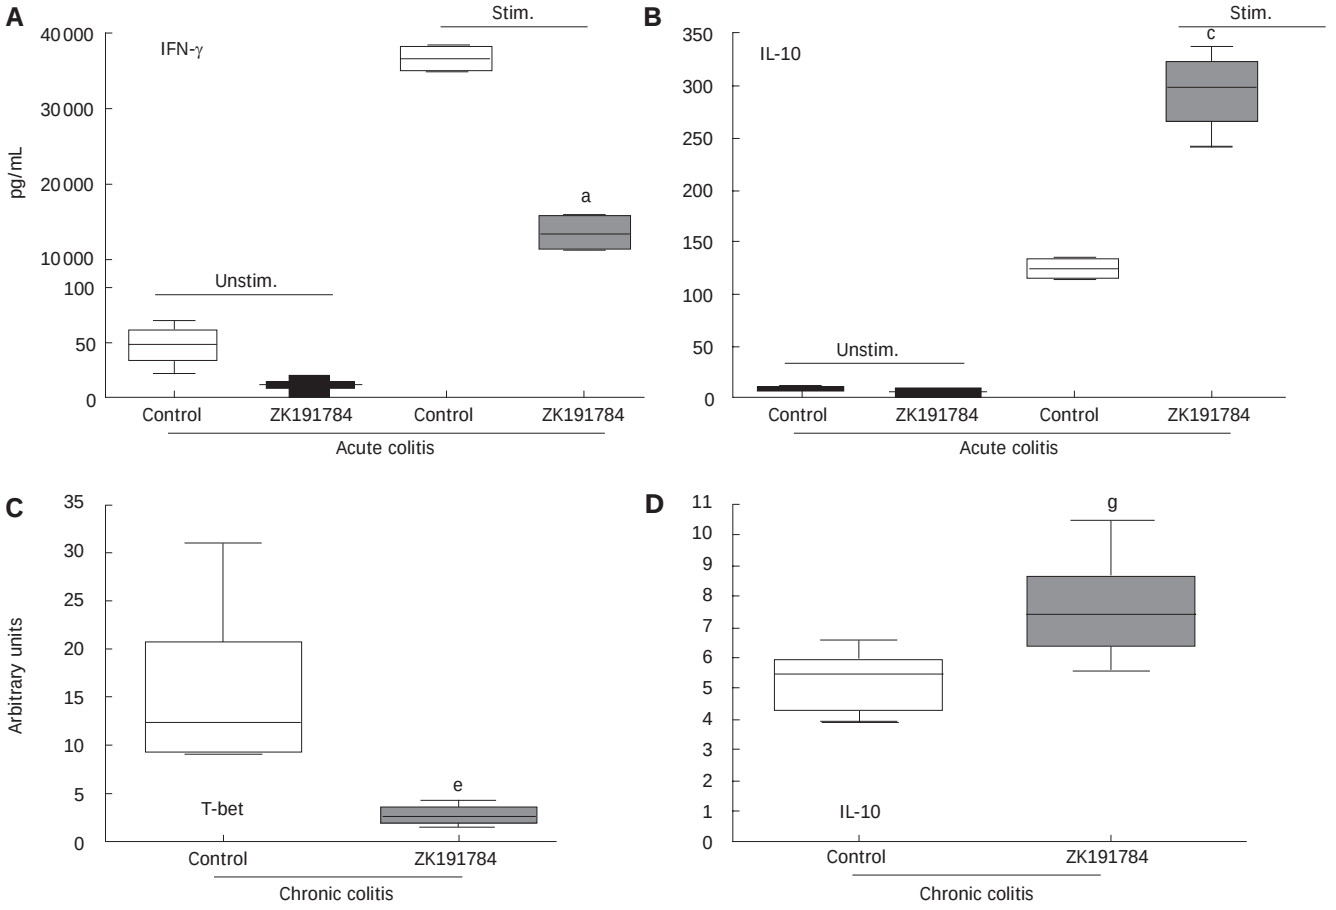

Figure 2 Effects of ZK191784 treatment on cytokine production in acute and chronic colitis. (**A** and **B**) $^{a}P < 0.05$, $^{c}P < 0.05$, $n = 5$ animals. Data presented are representative of three independent experiments. (**C** and **D**) $n = 8$ or 9 animals per group. Data presented show one of two independent experiments. $^{e}P < 0.05$, $^{g}P < 0.05$. Data are displayed as box plots, in which the box contains the middle half of the scores in the distribution, the median is shown as a line across the box, and the largest value below the upper hinge and the smallest value above the lower inner fence indicate the distribution.

been shown that calcitriol inhibits IL-12 production by human monocytes[31]. To determine whether this capacity was shared by ZK191784, the calcitriol analog was tested for its ability to inhibit the secretion of proinflammatory cytokines by BM-DCs that were stimulated with LPS overnight in the presence of different concentrations of ZK191784.

The secretion of IL-10 was not influenced by the presence of the compound (data not shown). However, ZK191784 was able to significantly inhibit the production of the proinflammatory cytokines IFN-γ and IL-12 by 60% and 40%, respectively, in a dose-dependent manner, after stimulation of cells with LPS (Figure 4A and B; IFN-γ, $P = 0.0227$; IL-12, $P = 0.0069$). Additionally, FACS analysis revealed reduced expression of costimulatory molecules (CD40, CD80 and CD86) after stimulation on the surface BM-DCs exposed to ZK191784 (Figure 4C). Therefore, the presence of the calcitriol analog within cell cultures seems to inhibit the activation of *in vitro*-derived BM-DCs.

ZK191784 inhibits the production of proinflammatory cytokines by primary DCs

To further evaluate the effects of ZK191784 on DC *in vivo*, mice were treated with the calcitriol analog or vehicle, and primary CD11c^{+} DCs were isolated from the spleen and MLNs. FACS analysis revealed no difference in

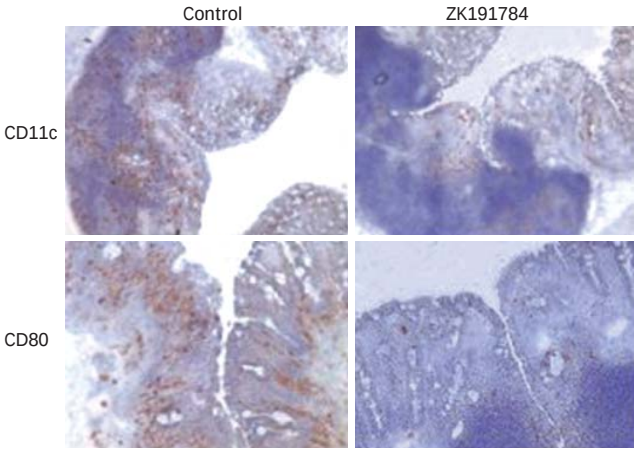

Figure 3 Effects of ZK191784 treatment on the distribution of CD11c^{+} DCs in the colonic mucosa. Sections were stained for CD11c or the costimulatory molecule CD80 (× 100). Staining with isotype controls revealed no background staining (data not shown). Representative sections from one of three mice per group are shown.

the expression of costimulatory molecules in DCs from different treatment groups. However, after stimulation with CpG *in vitro*, primary splenic and mesenteric DCs isolated from mice treated with ZK191784 secreted significantly lower levels of proinflammatory cytokines than those derived from control mice (Figure 5A and B). TNF-α secretion from splenic DCs from ZK191784-

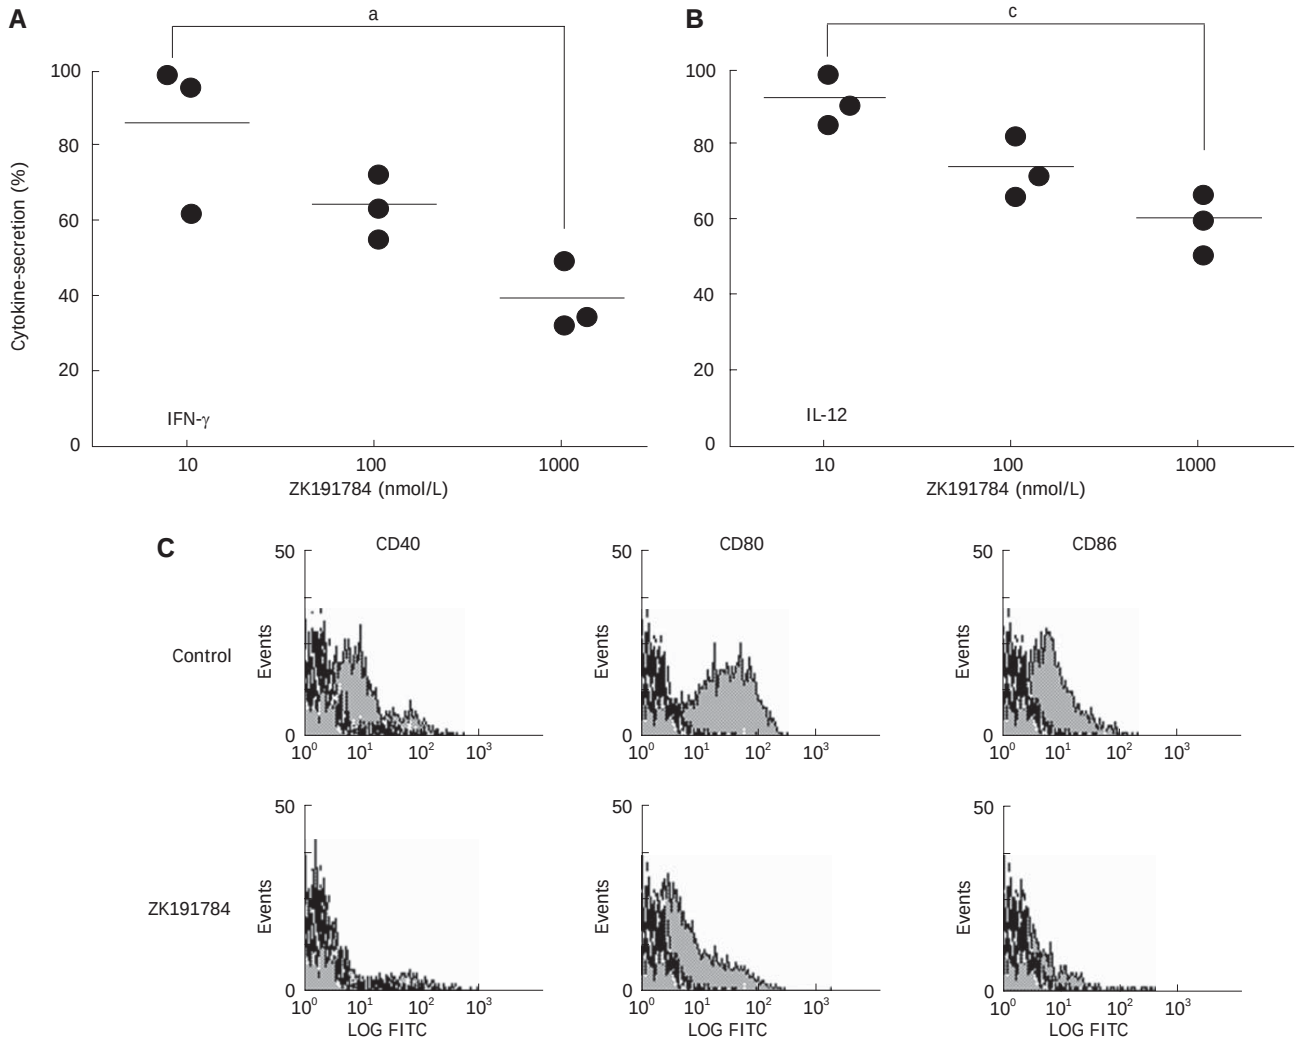

Figure 4 Effects of ZK191784 treatment on the secretion of cytokines and expression of costimulatory molecules by BM-DCs. DCs were generated from bone marrow of mice and stimulated with LPS (1 μg/mL) overnight in the presence of different concentrations of ZK191784 (10, 100 or 1000 nmol/L). Concentrations of the proinflammatory cytokines IFN-γ (**A**) and IL-12 (**B**) were measured within the supernatants by ELISA. $^{a}P < 0.05$, $^{c}P < 0.05$, data presented are representative of three independent experiments. BM-DCs were cultured in the presence of ZK191784 (1000 nmol/L) or vehicle, and were stimulated overnight with LPS. $CD11c^{+}$ DCs were stained with FITC-conjugated mAbs for expression of the costimulatory molecules CD40, CD80 and CD86. Isotype controls are shown with dark lines, and positive staining is shown in grey (**C**).

treated animals was reduced to 74% ($P = 0.0364$) and IL-12 production was decreased to 62%, as compared to control DCs ($P = 0.0136$). The effect was even more dramatic when secretion of proinflammatory cytokines from mucosal MLN DCs was evaluated. We were able to show that TNF-α and IL-12 levels from ZK191784-treated mice were reduced to 9.0% ($P = 0.0005$) and 4.4% ($P < 0.0001$), respectively, compared to cells from control animals. The results suggest that the *in vivo* effects of the calcitriol analog ZK191784 are more dramatic at mucosal sites of the intestine than in systemic lymphatic tissue.

DISCUSSION

In our study we extended previous data about the importance of calcitriol in colitis as we demonstrated that administration of ZK191784, a less calcemic analog of calcitriol, ameliorated not only acute but also chronic DSS-induced colitis. In contrast to previous studies, in which the influence of vitamin D deficiency was investigated in IL-10 knockout mice, our results were not obtained in cytokine-deficient animals, but in normal Balb/c mice. Additionally, our data suggested that the effects of the compound were at least partly due to its influence on DCs in the intestinal mucosa, as systemic administration of ZK191784 inhibited the activation of DCs within the spleen, MLNs and intestinal lamina propria by down-modulation of proinflammatory cytokines and inhibition of costimulatory molecule expression on the surface of DCs.

Calcitriol is known to act directly on T cells because vitamin D3 inhibits the proinflammatory transcription factor nuclear factor (NF)κB, and subsequently impairs the expression of proinflammatory cytokines TNF-α and IFN-γ[20]. TNF-α is known to be an important mediator of inflammation in IBD patients[32], and several TNF-α-blockers are effective in IBD[33]. Therefore, any treatment that targets the TNF-α pathway and Th1-associated cytokines is likely to be a possible treatment for intestinal inflammation. Indeed, stimulated splenic and mesenterial DCs produced lower amounts of TNF-α when mice were treated with the calcitriol analog, and secretion of the

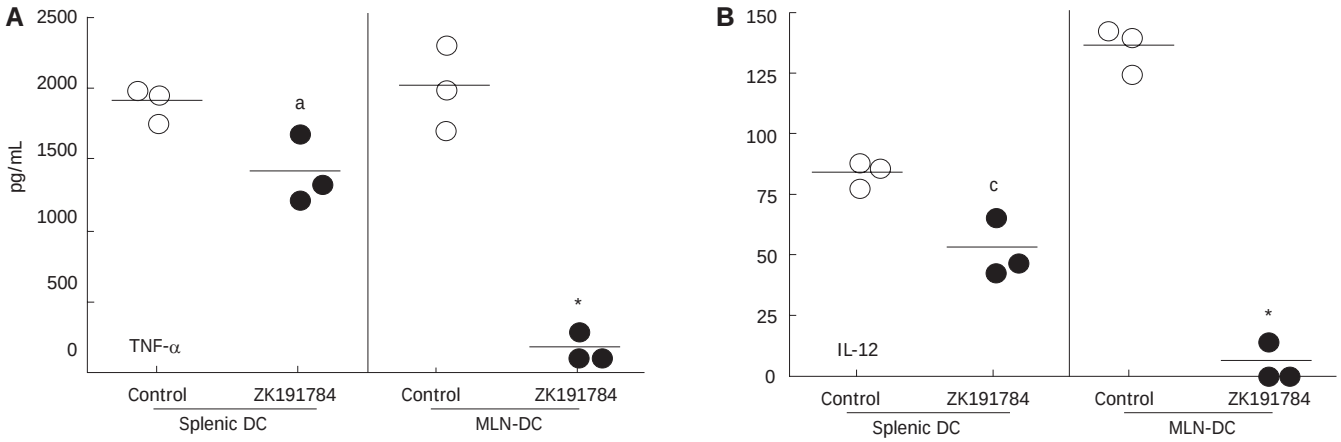

Figure 5 Effects of ZK191784 treatment on the secretion of cytokines by primary DCs derived from spleen and MLNs. $CD11c^+$ DCs were isolated from the spleen and MLNs of animals pretreated with ZK191784 or vehicle. Cells were stimulated overnight with CpG. Triplicate cultures were analyzed for each condition. Concentrations of the proinflammatory cytokines TNF-α (**A**) and IL-12 (**B**) were measured within supernatants by ELISA. $^aP < 0.05$, $^cP < 0.05$, data presented are representative of three independent experiments.

proinflammatory cytokines IFN-γ and IL-6 by MLN cells was dramatically reduced after ZK191784 administration. On the other hand, protein levels of the anti-inflammatory cytokine IL-10 increased in acute colitis and mRNA levels of these cytokines were also enhanced in the chronic colitis model after application of ZK191784.

In vitro experiments have demonstrated that calcitriol renders DCs in a perpetual state of immaturity, as it down-regulates the expression of MHC class Ⅱ and costimulatory molecules[34,35] and decreases the capacity of myeloid human DCs to induce Th1-cell development[36]. Also, it inhibits IL-12 production by both macrophages and DCs *via* inhibition of NFκB activation and transcriptional repression of the IL-12p40 gene[31,36]. The proinflammatory cytokine IL-12 is involved in the pathogenesis of colitis[37], as administration of anti-IL-12 substantially reduces the severity of intestinal inflammation, and mice treated with IL-12 during the application of DSS develop a more severe acute colitis as compared to controls[38]. Therefore, inhibition of IL-12 secretion by antigen-presenting cells can also be an important way to ameliorate disease.

However, so far, it is unclear whether mucosal DCs are also targets for the immunomodulatory activity of calcitriol. Our results demonstrate that infiltrating activated $CD11c^+$ DCs into the intestinal lamina propria were dramatically reduced in number after systemic administration of ZK191784. Additionally, the reduced expression of costimulatory molecules by DCs, accompanied by the inhibition of proinflammatory cytokine secretion, may contribute substantially to decrease DC-dependent T-cell activation within the intestinal mucosa and could largely account for the immunosuppressive properties of this compound on acute and chronic colitis development in our model.

Interestingly, recent data have suggested that *in vivo* macrophages, DCs and epithelial cells are a potential source of calcitriol[39,40]. Therefore, local calcitriol production may keep antigen-presenting cells in an immature state in the healthy intestinal mucosa, and support the suppression of mucosal Th1 cytokine secretion and T-cell proliferation. This mechanism would help to establish tolerance by inhibition of unnecessary inflammatory responses. It is possible that vitamin D deficiency, either due to malnutrition or malabsorption in patients with IBD, is an additional piece of the puzzle that helps to disturb the normal immunoregulation in the gut. Our data support this hypothesis, as administration of the calcitriol analog was able to ameliorate symptoms of DSS colitis by inhibition of activation of mucosal DCs, as demonstrated by lack of expression of costimulatory molecules that would otherwise drive the inflammatory process.

Another recent study suggests an essential function for DCs in programming lymphocyte homing and microenvironmental positioning[41]. The authors were able to demonstrate that calcitriol that was processed by antigen-presenting DCs upregulated the expression of the chemokine receptor CCR10 on the surface of responding T cells, and enabled them to migrate to the skin. On the other hand, the expression of the gut homing adhesion molecule α4β7 and the intestinal chemokine receptor CCR9 on the T-cell surface was suppressed. Therefore, it is possible that, in addition to changes in the phenotype and number of intestinal DCs, ZK191784 can act *via* DCs on T cells within the gut by up-regulation of skin homing chemokine receptors and down-modulation of gut homing molecules. This may reduce the number of infiltrating T cells within the gut during colitis and ameliorate severity of intestinal inflammation. Further studies are under way to investigate the expression of chemokine receptors on T cells in response to the calcitriol analog ZK191784.

The data presented by us and others point to a crucial role of calcitriol-regulated processes in IBD. As no interference by vitamin D compounds with the ability of animals to act defensively against opportunistic infections has so far been shown[17], calcitriol may be an attractive treatment strategy compared to other immunosuppressive reagents used in IBD patients. However, so far, development of hypercalcemia limits calcitriol administration. The new calcitriol analog ZK191784 that was used in our study has previously been shown to have reduced calcemic activity and

therefore, a more favorable therapeutic profile than calcitriol.

In conclusion, we believe that we showed for the first time that ZK191784, a low-calcemic calcitriol analog, significantly ameliorated acute and chronic DSS-induced colitis, most likely due to inhibition of DC activation that prevented development of proinflammatory pathogenic T cells. This less hypercalcemic calcitriol analog is therefore an attractive immunomodulatory agent with few side effects, which, either alone or in combination with other drugs, may have therapeutic applications in the treatment of IBD.

COMMENTS

Background

Chronic IBD in patients still has unknown etiology. However, it is thought that a dysregulated response of antigen-presenting DCs towards bacterial and food antigens within the gut plays a role within the disease process. Currently, treatment of disease consists of immunosuppressive drugs such as steroids and azathioprine, which have significant side effects. We investigated the effects of a calcitriol analog with few side effects for the treatment of murine colitis. Additionally, we were able to show that the calcitriol analog influenced the phenotype and number of DCs within the gut.

Research frontiers

Besides genetic factors that are thought to predispose individuals to develop IBD, the environment seems to contribute to the disease. There are reasons to believe that vitamin D may be an environmental factor that affects colitis, since vitamin D deficiency has been linked to IBD, even when the disease is in remission. Additionally, vitamin D deficiency has been shown to accelerate the development of colitis symptoms among mice that develop spontaneous enterocolitis. It has been shown that calcitriol selectively regulates the immune response without compromising the host's ability to fight infection, which makes it an attractive therapeutic option compared to standard immunosuppressive medication in patients with chronic colitis. However, calcitriol has clear dose-limiting hypercalcemic effects that interfere with its systemic clinical use, due to a strong influence on calcium homeostasis and the risk of associated side effects.

Innovations and breakthroughs

We were able to show that treatment with ZK191784, a low-calcemic calcitriol analog, resulted in significant amelioration of murine colitis in acute and chronic intestinal inflammation. The down-regulation of colonic inflammation was associated with a dramatic reduction in the secretion of proinflammatory cytokines and a significant increase in anti-inflammatory mediators by cells within local lymph nodes. Additionally, lower numbers of infiltrating activated DCs were found in the colon in mice that were treated with the calcitriol analog, and the secretion of proinflammatory cytokines by mucosal DCs was inhibited in the presence of the calcitriol analog.

Applications

We were able to show, as far as we are aware, for the first time that a low-calcemic calcitriol analog significantly ameliorated acute and chronic murine colitis. Inhibition of DC activation prevented development of proinflammatory pathogenic T cells. This calcitriol analog is therefore an attractive immunomodulatory agent with few side effects, which, either alone or in combination with other drugs, may have therapeutic applications in the treatment of IBD.

Terminology

IBD: Inflammatory bowel disease, chronic recurrent colitis in patients with an autoimmune background. DCs: Dendritic cells, cells that capture foreign antigens and present them to lymphocytes, therefore inducing an immune reaction.

Peer review

This paper by Strauch *et al* investigated the properties of ZK191784, a derivative analog of calcitriol (activated form of vitamin D3), with potentially fewer side effects and similar inhibition of T-cell function, to regulate colitis in an experimental mouse model. The results suggest that treatment with this inhibitor decreased the severity of acute and chronic colitis in this model.

Abstract

AIM: To investigate the chemopreventive efficacy of the Indian medicinal plant *Acanthus ilicifolius* L Acanthaceae in a transplantable Ehrlich ascites carcinoma (EAC)-bearing murine model.

METHODS: Male Swiss albino mice were divided into four groups: Group A was the untreated normal control; Group B was the EAC control mice group that received serial, intraperitoneal (ip) inoculations of rapidly proliferating 2 x 10^5 viable EAC cells in 0.2 mL of sterile phosphate buffered saline; Group C was the plant extract-treated group that received the aqueous leaf extract (ALE) of the plant at a dose of 2.5 mg/kg body weight by single ip injections, once daily for 10, 20 and 30 consecutive days following tumour inoculation (ALE control); and Group D was the EAC + ALE-treatment group. The chemopreventive potential of the ALE was evaluated in a murine model by studying various biological parameters and genotoxic markers, such as tumour cell count, mean survival of the animals, haematological indices, hepatocellular histology, immunohistochemical expression of liver metallothionein (MT) protein, sister-chromatid exchanges (SCEs), and DNA alterations.

RESULTS: Treatment of the EAC-bearing mice with the ALE significantly ($P < 0.001$) reduced viable tumour cell count by 68.34% (228.7 x 10^6 ± 0.53) when compared to EAC control mice (72.4 x 10^6 ± 0.49), and restored body and organ weights almost to the normal values. ALE administration also increased ($P < 0.001$) mean survival of the hosts from 35 ± 3.46 d in EAC control mice to 83 ± 2.69 d in EAC + ALE-treated mice. Haematological indices also showed marked improvement with administration of ALE in EAC-bearing animals. There was a significant increase in RBC count ($P < 0.001$), hemoglobin percent ($P < 0.001$), and haematocrit value ($P < 0.001$) from 4.3 ± 0.12, 6.4 ± 0.93, and 17.63 ± 0.72 respectively in EAC control mice to 7.1 ± 0.13, 12.1 ± 0.77, and 30.23 ± 0.57 respectively in EAC + ALE-treated group, along with concurrent decrement ($P < 0.001$) in WBC count from 18.8 ± 0.54 in EAC control to 8.4 ± 0.71 in EAC + ALE. Furthermore, treatment with ALE substantially improved hepatocellular architecture and no noticeable neoplastic lesions or foci of cellular alteration were observed. Daily administration of the ALE was found to limit liver MT expression, an important marker of cell proliferation with concomitant reduction in MT immunoreactivity (62.25 ± 2.58 *vs* 86.24 ± 5.69, $P < 0.01$). ALE was also potentially effective in reducing ($P < 0.001$) the frequency of SCEs from 14.94 ± 2.14 in EAC control to 5.12 ± 1.16 in EAC + ALE-treated group. Finally, in comparison to the EAC control, ALE was able to suppress *in vivo* DNA damage by abating the generations of 'tailed' DNA by 53.59% (98.65 ± 2.31 *vs* 45.06 ± 1.14, $P < 0.001$), and DNA single-strand breaks (SSBs) by 38.53% (3.14 ± 0.31 *vs* 1.93 ± 0.23, $P < 0.01$) in EAC-bearing murine liver.

CONCLUSION: Our data indicate that, ALE is beneficial in restoring haematological and hepatic histological profiles and in lengthening the survival of the animals against the proliferation of ascites tumour *in vivo*. Finally, the chemopreventive efficacy of the ALE is manifested in limiting MT expression and in preventing DNA alterations in murine liver. The promising results of this study suggest further investigation into the chemopreventive mechanisms of the medicinal plant *A. ilicifolius in vivo* and *in vitro*.

INTRODUCTION

Acanthus ilicifolius Linn., popularly known as "Harkach Kanta" belongs to the family Acanthaceae, has typical spinose margins on its evergreen leaves and stipular spines at stem nodes. The common name of the plant is Holy Leaved Acanthus. It is a gregarious, sparingly branched, evergreen shrub, 0.6-1.5 meters in height, common in the tidal swamps of creeks and rivers along the east and west coasts. The leaves are oblong or elliptic, pinnately toothed, acute or truncate and glabrous; its flowers are blue, sessile in opposite pairs and are in terminal crowded or interrupted spikes; the capsules are oblong, 2.5 cm long and are brown; the seeds are broad-ovate, compressed and are 0.6 cm in diameter. It is a plant of marshy habitat distributed widely throughout the mangroves of India including west coasts, Meghalaya and the Andamans and different parts of the Asian countries like Singhal, Burma, China, Thailand *etc*. The plant grows luxuriously by the side of the Ganges in Sunderbans, Hoogly, Howrah and 24 Parganas in West Bengal. The shrub is also planted as a sand-binder along the banks of tidal rivers and lakes. It is a folklore medicinal plant used mainly against rheumatism, paralysis, asthma and snake-bites. A decoction of the plant with sugar candy and cumin is used in dyspepsia with acid eructations. It is also considered to be a diuretic, and is used as a cure for dropsy and bilious swellings. In Goa, the leaves are employed as an emollient fomentation in rheumatism and neuralgia[1]. The leaves are bruised and soaked in water for external application and are also used as an expectorant. The analgesic, anti-inflammatory[2], and leishmanicidal[3] properties of *A ilicifolius* have been documented, whilst Babu *et al* have reported the antioxidant and hepatoprotective properties of the plant[4].

The propensity of cancer cells to show multiple genetic mutations underscores the concept that the carcinogenic process progresses by the accumulation of discrete genetic alterations. Evidence suggests that genomic instability may provide the driving force behind the genetic plasticity characteristic of cancer cells resulting in DNA damage, gene mutation, sister-chromatid exchanges (SCEs)[5], chromosomal aberrations (CAs), and cellular transformation[6,7]. Since SCEs data alone do not necessarily provide either a quantitative or a qualitative estimate of gross structural chromosomal damage, the SCEs assay should be regarded as a complement to rather than a substitute for CAs analysis. Earlier methods for detecting DNA unwinding in alkali have required physical separation of single- from double-stranded DNA using a hydroxyapatite column[8], specific nuclease digestion and precipitation or filter binding[9]. Moreover, radio-labeling of cells was required for detection of the small amounts of DNA involved. In cells where radio-labeling was not feasible, sensitive fluorimetric methods were substituted to permit detection and quantitation of DNA after column or filter separation. We have used a sensitive technique of Fluorimetric Analysis of DNA Unwinding (FADU) according to our established protocol[10] for the estimation of single-strand breaks (SSBs) *in vivo*. Besides FADU, single cell gel electrophoresis (SCGE) or the Comet assay, in particular the alkaline version of the assay, has also become a popular method for sensitive analysis, detection, and quantitation of DNA damage. Damage is detected as DNA strand-breaks, alkali-labile damage, and excision repair sites in individual interphase cells[11].

Our team workers visited the Sunderban area and gathered some information from the local people who used the plant as drugs for the regression of tumour growth with satisfactory results. Since the plant is easily available and information on the effect of this medicinal plant in a tumour-bearing animal model is not yet explored, it has encouraged us to proceed with the following objectives: firstly, to monitor the effect of its aqueous leaf extract (ALE) on mean survival time, liver histology, metallothionein (MT) expression, and haematological status, since the latter plays an important role in immunological and pathophysiological states of the animal; and secondly, to examine the antigenotoxic effects of the ALE in preventing hepatic DNA damage and SCEs and thereby chemoprotection of cells, particularly those undergoing drastic multiplication when transplanted as ascites cells within the peritoneal cavity of the host.

MATERIALS AND METHODS

Animals

Closed colony inbred male Swiss albino mice, 6-7 wk of age and weighing 20-22 g, obtained from the Indian Institute of Chemical Biology (IICB, CSIR, Govt. of India) Kolkata, India, were used throughout the study. The animals were supplied with standard mouse pellet diet (Hindustan-Lever, Mumbai, India) and water *ad libitum*. The recommendations of Jadavpur University "Institutional Animal Ethics Committee" ["Committee for the Purpose of Control and Supervision of Experiment on Animals" (CPCSEA Regn. No. 0367/01/C/CPCSEA) India] for the care and use of laboratory animals were strictly followed throughout the study and the recommendations were in accordance with the National Institute of Health (NIH) guidelines.

Materials

All the chemicals were purchased from Sigma Chemicals Co. (St. Louis, MO) unless otherwise mentioned.

Plant material

Air-dried over-ground parts of the plant *A ilicifolius* were supplied by the United Chemicals and Allied Products

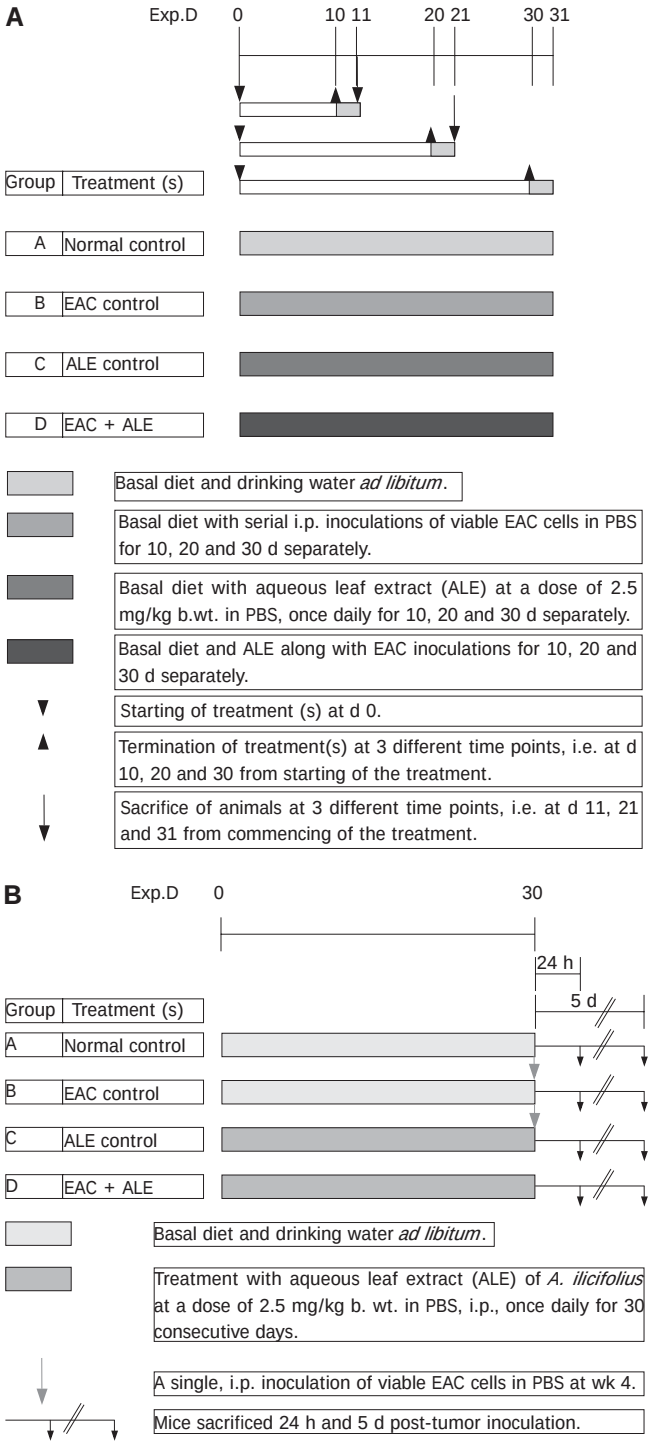

Figure 1 A: Basic experimental protocol for haematology and histology; **B:** Basic experimental protocol for DNA single-strand breaks assay.

(Calcutta, India). Dr. Alpana Bhattacharya, Department of Botany, Bethune College, Calcutta identified and authenticated the plant and a voucher specimen number [B.N.Chatterjee, 100A, 100B (CAL)] was deposited in the Central National Herbarium, Calcutta, India.

Preparation of the aqueous leaf extract (ALE) of the plant

50 g of air-dried powdered leaves of *A ilicifolius* were percolated with distilled water at room temperature until exhausted and filtered, and the filtrate was lyophilized and air-dried (quantity 5.3 g).

Tumour cell inoculation

EAC cells were maintained serially in ascites fluid in the peritoneal cavity of 7-wk-old Swiss albino mice. Viable cells were counted in a haemocytometer by the trypan blue dye exclusion method. An aliquot of 2×10^5 viable cells suspended in 0.2 mL of sterile phosphate buffered saline (PBS, pH 7.4, 0.2 mmol/L) was aseptically inoculated intraperitoneally (ip) into each mouse. The tumour growth was observed within 4-6 d following transplantation.

Experimental Long-term regimen

Mice were randomly divided into four different groups containing 10 mice in each group. Figure 1A shows the basic experimental regimen for haematology and immunohistology. Group A animals belonged to the normal (untreated) vehicle control that received a single, ip injection of 0.2 mL of PBS (pH 7.4) daily for 10, 20 and 30 consecutive days. Group B animals were the EAC-bearing mice (tumour-control group) that received serial ip inoculations of viable tumour cells in PBS. Group C animals were the ALE control group that received daily freshly prepared ALE of *A ilicifolius* in 0.2 mmol/L of PBS by ip administration at a dose of 2.5 mg/kg body weight for 10, 20 and 30 consecutive days of each phase of the study; while group D animals were the treatment group that had been transplanted with viable EAC cells followed by (24 h later) ip administration of the ALE at the same dose-regimen as in group C. The body weight of the animals was monitored after every five days. All the animals were fasted overnight and were sacrificed at three different time intervals separately, i.e. at 11, 21 and 31 d of tumour inoculation to carry out various experiments.

The second set of animals (all the above four groups, A-D) with 20 mice/group was maintained with the same treatment schedule throughout without any prior sacrifice for carrying out survival study.

Short-term regimen

The third set of animals (groups A-D) with 10 mice/group was maintained for SCEs and DNA-chain break studies. In this regimen, the animals were divided into the following treatment schedule (Figure 1B): Group A = Untreated control; Group B = EAC control group that received a single ip EAC inoculation 30 d post-ALE treatment; Group C = ALE control that received the plant extract for 30 d continuously at the same dose-regimen mentioned earlier; Group D = EAC + ALE - treatment group.

Determination of tumour cell count and haematological indices

Tumour cell count in ascites fluid was recorded by the trypan blue dye exclusion method from EAC-bearing mice at a regular interval of 5 d. The total RBC, WBC and haematocrit (Htc) estimations from EDTA - treated blood samples were carried out on d 0, 5, 10 and 15 after tumour transplantation by an improved Neubauer haemocytometer.

Histopathology of liver tissue

Liver slices were taken from each lobe of the liver. After proper fixation and dehydration with graded ethanol

solutions, sections of 5 μm in thickness were stained with haematoxylin and eosin (HE)[12]. The histopathological slides were observed under an ADCON-5591 (ADCON, Cleveland) photomicroscope.

Immunostaining of MT

Immunohistochemical detection of MT in cold acetone-fixed, paraffin-embedded liver sections was performed by the streptavidin-avidin-biotin-peroxidase-complex method[13]. After proper blocking with 1% H_2O_2 and normal goat serum separately, tissue sections were incubated overnight at 4℃ with the primary antibody rabbit anti-rat MT-1 (polyclonal) using a 1:50 dilution. Sections were then incubated with a biotinylated secondary antibody goat anti-rabbit IgG (Sigma) at 37℃ with 1:200 dilution. This was followed by incubation with streptavidin peroxidase (1:100) for 1 h and subsequent chromagen development with 0.5% 3, 3'-diaminobenzidine tetrahydrochloride (DAB) and 0.33% H_2O_2 in 0.5 mol/L Tris-NaCl as the substrate. The sections were then counterstained with Harris haematoxylin, dehydrated and mounted and served as positive control. Negative controls were prepared following all the above-mentioned steps omitting the primary antibody. MT immunostaining was considered positive when the nuclei and cytoplasm of the hepatocytes stained prominently purplish brown/reddish brown. MT immunoreactivity was expressed as percentage of immunopositive cells. A total of 10 high power fields were randomly chosen. The number of + ve cells was determined in relation to the total number of cells in that field[13].

SCE analysis

Mice were lightly ether anaesthetized and a vertical incision was made in the lower lateral abdominal region. The subcutaneous tissue was parted with forceps and 5-bromo-2'-deoxyuridine (BrdU) powder (1 mg/kg body wt.) was implanted by the method of Allen *et al*[14]. Approximately 24 h following BrdU implantation, and 1 h after ip injection of 0.04% colchicine at a rate of 1 mL/100 g body wt in 0.9% sodium chloride, mice were sacrificed and liver tissue was processed for chromosome preparation following the procedure of Horiuchi *et al*[15]. Staining for the detection of SCEs was accomplished by a modified fluorescence plus Giemsa (FPG) technique[16].

Scoring of SCEs

In order to determine the SCE levels, approximately 500 well-spread and differentially stained metaphase plates for second division mitosis were scanned from each treatment group, comprising of 10 animals. Each point of exchange was determined as SCE, including clear at the centromere. The SCE analysis was performed at five sequential time points.

Estimation of in vivo DNA damage by the Comet assay

Hepatic DNA damage was measured using the alkaline Comet assay, essentially as described by Olive *et al*[11]. The tissues were homogenized in phosphate-buffered saline (PBS; pH 8.0) under refrigeration and filtered. Cell viability was determined by the Trypan blue method. 4 μL of the homogenized tissue was then transferred to 50 μL of fresh PBS (pH 7.5), washed, suspended in 150 μL of 1% low melting point agarose at 37℃, and pipetted onto an agarose-precoated glass microscope slide. Slides were prepared in triplicate. The slides were immersed for 60 min in freshly-prepared, ice-cold lysis solution (2.5 mol/L NaCl, 0.1 mol/L Na_2EDTA, 10 mmol/L Tris-HCl (pH 10), 10% DMSO and 1% Triton X-100) at 4℃ in the dark, washed, and then subjected to horizontal electrophoresis using freshly made buffer (0.3 mol/L NaOH and 1 mmol/L Na_2EDTA, pH > 13). After electrophoresis, the slides were stained with 5 μg/mL ethidium bromide and viewed under a Zeiss fluorescence microscope equipped with a green excitation filter and a 590 nm barrier filter. Routinely, 150 cells (50 cells/slide) were screened per liver sample from each animal. Nucleoid DNA extends under electrophoresis to form 'comet tails', and the length of the comets was evaluated for determination of the percentage of tailed DNA. This value is linearly related to the frequency of DNA breaks[11].

Assay of DNA unwinding

The principle of fluorimetric analysis of DNA unwinding (FADU) is that the fluorescent dye ethidium bromide (EtBr) binds selectively to double-stranded DNA (DS-DNA) in the presence of single-stranded DNA (SS-DNA) when short duplex regions in SS-DNA molecules are destabilized by alkali treatment[17].

Shearing of DNA, alkali treatment and neutralization

Whole liver genomic DNA was isolated from the frozen murine liver by a modification of the published criteria[18] with enzymatic RNA digestion before proteinase K treatment. After isolation, the purity of DNA solution was checked spectrophotometrically by determining the ratios of absorbance at A_{260}/A_{280} and A_{260}/A_{230}. DNA was sheared by passing the DNA solution (20-25 times) through a 24-gauge needle using a hypodermic syringe. The optical density (OD) of the DNA sample was adjusted to 2.0 at 260 nm. For alkali denaturation, 2.0 mL of DNA solution in Tris-EDTA buffer (20 mmol/L Tris, 1 mmol/L M EDTA, pH 8.0) was mixed with an appropriate aliquot (about 2.4 mL) of alkali solution (0.1 mol/L NaOH, 0.001 mol/L M EDTA), so that the pH of the mixture becomes 12.8. After about 10 min (determined by trial experiments), the pH of the mixture was brought down to about 9.0 by addition of an approximate aliquot (about 1.3 mL) of an acid solution (0.025 mol/L Tris, 0.225 mol/L HCl).

FADU

DNA solutions from control and experimental groups were distributed into 12 test tubes[10]; in each time period (experiments were repeated four times) each tube contained 2.0 mL of the DNA solution of OD equal to 2.0 at 260 nm. The tubes were designated as T, P or B in each group. The DNA solution in tube B was sheared initially as described above. To the P and T tubes, alkali solutions were first added, mixed and then the tubes were incubated at 15℃ for 10 min. Denaturation was stopped by chilling the solutions at 0℃ and addition of acid solution, as described before.

Table 1 Body weight of different groups of mice

Days following tumour transplantation	Body weight (g)			
	Normal control	EAC control	ALE control	EAC + ALE
0	15.6 ± 0.33	15.7 ± 0.46	15.5 ± 0.28	15.6 ± 0.38
10	16.9 ± 0.36	18.4 ± 0.58[a]	17.2 ± 0.41	17.7 ± 0.29
20	18.3 ± 0.26	21.5 ± 0.51[b]	18.5 ± 0.29	19.8 ± 0.35[c]
30	20.6 ± 0.39	25.4 ± 0.66[b]	21.1 ± 0.35	21.7 ± 0.49[d]

Abbreviations: ALE: Aqueous leaf extract of *A ilicifolius*; EAC: Ehrlich ascites carcinoma. Values represent mean ± SE (n = 10). [a]$P < 0.05$, [b]$P < 0.001$ *vs* Normal control; [c]$P < 0.02$, and [d]$P < 0.001$ *vs* EAC control.

Table 2 Final weight of liver and kidney of different groups of animals sacrificed 30 d post-EAC inoculation

Organ (s)	Final weight (g)			
	Normal control	EAC control	ALE control	EAC + ALE
Liver	1.25 ± 0.04	1.13 ± 0.06	1.26 ± 0.08	1.23 ± 0.03
Kidney	0.38 ± 0.03	0.33 ± 0.05	0.38 ± 0.05	0.37 ± 0.04

Abbreviations: ALE: Aqueous leaf extract of *A. ilicifolius*; EAC: Ehrlich ascites carcinoma. Values represent mean ± SE (n = 10). No significant differences between Normal control and EAC control and between EAC control and EAC + ALE.

The T tube differs from P tube in that the alkali and acid solutions, i.e., denaturing and neutralizing solutions were mixed together before addition of DNA solution. An aliquot (0.2 μL) of EtBr solution was added to each tube and the fluorescence was read in a spectrofluorimeter (LS-45, Perkin Elmer, USA) with excitation and emission wavelengths at 525 and 591 nm, respectively. The extent of DNA unwinding after a given time of exposure to alkali is calculated from the fluorescence of T, P and B samples. The fluorescence of the sample less than the fluorescence of the blank (P-B) provide an estimate of the amount of DS-DNA remaining. Percent D is given by the equation: Percent D (DS-DNA %) = (P-B)/(T-B) × 100.

Estimation of SSBs

It is assumed that the distribution of single-strand breaks in the DNA population follows a simple Poisson's Law. Under this circumstance, it is possible to make an approximate estimate of the average number of single-strand breaks (n) per DNA fragment from the simple equation given by Basak[19]: $e^{-n} = D/S + D$; S = percentage DNA that remains single-stranded after alkali treatment; D = percentage remaining as DS-DNA. D/S+D represents the fraction (fo) of the molecules without strand-breaks. The values of 'n' corresponding to different DNA solutions isolated from different groups were then estimated.

Statistical analysis

The data were analyzed using the GraphPad Prism Software package, Version 4.01 (Barcode Softwares, Baltimore, MD). The results were expressed as the mean + SE and Student's t-test was performed to compare sample means. Statistical significance was set at $P < 0.05$ for all comparisons. Percent inhibition was obtained by using the formula [(mean control - mean treatment)/mean control] × 100.

Table 3 Effect of ALE on tumour cell count in Ehrlich ascites carcinoma-bearing mice

Days following tumour transplantation	Mean tumour cell count		Decrease (%)
	EAC control	EAC + ALE	
10	$18.2 \times 10^6 \pm 0.44$	$11.3 \times 10^6 \pm 0.35$[b]	37.91
20	$52.1 \times 10^6 \pm 0.76$	$24.9 \times 10^6 \pm 0.41$[b]	52.20
30	$228.7 \times 10^6 \pm 0.53$	$72.4 \times 10^6 \pm 0.49$[b]	68.34

Abbreviations: ALE: Aqueous leaf extract of *A ilicifolius*; EAC: Ehrlich ascites carcinoma. Values represent mean ± SE (n = 10). [b]$P < 0.001$ *vs* EAC control.

RESULTS

General observations

During the entire period of study, no differences in food and water consumptions were observed among the various groups of animals. Administration of the ALE at a dose of 2.5 mg/kg body weight to the group C animals indicates that the dose was well tolerated with adequate growth responsive effect, otherwise growth retardation or premature death would have occurred. Further, with this particular dose of ALE, there were no toxicologically significant changes in hematology, liver histology, clinical chemistry and clinical enzymology (data not shown), body and relative organ weights *etc*, suggesting that the administered dose of the plant extract was apparently devoid of toxicity.

The body weight of all groups of mice is recorded in Table 1. From the table, it is evident that there was no significant difference in the body weights of the normal control (Group A) and ALE control (Group C) mice suggesting that the plant extract does not have any adverse effect on the growth responses of the host. It can be seen that the body weights of all the four groups (Groups A-D) of animals were more or less the same and did not show any significant differences on the day of tumour transplantation (d 0). On d 10, the body weight of the EAC control (Group B) mice increased significantly ($P < 0.05$) from the normal control (Group A) mice. The body weight continued to increase on successive days (d 20 and 30; $P < 0.01$ and $P < 0.001$ respectively) when compared to the normal control (Group A). In the treatment group (Group D), there was no significant effect of the leaf extract on the reduction of the body weight on d 10 after tumour transplantation. In the following days, there was significant reduction in the body weights ($P < 0.02$ on d 20; $P < 0.001$ on d 30) compared to the EAC control (Group B). The body weights of Group D mice almost came down to normal on d 30 after continuous treatment with the leaf extract.

From Table 2, it is evident that there was no significant difference in liver and kidney weights between the normal control (Group A) and ALE control (Group C) groups suggesting that the aqueous extract probably do not have any adverse effect on the hosts' physiology. Although, there was a slight decrease in the final liver and kidney weights of EAC-bearing mice (Group B) than that of the normal control (Group A) and on the other hand, there was a gradual increase in the organ weights in the treatment group (Group D) than that of Group B,

Table 4 Changes in total count (TC), Hb level and haematocrit in different groups of mice treated with or without ALE

Days following EAC cell inoculation	Group	TC (RBC) (10^6/mm^3)	TC (WBC) (10^6/mm^3)	Hb (g%)	Haematocrit (%)
0	Normal control	7.3 ± 0.12	5.8 ± 0.23	12.6 ± 0.16	33.43 ± 0.16
	EAC control	7.2 ± 0.15	6.5 ± 0.52	12.0 ± 0.31	32.16 ± 0.27
	ALE control	7.3 ± 0.14	5.9 ± 0.22	12.5 ± 0.16	33.58 ± 0.25
	EAC + ALE	7.3 ± 0.13	6.2 ± 0.15	12.2 ± 0.27	33.11 ± 0.23
10	Normal control	7.4 ± 0.14	5.8 ± 0.63	12.6 ± 0.65	33.51 ± 0.32
	EAC control	6.6 ± 0.76	10.4 ± 0.72[b]	10.0 ± 0.78[a]	25.74 ± 0.53[c]
	ALE control	7.6 ± 0.18	5.7 ± 0.55	12.8 ± 0.61	33.75 ± 0.35
	EAC + ALE	6.9 ± 0.53	7.7 ± 0.68[e]	11.0 ± 0.49	29.08 ± 0.69[d]
20	Normal control	7.3 ± 0.54	5.7 ± 0.43	12.4 ± 0.78	33.46 ± 0.17
	EAC control	5.1 ± 0.67[a]	13.9 ± 0.56[b]	8.2 ± 0.92[f]	21.05 ± 0.26[c]
	ALE control	7.5 ± 0.51	5.7 ± 0.38	12.6 ± 0.73	33.71 ± 0.18
	EAC + ALE	6.7 ± 0.12	7.9 ± 0.48[d]	11.5 ± 0.57[h]	28.87 ± 0.35[d]
30	Normal control	7.5 ± 0.14	5.8 ± 0.23	12.7 ± 0.84	33.49 ± 0.16
	EAC control	4.3 ± 0.12[b]	18.8 ± 0.54[b]	6.4 ± 0.93[b]	17.63 ± 0.72[c]
	ALE control	7.7 ± 0.13	5.7 ± 0.24	12.9 ± 0.76	33.65 ± 0.21
	EAC + ALE	7.1 ± 0.13[d]	8.4 ± 0.71[d]	12.1 ± 0.77[d]	30.23 ± 0.57[d]

Abbreviations: ALE: Aqueous leaf extract of *A. ilicifolius*; EAC: Ehrlich ascites carcinoma; TC: Total count. Values represent mean ± SE (n = 10). [a]$P < 0.02$, [b]$P < 0.001$, [c]$P < 0.05$, and [f]$P < 0.01$ *vs* Normal control. [d]$P < 0.001$, [e]$P < 0.02$, and [h]$P < 0.01$ *vs* EAC control.

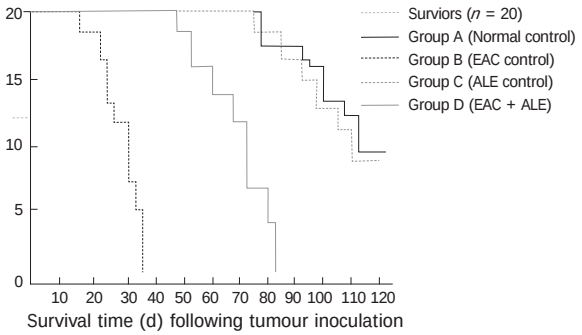

Figure 2 Survival curve of all the four groups of mice.

however all these changes were not statistically significant.

On inoculation of the male Swiss albino mice with EAC (Group B), all mice died of carcinoma within 35 ± 3.46 d of inoculation (Figure 2); while the concurrent administration of ALE to the EAC-bearing hosts (Group D) resulted in an increase ($P < 0.001$) in mean survival of the animals, maximum life-span being 83 ± 2.69 d. Mice from the normal control (Group A) and ALE control (Group C) survived for the entire period of study (i.e. 110 ± 2.12 d and more).

Effect of ALE on mean tumour cell count

The effect of the plant extract on mean tumour cell count is shown in Table 3. No tumour cell was detected on the animals for d 0. Viable tumour cells were observed from d 3/4. There was a gradual increase in cell count in tumour-bearing mice (Group B) from d 10 to d 30. Administration of the ALE to the EAC-bearing mice (Group D) resulted in a gradual significant decrease ($P < 0.001$) in the tumour-cell count from d 10 (37.91%) to d 30 (68.34%).

Effect of ALE on haematological indices

The total count (TC) of RBC, WBC, haemoglobin percent (Hb%) and haematocrit (Htc) of different groups of mice are shown in Table 4. From the table it is evident that, the TC of RBC gradually decreased from d 10 of tumour transplantation in EAC-bearing mice (Group B) and this reduction continued beyond d 30 until the death of the animals. Although the TC of RBC started to decrease from d 10, it showed statistical significance beyond d 10, i.e. on and from d 20 ($P < 0.02$) when compared to the normal vehicle control (Group A). Further reduction was observed on d 30 ($P < 0.001$) in the tumour-bearing animals. In the treatment group (group D), however, administration of ALE restored the TC of RBC significantly ($P < 0.001$ at d 30) almost to the normal value, when compared to Group B (EAC control).

In case of the TC of WBC, the result was just reverse to that of the TC of RBC. The WBC content went on increasing significantly ($P < 0.001$) in Group B since d 10 of tumour inoculation, when compared to the normal control (Group A). Administration of the plant extract significantly reduced the TC of WBC ($P < 0.001$ at d 30) when compared to EAC control (Group B). Furthermore, the Hb% and Htc values were also decreased significantly ($P < 0.001$ at d 30) in EAC-bearing mice compared to the normal control and restored to the normal level in Group D mice after administration of the plant extract.

Effect of ALE on hepatic architecture

Phenotypically altered hepatocyte populations were found scattered in the livers of EAC-bearing mice (i.e. Groups B and D); but no such alterations were noticeable in untreated normal control (Group A; Figures 3A and B) or in the ALE control (Group C, Figure 3F). The HE- stained sections of liver slices revealed extensive hepatocellular lesions that were clearly distinguishable from the non-nodular surrounding normal parenchyma (NNSP).

In Group B (Figures 3C-E), a gross alteration in hepatocellular architecture with neoplastic focal lesions was observed and hepatocytes appeared oval or irregular in shape upon EAC inoculation after 20 d and

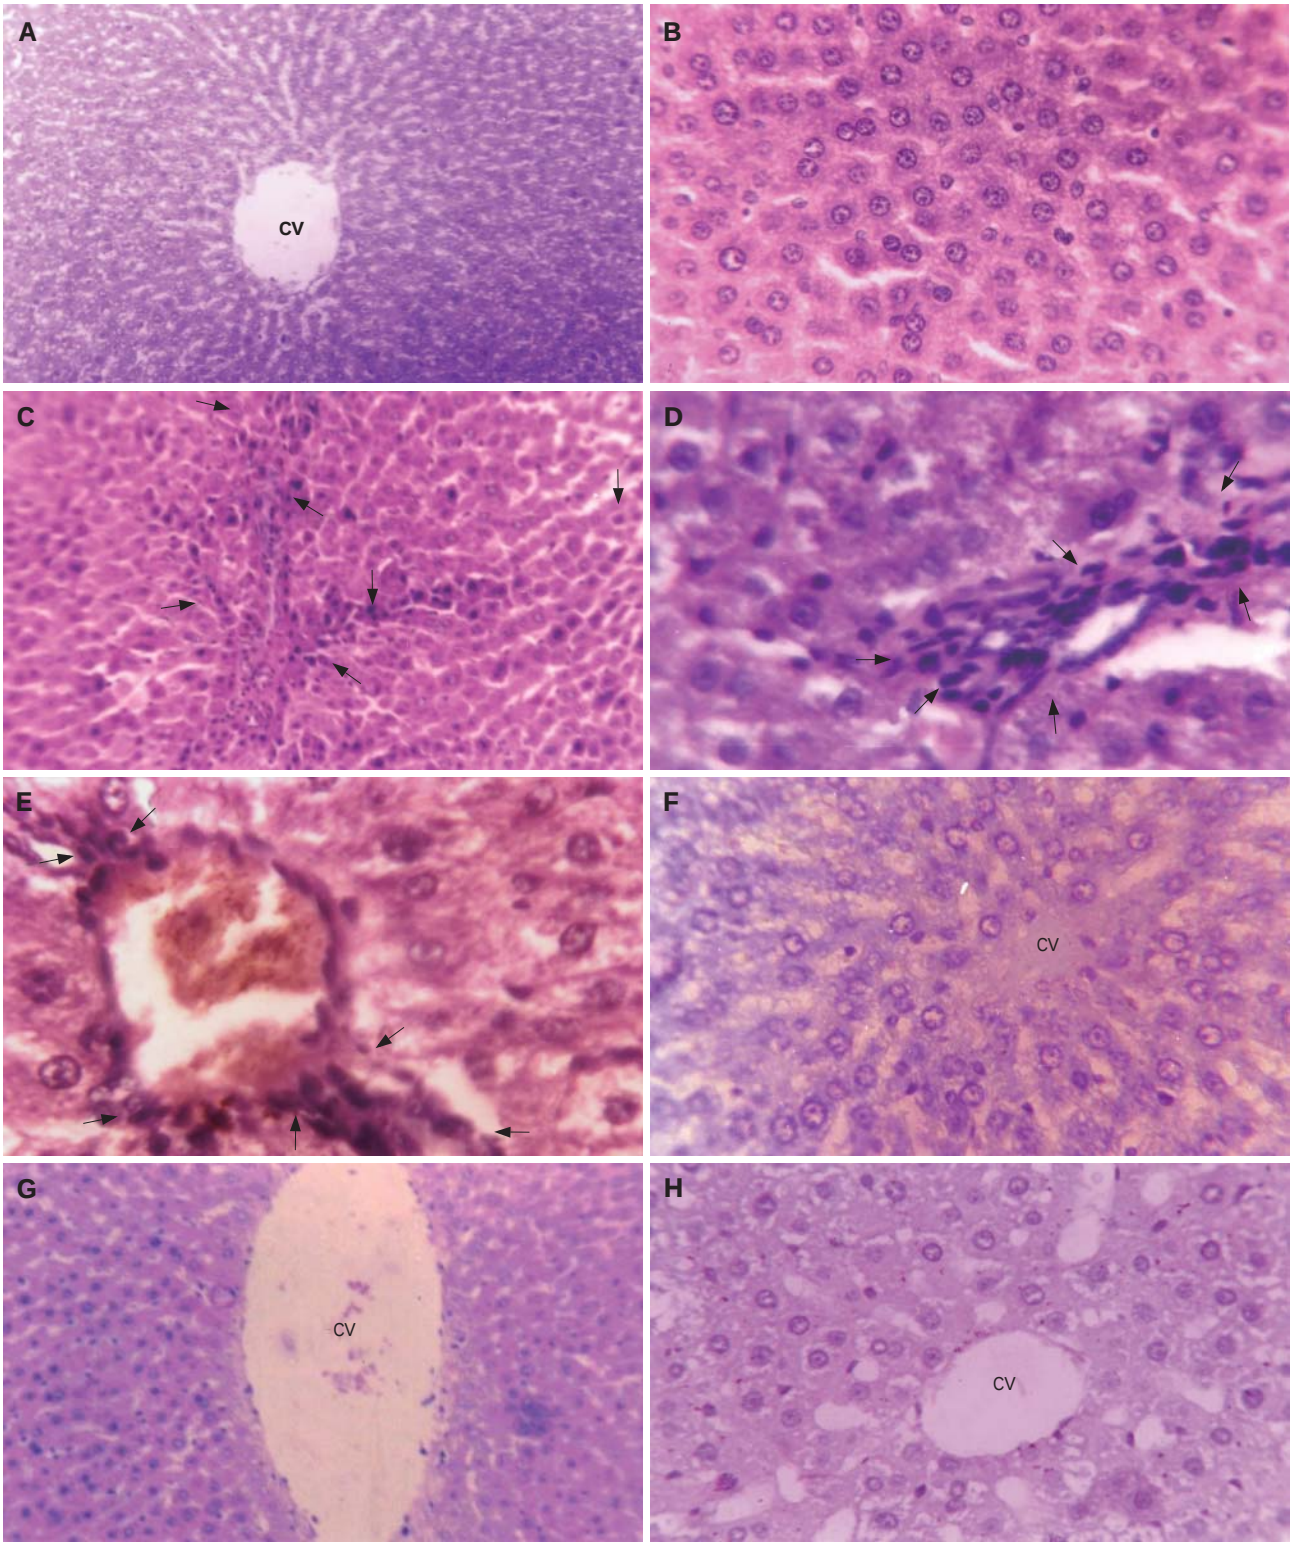

Figure 3 Contiguous liver sections from mice showing hepatocellular histological profiles. **A**, **B**, **F**: Normal hepatocellular architecture depicting hepatocytes radiating from the central vein; **C**, **D**, **E**: Aberrant hepatocellular phenotype with prominent basophilic focal lesions (black arrows) and the presence of eosinophilic and clear cell foci following serial, intraperitoneal (ip) inoculations of viable Ehrlich ascites carcinoma (EAC) cells; **G**, **H**: Almost normal hepatocellular architecture following simultaneous ip administrations of aqueous leaf extract (ALE) of *A. ilicifolius* and EAC. **A** and **B**: Untreated Control; **C**, **D**, and **E**: EAC Control; **F**: ALE Control; **G** and **H**: EAC + ALE. 30 d, with minimal histological changes being noticed after 10 d. The altered hepatocytes were found to be consistently enlarged with more than one nucleus, which were moreover largely vesiculated. They aggregated in clusters resulting in the appearance of prominent basophilic focal lesions. Some nuclei in the cells were large and hyperchromatic with clear and centrally located nucleoli (Figure 3D and E). Extensive vacuolation and necrosis were observed in the cytoplasm with masses of acidophilic (eosinophilic) material after 30 d. In contrast, the cellular architecture of hepatic lobules seemed to be almost like that of normal liver in Group D (Figures

3G and H) that received ALE treatment during the entire period of study. Liver sections from this group presented only a few altered hepatic cell foci. The cells were generally filled with cytoplasmic material and were less vacuolated. The size of the nuclei was essentially the same as that of normal cells and cells with two nuclei were considerably fewer than in group B.

Effect of ALE on liver MT expression

MT protein was detected *in situ* in the EAC-bearing liver tissue of mice (Group B) depicting a strong immunoexpression (Figures 4A and B). Generally, in sections (Figure 4B) with high MT-immunopositivity, the MT-positive cells formed contiguous foci or sheets and on some occasions isolated clusters of positive cells were

Table 5 Effect of ALE on sister-chromatid exchange (SCE) frequencies (500 plates/group) in different groups of mice killed at various time points

Weeks after tumour inoculation	Group	Mean SCE/cell	Reduction in frequency (%)
1	EAC control	4.59 ± 0.57	-
	EAC + ALE	3.62 ± 0.29	21.13
2	EAC control	6.89 ± 1.13	-
	EAC + ALE	3.78 ± 0.78[a]	45.14
3	EAC control	7.83 ± 1.05	-
	EAC + ALE	4.64 ± 0.54[b]	40.74
4	EAC control	10.26 ± 1.67	-
	EAC + ALE	4.83 ± 0.69[c]	52.92
5	EAC control	14.94 ± 2.14	-
	EAC + ALE	5.12 ± 1.16[d]	65.73

Abbreviations: ALE: Aqueous leaf extract of *A. ilicifolius*; EAC: Ehrlich ascites carcinoma. Values represent mean ± SE (n = 10). [a]$P < 0.05$, [b]$P < 0.02$, [c]$P < 0.01$, and [d]$P < 0.001$ *vs* EAC control.

seen. Figure 4A showed an intense staining of MT protein within the hepatic lesions indicating its focal expression. Semi-quantitative scoring of MT-positive cells showed that, there was substantial elevation of MT-immunoreactivity ($P < 0.0001$) (56.18% and 86.24% respectively at 20 and 30 d post-EAC inoculation; Table not shown) in Group B mice when compared to the basal expression level in normal control mice (Group A). In contrast, sections from ALE-treated murine liver (Group D) showed reduced MT-immunoreactivity [35.86% ($P < 0.05$) and 62.25% ($P < 0.01$) respectively at 20 and 30 d] with scattered MT-positive cells (Figure 4C).

Effect of ALE on the frequencies of SCEs in EAC-bearing mice

With transplantation of EAC, there was a moderate induction ($P < 0.05$) in mean SCE/cell in EAC-control mice (Group B) after 1 wk when compared to the untreated vehicle control (Group A) that showed spontaneous SCEs (2.89 ± 0.39) (Table 5). The induction showed steady increase ($P < 0.02$-0.001) in the frequency of SCEs on and from wk 2 with the progression of tumour development as a function of time and reached the peak (14.94 ± 2.14) prior to the death of the EAC-bearing animals at wk 5. In contrast, ALE administration to the EAC + ALE-treated mice offered a near complete inhibition of SCEs during the early phases of tumour growth. In this group, daily treatment with ALE resulted in a substantial decrement ($P < 0.05$-0.001) in the SCE frequency at all the time intervals (wk 2-5) when compared to EAC control animals at the same time points. Data of wk 2-5 showed 45.14%-65.73% reduction in SCE/cell from EAC + ALE-treated mice. As the mice from EAC control group died after wk 5, therefore, data obtained from the EAC + ALE-treatment group on and from wk 6 were compared with the last available data from EAC control mice at wk 5. Results showed that there were downhill trends in the SCE frequency in the ALE-treated EAC-bearing animals (Group D) until their survival up to wk 12 (data not shown). However, no significant difference between the normal control and ALE control in terms of SCE was noted.

Effect of ALE on hepatic DNA damage

The mean length to width (L:W) ratio of the DNA mass, indicating the extent of DNA damage, was increased in the EAC control group 5 d post-EAC inoculation in comparison with the untreated control ($P < 0.0001$; Figure 5A). There was also a significant increase in the frequency of tailed DNA in EAC control mice compared to untreated control ($P < 0.0001$; Figure 5B). Treatment with ALE to the EAC-bearing hosts reduced the L:W ratio of DNA mass (65.34% reduction; $P < 0.01$), and the mean frequency of tailed DNA (53.59% reduction; $P < 0.001$) compared to that of the EAC control group.

Effect of ALE on hepatic SSBs

The protective effect of ALE on SSBs in EAC-bearing hosts 24 h and 5 d post-tumour transplantation is shown in Table 6. In EAC control mice, a significant increase ($P < 0.001$) in the number of SSBs/DNA could be observed following EAC transplantation when compared to that of normal control. The percentage of DS-DNA and SS-DNA in EAC control mice was 79.57% and 20.43%, suggesting that, the extent of host DNA lesions only after 24 h of tumour transplantation was not so severe. Moreover, the amount of DS-DNA (88.23%) in the EAC + ALE-treated group was found to be markedly close to that of normal control (94.75%); whereas, there was almost a 3-fold increase in SS-DNAs (82.79%) and a 4-fold decrease in DS-DNA (17.21%) in EAC control mice sacrificed 5 d post-tumour inoculation, than that of the same group (SS-DNA 31.43%, and DS-DNA 68.57%) being transplanted with tumours only 24 h prior to sacrifice. Treatment with ALE strictly abated (38.53%; $P < 0.01$) the generation of SSBs/DNA fragment in EAC + ALE-treated mice when compared to the EAC control. Moreover, there were no significant differences between normal control and ALE control in the percentage of DS-DNAs, suggesting that ALE apparently is non-genotoxic.

DISCUSSION

The present study showed that administration of ALE reduced viable tumour cell count and brought about a marked increase in mean survival (average life-span) of tumour-bearing hosts, suggesting the tumour-combating efficacy of the said extract under investigation. Furthermore, ALE restored RBC count, Hb and Htc values, and reduced WBC count in EAC-bearing mice, thereby indicating its effectiveness in limiting haematological toxicity following tumour transplantation. There was substantial improvement in the hepatocellular architecture following daily administration of ALE over EAC control mice. We further report here the potential role of the ALE in controlling liver MT expression in mice. Finally, ALE treatment resulted in reduced SCEs and further prevented the generations of 'tailed' DNAs, SS-DNAs and SSBs in EAC-bearing mice hepatocytes as demonstrated by the Comet assay and FADU.

Analysis of the haematological toxicity during tumour transplantation and its possible alteration by ALE was monitored using a battery of haematological indices. Primarily, it resulted in an anemia probably due to severe red cell destruction, which was also reflected in the significantly lowered Htc value as compared to normal animals. The symptoms aggravated with time following tumour transplantation and the body weights of the EAC-bearing mice increased due to the accumulation of haemorrhagous ascitic fluid within the peritoneal cavity. The chemopreventive effects of the plant extract in reducing the severity of anaemia through improvement of RBC count and Htc value[20] not only maintained the normal body and organ weights of tumour-bearing mice, but also may account for the increased survival of the host as evident from our present findings. Administration of ALE further decreased viable tumour cell count in EAC-bearing animals. This may point toward the underlying chemopreventive potential of the plant extract *in vivo*. Although the mechanistic insights into the chemoprevention of the plant are unexplored, we may assume that ALE-mediated tumour cell apoptosis could be one possible pathway for the decreased number of viable tumour cells that warrants further investigation.

The beneficial effect of the plant extract was also apparent in elevating the Hb level, which was otherwise decreased in EAC-control animals. The exact mechanism of the ALE-mediated induction of Hb level during tumour growth is not clear at the present moment. We may speculate that it might somehow influence the process of haem synthesis, which may therefore account for the subsequent induction of Hb level. Whatever may be

the mechanism, induction of Hb by ALE, as observed herein, could have a broad implication with respect to the antitumour efficacy of the extract if one considers the fact that high Hb level has been found to possess an inhibitory influence on tumour growth[20,21]. The data described herein showed a significant increase in total leukocyte count at different time intervals following tumour inoculation as compared to normal animals. Abnormal mitotic activity as evident from the appearance of different forms of abnormal and aberrant neutrophils in large numbers was essentially observed in EAC-bearing hosts. Now, the role of ALE in reducing the TC of WBC in the treatment group could be influenced through a reversal of lymphoid-myeloid ratio. Thus, the stabilization of leukocyte count with parallel retainments of normal Hb level and Htc value in tumour-bearing animals by ALE may have a paramount importance in limiting hematological toxicity in hosts.

The study further demonstrates an intense immunostaining of MT in EAC-bearing liver tissue of mice in comparison to that of normal control. It is necessary to mention that the hyperbasophilic cells of the hepatocellular lesions stained more intensely for MT compared to that of the non-basophilic area of the same tissue, suggesting that the hyperbasophilic proliferative lesions consisting of rapidly proliferating cells may be considered to be the primary MT (-positive focal) expression zones. Up-regulation of MT expression in rapidly proliferating tissues appears to suggest its critical role in normal and neoplastic cell growth[13,22]. Treatment with ALE substantially reduced the expression of MT in the precancerous lesions along with decreased MT immunoreactivity. The precise mechanism of ALE-mediated down-regulation of MT expression is not clear at the moment. However, it is assumed that the antioxidant property[4] of *A. ilicifolius* may be involved in the elimination of reactive metabolites from the host cells, thereby posing low oxidative stress to the hosts and limiting MT expression thereby. Thus, control of liver MT expression, a cell-cycle dependent protein in EAC-transplanted mice by treatment with ALE might play an important role in controlling cell growth *in vivo*.

Inoculation of the hosts with EAC may act as primary agents producing secondary DNA cleavage and are potent inducers of chromosomal aberrations and SCEs[23]. Since a SCE represents the breakage of four strands of DNA (two double helices), a switch of these strands between chromatids of the same chromosome and the rejoining of these strands in their new location, it is important to know whether the breakage and rejoining events occur faithfully, that is without producing any modification in the genetic code. In early experiments using Chinese hamster cells in culture, it was found that the induction of SCEs was linearly related to the increase in single gene mutations when the cells were exposed to chemicals, each of which differed in the type of lesion produced in DNA[23,24]. Reports indicate that antioxidants suppress clastogenicity, and thus, many antioxidants are even anticarcinogens[25,26]. Studies have shown that *A ilicifolius* possesses antioxidant properties[4], and may therefore be effective in combating oxidative stress following tumour transplantation. In our present study, ALE-mediated suppression of SCEs indicates its anticlastogenicity and chemoprotection thereby. The decreased occurrence of SCEs may indirectly be related to increased cell survival or host's anti-cancer surveillance, since studies in search of a relationship between SCE induction and other expressions of genotoxicity have shown a positive relationship between SCEs and reduced cell survival.

DNA damage in the form of SSBs may play an essential role in the pathogenesis of neoplasia. The SSBs detected herein by the Comet assay and FADU can be converted to double-strand DNA breaks (DSBs) upon replication. DSBs are a highly deleterious form of DNA damage, since they lead to mitotic cell death or mutations[27]. DNA DSBs are generated when the two complementary strands of the DNA double helix are broken simultaneously at sites that are sufficiently close to one another that base-pairing and chromatin structure are insufficient to keep the two DNA ends juxtaposed. As a consequence, the two DNA ends generated by a DSB may become physically dissociated from one another, resulting in error-prone repair and providing the opportunity for inappropriate recombination with other sites in the genome. Error-prone/inaccurate repair or lack of repair of DSBs may lead to mutations or to larger-scale chromosomal aberrations and genomic instability[28,29]. In addition, mutations in many of the factors involved in DSB signaling and repair lead to increased predisposition to cancer in humans and in animal models[30]. In the present study, ALE treatment resulted in a substantial decrease in the amount of SS-DNAs, SSBs, 'tailed' DNA and DNA 'comets' in the tumour-bearing murine livers. This reduction in DNA damage reflects the potential of the ALE to reduce the genotoxicity caused by EAC in host cells. The exact mechanism of action of the ALE in limiting DNA damage warrants a more robust investigation.

In conclusion, the results of our study clearly indicate that the ALE of *A ilicifolius* is able to inhibit the survival and proliferation of EAC cells in laboratory mice, and this observation is potentially useful in medical oncology. Our data show that, ALE treatment is beneficial in increasing the mean survival of the animals, in remodeling of the liver lesions and in limiting clastogenicity and genotoxicity *in vivo*. Although this study is at its preliminary stage, the results are promising. Future studies are planned in our laboratory to isolate and characterize the active fractions/principles of the plant and to elucidate the mechanistic basis of chemoprevention in a defined chemical carcinogenesis model.

COMMENTS

Background

Herbal preparations/natural plant products constitute an important component of indigenous/traditional medicines. Herbs certainly have been an important source of many allopathic medicines. However, the way herbs are used in indigenous medical system is not supported by strong preclinical data with insights into the biological/pharmacological mechanisms. Ehrlich ascites carcinoma (EAC) is a strain-specific, rapidly proliferating transplantable epithelial tumour in mouse in which the neoplastic cells multiply and ascites fluid accumulates within the

peritoneal cavity of the host and ultimately the host dies. Inhibition of the growth and proliferation of EAC cells by administration of plant products would be a safe and effective treatment strategy.

Research frontiers

The most significant approach to cancer chemoprevention seems to be the administration of chemopreventive agents in order to inhibit the pathogenesis of cancer or to delay or halt or limit the progression of neoplastic transformation. With the increasing trend in the incidence of cancers in our country, biomedical research directed at early detection and diagnosis, prognosis and survival as well as prevention of progression of malignancy is of prime importance. Since India is a rich source of indigenous herbs and several studies have reported potential therapeutic/chemopreventive utilities of these medicinal herbs, it is therefore of great importance for us to explore the chemopreventive efficacy of an Indian medicinal plant *Acanthus ilicifolius* in preventing DNA damage in an EAC model in mice.

Innovations and breakthroughs

In this paper, the primary chemopreventive mechanisms of the plant *Acanthus ilicifolius* have been investigated in an *in vivo* EAC model in Swiss albino mice. In contrast to meager previous reports demonstrating analgesic and antioxidant properties of the plant, the results of the present study clearly showed that, the aqueous leaf extract (ALE) was quite effective in preventing hepatic DNA alterations and sister-chromatid exchanges in EAC-transplanted murines. Our study further showed that ALE treatment was able to limit liver metallothionein expression, a potential marker for cell proliferation and increased the mean survival of animals to a significant extent. Results indicate that *A ilicifolius* could be used as a potential chemoprotector against neoplasia.

Applications

This study opens up a promising avenue in cancer chemoprevention with indigenous plants. Lack of toxicity favours further preclinical evaluation of *A ilicifolius* in a defined chemical carcinogenesis model. Elucidation of its mechanisms of action at the intricate molecular circuits, and isolation and characterization of the active principles, will provide a better understanding of the treatment strategy, and we would have the beginning of a new chemoprevention programme that could have a broader implication for the well-being of the society.

Peer review

In this experimental study, the authors showed the importance of *Acanthus ilicifolius* plant extract as chemoprotector on EAC-bearing murine model.

RAPID COMMUNICATION

Choice of laxatives and colonoscopic preparation in pregnant patients from the viewpoint of obstetricians and gastroenterologists

Abstract

AIM: To elucidate the preferences of gastroenterologists at our institution and compare them to those of obstetricians when making decisions in the pregnant patient, including which type of bowel preparations to use for flexible sigmoidoscopy or colonoscopy, as well as which laxatives can be used safely.

METHODS: Surveys were mailed to all attending gastroenterologists (n = 53) and obstetricians (n = 99) at our institution. Each survey consisted of the 14 most common laxative or motility agents used in pregnancy and inquired about the physician's prescribing habits in the past as well as their willingness to prescribe each medication in the future. The survey also listed four common bowel preparations used prior to colonoscopy and sigmoidoscopy and asked the physician to rank the order of the preferred agent in each case.

RESULTS: With regard to common laxatives, both gastroenterologists and obstetricians favor the use of Metamucil, Colace, and Citrucel. Both groups appear to refrain from using Fleets Phosphosoda and Castor oil. Of note, obstetricians are less inclined to use PEG solution and Miralax, which is not the case with gastroenterologists. In terms of comparing bowel preparations for colonoscopy, 50% of gastroenterologists prefer to use PEG solution and 50% avoid the use of Fleets Phosphosoda. Obstetricians seem to prefer Fleets Phosphosoda (20%) and tend to avoid the use of PEG solution (26%). With regard to bowel preparation for sigmoidoscopy, both groups prefer Fleets enema the most (51%), while magnesium citrate is used least often (38%).

CONCLUSION: It is clear that preferences in the use of bowel cleansing preparations between the two groups exist, but there have not been many case controlled human studies in the pregnant patient that give clear cut indications for using one *versus* another drug. In light of the challenge of performing controlled trials in pregnant women, more extensive surveys should be undertaken to gather a larger amount of data on physicians' experiences and individual preferences.

INTRODUCTION

There is a degree of apprehension when it comes to altering medical care in pregnant female patients. On some occasions pregnant women will require colonoscopic evaluation and the clinician will be faced with a decision on what type of bowel preparation to use for flexible sigmoidoscopy or colonoscopy. Also, constipation is a common problem faced by many women during the course of pregnancy and a choice of laxatives must be made by the physician. Given the numerous pharmacological choices available and the lack of data in the medical literature, these decisions are not always easy to make.

When considering endoscopy in the pregnant patient, the physician must balance the safety concerns of both mother and fetus against the relative value of the information obtained or the diagnostic procedure performed[1]. All available evidence suggests that sigmoidoscopy is safe during pregnancy and the indications include rectal bleeding, chronic diarrhea, abdominal pain, and rectal pain[2]. Guidelines for colonoscopy in pregnancy are not readily available due to insufficient data, although studies which have been done demonstrate safety and efficacy of the procedure provided that obstetrical consultation and close monitoring take place. Colonoscopy

is indicated for suspected colon cancer, uncontrolled severe hemorrhage, or when necessary before colonic surgery[3] in pregnant women as well as the general population.

After the indications for an endoscopic procedure are established, the next question becomes which bowel preparation to use. Developing guidelines for this poses unique challenges since there are few controlled trials that include pregnant patients. However, there is some information available regarding the efficacy of agents such as tap water enemas, castor oil, polyethylene glycol (PEG) solution, magnesium citrate, senna, bisacodyl, docusate, and phosphosoda[4,5]. The purpose of this study was to elucidate the preferences of gastroenterologists at our institution and compare them to those of obstetricians when making such decisions.

MATERIALS AND METHODS

After obtaining IRB approval, surveys were mailed to all attending gastroenterologists (n = 53) and obstetricians (n = 99) at our institution. Each survey consisted of the 14 most common laxative or motility agents used in pregnancy and inquired about the physician's prescribing habits in the past as well as their willingness to prescribe each medication in the future. The survey also listed four common bowel preparations used prior to colonoscopy and sigmoidoscopy and asked the physician to rank the order of the preferred agent in each case. Descriptive statistics were computed using SPSS Version 14.0. (SPSS Inc. Chicago, Illinois). Valid percentages were used in order to account for those surveys that were incomplete. Utilizing Fisher's Exact Test, the proportion of gastroenterologists who would prescribe the listed laxatives was compared to the proportion of obstetricians who also indicated they would prescribe. $P < 0.5$ was *a priori* considered to indicate statistical significance.

RESULTS

Seventy five surveys were returned making the total response rate nearly 50% (53% of gastroenterologists and 47% of obstetricians). Among gastroenterologists, 96% of respondents were male and 4% female, while 55% of obstetricians were male and 45% female. The mean number of years in practice between both groups was 19 ± 11 years and the mean physician age was 41 ± 22 years.

With regard to the common laxatives, the overwhelming majority of gastroenterologists were inclined to prescribe Metamucil (psyllium), Citrucel (methylcellulose), and Colace (docusate). Some had a preference for using glycerin suppositories, Fleets enemas (sodium phosphate enemas), tap water enemas, and Miralax (PEG 3350), although not as often as the agents above. Meanwhile, most gastroenterologists are reluctant to prescribe Fleets Phosphosoda (oral sodium phosphate), castor oil, and oral Dulcolax (bisacodyl). Table 1 presents the exact percentages as described above.

The vast majority of obstetricians favor the use of Colace, Metamucil, and glycerin suppositories. They also prefer to use Citrucel, Fleets enemas, Dulcolax suppositories, and tap water enemas, although not as often as those listed above. The majority of obstetricians are less inclined to use PEG solution, Mineral oil, and Fleets Phosphosoda. Table 1 presents the exact percentages as described above.

As seen in Table 1, it is evident that both gastroenterologists and obstetricians favor the use of Metamucil (P = 1.00), Colace (P = 0.293), and Citrucel (P = 0.164). Both groups appear to refrain from using Fleets phosphosoda (P = 0.051) and Castor oil (P = 0.402). Of note, obstetricians are less inclined to use PEG solution (P = 0.001), Miralax (P = 0.000), and tap water enema (P = 0.046), which is not the case with gastroenterologists.

In terms of comparing bowel preparations for colonoscopy, it is apparent that 50% of gastroenterologists prefer to use PEG solution and 50% avoid the use of Fleets Phosphosoda. Obstetricians seem to prefer Fleets Phosphosoda (20%) and tend to avoid the use of PEG solution (26%), which is the exact opposite as gastroenterologists. With regard to bowel preparation for sigmoidoscopy, the preferences between gastroenterologists and obstetricians appear to be quite similar. Both groups prefer Fleets enema the most (51%), while magnesium citrate is used least often (38%).

DISCUSSION

Several conclusions can be drawn from the results of this physician survey. Both groups commonly prescribe Metamucil, Citrucel, and Colace. All are frequently used bulk-producing medications that carry low pregnancy risk factors and are without reported complications[6]. The overall frequency of PEG solution being used is much higher with gastroenterologists. Studies have shown that the systemic absorption of PEG is minimal and the problems with abdominal bloating and gas are less common as compared to other osmotic laxatives[5]. Another similarity common to both groups is the avoidance of phosphosoda preparations. This may be related to the fact that in published studies, newborns were shown to manifest bone demineralization and bone growth failure because of maternal phosphate overload[10], although a one time use in pregnancy has not shown to be detrimental. Another consideration when using phosphosoda preparations is the risk of phosphate nephropathy[12], which has been reported in select cases.

The overall majority of the available laxatives are without documented side effects; however castor oil carries an absolute contraindication for use in pregnancy (risk factor X) because it has been linked to uterine rupture[7]. Mineral Oil has also been associated with adverse effects during pregnancy and should be avoided because it can impair maternal fat soluble vitamin absorption, leading to neonatal coagulopathy and hemorrhage[8]. From the results above it appears to be generally avoided in both groups, but significantly more so among obstetricians. Another apparent difference is the prescribing of tap water enemas in both groups. Obstetricians seem more reluctant to prescribe it perhaps due to the possible induction of labor

Table 1 Comparison of gastroenterologists' (GI) *vs* obstetricians' (OB) preference of 14 common laxative/motility agents prescribed in the pregnant patient

	% of GI physicians who have prescribed in the past or would prescribe in the future	% of OB physicians who have prescribed in the past or would prescribe in future	% of GI physicians who would NOT prescribe	% of OB physicians who would NOT prescribe	*P* value
Metamucil (psyllium)	96.5	95.6	3.9	2.2	1.000
Citrucel (methylcellulose)	92.9	77.1	7.1	11.4	0.164
Colace (docusate)	89.3	97.7	10.7	2.3	0.293
Glycerin suppository	77.8	82.0	14.8	15.4	0.757
Fleets enema (sodium phosphate enema)	75.0	55.0	25.0	41.7	0.174
Tap water enema	70.4	44.5	22.2	50.0	0.046
Miralax (PEG 3350)	69.2	20.6	23.1	51.7	0.000
Magnesium Citrate	54.2	32.3	45.8	61.8	0.113
GoLytely (PEG solution)	53.8	12.9	46.2	80.6	0.001
Dulcolax (bisacodyl suppository)	50.0	45.8	34.6	54.3	0.799
Mineral Oil	46.2	25.0	42.3	75.0	0.106
Dulcolax (bisacodyl oral)	30.7	38.3	53.8	52.9	0.595
Castor Oil	26.1	37.6	60.9	62.5	0.402
Fleets Phosphosoda (oral sodium phosphate)	7.7	29.1	92.3	71.0	0.051

with the use of a rectal enema, although it has been shown to be quite safe in the pregnant patient[3].

Another explanation for the differences between the two groups may also be due to preexisting medical conditions in the pregnant patient such as Crohn's disease, which is exacerbated by various medications seen more frequently by gastroenterologists. Such exacerbations may adversely affect the pregnancy[11], although there is no established link with the 14 common laxatives to Crohn's disease exacerbation.

Regarding preparation for colonoscopy, gastroenterologists favor PEG solution, while there appears to be more hesitation among obstetricians. It is unclear whether this is because gastroenterologists have greater experience in its use or simply because data is lacking regarding the safety of medications for colonoscopy and pregnancy. For flexible sigmoidoscopies, both groups favor Fleets enemas, although it has been shown that tap water enemas appear to be the safest option, even if not as effective, particularly during the first trimester[9].

In conclusion, it is clear that preferences in the use of bowel cleansing preparations between the two groups exist, but there have not been many case controlled human studies in the pregnant patient that give clear cut indications for using one *versus* another drug. Therefore, it seems logical that both groups favor medications that seem to respond best with the majority of patients without causing harm or compromising the pregnancy. In light of the challenge of performing controlled trials in pregnant women, more extensive surveys should be undertaken to gather a larger amount of data on physicians' experiences and individual preferences. Perhaps this will provide a clearer understanding of which laxatives and purgatives are optimal to use during pregnancy.

COMMENTS

Background

Prescribing medications to the pregnant patient can be challenging. The purpose of the research study was to gain an understanding of the different practices used by obstetricians and gastroenterologists when prescribing laxatives and using bowel preparations for colonoscopy and sigmoidoscopy.

Research frontiers

There have not been many case controlled human studies in the pregnant patient, therefore surveys were used to gather data on physician prescribing habits.

Innovations and breakthroughs

Due to limited research in the pregnant patient, the majority of articles point toward individual physician preference and patient response when prescribing a particular medication.

Applications

In light of the challenge of performing controlled trials in the pregnant patient, more extensive surveys should be undertaken to gather a larger amount of data on physicians' experiences and individual preferences.

Peer review

This paper is well written and covers an important clinical area. This is an interesting manuscript on the preference of laxatives and colonoscopic preparation in pregnancy of obstetricians and gastroenterologists.

Abstract

AIM: To improve the results of New therapeutic strategies in hepatocellular carcinoma (HCC). We have conducted a phase Ⅱ study with pegylated liposomal doxorubicin (PLD), 5-fluorouracil (5FU) and folinic acid (FA).

METHODS: Thirty-one patients with hystologically-confirmed, inoperable HCC, received combination chemotherapy with PLD 25 mg/mq on d 1, 5FU 1200 mg/mq in 48 h continuous infusion, and oral FA 30 mg on d 1 and 2 every 3 wk until disease progression or intolerable toxicity.

RESULTS: The median age was 65 years (range 41-82) and 28 patients were hepatitis C virus seropositive (90%). The majority of patients were Child-Pugh Class B (55%). Two patients showed a partial response (PR), and 16 had stable disease (SD). With a median follow-up of 14 mo, the median time to progression of all evaluable patients was 4 mo (95% CI 1.7-7). Median overall survival was 9 mo (95% CI 3-24 mo). After 1 year, 9 of 18 PR/SD patients were alive. Chemotherapy was well tolerated.

CONCLUSION: PLD/FU/FA combination seems capable of achieving durable stabilization of HCC. The manageable toxicity supports a role for combination with other anticancer agents.

Key words: Pegylated liposomal doxorubicin; 5-fluorouracil; Folinic acid; Hepatocellular carcinoma

INTRODUCTION

Upward trends in incidence or mortality of hepatocellular carcinoma (HCC) have been reported in the United States, Japan and several European countries, including Italy, over the last two or three decades. This increase has been chiefly attributed to the spread of hepatitis C virus (HCV), which occurred earlier in Japan and Southern Europe than in the United States[1].

Surgical resection and liver transplantation are considered the only cures for HCC, but benefit only about 15% of patients[2]. Patients with unresectable or metastatic disease have a median survival of a few months[3].

It is estimated that about 60% of all patients with HCC have underlying chirrosis. In some patients, chirrosis associated with portal hypertension and thrombocytopenia makes systemic chemotherapy extremely difficult and contributes to the poor prognosis associated with HCC[4].

Free doxorubicin has been shown to be superior to symptomatic treatment of HCC[5], although a meta-analysis has revealed no efficacy of free doxorubicin for treatment of HCC[6]. Pegylated liposomal doxorubicin (PLD) is a novel formulation with markedly delayed clearance, decreased volume of distribution, and accumulation of the drug in malignant tissues, which results in both higher therapeutic efficacy and reduced toxicity[7]. A number of studies have shown, at best, response rates of 10%-17%, with different schedules and a well-tolerated profile[8-10].

5-Fluorouracil (5FU) has demonstrated a modest response rate in HCC[11]. There are no published studies

with combination of PLD and 5FU in HCC. Also, if both drugs show poor activity when used alone, it can be expected that activity will be better when they are used in combination.

We planned a phase Ⅱ study of PLD, 5FU and FA in patients with inoperable HCC. Our schedule was based on a previous phase I study in upper gastrointestinal cancer[12].

MATERIALS AND METHODS

Patients

Patients who were referred to two Italian Departments of Medical Oncology (Cotugno Hospital and Federico Ⅱ University, Naples) because of their metastatic and/or recurrent HCC were considered eligible for study entry. Main eligibility criteria are shown in Table 1. Patients were required to have histologically confirmed HCC, WHO Performance Status < 2, Stage Ⅲ or Ⅳ, Child-Pugh class A or B, and no prior systemic chemotherapy. Other inclusion criteria included an absolute neutrophil count of at least 1500 cells per cubic millimeter and/or at least 100 000 cells per cubic millimeter, adequate renal (serum creatinine level < 2 mg/dL) and cardiac (left ventricular ejection fraction > 50% by echocardiography) function, and signed written informed consent. The study protocol was reviewed and approved by institutional review board.

Treatment

Patients receive PLD (Caelyx; Schering-Plough, Milan, Italy) 25 mg/mq in 500 mL 5% dextrose i.v. over 1 h on d 1. 5FU (Teva Pharma Italia S.r.L., Milan, Italy) 1200 mg/mq was administered for 48 h continuous infusion, and oral FA (Folaren; Ist. Chim. Inter., Rende, Rome, Italy) 30 mg d 1 and 2. Each cycle was given every 3 wk. All patients received a standard supportive regimen consisting of hydration and antiemetics. No prophylactic administration of hematopoietic growth factors was allowed. Treatment was repeated until disease progression or unacceptable toxicity. Retreatment occurred upon recovery of platelets to > 100 000 cells per cubic millimeter, neutrophil count of at least 1500 cells per cubic millimeter and skin toxicity or stomatitis to grade ⩽ 1. A 25% dose reduction was permitted for delayed recovery from toxicity of grade ⩾ 2. Patients were withdrawn from the study if grade 3-4 hematologic toxicity persisted for more than 2 wk.

Response and toxicity evaluation

Baseline examinations were: complete history and examination, electrocardiography, echocardiography, complete blood count, serum alphafetoprotein, weighted magnetic resonance imaging (MRI) of the liver, abdominal ultrasound, and chest X-ray. If MRI was not feasible, computed tomography was used. Response and toxicity were evaluated every three cycles.

The following WHO criteria were used: (1) a complete response (CR) was defined as the disappearance of all radiological and clinical evidence of tumor, and the absence of all tumor-related symptoms for at least 4 wk; (2) a partial response (PR) was defined as a decrease of ⩾ 50% in the product of the largest perpendicular dimensions of measurable tumors, measured at least 4 wk apart; (3) stable disease (SD) was defined as no significant change in radiologic tumor measurements, without worsening in performance status; and (4) progressive disease (PD) was defined as a decline in performance status, the appearance of new malignant lesions, and an increase of ⩾ 25% in measurable disease. Toxicity was based on the National Cancer Institute Common Toxicity Criteria version 2.

Table 1 Main eligibility criteria

Age < 85 yr
WHO performance status 0 or 1
Histologically confirmed HCC
Stage Ⅲ-Ⅳ
No prior systemic chemotherapy
Child-Pugh A or B
Complete history of the patient (including previous treatment)
Informed consent
Normal hematologic, renal and cardiac functions

Statistical analysis

The primary end-point was the response rate and the secondary measures were survival and time to progression. Sample size was calculated to reject a 10% response rate in favor of a target response rate of 30%, with a significance level of 0.05 and a power of 80% by using Simon's optimal two-stage design[13]. In the initial stage, a total of 10 evaluable patients were entered and evaluated for response. If more than one response were observed in the first stage, then 21 additional patients were entered in the second stage to achieve a sample size of 31 evaluable patients. Survival rates and time to progression were assessed by the Kaplan-Meier method. All P values were two-sided, with $P < 0.05$ indicating statistical significance.

RESULTS

A total of 31 patients were included in the study between March 2004 and December 2006. Patient characteristics are summarized in Table 2. The median age was 65 years (range 41-82), and 14 and 17 patients were Child-Pugh class A and B, respectively. The majority of patients (20) had received prior antitumor therapy. The most common previous treatment for HCC was transarterial chemoembolization, which was received by 15 of 31 patients. Twenty-eight patients were HCV seropositive and 22 showed an alphafetoprotein (AFP) level at the upper limit of normal. Fifteen and 16 patients were in stage ⅢC and Ⅳ, respectively, according to the TNM system.

Treatment outcomes

The results are shown in Table 3. Two PR were obtained, and 16 had SD. Sixteen and 8 patients received 6 and 8 treatment cycles, respectively, while 2 were treated with 10 cycles. Among the 16 patients with SD, we observed 8 each in Child-Pugh A and B class. No differences in PR/SD were noted between patients who were pretreated

and those who were not, such as those in stage ⅢC and Ⅳ. With a median follow-up of 14 mo, the median time to progression of all evaluable patients was 4 mo (95% CI 1.7-7). Median overall survival was 9 mo (95% CI 3-24 mo). Among 18 responder/SD patients, 9 (50%) were alive at 12 mo, while at the same time, none of the PD patients were alive ($P < 0.05$). One responder who received 10 cycles of chemotherapy was alive at 24 mo. Of 31 evaluable patients, 16 (52%) showed a > 50% decrease in serum AFP from baseline. Among 13 patients with PD, 5 progressed to Child-Pugh C class. After disease progression, 6 patients had salvage treatment with platinum compound or thalidomide, while 25 patients received only supportive care.

Safety

In total, 130 cycles of chemotherapy were administered, with a median of 6 cycles (range 2-10), and 13 of the planned cycles were delayed because of toxic effects. Dose reduction was required in 20 cycles. All eligible patients were evaluable for toxic effects (Table 4). The most frequent toxic effects were neutropenia grade 1-2 and oral stomatitis in 7 patients each. These effects were well managed and did not require treatment discontinuation. Grade 3-4 anemia, neutropenia and thrombocytopenia were observed in 2, 3 and 2 patients, respectively. These side effects required hematopoietic growth factors and red-cell transfusion during the treatment. Hand-foot skin rash occurred in 5 patients and was limited to low-grade intensity.

DISCUSSION

There is no consensus on the treatment of patients with advanced-stage HCC. Locoregional approaches (embolization, intra-arterial chemotherapy and chemoembolization) and systemic treatments have offered marginal survival benefit in most clinical trials[14]. The overall response rate to systemic chemotherapy is generally < 10%[15], probably owing to the strong multidrug-resistance gene expression that is usually observed in this setting[16]. Doxorubicin has been widely evaluated in patients with advanced stage HCC, either alone or in combination. The combination of cisplatin, doxorubicin, 5FU and alpha-interferon (PIAF) has been assessed in 50 patients. The overall response rate was 26%, but considerable hematological toxicity and 2 treatment-related deaths occurred[17]. There was an expectation that doxorubicin efficacy would be enhanced with the better-tolerated PLD formulation[18].

A number of studies have shown, with different doses and schedules, at best, response rates of 10%-17% with PLD alone[8-10]. Two other studies have revealed no response, and with a median survival of 20 wk, the authors concluded that PLD was ineffective[19,20]. Based on a median survival of 1 year, Schmidinger *et al*[9] concluded that PLD warrented further study; however, Ruff *et al*[8] achieved a median survival of only 5.3 mo.

5-fluorouracil has been used alone in HCC, with modest activity[11]. In an attempt to achieve better effectiveness we have combined PLD and 5FU. To date, there have been no published studies with PLD and

5FU in HCC. We chose to use PLD 25 mg/mq and 5FU 1200 mg/mq every 3 wk since we considered, as a result of a previous phase I study[12], that these doses would be well tolerated. In our trial, the combination of PLD, 5FU and FA was well tolerated, and we achieved an overall response rate of 6.5%. However, despite the modest overall response rate, we observed SD in > 50% of patients. This information is encouraging, and PLD/FU/FA combination seems capable of achieving durable stabilization of HCC.

Median time to progression was 4 mo, which is longer than that in other PLD studies, such as those by Valle *et al* and Halm *et al*[19,21]. Median overall survival was 9 mo and was shorter than that in the study by Schmidinger *et al*[9], but longer than that in previous PLD studies[8,10,19,21].

Among 18 responder/SD patients, nine (50%) were alive at 12 mo, while at the same time, none of those with PD was alive ($P < 0.05$). Our SD rate (50%) was higher than that in the studies by Valle *et al* and Halm *et al*. Our study showed better results than those in a recent study by Poh *et al,* which showed no objective response after treatment with combined PLD and 5FU analogue (capecitabine)[22]. Higher PR and SD rates, and longer survival were observed by Louafi *et al*[23]. Thirty-four patients have been treated with gemcitabine plus oxaliplatin (GEMOX). The overall response rate was 18% and SD was observed in 58% of patients. Median overall survival was 11.5 mo.

However, these differences could have been due to different selection criteria. The GEMOX trial included few Child-Pugh Class B and pretreated patients compared to our study. It should be kept in mind that the degree of cirrhosis in our patients was not only limited to Child-Pugh class A but also Class B patients. In our trial, the majority of patients were Class B. Other studies have not included Class B patients[24], have not indicated whether they include Class B patients[21], or if this class was included, it was in the minority[19,23]. This point strengthens our results. In the past 15 years, about 10 new chemotherapeutic agents have become available, which has led to major advances in the medical treatment of several gastrointestinal tract cancers, such as colon adenocarcinoma. However, recent clinical trials of the taxanes irinotecan and topotecan have all given disappointing results for HCC[25-27]. New targeted antitumoral therapies have been tested in HCC patients over the past 2 years. Preliminary results of a phase Ⅲ randomized trial have shown that first-line treatment with sorafenib improves survival in HCC when compared to placebo[28].

In conclusion, a major limit of our study was that it was a small phase Ⅱ study; however, we believe that the results, especially in terms of long-term disease stabilization, merit further evaluation. For example, it would be interesting to carry out additional clinical studies that involve novel targeted agents in combination with cytotoxic agents such as PLD and FUFA. One of the next steps will be to combine this schedule with biological agents in HCC, such as bortezomib, since synergy between bortezomib and anthracyclines has been observed[29].

COMMENTS

Background

There is no consensus on the treatment of patients with advanced-stage HCC. Locoregional approaches (embolization, intra-arterial chemotherapy and chemoembolization) and systemic treatments have offered a marginal survival benefit in most clinical trials.

Research frontiers

The overall response rate to systemic chemotherapy is generally < 10%, probably owing to the strong multidrug-resistance gene expression that is usually observed in this setting.

Related publications

A number of studies have shown, with different doses and schedules, at best, response rates of 10%-17% with PLD alone. 5FU has been used alone in HCC, with modest activity.

Innovations and breakthroughs

In an attempt to achieve better effectiveness, we combined PLD and 5FU. To date, there have been no published studies with PLD and 5FU in HCC. In our trial, combination of PLD, 5FU and FA was well tolerated, and we achieved an overall response rate of 6.5%. However, despite the modest overall response rate, we observed SD in > 50% of patients. Our SD rate is higher than that in the studies of Valle *et al* and Halm *et al*. Median time to progression was 4 mo, which is higher than that in other PLD studies.

Applications

It should be kept in mind that the degree of cirrhosis of our patients was not only limited to Child-Pugh class A but also Class B patients. In our trial, the majority of patients were Class B. Other studies did not include Class B patients, did not indicate whether they included Class B patients, or if this class was included, it was in the minority. This point strengthens our results. We believe that our results, especially in terms of long-term disease stabilization, merit further evaluation. It would be interesting to carry out additional clinical studies that involve novel targeted agents, such as bortezomib, in combination with PLD and FUFA.

Terminology

Pegylated liposomal doxorubicin (PLD) is a novel formulation with markedly delayed clearance, decreased volume of distribution, and accumulation of the drug in malignant tissues, which results in both higher therapeutic efficacy and reduced toxicity.

Peer review

Although this study had a small sample size, the results are interesting. Inoperable HCC was stabilized with chemotherapy that was well tolerated. In addition, this is believed to be the first report of the use of PLD in combination with 5FU. As for reviewer comments, how do the authors explain the modest overall response rate of 6.5% and yet stabilization of disease in 51.1%? Was there any progression in the liver disease or hepatic function tests during the administration of chemotherapy? Did any patients progress to Child-Pugh class C?

Abstract

AIM: To explore the expression of PlexinA1 in gastric carcinoma and its relationship with tumor angiogenesis and proliferation.

METHODS: PlexinA1 mRNA and protein expressions of Semaphorin6D were measured using semi-quantity reverse transcription PCR and Western blotting in 20 cases of gastric carcinoma and corresponding normal gastric mucosa. PlexinA1, Ki-67 expression and microvessel density (MVD) were detected by immunohistochemistry in 50 cases of gastric carcinoma and 20 cases of normal gastric mucosa.

RESULTS: The mRNA and protein expressions of PlexinA1 in gastric carcinoma were significantly higher than that in normal gastric mucosa (0.71 ± 0.37 *vs* 0.60 ± 0.25, $P = 0.0299 < 0.05$, and 0.47 ± 0.16 vs 0.21 ± 0.08, $P = 0.0000 < 0.01$), and MVD within tumor tissues increased significantly with PlexinA1 mRNA expression ($r = 0.8736$, $P < 0.01$) and PlexinA1 protein expression ($r = 0.7286$, $P < 0.01$), and MVD of the PlexinA1 positive staining group (25.25 ± 3.93) was significantly higher than that of the negative group (19.56 ± 1.75), ($P < 0.01$). Proliferation index of tumor cells within tumor tissues were positively correlated with PlexinA1 mRNA expression ($r = 0.5420$, $P = 0.014 < 0.01$) and PlexinA1 protein expression ($r = 0.5024$, $P = 0.024 < 0.05$). The proliferation index of the PlexinA1 positive staining group (567.69 ± 125.61) was significantly higher than that of the negative group (369.58 ± 116.88), ($P < 0.01$).

CONCLUSION: PlexinA1 may play an important role in the occurrence and development of gastric carcinoma, and be related to tumor angiogenesis and proliferation.

Key words: PlexinA1; Gastric carcinoma; Angiogenesis; Proliferation

INTRODUCTION

Primary gastric carcinoma is one of the most common malignant tumors in China. Invasion and metastasis are the main causes for the death of cancer patients. On the other hand, invasion and metastasis of malignant tumors are closely related to the proliferation of tumor cells and angiogenesis of tumor tissues. PlexinA1 is a large transmembrane protein that is a major receptor for multiple classes of Somaphorins, either alone or in combination with neuropilins. Although PlexinA1 has pleiotropic function in formation of nervous systems, embryogenesis, angiogenesis and immunoreaction[1-4], the function of Plexin A1 in carcinogenesis remain unrevealed. Therefore, we detected the protein and mRNA expression of PlexinA1 in gastric carcinoma and normal gastric mucosa by the semi-quantitative RT-PCR, Western blotting and immunohistochemistry in order to explore the expression of PlexinA1 in gastric carcinoma and its relationship with tumor angiogenesis and proliferation.

MATERIALS AND METHODS

Patients

Twenty fresh gastric carcinoma specimens and corresponding normal gastric mucosa specimens were analyzed by RT-PCR and Western blotting. All specimens were obtained from patients (8 women and 12 man; mean age 54 years) who underwent surgery for gastric carcinoma between April 2006 and August 2006 in the General Hospital of PLA. Of the 20 patients, 9 showed high-moderate differentiation, 11 poor differentiation and 10 lymph node metastasis. Fifty paraffin-embedded gastric carcinoma specimens and twenty normal gastric mucosa specimens were collected respectively for immunohistochemistry. The patients with gastric carcinoma consisted of 21 women and 29 men with a mean age of 56 years. Of the 50 gastric carcinoma specimens, 23 were highly-moderately differentiated and

27 poorly differented, and 28 had lymph node metastasis. The diagnosis was confirmed by pathological examination.

Reverse transcription PCR (RT-PCR)

Total mRNA was isolated by Trizol reagent according to the procedure of the supplier (BioDev-tech, Beijing, China), and the concentration was determined by measuring the absorbance at 260 nm and using the following data???: 1 optical density unit = 40 mg of RNA/mL. A 1.5 μg aliquot of total RNA from each specimen was reverse-transcribed into single-strand cDNA using oligo (dT)16 primer for 2 h at 37℃, each single-strand cDNA was used for subsequent PCR amplification of PlexinA1 and β-actin with the latter used as a quantitative control. The PCR was carried out in a reaction volume of 50 μL for 5 min at 95℃ for initial denaturing, followed by 37 cycles of 94℃ for 50 s, 55℃ for 50 s, and 72℃ for 1 min, then extend at 72℃ for 10 min on the Authorized Thermal Cycler for PCR. The primer sequences used for amplification were 5'-TGTGGACGACCCCAAATT CTA-3' and 5'-CTGGGCAAACACGGTGAAC-3' for PlexinA1, 5'-ACACCTACCAGGGAACGGAG-3' and 3' -GCCTCTGCACATACCTGCT-5' for β-actin. The primer sequences were synthesized by Beijing Genomics Institute (China). PCR products were resolved in 2% agarose gels and visualized by staining with ethidium bromide. To quantify PCR products, the bands representing amplified products were analyzed by Quantity One Analysis Software (BIO-RAD Co. America).

Western blotting

Expression of the PlexinA1 protein was detected using the Western blot method. After washing in ice-cold PBS, the samples were finely minced and suspended in ice-cold homogenization buffer (2 mL/g tissue), which contained protease inhibitors to minimize protein degradation. The suspension was firstly homogenized, then centrifuged at 12000 × *g* for 30 min at 4℃ to remove the nuclei and cell debris. The supernatant (total protein extract) was collected. Equal amount (50 μg) of proteins was run on a 10% SDS-PAGE gel and electrotransferred onto Hybond-polyvinylidene difluoride membranes (Amersham, Arlington Heights, USA). The membranes were blocked for 2 h at room temperature, followed by incubation with the primary anti-PlexinA1 antibody 1:50 (Santa Cruz Co, USA) at 4℃ overnight. The primary antibody was diluted in TBST containing fat-free milk. After three 10-min washes in TBST, the membrane was incubated in peroxidase-conjugated secondary antibody (Sigma, St. Louis, USA) diluted 1:800 at room temperature for 1 h. Immunoreactive proteins were visualized by autoradiogram using ECL Western blotting detection reagents (Amershan Pharmacia, Uppsala, Sweden) and exposing to X-Omat BT film (Kodak, New York, USA). Bands were analyzed by Quantity One Analysis Software

Immunohistochemistry

PlexinA1 multiclonal antibody 1:50 was purchased from American Santa Cruz Co. Monoclonal antibody of factor Ⅷ and monoclonal antibody of Ki-67 (ready to use) were supplied by the Chinese Boster Co. All operations were performed according to the instructions of the manufacturers. Positive specimens were used as positive controls and PBS in substitution of the first antibody was used as a negative control at the same time.

PlexinA1 expression

The cytoplasm and membrane of positive cells were stained brown by PlexinA1. The result of immunostaining was recorded as negative or positive based on the expression of protein detected. At least 10 surface areas were scored, and the percentage of positive cells was calculated for each specimen. Specimens were classified as positive if more than 30% of the cells were stained at × 400 magnification.

Proliferation index of tumor cells

The nuclei of positive cells were stained deep brown by Ki-67. The number of positive cells among 1000 tumor cells was counted per slide and taken as the tumor cell proliferation index.

MVD of gastric carcinoma tissues

Gastric carcinoma vascular endothelial cells were stained brown. The isolated brown and yellow blood vessel endothelial cells or cell clusters in gastric carcinoma tissues were regarded as a single microvessel (Figure 1A). Areas with the highest microvessel densities were selected under × 100 microscopic magnification. Then the number of microvessels stained by facto Ⅷ antibody in 5 vision fields was counted under × 400 magnification, respectively. The average values were taken as MVD[5]. Indistinguishable or indistinct cells were excluded.

Statistical analysis

All data were analyzed by SPSS12.0 statistical software. *t* test, analysis of Chi-square test, and linear correlation analysis were used. $P < 0.05$ was taken as significant.

RESULTS

Expression of PlexinA1 mRNA by RT-PCR

Two percent of Agarose gel electrophoresis showed a 172 bp PlexinA1 fragment by RT-PCR amplification from gastric caner specimens and normal gastric mucosa (Figure 2). The PlexinA1 mRNA amplification was successful in all tissues. The expression level was higher in tumor (0.71 ± 0.37) than in normal gastric mucosa (0.60 ± 0.25, $P = 0.0299 < 0.05$).

Expression of PlexinA1 protein by western blotting

The affinity-purified anti-plexinA1 antibody detected a major band at 90 kD in protein extracts from all samples tested (Figure 3). The expression level was much higher in tumor (0.47 ± 0.16) than that in normal gastric mucosa (0.21 ± 0.08, $P < 0.01$). This result is matched with that of RT-PCR.

Expression of PlexinA1 by immunohistochemistry

In immunohistochemical staining, PlexinA1 located at the membrane and cytoplasm of gastric carcinoma cells appeared as brown particles. The positive expression rate of PlexinA1 in gastric carcinoma was 52%, significantly

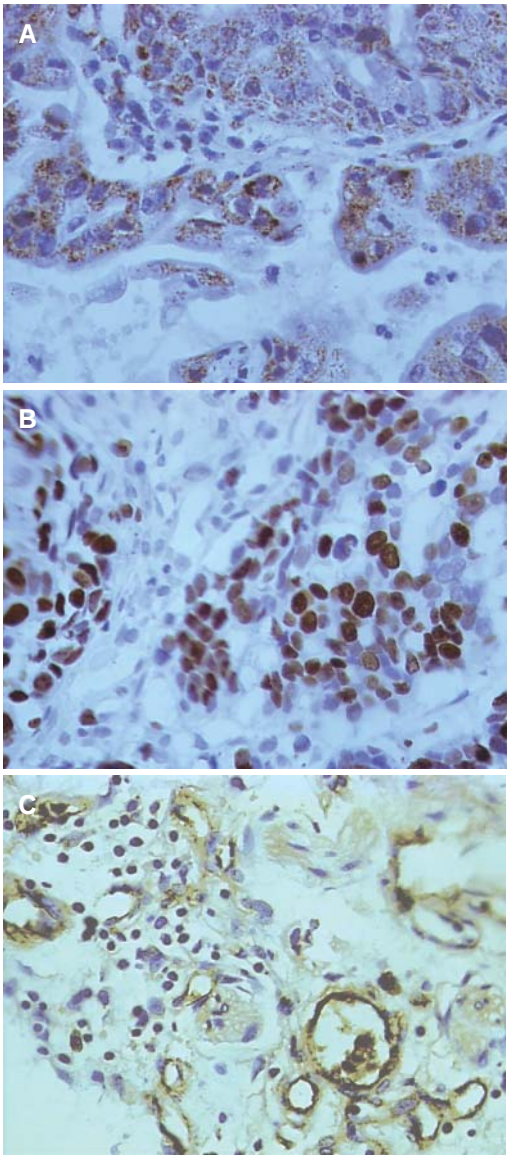

Figure 1 Expression of PlexinA1, Ki-67 and Ⅷ factor in gastric carcinoma tissue (S-P × 400). **A**: PlexinA1; **B**: Ki-67; **C**: Ⅷ factor.

higher than that in normal gastric mucosa (25%), ($P < 0.05$. However, the PlexinA1 expression level had no correlation with the age of patients, tumor size, invasion depth, differentiation degree and lymph node metastasis (Table 1).

Correlation between PlexinA1 and proliferation index of tumor cells in gastric carcinoma

PlexinA1 mRNA and protein expression ratio of gastric carcinoma and the corresponding normal gastric mucosa (T/N) was significantly correlated with proliferation index of tumor cells in gastric carcinoma. Proliferation index of tumor cells within tumorous tissues increased significantly with PlexinA1 mRNA expression ($r = 0.5420$, $P = 0.014 < 0.05$) and PlexinA1 protein expression ($r = 0.5024$, $P = 0.024 < 0.05$). The proliferation index of the PlexinA1 positive staining group (567.69 ± 125.61) was significantly higher than that of the negative group (369.58±116.88), ($P < 0.01$).

PlexinA1 expression and the MVD of tumor tissues

PlexinA1 mRNA and protein expression ratio of gastric carcinoma and the corresponding normal gastric mucosa (T/N) was significantly correlated with the MVD of gastric carcinoma. MVD was elevated with the increase of PlexinA1 mRNA and protein expression. MVD within tumorous tissues increased significantly with PlexinA1 mRNA expression ($r = 0.8736$, $P < 0.01$) and PlexinA1 protein expression ($r = 0.7286$, $P < 0.01$). Also, with increase of PlexinA1 expression of gastric carcinoma tissues by immunohistochemistry, MVD rose as well. The MVD of the PlexinA1 positive staining group (25.25 ± 3.93) was significantly higher than that of the negative group (19.56 ± 1.75), ($P < 0.01$).

DISCUSSION

PlexinA1 is a large transmembrane protein that is receptor

of Semaphorins, either alone or in combination with neuropilin-1 or -2[1,6]. Despite the fact that PlexinA1 plays a crucial role in formation of the nervous system, increasing evidence attested to the significance of PlexinA1 in cardiogenesis. Some works reported that PlexinA1 has multiple functions in cardiogenesis as a receptor for the transmembrane Semaphorin, Sema6D, independent of neuropilins, and it plays a critical role in cardiac morphogenesis by regulating epithelial cell migration[2,7]. These findings suggest that PlexinA1 may regulate angiogenesis in vivo, and raise the intriguing possibility that PlexinA1 may play a role in tumor-induced angiogenesis.

As it is well known, the growth and metastasis of tumors require induction of angiogenesis[8,9]. Without the ability to induce angiogenesis, most neoplasms would fail to grow > 2 mm in diameter or metastasize, including gastric carcinoma. We detected the mRNA and protein expression of PlexinA1 in gastric carcinoma and normal gastric mucosa by the semi-quantity RT-PCR and Western blotting. The results showed that the expression of PlexinA1 in gastric carcinoma was significantly higher than those in normal gastric mucosa. We further detected the expression of PlexinA1 in gastric carcinoma and normal gastric mucosa by immunohistochemistry. The positive expression rate of PlexinA1 in gastric carcinoma was significantly higher than that in normal gastric mucosa. However, the PlexinA1 expression level was not correlated with the age of patients, tumor size, invasion depth, differentiation degree, and lymph node metastasis. These results suggest that PlexinA1 may play an important role in the occurrence and development of gastric carcinoma. MVD and Ki-67 are important index of judging tumor angiogenesis and tumor cell proliferation[10-12].

Under the effect of angiogenesis and proliferation factors, tumor and endothelial cells proliferate and migrate to form new blood vessel networks and induce tumor invasion and metastasis. This study showed that MVD within tumor tissues increased significantly with PlexinA1 mRNA and protein expression, and PlexinA1 expression level of cancer tissues was positively correlated with Ki-67. These results suggest that PlexinA1 may contribute to tumor angiogenesis and tumor cell proliferation through binding its ligands named Semaphorins.

In conclusion, this is the first investigation about the expression of PlexinA1 in gastric carcinoma and its clinicopathological significance. The results of our study shed some light on the pathogenesis of gastric carcinoma, and may represent a new therapeutic target for gastric carcinoma treatment.

COMMENTS

Background

Primary gastric carcinoma is one of the most common malignant tumors in China. Invasion and metastasis are the main causes for the death of cancer patients, and invasion and metastasis of malignant tumors are closely related with proliferation of tumor cells and angiogenesis of tumor tissues. PlexinA1 is a large transmembrane protein that is a major receptor for multiple classes of Somaphorins, and has pleiotropic function in formation of nervous systems, embryogenesis, angiogenesis and immunoreaction, yet the function of PlexinA1 in carcinogenesis has not been intensively studied, including in gastric carcinoma.

Research frontiers

Experiments have been employed to study the expression of PlexinA1 in gastric carcinoma and its relationship with tumor angiogenesis and proliferation. These studies show that the expression level in gastric carcinoma is higher than that in normal gastric mucosa, and is positively related to tumor angiogenesis and proliferation.

Innovations and breakthroughs

This is the first investigation about the expression of PlexinA1 in gastric carcinoma and its clinicopathological significance. PlexinA1 is found positively related to tumor angiogenesis and proliferation, which shed some light on the pathogenesis of gastric carcinoma.

Applications

This study may represent a new therapeutic target for gastric carcinoma treatment.

Peer review

The authors studied the expression of PlexinA1 in gastric carcinoma and its relationship with tumor angiogenesis and proliferation, and showed that the expression level in gastric carcinoma is higher than that in normal gastric mucosa, and is positively related to tumor angiogenesis and proliferation, which may be useful in basic research of gastric carcinoma, and provide a new thought about gastric carcinoma treatment.

Abstract

AIM: To explore the essential characteristics of serum pepsinogen (PG) levels in Chinese people, by analyzing the population-based data on the serum levels of PG Ⅰ and Ⅱ and the PG Ⅰ/Ⅱ ratio, and their influencing factors in Chinese from North China.

METHODS: A total of 6990 subjects, who underwent a gastric cancer screening in North China from 1997 to 2002, were collected in this study. Serum pepsinogen levels were measured by enzyme-linked immunosorbent assay (ELISA). *H pylori* status was determined by histological examination and *H pylori*-IgG ELISA. The cut-off point was calculated by using receiving operator characteristics (ROC) curves. Factors linked to serum PG Ⅰ/Ⅱ ratio were identified using a multivariate logistic regression.

RESULTS: The serum PG Ⅰ and PG Ⅱ levels were significantly higher in males than in females (95.2 μg/L *vs* 79.7 μg/L, $P < 0.01$; 12.1 μg/L *vs* 9.4 μg/L, $P < 0.01$), PG Ⅰ/Ⅱ ratio was significantly lower in males than in females (7.9 *vs* 8.3, $P < 0.01$). The PG Ⅰ/Ⅱ ratio decreased significantly in the aged groups following the progression of gastric mucosa from normal to non-atrophic and atrophic lesions (10.4, 8.8, and 6.6, respectively). The serum PG Ⅰ and Ⅱ levels were significantly higher in patients with *H pylori* infection than in those without *H pylori* infection (88.7 μg/L *vs* 81.4 μg/L, $P < 0.01$; 11.4 μg/L *vs* 8.4 μg/L, $P < 0.01$), while the PG Ⅰ/Ⅱ ratio was significantly lower in patients with *H pylori* infection than in those without *H pylori* infection (7.7 *vs* 9.6, $P < 0.01$). For patients with atrophic lesions, the area under the PG Ⅰ/Ⅱ ROC curve was 0.622. The best cut-off point for PG Ⅰ/Ⅱ was 6.9, with a sensitivity of 53.2%, and a specificity of 67.5%. Factors linked to PG Ⅰ/Ⅱ were sensitive to identified PG using a multinomial logistic regression relying on the following inputs: males (OR: 1.151, 95% CI: 1.042-1.272, $P = 0.006$), age ⩾ 61 years (OR: 1.358, 95% CI: 1.188-1.553, $P = 0.000$), atrophic lesion (OR: 2.075, 95% CI: 1.870-2.302, $P = 0.000$), and *H pylori* infection (OR: 1.546, 95% CI: 1.368-1.748, $P = 0.000$).

CONCLUSION: The essential characteristics of serum PG levels in Chinese are significantly skewed from the normal distribution, and influenced by age, sex, gastric mucosa lesions and *H pylori* infection. PG Ⅰ/Ⅱ ratio is more suitable for identifying subgroups with different influence factors compared with PG Ⅰ or PG Ⅱ alone.

INTRODUCTION

Human pepsinogens (PGs) are inactive pro-enzymes for the specific digestive enzyme--pepsin originating from the gastric mucosa, and can be classified biochemically and immunochemically into pepsinogen Ⅰ (PG Ⅰ) and pepsinogen Ⅱ (PG Ⅱ). Both of them are secreted by the chief and mucous neck cells of the gastric fundus and corpus. PG Ⅱ is also secreted by the pylori glands in the antrum and Brunner's glands in the proximal duodenum. PG Ⅰ and PG Ⅱ are secreted into the gastric lumen and 1% of them are also leaked into circulating blood[1,2]. PG levels in blood seem to be related to the morphologic and functional changes in the stomach, and their use as 'serological biopsy' has been reported over 20 years before[3-5]. Recently, more and more investigators are concerned about the relationship between serum PG levels and gastric precancerous diseases, gastric carcinogenesis, and the significance of them being a marker for the screening of gastric cancer (GC). In most Western countries, the focus has been on the

identification of individuals for intervention studies, whereas in Japan the use of PG levels is to identify those for endoscopic examination and those at risk for GC[6-10]. However, the limited knowledge about their characteristics in different populations and the significant differences in methodologies may prejudice the assessment of consistency. For instance, different cut-off values are used for the positive definition when either PG Ⅰ levels or both PG Ⅰ and PG Ⅱ levels are considered[11-13]. Furthermore, due to few cohort studies have been done in Chinese, the population-based data on serum PG levels and their influencing factors, such as age, sex, the presence of different gastric diseases and *H pylori* infection, are limited[14,15].

In the present study, we measured the serum PG Ⅰ, PG Ⅱ levels in residents from the Zhuanghe County, Liaoning Province, in North China, in order to investigate the essential characteristicss of serum PG levels in Chinese, which is expected to provide a valuable reference for large-scale surveys of gastric cancer.

MATERIALS AND METHODS

Subjects

A total of 6990 subjects (3455 men and 3535 women), who underwent gastric cancer screening in North China from 1997 to 2002, were enrolled in this study. Their mean age was 48.84 years, ranging 11-82 years. Information about gender, age and other factors was obtained by means of a questionnaire administered to each subject. The study was approved by the Human Ethics Review Committee of China Medical University. Written informed consent was obtained from participants in accordance with the Declaration of Helsinki and its later revision.

Serum pepsinogen level

Approximately 5 mL fasting blood was collected from each participant and kept at 4℃ for 24 h. The blood was centrifuged at 3000 r/min for 10 min and the serum aliquot was stored immediately at -20℃ and then shifted to an environment at -70℃ for the determination of various parameters. Serum PG concentration was measured by enzyme-linked immunosorbent assay (ELISA) with PG Ⅰ/PG Ⅱ ELISA kits (Biohit Co., Ltd., Finland).

Endoscopic and clinicopathological examinations

Gastrointestinal endoscopy was performed for observing the entire stomach. Experienced endoscopists performed each examination without knowledge about the serological data on the study subjects. Gastric mucosa was examined, and 4 biopsy specimens were obtained from the body, angulus, antrum and lesions, respectively. The biopsies were routinely bathed in 10% formalin, embedded in paraffin, then sectioned and stained in each local center. The stained sections were evaluated independently by two gastrointestinal pathologists. Each subject was assigned a global diagnosis based on the 4 specimens. Microscopic findings were assessed according to the consensus on chronic gastritis at the national symposium[16] or in combination with the visual analog scale of the updated Sydney System[17], including normal mucosa (NOR, n = 494), superficial gastritis (SG, n = 3954), erosive gastritis and ulcers (GEU, n = 362), superficial gastritis accompanying IM (SG-IM, n = 347), atrophic gastritis (AG, n = 870), gastric polyp(GP, 73 cases), dysplasia (GD, n = 110) and GC (n = 80).

Identification of H pylori infection

Gastric biopsies were evaluated for *H pylori* infection by histological examination. *H pylori* could be found in gastric epithelium or in mucus. Serum immunoglobulin (Ig)G antibodies to *H pylori* were detected by ELISA with *H pylori*-IgG ELISA kit (Biohit Co., Ltd., Finland) in duplicate. Patients whose antibody titer defined by optical density (OD)values according to the manufacturer's protocol, was higher than the cut off value of 42EIU, were regarded as positive for *H pylori* infection.

Statistical analysis

All statistical analyses were performed using SPSS 11.5 software (SPSS Inc. Chicago, USA). The distribution of variables was tested by "Kolmogorov-Smirnov". The relation between two continuous variables was assessed by Spearman's correlation coefficient. The median of variables was compared between two groups by the Mann-Whitney U test and multiple comparisons by the Kruskal-Wallis test. The receiving operating characteristics (ROC) curve for each evaluation was used to extract the corresponding cut-off point, which can be used to discriminate different histological patterns of patients. For that purpose, the area under each ROC curve was used to measure the discriminatory ability of the model. The resulting value of the cut-off point for each evaluation was applied to the determination of the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of the test. Consequently, 95% confidence interval was calculated. Different variables influencing the values of PG Ⅰ, PG Ⅱ and PG Ⅰ/Ⅱ ratio were identified with multivariate logistic regressions adjusted by the histological diagnosis. The value was shown as the median. A two-sided P value of less than 0.05 was considered statistically significant.

RESULTS

Basic population data on PG levels in Chinese

Among the 6990 subjects analyzed, the serum levels of PG Ⅰ and PG Ⅱ and the PG Ⅰ/Ⅱ ratio were significantly skewed from the normal distribution. The median value was 86.9 μg/L, 10.6 μg/L and 8.1 μg/L, respectively.

PG levels in different gender groups

The gender was significantly correlated with the serum PG Ⅰ and PG Ⅱ level (r = -0.178, r = -0.147, P = 0.000). The PG Ⅰ and PG Ⅱ levels were significantly higher in males than in females, while the PG Ⅰ/Ⅱ ratio was significantly lower in males than in females (Table 1).

PG levels in different age groups

All the objects were assigned to four groups based on their

Table 1 Serum PG levels in different gender groups (median)

Gender	Cases (*n*)	PG Ⅰ (μg/L)	PG Ⅱ (μg/L)	PG Ⅰ / Ⅱ
Male	3455	95.2	12.1	7.9
Female	3535	79.7	9.4	8.3
P value		0.000	0.000	0.000

Table 2 Serum PG levels in different age groups (median)

Age (yr)	Cases (*n*)	PG Ⅰ (μg/L)	PG Ⅱ (μg/L)	PG Ⅰ / Ⅱ
A (≤ 40)	1813	86.6[a]	9.9	8.7
B (41-50)	2225	86.9[b]	10.6[d]	8.3[f]
C (51-60)	1840	88.6[c]	11.3[e]	7.8[g]
D (≥ 61)	1112	84.0	10.9	7.0[h]

PG Ⅰ: [a]*P* = 0.017, [b]*P* = 0.031, [c]*P* = 0.019 *vs* D group; PG Ⅱ: [d]*P* = 0.018 *vs* A group, [e]*P* = 0.010 *vs* B group; PG Ⅰ / Ⅱ: [f]*P* = 0.003 *vs* A group, [g]*P* = 0.002 *vs* B group, [h]*P* = 0.002 *vs* C group.

age: group A (≤ 40 years of age), group B (41-50 years of age), group C (51-60 years of age) and group D (≥ 61 years of age), respectively. The serum PG levels were compared between different groups (Table 2). The serum PG Ⅱ level increased with age (correlation coefficient: 0.065, *P* = 0.000), while the PG Ⅰ / Ⅱ ratio decreased with age (correlation coefficient: -0.104, *P* = 0.000).

The PG Ⅰ value increased in groups A (86.6 μg/L), B (86.9 μg/L) and C (88.6 μg/L), though the difference was not significant (*P* = 0.754, *P* = 0.683, respectively). The PG Ⅰ value in group D (84.0 μg/L) was significantly lower than that in groups C (*P* = 0.017), B (*P* = 0.031) and A (*P* = 0.019). The PG Ⅱ value in groups A (9.9 μg/L), B (10.6 μg/L) and C (11.3 μg/L) increased significantly in the sequence indicated (*P* = 0.018, *P* = 0.010, respectively). There was no significant difference in the PG Ⅱ level between groups D (10.9 μg/L) and C (*P* = 0.803). The PG Ⅰ / Ⅱ ratio in groups A (8.7), B (8.3), C (7.8) and D (7.0) decreased significantly in the sequence indicated (*P* = 0.003, *P* = 0.002, *P* = 0.002, respectively).

PG levels and kinds of gastric disease

Along the sequence of NOR→SG→GEU→AG→GC groups, the serum PG Ⅰ and PG Ⅱ levels increased and then decreased, while the PG Ⅰ / Ⅱ ratio decreased gradually. The PG Ⅰ and PG Ⅱ levels in the NOR group were lower than those in other groups, while both of them were the highest in GEU. The PG Ⅰ / Ⅱ ratio in the NOR group was higher than that other groups, while it was the lowest in the GC group. Several statistical differences were noticed. The differences in the PG Ⅱ level and the PG Ⅰ / Ⅱ ratio between NOR and other groups were of statistical significance. The differences in the PG Ⅰ / Ⅱ ratio between SG and other groups were of statistical significance. The differences in PG Ⅰ and PG Ⅱ levels in GEU and other groups were of statistical significance. Compared to SG and GEU groups, the differences in PG Ⅱ level and the PG Ⅰ / Ⅱ ratio were of statistical significance in the AG group, while compared to the GC group, the differences in PG, PG Ⅱ level and the PG Ⅰ / Ⅱ ratio had no statistical significance (Tables 3 and 4).

Table 3 Serum PG levels in different gastric disease groups (median)

Gastric disease	Cases (*n*)	PG Ⅰ (μg/L)	PG Ⅱ (μg/L)	PG Ⅰ / Ⅱ
NOR	494	79.3	7.4	10.4
SG	3654	86.0	9.4	9.0
GEU	362	102.5	14.4	7.5
SG-IM	1347	89.9	12.8	6.8
AG	870	84.8	13.0	6.5
GP	73	87.5	13.3	6.1
GD	110	96.9	15.9	5.7
GC	80	84.4	11.3	6.4

Table 4 Results of Mann-Whitney *U* test

Group	*P* value		
	PG Ⅰ	PG Ⅱ	PG Ⅰ / Ⅱ
NOR *vs* SG	0.000	0.000	0.000
NOR *vs* GEU	0.000	0.000	0.000
NOR *vs* AG	0.021	0.000	0.000
NOR *vs* GC	0.892	0.000	0.000
SG *vs* GEU	0.000	0.000	0.000
SG *vs* AG	0.173	0.000	0.000
SG *vs* GC	0.218	0.060	0.000
GEU *vs* AG	0.000	0.017	0.002
GEU *vs* GC	0.000	0.023	0.137
AG *vs* GC	0.422	0.251	0.809

As described in Table 3, atrophic diseases including AG and GC could be taken as the "low group" (L), and non-atrophic diseases including SG and GEU as the "middle group" (M), and NOR as the "high group"(H). The SG-IM could be assigned to the L group. The argument for the categorization of GP and GD was different. Both of them could be assigned to the L group too, since the PG Ⅰ / Ⅱ ratio decreased along with AG→GC→GP→GD, but there was no significant difference between them (*P* = 0.566). Therefore, the median value of the PG Ⅰ / Ⅱ ratio in H (NOR), M (SG + GEU) and L (SG - IM + AG + GC + GP + GD) groups was 10.4, 8.8 and 6.6, respectively, while the corresponding differences between neighboring groups were of statistical significance (*P* = 0.000, *P* = 0.000). More interestingly, it was possible to differentiate three histological groups according to their median PG Ⅰ / Ⅱ ratio: > 10 for normal mucosa, < 7 for atrophic mucosa, and an intermediate value for non-atrophic mucosa.

ROC curves were plotted for each of the serum tests as a predictor of atrophy. The results obtained from the ROC curves could discriminate between patients with atrophy, normal and non-atrophy (Figure 1). The areas under the ROC curves for PG Ⅰ, PG Ⅱ, and the PG Ⅰ / Ⅱ ratio were 0.494, 0.398 and 0.622, respectively, suggesting that the PG Ⅰ / Ⅱ ratio was the only useful biomarker for screening atrophy in this population. The best cut-off point of the PG Ⅰ / Ⅱ ratio for predicting atrophy was 6.9. The corresponding validity parameters were sensitivity (53.2%), specificity (67.5%), PPV (47.3%), and NPV (72.4%). The accuracy of the PG Ⅰ / Ⅱ ratio as a diagnostic test was 62.4%.

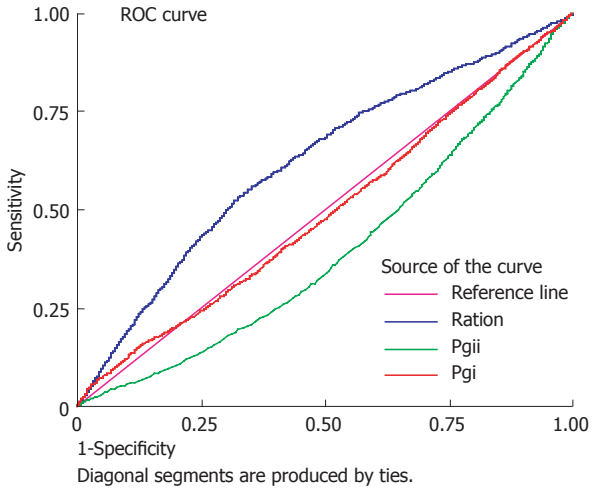

Figure 1 Unadjusted ROC curves for PG Ⅰ, PG Ⅱ and the PG Ⅰ/Ⅱ ratio to discriminate between patients with atrophic lesions and those with normal or inflammatory gastric mucosa.

PG levels and status of H pylori infection

Among the 6990 cases tested, 5285 were positive for *H pylori* infection and 1705 were negative for *H pylori* infection. The PG Ⅰ and PG Ⅱ levels in the positive group were significantly higher than those in the negative group (88.7 μg/L *vs* 81.4 μg/L, $P = 0.000$; 11.4 μg/L *vs* 8.4 μg/L, $P = 0.000$, respectively), while the PG Ⅰ/Ⅱ ratio in the positive group was significantly lower than that in the *H pylori* group (7.7 *vs* 9.6, $P = 0.000$).

Determination of independent variables by multivariable logistic regression

A multivariable logistic regression was performed to determine the dependent variables that could explain the variation of biomarkers. The applied model took four variables of gender, age (< 60 years, ≥ 61 years), gastric mucosal lesion (atrophic or non-atrophic), and *H pylori* infection (+, -) as inputs and considered the PG Ⅰ/Ⅱ ratio (≤ 7, > 7) as the outcome. Results from this regression gave a statistical significance ($\chi^2 = 341.535$, $P = 0.000$). Another qualification for this model was its fitting confidence (13.695, $P = 0.250$). The testing result from this model showed a statistical significance in gender ($P = 0.006$), age ($P = 0.000$), atrophic lesion ($P = 0.000$) and *H pylori* infection ($P = 0.000$). Their corresponding risk factors were male (OR: 1.151, 95% CI: 1.042-1.272), age≥ 61 years (OR: 1.358, 95% CI: 1.188-1.553), atrophic lesion (OR: 2.075, 95% CI: 1.870-2.302) and *H pylori* infection (OR: 1.546, 95% CI: 1.368-1.748) (Table 5). The overall accordance of this model was 64.6%.

Table 5 Multivariable logistic regression of the Pg Ⅰ/Ⅱ ratio

	n	Coeff.	95% CI	*P*-values
Gender				
Female	3535	Baseline		
Male	3455	1.151	1.042-1.272	0.006

H pylori				
H pylori$^-$	1705	Baseline		
H pylori$^+$	5285	1.546	1.368-1.748	0.000

DISCUSSION

In this study, we reported for the first time the essential serum PG levels in the Chinese population, including some influence influencing factors such as sex, age, the presence of gastric diseases, and *H pylori* infection.

Studies have reported some conflicting results with regard to the correlation between serum PG level and age or sex. For instance, men have higher normal PG Ⅰ values than women[18], which is in agreement with the data on blood donors[19]. In contrast, in 20-70 year old Japanese, serum PG level is dependent on the age and PG Ⅰ increases gradually with age, while the PG Ⅰ/PG Ⅱ ratio decreases significantly[20]. In our study, the PG Ⅰ and PG Ⅱ levels were significantly higher in males than in females. The PG Ⅰ/Ⅱ ratio of the males was significantly lower than that of the females. Both PG Ⅰ and PG Ⅱ levels increased gradually till the age of 60 years, while the PG Ⅰ/Ⅱ ratio showed a significant stage reduction. These findings are in agreement with the reported data[9]. These different age-dependences therefore require a thorough checking of the characteristically different distribution, and difference among populations in application value for serum PG. Another important aspect needing special attention is the identification of its normal distribution in different age and gender groups by stratification.

Serum PG is a well-known indicator and "serological biopsy" of corpus mucosa[21,22]. A cascade of mucosal lesions, from chronic gastritis, atrophy, intestinal metaplasia, to dysplasia has been consistently identified, at least for Lauren's intestinal subtype of GC[23]. In this study, along with the sequence of NOR→SG→GEU →AG→GC, the serum PG Ⅰ and PG Ⅱ levels increased while the PG Ⅰ/Ⅱ ratio decreased. When it came to the atrophic lesion from the non-atrophic lesion, both PG Ⅰ and PG Ⅱ levels had a trend to go down, suggesting that the PG Ⅰ/Ⅱ ratio reflects the development of atrophic lesion on gastric membranes better than either PG Ⅰ or PG Ⅱ alone. The PG Ⅰ/Ⅱ values for atrophic gastritis were significantly lower than those for NOR and non-atrophic lesions, while there was no difference among these atrophic lesions, suggesting that the PG Ⅰ/Ⅱ ratio is an effective parameter for screening individuals at high risk of GC[24-28]. We obtained the best cut-off points of the PG Ⅰ/Ⅱ ratio for detecting GC and its precursors by ROC curve with a sensitivity of 53.2% and a specialty of 67.5%, which can be used for further investigation as a screening tool in the first period.

H pylori infection frequently persists lifelong in the host stomach and is associated with a wide spectrum of human gastric and duodenal diseases, ranging from gastritis to duodenal ulcer, GC and MALT lymphoma[29,30]. In 1994, it was defined as a definite carcinogen by the International

Agency for Research on Cancer[31]. It was reported that *H pylori* stimulates G cells in the antrum, thus increasing the level of gastrin they secreted[32]. Gastrin directly stimulates the main cells and is able to stimulate the synthesis and secretion of PGs, especially PGⅡ by increasing the density of calcium-ion flux, cAMP and phosphoinositide inside the main cells. Serum epidemiological studies showed that *H pylori* infection correlates significantly to the elevated serum PG especially PGⅡ, and the reduced PG Ⅰ/Ⅱ ratio[33]. Our previous study revealed that the incidence of *H pylori* infection is 79.3% in Zhuanghe County[34]. In the present study, the serum PG Ⅰ and Ⅱ levels in positive *H pylori* individuals were significantly higher than those in negative *H pylori* individuals, and the PG Ⅰ/Ⅱ ratio was lower in positive *H pylori* individuals than in negative *H pylori* individuals, confirming that *H pylori* infection influences the serum PG level in residents of Zhuanghe County.

Multivariable logistic regression with the PG Ⅰ/Ⅱ ratio as the outcome showed that the PG Ⅰ/Ⅱ levels were significantly affected if the surveyed samples met any one of the following qualifications: male, age > 60 years, atrophic lesion and *H pylori* infection, showing that all these factors should be taken into account in the screening of GC with serum PGs.

In summary, our results from this population-based study provide the essential characteristics of serum PG in Chinese. The PG Ⅰ/Ⅱ ratio is more suitable for identifying subgroups with different influencing factors, compared with PG Ⅰ or PGⅡ alone. This implies that low PG Ⅰ/Ⅱ ratio can be used as a serological indicator of gastric atrophic diseases.

COMMENTS

Background

Human pepsinogens (PGs) are inactive pro-enzymes for the specific digestive enzyme--pepsin originating from the gastric mucosa, and can be classified biochemically and immunochemically into pepsinogen Ⅰ (PG Ⅰ) and pepsinogen Ⅱ (PG Ⅱ). Serum PG levels are related to the morphologic and functional changes in the stomach, and can be used as a 'serological biopsy'.

Research frontiers

In the present study, we investigated the essential characteristics of serum PG in Chinese, which provides a valuable reference for large-scale surveys of gastric cancer in China.

Innovations and breakthroughs

In this study, we analyzed the essential characteristics of serum PG levels and their influencing factors in residents from the Zhuanghe County in North China. Our results that serum PG skewed from the normal distribution significantly, and was influenced by age, sex, the gastric mucosa lesions and *H pylori* infection. The PG Ⅰ/Ⅱ ratio was more suitable for identifying subgroups with different influencing factors, compared with PG Ⅰ or PGⅡ alone.

Applications

The essential characteristics of serum PG in Chinese are described. The PG Ⅰ/Ⅱ ratio is more suitable for identifying subgroups with different influence factors and can be used as a serological indicator of gastric atrophic diseases.

Peer review

This paper presents the serum pepsinogen values and their influencing factors in a large group of Chinese from North China, which is of certain importance. However, a large room for improvement in its language.

Abstract

AIM: To identify and understand the regular distribution pattern and primary penetration site for *Salmonella* enteritidis (*S*. enteritidis) in the gastrointestinal tract.

METHODS: Based on the species-specific DNA sequence of *S.* enteritidis from GenBank, a species-specific real-time, fluorescence-based quantitative polymerase chain reaction (FQ-PCR) was developed for the detection of *S.* enteritidis. We used this assay to detect genomic DNA of *S.* enteritidis in the gastrointestinal tract, including duodenum, jejunum, ileum, cecum, colon, rectum, esophagus and stomach, from mice after oral infection.

RESULTS: *S.* enteritidis was consistently detected in all segments of the gastrointestinal tract. The jejunum and ileum were positive at 8 h post inoculation, and the final organ to show a positive result was the stomach at 18 h post inoculation. The copy number of *S.* enteritidis DNA in each tissue reached a peak at 24-36 h post inoculation, with the jejunum, ileum and cecum containing high concentrations of *S.* enteritidis, whereas the duodenum, colon, rectum, stomach and esophagus had low concentrations. *S.* enteritidis began to decrease and vanished at 2 d post inoculation, but it was still present up to 5 d post inoculation in the jejunum, ileum and cecum, without causing apparent symptoms. By 5 d post inoculation, the cecum had significantly higher numbers of *S.* enteritidis than any of the other areas ($P < 0.01$), and this appeared to reflect its function as a repository for *S.* enteritidis.

CONCLUSION: The results provided significant data for clarifying the pathogenic mechanism of *S.* enteritidis in the gastrointestinal tract, and showed that the jejunum, ileum and cecum are the primary sites of invasion in normal mice after oral infection. This study will help to further understanding of the mechanisms of action of *S.* enteritidis.

Key words: Fluorescence-based quantitative polymerase chain reaction; Gastrointestinal tract; *Salmonella* enteritidis

INTRODUCTION

Salmonella is an enteric pathogen that colonizes the intestinal tract of a variety of animals, especially humans and poultry, and accounts for millions of cases of gastroenteritis and food-borne illness each year[1,2]. *Salmonella* enteritidis (*S*. enteritidis) can be transmitted to humans through the food production chain, and undercooked or raw eggs and poultry meat are a particularly high risk for humans[3]. In the last few decades, *S*. enteritidis has emerged as a major cause of food-borne illness worldwide. As a result of the increased prevalence of *S*. enteritidis and its complex life cycle, identifying the regular distribution pattern of *S*. enteritidis in the gastrointestinal tract will help to understand its mechanism of action.

Previous studies have shown that orally introduced *S*. enteritidis has a rapid transit time through the intestine, and a small proportion of the inoculum establishes itself within the walls of the small intestine and cecum several

days before systemic infection[4,5]. However, the primary site of infection and the route taken by the organism to reach the heart, liver and spleen, are unclear. Infection with *Salmonella* is usually started by oral ingestion of the pathogen, and is followed by bacterial colonization of the gut and invasion of internal tissues. Therefore, knowledge about the mechanisms leading to invasive infections may ultimately lead to new insights into prevention and therapy.

We evaluated the specific fragment (Sdf I) reported by Agron[6], which was screened for using the Supression Subtractive Hybridization method. Sdf I appears to only be found in serovar enteritidis strains, which includes a wide range of clinical and environmental species. Here, based on the specific DNA sequence of serovar enteritidis, a specific fluorescent quantitative polymerase chain reaction (FQ-PCR) for detection of serovar enteritidis was developed and applied to the study of the gastrointestinal tract distribution of *S*. enteritidis.

MATERIALS AND METHODS

Bacterial strains

A total of 14 *Salmonella* strains were included in this study. Most strains were purchased from the National Center for Medical Culture Collection, including *S*. enteritidis (Human, No. 50041), *S*. enteritidis (Human, No. 50040), *S*. enteritidis (Mouse, No. 50338), *Salmonella* Choleraesuis (No. 50191-1), *Salmonella* Typhi (No. 50013), *Salmonella* Typhimurium (No. 50115-13), *Salmonella* Paratyphi (No. 50001-24), *Salmonella* Pullorum (No. 50047-2), *Salmonella* Anatum (No. 50083-4), *Salmonella* Gallinarum (No. 50770), *Salmonella* Dublin (No. 50761). Three strains were isolated and maintained by the Research Center of Poultry Diseases, Collage of Animal Science and Veterinary Medicine of Sichuan Agricultural University, including *S*. enteritidis (Duck, No. MY_1), *S*. enteritidis (Duck, No. SC1) and *S*. enteritidis (Chicken, No. CD1).

Preparation of bacterial samples and generation of standard templates

For the bacterial samples, 5 mL of an overnight culture grown in Luria-Bertani broth was prepared, and then the *S*. enteritidis cells were harvested by centrifugation. The pellet was resuspended in lysozyme solution, followed by lysis using 10% SDS at 60℃ for 1 h. DNA was purified by extraction with an equal volume of phenol/chloroform/isoamyl alcohol (25:24:1). Then, a 1/10 volume of 3 mol/L sodium acetate and 2 vols absolute ethanol were added, and the nucleic acid was then pelleted by centrifugation, washed with 70% ethanol, and dried under vacuum. The DNA genomic pellet was resuspended in 40 μL TE buffer, and stored at -20℃ until use.

A conventional PCR was carried out using a template from *S*. enteritidis (Mouse, No. 50338), with primers F_1 and R_1 (designed with Sdf I , GenBank Accession No. AF370707.1, generated by TakaRa Biotech, Dalian, China). The primer sequences from 5' to 3' were as follows: F_1, TGTGTTTTATCTGATGCAAGAGG; and R_1, CGTTC TTCTGGTACTTACGATGAC. Amplification was carried out in a total volume of 50 μL, containing 1 μL each primer (25 μmol/L), 1 μL dNTPs (10 mmol/L), 2.5 U Taq DNA Polymerase (TaKaRa Taq; TakaRa Biotech), 5 μL 10 × PCR buffer (with Mg^{2+}, 25 mmol/L) and 2 μL templates, which were then made up to a volume of 50 μL with deionized water. An initial denaturation at 95℃ for 5 min was followed by 32 cycles of denaturation at 94℃ for 30 s, annealing at 52.5℃ for 30 s, and extension at 72℃ for 40 s. Finally, an additional extension was achieved for 10 min at 72℃. The product size was 293 bp.

Finally, the product was gel-excised and quantified with appropriate standards. Its concentration was determined spectrophotometrically using the Bio-Rad Smartspec-3000, according to the manufacturer's instructions. The standards were diluted, divided into aliquots, and frozen before use.

Specific verification of FQ-PCR and its products

The FQ-PCR assay, including volume, Mg^{2+} concentration, probe and primer concentrations, and annealing temperature were optimized. Subsequently, the sensitivity of the assay, the linear range and standard curve were determined by using known amounts of purified template DNA (generated as described above). The primers (F_2 and R_2) and TaqMan-probe (FP) of FQ-PCR were designed using an internal region of the 293 bp sequences (described above, generated by TakaRa Biotech), and were used as follows, from 5' to 3': F_2, TTGATGTGGTTGGTTCGTCACT; R_2, TCCCTGAA TCTGAGAAAGAAAAACTC; and TaqMan-probe (FP), FAM-TGCAGCGAGCATGTTCTGGAAAGC-TAMRA. Amplification was carried out in a total volume of 25 μL, containing 0.6 μL each primer (10 μmol/L), 0.75 μL dNTPs (10 mmol/L), 1.25 U Ex Taq DNA Polymerase (TaKaRa Ex Taq Hot Start Version; TakaRa Biotech), 5 × PCR buffer (free Mg^{2+}) 5 μL, 0.8 μL TaqMan probe (5 μmol/L), 0.5 μL Mg^{2+} (250 mmol/L) and 1 μL templates, then made up to a volume of 25 μL with deionized water. Each run consisted of a 95℃ 5 min hot start, which activated the conjugated polymerase, followed by 45 cycles (50 cycles for sensitivity experiments) with 94℃ denaturation for 30 s, 55℃ annealing for 30 s, and reading the fluorescent signal at this step.

The primers of FQ-PCR (F_2 and R_2) were used for conventional PCR with *S*. enteritidis (Mouse, No. 50338) DNA templates, in order to verify the specific amplification. Amplification was carried out in a total volume of 50 μL, containing 1 μL each primer (25 μmol/L), 1 μL dNTPs (10 mmol/L), 2.5 U Taq DNA polymerase (TaKaRa Taq; TakaRa Biotech), 10 × PCR buffer (with Mg^{2+}, 25 mmol/L) 5 μL, and 2 μL templates, then made up to a volume of 50 μL with deionized water. Initial denaturation at 95℃ for 5 min was followed by 32 cycles of denaturation at 94℃ for 30 s, annealing at 49℃ for 30 s, and extension at 72℃ for 40 s. Finally, an additional extension was achieved for 10 min at 72℃. A 10 μL aliquot of PCR product was electrophoresed on a 1.5% agarose gel for 40-50 min at 80 V, and visualized and photographed under UV illumination.

FQ-PCR standard curve

Based on previous studies, the standard curve was generated as follows[7-9]: Standard DNA from *S*. enteritidis

was used to establish a standard curve. The standard DNA contained amplified target DNA in different quantities which was included in each LightCycler run. The Primers F_2 and R_2 were used for this amplification, and a range of 9×10^8 - 9×10^3 gene copies was used. Concentrations of the standards were measured by fluorometric analysis, and an analysis of key LightCycler measures was performed after each run to verify identical amplification efficiencies and conditions between runs. Finally, these data were used to generate the standard curve through the iCycler IQ Detection System (Bio-Rad, USA) software.

Reproducibility

To evaluate the variability between experiments, four different known concentrations of DNA were amplified by performing the assay described above in triplicate. For each experiment, the crossing point, average crossing point, standard deviation, and coefficient of variation for each assay were calculated.

Sensitivity of FQ-PCR

To determine the detection limit of this FQ-PCR assay, different quantities of standard DNA and different cell numbers of *S*. enteritidis were introduced in the FQ-PCR. A range of 4×10^3 - 4×10^{-1} copies of standard DNA of *S*. enteritidis was added. Then, the results of each concentration were measured by fluorometric analysis. Bacterial cell limit detection was as follows: *S*. enteritidis (Mouse, No. 50338) grown aerobically at 37℃ for 18 h in 5 mL Luria-Bertani broth. Subsequently, 1 mL of overnight culture was harvested, and the pellet was resuspended in 500 μL TE buffer (pH 8.0), from which the number of *S*. enteritidis cells was obtained by conventional viable count method. Then, a 10 fold serial dilution was performed on the overnight culture liquor, and the phenol/chloroform/isoamyl alcohol method was used to extract the DNA template serially from 10^{-6} - 10^{-10} serial dilutions of bacterial liquor. Finally, 1 μL aliquot per concentration of the DNA template was subjected to a test of bacterial cell sensitivity, and the result of the viable count was used to obtain the final result. The FQ-PCR was performed and analyzed as described above.

Specificity of the FQ-PCR

All 14 bacterial strains were used to assess the specificity of the FQ-PCR. The boiling method was used to prepare the DNA template, and 4 μL of this was used in FQ-PCR.

Experimental infection of mice

Our infection model was based on previous studies, which showed that orally introduced *S*. enteritidis had a rapid transit time through the intestine and establishes itself within the walls of the gut for more than 3 d[4,5,10-12,20]. Twenty-eight mice (age 9 wk, specific-pathogen-free) were purchased from the Animal Center of Sichuan University, China. In brief, a group of 14 white mice were orally infected with a virulent S. enteritidis strain (Mouse, No. 50338), at 2.0×10^4 cells per mouse. Another group of 14 white mice was treated with an equal volume of water as a control. Duodenum, jejunum, ileum, cecum, colon, rectum, esophagus and stomach were analyzed by FQ-PCR at different post-inoculation time points, at 30 min, 1, 2, 4, 8, 12, 16, 18, 24 and 36 h, and 2, 3, 4 and 5 d.

One mouse from each group was sacrificed at each time point and its organs were aseptically removed and immediately placed in 1.5 mL labeled snap-cap tubes. The contents were gently removed by lightly squeezing the excised organ and washing twice with 0.85% NaCl. Finally, the tissue samples, without contents in lumens, were placed in 1.5 mL labeled snap-cap tubes and frozen before use.

DNA extraction from the tissue samples was as follows. 0.3 g tissue samples from different segments of the gastrointestinal tract were washed with 0.85% NaCl twice in order to confirm the removal of contents in lumens. Then, the samples were ground in 1.5 mL Eppendorf tubes using a conventional method. The pellet was resuspended in 500 μL TE buffer (pH 8.0) with 10 μL proteinase K (30 mg/mL) and incubated at 37℃ for 3 h. Finally, a conventional phenol/chloroform/isoamyl alcohol method (preparation described above) was used to extract the genomic DNA of *S*. enteritidis from tissue, and 1 μL aliquot of the sample DNA template was used for FQ-PCR detection.

RESULTS

Specific verification of FQ-PCR products

The primers of FQ-PCR were used for conventional PCR with *S*. enteritidis (Mouse, No. 50338) DNA templates, in order to verify the specific amplification. Results showed that the PCR produced an intense band with the expected 130 bp for *S*. enteritidis, which indicated 100% specificity.

FQ-PCR standard curve

One of the main advantages of FQ-PCR is the ability to quantitate unknown samples. With this assay, it is possible to carry out a rapid quantitative analysis of DNA over a wide linear range, with an unknown template. By using a standard template containing from 9×10^8 - 9×10^3 copies, accurate results for a series of samples were obtained, based on the data used to generate the standard curve with the iCycler IQ Detection System. The correlation coefficient for the associated standard curve was 1.000 and PCR efficiency was 97.3%, indicating that the crossing threshold values for the standards fell within an acceptable range. Using the following formula, we could quantitate the number of DNA copies of *S*. enteritidis for unknown samples: $Y = -3.389X + 44.276$ (where Y is the threshold cycle, and X the log of the starting quantity) (Figure 1).

Sensitivity of PCR

A range of 4.0×10^3-4.0×10^{-1} copies of the *S*. enteritidis standard template was used, and the limit of detection was 4 copies/μL. A sensitivity of 6 cfu/mL was obtained when 10-fold serial dilutions of bacterial cell cultures were used as the PCR template (Figure 2).

Reproducibility

Four different, known concentrations of DNA (1.2×10^9-1.2×10^6 copies/μL) were amplified by performing the

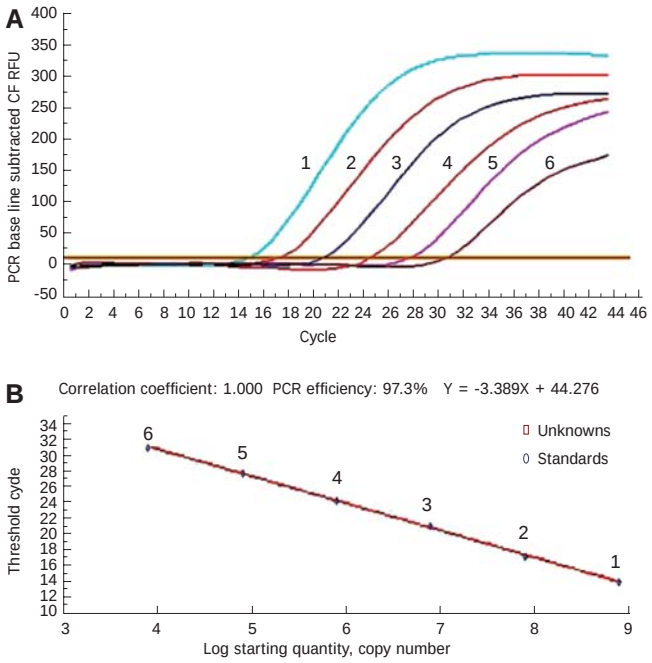

Figure 1 Standard DNA template with 10 fold serial dilutions used to develop the standard curve. 1: 9 ×10^8 copies/μL; 2: 9 × 10^7 copies/μL; 3: 9 × 10^6 copies/μL; 4: 9 × 10^5 copies/μL; 5: 9 × 10^4 copies/μL; 6: 9 × 10^3 copies/μL.

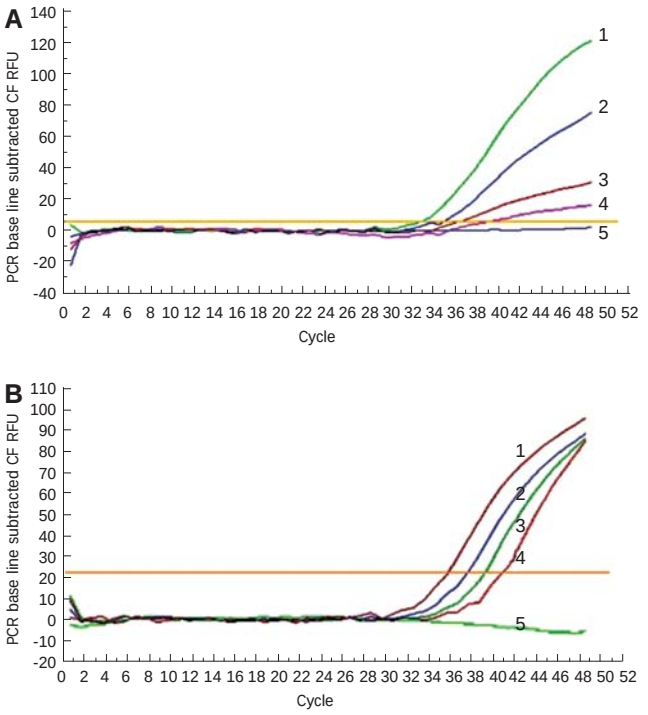

Figure 2 **A**: Sensitivity of FQ-PCR detection using 10 fold serial diluted S. enteritidis (Mouse, 50 338) standard template. 1: 4.0 × 10^3 copies/μL; 2: 4.0 × 10^2 copies/μL; 3: 4.0 × 10^1 copies/μL; 4: 4.0 × 10^0 copies/μL; 5: 4.0 × 10^{-1} copies/μL; **B**: Sensitivity of FQ-PCR detection used 10 fold serial diluted S. Enteritidis (Mouse, 50338) cell number. 1: 6.0 × 10^3 CFU/mL; 2: 6.0 × 10^2 CFU/mL; 3: 6.0 × 10^1 CFU/mL; 4: 6.0 × 10^0 CFU/mL ; 5: 6.0 × 10^{-1} CFU/mL.

assay described above in triplicate. Analysis of these values proved that the assay was reproducible, as the coefficient of variation was statistically low, at < 1.5%. The threshold cycle for each concentration ranged from 1.2 × 10^9-1.2 × 10^6 copies/μL and was different between 0.1-0.3 cycles and highly reproducible (Figure 3).

Specificity of the PCR

All 14 bacterial strains used to assess the specificity of the PCR indicated that only *S. enteritidis* genomic strains showed positive results, while there was no amplification with non-*S.* enteritidis strains (data not shown).

Distribution of S. enteritidis in the gastrointestinal tract

The distribution of *S.* enteritidis within the gastrointestinal tract after oral infection was determined by means of FQ-PCR at intervals on separate segments of gut over a 5-d period. Results showed that the jejunum and ileum were positive at 8 h postinoculation, with approximately 200 copies/g. Then, *S.* enteritidis was consistently detected in all segments of the gastrointestine at 8 h post inoculation, and the last organ to show a positive result was the stomach at 18 h post inoculation. The copy numbers of *S.* enteritidis in each tissue reached a peak at 24-36 h, with the jejunum, ileum and cecum containing high concentrations of *S.* enteritidis, whereas the duodenum, colon, rectum, esophagus and stomach had low concentrations. Numbers of bacteria decreased at 2-3 d, and by 4 d the level of *S.* enteritidis had clearly decreased, with the duodenum, colon, esophagus and stomach not having a positive result. The rectum had about 10 copies/g at 4 d post inoculation, and then the bacteria vanished. The rectum carried the *S.* enteritidis for up to 5 d in others without causing apparent symptoms. Importantly, with respect to the number of

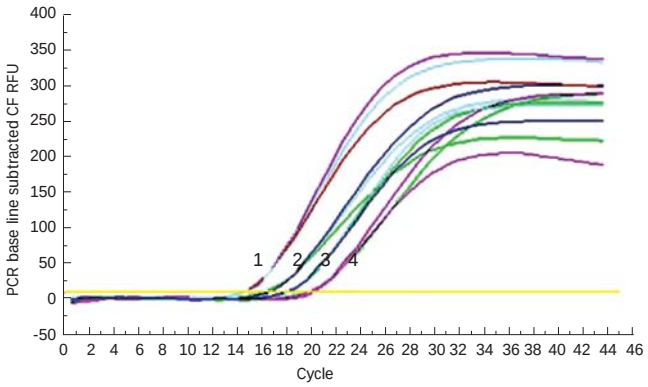

Figure 3 Reproducibility of FQ-PCR. 1: 1.2 × 10^9 copies/μL; 2: 1.2 × 10^8 copies/μL; 3: 1.2 × 10^7 copies/μL ; 4: 1.2 × 10^6 copies/μL.

S. enteritidis cells at 5 d postinoculation, compared to the other organs the cecum had significantly higher numbers of *S.* enteritidis than all of the other regions, with $10^{3.3}$ copies/g, whereas the jejunum had $10^{1.5}$ copies/g, and the ileum had $10^{1.3}$ copies/g ($P < 0.01$). The control group did not have any positive results at any time in any location. The details are given in Table 1.

DISCUSSION

Attachment to host tissues is the first important step for establishing a bacterial infection[13,14]. The fimbria *Sef* 14 is found in a limited number of *Salmonella enterica*

serovars, including enteritidis. This surface structure appears to be required for macrophage uptake and survival in intraperitoneal infections[15], in contrast to other *Salmonella* fimbriae that promote binding to host epithelial cells[16]. There is also evidence that quorum sensing plays an important role in the life cycle of *Salmonella* serovar enteritidis[17]. Upon interaction with the intestinal epithelium, *Salmonella* can induce changes in the brush border known as membrane ruffles, survive and multiply there[18]. This study showed that *S.* enteritidis in orally infected mice very quickly reached the intestinal tract, especially the jejunum and ileum. We suggest that penetration by *S.* enteritidis occurs in the upper half of the gastrointestinal tract, which possibly indicates sites that are more easily penetrated by *S.* enteritidis. This finding is compatible with results obtained in previous studies, which showed that *S.* enteritidis has a rapid transit time through the normal mouse intestine; a small proportion of the inoculum establishes itself within the walls of the small intestine, before a systemic infection can be demonstrated[4,5,19]. However, these studies were unable to precisely establish the primary site of bacterial invasion in these animals. From our study, it seems reasonable that the jejunum and ileum are most likely sites for bacterial penetration that is responsible for systemic infection. First, the jejunum and ileum were positive at 8 h post inoculation. Second, the *S.* enteritidis copy number reached a maximum between 8 h and 36 h post inoculation, with copies of *S.* enteritidis being about 10-10 000 times that of other regions. Finally, by 4 d post inoculation, the level of *S.* enteritidis clearly decreased, with no bacteria in the duodenum, colon, esophagus and stomach, but *S.* enteritidis remained in the jejunum, ileum and cecum for up to 5 d post inoculation. At 12 h post inoculation, the *S.* enteritidis in the cecum were increasingly obvious, but less so in the jejunm and ileum (about 10 times fewer) at 24-36 h post inoculation. By 5 d post inoculation, the cecum had significantly higher numbers of *S.* enteritidis than all the other areas, with $10^{3.3}$ copies/g, whereas the jejunum had $10^{1.5}$ copies/g, and the ileum had $10^{1.3}$ copies/g ($P < 0.01$). Therefore, this appeared to reflect the function of the cecum as a repository for *S.* enteritidis and a site for its penetration. By way of contrast, Ozawa[20] has concluded that the primary site of *Salmonella* infection involves the cecum and the large intestine.

Mucosal immunity provides the first line of protection following oral exposure to pathogens. In particular, the involvement of mucosal IgA in protection against salmonellosis has been reported[21]. Secretory IgA limits mucosal colonization by *S.* enteritidis by preventing adherence and subsequent invasion of the bacteria[22,23]. The environment of the gastrointestinal tract can also prevent invasion by *S.* enteritidis to some extent. The lowest concentration of *S.* enteritidis was found in the stomach, and this was the last area in which *S.* enteritidis was detected, which indicates that environmental factors, such as pH, can influence the survival and virulence of *S.* enteritidis. It has been reported that normal host defenses are capable of eliminating > 80% of organisms from the gut within hours[20]. Most of the *Salmonella* in the challenge inoculum had no pathogenic significance, since only a few organisms passed through the mucosa of the ileum during the initial hours of infection. A previous study has shown that *S.* enteritidis colonization in the gastrointestinal tract can persist for as long as 18 wk post inoculation in hens[24]. Nevertheless, these few organisms have the potential to cause a lethal systemic infection[20]. Changes in the microenvironment in the gastrointestinal tract have important implications for understanding the gastrointestinal factors necessary for protection against *S.* enteritidis infection. *S.* enteritidis is distributed evenly along the intestinal tract, and the microenvironment may be a predictor for severity of *S.* enteritidis invasion and infection[25,26].

FQ-PCR has become a potentially powerful alternative in microbiological diagnosis due to its simplicity, rapidity, reproducibility and accuracy. The specific primer-probe combination is a powerful tool for detecting the genetic content of closely related bacterial species[27,28]. A series of sensitivity experiments was performed and proved that the detection limit of this method was 4 copies/μL for standards template, and 6 cfu/mL for bacterial cell number. Four different, known concentrations of DNA were amplified by performing the assay described above in triplicate, and showed a coefficient of variation less than 1.5%. Also, one of the main advantages of FQ-PCR is the ability to quantitate unknown samples. With this assay, it is possible to carry out a rapid quantitative analysis of DNA over a wide linear range, with an unknown template. Simultaneously, variation in results may be due to the extraction efficiency of DNA, the PCR inhibitors, or a large amount of DNA from background organisms.

In conclusion, our results provide significant data for clarifying the pathogenic mechanism of *S.* enteritidis in the gastrointestinal tract, and show that the jejunum, ileum and cecum are the primary sites of invasion in normal mice after oral infection. This study will help to understand the mechanisms of action of *S.* enteritidis.

COMMENTS

Background

There are over 2500 serovars in the genus *Salmonella*. It has been a public health concern for over 100 years, and the incidence of *Salmonella* infections has risen dramatically, especially those caused by *S.* enteritidis. Therefore, knowledge about *Salmonella* infection could be an additional means for decreasing the incidence of infection. Infection with *Salmonella* is usually started by oral ingestion of the pathogen, and is followed by bacterial colonization of the gut and invasion of internal tissues. Therefore, it is necessary to understand its mechanisms of action in the gastrointestinal tract.

Research frontiers

To date, the exact site of primary penetration of *S.* enteritidis in the gut has not been established. FQ-PCR, as a rapid, sensitive technique for precise quantitation of nucleic acid, will be an ideal method to study the distribution of *S.* enteritidis in the gastrointestinal tract.

Innovations and breakthroughs

Previous studies have shown that *S.* enteritidis establishes itself within the walls of the small intestine before a systemic infection can be demonstrated. However, these studies have been unable to identify the regular distribution pattern and the primary site of *S.* enteritidis invasion. In this study, we offered a significant improvement over previous studies, and suggested that the jejunum, ileum and cecum are the primary sites of invasion after oral infection.

Applications

This study will provide significant data for clarifying the pathogenic mechanisms of *S.* enteritidis in the gastrointestinal tract, and may ultimately lead to new insights in prevention and therapy.

Terminology

Standard DNA template: The purified target DNA fragment for FQ-PCR amplification that is usually used to generate standard curves. It can be generated by gel excised directly after a conventional PCR amplification or after the target fragment is cloned using plasmid DNA.

Peer review

This study detected FQ-PCR *S.* enteritidis in different segments of the gastrointestinal tract in mice after oral infection, and demonstrated the regular distribution pattern and primary penetration sites of *S.* enteritidis. The method is simple and accurate, and it may lead to new ways to prevent *S.* enteritidis infection.

Abstract

AIM: To study the inhibitory effects of a Shuangling Fuzheng anticancer preparation (SFAP) on the human gastric cancer cell line SGC-7901 *in vitro* as well as its immune-modulated effects in a cyclophosphamide-treated murine model.

METHODS: MTT experiments and immunocytochemistry ABC experiments were performed for detecting the proliferation of SGC-7901 cells *in vitro* and protein expression of c-myc. The staphylococcal protein A (SPA) rosette test was utilized for measuring the ratio of T-lymphocyte subsets from peripheral blood in a cyclophosphamide-treated murine model. Enzyme-linked immunosorbant assay (ELISA) was performed for measuring the levels of serum sIL-2R in treated mice, while immunoturbidimetry was used for measuring the levels of immunoglobulins (Ig).

RESULTS: SFAP (40-640 mg/L, 48 h) inhibited the proliferation of SGC-7901 cells, and a positive correlation was noted between inhibitory effects and dosage. At a dosage of 160-320 mg/L in cultured cells, the expression of c-myc was decreased. SFAP (50-200 mg/kg) increased the percentage of $CD3^+$ and $CD4^+$ T-lymphocytes, the ratio of CD4/CD8, and the contents of Ig such as IgM, IgG or IgA, but decreased the levels of serum sIL-2R in peripheral blood from cyclophosphamide-treated mice.

CONCLUSION: SFAP can inhibit the proliferation of SGC-7901 cells *via* the c-myc gene. In addition, SFAP can modulat the cellular and humoral immunity in cyclophosphamide-induced immunosuppressed mice.

INTRODUCTION

Shuangling Fuzheng anticancer preparation (SFAP) is made through the basic modification of Fuzheng anticancer granules (FAG). Clinical research has shown that FAG have a therapeutic effect for many tumor patients. An empirical study has shown that FAG can prolong the life of tumor-bearing mice and inhibit transplanted tumors. However, this inhibition ratio is lower than 30%[1-3]. Modern pharmacologic studies have shown that atractylodes macrocephalae volatile oil[4], coixenolide[5-7], polysaccharides[8,9] and some other active constituents have anticancer activities. At the precondition of Chinese Medical Syndrome Differentiation, we extracted some of the effective anticancer constituents from FAG and developed SFAP. The main of making SFAP include extraction of volatile oils from atractylodes macrocephalae, coixenolide from coix seed, and polysaccharides from part of Fuzheng traditional Chinese medicines, boiling the other drugs with water as per the traditional method, and concentrating all constituents into a capsule preparation. The results of this experiment showed that the ratio of SFAP anticancer activity was significantly greater than 30%[10]. The present study reports the effects of SFAP on the proliferation of human gastric cancer cells and the expression of related genes *in vitro*, as well as its modulating effects on immune function in a cyclophosphamide-treated murine model.

MATERIALS AND METHODS

Cell line and animals

Human gastric cancer SGC-7901 cells, purchased from the Department of Cellular and Molecular Biology, Shanghai Institute of Biochemistry and Cell Biology, Academia

Sinica, were cultured *in vitro* for 2-3 d. ICR mice (at the age of 6-7 wk, weighing 18-22 g; 50% females) were obtained from Yangzhou University Medical Centre [animal production license number: SCXK (Su) 2002-0009].

Drugs and reagents

SFAP was made from *Smilacis rhizome*, Tuckahoe, honey-fried *Astragalus mongholicus*, *Atractylodes macrocephala*, coix seed, processed *Pinelliae tuber*, *Aurantii nobilis pericarpium* and the like. We extracted volatile oil from *Atractylodes macrocephala*, coixenolide from *Coicis semen*, and polysaccharides from other drugs by boiling in water. They are then mixed at the concentrations specified according to previous formulations. Lastly, the dried drugs were ground into coffee granules. An invention patent for the SFAP preparation protocol has been applied (application No.: 200610161699.5). SFAP was resuspended with RPMI 1640 (GibcoBRL, Maryland, USA) to a suitable dosage, filtrated, sterilized and stored at 4℃ for testing *in vitro*. MTT was from Sigma (St. Louis, MO, USA). Calf serum, trypsin (1:250), ABC immunohistochemical detection kit (concentrated type) and DAB substrate kit were from Huamei Biotechnology Company. Monoclonal mouse anti-human c-*myc* antibodies were provided by Huamei Biotechnology Company. Red blood cell rosette reagent used to restrain the monoclonal antibody hypersusceptibility to CD3, CD4 or CD8 from treated mice was from the Wuhan Biologic Product Institute. The soluble interleukin-2 receptor (sIL-2R) quantitative EIA kit was from Shanghai Senxiong Technology Industry Limited Company. Ig kit was obtained from Shanghai Sun Biological Products Co. Ltd. Injectible cyclophosphamide (CTX, batch number: 20051204) was obtained from Shanxi Jinde Medicine Limited Company. Ultrapure water was self-prepared. Other reagents were all analytical reagents made in China. Adriamycin was from Shenzhen Wanle Pharmaceutical Co. Ltd.

MTT experiment

SGC-7901 cells growing exponentially were digested with 2.5 g/L trypsin, then washed several times with PBS (pH 7.2). They were then counting and RPMI 1640 contained 100 mL/L newborn bovine serum medium in order to adjust cell density to 1×10^8 cells/L. After the final cell suspensions were adjusted the to 100 μL/well, 96-well plates were put into an incubator that containing 50 mL/L CO_2, at 37℃ for 24 h. Then, 100 μL RPMI 1640 containing different concentrations of SFAP (40-640 mg/L) was added to each well. Cells were cultured for 48 h. Four hours before the end of culture, 100 μL supernatant was removed and 10 μL MTT (the final concentration was 5 g/L) was added and cultured for 4 h, to which acid isopropyl alcohol was subsequently added per routine. The absorbance (A) for each well were measured at 570 nm with an ELISA reader. The inhibition ratios were calculated with the following formula: (1 - the mean of treated group/the mean of control group) × 100.

Immunohistochemical detection

Cells were cultured as previously described and the cell density was adjusted to 2×10^8 cells/L. After the above-mentioned cell suspensions were added to a 4 mL culture flask, the flask was placed into an incubator containing 50 mL/L CO_2 at 37℃ for 24 h. Then, culture flasks were randomly divided into groups for different concentrations of SFAP (4 mL), and in the control group RPMI 1640 (4 mL) was added. After continuous culture for 48 h, cells were isolated, digested, and washed. The cells were fixed with 40 g/L formalin, imbedded with paraffin, and then consecutively sliced at a thickness of 3 μm. The paraffin slices were dewaxed and washed with graded alcohol, 3 mL/L H_2O_2 methanol, and incubated for 10 min at room temperature in order to inactivate the endogenous peroxidase activity and eliminate non-specific staining. Next, mouse anti-human c-myc monoclonal antibody attenuated at 1:100 was added, and incubated at 4℃ following the addition of biotinylated sheep anti-mouse IgG. After the above-mentioned mixture was incubated at 37℃ in a moisture-saturated plastic chamber for 30 min, ABC compound was added and incubation was continued for 30 min, followed by three 5-min PBS washes. Staining with DAB was observed by microscope for 5-10 min, after which the cells were washed with tap water for 3 min in order to terminate the reaction. Finally, the slices were stained with haematoxylin, dehydrated, cleared, mounted and observed with a microscope. A light yellow cytolymph indicated positive expression of c-myc protein. Every slice was observed under five high power fields and each positive expression ratio was counted per the following formula: positive expression ratio = (the sum of positive cells/the sum of all the cells) ×100%.

Influence on of SFAPT-lymphocyte subsets from the peripheral blood

The animal study protocol was approved by the Ethics Committee of Yangzhou University Medical College.

A total of 30 ICR mice, half being female, were randomly divided into five groups: NS group, CTX group and three (CTX + SFAP) treatment groups. The ICR mice in the NS group were treated *ig* and *ip* with 0.01 mL/g normal saline (NS) once a day for 5 d; the CTX group was treated ip with 40 mg/kg CTX and ig with NS once a day for 5 d; three (CTX + SFAP) treatment groups were treated ip with CTX 40 mg/kg and *ig* with SFAP, such that the dose was 50, 100 or 200 mg/kg SFAP once a day for 5 d. The Staphylococcal protein A (SPA) rosette test was utilized on the sixth day for measuring the ratio of T-lymphocyte subsets from peripheral blood. The eyes of the mice were removed and venous blood was gathered (about 1 mL), which was then placed into an anticoagulated heparin test tube. One milliliter of NS was added to the test tube. After mixing, 2 mL of T-lymphocyte cell separating medium was added, and then the blood sample was centrifuged for 15 min at 3000 r/min. The intermediate buffy coat was collected and washed three times with Hank's solution. The number of T-lymphocytes was then adjusted to 1000/mm^3. The intermediate lymphocyte suspension (10 μL) was placed into three test tubes and 10 μL of the red blood cell suspension was added to each tube in order to restrain monoclonal antibody hypersusceptibility of CD3, CD4 or CD8 in mice. After incubating the above-mentioned suspension at 37℃ for 30 min, it was centrifuged for

Table 1 Inhibitory effect of SFAP on proliferation of SGC-7901 cells (mean ± SD)

Group	Dose (mg/L)	A value	Rate Inhibition (%)
Control	0	0.290 ± 0.027	0
SFAP	40	0.248 ± 0.055	14.5
SFAP	80	0.239 ± 0.044	17.6
SFAP	160	0.230 ± 0.034	20.7
SFAP	320	0.220 ± 0.041[a]	24.1
SFAP	640	0.212 ± 0.009[b]	26.9
Adriamycin	2	0.125 ± 0.037[b]	56.9

[a]$P < 0.05$, [b]$P < 0.01$ *vs* Control.

Table 2 Influence of SFAP on expression of *c-myc* protein in SGC-7901 cells (mean ± SD)

Group	Dose (mg/L)	Positive c-myc rate (%)
Control	0	22 ± 6
SFAP	160	11 ± 3[b]
SFAP	320	9 ± 3[b]

[b]$P < 0.01$ *vs* control.

3 min at 1000 r/min, made into a slice, dried, and was colored with Gliemsa solution for 30 min. The number of cells positive for CD3, CD4 or CD8 were then observed through a microscope. A T-lymphocytes binding with more than 3 red cells (rosette formation) was defined as positive. More than 200 T-lymphocyte were counted, and the percentage of cells with rosette formation was calculated.

Influence on serum sIL-2R contents

As described above, ICR mice were grouped and treated; in this case, the dose of CTX administered was 10 mg/kg. The eyes were removed, venous blood was gathered (about 1 mL) and blood serum was centrifuged on the sixth day. Per kit instructions, ELISA was used to measure the levels of sIL-2R from blood serum in treated mice. The sample dilution (50 μL) and the solution awaiting detection (50 μL) were put into each well of the reaction plate. After mixing, the reaction plate was stored at 37℃ for 2 h, and was subsequently washed 4-6 times and blotted on filter paper. The first antibody (100 μL) was placed into each well, the reaction plate was stored at 37℃ for 1 h, and then washed as described above. The enzyme-labeled antibody (100 μL) was placed in each well and was stored at 37℃ for 1 h; the reaction plate was then washed as described above. The substrate (100 μL) was placed into each well, and was allowed to react for 5-10 min in the dark at 37℃. Lastly, one drop of stop buffer was put in each well and mixed, from which absorption was then detected at 492 nm. The levels of sIL-2R were determined according to the standard curve of absorption-concentration.

Influence on serum Ig contents

As described above, the dose of CTX was changed to 10 mg/kg. Immunoturbidimetry was utilized for measuring the levels of Ig from blood serum in mice on the sixth day. The eyes were removed, venous blood was collected (1 mL), and the sample was centrifuged. The diluted blood serum (40 μL, 10 μL or 80 μL) was put into a test tube, and 1 mL IgA, IgG or IgM was added to each tube. After mixing, the samples were immersed in a water bath at 37℃ for 15 min, a semi-automatic biochemistry analyzer zero was adjusted to 340 nm with NS, and the absorption for each test was detected. The levels of IgA, IgG or IgM were computed according to the absorption-concentration standard curve.

Table 3 Influence of SFAP on T-lymphocyte subsets from peripheral blood in cyclophosphamide-treated mice

Group	Dose (mg/kg)	CD3 (%)	CD4 (%)	CD8 (%)	CD4/CD8
NS control	0	46.2 ± 4.5	28.5 ± 1.4	17.7 ± 2.16	1.6 ± 0.1
CTX control	40	37.5 ± 2.4[b]	21.5 ± 2.2[b]	16.3 ± 1.6	1.3 ± 0.1[b]
SFAP + CTX	50 + 40	38.7 ± 2.2	22.2 ± 2.3	16.7 ± 2.0	1.3 ± 0.2

Statistical analysis

Data are presented as the mean ± SD for all experiments. Comparisons of numerical data were performed using the *t* test, and comparisons of categorical data were performed using χ^2 test.

RESULTS

Effect of SFAP on proliferation of SGC-7901 cells

SFAP (40-640 mg/L, 48 h) inhibited proliferation of SGC-7901 cells in a dose-dependent manner. This effect was statistically significant at dosages of 160 mg/L and 320 mg/L (Table 1).

Effect of SFAP on c-myc protein expression in SGC-7901 cells

SFAP decreased the expression of c-*myc* protein in SGC-7901. This was statistically significant when compared with the control group (Table 2).

Effect of SFAP on distribution of T-lymphocyte subsets from the peripheral blood in mice

CTX (40 mg/kg) decreased the percentage of $CD3^+$ and $CD4^+$ T-lymphocytes and the ratio of CD4/CD8 from the peripheral blood, which was statistically significant compared with the control group. The percentage of the $CD3^+$ and $CD4^+$ T-lymphocytes was increased in all three SFAP dosage groups (50, 100 or 200 mg/kg), with the difference being statisticall significanct in the largest dosage group (200 mg/kg), compared with the CTX group. The moderate and largest dosage groups (100 and 200 mg/kg, respectively) increased the ratio of CD4/CD8 from the peripheral blood, and this was statistically significant compared with the CTX group (Table 3).

Effect of SFAP on serum sIL-2R and Ig contents

CTX (10 mg/kg) increased the levels of sIL-2R in the serum, which was highly significantly different compared with the NS control group ($P < 0.01$). Both moderate and largest dosage

groups (100 mg/kg and 200 mg/kg) decreased the levels of sIL-2R in serum from mice treated with cyclophosphamide, which was statistically significant compared with the CTX group (Table 4). In addition, CTX (10 mg/kg) inhibited the elaboration of Ig, and was significantly different compared with the NS control group. All three SFAP groups increased the levels of IgA, IgG and IgM in the serum when induced by cyclophosphamide, with statistical significance for the large and moderate dose groups when compared with the CTX control group (Table 4).

DISCUSSION

The target cells in this study were from the cell line SGC-7901. After culturing *in vitro* for 48 h, MTT experiments were utilized to detect SGC-7901 proliferation *in vitro*. The results proved that SFAP (40-640 mg/L) inhibited the proliferation of SGC-7901 and the correlation between the inhibitory effects and the dosage was positive, such that there was a dose-effect relationship. From this observation, we postulate that SFAP directly inhibits the proliferation of SGC-7901 cells. The c-myc protein is the key to controlling the proliferation of these cells, and has been shown to induce tumor cells into multiplication cycles and promote hyperplasia[11-14]. We utilized the immunocytochemistry ABC experiment to detect the influence of SFAP on protein expression of c-myc in SGC-7901 cells. The results proved that SFAP (40-640 mg/L) decreased protein expression of c-myc in these cells. These data imply that c-myc probably affects the regulation of tumor cell proliferation. Considerable evidence has demonstrated that when immunomodulatory mechanisms are suppressed, the incidence rate of the tumor increases and the speed of cancer metastasis and growth quickens. When the malignancy grows constantly or radiotherapy and/or chemotherapy are applied to manage the tumor, the immunomodulatory mechansisms of the patient decline. Thus, there is a close relationship between immunomodulatory activity and the appearance of cancer[15-18].

Cellular immunity is the key to host tumor immunity, and T-lymphocytes are the critical immune component for tumor immunity. The cluster differentiation (CD) antigen is an important immune cell membrane molecule. CD3 antigen is present on the cell membrane of all mature T-lymphocytes in the peripheral blood and is involved in $CD4^+$ and $CD8^+$ T-lymphocyte response. The former is mainly a helper T-lymphocyte, which can also assist B cells to generate antibodies, and the later is chiefly a suppressor T-lymphocyte which can release suppressive cytokines to suppress cellular and humoral immune responses. When T-lymphocyte-mediated cellular immunity is weakened, CD4 is decreased while CD8 is increased, thus the ratio of CD4/CD8 decreases[19-23]. Our experimental results show that SFAP treatment at all used dosages increased the percentage of $CD4^+$ cells in the CTX mouse model, and at the same time increased the ratio of CD4/CD8. IL-2 is an important immune factor secreted by helper T-lymphocytes, which after combining with IL-2R could promote immune cell proliferation and suppress tumor cell division. sIL-2R derives mainly from active T-lymphocyte membrane receptor proteins which could competitively bind to IL-2, thereby restraining the biological activity of IL-2. Thus, sIL-2R is regarded as an important immune suppressor[24-28]. The experimental results in the present study show that SFAP significantly decreased the level of sIL-2R in a CTX mouce model, which suggests that SFAP could enhance cellular immune function in mice inhibited by CTX.

Humoral immunity is critical to host tumor immunity[29]. For example, a variety of antibodies from the blood promote effector cells to recognize and kill tumor cells. Our results show that SFAP is capable of enhancing humoral immune function in mice inhibited by CTX by increasing the serum levels of IgA, IgG and IgM.

Many traditional Chinese medicines derived from the Fuzheng drug are capable of enhancing immune function with few adverse effects; however, the amount of tumor death is small. Traditional cytotoxic drugs are powerful enough to kill tumor cells, but they come with high toxicity, especially with regards to immune and hemotologic function[30]. Thus, many doctors avoid using these kinds of drugs to their patients. The results of our experiments show that SFAP directly inhibits the proliferation of SGC-7901 cells and enhances the cellular and humoral immune function inhibited by CTX. These effects may be beneficial for cancer prevention, anti-cancer therapies, prevention of cancer relapse and metastasis, and avoidance of adverse reactions from radiotherapy and chemotherapy.

COMMENTS

Background

Malignant tumors are one of the most common causes of mortality in China and the world. While surgical treatment predominates in comprehensive therapy

for tumors, anti-tumor drugs still play an important role. Currently, cytotoxic compounds remain the major constituent of chemotherapy drugs. However, cytotoxic compounds have poor therapeutic effects on the solid tumors and generate higher toxic side-effects and drug resistance. Many Chinese traditional medicines can enhance the immune function of the host, with few toxic side-effects when used in the treatment of tumors.

Research frontiers

Shuangling Fuzheng anticancer preparation (SFAP) consists of Fuzheng and Quxie Chinese traditional medicines. SFAP directly inhibits the proliferation of cancer cells through the action of Fuzheng, and also promotes cellular and humoral immune function in a cyclophosphamide-treatment mouse model through its Quxie action.

Innovations and breakthroughs

Fuzheng anticancer granules (FAG) promote immune function and inhibit transplanted tumors in mice, but the inhibition rate is less than 30%. SFAP has the same constituents of FAG, but improves the action of FAG. At the precondition of Chinese Medical Syndrome Differentiation, the main characteristics of SFAP production were extraction of volatile oils from *Atractylodes macrocephalae*, coixenolide from coix seed, and polysaccharides from part of Fuzheng traditional Chinese medicines, boiling the other drugs with water as per the traditional method, and concentrating all constituents into a capsule preparation. The results of this experiment showed that the ratio of SFAP anticancer activity was significantly greater than 30%. Moreover, SFAP could directly inhibit the proliferation of the cancer cells *in vitro*, and also promote immune function in cyclophosphamide-treated immunosuppressive mice.

Applications

The immune function of the human body has a close association with the development of cancer. On the one hand, when immune function is suppressed, the incidence of cancer increases and the speed of cancer metastasis quickens. On the other hand, when the malignancy grows constantly *in vivo* or radiotherapy or chemotherapy is given to cancer patients, immune function declines as the state of illness worsens. SFAP could directly control tumor cell growth and adjust the balance of cellular and humoral immunity of human body under different conditions. It exerts not only Fuzheng action, but also Quxie action. SFAP may be beneficial for all cancer patients and of applications in cancer prevention, anticancer therapy with few adverse reactions.

Peer review

The Chinese traditional medicine constituents of SFAP are logical and scientific. Its preparation process has many salient features. The preparation exerts not only Fuzheng action, but also Quxie action. The inhibition ratio of SFAP on tumor is higher than common Chinese traditional medicine, and the toxic side-effects are less than those of conventional anti-tumor chemotherapy drugs. As a new compound for anti-tumor therapy, SFAP should be developed as soon as possible.

Abstract

AIM: To observe the gene silencing mediated by the specific shRNA targeted against β-catenin and its effect on cell proliferation and cycle distribution in the human colon cancer cell line Colo205.

METHODS: Two shRNA plasmid vectors against β-catenin were constructed and transfected into Colo205 cells with Lipofectamine™2000. The down-regulations of β-catenin, c-myc and cyclinD1 expressions were detected by RT-PCR and western blot analysis. The cell proliferation inhibitions were determined by MTT assay and soft agar colony formation assay. The effect of these two β-catenin shRNAs on cell cycle distribution and apoptosis was examined by flow cytometry.

RESULTS: These two shRNA vectors targeted against β-catenin efficiently suppressed the expression of β-catenin and its down stream genes, c-myc and cyclinD1. The expression inhibition rates were around 40%-50% either at the mRNA or at the protein level. The shRNA-mediated gene silencing of β-catenin resulted in significant inhibition of cell growth both on the culture plates and in the soft agar. Moreover, the cancer cells showed significant G_0/G_1 arrest and increased apoptosis at 72 h post transfection due to gene silencing.

CONCLUSION: These specific shRNAs targeted against β-catenin could have a gene silencing effect and block the WNT signaling pathway. They could inhibit cell growth, increase apoptosis, and induce cell cycle arrest in Colo205 cells. ShRNA interference against β-catenin is of potential value in gene therapy of colon cancer.

Key words: β-catenin; RNA interference; Apoptosis; Colon cancer; WNT

INTRODUCTION

Colon cancer is still a serious disease and an abnormal WNT signaling transduction pathway is considered to play an important role during its carcinogenic process. Mutations that activate the WNT pathway have been implicated in colon cancer by turning on genes encoding oncoproteins and cell-cycle regulators. In the absence of the WNT signal, β-catenin is localized in cell-cell junctions, but very low in the cytoplasm and nucleus because excessive β-catenin in cytoplasm is targeted to proteasome-mediated degradation by a complex containing GSK-3β, Axin and APC[1-4]. The binding of WNT proteins to their receptor, frizzled, stabilizes β-catenin by inhibiting the activity of the GSK-3β. Then β-catenin associates with members of the TCF/LEF family and migrates to the nucleus, where this complex activates the transcription of genes, such as c-myc and cyclinD1, which promote proliferation and regulate the cell cycle[5-7]. So, the key step in activating the WNT pathway is the stabilization of β-catenin and its translocation into the nucleus, which may serve as a potential target for colon cancer therapy.

RNA interference (RNAi) is a post-transcriptional gene-silencing mechanism, which was first discovered by Fire and his colleagues in 1998[8]. RNAi is often exploited for specific gene silencing, which is initiated by introduction into cells of double-stranded RNA (dsRNA) that are homologous to the sequence of the target gene. In order to avoid the nonspecific global shutdown of protein synthesis inside the cells and adapt to mammalian cells, the short duplexes of synthetic 21-23 nt RNAs were annealed and then introduced into mammalian cells. This was called small interfering RNA technique (siRNA)[9-11]. In this study, two shRNA plasmid vectors against β-catenin, which could persistently generate siRNA inside cells, were constructed and transfected into the colon cancer cell line Colo205. Its effect on cell proliferation and cycle distribution in this cell line was investigated.

MATERIALS AND METHODS

Cell line and culture

The human colon cancer cell line Colo205, which was kindly provided by my team colleague, Dr Liyong, was cultured in DMEM (Gibco, USA), and supplemented with 10% FBS (Sigma, USA), 100 units/mL penicillin G, and 100 μg/mL streptomycin (Gibco, USA) at 37℃ in a humidified 5% CO_2/95% air atmosphere.

Design of shRNA and plasmid preparation

Plasmid vector Pgenesil was purchased from Wuhan Genesil Biotechnology Co Ltd. Two different targeted sequences were designed to be homologous to the β-catenin mRNA consensus sequence (GeneBank NM_001904). A negative control sequence was also designed as the same process, which had no homology with human beings or mice. The complementary oligonucleotides encoded a hairpin structure with a 21-mer stem and a 9-bp loop. The stem was derived from the mRNA target site. The loop sequence separated the two complementary domains. All the sequences were transcribed with DNA polymerase Ⅲ U6 promoter in plasmid Pgenesil. These two β-catenin plasmids were named Pgenesil-CAT1 and Pgenesil-CAT2 respectively. The negative control plasmid was named Pgenesil-Neg. (Table 1) The transformation of these plasmids into competent cells DH5α and extraction of plasmids followed the routine process.

Plasmid transfection

Approximately, 1×10^6 cells/well were plated in 6-well plates in medium containing 10% FBS to grow overnight to 80%-90% confluency. Transfection of the shRNA oligonucleotides was performed by using LipofectamineTM2000 (Invitrogen, USA). Colo205 cells were divided into blank control group, negative control group and two test groups (CAT1 and CAT2). Only LipofectamineTM2000 was used for transfection in the blank control group. Plasmid Pgenesil-Neg was used for transfection in the negative control group. Plasmids Pgenesil-CAT1 and Pgenesil-CAT2 were used for transfection in the test groups (CAT1 and CAT2) respectively. In the above three groups, the cells were all transfected with the mixture of plasmid and Lipofectamine TM2000 (1:3) in 2 mL serum-free medium. At 6 h post-transfection, 500 μL FBS/well was added. At 26 h after transfection, the medium was replaced by normal medium containing 10% FBS and antibiotics up to 72 h post-transfection.

RNA isolation and semiquantitative reverse transcription PCR(RT-PCR)

At forty-eight hours post-transfection, 1×10^6 cells were collected and total RNA was extracted, using the Trizol reagent (Invitrogen, USA) under its operational instruction. The concentration and purity of the total RNA were detected with UV spectrophotometer analysis at 260 nm and the electrophoresis detection showed good quality of purified RNA. RT-PCR was performed by the two-step method. Synthesis of cDNA was performed by using the cDNA synthesis kit (Fermentas, USA) and following the manufacturer's instructions. For quantitative analysis of β-catenin, c-myc and cyclinD1 mRNA, the expression of house keeping gene, β-actin mRNA, was used as an internal standard. Primer pairs were designed according to the sequences in the GenBank (Table 2).

Table 1 Oligonucleotides sequences of β-catenin specific and negative control siRNA

Name	Sequence of siRNA	Target sites
Pgenesil-CAT1	AACAGTCTTACCTGGACTCTG	0290-0310
Pgenesil-CAT2	AAAGGCAATCCTGAGGAAGAG	0355-0375
Pgenesil-Neg	GACTTCATAAGGCGCATGC	No homology

The PCR fragments were separated and visualized in 1.5% agarose gels stained with ethidium bromide. Semiquantitative analysis was performed with the Bio-1D gel analysis software. All experiments were done in triplicate. The ratio of the photodensity of the RT-PCR product of goal gene and β-actin was used to identify the expression intensity of goal gene. The inhibition rate of goal gene expression was calculated with the following formula: inhibition rate of goal gene expression (IR) = $(1 - E_1/E_2) \times 100\%$. E_1: the expression intensity of goal gene in the observation group; E_2: the expression intensity of goal gene in the blank control group.

Western blot

The cells were divided and transfected as above for 48 h. After collection from the culture medium, the cells were washed three times with PBS and lysed in 150 μL of ice-cold Tris buffer (50 mmol/L, pH 7.5). The Tris buffer contains 5 mmol/L edetic acid, 150 mmol/L NaCl, 0.1% NP-40, 0.1% SDS, 2.0 g/L aprotinin, 0.02% NaN_3, 0.2 mmol/L PMSF, and antiprotease mixture. Then the cells were sonicated, and centrifuged at 12000 × *g* for 15 min. The Coomassie brilliant blue G-250 was used to determine the concentration of protein in each lysate. Loading buffer was added to each lysate, which was subsequently boiled for 3 min and then electrophoresed by SDS-PAGE. The proteins were mixed with 2 × loading buffer with the same volume before electrophoresis. After transferring onto nitrocellulose, proteins were incubated with antibodies (β-catenin, c-myc and cyclinD1, purchased from Santa Cruz, USA) and then with peroxidase-conjugated secondary antibody (Bolster, China). Detection was performed with an enhanced chemiluminescent agent. Signals were detected with the ECL Test Kit (Maixin, China). The β-actin staining served as the internal standard for all membranes. The inhibition rate calculating formula is the same as that described in the RT-PCR section. All experiments were done in triplicate.

MTT assay

The transfected cells were seeded in 96-well plates (1×10^4/mL) and allowed to attach for about 24 h. The MTT (Sigma, USA) was dissolved in PBS at a concentration of 5 mg/mL and filtered. Ten microlitres of stock solution were added to 100 microlitres of medium in each well. Then, the plates were incubated for 4 h at 37℃. After loading of MTT, the medium was replaced with 100 μL DMSO and left for 30 min at room temperature for colour development. The 96-well plates were read by an

enzyme-linked immunosorbent assay reader (570 nm, DG-3022A, USA) to determine absorbance values (A). The absorbance values were determined at 36, 48, 60, 72 h after transfection in each group respectively. The experiments were repeated three times. The Inhibition rate was calculated by the following formula. Inhibition rate (IR) = [1 - A_1/A_2] × 100% A_1: absorbance value of the observation group A_2: absorbance value of the control group.

Soft agar colony formation assays

At 24 h after transfection as above, the cells of different groups were mixed with the above mentioned culture media containing 0.4% agar. Then 1000 cells were resuspended and seeded in triplicate into 6-well plates coated with 0.5% agar in DMEM containing 10% FBS. After 10 d incubation, the colonies were counted. Colony efficiency (CE) was determined by counting the number of colonies greater than 60 μm in diameter at × 100 magnification in each plate.

Flow cytometry

Cells of each group seeded in culture plates were transfected as described above. After incubation for 72 h, cells were harvested by trypsinization and centrifugation, washed with cold PBS and fixed overnight with 80% ethanol at -20℃. The fixed cells were collected, washed and resuspended in PBS containing 10 μg/mL propidium iodide (Sigma, USA) and 100 μg/mL RNase A (Takara, Dalian, China), then incubated at 4℃ for at least 30 min avoiding light to eliminate the intracellular RNA. Subsequent analyses were performed by flow cytometry (Becton Dickinson, USA). The experiments were repeated three times.

Table 3 The mRNA expression intensities of genes in different groups normalized by β-actin

Goal gene	Blank Control	Negative	CAT1	CAT2
β-catenin	0.98 ± 0.02	0.96 ± 0.03	0.51 ± 0.03	0.55 ± 0.01
C-myc	0.97 ± 0.01	0.96 ± 0.02	0.48 ± 0.04	0.52 ± 0.01
CyclinD1	0.98 ± 0.02	0.97 ± 0.03	0.47 ± 0.02	0.50 ± 0.02
P		[a]*P* > 0.05	[a]*P* > 0.05	[a]*P* > 0.05

[a]*P*: Observation group *vs* blank control group.

Statistical analysis

The results were expressed as mean ± SD. The data were treated by one-way analysis of variance and Student's *t*-test to determine statistical significance with SPSS 11.5 statistic software. $P < 0.05$ was considered statistically significant.

RESULTS

Construction and verification of plasmids

The multiclone sites of plasmid Pgenesil were as follows: *HindIII-ShRNA-BamHI-U6Promotor-EcoRI-SalI-XbaI-DraIII*. *A SalI* site for plasmid Pgenesil was designed in the inserted fragments between the sites of *BamHI* and *HindIII*. If the insertion was correct, a band about 400 bp should be cut off by *SalI*. The results of digestion with restriction endonucleases and sequencing showed correct plasmids (Figure 1).

Inhibition of mRNA expression by β-catenin shRNA

The mRNA expression intensities of goal genes, inhibited by specific shRNAs in the colon cancer cells, were analyzed by semiquantitive RT-PCR. The mRNA levels were normalized by internal control β-actin (Figure 2). At forty-eight hours post-transfection, the expression intensities of β-catenin mRNAs in the blank control, negative control and test groups (CAT1, CAT2) were 0.98 ± 0.02, 0.96 ± 0.03, 0.51 ± 0.03 and 0.55 ± 0.01, respectively. The other genes' mRNA expression intensities were shown in the table (Table 3). The statistical analysis showed that β-catenin mRNAs of Colo205 cells in the CAT1 and CAT2 groups were down regulated significantly after transfection with either plasmids Pgenesil-CAT1 or Pgenesil-CAT2, compared with that in the blank group ($P < 0.05$). The inhibition rates were 47.89% and 43.91% in the CAT1 and CAT2 group, respectively (Figure 2). But there is no significant difference between these two groups. The plasmid Pgenesil-Neg had no significant inhibitive effect on the expression of β-catenin mRNA ($P > 0.05$, *vs* blank) (Table 3). The statistical results of gene c-myc and cyclinD1 were similar to that of β-catenin. (Table 3).

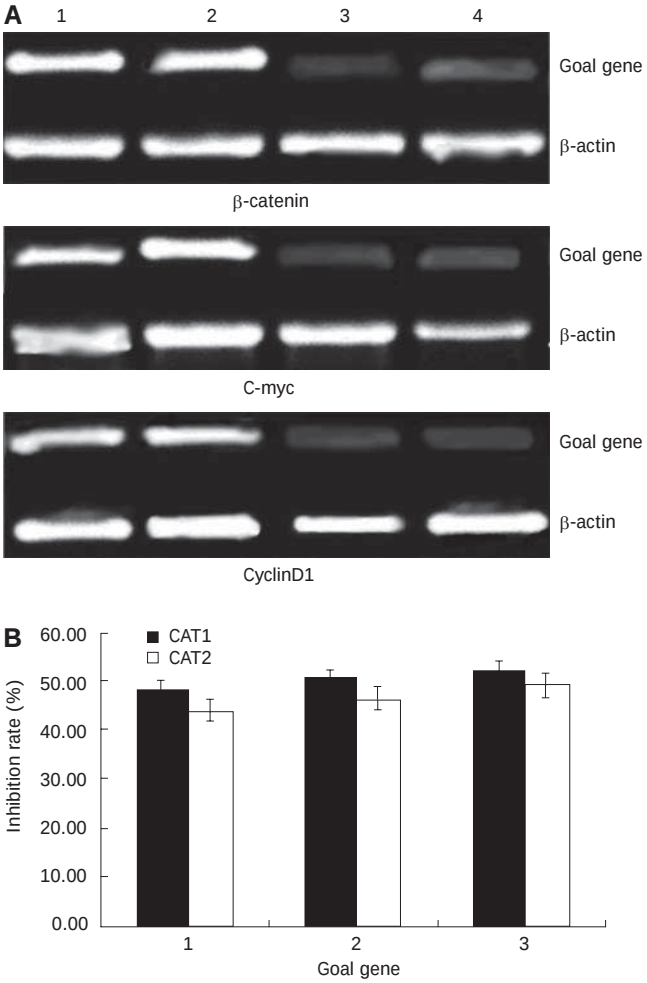

Figure 2 RNA interference-mediated suppression of cellular mRNA. **A**: The mRNA expressions of different goal genes in colon cancer cells at 48 h post-transfection were examined by semiquantitive RT-PCR. Inhibition of protein expression by β-catenin shRNA

The down-regulated efficiencies of protein expressions inhibited by specific shRNAs in Colo205 cells were analyzed by western blot. The protein levels were normalized by internal control β-actin. (Figure 3) At forty-eight hours post-transfection, all the protein expression ratios (protein *vs* β-actin) were calculated and shown in Figure 3 and Table 4. For example, the ratio of β-catenin /β-actin were 0.95 ± 0.02, 0.89 ± 0.04, 0.52 ± 0.02 and 0.56 ± 0.03, in the blank control, negative control and test groups (CAT1,CAT2) respectively. The statistical analysis showed that both the plasmid Pgenesil-CAT1 and Pgenesil-CAT2 could have a significant down-regulation effect on the protein expression of β-catenin in Colo205 cells ($P < 0.05$, *vs* blank). But there is no significant difference between these two groups. The similar statistical results could be detected on the protein expression of gene c-myc and cyclinD1 ($P < 0.05$, *vs* blank). The inhibition rates were around 40%-50%. Reasonably, the plasmid Pgenesil-Neg had no inhibitive effect on any gene of β-catenin, c-myc and cyclinD1 ($P > 0.05$, *vs* blank).

Inhibition of cell proliferation by β-catenin shRNA

The proliferation of Colo205 cells inhibited by specific shRNAs was analyzed by the MTT assay. The results were shown in Table 5. The statistical analysis showed that both the plasmids Pgenesil-CAT1 and Pgenesil-CAT2 could have significant inhibitive effects on the proliferation of Colo205 cells, compared with the blank group at 72 h after transfection ($P < 0.05$, *vs* Blank). But the plasmids Pgenesil-Neg had no significant inhibitive effect on cell proliferation ($P > 0.05$, *vs* Blank).

Inhibition of anchorage-independent proliferation of Colo205 cells by β-catenin shRNA

The anchorage-independent proliferation of Colo205 cells inhibited by specific shRNAs was analyzed by soft agar colony formation assays. The average numbers of colonies in the blank, negative, CAT1, CAT2 group were

Table 4 The western blot analysis for genes in different groups normalized by β-actin

Goal gene	Blank Control	Negative	CAT1	CAT2
β-catenin	0.95 ± 0.02	0.89 ± 0.04	0.52 ± 0.02	0.56 ± 0.03
C-myc	0.97 ± 0.01	0.92 ± 0.02	0.54 ± 0.01	0.54 ± 0.04
CyclinD1	0.94 ± 0.03	0.95 ± 0.01	0.53 ± 0.02	0.51 ± 0.01
P		[a]*P* > 0.05	[a]*P* < 0.05	[a]*P* < 0.05

[a]*P*: Observation group *vs* blank control group.

Table 5 The Inhibition rate of cell proliferation in different group

	Blank Control (%)	Negative (%)	CAT1 (%)	CAT2 (%)
36 h	10	14	21	18
48 h	13	17	28	24
60 h	15	19	39	33
72 h	18	21[c]	54[a]	47[a]

[a]*P* < 0.05 (*vs* Blank), [c]*P* > 0.05 (*vs* Blank).

46, 43, 9 and 11 respectively. The Colo205 cells in the CAT1 and CAT2 groups formed significantly less colonies (4-5 fold decrease) in soft agar than the cells in the blank and negative control groups did ($P < 0.05$, *vs* Blank). At the same time we observed that most of the colonies in the CAT1 and CAT2 groups were much smaller than those in the blank and negative control groups. All these results suggested that reductions in β-catenin protein level induced by the β-catenin gene silencing decreased the abilities of Colo205 cells to form colonies in soft agar.

Effect of β-catenin shRNA on cell cycle distribution and apoptosis

In comparison to the blank control group, the CAT1 and CAT2 groups both showed cell accumulation in the G_0/G_1 phase and reduction in the phases of S and G_2/M. Moreover, the cells with sub- G_1 DNA content also increased and apoptosis rates were around 5% in these two groups. No statistically significant difference was found between the negative control group and the blank control group (Table 6).

Table 6 Effect of shRNA interference on cell cycle distribution and apoptosis

Group	G_0/G_1 (%)	S (%)	G_2/M (%)	Apoptosis (%)
Blank	36.51 ± 2.52	47.32 ± 3.31	16.45 ± 1.52	0.78 ± 0.11
Negative	40.32 ± 2.74[c]	43.21 ± 2.12	16.57 ± 1.83	1.05 ± 0.15[c]
CAT1	81.71 ± 5.73[a]	14.34 ± 1.34	4.55 ± 0.35	5.21 ± 0.47[a]

[a]*P* < 0.05 (*vs* Blank); [c]*P* > 0.05 (*vs* Blank).

DISCUSSION

RNA interference is a ubiquitous mechanism of eukaryotic gene regulation and an excellent strategy for specific gene silencing. The specificity of RNAi is determined by 21-23 nt RNA duplexes, referred to as micro-RNA (miRNA) or small interfering RNAs (siRNA)[12]. ShRNA is formed by hairpin structures and stretches of double-stranded RNA, which will be cleaved by the ribonuclease dicer to produce mature miRNA inside the targeted cells. After unwinding, one of the strands becomes incorporated into the RNA-induced silencing complex (RISC) and guides the destruction or repression of complementary mRNA[13]. Recently the vector-based approach of shRNA interference has been developed in order to achieve stable, long-term, and highly specific suppression of gene expression in mammalian cells[14]. These shRNA expression vectors have many advantages: they can be stably introduced into cells and persistently effective, either as selectable plasmids or as retroviruses. They are relatively cheap to generate[15,16]. These vectors are often under the control of an RNA polymerase Ⅲ promoter such as U6 or H1[17]. They can transcribe and generate siRNA continuously and the gene silencing effect can last persistently inside the cells. These findings have opened a broad new avenue for the analysis of gene function and gene therapy[18].

The coordination of cell proliferation and apoptosis in cells is one of the hot spots in cancer research. The balance between cell proliferation and apoptosis, and the distribution of cell cycles play very important roles in the carcinogenesis process of colon cancer. The WNT/β-catenin signaling transduction pathway is a highly conservative pathway in the development of colon cancer, which regulates intestinal epithelial proliferation and patterning[19,20]. Mutations that activate the WNT signaling pathway cause the hyper-proliferation of intestinal crypt progenitors and a series of consequential changes finally lead to the occurrence of colon cancer[21,22]. β-catenin is the key component in this pathway. The increased levels of β-catenin frequently found in both premalignant and malignant cells are associated with increased rates of cellular proliferation[23]. Moreover, modest over-expression of β-catenin in epithelial cells can lead to increased proliferation and result in transformation[24-26]. It has been reported that the excessive expression of stabilized β-catenin leads to tumorigenesis in the colorectum, central nervous system, skin and other tissues[27-30]. So, β-catenin has attracted much attention as gene therapy target for carcinomas, including colon cancer. β-catenin has been successfully down-regulated by RNAi in some previous study. For example, Udit N Verma *et al* synthesized siRNA and interfere with the β-catenin gene in the cell line SW480 and HCT116[31]. However, the down-regulation of β-catenin expression by RNAi in the colon cancer Colo205 cell line has not been reported before. Furthermore their research used synthesized small interference RNA as a gene silencing tool, which just transiently suppressed the gene expression and was often limited to cells that are easily transfected[17]. In our study, we did differently by using the vector-based RNA interference technique. According to the design of the shRNA, we selected two shRNA sequences from the β-catenin (CTNNB1) gene and used the plasmid Pgenesil as the vector. The plasmid Pgenesil vector contains the EGFP gene that makes it convenient to observe the result of transfection.

When successfully transfected into the colon cancer cells, the vector Pgenesil could transcribe and generate the interfering RNAs continually under the control of the U6 promotor. So the concentration of intracellular interfering RNA oligonucleotides can remain stable long after transfection. That is what we thought to be the mechanism for the persistently inhibitive effect of the vector-based interference technique. This is the major advantage against the common siRNA technique.

In this study, these two β-catenin specific shRNAs showed their evident effect on silencing the β-catenin gene. Our results demonstrated that after transfection with the β-catenin specific shRNA vectors, β-catenin mRNA and protein expression were significantly suppressed, detected by RT-PCR and western blot. At the same time, we could observe that the genes c-myc and cyclinD were also significantly depressed both at the mRNA and protein levels due to the β-catenin gene silencing. This result confirmed that the c-myc and cyclinD1 genes are the downstream genes regulated by β-catenin. Gene silencing of β-catenin can sequentially lead to the silence of c-myc and cyclinD. Furthermore, no significant differences of β-catenin mRNA or protein expression were observed between these two vectors (CAT1 and CAT2). On the other hand, the negative control plasmid had no inhibitory effect on β-catenin mRNA and protein expression. Neither did it in the genes c-myc and cyclinD1. These results together confirmed that the inhibitions of β-catenin and its downstream genes were specifically induced by these shRNAs aimed at β-catenin. The MTT assays demonstrated that the proliferation curves of the cells were similar in the blank and negative control groups. Viability of cells transfected with the negative control vectors did not significantly decline compared with that of the blank control group. Thus the vector plasmid Pgenesil could be used as a safe and non-toxic carrier for shRNA interference. However, cell proliferation in test groups, which were transfected with β-catenin specific shRNAs, showed increasingly slow down in relation to the time after transfection. At 72 h post-transfection, the inhibitive rates of cell proliferation were 54% and 47% in the CAT1 and CAT2 group respectively, which have significant differences compared with that of the blank control group. As for the anchorage-independent proliferation, we could also detect the significant reduction of colonies in either amounts or sizes in soft agar in the test groups. The MTT and soft agar assay together revealed that these two β-catenin specific shRNAs possessed the anti-proliferation function. Our flow cytometry results indicated that the cell growth inhibition by β-catenin shRNA was due to the cell cycle G_0/G_1 arrest and induction of apoptosis. This was somewhat controversial to Udit N Verma's report, which implied that the decreased cell proliferation did not depend on the mechanism of increased apoptosis[31]. We think that the controversy may be due to different cell lines. In our opinion, we think that the imbalance between cell proliferation and apoptosis induced by the β-catenin shRNA could be possibly explained by mechanisms of β-catenin gene silencing and its consequential downstream genes silencing, such as c-myc and cyclinD1, which regulate the cell cycle transition checkpoints and cellular proliferations. As we know, c-myc is a positive regulator of G1-specific cyclin-dependent kinases (CDKs). Even in quiescent cells, c-myc activation is sufficient to induce cell cycle entry in the absence of growth factors[32,33]. CyclinD1 is a regulatory kinase that is a critical modulator of progression through the G1 to S phase transition of the cell cycle. When quiescent cells re-enter the cell cycle and divide, cyclinD1 is the first cyclin to be activated[34,35]. Overexpression of these two genes may stimulate the cells to overcome the cell cycle checkpoints and enhance cell proliferation[36]. Inhibitions of these two genes may result in cell cycle arrest and increased apoptosis, thus inhibiting cell growth. But whether this mechanism is of universality in other colon cancer cell lines or even malignant tumors, further detailed investigations need to be carried out.

In conclusion, our experiments showed that the shRNA targeted against β-catenin could specifically mediate the β-catenin gene silencing and consequentially suppress the expression of its downstream genes, c-myc and cyclinD1. These genes' silencing effect could efficiently inhibit the growth of colon cancer Colo205 cells. The shRNA interference targeted against β-catenin may have potential therapeutic utility in human colon cancer.

ACKNOWLEDGMENTS

We would like to thank my team colleague, Dr Liyong, for the generous gift of Colo205 cells. We are grateful for Dr Jia-Wei Liao for his technical support.

COMMENTS

Background

Abnormal WNT signaling transduction pathway is considered to play an important role during the carcinogenesis process. The key step in activating WNT pathway is the stabilization of β-catenin and its translocation into nucleus, which may serve as a potential target for colon cancer therapy. RNAi is often exploited for specific gene silencing, which provides a strategy for cancer gene therapy. Therefore, we would do some basic research for colon cancer therapy by using this technique.

Research frontiers

The coordination of cell proliferation and apoptosis in cells is one of the hotspots in cancer research. The balance between cell proliferation and apoptosis, and the distribution of cell cycles play very important roles in the carcinogenesis process of colon cancer. β-catenin is the key component in this process. Thus β-catenin has attracted much attention as gene therapy target for colon cancer.

Innovations and breakthrough

In this study, two β-catenin specific shRNAs showed their evident effect on silencing the β-catenin gene. The results also indicated that the cell growth inhibition by β-catenin shRNA was due to the cell cycle G_0/G_1 arrest and induction of apoptosis, although this was somewhat different from other's report.

Applications

The shRNA interference targeted against β-catenin may have potential therapeutic utility in human colon cancer.

Terminology

ShRNA: ShRNA is the short form of "short hairpin RNA". It is formed by hairpin structures and stretches of double-stranded RNA, which will be cleaved by the ribonuclease dicer to produce mature miRNA inside the targeted cells.

Peer review

This paper investigated the gene silencing mediated by the specific shRNA

targeted against β-catenin and its effect on cell proliferation and cycle distribution in human colon cancer cell line Colo205. The authors conclude that The specific shRNAs targeted against β-catenin could have gene silencing effect and block the WNT signaling pathway. They could inhibit cell growth, increase apoptosis, and induce cell cycle arrest in Colo205 cells. ShRNA interference against β-catenin is of potential value in gene therapy of colon cancer.

Abstract

AIM: To evaluate the predictive value of D-dimer as a predictive indicator of portal vein thrombosis (PVT) after portal hypertension surgery in hepatitis B virus-related cirrhosis.

METHODS: A prospective study was carried out in 52 patients who had undergone surgery for portal hypertension in hepatitis B virus-related cirrhosis. Changes in perioperative dynamic D-dimer were observed. The sensitivity, specificity, positive predictive values and negative predictive values of D-dimer were calculated, and ROC curves were analyzed.

RESULTS: The D-dimer levels in the group developing postoperative PVT was significantly higher than those in the group not developing PVT (P = 0.001), and the ROC semi-quantitative and qualitative analysis of D-dimer showed a moderate predictive value in PVT (semi-quantitative value Az = 0.794, P = 0.000; qualitative analysis: Az = 0.739, P = 0.001).

CONCLUSION: Dynamic monitoring of D-dimer levels in patients with portal hypertension after surgery can help early diagnosis of PVT, as in cases where the D-dimer levels steadily increase and exceed 16 μg/mL, the possibility of PVT is very high.

Key words: Portal hypertension; Portal vein thrombosis; Splenectomy; D-dimer; Diagnosis

INTRODUCTION

Portal vein thrombosis (PVT) is a significant postoperative complication in patients with portal hypertension, and procedures such as devascularization, portal systemic shunt and liver transplantation can cause PVT[1-3]. As the degree of obstruction and location vary greatly, the clinical manifestations of PVT are also highly variable[4-6]. Depending on the severity of the condition, it may even result in death of patients.

The incidence of PVT after portal hypertension surgery ranges from 22.2%-37.5%[1,7], depending on the surgical techniques used and patients selected. In China, the most common cause for portal hypertension is liver cirrhosis due to hepatitis B. There is an increasing trend in PVT after portal hypertension surgery for hepatitis B liver cirrhosis.

Currently, diagnosis of portal vein thrombosis is mainly based on imaging studies[8-10], especially colour Doppler ultrasound, because of its ability to provide not only information on blood vessel location, blood flow rate and direction, but also haemodynamic information, which aids diagnosis accuracy[11,12]. It is able to provide information on the thrombosed veins via echo analysis, detect the presence of post-stenotic dilatation, as well as flow defects and turbulence due to venous thrombosis[13,14]. Although portal vein thrombosis can be accurately diagnosed using this method, it produces side effects simultaneously. Therefore, the focus of clinicians is to prevent portal vein thrombosis after portal hypertension surgery as early as possible, the early predictive indicator of postoperative PVT is still lacking.

Currently, clinicians use the incrteased platelet count as the main deciding factor for initiating prophylactic treatment, but the prognostic value of platelet count in PVT is debatable[15,16]. Some studies showed that even at the time of portal vein thrombosis formation, the level of platelet count has not yet reached 500×10^9/L, and patients showing increased levels of platelet count do not

have portal vein thrombosis[17]. Hence, the question of the indicator for initiation of preventive and therapeatic measures is still debatable.

Clotting factors are important in the assessment of liver function and have certain clinical significance, but have yet to show a good clinical value as a diagnostic indicator for thrombotic diseases. At present, D-dimer, the molecular marker in the fibrinolysis cycle, has shown a good negative and positive predictive value in thrombotic diseases such as deep vein thrombosis in the lower limbs and pulmonary embolism, and has therefore been used in studies on its clinical application[18,19]. However, since patients with portal hypertension due to liver cirrhosis have innate clotting and fibrinolytic disorders[20,21], more studies are required to show whether D-dimer has a better predictive value PVT after portal hypertension surgery due to the combined effects of portal vein thrombosis on platelets, clotting and fibrinolysis[22].

MATERIALS AND METHODS

Patient selection criteria

Patients who were admitted to the Third Affiliated Hospital of the Sun Yat-Sen University from September 2004 to March 2006, and diagnosed with portal hypertension due to liver cirrhosis (hepatitis B) were included in this study. The patients with splenomegalia and hypersplenia underwent splenectomy, and the patients with esophageal variceal bleeding underwent splenectomy with gastroesophageal devascularization, or with endoscopic variceal ligation (EVL). Patients who underwent portal hypertension shunting surgery, liver transplant patients, and patients having concurrent liver cirrhosis and hepatocellular carcinoma, and patients diagnosed with PVT before surgery, were excluded from this study.

General demographics

A total of 52 patients (46 males and 6 females) fulfilled the selection criteria. Their age ranged from 20-60 years, with a median age of 46 years (Table 1). Surgical procedures performed on patients included splenectomy and gastroesophageal devascularization (Hassab's operation) as previously described[23]. In brief, an extended left subcostal incision or a L incision of the left upper abdomen was used for extreme splenomegaly. After routine splenectomy, the gastric branch and 5-8 small branches of the gastric coronary veins were disconnected. The esophageal branch was disconnected and suture-ligated. The gastric posterior vein was ligated by suturing, and the left subphrenic vein was ligated as well. In cases of splenectomy with EVL, after splenectomy, an endoscope (GIF 240 or 260, Olympus Optical, Tokyo) was introduced during operation. Ligation was carried out 6-12 times by placing a single rubber band (Bard Interventional Products, Tewksbury, Mass.) over a varix.

Diagnosis of PVT

When colour Doppler ultrasonography imaging showed changes consistent with thrombus formation in the main portal vein, right portal vein, right anterior branch, right posterior branch, left portal vein, left horizontal branch, left sagittal portion, splenic vein, proximal and distal mesenteric vein, PVT was confirmed to be a complication after surgery.

Table 1 Characteristics of 52 patients studied

		Thrombus	Non-thrombus	*P* value
Age (mean ± SD)		41.45 ± 10.83	44.3 ± 8.65	0.388
Gender	Male	15	31	
	Female	2	4	0.649
Child's grade	Grade A	6	12	
of Liver function	Grade B	10	21	0.997
	Grade C	1	2	
Surgical	Splenectomy	7	13	
procedure	Splenectomy + EVL[1]	9	19	0.923
	Splenectomy + ligation[2]	1	3	

[1]Refers to endoscopic variceal ligation; [2]Refers to gastroesophageal devascularization.

Measurement of D-dimer levels

Dynamic D-dimer changes in 52 patients were monitored perioperatively, and the portal vein patency and the incidence of PVT were detected routinely by color Doppler ultrasonography from 7 to 14 d postoperatively. The 52 patients were divided into thrombosis group and non-thrombosis group, depending on the occurrence of PVT after surgery. Peripheral venous blood was collected perioperatively. Three mL blood was centrifuged at 1000 r/min for 15 min before plasma was prepared for D-dimer detection. D-dimer was detected by latex-agglutination assay (semi-quantitative method), and the reagent was provided by Shanghai Sun Company, and the procedure was performed following the instructions provided with the reagent pack.

Statistical analysis

After normality tests, D-dimer indicators showing a skewed distribution were subjected to signed rank test between the thrombosis and non-thrombosis groups, using the difference in the median and interquartile range to illustrate the central and disperse tendency. Chi-square test was used to analyze the dispersion. Sensitivity, specificity, positive and negative predictive value were calculated. ROC curve was plotted. Statistical analysis was performed using the SPSS software version 13.0 for Windows.

RESULTS

Characteristics of the 52 patients studied

Of the 52 patients, 17 developed PVT after surgery, and the incidence of PVT 7-14 d after portal hypertension surgery was 33.69%. There was no significant statistical difference in age, gender, liver function and surgical procedure between the thrombosis and non-thrombosis groups (Table 1).

Table 2 D-dimer level in the thrombosis and non-thrombosis groups (μg/mL)

	Before surgery	Day 1 after surgery	Day 5 after surgery
Non-thrombus group	1 (0.5, 2)	4 (2, 8)[1]	4 (2, 4)[1,2]
Thrombus group	1 (0.5, 2)	4 (2, 8)[1]	8 (4, 8)[1,3]
Z value	1.863	0.318	3.264
P value	0.062	0.751	0.001

[1]Refers to the higher level that is statistically significant after surgery than that before surgery; [2]Refers to the lower level that is statistically significant before surgery than that one day after surgery; [3]Refers to the higher level that is statistically significant before surgery than that one day after surgery.

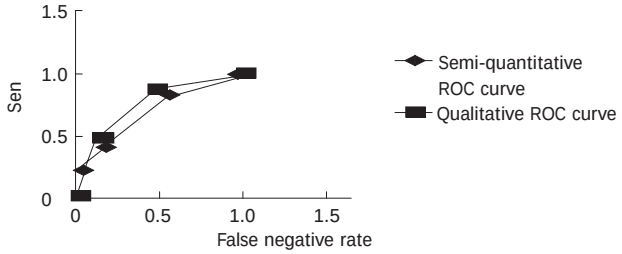

Figure 1 Semi-quantitative and qualititive ROC curves.

Perioperative D-dimer level

The D-dimer level was significantly higher in the thrombosis group than in the non-thrombus group on day 5 after surgery ($P = 0.001$) (Table 2).

Analysis of predictive value for D-dimer in PVT after surgery

By using the change in D-dimer level post-surgery (used as the standard) and the D-dimer (used as semi-quantitative standard) as the diagnostic standard for PVT in liver cirrhosis patients after portal hypertension surgery, we achieved 37.5% accuracy in predicting PVT incidence, which is consistent with the reported data[1]. The sensitivity (Sen), specificity (Spe), positive predictive value (PPV) and negative predictive value (NPV) are listed in Table 3. It can be seen from Table 3 that the positive predictive value was 66.7% for the D-dimer one day after surgery, and the negative predictive value for the continuous increasing was 77.5%, which was significantly higher than the semi-quantitative value of 61.65% for PPV and 70.83% for NPV. Under the extreme circumstances, the semi-quantitative value for PPV and NPV was 100%, respectively.

Based on the different changes in D-dimer levels and the false positive rates and sensitivity rates under different D-dimer levels, a ROC curve was plotted. The semi-quantitative and qualitative standards for ROC curve are shown in Figure 1. Using the ROC analysis, the area under the semi-qualitative ROC curve was Az = 0.794, $P = 0.000$, and the 95% confidence level was 0.794 ± 0.114. The area under the qualitative ROC curve was Az = 0.739, $P = 0.001$, and the 95% confidence level was 0.795 ± 0.146. Both standards had a median diagnostic value, and there was no statistical significant difference in the areas under the ROC curve ($Z = 0.586$, $P = 0.719$).

Table 3 Diagnostic value for different D-dimer diagnostic standards (%)

		Sensitivity	Specificity	PPV	NPV
Qualitative	No decrease	88.2	57.14	42.85	88.25
standard	Increase	47.06	88.57	66.67	77.50
Semi-quantitative	> 0.5	1	0	37.50	0
standard	> 1	1	0.05714	38.88	100
	> 2	0.8235	0.4858	49	82.00
	> 4	0.4118	0.8571	61.65	70.83
	> 8	0.2353	1	100.00	33.89
	> 16	0.2353	1	100.00	33.89

DISCUSSION

D-dimer is an antigenic determinant of fibrin, which, at the D-region, combines with factor XIIIa, and persists as an X-oligopolymer, as well as with other fibrin degradation products. However, it does not exist with profibrin breakdown products, and is a specific indicator of synthesis and breakdown of fibrin in the system. An increasing D-dimer level indicates active clotting and fibrinolysis in the system[24,25].

At present, D-dimer has a good negative and positive predictive value, which is used in the outpatient and emergency setting, to aid selective diagnosis of suspected thrombotic diseases[19,26-28]. Risch *et al*[29] reported that at D-dimer levels of 1 μg/mL and 10 μ/mL (VIDAS DD), the sensitivity is 83.3% and 23.8%, respectively, and the specificity is 65.8% and 98.7%, respectively. In our study, the D-dimer level was higher than the reported level in liver cirrhosis patients after portal hypertension surgery, measured at similar sensitivity conditions, but had a lower specificity than the reported one. This may be attributed to the hyperactive state of the coagulation pathway due to the high coagulability state in liver cirrhosis patients, activated fibrinolysis, blood products used perioperatively, and trauma due to surgery[20-22,30].

Dynamic D-dimer value monitoring during the early stages after portal hypertension surgery may be more useful in achieving a meaningful diagnosis of PVT due to thrombosis formation. By analyzing the D-dimer after surgery and its predictive value for PVT, our study proved that the positive predictive value was 100% at ⩾ 16 μg/mL (Table 3). From the ROC curve (Figure 1), we could see that the qualitative standard was situated towards the left upper side of the semi-quantitative standard ROC curve, showing a higher sensitivity, but a lower rate of false positive response. Under the two extreme ends, the semi-quantitative standard curve was on the left-hand-side of the qualitative ROC curve, suggesting that the former may have a better diagnostic value. Therefore, combining semi-quantitative and qualitative measurement may be the best option for diagnosing PVT in liver cirrhosis patients after portal hypertension surgery.

In conclusion, D-dimer is an early predictive indicator of PVT after portal hypertension surgery in hepatitis B virus-related cirrhosis. Dynamic D-dimer monitoring should be performed perioperationly, and if elevation of the D-dimer levels persists or exceeds 16 μg/mL, PVT may occur, and anti-coagulation prevention and treatment should be considered.

COMMENTS

Background

Portal vein thrombosis (PVT) is a significant complication after portal hypertension surgery due to liver cirrhosis. The focus of clinicians is to prevent it as early as possible, but we still lack the early predictive indicator of postoperative PVT.

Research frontiers

PVT is a significant postoperative complication in patients with portal hypertension, especially after splenectomy. Since the mechanism of postoperative PVT remains unknown, it is difficult to prevent postoperative PVT. Most studies indicate that local operation may be the factor for postoperative PVT. Some studies indicate that D-dimer may be helpful in the diagnosis of deep vein thrombosis of lower extremity.

Innovations and breakthroughs

At present, most researchers and doctors diagnose PVT *via* imageology, especially color Doppler ultrasonography, and some reports indicate that platelets may be the predictive factor for PVT. D-dimer is a good predictive factor for deep vein thrombosis of lower extremity. The results of our study indicate that D-dimer may be a predictive factor for PVT after portal hypertension surgery in hepatitis B virus-related cirrhosis.

Applications

Since D-dimer is a predictive factor for PVT, PVT and its fatal complications can be prevented. By combining imageology, we can institute a scheme for the management of PVT, which helps to understand the mechanism of PVT.

Terminology

D-dimer: known as fragment D-dimer, fibrin degradation fragment; PVT: portal vein thrombosis. ROC curve: a graphic means for assessing the ability of a screening test to discriminate between healthy and diseased persons.

Peer review

This is a well-conducted study. It describes another way for the predictive diagnosis of PVT, but the relationship between the mechanisms of PVT and D-dimer remains unknown. D-dimer is only of a predictive diagnostic value.

Abstract

AIM: To prospectively evaluate the efficacy and safety of partial splenic embolization (PSE) combined with transcatheter hepatic arterial chemoembolization (TACE) in treatment of hepatocellular carcinoma (HCC).

METHODS: Fifty patients suffering from primary HCC associated with hypersplenism caused by cirrhosis were randomly assigned to 2 groups: group A receiving PSE combined with TACE (n = 26) and group B receiving TACE alone (n = 24). Follow-up examinations included calculation of peripheral blood cells (leukcytes, platelets and red blood cells) and treatment-associated complications.

RESULTS: Prior to treatment, there was no significant difference in sex, age, Child-Pugh grade, tumor diameter, mass pathology type and peripheral blood cell counts between the 2 groups. After treatment, leukocyte and platelet counts were significantly higher in group A during the 3-mo follow-up period (P < 0.05), but lower in group B (P < 0.05). Severe complications occurred in 3 patients (11.5%) of group A and in 19 patients (79.2%) of group B (P < 0.05), and there was no significant difference in symptoms of post-embolization syndrome, including abdominal pain, fever, mild nausea and vomiting between the 2 groups (P > 0.05).

CONCLUSION: PSE combined with TACE is more effective and safe than TACE alone for patients with HCC associated with hypersplenism caused by cirrhosis.

INTRODUCTION

Transcatheter hepatic arterial chemoembolization (TACE) has become the first choice of treatment for unresectable hepatocellular carcinoma (HCC)[1-4]. Since 70%-90% of HCC patients are associated with liver cirrhosis, portal hypertension and hypersplenism, treatment of HCC is usually affected by low peripheral blood cell counts (leukcytes, platelets and red blood cells) and high incidence of hemorrhagic complications due to treatment and/or portal hypertension[5-8]. Moreover, chemotherapeutics during TACE is another cause for low peripheral blood cell counts because of myelosuppression. Partial splenic embolization (PSE), which is thought to be an effective alternative to splenomegaly[9,10] because of its milder injury and fewer complications, has been widely used in treatment of leukocytopenia and thrombocytopenia caused by splenomegaly since the report of Maddison in 1973[11].

MATERIALS AND METHODS

Patients

From December 2002 to May 2006, 50 consecutive patients with HCC associated with hypersplenism caused by liver cirrhosis and portal hypertension were enrolled in this study. The diagnosis of HCC was established on the basis of clinical laboratory data, computed tomography and biopsy. The diagnosis of hypersplenism and splenomegaly was made in the light of clinical laboratory data and computed tomography. The enrolling criteria for this study were patients with splenomegaly and thrombocytopenia (platelet count $\leqslant 60 \times 10^9$/L) and/or leukocytopenia (leukocyte count $\leqslant 3.0 \times 10^9$/L). Adequate supporting therapies were performed for patients having severe peritonealgia before treatment with PSE and TACE or TACE alone in order to decrease the amount of ascites. Patients meeting the above criteria were randomly assigned to either group A or group B based on the computer-generated randomization sequences. Of the 50 patients,

26 received PSE in combination with TACE (group A), 24 received TACE alone (group B).The characteristics of these patients are summarized in Table 1.

Methods

The patients in group A were treated with PSE and TACE, first with PSE, and then with TACE, while the patients in group B received TACE alone.

PSE was performed as follows. In brief, a 5.0 French catheter (Terumo, Tokyo, Japan) was inserted into the femoral artery by the Seldinger method, celiac angiography and selective splenic arterial angiography were routinely performed to observe the distribution of splenic arteries and collateral circulation routes (Figure 1A), the tip of the catheter was placed as distal as possible at the hilus of the spleen, and embolization was performed using gelfoam particles (1-2 mm) suspended in an antibiotic solution (16 mg gentamicin sulfate) and contrast medium. The extent of embolization was set at 50%-70%. To achieve this, embolization was performed progressively by means of repeated injections of gelfoam particles under angiography control. Immediate angiography was done after each injection and the extent of embolization was expressed as the percentage of the ablated splenic parenchyma area shown by post-embolization angiography against the total splenic parenchyma area given by pre-embolization angiography. When a 50%-70% ablation of the splenic parenchyma was obtained (Figure 1B), the embolization was terminated. The extent of embolization was simultaneously estimated on angiography. In case the two estimates failed to agree, the mean value was taken. Finally, the precise extent of embolization was determined by CT scan 2 wk later.

Under strict conditions, TACE was performed as follows. In brief, a 5.0 French catheter (Terumo, Tokyo, Japan) was inserted into the femoral artery with the Seldinger method, celiac angiography and selective hepatic arterial angiography were routinely performed to observe the tumor blood-supply, distribution of hepatic arteries and collateral circulation routes (Figure 1C), the tip of the catheter was placed at the feeding artery of the tumor, and embolization was performed using an emulsion mixture of lipoidal ultra-fluid (Guerbet, France), perarubicin (50 mg/m^2) and DDP (80 mg/m^2). The maximum dose for embolization was based on the size of the tumor, blood supply and hepatic function of the patient. When the tumor was filled well with emulsifier, the embolization was terminated (Figure 1D).

Follow-up protocol

All patients underwent abdominal CT scanning (Light Speed QX/I CT scanner, GE Medical Systems, Milwaukee, Wis) 1 wk before operation (Figure 1E). Patients in group A also underwent abdominal CT scanning (Light Speed QX/L CT scanner,GE Medical Systems,Milwaukee,Wis) 2 wk after PSE/TACE treatment (Figure 1F). The extent of embolization (%) was determined by dividing the infarction volume, which is the whole splenic volume minus the residual splenic volume, by the whole splenic volume based on the CT examination 2 wk after PSE/TACE treatment.

After treatment with PSE in combination with TACE or with TACE alone, all patients remained in the hospital with their severe complications observed and were then followed up at the Outpatient Clinic. Peripheral blood cell parameters including white blood cells (WBC), platelets (PLT) and red blood cells (RBC) in group A after PSE/TACE treatment and in group B after TACE treatment were respectively monitored during the 1-wk, 2-wk, 1-mo, 2-mo and 3-mo follow-up after PSE/TACE treatment.

Statistical analysis

All data were analyzed using the SAS software (Vertion 8.1, SAS Institute, Cary, NC). Significance was established at $P < 0.05$. To determine statistically significant difference between the two groups, the *t*-test or the χ^2 test was used. The paired *t*-test was used to determine the difference in group A before and after PSE/TACE treatment and in group B before and after TACE treatment, and between groups A and B after treatment.

RESULTS

Chronological changes in peripheral blood cell counts

No significant difference was found in sex, age, Child-Pugh grade, tumor diameter, mass pathology type and peripheral blood cell counts between the 2 groups (Table 1). The peripheral blood cell counts before PSE/TACE or TACE treatment and from the third day to the forth week after PSE treatment are listed in Tables 2-4. There were no significant differences in WBC, PLT and RBC counts between the 2 groups before PSE/TACE or TACE treatment ($P > 0.05$). There were significant differences in WBC and PLT counts before and after PSE/TACE treatment ($P < 0.001$, Tables 2 and 3). WBC and PLT counts were significantly higher from the first week to the third month after PSE/TACE treatment. There were significant differences in WBC and PLT counts before and

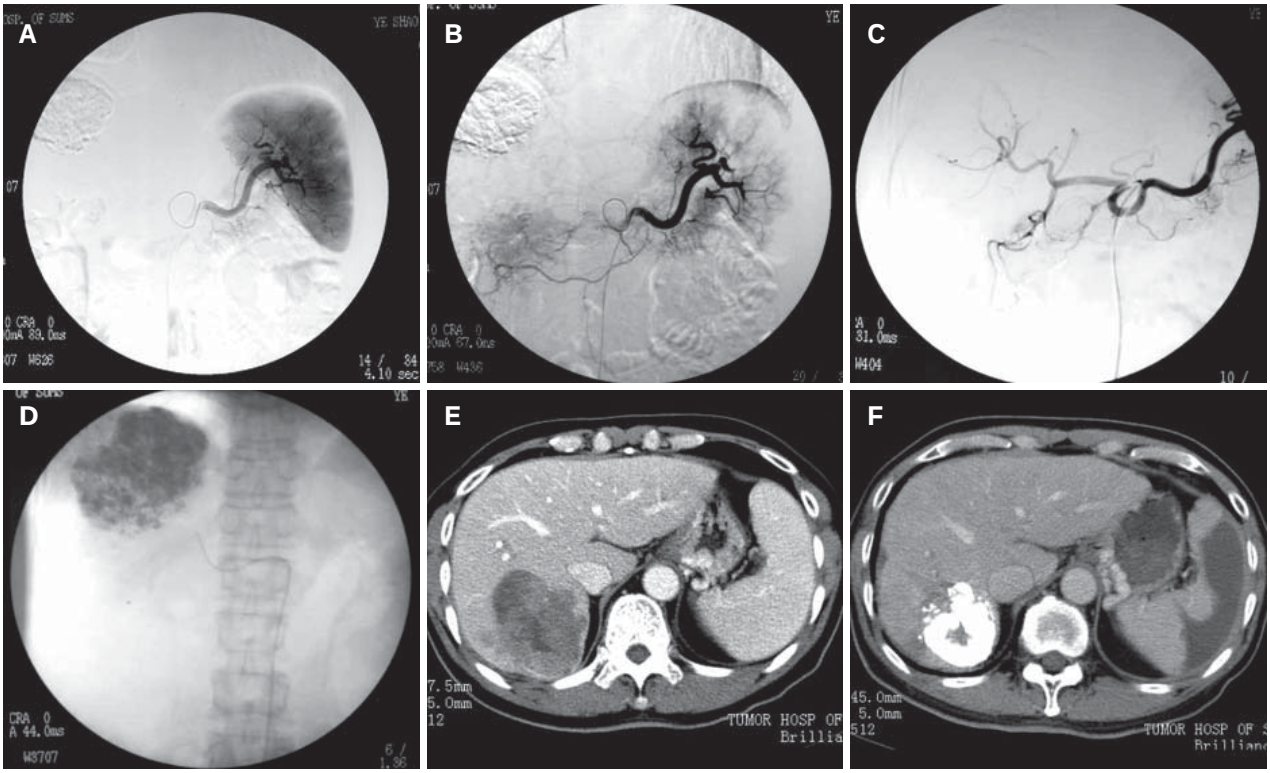

Figure 1 PSE treatment for a 68-year-old male case of HCC with splenomegaly and thrombocytopenia. **A**: Splenic arteriography before PSE showing the whole splenic parnchymal image; **B**: Splenic arteriography after PSE showing the residual splenic parnchymal image, part of the peripheral splenic parenchyma was ablated, and the extent of embolization was roughly estimated of approximately 60%; **C**: Celiac arteriography before TACE showing the tumor blood-supply image; **D**: TACE is terminated when the tumor is filled with emulsifier; **E**: Transverse CT image revealing splenomegaly at 1 wk before PSE/TACE; **F**: Transverse CT image revealing the infarction of peripheral splenic parenchyma at 2 wk after PSE. The extent of embolization was 62% calculated by CT volume analysis software.

after TACE treatment in group B ($P < 0.05$, Tables 2 and 3). WBC and PLT counts were significantly lower in group B from the first week to the third month after TACE treatment. There were significant differences in WBC and PLT counts between groups A and B ($P < 0.001$, Tables 2 and 3). WBC and PLT counts were significantly higher in group A after PSE/TACE treatment than in group B from the first week to the third month after TACE treatment. However, there were no significant differences in RBC counts between the 2 groups ($P > 0.05$, Table 4).

Complications

Symptoms of post-embolization syndrome, including abdominal pain, fever and mild nausea and vomiting, occurred in our patients. Abdominal pain was found in 76.9% (20/26) patients of group A and was alleviated by durogesic or oxycodone, in 75.0% (18/24) patients of group B and was alleviated by Tramadol with no significant differences between the two groups. The incidence of fever was 84.6% (22/26) in group A and was lowered by dexamethasone, 83.3% (20/24) in group B and was lowered by salicylic acid drugs with no significant differences between the two groups. The incidence of mild nausea and vomiting was 19.2% (20/26) in group A, 25.0% (6/24) in group B with no significant differences between the two groups. Severe complications occurred in 3 patients (11.5%) of group A, in 19 patients (79.2%) of group B (Table 5). A large amount of pleural effusion

Complications	Group A	Group B	*P*-value
Abdominal pain	20 (76.9)	18 (75.0)	0.874[1]
Fever	22 (84.6)	20 (83.3)	0.903[1]
Mild nausea and vomiting	5 (19.2)	6 (25.0)	0.623[1]
Large amount of pleural effusion or ascites	1 (3.9)	6 (29.2)	0.016[1]
Bacterial peritonitis	1 (3.9)	6 (25.0)	0.033[1]
Variceal bleeding	1 (3.9)	7 (29.2)	0.016[1]

[1]Data are determined with the χ^2 test.

and ascites was found in 1 patient of group A and in 6 patients of group B, leading to dyspnea or abdominal pain which was resolved by thoracentesis and paracentesis. Bacterial peritonitis occurred in 1 patient of group A and in 6 patients of group B 1 mo after PSE treatment. Variceal bleeding was observed in 1 patient of group A and in 7 patients of group B and was controlled by conservative therapy. There were significant differences in severe complications between the 2 groups ($P < 0.05$, Table 5). The occurrence of severe complications such as pleural effusion or ascites, bacterial peritonitis and variceal bleeding was significantly higher in group B than in group A after treatment.

DISCUSSION

HCC is often associated with hypersplenism due to liver cirrhosis. In such cases, it is very difficult to perform TACE because of the high incidence of hemorrhagic complications and/or portal hypertension, as well as poor tolerance of cirrhotic patients to chemotherapeutic drugs[12]. PSE is a useful support therapy for portal hypertension or hypersplenism and has taken the place of surgical splenectomy[9,10,13,14]. PSE appears to be effective in reducing episodes of variceal bleeding, improving hematologic parameters, enhancing hepatic protein synthesis, and reducing the severity of hepatic encephalopathy[15-18]. Roversi *et al*[12] reported that complications such as pleural effusion or ascites, bacterial peritonitis and variceal bleeding occurred in six patients with nodular HCC and cirrhosis (Child B) after treated with TACE in combination with PSE. In our study, thrombocytes, leucocytes and erythrocytes increased markedly, severe complications occurred in 3 patients (11.5%) of group A and in14 patients (79.2%) of group B. N'Kontchou *et al*[19] showed that severe complications occurred in six patients (16%) in their study, namely transient ascites in 2, splenic and/or portal vein thrombosis in 2, and splenic abscess in 2. Sakai *et al*[20] observed two cases suffering from severe complications after PSE treatment in 17 patients with cirrhosis. Other severe complications of PSE treatment such as pleural effusion, rupture of spleen, portal vein thrombosis have also been reported[13,21,22].

In this study, embolization ranged from 50% to 70%. Lee *et al*[23] reported that there are significant differences in platelet values between low and high embolization areas in patients with cirrhosis. The complication rate for < 30% and > or = 30% embolization areas is 50% and 100%, respectively. In our study, severe complications had a close relationship with the extent of embolization of the spleen. Among the 4 patients with an embolization of over 70%, 3(75%) developed severe complications. On the contrary, among the 22 patients with embolization of 70% or lower, only 1 (5%) developed severe complications, suggesting that PSE should be strictly limited to less than 70% of the splenic volume in order to reduce severe complications.

Gelfoam particles are the most commonly used embolic material in PSE [9,10,13,14,24-26], and extensive research has confirmed the short- or long-term efficacy of PSE using gelfoam particles as embolic material[9,13,14,25]. N' Kontchou *et al*[19] also performed PSE using PVA particles as embolic material (200-1000 μm in diameter) in patients with cirrhosis, but the efficacy and safety were uncertain, especially the long-term efficacy in peripheral blood cell count and safety. In this study, we used gelfoam particles as embolic material in PSE and achieved good results, indicating that gelfoam particles are safe materials in PSE.

In conclusion, combined one-step TACE/PSE treatment can improve the tolerance of HCC patients with advanced/decompensated cirrhosis and hypersplenism to chemotherapeutic drugs and reduce the risk of complications of invasive radiologic procedures and/or portal hypertension. PSE may resolve cytopenia and clinical complications related to hypersplenism or splenomegaly. However, due to severe complications, particularly splenic abscess, the indications for PSE should be limited and the extent of necrosis should be controlled during the PSE procedure.

COMMENTS

Background

In many cases of hepatocellular carcinoma (HCC) associated with liver cirrhosis and hypersplenism, it is very difficult to perform TACE because of the high incidence of hemorrhagic complications and poor tolerance of patients to chemotherapeutic drugs. The combined one-step TACE/PSE treatment can improve the tolerance of patients to chemotherapeutic drugs and reduce hemorrhagic complications of invasive radiologic procedures and/or portal hypertension.

Research frontiers

In this study, hematologic parameters and severe complications such as pleural effusion or ascites, bacterial peritonitis and variceal bleeding were observed. PSE may resolve cytopenia and clinical complications related to hypersplenism

or splenomegaly. Embolization and embolic material in PSE have not been standardized, but in our study, 50% to 70% of embolization was achieved with gelfoam particles as embolic material.

Innovations and breakthroughs

TACE has become the best choice of treatment for unresectable HCC. PSE may resolve cytopenia and clinical complications related to hypersplenism or splenomegaly. However, there have been few reports on the feasibility and effects of the combined one-step TACE/PSE treatment in cases of HCC associated with liver cirrhosis and hypersplenism.

Applications

Based on the results of our study, PSE in combination with TACE is more effective and safer for patients with HCC associated with hypersplenism caused by cirrhosis than TACE alone.

Terminology

TACE, an abbreviation of transcatheter hepatic arterial chemoembolization, is now widely used in treatment of HCC. PSE means partial splenic embolization.

Peer review

This paper provides some information about combining splenic embolization with TACE for gastroenterologists, hepatologists, and interventional radiologists.

Abstract

AIM: To discuss the surgical method and skill of biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury.

METHODS: From November 2005 to December 2006, eight patients with biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury were admitted to our hospital. Their clinical data were analyzed retrospectively.

RESULTS: Bile duct injury was caused by cholecystectomy in the eight cases, including seven cases with laparoscopic cholecystectomy and one with mini-incision choleystectomy. According to the classification of Strasberg, type E1 injury was found in one patient, type E2 injury in three, type E3 injury in two and type E4 injury in two patients. Both of the type E4 injury patients also had a vascular lesion of the hepatic artery. Six patients received Roux-en-Y hepaticojejunostomy for the second time, and one of them who had type E4 injury with the right hepatic artery disruption received right hepatectomy afterward. One patient who had type E4 injury with the proper hepatic artery lesion underwent liver transplantation, and the remaining one with type E3 injury received external biliary drainage. All the patients recovered fairly well postoperatively.

CONCLUSION: Roux-en-Y hepaticojejunostomy is still the main approach for such failed surgical cases with bile duct injury. Special attention should be paid to concomitant vascular injury in these cases. The optimal timing and meticulous and excellent skills are essential to the success in this surgery.

Key words: Bile duct injury; Biliary stricture; Roux-en-Y hepaticojejunostomy; Hepatic artery injury

INTRODUCTION

Since its introduction in the 1990s by Dubois[1], laparoscopic cholecystectomy has become the "gold standard" treatment for symptomatic gallbladder stone disease. Limited postoperative discomfort, shorter hospitalization, and rapid postoperative recovery have been proven to be advantageous of the procedure. Concomitantly, it became obvious that the incidence of bile duct injury rose from 0.06% to 0.3%, as known for open cholecystectomy, to 0.5% to 1.4% when performed laparoscopically[2-6]. Bile duct injury following cholecystectomy is an iatrogenic catastrophe associated with significant perioperative morbidity and mortality[7,8], reduced long-term survival and quality of life[9,10], and high rates of subsequent litigation. Apparently, it is a great surgical challenge to handle with biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury. The operation can be much more complex and difficult when compared with the first attempt for bile duct injury reparation.

MATERIALS AND METHODS

Methods

From November 2005 to December 2006, eight cases of biliary restricture after Roux-en-Y hepaticojejunostomy, performed at other hospitals for bile duct injury, were admitted to our hospital. The average age of those patients, seven female and one male, was 48.9 ± 7.5 (35-60) years. Bile duct injuries were all caused by cholecystectomy in other hospitals, including seven cases with laparoscopic cholecystectomy and one case with mini-incision choleystectomy. Although bile duct injury in three patients was initially treated by a T-tube placement within a choledocho-choledochostomy, Roux-en-Y hepaticojejunostomy was performed afterward (with a range of 4-13 mo) in those patients because of failure

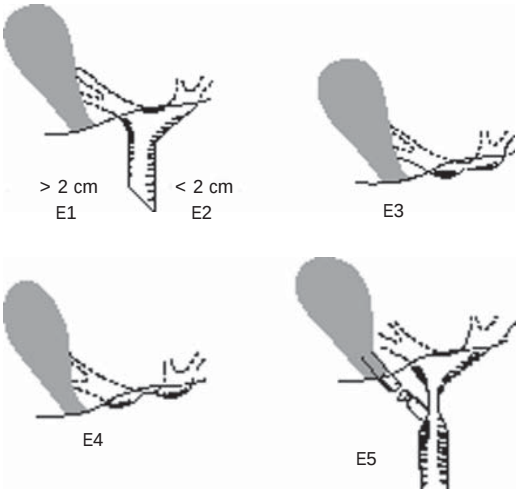

Figure 1 Strasberg classification of bile duct injury. E1: Transected main bile duct with a stricture more than 2 cm from the hilus; E2: Transected main bile duct with a stricture less than 2 cm from the hilus; E3: Stricture of the hilus with right and left ducts in communication; E4: Stricture of the hilus with separation of right and left ducts; E5: Stricture of the main bile duct and the right posterior sectoral duct.

in primary reparation. For the remaining five patients, Roux-en-Y hepaticojejunostomy was performed initially either during the operation of cholecystectomy or within a week after cholecystectomy. Unfortunately, all patients developed biliary restricture during the follow-up period, and were therefore transferred to our hospital.

Bile duct injury was classified according to Strasberg[11] when the medical files from the referring hospital were reviewed. After admission, those patients received abdominal CT and MRCP examination. Type E1 injury was found in one patient, type E2 injury in three, type E3 injury in two and type E4 injury in two patients (Table 1 and Figure 1). Both of the patients with type E4 injury also had a vascular lesion of the hepatic artery, with disruption of either the right hepatic artery or the proper hepatic artery. The average period between the primary Roux-en-Y hepaticojejunostomy and the operation in our hospital was 41.3 ± 46.5 (5-148) mo. Six of the eight patients received Roux-en-Y hepaticojejunostomy for the second time without stent implantation, and one of the six patients who had type E4 injury with the right hepatic artery disruption underwent right hepatectomy afterward. One patient who had type E4 injury with the proper hepatic artery lesion received liver transplantation, and the remaining one patient with type E3 injury received external biliary drainage.

RESULTS

All patients recovered uneventfully, and no significant complications occurred postoperatively. Three patients received additional or alternative surgical procedures. In one patient who had type E4 injury with the right hepatic artery disruption, the primary bile-enteric anastomosis of the left hepatic duct was fairly good, however the scarred biliary stricture occurred in the primary biliary-enteric anastomosis of the right hepatic duct, and multiple small abscesses were located in the right lobe of the liver. Considering the possibility of liver failure caused by insufficient remnant liver volume, we did not perform right hemihepatectomy at that time. Carefully removing those

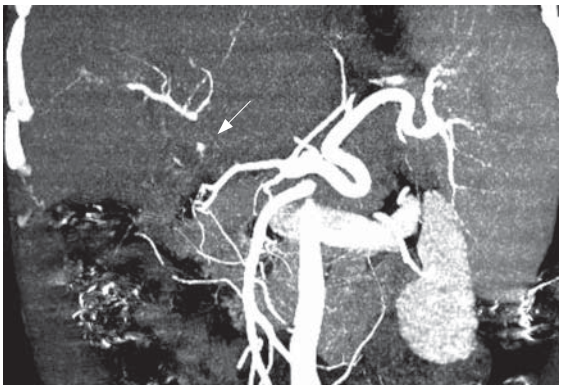

Figure 2 Computed Tomography angiography (CTA) of one type E4 injury patient displayed the lesion of the proper hepatic artery (arrow), although some compensatory collateral arterial blood supply from the left gastric artery could be identified. This patient received liver transplantation.

inflammatory scar tissues, we identified the openings of the right anterior hepatic duct and the right posterior hepatic duct. We connected these two bile duct openings into one by plastic reconstruction and performed biliary-enteric reanastomosis. Six weeks later, the abscess was found in the right hepatic lobe of this patient on CT with clinical symptoms. However, the left hepatic lobe compensatory enlarged and liver function improved, and thus the right hemihepatectomy was performed safely afterward. The other patient with type E4 injury had proper hepatic artery disruption, although compensatory collateral arterial blood supply from the left gastric artery could be identified by CT (Figure 2). The patient presenting secondary biliary cirrhosis combined with portal hypertension at admission received liver transplantation. The remaining patient with type E3 injury suffered from severe biliary infection, and the general condition was extremely poor. Although several stones were removed in the biliary-enteric anastomosis of the left duct during the operation, we could not expose

the main opening of the right hepatic duct even when painstakingly dissecting hepatic hilar tissue about 3 cm in depth. As a result, external biliary drainage had to be carried out.

At a median follow-up of 10 (range 4-17) mo, the six patients who received Roux-en-Y hepaticojejunostomy for the second time and one undergoing liver transplantation was clinically and biochemically stable without any pathologic findings. The symptoms of biliary infection of the patient receiving external biliary drainage were controlled, the liver function was ameliorated, and total bilirubin dropped from the preoperative level of 318 μmol/L to a level of around 100 μmol/L. This patient was waiting for liver transplantation.

DISCUSSION

In the United States and Canada, 34%-49% of surgeons have experienced a major bile duct injury, in one or two cases[5,12]. Increasing evidence has suggested that such injury should be managed by an experienced hepatobiliary surgeon[13] and the early recognition of injury directly affects the outcome[7]. Patients treated by the injuring surgeons have an increased death risk of 11% at nine years[14], yet in North America 58%-75% of injuries are still repaired by the injuring surgeons[9,12]. Similarly, such situation also occur in China. Undoubtedly, it is a surgical challenge to handle the failed cases of Roux-en-Y hepaticojejunostomy for bile duct injury.

Preoperative preparation

Initial treatment should focus on resuscitation of the patient, drainage of any collections to create a controlled enterocutaneous fistula and treatment of sepsis. Any unuseful intra-abdominal drains may be withdrawn subsequently from the hilum, reducing the inflammation caused by such a foreign body, thereby allowing the tissue to mature. Nutritional supports should be maintained during the whole perioperative period[15], since bile duct injury may even result in a systemic inflammatory response, with subsequent development of multiorgan failure. A low serum level of albumin at the time of surgery is often associated with a poor outcome[16]. Thus, it is important to address any nutritional deficit with enteral feeding, as long periods of biliary-enteric discontinuity will impair the function of the intestinal barrier and increase the risk of endotoxaemia and fat soluble vitamin deficiency[17].

Choice of operative method

If the biliary confluence is intact and there is no associated vascular injury, a hepaticojejunostomy onto the extrahepatic bile duct gives the best result[15,18-20]. Based on our preliminary experience, the number and diameter of bile duct openings at the hilum is not the limiting factor of the surgery. Murr *et al*[20] reported a 91% success rate and an 88% 5-year stricture-free survival. In liver transplantion surgery, biliary complications are almost universal following hepatic artery thrombosis. Vascular injuries contribute significantly to postoperative morbidity and mortality, particularly in cases of delayed diagnosis[21]. It has been shown that ductal ischemia due to concomitant hepatic arterial damage may be a cause of failed primary hepatojejunostomal reconstruction or late peripheral bile duct stenosis[22,23]. Occlusion of the right hepatic artery can lead to necrosis of the right hepatic lobe; therefore, it may be appropriate to consider a right hemihepatectomy[21]. In the case of poor general condition and uncontrollable biliary system infection, external biliary drainage might be the unique choice at the time of emergency. Patients who have developed secondary biliary cirrhosis should be considered to be the candidates for liver transplantation rather than further reconstruction, especially if there is significant portal hypertension[15]. Bile duct injury associated with complex vascular lesions might even necessitate liver transplantation[24].

Exposure of proximal bile duct

It is extremely important to create the biliary-enteric anastomosis to a healthy, non-inflamed, non-scarred duct. After the failure of the first attempt of Roux-en-Y hepaticojejunostomy, such dissection would become particularly difficult, for the level of scarred biliary stricture could be much higher than that of the primary bile duct injury. Once all adhesions of the right upper quadrant are sectioned, dissection of the jejunal limb is perfomed because misplacement and erroneous construction of Roux-en-Y are found in some patients[25]. For a correct hilar dissection, it is necessary to avoid the interruption of arterial branches as much as possible. No effort is given to completely dissect the arterial supply to the liver[26]. The hepatic artery itself and the previous surgical suture could be a useful anatomical mark in searching the bile duct at the hepatic hilum. The hilar plate is sectioned and the hilus is retracted caudally. If bile leak is observed during dissection, fine bile dilators are carefully inserted to identify the main ducts. Once the bile duct is explored, the scarred duct has to be removed up to a level at which a healthy duct is found. If the bifurcation is lost, with the isolated left and right hepatic duct, or the confluence is high and deep in the liver, dissection of the proximal bile ducts is not easily obtained. In such cases, partial liver resection of the segment Ⅳ and Ⅴ is done to allow adequate exposure of the left and right ducts, as described by Strasberg[27].

Surgical technique

In the present study, all patients received surgical repairs at their primary hospitals, and some even experienced numerous attempts. All those failed biliary-enteric anastomoses were placed at a too low level and exhibited technical faults such as the use of non-absorbable silk suture materials or a two-layer anstomotic technique. Attention to the anatomical placement of the anastomosis is of great importance[19,28,29], as failure after hepaticojejunostomy is usually caused by an anastomotic stricture, which is often ischemic in nature[28]. The healthy soft opening of the bile duct is crucial to the success of biliary-enteric reconstruction, however, the number and diameter of bile duct openings are comparatively of less importance. If bile duct openings at the hilum are nearby, plastic reconstruction could merge them into one or two openings (Figures 3 and 4). Although it is still controversial whether interrupted suturing or continuous

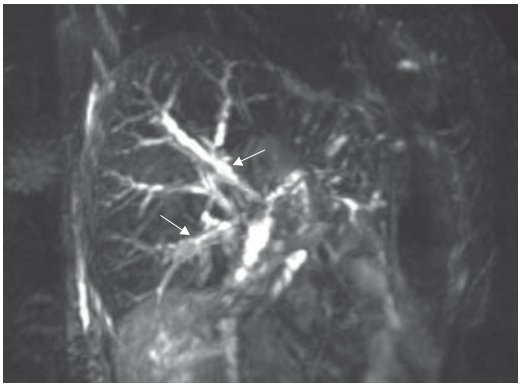

Figure 3 MRCP appearance of one type E3 injury patient showing dilation of intrahepatic bile ducts (arrows).

Figure 4 Plastic reconstruction in one type E3 patient merging several bile duct openings into one at the hilum after removal of the scarred ducts (the same patient in Figure 3).

running suturing is better for biliary-enteric anastomosis, we prefer the latter even in those extremely difficult cases with a single bile duct opening less than 3 mm in diameter. Actually, the distribution of tension in a continuous running suture would be more equal than an interrupted suture. Moreover, without the disturbance of multiple stitches as in interrupted suture, a continuous running suture would provide surgeons an easier way to focus their attentions to performing the anastomosis. The assistant surgeon should never pull the suture too tight during the entire procedure as we do expect to leave a 'growth factor' in every stitch. To improve the quality of biliary-enteric anastomosis is beyond the quarrel of the interrupted suture or continuous running suture. Based on our experience, traditional silk suturing should be abandoned in biliary-enteric anastomosis, since it might cause 'silk suture reactive stones,' looking like a necklace around the anastomosis area in some cases. Compared to most of the reported literature using absorbable PDS® suture for the anastomosis, we routinely use the non-absorbable Prolene® suture. Having observed a few cases of anastomotic edema of bile duct reconstruction using PDS® suture in previous liver transplanted patients, we consider that such absorbable suturing might be responsible for the foreign body reaction. However, this requires further investigations to draw a conclusion as to whether the absorbable PDS® suture or the non-absorbable Prolene® suture is advantageous in biliary-enteric anastomosis.

Attention to concomitant hepatic artery injury

It was reported that concomitant vascular injury was present in 71% of patients with Bismuth level Ⅳ lesions and in 63% of those with Bismuth level Ⅲ bile duct injury[23]. In our group, both of the type E4 injury patients had a hepatic artery lesion. Special attention should be paid to concomitant vascular injury in those complicated cases. The prognostic impact of vascular damage was underlined by Buell *et al*, who reported a 38% mortality rate in the presence of arterial lesions as against 3% in patients with injuries limited solely to the bile duct[30]. When vascular injury is recognized during the original operation, we would recommend immediate arterial reconstruction if the surgeon is capable or transfer the patient to a tertiary specialty department/clinic for definitive surgical repair. Delayed diagnosed vascular lesions are mostly not accessible for revascularization and can be followed by hepatic necrosis or persistent cholangitis resulting in end-stage liver cirrhosis. Based on our limited experience on one patient receiving liver transplantation and data reported by others, patients with bile duct injury associated with severe vascular lesion might be considered for liver transplantation.

Major bile duct injury during cholecystectomy is a disaster not only for the patient, but also for the surgeon. Although it would be extremely difficult to manage the patients with biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury, good results could be achieved in the form of Roux-en-Y hepaticojejunostomy for the second time in those complicated cases. Undoubtedly, a better general preoperative condition, careful selection of the operation method, excellent surgical skills and meticulous postoperative management would account for a favourable outcome in bile duct injury cases.

COMMENTS

Background

Laparoscopic cholecystectomy has become the first choice of management for symptomatic cholecystolithiasis. While it is associated with decreased postoperative morbidity and mortality, bile duct injuries are reported more severe and more common when compared with open cholecystectomy.

Research frontiers

Bile duct injury would be aggravated by delayed recognition or a failed initial repair. It is a great challenge for surgeons to handle the biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury. In most cases, if the biliary confluence is intact and there is no associated vascular injury, a secondary hepaticojejunostomy on the extrahepatic bile duct gives the best result.

Innovations and breakthroughs

It is extremely important to create the biliary-enteric anastomosis to a healthy, noninflamed, nonscarred duct, although the level of scarred biliary stricture could be much higher than that of the primary bile duct injury. Based on our preliminary experience, the number and diameter of bile duct openings at the hilum are not the limiting factors of the surgery. We prefer continuous running suture for biliary-enteric anastomosis.

Applications

Although it would be of great difficulty to manage the patients with biliary restricture

after Roux-en-Y hepaticojejunostomy for bile duct injury, good results could be achieved in a secondary Roux-en-Y hepaticojejunostomy in those complicated cases.

Terminology

Hepaticojejunostomy: anastomosis of hepatic duct and jejunum.

Peer review

The paper by Yan *et al* describes their surgical experience on biliary restricture after Roux-en-Y hepaticojejunostomy for bile duct injury in a Chinese university hospital. The results of the surgery seem to be impressive.

Abstract

Littoral-cell angioma (LCA) is a primary splenic vascular tumor that arises from the normal littoral cells lining the sinus channels of the splenic red pulp. We report a case of LCA of the spleen, which has been infrequently communicated in the literature. A 76-year-old man with a 2-wk history of weight loss, abdominal pain and changes in bowel habits was admitted to our hospital. Imaging studies (CT and MRI) showed multiple lesions in the spleen. Splenectomy was performed. Lining cells were positive for CD31/CD68 markers. Our case was associated with a serrated colonic adenoma. LCA is a benign vascular tumor of the spleen that needs to be included in the differential diagnosis of multiple splenic nodules.

Key words: Littoral-cell angioma; Spleen

INTRODUCTION

Littoral-cell angioma (LCA) is a rare primary tumor of the spleen that was first described by Falk *et al* in 1991[1]. Considered a benign condition, this neoplasm arises from the red cell pulp sinuses and has intermediate features between those of endothelial and histiocytic cells. To the best of our knowledge, there have been 11 cases of LCA reported in the English-language literature since the description of this disease in 1991[2]. We report a case of LCA in a patient who had symptoms of weakness, pain and change in bowel habits. The combination of CT and MRI showed multiple lesions in the spleen. Postoperative pathology examination confirmed the final diagnosis of LCA.

CASE REPORT

A 76-year-old man was admitted to our hospital with a 2-wk history of weakness, weight loss, anorexia, hypogastric abdominal pain and change in bowel habits. His past medical history showed gastrectomy due to peptic ulcer at the age of 63 years and polypectomy of villous colonic adenoma 2 years before admission. Physical examination was normal. No splenomegaly was found. Results of routine laboratory tests were normal. Colonoscopy identified a polylobulated polyp $\geqslant$ 3 cm in size in the sigmoid colon, and polypectomy was performed. Pathology was conclusive for serrated adenoma. An enhanced CT scan of the abdomen showed multiple round, hypodense lesions in the spleen. Abdominal MRI revealed multiple splenic hypointensive lesions (Figure 1). Our presumptive preoperative diagnosis was lymphoma or hemangioma. Splenectomy was performed. Microscopically, lesions consisted of anastomosing vascular channels with papillary projections and cyst-like spaces. They were lined with endothelial cells that showed hemophagocytosis. Lining cells were positive for both vascular (CD31) and histiomonocytic (CD68) markers (Figure 2), but CD8 and CD3 were negative. Ten months after surgery, the patient was asymptomatic.

DISCUSSION

LCA of the spleen may occur at any age (1-77 years; median age, 50 years), with no sex-based predilection (female: male ratio, 5:3)[2,3]. Clinically, patients have splenomegaly, abdominal pain, pyrexia of unknown origin[4] or hypersplenism. LCA may present as an incidental finding. LCA may appear as single or multiple lesions in the spleen. Splenic lesions ranged from 0.2 to 6.0 cm. An extensive list of possibilities such as multiple hemangiomas, lymphoma, metastatic disease, and disseminated infections caused by fungi, mycobacteria, *Pneumocystis carinii* and *sarcoidosis*, should be considered in the differential diagnosis of multinodular splenomegaly. CT, MRI, US, and Tc99m RBC scan characteristics have been correlated with histological and immunohistochemical pathological features[5]. Consistent CT features of splenic LCA reported in the medical

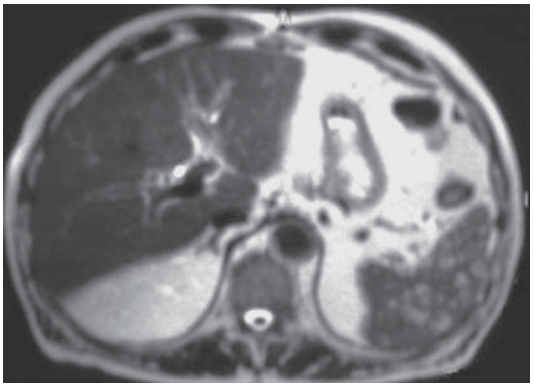

Figure 1 MRI: multiple hypointense lesions in the spleen (T_2).

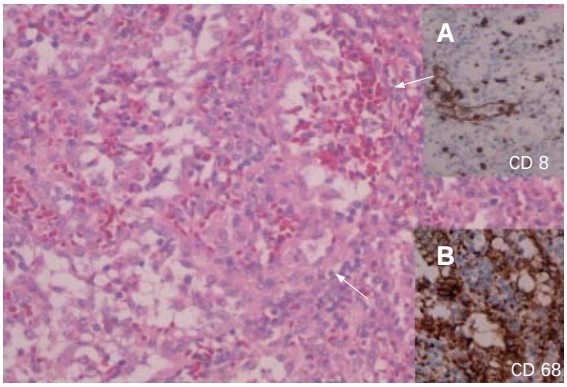

Figure 2 Vascular proliferation, well established (arrows), and very similar to normal spleen sinusoids. **A**: Negative for CD8; **B**: Positive for histiomonocytic markers.

literature include low-attenuating lesions on contrast-enhanced images[2,6]. Morphological diagnosis is based on the presence of anastomosing vascular channels lined with tall endothelial cells, focal papillary fronds, and normal splenic sinuses at the periphery of the lesion. Combination of morphological and immunohistochemical analyses that show a hybrid endothelial-histiocitic phenotype establish the diagnosis of LCA[1,7]. Two case reports have described variants of LCA with histological features of malignancy[8,9].

One third of the previously reported cases were associated with tumors of visceral organs, including colorectal, renal, hepatocellular[10], lung[11] and pancreatic adenocarcinomas, malignant lymphoma[12], myelodysplastic syndrome[13], or aplastic anaemia[14]. Since the malignant potential of LCA has not been firmly established in the literature, we recommend close clinical follow-up of patients with LCA of the spleen.

Abstract

Gossypiboma is the technical term for a retained surgical sponge. Because of legal-ethical concerns, there have not been many publications on this topic. Delays in diagnosis and treatment might increase mortality and morbidity. Radiological imaging is used in diagnosis. We present a case of gossypiboma that had fistulized to bulbous following hydatic cyst surgery. We established the diagnosis with endoscopy and followed its migration endoscopically.

Key words: Gossypiboma; Retained surgical sponge; Endoscopy

INTRODUCTION

Gossypiboma (textiloma, gauzoma, muslinoma) is a rare iatrogenic mass caused by the retention of gauze fibers during surgery. The retention of surgical sponges in body cavities is a rare clinical condition which is preventable[1,2]. Retained surgical sponge or gossypiboma in the abdominal cavity is an infrequent but serious surgical complication that may lead to medicolegal problems. The condition has not been very frequently reported due to possible medicolegal concerns[1,3-5].

CASE REPORT

A 44-year-old woman was admitted with a complaint of abdominal pain that was present for the previous 15 d and was increasing in intensity, together with nausea. In her history she mentioned being operated on 2 mo previously for hydatic cyst, with cystotomy and drainage (Figure 1). On physical examination, there was epigastric pain and tenderness, and laboratory findings were not remarkable, other than for mild leukocytosis. Gastroduodenoscopy was performed for her gastric complaints. Upon endoscopy, a foreign body (gauze) that protruded from the pylorus to the antrum was identified. The gauze could not be retrieved after being approached by biopsy forceps and a polypectomy snare (Figure 2). In upper abdominal CT, there was a foreign body (3 cm × 3.5 cm) with intramural localization in the first and the second parts of the duodenum. It was surrounded by a thin wall, had a density with-600-700 HU (air density/air bubble), heterogeneous internal structure and was protruding in to the duodenum (Figure 3). As there was no free perforation, the decision was taken for conservative treatment, and proton pump inhibitors and liquid diet were recommended. The patient had a stable clinical course and was endoscopically followed-up at 5-d intervals. During the follow-up, the gauze slowly migrated to the lumen. On the fourth endoscopic examination, there was no gauze in the lumen, and there was an ulcerated area with a fistula opening in the middle at the same position (Figure 4). There was no foreign body observed on control CT (Figure 5). Upon questioning the patient, no information could be obtained about the passage of the gauze. Following 3 mo of medical treatment, all the symptoms were gone; upon control endoscopy, ulcer scar was observed on the bulbous.

DISCUSSION

The incidence of surgical sponge being retained during operation is difficult to estimate, but it has been reported as 1 in 100-3000 for all surgical interventions and 1 in 1000-1500 for intra-abdominal operations[4]. Retained sponges are most frequently observed in patients with obesity, during emergency operations[6] and following laparoscopic interventions[7]. Gossypiboma is most frequently diagnosed in the intra-abdominal cavity; however, it can also be seen in paraspinal muscles[8] and the intrathoracic region[9], legs[10] and shoulders[11].

Gossypiboma results in significant morbidity and

possible mortality[5,12]. It can present itself as an intra-abdominal mass and might lead to erroneous biopsy attempts and unnecessary manipulations[13]. It commonly leads to misdiagnosis and unnecessary surgery[12]. Clinical presentation may be acute or subacute, and may follow months or even years after surgery[14]. Presentation of gossypiboma may vary and can be caused by pseudotumoral, occlusive or septic syndromes[5]. Of 14 patients with a diagnosis of gossypiboma, 13 were admitted with non-specific abdominal pain and intestinal obstruction. Four patients required emergency surgery due to intestinal obstruction or intra-abdominal sepsis[15]. Six patients with abdominal gossypiboma had symptoms of a mass, nausea, vomiting, abdominal distention and pain. Three patients were diagnosed with intestinal obstruction and two with pseudotumoral syndrome[16]. If the patients do not recover in the postoperative period and are readmitted with extraordinary problems, gossypiboma should definitely be considered as the differential diagnosis in such cases[12]. During the period that gossypiboma remains in the body, extrusion of the gauze can occur externally through a fistulous tract or internally into the rectum, vagina, bladder or intestinal lumen[17]. By either fistulizing to a luminal organ or through direct migration, it can cause intestinal obstruction[18-21]. There are reports of spontaneous migration of the sponge from the colon or rectum in the literature[3,6].

There has also been a case report demonstrating the migration of endoscopically confirmed intra-abdominal gossypiboma through fistulization to a luminal organ. In addition to assisting with a definitive diagnosis, endoscopy can also be helpful in planning treatment[18]. The gauze that

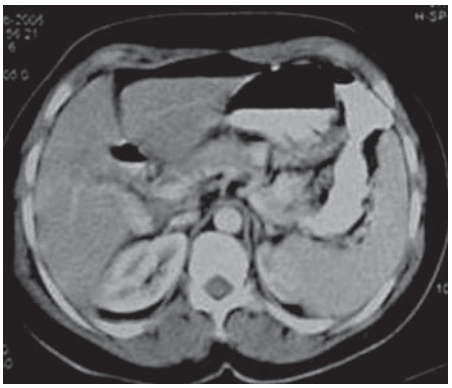

Figure 5 Control CT following the intraluminal migration of the intramurally localized gauze in the first and the second parts of the duodenum.

was endoscopically diagnosed in our case was found to have been corrected in the endoscopic follow-up, without necessitating surgical intervention.

They are mostly diagnosed by radiological methods in clinical practice. In radiological examinations, they are mostly seen as radio-opaque material, yet radiolucent material like sponges can cause diagnostic problems[3]. Plain radiographs suggest the diagnosis if a textile foreign body is calcified, that is, is equipped with a radio-opaque marker, or when a characteristic "whirl-like" pattern is present[22]. In the presence of radio-opaque markers, retained surgical sponges can be easily diagnosed by direct abdominal radiography; yet, if they penetrate and migrate inside the small bowel or bladder, it is difficult to localize them[20]. US images can be classified into two groups, a cystic type and a solid type[19]. US that shows a hyper-reflective mass with a hypoechoic rim, along with a strong posterior shadow, and CT that reveals a whirl-like spongiform pattern

in a hypodense mass, with a thick peripheral rim, are considered the mainstay of investigation[5]. CT and US are necessary procedures in chronic cases, since the lesion may mimic a mass. CT usually reveals a hypodense mass with a thick peripheral rim[22]. Upper abdominal CT examination of our patient revealed a hypodense lesion surrounded by a regular capsule.

Surgery is the preferred method of treatment for gossypiboma. Of eight patients who were diagnosed 12 mo after initial surgery, seven were treated surgically and one was cured with spontaneous migration from the rectum[6]. One patient who developed perforation and an abscess because of migration to the ileum required surgery[7]. There have been rare case presentations like our own, in which total migration to a luminal organ results in recovery without requiring a second operation. However, we think that in the absence of free perforations, as in our case, and in the presence of migration to luminal organs, conservative treatment with clinical and radiological follow-up should be considered.

In order to prevent these types of complications, we need to abide by the rule of total control of all surgical material before and after surgery, which is the main principle in all procedures. Strict measures must be taken to prevent this complication.

Abstract

Imatinib mesylate is a drug that has been approved for treatment of chronic myeloid leukemia (CML) in blast crisis, accelerated or chronic phase, and also for advanced gastrointestinal stromal tumors. Severe hepatic toxicity and three deaths from hepatic failure have been reported. We report the case of a 51-year-old woman who was admitted to our institution with severe acute hepatitis. She was diagnosed with CML and began treatment with imatinib mesylate at a dose of 400 mg/d. Five months after beginning treatment, she developed severe hepatitis associated with coagulopathy, and was admitted to our institution. She had been consuming acetaminophen 500-1000 mg/d after the onset of symptoms. She had a progressive increase in bilirubin level and a marked decrease of clotting factor Ⅴ. Five days after admission, grade Ⅱ encephalopathy developed and she was referred for liver transplantation. Her clinical condition progressively deteriorated, and 48 h after being referred for transplantation she suffered a cardiac arrest and died. This report adds concern about the possibility of imatinib-mesylate-induced hepatotoxicity and liver failure, particularly in the case of concomitant use with acetaminophen. Liver function tests should be carefully monitored during treatment and, with the appearance of any elevation of liver function tests, treatment should be discontinued.

Key words: Imatinib mesylate; Hepatotoxicity; Acute liver failure; Liver transplantation

INTRODUCTION

Imatinib mesylate (Gleevec; Novartis, East Hanover, NJ, USA) is a drug that targets *bcr-abl* tyrosine kinase, an enzyme that is regarded as the cause of Philadelphia-chromosome-positive chronic myelogenous leukemia (CML). It induces a much higher rate of complete cytogenetic remission (CCR), with improved tolerability and better progression-free survival compared to other therapies. It has been approved for treatment of CML in blast crisis, accelerated or chronic phase[1,2], and also for advanced gastrointestinal stromal tumors[3].

Severe hepatic toxicity has been reported in clinical trials. This includes grade 3 (5-20 times ULN) or 4 (> 20 times ULN) transaminase elevation in 1%-5.1% of patients, and grade 3 (3-10 times ULN) or 4 (> 10 times ULN) bilirubin elevation in 0.4%-3.5% of patients. Hepatotoxicity is usually resolved with imatinib dose reduction or interruption. Yet, permanent imatinib discontinuation for hepatic toxicity has been required in 0.5% of patients[4-6]. Three deaths from hepatic failure have been reported: two during treatment for CML (one in a phase 2 clinical trial[4,5] and the other during regular treatment[7]) and one during treatment for polycythemia vera[8]. We report another case of fatal acute hepatic failure in a patient receiving imatinib for CML.

CASE REPORT

A 51-year-old woman was admitted to our institution with severe acute hepatitis. She was diagnosed with CML 7 mo before admission. She was initially treated with hydroxyurea for 1 mo and then began treatment with imatinib mesylate at a dose of 400 mg/d. Five months after starting treatment, she developed asthenia. Laboratory tests showed elevated aminotransferases with normal bilirubin (Table 1). Treatment with imatinib was discontinued. Liver function tests worsened and she developed jaundice (Table 1). Fourteen days after imatinib was discontinued she was admitted to our institution with severe hepatitis associated with coagulopathy (prothrombin time 30% and clotting factor V level 19%) (Table 1). On admission she was jaundiced, had no signs of chronic liver disease and no evidence of encephalopathy. Abdominal ultrasound showed a reduced-size, homogeneous liver. The spleen was normal, and there were no signs of biliary

obstruction. Portal and suprahepatic veins were patent, with adequate blood flow. Minimal ascitic fluid was observed.

The patient had no known risk factors for viral or alcoholic liver disease. She had not recently used any dietary products or herbal remedies. She had been consuming acetaminophen 500-1000 mg/d after the onset of symptoms. Screening was negative for viral (HAV, HBV, HCV, CMV, EBV, HSV I and Ⅱ) and autoimmune hepatitis (ANA, ASMA, ANCA, LKM1 negative). Urinary copper level was normal, and she had a mild iron overload.

Concerning her CML, status detection of t (9; 22) BCR ABL (p 210) was performed by RT-PCR. It tested positive in peripheral blood and in the bone marrow. During the following days, the patient had a progressive increase of bilirubin level and a marked decrease of clotting factor V (Table 1). Five days after admission, grade Ⅱ encephalopathy developed. Prothrombin time was 6% and clotting factor V level was 10%, with a bilirubin level of 360 mg/L. She was referred for liver transplantation.

On arrival at the transplantation unit, the patient was admitted to the intensive care unit. Encephalopathy progressed to grade Ⅲ. During the following 24 h, she developed multiorgan failure with hypotension, low urinary output, respiratory distress and metabolic acidosis. Vasopressors were required, and high dose steroids (60 mg/d per nasogastric tube) and broad-spectrum antibiotics were started empirically. She was intubated and mechanical ventilation was initiated. Blood, urinary and ascites cultures were negative. Neutrophil count in peritoneal fluid was < 250/mm^3. No evidence of major bleeding was observed. Her clinical condition progressively deteriorated, and 48 h after admission she suffered a cardiac arrest that was unresponsive to resuscitation, and died.

DISCUSSION

Imatinib mesylate is a selective tyrosine kinase inhibitor that is used in CML, Philadelphia-positive acute lymphoblastic leukemia, and also gastrointestinal stromal tumors. Grade 3 or 4 transaminase elevation has been reported in up to 5.1% of patients in phase 2 and 3 clinical trials[4-6]. There have been three reported cases of fatal acute liver failure. In a phase 2 clinical trial, one death was suspected to be related to treatment in a patient taking 600 mg/d. The patient had received a bone marrow transplant and had been concomitantly taking 3000-3500 mg/d acetaminophen 1 mo before starting treatment. The patient died 12 d after beginning treatment[5]. A 46-year-old woman with CML developed abnormal liver function tests and subsequent acute liver failure after 18 mo of treatment with 400 mg/d. She received a liver transplant but later died due to sepsis. The explanted liver had histological features of severe hepatic necrosis[7]. In the third case, a 61-year-old woman with polycythemia rubra vera in spent phase/myelofibrosis received treatment with 400 mg/d 7 wk. She died 6 d after admission, secondary to extensive hepatic necrosis. Post-mortem histology revealed microthrombi within the vasculature of the liver, lungs and spleen. The authors postulated that the mechanism of hepatic necrosis was due to an exacerbation of the underlying prothrombotic tendency of polycythemia vera, which is not present in CML[8].

There are other references to liver toxicity with imatinib, yet all of them resolved after discontinuation of treatment. Data about liver histology varies between reports of focal necrosis with lymphocytic infiltration[9,10]; from marked periportal necrosis with mixed lymphocyte, neutrophil and plasmocyte infiltration[13]; to massive hepatic necrosis[11] or cytolytic acute hepatitis[12]. The time between beginning treatment and development of liver toxicity varies from 11 d to 49 wk[9-12]. In one study, treatment was reinitiated twice after normalization of laboratory tests. In both cases of re-challenge, including one with 2.5% of the current therapeutic dosage, liver toxicity reappeared[13]. See Table 2 for a comparison of previously reported cases of serious (fatal and non-fatal) drug-induced liver damage following treatment with imatinib mesylate (adapted from the report of Cross *et al*[7]).

Data about management of imatinib liver toxicity are scarce. Ferrero *et al* have reported that corticosteroids at low to intermediate dosage can reverse imatinib-induced hepatotoxicity. The use of prednisone (25-37 mg/d) or methylprednisolone (40 mg/d) resulted in the normalization of aminotransferase levels in 2-4 wk in all five patients treated. Imatinib therapy was then resumed at increasing dosage while corticosteroids were gradually tapered, without reappearance of liver toxicity[14].

Novartis, the manufacturer of imatinib, recommends in the package insert of Gleevec that liver function tests (transaminases, bilirubin, alkaline phosphatase and prothrombin time) should be monitored before initiation of treatment and then monthly, or as clinically indicated. If elevation in bilirubin is > 3 × the institutional upper limit of normal (IULN) or if liver transaminase is > 5 × IULN, then Gleevec should be withheld until bilirubin levels have returned to < 1.5× IULN and transaminase has returned to < 2.5 × IULN. Deininger *et al* have recommended obtaining liver function tests before

Table 2 Summary of previously reported cases of serious (fatal and non-fatal) drug-induced liver damage following treatment with imatinib mesylate

Reference	Diagnosis	Time to hepatic dysfunction	Liver histology	Outcome of liver enzymes
Ohyashiki *et al* (2002)	CML	12 d	Focal necrosis of hepatocytes	Resolution after stopping drug
Lin *et al* (2003)	Polycythemia vera	7 wk	Hepatic necrosis	Patient died fatal acute hepatic necrosis
James *et al* (2003)	CML	49 wk	Acute severe cytolytic hepatitis. With necrosis and mild cholestasis	Resolution after stopping drug
	CML	22 wk	Acute cytolytic hepatitis with spotty and some piecemeal necrosis	Resolution after stopping drug
Kikuchi *et al* (2004)	CML	36 wk	Hepatic necrosis	Resolution after stopping drug
Ayoub *et al* (2005)	CML	2 yr	Portal and lobular inflammation. Bridging and multifocal lobular necrosis	Resolution after stopping drug
Cross *et al* (2007)	CML	77 wk	Severe necrosis with multilobular confluent cell dropout and reticulin collapse, multinodular regeneration	Patient died 10 d after liver transplantation
Ridruejo *et al* (2007)	CML	22 wk	Not available	Patient died fatal acute hepatic necrosis

treatment is started, every other week during the first month of therapy, and at least monthly thereafter[15].

Acetaminophen is widely known as a cause of acute liver failure[16] and has been implicated as a significant co-factor in the pathogenesis of acute liver failure in patients with acute hepatitis B and in those taking antitubercular therapy[17]. Even though there is some controversy regarding the safety of acetaminophen in patients treated with imatinib, Deininger *et al* have recommended that patients be advised to use it with caution[15].

Acute liver failure is a rare condition that requires prompt evaluation for liver transplantation[18]. Pretransplant evaluation is required to exclude contraindications, such as malignancy[18,19]. Acute liver failure in patients with potentially treatable or curable cancer, such as hematological malignancy, is extremely unusual. The role of liver transplantation in these cases is unknown. The decision must be individualized to each patient, and discussed between the liver transplant and oncology teams.

The present case report confirms the possibility of imatinib-mesylate-induced liver failure, particularly in the case of concomitant use with acetaminophen. Liver function tests should be carefully monitored during treatment, and with the appearance of any elevation, treatment should be discontinued. Corticosteroids might be an option for treatment in selected cases.

Rudi Schmid, PhD, 1922-2007. Dr. Rudi Schmid, a leading academic physician and scientist in the field of hepatology died in his sleep on Saturday, October 20th, in Kentfield, California. He was 85.

Dr. Schmid was a former dean of the University of California, San Francisco School of Medicine and a liver specialist whose early studies of porphyrins led to several significant fundamental discoveries. He was the first to demonstrate that there were different forms of porphyria. He also developed the first experimental model for hepatic porphyria, a model that for many years was used for most of the work in this field and cited in hundreds of papers. His contributions were recognized when he was awarded the 1990 Friedenwald Medal by the American Gastroenterological Association, its most coveted award for lifetime achievement.

While taking a brief scientific detour from hepatology, he identified the enzymatic defect in McArdle's disease, a hereditary muscle disease, and defined its pattern of inheritance in a family in California's Central Valley.

Dr. Schmid's career as an academic administrator was equally distinguished. Recruited to UCSF in 1966 as a professor of medicine, he was the architect of one of the leading centers for gastroenterology and hepatology research, education and clinical care in the country.

He served as dean of the UCSF School of Medicine from 1983 to 1989. He often cited as his most important achievement as dean helping the faculty understand their crucial role as teachers of medical students. It was his insight that the pace of knowledge generation in basic science was far outstripping the ability of clinicians to understand and apply it in the patient setting. He strongly supported training medical students in the thinking and tools of fundamental science so that as clinicians they could understand the mechanisms and causes of disease. By the end of his deanship scientists such as Nobel laureate J. Michael Bishop were being recognized by the students as much for their teaching as their science.

Dr. Schmid's contributions to academic medicine continued after his deanship. As associate dean for international relations in medicine and pharmacy at UCSF, he particularly focused on developing formal mechanisms for student and faculty exchanges with China, which was starting to be receptive to overtures from the West. Through the Cheng Scholars Program, which he had persuaded his friend, Dr. YT Cheng of Hong Kong, to support, he built a bridge of scientific training and collaboration that is still an active program at UCSF.

His exquisite appreciation of scientific excellence translated to unprecedented support of the basic science graduate programs at UCSF, enabling them to become among the best in the nation. He fostered an environment of interdisciplinary collaboration which is a hallmark of UCSF to this day.

During his tenure as dean he had the unusual opportunity to appoint the chairs of 11 departments, many of whom went on to extremely distinguished careers within UCSF and at the national level. These include Dr. Bruce Alberts, president emeritus of the National Academy of Sciences; Dr. Zach Hall, director emeritus of the National Institute for Neurological Disorders and Stroke; and Dr. Haile T. Debas, chancellor emeritus of UCSF.

As dedicated and serious as he was about his work, Dr. Schmid was also known for his athleticism, passion for travel and sense of fun. A skier and mountain climber for most of his life, as a young man he was on the Swiss National Ski Team and made a number of first ascents in Europe and Peru. His approach to life was deeply influenced by a poem describing the meaning of "youth" given to him as a boy by his father. In it, Samuel Ullman

describes youth as ". . . not a time of life; it is a state of mind . . . it is a matter of the will, a quality of the imagination, a vigor of the emotion . . . the temperamental predominance of courage over timidity of the appetite, for adventure over the love of ease . . ." Those who knew Dr. Schmid say that this described him exactly.

Born in 1922 in Glarus, Switzerland, to physician parents, he studied medicine in Switzerland and completed his medical training and earned his PhD at the University of Minnesota. Dr. Schmid originally vowed to pursue anything but medicine and later said that he supposed he went to medical school because he didn't know anything else. Although he originally came to the Americas after medical school to climb mountains, a series of fortuitous events directed his career first to UCSF, then to Minnesota, the NIH, Harvard, and Chicago and back to UCSF.

Against his father's wishes, he stayed in the US. In an interview several years ago, Dr. Schmid said, "America was unbelievably good to me. It was a country after the Second World War where anybody who had talent and a willingness to work and to fight intellectually could succeed." He was describing himself in that statement.

Among the many honors Dr. Schmid received in his lifetime, most notable are election to the National Academy of Sciences, the Institute of Medicine, the American Association of Arts and Sciences, and Leopoldina, the German Academy of Sciences. In 2005 he was awarded the UCSF Medal, its highest honor.

Served as an honorable Editor-in-Chief of WJG since 2005, Dr. Schmid had given very valuable comments and peer reviews to 24 articles related to hepatology, almost one article every month. As an esteemed hepatologist, Dr. Schmid was invited to take part in the World Chinese Congresson of Digestology sponsored by WJG in October 1998. He gave a very interesting lecture,Gastroenterology in the next century: megatrends in science and practice. He highly evaluated the success of the congresson, and wrote a letter to Lian-Sheng Ma, Editor-in-Chief of WJG, to discuss some confusing concepts and hot topics for Chinese Gastroenterologists and world wide experts. In the past ten years, Dr. Schmid had provided valuable suggestions and made great contributions to the development of WJG.

The staff, particularly Lian-Sheng Ma, Editor-in-Chief, are very sorrowful to Dr. Schmid's pass away on October 20, 2007. A forever memorial is dedicated to the beloved hepatologist.

Dr. Schmid is survived by Sonja, his wife of 58 years, son Peter Schmid and daughter-in-law Diane of San Francisco; daughter Isabelle, son-in-law Michael Franzen and grandson Alexander.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.
EDITORIAL and LETTERS TO THE EDITOR are free of charge.
