Pre-malignant stomach epithelial neoplasms, gastric adenomas, have no nodal metastases. It is still controversial whether we should treat gastric adenomas endoscopically or follow them. A series with a small number of cases with a preoperative diagnosis of pre-malignant lesion revealed that 37% (16/43) of them were finally diagnosed as adenocarcinoma and a lesion > 1 cm was considered to pose a risk of malignancy<sup>[6]</sup>. Another study revealed that 6.8% (8/118) of cases were finally diagnosed as adenocarcinoma and high-grade dysplasia by endoscopic biopsy was considered to be an independent risk factor for malignancy<sup>[7]</sup>. Furthermore, preoperative diagnosis of depressed adenoma is considered to represent a higher risk of malignancy than protruding adenoma<sup>[8]</sup>. So, when the lesions have these characteristics, endoscopic treatments are recommended, similarly to intramucosal carcinomas. Although local recurrence should be taken into account, piecemeal resection by using EMR techniques to remove the apparent gastric adenomas is allowed.

In terms of malignant stomach epithelial neoplasms, the following types of early gastric cancers without lymphovascular infiltration of cancer cells may have

little likelihood of nodal metastases: (1) intramucosal, differentiated adenocarcinoma without ulcer findings of any size; (2) intramucosal, differentiated adenocarcinoma with ulcer findings when the lesion is ≤ 3 cm; (3) intramucosal, undifferentiated adenocarcinoma without ulceration when the lesion is ≤ 2 cm; and (4) differentiated adenocarcinoma with minute submucosal penetration (500 micrometers below the muscularis mucosa; sm1) when the lesion is ≤ 3 cm<sup>[9]</sup>.

### Technical aspects

When the endoscopists are well trained for ESD, the technical aspects may not restrict indications to perform ESD, based on the above criteria of no nodal metastasis. However, in our opinion, cases of ulcer findings with fusion of the muscle layer and the mucosal layer and cases of undifferentiated adenocarcinoma may be excluded from the indication or be carefully resected, at least until now. The former cases occur in cancers that previously had a deep ulcer extending into the proper muscle layer, where it is difficult to identify the gastric wall plane during submucosal dissection, which increases the possibility of perforation or incomplete resection by ESD<sup>[10]</sup>. In the latter cases, first, the margin is very unclear and the possibility of incomplete resection is fairly high, second, the clinical course after recurrence may be more miserable than that of differentiated-type, and third, the differentiation between ulcerative finding or biopsy-inducing fibrosis is sometimes difficult, even though small intramucosal undifferentiated adenocarcinoma with ulcer findings may be associated with nodal metastases<sup>[9]</sup>.

## ESOPHAGEAL SQUAMOUS EPITHELIAL NEOPLASMS

### Aspects of nodal metastases

Low- and high-grade squamous intraepithelial neoplasms, including carcinoma *in situ* (m1), have no nodal metastases. It is still controversial whether one should treat these intraepithelial neoplasms endoscopically or just follow them. However, when the lesions are diagnosed as high-grade intraepithelial neoplasms, endoscopic treatment is recommended, to avoid future development of invasive carcinoma or to contain foci of invasive carcinoma<sup>[11,12]</sup>. Although local recurrence should be taken into account, piecemeal resection by using EMR techniques to remove the apparent intraepithelial neoplasms is allowed<sup>[13-15]</sup>.

Esophageal squamous cell carcinomas invading the lamina propria (m2) pose little risk of nodal metastases. For those invading the muscularis mucosa (m3) and those with minute submucosal invasion (< 200 micrometers below the muscularis mucosa; sm1), the nodal metastases rate is 9.3% and 19.6%, respectively. The nodal metastases rate of m3 or sm1 cancers with 0-II type, < 5 cm, well or moderately differentiated type, and no lymphovascular infiltration of cancer cells is 4.2%<sup>[16]</sup>. It has been reported that no nodal metastasis was found in patients with sm1, low

histologic grades, and no lymphovascular infiltration of cancer cells<sup>[17]</sup>. Therefore, for patients unwilling to undergo esophagectomy or chemoradiation and patients with comorbid diseases, ESD may be applied taking into consideration the risks of nodal metastases and treatment-related morbidity.

#### **Technical aspects**

When the endoscopists are well trained for ESD, the technical aspects by themselves may not restrict indications to perform ESD, except in special circumstances, such as lesions located in the diverticulum. When lesions spreading > 3/4 of circumference are resected as circular or semi-circular resection, post-operative stricture occurs to a high rate<sup>[18]</sup>. So, it is controversial to treat these lesions endoscopically. However, intensive balloon dilatations or tentative stent insertion may rescue from the stricture.

## **ESOPHAGEAL BARRETT NEOPLASMS**

#### **Aspects of nodal metastases**

Columnar intraepithelial neoplasms have no nodal metastases. Although local recurrence should be taken into account, piecemeal resection by using EMR techniques and additional ablation therapy to remove the apparent intraepithelial neoplasms is allowed<sup>[19-23]</sup>.

There are no data about nodal metastases from the large numbers of surgically resected cases due to limited number of cases of esophageal columnar epithelial carcinomas at an early stage, although a small number of cases revealed no nodal metastasis for the intramucosal and sm1 cancer, where sm1 was determined by upper third of the submucosa<sup>[24]</sup>. There is no consensus whether one should apply to this kind of malignancy the same criteria that are applied to stomach epithelial neoplasms or esophageal squamous epithelial neoplasms as far as the depth of sm1 to be measured. International workshops of esophagogastric neoplasms adopted the cut-off line of 500 micrometers below the deeper muscularis mucosae, similarly to the stomach<sup>[25,26]</sup>.

#### **Technical aspects**

Similarly to esophageal squamous epithelial neoplasms, the technical aspects by themselves may not restrict indications to carry out ESD, when the endoscopists are well trained for ESD. When lesions spreading > 3/4 of the circumference of the esophagus (a situation which commonly occurs in long segment Barrett epithelium) are resected (with circular or semi-circular resection), post-operative strictures occur at a high rate<sup>[19-23]</sup>.

## **RECTAL EPITHELIAL NEOPLASMS**

#### **Aspects of nodal metastases**

Pre-malignant rectal epithelial neoplasms, rectal adenomas, have no nodal metastases. From the standpoint of adenoma-carcinoma sequence, all adenomas, including diminutive polyps, are targets for

endoscopic resection<sup>[27,28]</sup>, although some investigators agree with endoscopic removal only if the size is > 5 mm<sup>[29]</sup>. *En bloc* resection is not always necessary for rectal adenoma or intramucosal carcinoma. However, higher rate of local recurrence was reported when multiple resections were performed<sup>[30-32]</sup>. Intramucosal carcinomas and those with slight submucosal invasion (< 1000 micrometers below the muscularis mucosa; sm1) without lymphovascular infiltration have little risk of nodal metastasis<sup>[33]</sup>.

Tumor morphology and surface pit pattern are good endoscopic indicators for submucosal invasion. From this aspect, depressed lesions, laterally spreading tumors of non-granular type (LST-NG) and large protruding tumors are considered as good candidates for ESD because these lesions have a high risk of submucosal invasion, which may be difficult to diagnose preoperatively, and a thorough histopathological assessment of the resected specimen is essential. It is controversial whether one should perform ESD or piecemeal EMR for laterally spreading tumors of granular type (LST-G), because most lesions are intramucosal and the endoscopic prediction of invasiveness is highly feasible<sup>[34]</sup>.

#### **Technical aspects**

Even for lesions that meet the criteria above, laparoscopic or open surgery may be selected in some institutions considering the location and size of the lesion. The lesions with submucosal fibrosis due to previous endoscopic treatment or biopsy are also resectable by ESD, even though the indication should be carefully weighed considering risks and benefits of ESD *vs* surgery<sup>[35,36]</sup>. The rectum is fixed to the retroperitoneum, therefore the endoscope is more easily manoeuvred than in other organs of the gastrointestinal tract. Furthermore, panperitonitis may be less likely than in the rest of the colorectum, even if the muscularis propria is teared, although penetration leads to air accumulation in the retroperitoneal space, which may then spread to a wider area<sup>[37,38]</sup>.

## **COLONIC EPITHELIAL NEOPLASMS**

#### **Aspects of nodal metastases**

The criteria for absence of nodal metastases are the same as those of rectal epithelial neoplasms (see above).

#### **Technical aspects**

There are several tortuous folds in the colon. Peristalsis and residual feces may sometimes disturb ESD procedure. So it is commonly believed that the technical difficulty of colon ESD exceeds those of the stomach, the esophagus, and the rectum, although there are many differences. In all cases, should one consider the substantial risks and expected benefits of ESD. However, promising results of ESD are reported from very experienced endoscopists at advanced institutions, similarly to those of the rectal epithelial neoplasms<sup>[39-43]</sup>.

## EPITHELIAL NEOPLASMS IN THE SMALL INTESTINE, INCLUDING DUODENUM

### Aspects of nodal metastasis

Pre-malignant epithelial neoplasms in the small intestine have no nodal metastases. Although local recurrence should be taken into account, piecemeal resection by using EMR techniques and ablation therapy to remove the apparent intraepithelial neoplasms is allowed<sup>[44]</sup>. There are no data about nodal metastases from the large numbers of surgically resected cases due to limited number of cases of epithelial carcinomas in the small intestine. There is no consensus whether one should apply the same criteria of stomach epithelial neoplasms or colorectal epithelial neoplasms to this malignancy.

### Technical aspects

The small intestine, including the duodenum, is considered to be the most difficult organ where to perform ESD. The endoscope does not easily reach the target lesion and the organ is not fixed tightly except at the level of the duodenum, which results in fairly bad maneuverability. Peristalsis is the most active and the wall is the thinnest among the other gastrointestinal organs. Even if the resection is completed successfully, pancreatic juice and bile cause chemical damage to the mucosal wound, which may lead to prolonged bleeding and perforation. In our opinion, closure of the mucosal wound is recommended after ESD. When considering these issues, indication to perform ESD in the small intestine should be carefully assessed and limited. Due to the structural specificity of the papilla, ESD for ampullary neoplasms is not performed.

## PHARYNGEAL EPITHELIAL NEOPLASMS

### Aspects of nodal metastasis

Pre-malignant epithelial pharyngeal neoplasms have no nodal metastases. Although local recurrence should be taken into account, piecemeal resection by using EMR techniques and ablation therapy to remove the apparent intraepithelial neoplasms is permissible<sup>[45]</sup>. There are no data about nodal metastasis from the large numbers of surgically resected cases due to limited number of cases of pharyngeal epithelial carcinomas at an early stage. So, indication for invasive carcinoma is still controversial due to the lack of data. Owing to the structural differences, it is impossible to apply the criteria of esophageal squamous epithelial carcinomas for this malignancy.

### Technical aspects

ESD is technically possible in this organ, and ESD may be the optimal endoscopic treatment not only because it enables an *en bloc* resection but also because it can prevent removal of excess mucosa of the pharynx, which is a very narrow and important organ related to swallowing and speech<sup>[46]</sup>.

## CARCINOID

### Aspects of nodal metastasis

Carcinoids are classified based on organ site and cell of origin and occur most frequently in the gastrointestinal tract (67%) where they are most common in small intestine (25%), appendix (12%), and rectum (14%)<sup>[47]</sup>. Primary size > 2 cm, serosal penetration, and primary site in the small intestine are considered to be risk factors for metastases in the case of gastrointestinal carcinoids<sup>[48]</sup>.

Nodal metastases are most commonly found with small intestine carcinoids (20%-45%), providing the rationale for an extended resection including the adjacent lymph node drainage area. Carcinoids of the appendix < 1 cm rarely metastasize, simply requiring appendectomy for treatment. Rectal carcinoids < 2 cm rarely metastasize, directing local excision, including endoscopic resection<sup>[49]</sup>. Another group revealed that colorectal carcinoids < 1 cm without lymphovascular infiltration could be curatively treated by local resection, but others would need radical nodal dissection<sup>[50]</sup>. Duodenal carcinoids < 2 cm may be excised locally because they rarely metastasize<sup>[51]</sup>.

Multiple gastric carcinoids, usually no more than 1 cm, can be followed up by endoscopy and biopsy<sup>[52,53]</sup>. Sporadic gastric carcinoids should be treated by gastrectomy with lymphadenectomy, because some of those have nodal metastases even when they have a small size<sup>[54-56]</sup>. However, differentiation of types of gastric carcinoids is not always easy, so endoscopic resection, as a first step to obtain histology, may be acceptable for small gastric carcinoids < 1 cm to predict nodal metastases.

### Technical aspects

Because almost all lesions for local resection are less than 1 cm in all the gastrointestinal organs, band ligation resection<sup>[57,58]</sup>, cap-technique<sup>[59]</sup> or strip biopsy<sup>[60-62]</sup> result in good outcome. So the application of ESD for carcinoids may be limited. When the lesions are in intermediate size, such as 1-2 cm, or invade massively the submucosal layer, which may result in tumor-positive margin resection, ESD should be applied<sup>[56,63]</sup>.

## SUBMUCOSAL TUMOR

### Aspects of metastases

Submucosal tumors (SMTs) are mesenchymal tumors, which may have very diverse origins. SMTs are classified and defined as benign or malignant based on a combination of size, histological, immunohistochemical, and ultrastructural criteria. The majority of them are classified into gastrointestinal stromal tumor (GIST), of muscular origin, of neurogenic origin, of vascular origin, and of adipose tissue origin. SMTs < 3 cm are generally considered benign tumors. SMTs > 3 cm with high mitotic counts are considered tumors at high-risk of malignancy. In case of GIST, the cutoff of the size between pre-malignancy and malignancy may be

2 cm. Sarcomas including malignant GIST generally do not metastasize to regional lymph nodes, but instead spread hematogenously to the liver or metastasize to the peritoneum<sup>[64]</sup>. Benign SMTs should generally only be treated if they are symptomatic. So the SMTs > 2 cm or 3 cm without evidence of metastasis may be candidates for local resection<sup>[65]</sup>.

### Technical aspects

From the rationale of ESD, the targets should originate from over the muscularis propria. The lesions originating from the inner layer of the muscularis propria may be resectable by careful resection over the outer layer of the muscularis propria, but the high probability of perforation and the artificial peritoneal dissemination by tear of the tumor capsule should be taken into consideration. When considering that the small size lesions located in the mucosal or submucosal layers are mostly benign, the indication of ESD for SMTs is quite limited, although some investigators reported promising results of ESD for SMTs<sup>[66,67]</sup>.

### FUTURE PERSPECTIVES

The perspectives on the current indication of ESD are described based on a review of data available in the literature until the end of 2007. Further investigations in both aspects, the assessment of nodal metastases and the technical innovations, may change widely the above perspectives in the future. Recently, a new application of ESD is being investigated in cooperation with laparoscopic surgeons for the treatment of possible node-positive gastric carcinoma and gastric GIST<sup>[68,69]</sup>. There is no doubt that these attempts will expand ESD into a new field, which will be added to the upcoming practical guidelines for ESD.

## Abstract

Deposition of pigment in the intestinal mucosa is commonly observed by the endoscopist, especially within the colon, and particularly during investigations for constipation. Pigment may also be detected in the small intestine. Although labeled as melanosis, electron microscopy and X-ray analytical methods have provided evidence that this pigment is not melanin at all, but lipofuscin. Often, herbal remedies or anthracene containing laxatives are often historically implicated, and experimental studies in both humans and animal models have also confirmed the intimate relationship with these pharmacological or pseudo-pharmacological remedies. The appearance of melanosis coli during colonoscopy is largely due to pigment granule deposition in macrophages located in the colonic mucosa. The pigment intensity is not uniform, being more intense in the cecum and proximal colon compared to the distal colon. Possibly, this reflects higher luminal concentrations of an offending agent in the proximal compared to distal colon, differential absorption along the length of the colon, or finally, differences in macrophage distribution within the colon. Mucosal lymphoid aggregates normally display a distinct absence of pigment producing a "starry sky" appearance, especially in the rectosigmoid region. Interestingly, some focal, usually sessile, colonic mucosal neoplastic lesions, rather than submucosal lesions, may be better appreciated as pigment deposition may be absent or limited. If detected, removal and further histopathologic analysis of the polyp may be facilitated.

## INTRODUCTION

Prior studies using electron microscopy and X-ray analysis refined information regarding the composition of pigment granules in the intestinal tract. In particular, the distinction between lipofuscin, melanin and hemosiderin was more readily accomplished since separation of these pigment materials appeared to be possible based solely on their morphological characteristics<sup>[1]</sup>. X-ray analysis also permitted *in situ* analysis of tiny cellular inclusions in sectioned material with a high degree of sensitivity and sensitivity. As a result, a better understanding of pigments found in the intestinal tract has emerged.

## PIGMENT GRANULES

Lipofuscin granules are residual bodies with undigested and/or oxidized lipids. These granules are thought to result from the processes of sequestration and enzymatic dissolution of cellular organelles within lysosomes. Electron microscopy is reported to show single membrane-bound bodies containing electron-dense lipid material along with electron-lucent or medium density neutral fat. Melanin is synthesized in the melanosome by oxidation of tyrosine to dopa and, eventually, melanin. Characteristic striated rod-like structures are observed under electron microscopy. Hemosiderin develops in residual bodies that result from macrophage phagocytosis of erythrocytes and/or their breakdown products. Lysosomal digestion results in electron-dense iron-containing particles. Each granule type is distinctive and has been well illustrated by others elsewhere<sup>[1]</sup>.

## MELANOSIS COLI

Melanosis coli is probably the most common pigmentation change seen in the intestinal tract mucosa

**Figure 1** Typical alligator or snake-skin appearance of melanosis coli. Despite routine colon preparation, residual fecal debris is common, likely reflecting reduced colonic propulsive activity.

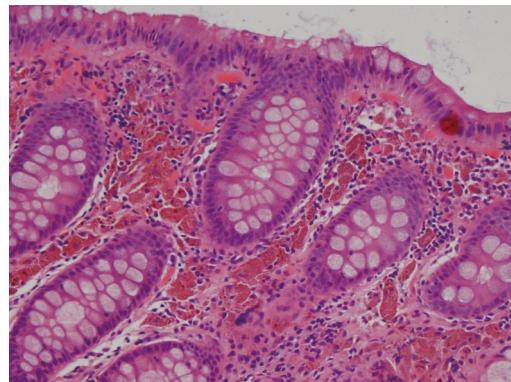

**Figure 2** Rectosigmoid mucosa illustrating focal areas of patchy intense pigmentation as well as focal areas of absent pigment, the latter reflecting the presence of normal mucosal aggregates of lymphoid cells (so-called "starry sky" appearance of melanosis coli).

during endoscopic evaluation and in biopsy materials submitted for histopathologic evaluation. It was, however, first described by Cruveilhier in 1829 before the emergence of endoscopic technologies. The abnormally brown or black pigmentation can even be visualized in the biopsy specimen in tissue forceps or on the filter paper prior to fixation immersion. Representative endoscopic appearances of melanosis coli are shown in Figures 1-3.

As shown, the pigment in melanosis coli is well localized within the colon as there is usually no pigment deposition in the more proximal small intestine, including the ileum. Occasionally, the pigment may extend through the entire colon, including the appendix and into the most distal ileal transition region with the cecum. It appears to be most intense and most readily detected in the cecum and ascending colon, but pigment changes are variable in their intensity, even within the same colon. In some areas of the colonic mucosa where lymphoid cell aggregates in the lamina propria are numerous, such as the rectum, the pigmented colonic mucosa shows a characteristic "starry sky" appearance, as these lymphoid cells do not accumulate intracellular pigment. As shown in Figure 4, a biopsy routinely treated with a standard hematoxylin-eosin stain shows

**Figure 3** Ileal and cecal mucosa in melanosis coli. Melanosis is generally confined to the cecal mucosa although there is a very limited area of transition into ileal mucosa that is not pigmented.

**Figure 4** Photomicrograph showing typical pigment granule laden macrophages in the lamina propria.

lamina propria macrophages filled with brown colored pigment granules.

A variation in the intensity of the pigmentation through the length of the colon appreciated in some patients with melanosis coli at endoscopy may reflect differences in the luminal concentrations of possible offending agents (i.e., higher in proximal colon), such as laxatives or their byproducts. Alternatively, there may be differential regional rates of mucosal absorption within the colon. Finally, there may be colonic regional differences in the topographic distribution of macrophages within the colonic lamina propria. Studies on granule composition have demonstrated primarily lipofuscin, rather than the melanin pigmentation historically suggested by histochemical staining reactions. Indeed, it has been suggested by others that this entity might be more precisely labeled "pseudomelanosis coli" or colonic "lipofuscinosis". Recently, however, a lectin method for application to formalin-based and paraffin-embedded colon<sup>[2]</sup> was used to explore changes in biopsies from patients with melanosis coli associated with laxative use<sup>[3]</sup>. These studies revealed increased apoptotic bodies in the colonic epithelium with pigment accumulation in macrophages. The results based on application of these lectins were typical of lipofuscin as well as ceroids. In addition, however, an intense argentaffin reaction abolished by bleaching was present,

**Figure 5** Easily visualized small sessile polypoid lesion in ascending colon with adjacent background pigmented mucosa typical of melanosis coli. Resected specimen confirmed absence of pigmented macrophages in the body of the resected adenoma.

**Figure 6** Small pigmented polypoid lesion similar to background pigmented colonic mucosa. Resected specimen revealed a submucosal leiomyoma along with pigmented macrophages in the overlying colonic mucosa due to melanosis coli.

most typical of a melanic substance. The apoptotic bodies in the colonic epithelium were thought to be due to laxative-induced cell death, not from natural programmed cell renewal. In addition, these apoptotic epithelial cells were believed to be the source of the pigment saccharides (as detected by lectins) while the melanic substance appeared to be derived directly from the anthraquinones<sup>[3]</sup>.

Melanosis coli is most often detected during investigation for long-standing constipation, often in conjunction with a history of the chronic use of anthracene cathartics (including cascara, senna, aloes and rhubarb). Experimental studies in different mammalian species along with humans previously documented the appearance, disappearance and re-appearance of the pigment in colorectal mucosa with repeated cycles of laxative administration. Interestingly, as shown in Figure 5, pigment deposition also may spare some neoplastic colonic lesions, including both adenomas and carcinomas. Thus, biopsy or removal of these non-pigmented foci in melanosis coli has been recommended elsewhere to exclude the presence of neoplastic epithelial cells. Other lesions, including submucosal leiomyomas shown in Figure 6, however, may still have pigment deposits within mucosal macrophages overlying these

focal submucosal lesions.

Anthraquinones appear to damage the colonic epithelial cells causing irreversible injury to some organelles. These cells are either shed into the colonic lumen, or the damaged organelles are sequestered in autolysosomes in macrophages where digestion to residual lipofuscin bodies results. In some, lymph node involvement has also been observed. It is possible that this relatively selective colonic mucosal involvement may reflect the qualitative or quantitative differences in colonic microbial flora (as opposed to the small intestine). Alternatively, some other structural difference in colonic cells or their response to anthraquinone cathartics may be responsible for the colonic mucosal regionalization of the lipofuscin pigment deposition.

Treatment of this condition has not been established. Often, a recommendation is made to manage symptomatic constipation with fiber-containing foods or substances with mucilage, including psyllium, along with avoidance of anthraquinone cathartics.

## MELANOSIS OF SMALL INTESTINE

Melanosis has been rarely recorded in the small intestine, at least, in the most readily visualized areas during routine endoscopic evaluation, including the duodenum or distal ileum. As noted earlier, pigment may extend for a very limited distance into the most distal ileum transitional mucosa in association with melanosis coli. Melanosis ilei alone and exclusive of pigmentation elsewhere, however, has also been noted, usually as an incidental observation during autopsy. In this setting, it has also been historically recorded to occur with carcinoma of the colon<sup>[4]</sup>. Pigment in the ileum is thought to arrive there through ingested materials found either in food or even inhaled dust that has been swallowed<sup>[5,6]</sup>. Although aluminum and silicon-containing compounds are common and may be detected as food additives or in medicines, hemosiderin pigment has also been detected in the ileum and hypothesized to result from intermittent bleeding within the upper gastrointestinal tract. Similarly, melanosis duodeni has also been related to occasional bleeding, usually from peptic ulceration<sup>[7-10]</sup>.

## EPIDEMIOLOGY

Hepatocellular carcinoma (HCC) is the commonest primary cancer of the liver. Incidence is increasing and HCC has risen to become the 5th commonest malignancy worldwide and the third leading cause of cancer-related death, exceeded only by cancers of the lung and stomach<sup>[1]</sup>. The estimated incidence of new cases is about 500 000-1 000 000 per year, causing 600 000 deaths globally per year<sup>[2-6]</sup>. However, important differences have been noted between countries. Most cases of HCC occur in Asia<sup>[1]</sup> where several countries, particularly in East Asia, have a very high incidence (over 20 cases/100 000 population). For example, the incidence is 99 per 100 000 persons in Mongolia, 49 per 100 000 in Korea, 29 per 100 000 in Japan, and 35 per 100 000 in China<sup>[3]</sup>. Hong Kong and Thailand also have similarly high rates. Another region of concern is sub-Saharan Africa, particularly the western region of Africa, including Gambia, Guinea, and Mali, and also the Republic of Mozambique in south-east Africa. Areas with moderately high risk (11 cases/100 000-20 cases/100 000) include Italy, Spain and Latin American countries, and those at intermediate risk (5 cases/100 000-10 cases/100 000) include France, the United Kingdom, and the Federal Republic of Germany. A relatively low incidence (less than 5 cases/10 000) is found in the United States, Canada, and in Scandinavia. However, there are large areas of the world where the incidence is still unknown<sup>[3,7,8]</sup>.

## Abstract

Hepatocellular carcinoma (HCC) is the commonest primary malignant cancer of the liver in the world. Given that the burden of chronic liver disease is expected to rise owing to increasing rates of alcoholism, hepatitis B and C prevalence and obesity-related fatty liver disease, it is expected that the incidence of HCC will also increase in the foreseeable future. This article summarizes the international epidemiology, the risk factors and the pathogenesis of HCC, including the roles of viral hepatitis, toxins, such as alcohol and aflatoxin, and insulin resistance.

**Table 1 Global frequency of new cases of hepatocellular carcinoma**

Year (reference)	Total number	Males	Females
1990	437408	316300	121100
2000	564300	398364	165972
2002 (The World health report, 2003)	714600	504600	210000

Adapted from Parkin *et al.*, 2001, 2005<sup>[2,5]</sup> and Bosch *et al.*<sup>[8]</sup>.

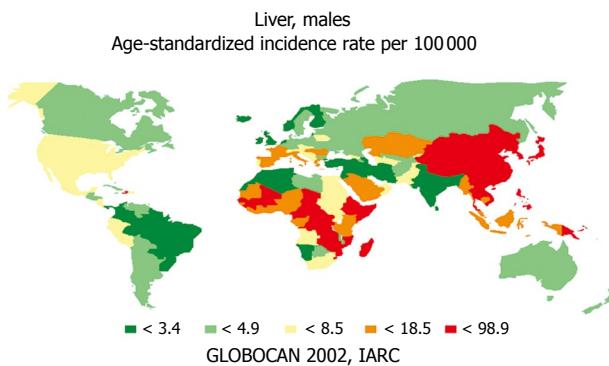

Although currently relatively low, the incidence of HCC is rising in developed western countries<sup>[9-12]</sup>. In the United States, there has been an increase of about 80% in the annual incidence of HCC during the past two decades. HCC rates increased from 1.4/100 000 per year from 1976-1980 to 2.4/100 000 per year from 1991-1995<sup>[3,10]</sup>. This increase has been most marked in men, with African-American men having higher incidence rates than US Caucasian men. This was explained by the emergence of hepatitis C during this same period, although the rise in immigration from HBV-endemic countries may also have played a role<sup>[9,10]</sup>.

Other developed western countries have noted similar increasing trends. An increase in incidence of HCC has been reported in Italy, the United Kingdom, Canada, Japan, and Australia. The increase was reported among immigrants from parts of the world with high prevalence, such as sub-Saharan Africa and parts of Asia, being associated with a parallel increase in hospitalization and mortality for HCC<sup>[3,10]</sup>. In Egypt, between 1993 and 2002, there was an almost twofold increase in HCC amongst chronic liver patients<sup>[13]</sup>.

However, it is not obvious when this rising trend, observed in many countries, will reach a peak. The Disease Control Center in Atlanta has estimated that deaths related to chronic hepatitis C in the United States will triple from the current rates of 8-10 000 per year during the next decade. While most of these deaths will be due to liver failure and its complications, a considerable proportion can be expected to be due to HCC as well<sup>[9]</sup>.

The most recent World Health report (World Health Organization<sup>[14]</sup>, Table 1) indicated a total of 714 600 new cases of HCC worldwide, with 71% among men (Figure 1). HCC is the 4th commonest cause of death due to cancer, after cancers of the respiratory system, stomach, and colon/rectum. Liver cancer ranked 3rd for male subjects and 5th for women. Geographically, there were 45 000 liver cancer deaths in Africa, 37 000 in the Americas, 15 000 in the eastern Mediterranean, 67 000 in Europe, 61 000 in South-East Asia, and 394 000 in the western Pacific region, including China and Japan. In the same year, 783 000 persons died from cirrhosis, of which 501 000 were men and 282 000 were women<sup>[15]</sup>.

The incidence of HCC increases with age, reaching its highest prevalence among those aged over 65 years<sup>[16,17]</sup>. Although HCC is rare before the age of 50 years in North America and Western Europe<sup>[18]</sup>, a shift in incidence towards younger persons has been noted in the last two decades. HCC tends to occur in the background of cirrhosis of the liver. In western countries, this holds

**Figure 1** Age-standardized incidence rates of liver cancer in males per 100 000 population (Adapted from GLOBOCAN 2002 with permission)<sup>[134]</sup>.

true in over 90% of cases, whereas in Asia and Africa the percentage of cases of HCC is higher in individuals with non-cirrhotic livers, compared to those with cirrhotic livers<sup>[3,19]</sup>.

## RISK FACTORS

The major risk factor for the development of HCC is cirrhosis of the liver. However, about one quarter of HCC cases diagnosed in the United States do not have any known predisposing risk factors. The major known risk factors for HCC are viral (chronic hepatitis B and hepatitis C), toxic (alcohol and aflatoxins), metabolic (diabetes and non-alcoholic fatty liver disease, hereditary haemochromatosis) and immune-related (primary biliary cirrhosis and autoimmune hepatitis)<sup>[17]</sup>. Recently, the geographical variability in the incidence of HCC has been attributed to the changing distribution and the natural history of Hepatitis B virus (HBV) and Hepatitis C virus (HCV) infection<sup>[20]</sup>.

## HCV

HCV is the most important risk factor for HCC in western European and North American countries, since epidemiological studies have shown up to 70% of patients with HCC have anti-HCV antibody in the serum<sup>[3,21-23]</sup>. Liver cancer has a higher prevalence in patients with HCV-associated cirrhosis than in non-viral aetiologies of chronic liver disease, while only a few cases of HCV-associated HCC have been reported in the non-cirrhotic liver, indicating that the virus possibly has a mutagenic effect<sup>[3,24,25]</sup>.

The prevalence of HCV infection varies considerably by geographical region. African and Asian countries reported high HCV infection prevalence rates, while rates in North America, Europe and Australia have usually reported lower rates<sup>[26,27]</sup>. Egypt has the highest prevalence of HCV in the world<sup>[28-34]</sup> (predominantly genotype 4), which has been attributed to previous public health eradication schemes for schistosomiasis<sup>[28,34]</sup>. Even higher HCV infection rates, up to 60%, have been reported in older individuals, in rural areas such as the Nile delta, and in lower social classes<sup>[28,30,32,34]</sup>.

The natural history of HCV infection has been investigated in several studies<sup>[3]</sup>. A Japanese study<sup>[35]</sup> reported a time lag of 13 years from infection by transfusion of

HCV infected blood to the development of chronic hepatitis. This time period was reported to be approximately 10 years in an American study and it took about 20 years for the same patients to develop cirrhosis of the liver<sup>[56]</sup>. Development of HCC took 28 years in the American subjects and 29 years in the Japanese cohort<sup>[35,56]</sup>. The annual risk of developing HCC in HCV-infected patients depends on the presence and severity of the underlying liver disease<sup>[3]</sup>.

Up to 80% of HCV-infected individuals fail to eliminate the virus acutely and progress to chronic HCV infection<sup>[27,37-40]</sup>. Continuous inflammation and hepatocyte regeneration in the setting of chronic hepatitis and subsequent progression to cirrhosis is thought to lead to chromosomal damage and possibly to initiate hepatic carcinogenesis<sup>[27,41]</sup>.

The rate of fibrotic progression following HCV infection is markedly variable, since the natural history of the disease typically extends over several decades<sup>[40,41]</sup>. The rate of fibrotic progression in HCV-infected patients is influenced by age at the time of infection, male sex, HCV genotype and alcohol consumption<sup>[42-50]</sup>.

It is not clear whether any of these factors affect the onset of liver-related complications by mechanisms other than their effects on the rate of fibrotic progression. To determine which interactive variables were independent determinants of adverse clinical outcomes, Khan and colleagues examined the development of liver-related complications of chronic HCV in a large cohort of patients who were heterogeneous in age, country of birth, mode of HCV acquisition, HCV genotype, and histological and functional severity of liver disease. Patients were followed up for five years. These authors found that the major independent predictors of liver-related complications were sporadic transmission, advanced liver fibrosis at entry and low albumin<sup>[43]</sup>.

## **HBV**

The WHO has reported HBV to be second only to tobacco as a known human carcinogen<sup>[51]</sup>. Many studies on HCC risk following chronic HBV infection have been conducted in the East Asian countries, where most patients acquired HBV as newborn infants<sup>[52,53]</sup>. The incidence of HCC in HBV-related cirrhosis in this area of the world has been reported to be 2.7%<sup>[53]</sup>. The annual risk of HCC is 0.5% for asymptomatic HBsAg carriers and 0.8% for patients with chronic hepatitis B<sup>[53,54]</sup>, while patients with HBV-cirrhosis have 1000 times higher risk of developing HCC, compared to HBsAg negative individuals<sup>[53,55]</sup>. Thus, it is likely that the probability of acquiring HCC increases with severity of underlying liver disease<sup>[53]</sup>. In Japan, the mean interval between HBV initial infection and the occurrence of HCC is 50 years. As most people are infected at birth, HBV-related cirrhosis usually develops earlier than in Western Europe or North America<sup>[35,53]</sup>.

Few adequate studies have been performed in Europe or North America to address the issue of the incidence of HCC in individuals who are positive for HBsAg. Most of the studies in Western countries are based on small

numbers of HBsAg positive patients and/or have not specifically analysed the group of HBsAg carriers. Additionally there is lack of uniformity in the timing of initiation of follow-up monitoring. In a cohort of 350 Western European patients with compensated cirrhosis, followed for about 6 years, the 5-year cumulative incidence of HCC was 6%<sup>[53,56,57]</sup>. A retrospective analysis of European patients with HBV-related cirrhosis found the 5-year incidence of HCC was 9%, irrespective of HBeAg or HBV DNA status at the time of diagnosis of cirrhosis<sup>[53,58]</sup>.

HCC has been the first human cancer amenable to prevention using mass vaccination programmes. From a global perspective, the burden of chronic HBV infection is expected to decline because of the increasing utilisation of HBV immunization, since the early 1980s<sup>[20,59,60]</sup>. The Taiwanese mass vaccination program against HBV has considerably reduced the rate of HBsAg carrier in children and adolescents and consequently the incidence of childhood HCC<sup>[20,61,62]</sup>. The average annual incidence of HCC in children aged 6-14 years declined gradually (0.70 per 100 000 children in 1981-1986, 0.57 in 1986-1990 and 0.36 in 1990-1994). A significant decrease in HCC incidence in adults was also observed, 3-4 decades later<sup>[20,63]</sup>.

## **HBV factors in HBV-related HCC**

The mechanisms of carcinogenesis in HBV infection have been extensively studied, and a major factor is chronic necroinflammation with subsequent fibrosis and hepatocyte proliferation. However, HCC may occur in HBsAg carriers without cirrhosis. Both HBV and host hepatocytes may contribute to the final pathogenic outcomes, either individually or synergistically. Therefore, it is reasonable to consider that apart from host factors, viral factors are likely involved in HBV-related hepatocarcinogenesis<sup>[20]</sup>.

## **Viral proteins in hepatocarcinogenesis**

HBV may encode oncogenic viral proteins that may contribute to hepatocarcinogenesis<sup>[20]</sup>. For example, HBx is a well-known viral non-structural gene that has roles as a multifunctional regulator modulating gene transcription, as well as controlling cell responses to genotoxic stress, protein degradation, apoptosis, and several signalling pathways<sup>[20,64-67]</sup>. Although the specific mechanisms are still unknown, its critical role in liver malignant transformation has been demonstrated in studies of transgenic mice with HBx overexpression<sup>[20,68]</sup>. HBx protein has been shown to complex the tumor suppressor p53 protein and to suppress its function<sup>[53,69,70]</sup>.

## **HBV genotype, basal core promoter (BCP) mutation and viral load in hepatocarcinogenesis**

Several viral factors other than viral proteins as viral genotype, BCP mutations in the viral genome and viral load have been associated with hepatocarcinogenesis<sup>[20]</sup>. Eight HBV genotypes (A-H) have been described, based on genomic sequence divergence<sup>[20,71,72]</sup>. These have distinct geographical and ethnic distributions: genotypes A and D prevail in Africa, Europe, and India; genotypes B and C in Asia; genotype E only in West Africa; and genotype

F in Central and South America<sup>[20,73]</sup>. It is reported that HBV genotype affects clinical outcome and treatment responses. For example, in Asia, genotype C is found to be commonly associated with more severe liver disease, cirrhosis and the development of HCC, compared to genotype B<sup>[20,65,68,74-78]</sup> whereas in Western Europe and North America, genotype D is more associated with severe liver disease and a higher incidence of HCC, than genotype A<sup>[20,79]</sup>. In addition to viral genotype, specific viral genomic mutations, particularly the BCP T1762/A1764 mutation, also correlate with HCC risk<sup>[20,80,81]</sup>.

A prospective cohort study with 11 years of follow-up assessed the relationship between HBV viral load and mortality. Viral load was found to be associated with increased mortality from HCC and chronic liver disease in HBV-infected subjects. The relative risk (RR) for HCC mortality in patients with viral load < 10<sup>5</sup> copies/mL was 1.7 (95% CI, 0.5-5.7), whereas it was 11.2 (95% CI, 3.6-35.0) in patients with viral load > 10<sup>5</sup> copies/mL<sup>[74-76]</sup>. Viral load may thus be a useful prognostic tool in HBV infection.

### **HBV factors in young-onset HCC**

Viral factors in association with the development of HBV-related HCC in young patients seem to be different from their old-aged counterparts<sup>[20,82]</sup>. Tsai and colleagues compared serum viral loads in young (less than 40 years of age) and older (over 40 years) patient groups in 183 HBV-related HCC patients and 202 HBV carriers. These authors found high serum HBV DNA levels were associated with the development of HCC in older patients, rather than those under 40 years<sup>[20,83]</sup>. Another study from Taiwan demonstrated that genotype B was significantly more common in patients with HCC, aged under 50 years, compared to age-matched inactive carriers (80% vs 52%,  $P = 0.03$ )<sup>[20,80]</sup>. This predominance was even more striking in younger patients with HCC, with 90% in those under 35 years. Most of these patients did not have cirrhosis. A further Taiwanese study reported that 26 children with HBV-related HCC were documented among 460 HBV carriers during 15 years follow up and genotype B was the major genotype (74%)<sup>[20,84]</sup>. These data suggest that genotype B-HBV may be associated with the development of HCC in young carriers without cirrhosis<sup>[20]</sup>.

### **Viral factors in HCC in the absence of cirrhosis**

Studies of HBV-related HCC in patients without cirrhosis have helped to explain the effect of viral factors in HCC development. Liu *et al* (2006) examined the role of BCP T1762/A1764 mutation, pre-core A1896 mutation and serum viral load in liver cancer, presenting in the absence of cirrhosis, by comparing 44 patients without cirrhosis, but with HBV-related HCC, to 42 individuals with cirrhosis and HBV-related HCC. These authors found that male gender, BCP T1762/A1764 mutation and viral load greater than 10<sup>5</sup> copies/mL were independently associated with the risk of HCC development in the absence of cirrhosis. They suggested that viral features predisposing to HCC might be similar between cirrhotic and non-cirrhotic groups<sup>[20,85]</sup>.

### **Pre-S deletion in HCC**

Recently, pre-S deletion of HBV has been found to be associated with the progression of liver disease and development of HCC in HBV carriers<sup>[20,86]</sup>. PreS deletion mutants hasten the storage of large envelope proteins in hepatocyte cytoplasm which can stimulate cellular promoters by inducing endoplasmic reticulum stress<sup>[53,87,88]</sup>.

The interactions between pre-S deletion, PC mutation and BCP mutation of various stages of chronic HBV infection were investigated in 46 chronic HBV carriers and 106 age-matched carriers with different stages of liver diseases; 38 with chronic hepatitis, 18 with cirrhosis, and 50 individuals with HCC<sup>[87]</sup>. Logistic regression analysis demonstrated that pre-S deletion and BCP mutation were significantly associated with the development of progressive liver disease. Combinations of mutations, especially the pre-S deletion, rather than single mutation were correlated with a greater risk of progressive liver disease. Sequencing analysis showed that the deleted regions were more common in the 3' terminus of pre-S1 and the 5' terminus of pre-S2<sup>[20,86]</sup>.

### **Combined hepatitis B and hepatitis C**

Follow up studies have shown that patients with combined HCV and HBV infection have a higher risk of developing HCC than those with a HCV or HBV alone<sup>[53,89]</sup>. The cumulative risk of developing HCC was 10%, 21%, and 23%, respectively, after 5 years and 16%, 28% and 45%, respectively, after 10 years<sup>[5,90]</sup>.

The HCC risk in subjects with both infections was investigated in a meta-analysis of 32 epidemiological studies between 1993 and 1997<sup>[53,91]</sup>. The OR for development of HCC in HBsAg positive, anti-HCV/HCV RNA negative subjects was 20.4; in HBsAg negative, anti-HCV/HCV RNA positive subjects, 23.6; and subjects positive for both markers, the OR was 135. These data suggest a more than additive effect of HBV and HCV coinfection on HCC risk. The two viruses may possibly act through common, as well as different, pathways in the carcinogenic process. Given that HBV acts as a cofactor in the development of HCV related cirrhosis and HCC, vaccination of patients with chronic hepatitis C against HBV has been recommended aiming to avoid further liver injury<sup>[53,92,93]</sup>.

### **Coinfection of HBV and hepatitis D virus (HDV)**

HDV coinfection with HBV is associated with increased liver damage. Verme and coworkers showed that HBsAg positive patients with HDV superinfection develop cirrhosis and HCC at an earlier stage (mean age 48 years), compared to HBsAg carriers without HDV infection (mean age 62 years)<sup>[53,94]</sup>.

### **Coinfection with HIV**

Chronic hepatitis C is more aggressive in HIV positive subjects, leading to cirrhosis and liver failure in a shorter time period<sup>[53,95]</sup>. Coinfection with HIV is a frequent occurrence because of shared routes of transmission. A recent study of HCC in HIV-HCV coinfecting patients indicated rapid development of HCC in these patients<sup>[53,96]</sup>.

### **Role of schistosomiasis**

Schistosomiasis is a common parasitic infestation in some parts of the world. In Egypt, Schistosomiasis is a major public health problem and infection with *Schistosoma mansoni* constitutes the major cause of liver disease. From 1950s until 1980s, the Egyptian Ministry of Health (MOH) conducted a community-wide therapy campaign using parenteral tarter emetic to control the Schistosomiasis infestation. However, this unfortunately established a large reservoir of HCV infection in the country through needle re-usage at the time of treatment<sup>[97]</sup>. There is some epidemiological evidence that the presence of schistosomal infection may modify the course of hepatitis C genotype 4 co-infection and may lead to significantly more complications, such as portal hypertension at an earlier stage with accelerated progression to hepatitis C-associated fibrosis and thus quicker progression to HCC, than those patients who do not have a parasite burden<sup>[13,31-34]</sup>.

### **Role of aflatoxin B1 (AFB1)**

AFB1 is produced by a fungus of the genus, *Aspergillus* spp, in Asia and sub-Saharan Africa in which climatic factors and storage techniques favour the fungus to be a common contaminant of foods, such as grain, corn, peanuts and legumes. Areas with high exposure of AFB1 coincide with areas with a high prevalence of HCC. It has also been suggested that a high intake of AFB1 in HBV-infected patients is an added risk factor for HCC development<sup>[3,73,98,99]</sup>. It has been observed that areas with a high prevalence of HCC and high aflatoxin intake also correspond to areas with endemic HBV infection, and that patients at highest risk of developing HCC are those who are exposed to both HBV and AFB1<sup>[3,98]</sup>.

Somatic mutations of the tumor suppressor p53 gene are the commonest genetic abnormality in human cancer and evidence supports a high level of p53 alterations in HCC. El Far and colleagues investigated p53 mutations in Egyptian patients with HCC and its relation to other prognostic factors, such as tumor grade,  $\alpha$ -fetoprotein (AFP) and liver function tests to elucidate their implication in HCC pathogenesis. These authors found that p53 detection increased the frequency of HCC prediction from 79.5% to 86.3%. Moreover, significant positive correlation between p53 mutation and tumor size for tumor grade II and III was identified. Thus, serum concentration of p53 protein may be a potential non-invasive screening test for predicting risk of HCC<sup>[100]</sup>.

It has been suggested that AFB1 can lead to HCC through inciting a specific mutation of codon 249 of the p53 tumor suppressor gene<sup>[101]</sup>. However, this mutation has also been found in patients who had previous contact with the HBV<sup>[3,78]</sup>.

### **Pesticides**

Pesticides exposure is one of the environmental factors hypothesized to increase the risk of HCC. Pesticides are considered to be possible epigenetic carcinogens through one or several mechanisms, such as spontaneous initiation of genetic changes, cytotoxicity with per-

sistent cell proliferation, oxidative stress, inhibition of apoptosis, suppression of intracellular communication and construction of activated receptors<sup>[102,103]</sup>.

A case-control study of HCC in HBV and/or HCV infected patients from Egypt suggested pesticides had an additive effect on the risk of HCC in rural males, amongst whom the use of carbamate and organophosphate compounds is commonplace<sup>[103]</sup>.

### **Diabetes mellitus**

A population-based study from the USA found diabetes to be an independent risk factor for HCC, regardless of chronic HCV or HBV infection, alcoholic liver disease, or non-specific cirrhosis. Diabetes was associated with a two- to threefold increase in HCC risk. About 60% of patients with HCC in this study were not diagnosed with chronic HCV-related or HBV-related hepatitis, alcoholic liver disease, or other known causes of chronic liver disease. Among these patients, 47% had diabetes, which was higher than those with other risk factors (41%). This suggests that diabetes may represent a considerable proportion of patients with idiopathic HCC<sup>[104]</sup>.

An increased risk of HCC among patients with diabetes alone was also reported in a population based study using data obtained from the Denmark cancer registry<sup>[104,105]</sup>. Also, it is reported a threefold increased risk of liver cancer among patients hospitalized with diabetes, as well as and a fourfold risk in the presence of hepatitis, cirrhosis, and alcoholism in a Swedish study<sup>[104,106]</sup>.

Diabetes, as part of the insulin resistance syndrome, has been implicated as a risk factor for non-alcoholic fatty liver disease (NAFLD), including in its most severe form, non-alcoholic steatohepatitis (NASH). NASH has been identified as a cause of both "cryptogenic cirrhosis" and HCC<sup>[104,107-112]</sup>.

### **Diet**

Many epidemiological studies have examined the relationship between diet and HCC risk<sup>[113]</sup>. The results are somewhat conflicting. Some studies have shown an inverse relationship between HCC and diets which are high in milk, wheat, vegetable, fish and fruit content. Other studies have shown no association.

With regard to egg consumption, two studies reported an inverse relation with HCC risk<sup>[114,115]</sup>, while three others reported an increased risk<sup>[115-117]</sup>. Similarly, two studies<sup>[118,119]</sup> demonstrated that meat and animal protein consumption were associated with increased risk of HCC, although other studies<sup>[114-116]</sup> did not support this finding<sup>[113]</sup>.

To verify if consumption of soya foods reduce the HCC risk, Sharp and his colleagues conducted a case-control study within a cohort of Japanese A-bomb survivors. They compared the pre-diagnosis intake of isoflavone-rich miso soup and tofu to HCC risk, adjusting for hepatitis B (HBV) and C (HCV) viral infections. They concluded that consumption of miso soup and other soya foods may reduce HCC risk and this is consistent with the results of epidemiological, animal and laboratory-based studies, as well as some clinical trials<sup>[120]</sup>.

This is explained by the opposing effect of isoflavones on oestrogen and testosterone levels which reduce HCC risk, possibly by modifying the hormonal profile and reducing cell proliferation, associated with increased cancer risk. An alternative explanation may be that isoflavones provide an independent anti-tumour effect, such as suppression of angiogenesis, or stimulation of apoptosis<sup>[120]</sup>.

A 41% reduction in HCC risk among coffee drinkers, compared to non-drinkers, has been observed in a meta-analysis study<sup>[121]</sup>. This favourable effect of coffee drinking was established both in studies from southern Europe<sup>[122-124]</sup>, where coffee is widely consumed, and from Japan<sup>[125,126]</sup>, where coffee intake is less frequent, and in subjects with chronic liver disease<sup>[121]</sup>. Some compounds in coffee, including diterpenes, cafestol, and kahweol, may act as blocking agents *via* modulation of multiple enzymes involved in carcinogenic detoxification as demonstrated in animal models and cell culture systems<sup>[119,127,128]</sup>. Moreover, coffee components modify the xenotoxic metabolism *via* induction of glutathione-S-transferase and inhibition of N-acetyltransferase<sup>[121,129]</sup>. Other components of coffee, including caffeine and antioxidant substances from coffee beans, have been related to favorable modifications in liver enzymes such as  $\gamma$ -glutamyltransferase and aminotransferase activities<sup>[119,130-133]</sup>.

## CONCLUSION

HCC is one of the commonest cancers worldwide. It is a major health problem and its incidence is increasing. The presence of cirrhosis is the major risk factor and worldwide this is largely due to chronic HCV and HBV infection. HCC carcinogenesis is likely to involve interplay of viral, environmental and host factors. The advent of mass-vaccination programmes for hepatitis B, particularly in East Asia is beginning to reduce prevalence rates for HCC in some countries, but for the most part, HCV-related HCC is increasing. Concerted strategies need to be developed for HCC surveillance in at risk populations.

observed at 70 µg/mL after 72 h of treatment. During the process, cytosolic HepG2 cytochrome C staining showed a markedly stronger green fluorescence than in control cells in a dose-dependent fashion, and CWO also caused mitochondrial transmembrane depolarization. Furthermore, the results clearly demonstrated that both, activity of caspase-3 enzyme and protein levels of cleaved PARP, significantly increased in a dose-dependent manner after treatment with CWO.

**CONCLUSION:** CWO exhibits an antiproliferative effect in HepG2 cells by inducing apoptosis. This growth inhibition is associated with cell cycle arrest, cytochrome C translocation, caspase 3 activation, Poly-ADP-ribose polymerase (PARP) degradation, and loss of mitochondrial membrane potential. This process involves a mitochondria-caspase dependent apoptosis pathway. As apoptosis is an important anti-cancer therapeutic target, these results suggest a potential of CWO as a chemotherapeutic agent.

### Abstract

**AIM:** To investigate the effects of the essential oil of *Curcuma wenyujin* (CWO) on growth inhibition and on the induction of apoptosis in human HepG2 cancer cells.

**METHODS:** The cytotoxic effect of drugs on HepG2 cells was measured by 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. DNA fragmentation was visualized by agarose gel electrophoresis. Cell cycle and mitochondrial transmembrane potential ( $\Delta\psi_m$ ) were determined by flow cytometry (FCM). Cytochrome C immunostaining was evaluated by fluorescence microscopy. Caspase-3 enzymatic activity was assayed by the cleavage of Ac-DEVD-R110. Cleaved PARP and active caspase-3 protein levels were measured by FCM using BD™ CBA Human Apoptosis Kit.

**RESULTS:** Treatment with CWO inhibited the growth of HepG2 cells in a dose-dependent manner, and the IC<sub>50</sub> of CWO was approximately 70 µg/mL. CWO was found to inhibit the growth of HepG2 cells by inducing a cell cycle arrest at S/G<sub>2</sub>. DNA fragmentation was evidently

### INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer with more than 1 million fatalities occurring annually worldwide<sup>[1]</sup>. Most HCCs, unlike their normal counterparts, are quite resistant to death receptor-mediated apoptosis, because cell surface death receptors are cross-linked with either agonistic antibodies or soluble death ligand proteins<sup>[2,3]</sup>. HCCs also display high resistance to tumor necrosis factor-related

apoptosis-inducing ligand-mediated cell death<sup>[4,5]</sup>, which, together with other apoptosis resistance mechanisms, suggests that alternative approaches are needed to control HCC growth and metastasis.

*Ezhu*, as a Chinese traditional medicine has been used for a long time. It belongs to the family of *Zingiberaceae*. This genus is composed of about 70 species of rhizomatous herbs which are distributed all over the world, and about 20 species could be identified in China. Actually, Chinese Pharmacopoeia indicated that the rhizomes of three species including *Curcuma phaeocaulis*, *C. kwangsiensis*, and *C. wenyujin* are used as *Ezhu*, which has been used for removing blood stasis, alleviating pain, and liver disease protection<sup>[6]</sup>. In order to control the quality of *Ezhu* and develop *Ezhu* as an effective therapeutic agent, we have developed quality control methods and conducted studies comparing the quantities of several chemical components of different types of *Ezhu*<sup>[7]</sup>. Nowadays in China, the essential oil of *Curcuma wenyujin* (CWO) has been used as injection to cure paediatric diseases such as acute upper respiratory infections, viral myocarditis, or acute pneumonia<sup>[8]</sup>. Besides, the essential oil of *Ezhu* has been used as a preparation to treat vaginitis<sup>[9]</sup>. Also, in some other countries, as in France, Japan, or India, the essential oil of *Ezhu* has been reported to possess anti-microbial<sup>[10]</sup>, anti-bacterial, vasorelaxant<sup>[11]</sup>, and anti-inflammatory activities<sup>[12]</sup>. In China, the essential oil of *Ezhu* has shown promising effects in the treatment of liver<sup>[13]</sup>, gastric, lung, and cervical cancers. For instance, inhibitory effects of CWO on the growth of SMMC-7721 cells, cervical cells, L615 cells, and K562 cells have been reported<sup>[14]</sup>. In addition, we recently identified furanodiene, one of *Ezhu*'s ingredients, to activate p38 and to inhibit of ERK mitogen-activated protein kinase (MAPK) signaling in HepG2 cells. The result suggests *Ezhu* as a potential candidate for the treatment of liver diseases<sup>[15]</sup>. *Ezhu* has a long history on treating liver disease and protecting liver functions; however, there is no report about inhibitory effects of the essential oil of *Ezhu* on human HepG2 cell growth and the underlying mechanism of action. This study aimed determining the cytotoxicity of CWO, one species of *Ezhu*, in human hepatoma HepG2 cells and the underlying molecular mechanism of action.

## MATERIALS AND METHODS

### Materials

CWO was purchased from Zhejiang RuiAn Pharmaceutical Company (Lot No. 011001). CWO (0.1 mL) was diluted in 10 mL methanol. The solution thus obtained was filtered through a 0.45 µm Econofilter (Agilent Technologies, Palo Alto, CA, USA) and injected into Agilent Series 1100 (Agilent Technologies, USA) liquid chromatograph, equipped with a vacuum degasser, a quaternary pump, an autosampler, and a diode array detection (DAD) system, and analyzed under the conditions described in a previous report<sup>[7]</sup>. In brief, A Zor-

bax ODS column (250 mm × 4.6 mm I.D., 5 µm) with a Zorbax ODS C18 guard column (20 mm × 3.9 mm I.D., 5 µm) was used. Solvents that constituted the mobile phase were A (water) and B (acetonitrile). The elution conditions applied were: 0-15 min, linear gradient 30%-47% B; 15-30 min, isocratic 47% B; 30-40 min, linear gradient 47%-60% B; 40-50 min, linear gradient 60%-90% B; 50-60 min, linear gradient 90%-100% B; and finally, washing the column with 100% B for 10 min before reconditioning the column for 15 min with 30% B. The flow-rate was 1 mL/min and the injection volume was 10 µL. The column operated at 25°C. The analytes were monitored with DAD at 214 nm and 256 nm. In addition, methanol solutions, containing known concentrations of standards including curcumeneone, curcumenol, neocurdione, curdione, isocurcumenol, furanodieneone, curcumol, germacrone, curzerene, furanodiene, and β-elemene were prepared and subjected to the LC-DAD system for comparison. 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT), JC-1 dye, caspase-3 assay kit, and 488 cytochrome C apoptosis detection kit were purchased from Molecular Probes. Human apoptosis kits were purchased from BD Bioscience.

### Methods

**Cell culture and drug treatment:** The human hepatoma cell line HepG2 was obtained from the American Type Culture Collection (ATCC, Rockville, MD). Cells were cultured in RPMI 1640 medium (GIBCO, Grand Island, NY) supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) (Life Technologies Inc., Gaithersburg, MD), 100 µg/mL streptomycin, and 100 U/mL penicillin in 75 cm<sup>2</sup> tissue culture flasks in a humidified atmosphere at 37°C with 5% CO<sub>2</sub>. CWO was dissolved in 1 mL DMSO to make a 1 mmol/L stock solution and diluted to the concentrations as needed. The final volume of drug solution added to medium was 1%. Control samples contained 1% DMSO.

**Growth inhibitory assay:** Cells were seeded in 96-well microplates ( $1 \times 10^5$  cells/well in 100 µL medium). CWO was added to the cultures in serial concentrations and cultures were incubated for 48 h. Medium was discarded and 30 µL tetrazolium dye (MTT) solution (5 mg/mL in PBS) were added to each well. Plates were incubated for additional 4 h. DMSO (10 µL) was added to dissolve the formed formazan crystals. The plate was read in a microplate reader at 570 nm. MTT solution with DMSO (without cells and medium) acted as blank while the DMSO (1%)-treated cells served as control of 100% survival.

**Agarose gel electrophoresis for analysis of DNA fragmentation:** HepG2 cells were treated with the drug for 72 h while the DMSO (1%) containing medium treated cells served as control. Adherent cells ( $2 \times 10^6$ /mL) were harvested, washed once with 400 µL PBS, and

taken up in 400  $\mu$ L lysis buffer (containing 200 mmol/L Tris-HCl (pH 8.3), 100 mmol/L EDTA, and 1% SDS). Twenty  $\mu$ L of 10 mg/mL proteinase K were added for protein digestion, and the tubes were incubated in a 37°C water bath overnight. The samples were allowed to cool down to room temperature before 300  $\mu$ L saturated NaCl solution were added. After centrifugation for 15 min at 9000 r/min, supernatants were collected. DNA fibers were obtained by adding 1 mL cold absolute ethanol (EtOH) and a centrifugation for 20 min at 4°C at 16000 r/min. DNA fibers were washed once with 500  $\mu$ L of -20°C 70% EtOH, and the DNA pellet was dried in a 70°C oven. Fifteen  $\mu$ L TE buffer (10 mmol/L Tris-HCl pH 8.0, 1 mmol/L EDTA) containing 0.2 mg/mL RNase A were added. After an incubation at 37°C for 90 min, 10  $\mu$ L of each sample were loaded on a 1.5% TBE agarose gel to visualize DNA.

**Cell cycle analysis:** Cells were seeded in 6 well plates and treated with CWO at various concentrations for 48 and 72 h. DMSO (1%)-treated cells served as control. After treatment, media were discarded. The adherent cells were washed with PBS, and 300  $\mu$ L trypsin were added for 5 min at room temperature to detach the cells. After centrifugation at 350 g at 4°C for 5 min, the cell pellet was resuspended with 1 mL cold 70% EtOH at 4°C for 12 h and centrifuged again for 5 min at 4°C at 350 g. Finally, 1 mL propidium iodide (PI) staining solution (20  $\mu$ g/mL PI, 8  $\mu$ g/mL DNase free RNase) was added to the samples. The samples were analyzed by flow cytometry (FCM) (BD FACS Canto<sup>TM</sup>). The results were analyzed by Mod Fit LT 3.0 software.

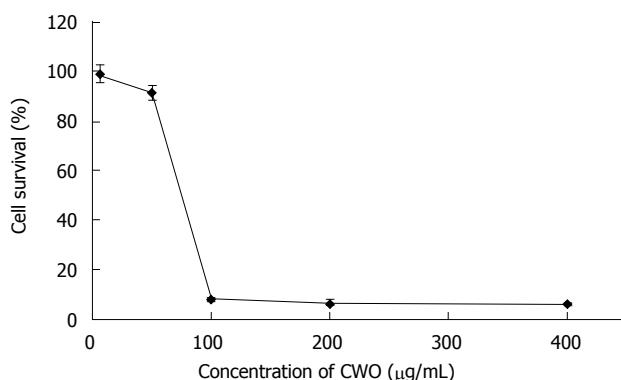

**Measurement of mitochondrial transmembrane potential ( $\Delta\Psi_m$ ):**  $\Delta\Psi_m$  was assessed by JC-1 (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide), Mitochondrial Potential Sensors (Molecular Probes, Leiden, Netherlands). Red fluorescence J-aggregate form of JC-1 indicates intact mitochondria, whereas green fluorescence shows monomeric form of JC-1 due to breakdown of the mitochondrial membrane potential. Cells were seeded in 6-well plates and then incubated with the desired concentrations of CWO for 48 h. The medium of each well was discarded, cells were treated with 1 mL medium containing 5 mg/mL JC-1 for 15 min at 37°C and 5% CO<sub>2</sub> in the dark, washed twice in PBS, resuspended in 1 mL medium and measured by FCM.

**Immunostaining of cytochrome C:** Cytochrome C release was assessed by SelectFX Alexa Fluor 488 cytochrome C apoptosis detection kit (Molecular Probes, Leiden, Netherlands). Cells were seeded in 24-well plates, and treated with various amounts of CWO in an humidified atmosphere (37°C in 5% CO<sub>2</sub>) for 24 h while the DMSO (1%)-treated cells served as control. Media were discarded and the cells were washed with warm PBS, fixed with freshly prepared 4% formaldehyde in PBS for 15 min at 37°C, and permeabilized with 0.2%

Triton X-100 for 5 min at room temperature. The cells were washed, incubated in a blocking buffer (10% heat-inactivated normal goat serum (NGS) for 30 min at room temperature, and finally for 1 h with 1  $\mu$ g/mL primary antibody (anti-cytochrome C, mouse IgG) at room temperature. Green fluorescence was observed by fluorescence microscopy.

**Caspase-3 enzymatic activity assay:** Caspase-3 enzymatic activity was determined by measuring the cleavage of Ac-DEVD-R110 according to the protocol with the caspase-3 assay kit supplied by Molecular Probes. Cells were treated with various amounts of CWO in an humidified atmosphere (37°C in 5% CO<sub>2</sub>) for 24 h while DMSO (1%)-treated cells served as control. Cells were harvested at a concentration of a minimum of  $1 \times 10^6$ /mL, pellets were collected, appropriate cell lysis buffer was added, and the samples were incubated on ice for 30 min. The samples were then centrifuged and supernatants were collected and transferred to microplates. Cell lysis buffer was used as a no-enzyme control to determine the background fluorescence of the substrate. At the same time, 1  $\mu$ L of 1 mmol/L Ac-DEVD-CHO inhibitor was added to selected samples. One  $\mu$ L of DMSO was added to no-inhibitor samples to serve as control and incubated for 10 min simultaneously. Finally, 0.05 mmol/L Z-DEVD-R110 substrate was added and samples were incubated for 30 min prior to the fluorescence measurement.

**Measurement of cleaved PARP and active caspase-3 protein levels:** The BD<sup>TM</sup> CBA human apoptosis kit (BD, Franklin Lakes, USA) was applied to quantify the active caspase-3 and Poly-ADP-ribose polymerase (PARP) protein levels; cytometric Bead Array (CBA) employs a particle with a discrete fluorescence intensity to detect a soluble analyte. This kit provided two types of bead populations with distinct fluorescence intensities that have been coated with capture antibodies specific for cleaved caspase-3 and PARP. Cells were seeded in 6-well plates and incubated with various concentrations of CWO in an humidified atmosphere (37°C with 5% CO<sub>2</sub>) for 48 h.  $1.0 \times 10^6$  cells per sample were counted, harvested, and washed with PBS. Fifty  $\mu$ L of cell lysis buffer was added to each sample for 30 min on ice and samples were vortexed at 10-min intervals. Pellet cellular debris was removed by centrifugation at 12500 r/min for 10 min. Protein concentrations were measured by 2-D Quant Kit (Amersham Biosciences, Piscataway, USA). Each sample was normalized in a final concentration of 0.2  $\mu$ g/ $\mu$ L. Thirteen standard curves (standard ranging from 0 to 6000 U/mL) were obtained from one set of calibrators. For each sample and the standard mixture of lysate standard (caspase-3 and PARP beads), 50 mL of sample or standard of beads were added to the mixture of 50 mL of 2 mixed capture beads incubated for 1 h, and mixed 50 mL of PE detector bead for another 1 h. After that, samples were washed before data acquisition with a FCM. The results were analyzed by FCAP Array V1.0.

**Figure 1** HepG2 cells were treated with the indicated concentrations of CWO for 48 h. Cell growth was determined by the MTT assay and was directly proportional to the absorbance at a wavelength of 570 nm. Data are expressed as mean  $\pm$  SD from three independent experiments.

### Statistical analysis

The data are expressed as mean  $\pm$  SD from at least 3 independent experiments. Differences between groups were analyzed using a Student's *t*-tests.

## RESULTS

### CWO inhibits cell growth and induces DNA fragmentation in HepG2 cells

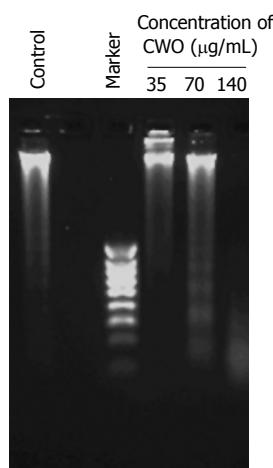

CWO treatment inhibited the growth of HepG2 cells in a dose-dependent manner, and the IC<sub>50</sub> of CWO was approximately 70  $\mu$ g/mL (Figure 1). We then examined whether CWO inhibited HepG2 cell growth through inducing cell death and apoptosis. HepG2 cells were treated with different concentrations of CWO for 72 h. Figure 2 shows that DNA fragmentation was evidently observed at a concentration of 70  $\mu$ g/mL after 72 h of treatment.

### CWO causes S/G<sub>2</sub> cell cycle arrest

The effect of different concentrations of CWO on cell-cycle progression was studied after 48 and 72 h of drug exposure. CWO treatment resulted in the accumulation of cells in S/G<sub>2</sub> phase with concomitant losses from G<sub>0</sub>/G<sub>1</sub> phase (Figure 3). Since substantial proportions of cells were dead in groups treated with 50  $\mu$ g/mL and 70  $\mu$ g/mL CWO, only cultures treated with 35  $\mu$ g/mL were used for the analysis as shown in Figure 4.

### CWO causes mitochondrial transmembrane depolarization in HepG2 cells

Some chemotherapeutic drugs induced apoptosis via mitochondrial pathways by altering  $\Delta\Psi_m$ . To monitor the  $\Delta\Psi_m$ , we used JC-1 probe to determine the  $\Delta\Psi_m$  in cells that were treated with CWO for 48 h at different concentrations. Mitochondria with normal  $\Delta\Psi_m$  concentrate JC-1 into aggregates (red/orange fluorescence), while in depolarized mitochondria, JC-1 forms monomers (green fluorescence). As compared to non-treated HepG2 cells, green fluorescence increased while red/orange fluorescence decreased after CWO exposure. Figure 4 indicates an only minor shift from

**Figure 2** Agarose gel of electrophoresis of genomic DNA obtained from HepG2 cells treated with different concentrations of CWO for 72 h. DNA fragmentation with a ladder pattern is a characteristic for apoptosis.

red/orange to green fluorescence in groups treated with 17.5  $\mu$ g/mL and 35  $\mu$ g/mL CWO, while 50  $\mu$ g/mL and 70  $\mu$ g/mL CWO led to significant changes in  $\Delta\Psi_m$ .

### CWO causes cytochrome C release from mitochondria into cytosol

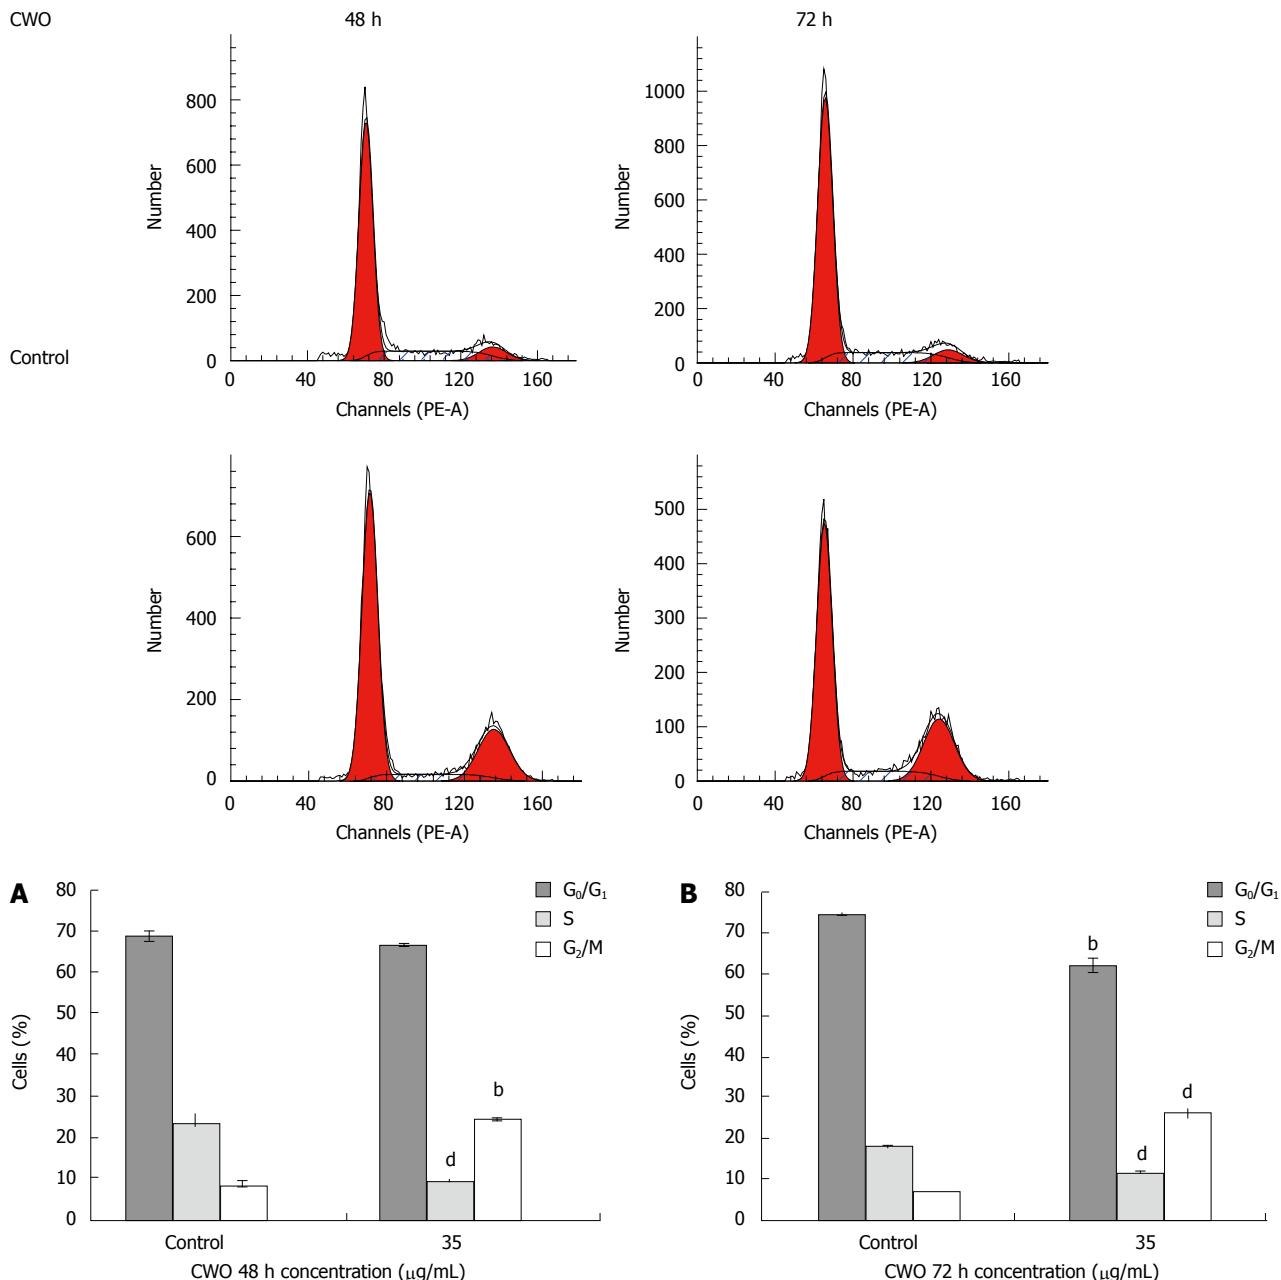

Cytochrome C release from mitochondria to the cytosol is implicated in mitochondria dependent apoptosis<sup>[16]</sup>. Cytochrome C staining in the cytosol of HepG2 cells showed markedly stronger green fluorescence than in control cells in a dose-dependent fashion (Figure 5). CWO treated cells showed obvious punctate green fluorescence staining or appeared to have green fluorescence accumulated in large aggregates compared to the control.

### CWO activates caspase-3 enzymatic activity

Many studies previously have demonstrated that programmed cell death is associated with the activation of caspase as key elements involved in the sequence of events that lead to cell death<sup>[17]</sup>. Caspase-3 particularly, is essential for propagation of the apoptotic signal after exposure to many DNA-damaging agents and anticancer drugs. We examined caspase-3 activity after cells were treated with 17.5-70  $\mu$ g/mL CWO for 24 h. The result clearly demonstrated that caspase-3 activity increased in a dose-dependent manner (Figure 6). Caspase-3 activities were 2 and 5.5 times higher in 35  $\mu$ g/mL and 70  $\mu$ g/mL CWO treated cultures, respectively, when compared to the control. When the cellular samples were incubated with specific Ac-DEVD-CHO inhibitors simultaneously, caspase-3 activity was blocked.

### CWO increases cleaved PARP and active caspase-3 protein levels

Drug-induced cell death via apoptosis pathway, signaling can generally be divided into receptor- and mitochondrial-mediated pathways. These pathways converge at several downstream points including the mitochondria, caspase activation, and substrate cleavage<sup>[18]</sup>. Figure 7 showed that there was significant increase in protein levels of cleaved PARP and active caspase-3 in a dose-dependent manner as determined by BD™ CBA Human

**Figure 3** Effect of CWO on HepG2 cell cycle progression. Flow cytometric analysis of propidium iodide-stained HepG2 cells treated with 35 µg/mL CWO for 48 h (A) and 72 h (B). The results of HepG2 cells treated with CWO were analyzed by Mod Fit LT 3.0. Data expressed as mean ± SD from three independent experiments. \*P < 0.01, \*\*P < 0.001 vs control.

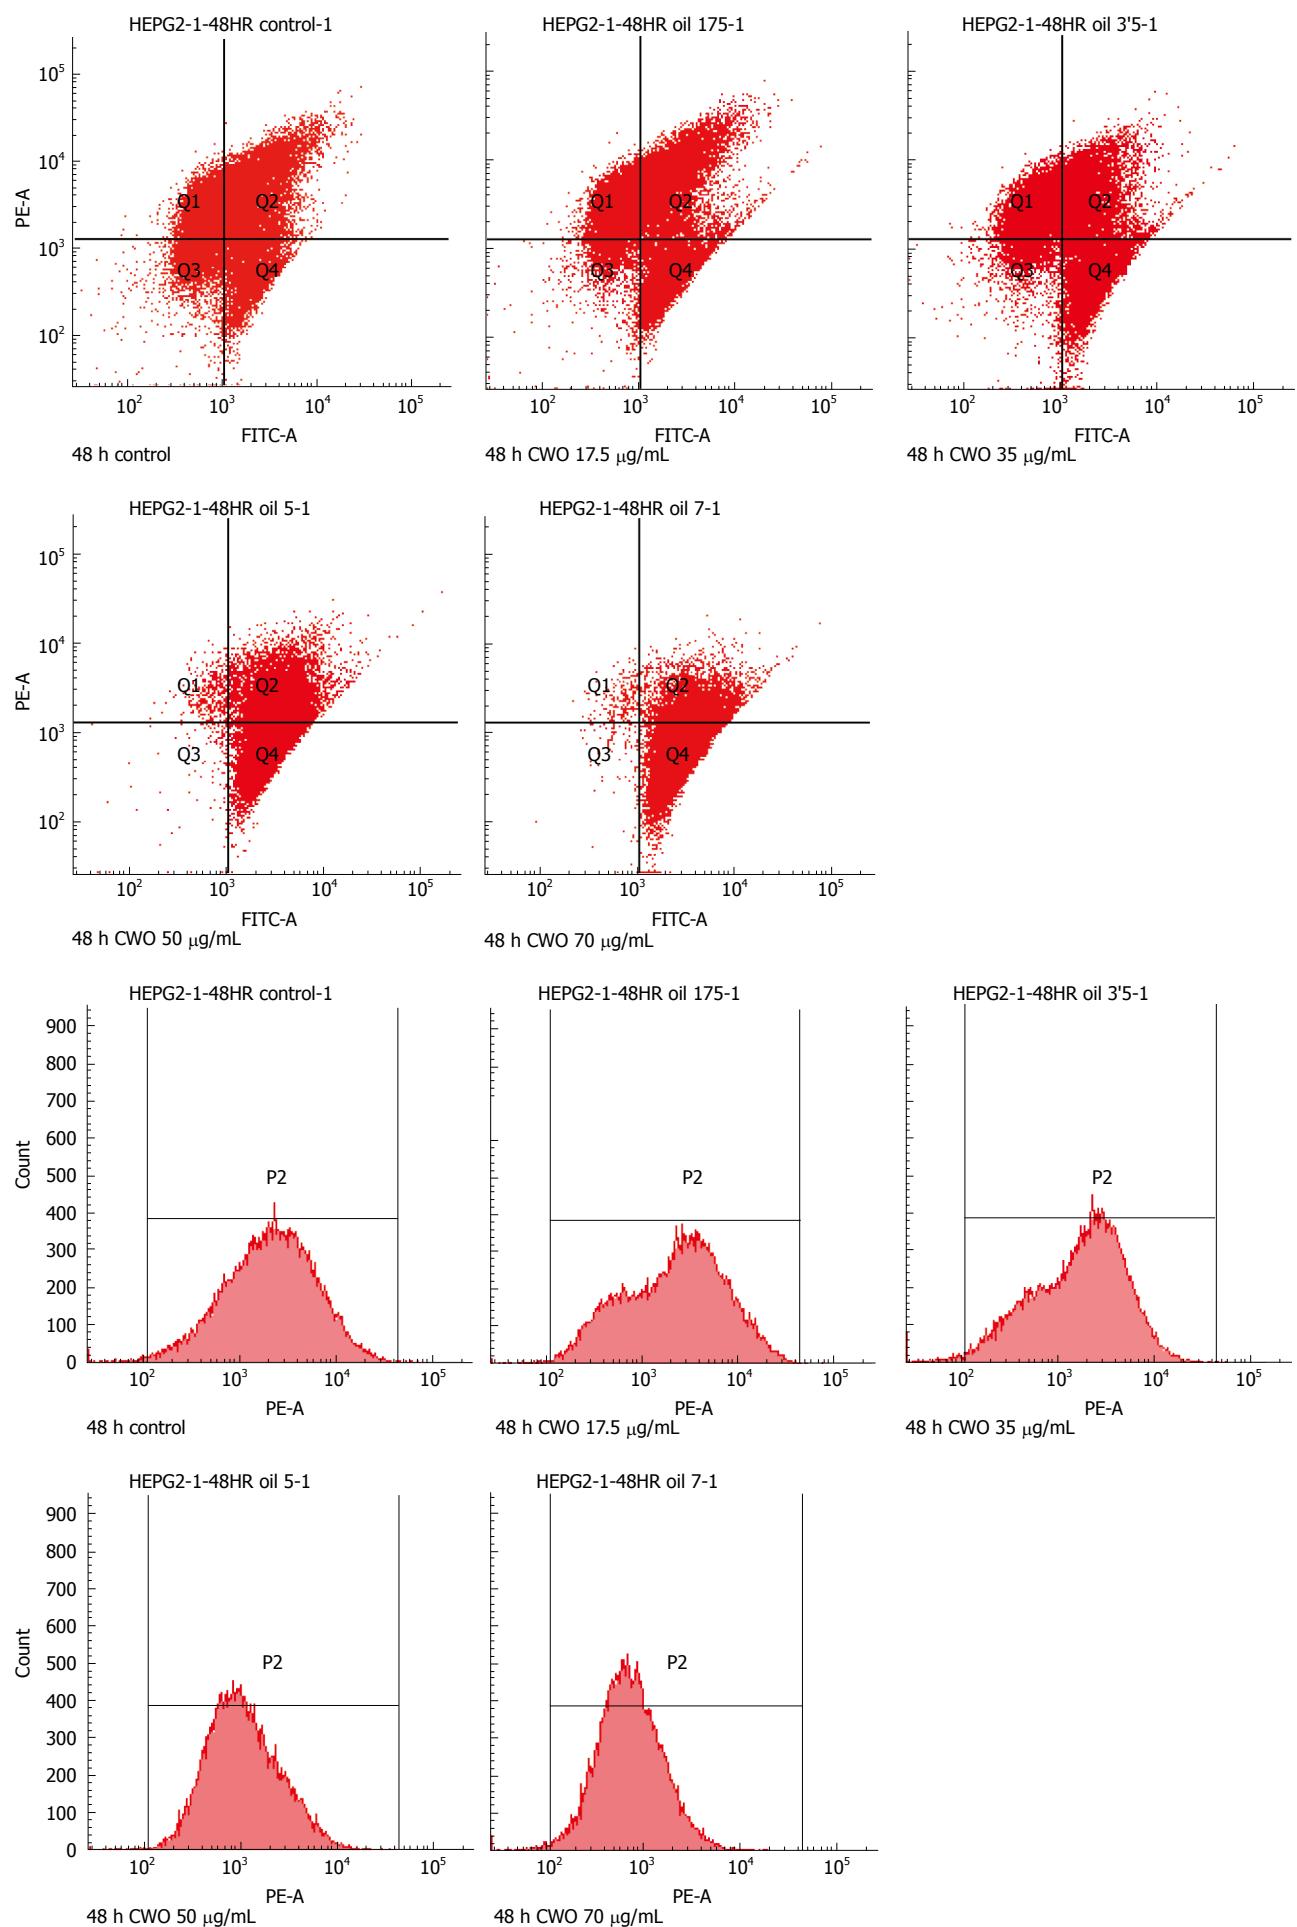

Apoptosis Kit. HepG2 cells treated with 17.5, 35, and 70 µg/mL CWO were 6, 4, and 7 times higher in caspase-3 protein level than control group (Figure 7A). The level of cleavage of PARP had a 2-fold increase in HepG2 cells treated with 70 µg/mL CWO compared to the control (Figure 7B).

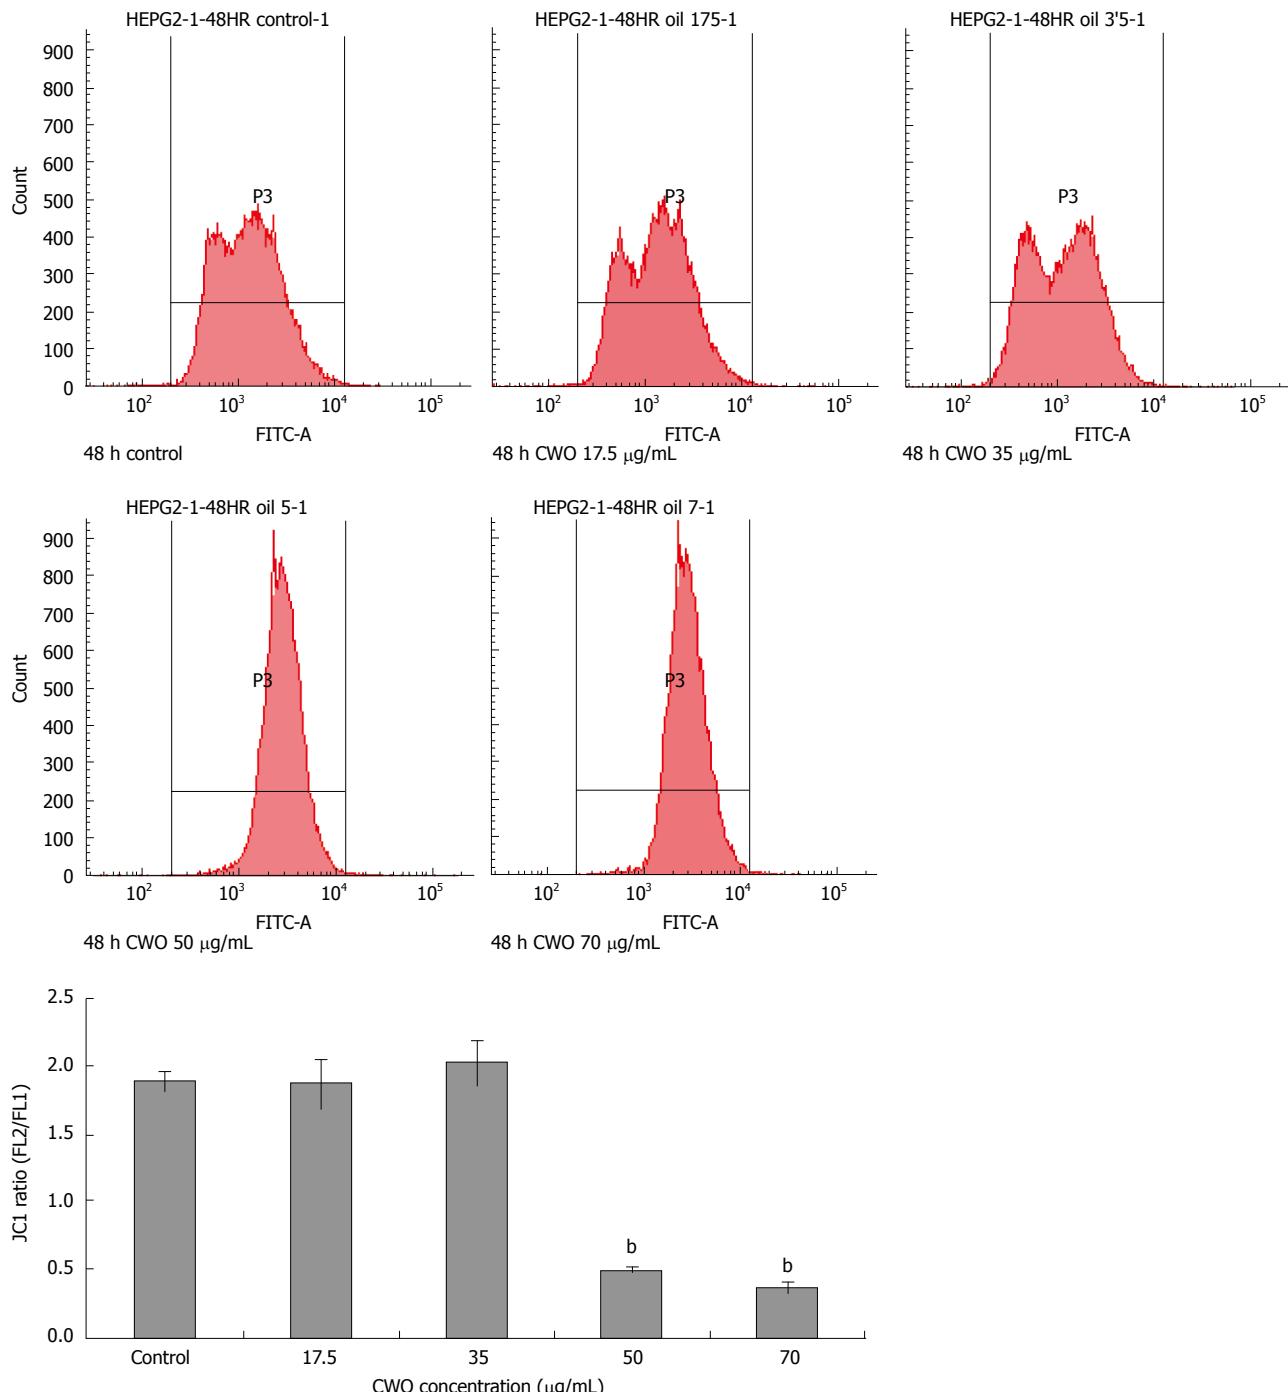

## DISCUSSION

The essential oil of *Ezhu* and its ingredients have been widely used for treatment of malignant tumors in China<sup>[19]</sup> and have been identified to have hepatoprotective effects<sup>[20,21]</sup>. Previously, we have already identified an active ingredient furanodiene, a sesquiterpene compound, which have been isolated from CWO, one of species of

*Ezhu*. Furanodiene has been found to induce apoptosis in HepG2 cells through activation of mitochondrial and caspase dependent pathway which involved activation of P38, and inactivation of ERK1/2 MAPK signaling cascades<sup>[15]</sup>. In the present study, we have found that CWO inhibited HepG2 cells growth with IC<sub>50</sub> at approximately 70 µg/mL and it has been identified to inhibit HepG2 cell growth via inducing apoptosis as evidenced by activation of depolarization of ΔΨ<sub>m</sub>, mitochondrial cytochrome C release, caspase-3, PARP cleavage, S/G<sub>2</sub> cell cycle arrest, and finally DNA fragmentation.

Active caspase-3 has been considered to be indicative of apoptosis<sup>[17]</sup> and another characteristic event of apoptosis is the proteolytic cleavage of PARP, a nuclear enzyme involved in DNA repair, DNA stability, and

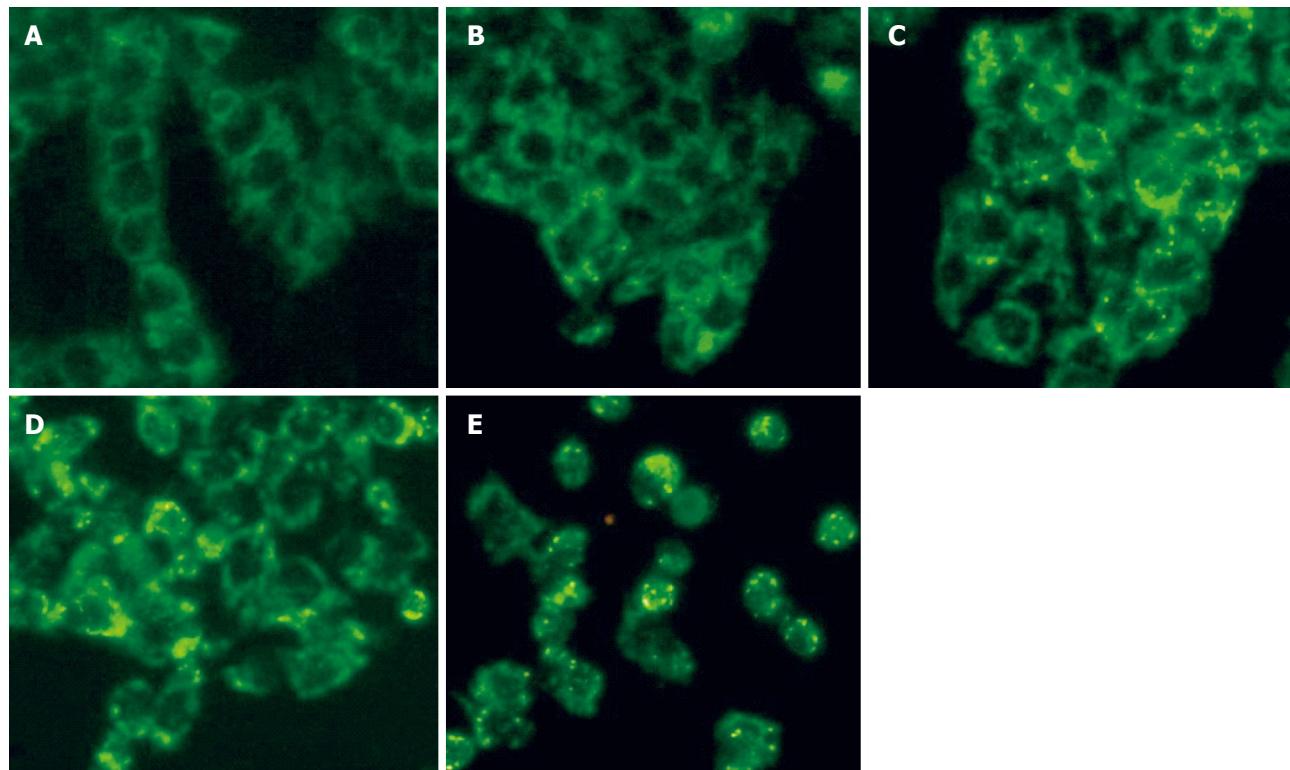

**Figure 4** Analysis of change of  $\Delta\Psi_m$  in HepG2 cells. HepG2 treated with 17.5, 35, 50, and 70  $\mu\text{g/mL}$  for 48 h, were stained with JC-1 probe. The cells were analyzed by FCM. Red and green fluorescence were measured by FL2 and FL1 channel, respectively. Red fluorescence indicates intact mitochondrial potential while green fluorescence indicates breakdown of mitochondrial potential. The ratio of intensity of FL2 to FL1 indicates the change of  $\Delta\Psi_m$ . Data expressed as mean  $\pm$  SD from four independent experiments. <sup>b</sup> $P < 0.001$  vs control.

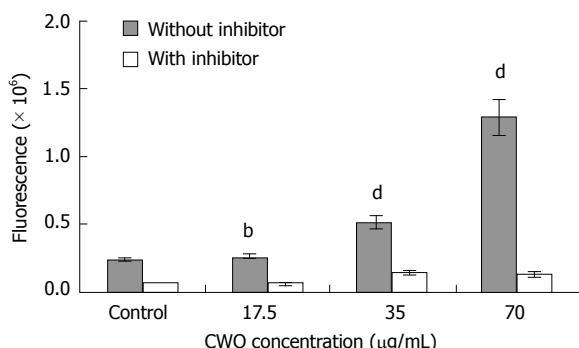

transcriptional regulation<sup>[22]</sup>. An experiment was performed to simultaneously and quantitatively evaluate CWO induced changes of active caspase-3 and cleaved PARP protein levels using CBA technology as demonstrated in Figure 7. As shown, active caspase-3 protein expressions were enhanced approximately 7-fold compared to the control. Meanwhile, we attempted to detect CWO-induced caspase-3 enzymatic activity increases using caspase-3 specific substrate Z-DEVE-R110, and have found that the enhancements disappeared when treated with Ac-DEVD-

CHO inhibitor as shown in Figure 6. This showed the increases in caspase-3 enzymatic activities were specific to CWO treatment and suggested that CWO induces apoptosis via a caspase-3-dependent pathway.

CWO induced significant increase in caspase-3 enzymatic activity as well as the protein levels of active caspase-3 and cleaved PARP (Figure 7). These results suggested that CWO induced apoptosis via caspase pathway. Moreover, whether CWO induced apoptosis in HepG2 cell is mitochondria-dependent is unknown.

**Figure 5** Cytochrome C release into the cytosol in CWO treated HepG2 cells for 12 h. Cytochrome C immunofluorescence was observed with fluorescent microscope. **A:** Control; **B:** 17.5  $\mu\text{g}/\text{mL}$ ; **C:** 35  $\mu\text{g}/\text{mL}$ ; **D:** 70  $\mu\text{g}/\text{mL}$ ; **E:** 120  $\mu\text{g}/\text{mL}$ . Fine punctate/granular stainings for cytochrome C are observed. Cytochrome C release also increases the global cytosolic fluorescent signal. Similar results were obtained for 3 independent experiments ( $\times 20$ ).

**Figure 6** The fluorescence was increased in a dose-dependant manner after 24 h treatment with CWO. Caspase-3 cleaves substrate Ac-DEVD-R110 to emit green fluorescence. Higher fluorescent intensity indicates higher caspase-3 enzymatic activity. Ac-DEVE-CHO inhibitor can inhibit caspase-3 enzymatic activity. Data are expressed as mean  $\pm$  SD from three independent experiments. <sup>b</sup> $P < 0.001$ , <sup>d</sup> $P < 0.01$  vs control.

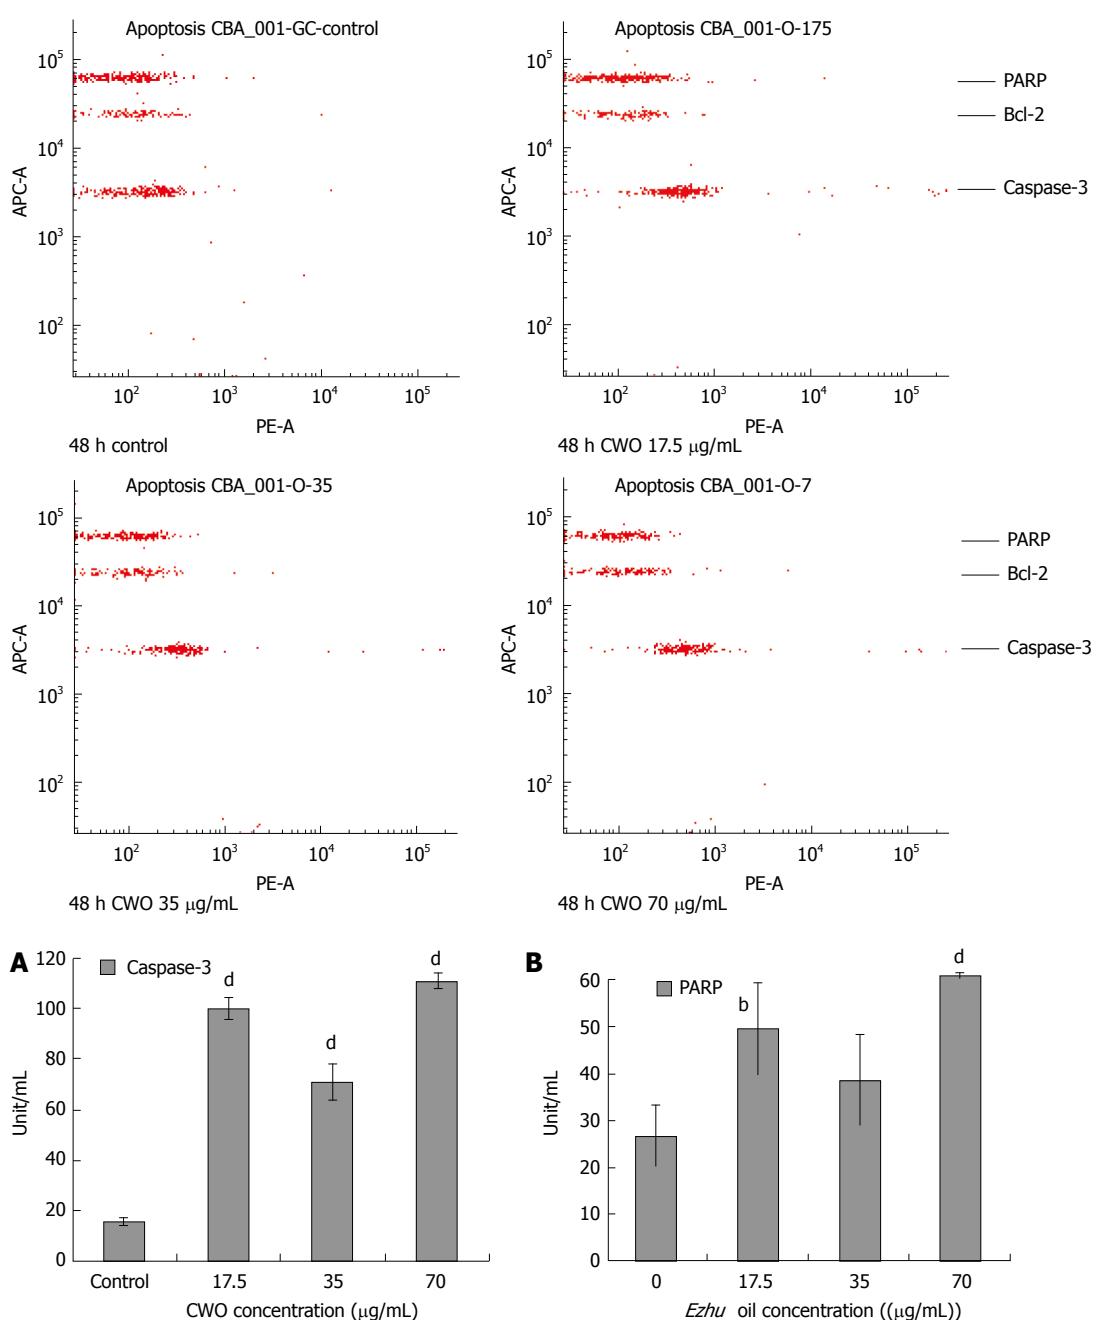

To address this question, the change of  $\Delta\Psi_m$  and mitochondrial cytochrome C release were determined. Figures 4 and 5 suggested that CWO-mediated apoptosis was accompanied with the  $\Delta\Psi_m$  as well as the release of mitochondrial cytochrome C into cytosol. These results demonstrated that a mitochondrial pathway was also involved in CWO-induced apoptosis.

It is now widely believed that p38 and JNK mediate apoptotic signals, while ERK promotes growth, differentiation, and proliferation. Nowadays, many studies have shown that p38 MAPK activation is necessary for cancer cell death initiated by a variety of anti-cancer agents<sup>[23]</sup>. Furthermore, different MAPK

signaling pathways can be coordinately manipulated to enhance the efficacy of anticancer drug. Co-treatment of anticancer drugs with ERK inhibitors has been found to enhance anticancer effects. Anti-cancer drug paclitaxel (Taxol) induces tumor cell apoptosis through activating endogenous JNK in tumor cells<sup>[24]</sup>. When paclitaxel and ERK inhibitor were combined in cancer treatment, ERK inhibitor significantly enhances the JNK activation-mediated cytotoxic effect of paclitaxel. ERK inhibitor also found to enhance docetaxel-induced apoptosis of androgen-independent human prostate cancer cells<sup>[25]</sup>.

CWO, possibly act as chemopreventive agents with respect to inhibition of the growth of human HepG2 cells through the induction of apoptosis. As apoptosis has become a new therapeutic target in cancer research, these results confirm the potential of CWO as an agent of chemotherapeutic and cytostatic activity in human HepG2 cells. Besides, in our previous study, furanodiene, isolated from CWO, has been identified induce HepG2 cell apoptosis through alternating MAPK signaling. Furanodiene obviously elevated phosphorylated form of P38 and reduced phosphorylated form of ERK1/2 in a dose-dependent manner, but a slightly and statistically insignificant change in phosphorylated form of JNK. Therefore, furanodiene induced-apoptosis in HepG2, involve activation of P38 and inhibition of ERK MAPK signaling. Whether CWO acts on these signaling pathways should be an interesting area for further study.

In short, we conclude that CWO induces apoptosis in HepG2 cells through activation of mitochondrial and caspase-3 pathway.

## COMMENTS

### Background

*Ezhu* has a long history on treating liver diseases and protecting liver functions. Chinese Pharmacopoeia indicated that the rhizomes of three species including *Curcuma phaeocaulis*, *C. kwangsiensis* and *C. wenyujin* are used as *Ezhu*. The essential oil of *Ezhu* has been reported to possess various biological roles such as antimicrobial, anti-inflammatory, and anti-tumor activity. Some sesquiterpene compounds isolated from essential oil of *Curcuma wenyujin* (CWO) has been identified to have hepatoprotective effects. The total effects of the complex interactions of different compounds in extracts isolated from CWO are not well characterized.

### Research frontiers

Hepatocellular carcinoma (HCC) is the fifth most commonly diagnosed cancer with more than 1 million deaths reported annually worldwide. Many sesquiterpenes are identified to possess protective effects against carcinogenesis or tumor growth. For example, artemisinin, a sesquiterpene lactones, killed human oral cancer cells through apoptosis and may be useful as an alternative treatment for oral cancer. In order to develop effective means for prevention and treatment of HCC and related liver diseases, extensive research is being

carried out to isolate and identify chemical extracts and pure compounds from Chinese medicine with hepatoprotective, anti-hepatoma, anti-multidrug resistant hepatoma, and anti-viral effects.

### Innovations and breakthroughs

This is the first study to report the biological activity and mechanism of action of CWO on HCC cells.

### Applications

CWO induce apoptosis in HepG2 cells through activation of mitochondrial and caspase-3-pathway and the result suggests the potential value of development of *Ezhu* on treatment of liver diseases and further study on anti-apoptotic effect of CWO may lead to identification of new lead compounds and novel drug targets for treatment of liver cancer and diseases.

### Peer review

This is an interesting study showing that CWO inhibits growth and induces apoptosis in human HepG2 hepatoma cells. These findings are of interest.

**CONCLUSION:** Biopsy of Turkish patients with the diagnosis of chronic non-bloody diarrhea of unexplained etiology and normal colonoscopic findings will reveal microscopic colitis in approximately 10% of the patients. Lymphocytic colitis is 4 times more frequent than collagenous colitis in these patients.

## Abstract

**AIM:** To investigate the prevalence and demography of microscopic colitis in patients with diarrhea of unknown etiology and normal colonoscopy in Turkey.

**METHODS:** Between March, 1998 to July, 2005, 129 patients with chronic non-bloody diarrhea of unexplained etiology who had undergone full colonoscopy with no obvious abnormalities were included in the study. Two biopsies were obtained from all colonic segments and terminal ileum for diagnosis of microscopic colitis. On histopathologic examination, criteria for lymphocytic colitis (intraepithelial lymphocyte  $\geq 20$  per 100 intercryptal epithelial cells, change in surface epithelium, mononuclear infiltration of the lamina propria) and collagenous colitis (subepithelial collagen band thickness  $\geq 10 \mu\text{m}$ ) were explored.

**RESULTS:** Lymphocytic colitis was diagnosed in 12 (9%) patients (Female/Male: 7/5, mean age: 45 year, range: 27-63) and collagenous colitis was diagnosed in only 3 (2.5%) patients (all female, mean age: 60 years, range: 54-65).

## INTRODUCTION

Chronic diarrhea with no obvious reason is one of the challenges of gastroenterology. In 1980, Read *et al*<sup>[1]</sup> introduced microscopic colitis characterized by chronic diarrhea with normal endoscopic and radiologic findings, but with increased colonic mucosal inflammatory cells and epithelial lymphocytic infiltration on histologic examination. Later, Leivonen *et al*<sup>[2]</sup> emphasized that microscopic colitis covered all cases of colitis with normal colonoscopy, but abnormal histopathologic features and described lymphocytic colitis separately. Collagenous colitis, which is a closely related condition, was first described in 1976 as a separate subtype with additional histological finding of increased subepithelial collagen band thickness<sup>[3]</sup>. Thus, microscopic colitis is a condition with two subtypes having similar clinical, but different histological characteristics. In collagenous colitis subepithelial collagenous band thickness is important.

The prevalence of microscopic colitis has been difficult to estimate. The symptoms of microscopic

colitis have been frequently attributed to diarrhea-predominant irritable bowel syndrome, often for many years before diagnosis. Diagnostic awareness of these conditions by physicians in the geographic area of interest significantly effects the likelihood of diagnosis and, therefore, the prevalence.

Clinical and histological characteristics of microscopic colitis have been well established<sup>[4-8]</sup>. However, limited data is available regarding the prevalence, pathogenesis and progress of the disease and its treatment. The diagnosis is made only by histologic examination and most of these patients are treated and followed up erroneously as irritable bowel syndrome. Recently, several studies from Sweden and Iceland reported high prevalence of microscopic colitis<sup>[9-11]</sup>. In this prospective study we aimed to determine the prevalence of lymphocytic and collagenous colitis in Turkey in a subset of patients with chronic non-bloody diarrhea of unknown origin in which colonoscopy was not conclusive.

## MATERIALS AND METHODS

### **Patients**

Between March, 1998 and July, 2005, in three centers around Istanbul (two gastroenterology clinics and one private endoscopy laboratory), 129 consecutive patients with unexplained chronic (at least 3 mo duration), non-bloody diarrhea have undergone colonoscopy with visualization of terminal ileum and normal mucosal appearance noted. These patients were included in the study. Inclusion criteria are shown in Table 1. All patients underwent abdominal ultrasonography and/or computer tomography (CT). Patients who received radiotherapy, chemotherapy, or who had undergone operation related to bowel, stomach or gallbladder or patients with inflammatory bowel disease, chronic liver disease, renal disease or pancreatitis, and patients with the history of long term laxative and antibiotic use were excluded from the study. Stool consistency (liquid, semiliquid, soft), number of daily defecation, duration of diarrhea, and other gastrointestinal symptoms (abdominal pain, weight loss, etc) and previous medication were recorded.

### **Colonoscopy and histology**

Patients were prepared for colonoscopy with 90 mL oral monobasic sodium phosphate and dibasic sodium phosphate. During colonoscopy two biopsies were taken from terminal ileum and all segments of the colon. Specimens were stained with HE and Masson's Trichrome or Van Gieson dyes.

### **Diagnostic criteria**

Increased chronic inflammatory infiltration in the lamina propria, increased intraepithelial lymphocytes (IELs), degeneration of surface epithelium and increased mitosis in crypts were sought for the diagnosis of microscopic colitis. Over 20 IEL per 100 intercryptal epithelial cells (normal < 1-5/100) were deemed necessary for

**Table 1 Inclusion criteria for study**

#### **Inclusion criteria**

Diarrhea without blood (> 3 mo)
Normal stool microscopy
No growth in stool culture
Normal D-Xylose absorption test
Normal biochemical profile
Normal thyroid tests, normal serum gastrin
Negative antigliadin antibodies (IgA, IgG)
Negative <i>Clostridium difficile</i> toxins (A, B)
Negative HIV test
Normal urine 5-HIAA
Normal upper GI endoscopy
Normal abdominal US
Normal small bowel radiology
Normal duodenal biopsy
Normal colonoscopy including terminal ileum

**Table 2 Histopathologic criteria for diagnosis of lymphocytic colitis and collagenous colitis**

#### **Histopathologic criteria**

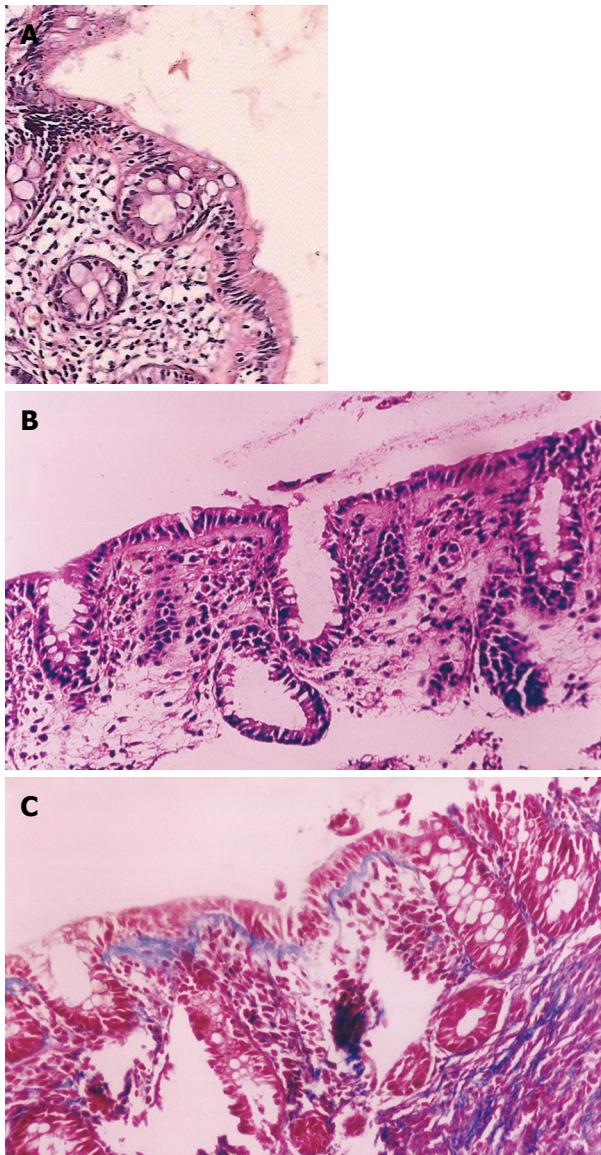

Lymphocytic colitis	Chronic inflammatory infiltration in lamina propria Increased IELs Superficial epithelial degeneration and increased mitosis in crypts IELs/100 intercryptal epithelial cell > 20/100
Collagenous colitis	A diffusely distributed and thickened subepithelial collagen band > 10 µm Chronic inflammatory infiltration in lamina propria

the diagnosis of lymphocytic colitis<sup>[7,8,12]</sup> (Table 2). For collagenous colitis subepithelial collagen band thickness was measured by ocular micrometer in Masson's Trichrome stained specimens. Thickness over 10 µm was required for the diagnosis<sup>[7,8,12]</sup> (Table 2).

## RESULTS

During the mentioned period, colonoscopy was performed in a total of 9862 patients due to various reasons. One hundred and twenty-nine of those patients had chronic non-bloody diarrhea with no apparent cause even after laboratory and radiologic examination and full colonoscopy with terminal ileal visualization. These patients were included in the study. After colonoscopic biopsy of colonic segments in 114 patients, histopathologic examinations of colonic biopsies were normal. In all patients, biopsies from terminal ileum revealed normal epithelial features.

Fifteen patients (11.5%) had microscopic colitis (12 lymphocytic colitis and 3 collagenous colitis; 9%, 2.5%, respectively) (Figure 1A and B). Seven of the lymphocytic colitis patients were female, mean age was  $45 \pm 11.6$  (27-63), mean duration of diarrhea was 22 mo (4-96) and mean number of daily defecation was 5 (3-9). Criteria of lymphocytic colitis were present in specimens obtained from all segments of the colon of these patients. Mean number of IEL per 100 intercryptal

**Figure 1** Pathologic view ( $\times 200$ ). **A:** Lymphocytic colitis. Note the increased number of chronic inflammatory cells in the lamina propria and within the surface epithelium (HE); **B:** Collagenous colitis. Note the subepithelial thick collagenous band (HE); **C:** Collagenous band thickness on Mason trichrome dye.

epithelial cells was  $28.2 \pm 6.8$  (range 20-60) (Figure 1A). All patients with collagenous colitis were female (ages 65, 54 and 61 years) and their subepithelial collagenous band thickness was 31, 21 and  $17.5 \mu\text{m}$  (Figure 1B and C). Mean durations of diarrhea were 34, 11 and 68 mo and mean daily stool frequencies were 5, 8 and 4 times, respectively.

## DISCUSSION

Microscopic colitis, which is characterized by chronic watery diarrhea with normal radiological and endoscopic appearances, is diagnosed only by histopathologic examination. This condition which consists of two main subtypes (lymphocytic and collagenous colitis) is a relatively common cause of chronic watery diarrhea, often accompanied by abdominal pain and weight loss.

Studies from different countries reported microscopic colitis rates between 4%-13% in the cohort of population with non-bloody diarrhea of unknown origin<sup>[10-13]</sup>. In the current study, we found this rate to be 11.5% in Turkey.

Diagnosis of this condition is possible only with the awareness of health workers and careful assessment of the criteria. Therefore, the reported prevalence seems to change within years. In Sweden, microscopic colitis was reported in 4% of patients with non-bloody chronic diarrhea in 1993, but this rate was reported as 10% in 1998<sup>[9,10,13]</sup>. The prevalence of collagenous colitis in Sweden between 1984-1988 was  $0.8/10^5$  inhabitants, but increased to  $6.1/10^5$  inhabitants between 1996-1998<sup>[9,10,13,15]</sup>. Recently, higher prevalence values have been reported from Iceland where the mean annual prevalence of collagenous colitis was  $5.2/10^5$  inhabitants and the mean annual incidence of lymphocytic colitis was  $4.0/10^5$  inhabitants in the period 1995-1999<sup>[11]</sup>. According to various studies prevalence of collagenous colitis and lymphocytic colitis is  $10-15.7/100000$  and  $14.4/100000$ , respectively<sup>[12-14,16]</sup>.

In a study performed in Spain, lymphocytic colitis was found in 9.5% of patients who had undergone colonoscopy because of chronic diarrhea during a period of 5 years<sup>[14]</sup>. In this study, the prevalence of lymphocytic colitis was three times that of the prevalence of collagenous colitis, female/male ratio in lymphocytic and collagenous colitis was found 2.7/1 and 4.7/1, respectively. Female/male ratio were reported as 5/1 from Iceland and 2.1 from Sweden<sup>[10-15]</sup>. In reported series this ratio for collagenous colitis was found as 4/1-20/1<sup>[13-17]</sup>. In our study, female/male ratio for lymphocytic colitis was 1.4/1 and lymphocytic colitis was 4 times more than that of collagenous colitis.

Marshall *et al*<sup>[18]</sup> encountered 13 lymphocytic colitis and 1 collagenous colitis in their 111 chronic-diarrhea patients with unexplained etiology. In another study of 132 consecutive patients who had undergone colonoscopy for chronic diarrhea and abdominal pain, lymphocytic and collagenous colitis found in 21 (16%) and 7 (5%) of patients, respectively<sup>[19]</sup>.

Mean ages of the patients with lymphocytic and collagenous colitis in other studies were between 51-59 years, and 64-68 years, respectively<sup>[13-17]</sup>. In our study, the mean age of the patients with lymphocytic colitis was 45 years (range 27-63). The mean age of our three collagenous colitis patients was 60 years.

In the studies of Lazenby *et al* and Baert *et al*, the mean IEL per 100 intercryptal epithelial cells was 34.7 and 29.4, respectively<sup>[5,8]</sup>. In the current study, the mean IEL per 100 intercryptal epithelial cells was 28.2. Normal subjects may have up to 1 to 5 IEL per 100 intercryptal epithelial cells. Some studies have reported that biopsy specimens from all segments of the colon revealed similar number of IEL and, therefore, biopsy obtained only from sigmoid colon would be enough for diagnosis<sup>[7,12]</sup>. In our study, the number of IEL was increased in all bowel segments.

Since subepithelial band thickness was less than  $8 \mu\text{m}$

in all our cases of lymphocytic colitis, the diagnosis of collagenous colitis and overlapping form was excluded. In normal subjects subepithelial collagen band thickness of 5-7  $\mu\text{m}$  is considered as normal and band thickness of 7-80  $\mu\text{m}$  is found in collagenous colitis<sup>[7,8,12]</sup>. In our 3 collagenous colitis patients the mean band thickness was 23  $\mu\text{m}$ .

As yet, the etiology of lymphocytic colitis has not been well understood. Gastrointestinal infections, autoimmune diseases and various drugs (non-steroidal anti-inflammatory drugs, ranitidine, carbamazepine, simvastatin, ticlopidine, flutamide etc) were reported to be causative factors<sup>[12,16,17,20]</sup>. Some gastrointestinal rheumatologic disorders (celiac sprue, rheumatoid arthritis, uveitis, idiopathic pulmonary fibrosis, diabetes mellitus, pernicious anemia, autoimmune thyroiditis etc) and positivity of some autoantibodies, particularly antinuclear antibody (ANA) may be associated with both lymphocytic and collagenous colitis<sup>[14,21-24]</sup>. Giardiello *et al* found 4 ANA positive patients in their 12 lymphocytic colitis patients<sup>[24]</sup>. We found only one case of ANA positivity in our patients, but none of them were associated with any of the disorders or conditions mentioned above.

Patients with lymphocytic colitis were reported to be effectively treated with medications used in inflammatory bowel disease such as sulfasalazine and 5-ASA. If this regimen fails, bismuth subsalicylate, corticosteroids, azathioprine and cyclosporine may be given<sup>[12,15-17,25,26]</sup>. In the present study sulfasalazine or 5-ASA was used as first line treatment agents. Preliminary results show positive response in terms of symptom relief. Evaluation of long term outcome should wait completion of the study.

In conclusion, considering 11.5% of the patients with chronic diarrhea of unknown etiology and normal colonoscopy would have microscopic colitis, biopsy should be taken during colonoscopy in this subset of patients. Although the number of our cases was not enough to answer the question of how many biopsies should be taken and from which part of the colon, the fact that histopathological criteria were determined on all colonic regions in patients with lymphocytic colitis on whom biopsy was performed is promising in terms of diagnostic convenience. Lymphocytic colitis in Turkish patients was found to be 4 times more frequent than collagenous colitis.

## COMMENTS

### Background

Microscopic colitis is a chronic diarrheal disease with normal colonoscopic, but with abnormal histopathologic features. It is a disease with two subtypes of similar clinical but different histological features: lymphocytic colitis, which is characterized by pronounced colonic mucosal lymphocyte infiltration and collagenous colitis, which is characterized by increased subepithelial collagenous band thickness. In limited number of studies from various countries the rates of microscopic colitis in patients with chronic diarrhea have been reported between 4%-13%.

### Research frontiers

Although the number of the cases was not enough to answer the question of how many biopsies should be taken and from which part of the colon, the fact that histopathological criteria were determined on all colonic regions in patients

with lymphocytic colitis on whom biopsy was performed is promising in terms of diagnostic convenience.

### Applications

Considering 11.5% of the patients with chronic diarrhea of unknown etiology and normal colonoscopy would have microscopic colitis, biopsy should be taken during colonoscopy in this subset of patients.

### Terminology

Microscopic colitis is characterized by chronic watery diarrhea with normal radiological and endoscopic appearances. Lymphocytic colitis has similar characteristics with over 20 intraepithelial lymphocytes (IELs) per 100 intercryptal epithelial cells. Collagenous colitis has same characteristics with additional histological finding of increased subepithelial collagen band thickness.

### Peer review

This is an epidemiologic study confirming findings reported from other countries about the frequency of lymphocytic and collagenous colitis and the importance of biopsies for the diagnosis. It's a nice paper, well written and well designed.

viability and p-JNK1/2 activity (at 180 min).

**CONCLUSION:** This study suggests that ethanol-induced p-JNK1/2 activation is associated with the IGF- I system and cell viability in hepatocytes. Furthermore, alcohol dehydrogenase is involved in the relationship between ethanol-induced inactivation of p-JNK1/2 and the changes of the IGF- I system and cell viability.

## Abstract

**AIM:** To evaluate the effects of ethanol on the insulin-like growth factor- I (IGF- I ) system involved in c-Jun N-terminal kinase (JNK1/2) and alcoholdehydrogenase (ADH) activity in primary cultured rat hepatocytes.

**METHODS:** Hepatocytes isolated from male Sprague-Dawley rats were incubated with various concentrations of ethanol for different durations of time. The cells were pretreated with SP600125 (10 μmol/L) and 4-MP (200 μmol/L), and then treated with ethanol (200 mmol/L). We then measured IGF- I secretion, IGF- I mRNA expression, cell viability and JNK1/2 activity by radioimmunoassay, RT-PCR, MTT assay and Western blot, respectively ( $n = 6$ ).

**RESULTS:** Ethanol induced the activity of phospho (p)-JNK1/2, reaching a maximum at 60 min and then decreasing at 180 min. The effects of ethanol on the IGF- I system were increased at 60 min (secretion:  $7.11 \pm 0.59$  ng/mg protein vs  $4.91 \pm 0.51$  ng/mg, mRNA expression:  $150.2\% \pm 10.2\%$  vs  $101.5\% \pm 11.3\%$ ,  $P = 0.045$ ) and then decreased at 180 min (secretion:  $3.89 \pm 0.25$  ng/mg vs  $5.4 \pm 0.54$  ng/mg protein; mRNA expression:  $41.5\% \pm 10.4\%$  vs  $84.7\% \pm 12.1\%$ ,  $P = 0.04$ ), however cell viability was decreased in a dose- and time-dependent manner. SP600125 blocked the ethanol-induced changes (at 60 min). Additionally, 4-methylpyrazole prevented the ethanol-induced decreases in the IGF- I system, cell

## INTRODUCTION

Ethanol abuse exerts deleterious effects on the internal organs of the body, particularly the liver and brain, and alcohol-induced liver damage is one of the major causes of morbidity and mortality in alcoholics<sup>[1]</sup>. Ethanol alters hepatic carbohydrate and lipid metabolism as well as the synthesis of protein and DNA, which leads to hepatic dysfunction and cirrhosis<sup>[2]</sup>. Although the spectrum of ethanol toxicity is well known, the underlying pathophysiology of the signal transduction pathways has not been elucidated.

Ethanol alters cell functions via multiple signaling pathways, particularly those involving mitogen-activated protein kinases (MAPKs), which are involved in a variety of cellular responses including proliferation, differentiation, and apoptosis<sup>[3]</sup>. Several MAPK cascades have been identified, including those involving p42/44

and p38 MAPKs, and c-Jun N-terminal kinase (JNK1/2, also known as stress-activated protein kinase)<sup>[4]</sup>. JNK1/2 activity has been linked to the proliferation and apoptosis of hepatocytes<sup>[5]</sup>.

Ethanol also induces prolonged activation of tumor necrosis factor (TNF)-stimulated JNK1/2 after hepatocytes are stimulated with various agonists, and prolonged activation of JNK1/2 and activator protein 1 (AP-1) is associated with the apoptosis and necrosis of hepatocytes that occurs in response to oxidative stress<sup>[4]</sup> and ischemia/reperfusion injury<sup>[6]</sup>.

Insulin-like growth factor (IGF)- I is a peptide that plays an important role in regulating cell metabolism, growth, and differentiation<sup>[7]</sup>. The dose-dependent effects of ethanol on the IGFs system have been previously described in male rats<sup>[8]</sup>. The cellular action of IGF- I is mediated *via* the insulin-like growth factor- I receptor (IGF-IR), which exhibits tyrosine kinase activity<sup>[7]</sup>. IGF-IR is a key regulator of normal cellular processes, and plays a critical role in the development and progression of many types of cancer<sup>[9]</sup>. It has been reported that the renin-angiotensin system regulates the IGF- I system in hepatocytes<sup>[10]</sup>, and it is known that retinoic acid inhibits growth-hormone-stimulated IGF- I production *via* protein kinase C (PKC)- $\delta$  in breast cancer cells. We recently found that the inhibitory effects of the ethanol-induced IGF- I system are related to p42/44 activity<sup>[11]</sup>. Although the relationships between ethanol-induced cellular action and apoptosis *via* MAPK including JNK1/2 activity have been reported previously, the secretion control mechanisms of the IGF- I system (IGF- I secretion, IGF- I mRNA expression, and IGF-IR activity) remain to be elucidated in primary cultured hepatocytes.

In the present study, we investigated the effects of ethanol on the IGF- I system, with particular attention to the JNK1/2 activity and alcoholdehydrogenase (ADH) in primary cultured rat hepatocytes.

## MATERIALS AND METHODS

### Materials

IGF- I antigen and IGF- I antibodies were purchased from GroPep (Adelaide, Australia), and the JNK1/2 inhibitor SP600125 was purchased from New England Biolabs (Beverly, MA, USA). An enhanced chemiluminescence (ECL) kit was purchased from Cell Signaling (Beverly, MA, USA). All routine culture media were obtained from Gibco-BRL (Grand Island, NY, USA). Aquasol, reflection X-ray film, and  $^{125}\text{I}$  isotope were purchased from Dupont-NEN (Boston, MA, USA). Polyvinylidene difluoride (PVDF) membranes were purchased from BioRad (Hercules, CA, USA). BSA (fraction V), glycine, SDS, acrylamide, glycerol, and Tween-20 were obtained from Sigma (St. Louis, MO, USA).

### IGF- I radioimmunoassay

Recombinant human IGF- I was iodinated to a specific radioactivity of 150-300 Ci/g using the  $^{125}\text{I}$  isotope

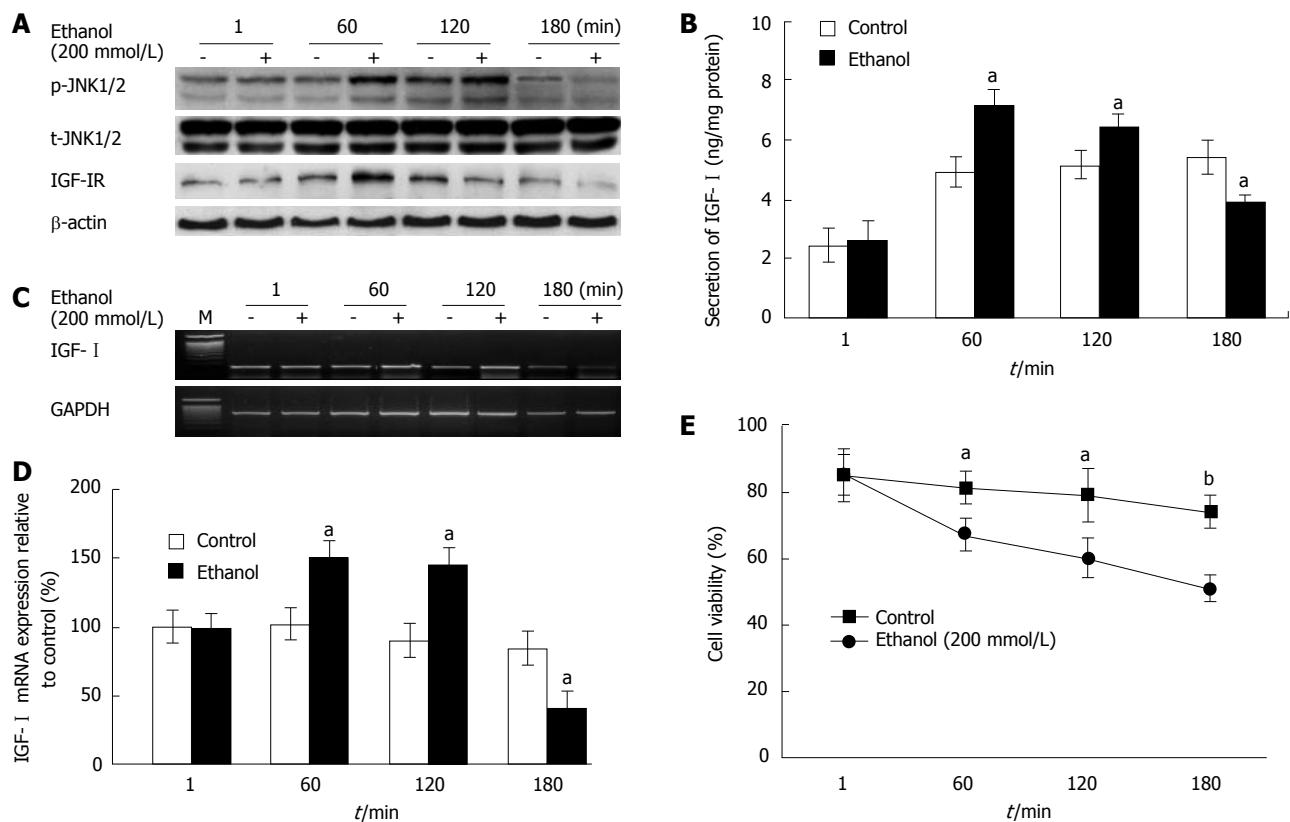

following a modified version of the chloramine-T (Kodak, Grand Island, NY, USA) method. The specific activity of the iodinated IGF- I was typically 60-110 Ci/g protein. The iodination mixture was purified on a Sephadex G-50 column (150 cm) and pre-equilibrated with phosphate-buffered saline (0.1 mol/L, pH 7.4). The samples were then separated, after which the immunoreactive IGF- I was determined as previously described<sup>[11]</sup> with some modifications. All IGF- I data were expressed as nanograms of pure human IGF- I per milliliter, while assuming that equal cross-reactivity occurred between the rat and human IGF- I in the radioimmunoassay. Fifty microliters of rat polyclonal IGF- I antibody diluted to 1:1500 was added to 100  $\mu\text{L}$  of each sample/standard and then incubated for 1 h at room temperature. Next,  $[^{125}\text{I}]$ -IGF- I was added at 20000 cpm, and the samples and standards were then incubated for an additional 18 h at 4°C. Fifty microliters of horse serum (Sigma, St. Louis, MO, USA) was then added to the sample, which was then centrifuged at 3000  $\times g$  for 30 min. After discarding this supernatants, the radioactivities of the precipitates containing the bound  $[^{125}\text{I}]$ -IGF- I were counted with a gamma scintillation counter (Wallac, Finland). The intra- and interassay coefficients of variation for IGFs were 8% and 10%, respectively.

### Isolation and culture of rat hepatocytes

Hepatocytes were isolated from male Sprague-Dawley rats weighing 200-300 g by a two-step perfusion procedure using 0.05% collagenase as described previously<sup>[12,13]</sup>. Cell viability, which was assessed by the exclusion of trypan blue, was 90%  $\pm$  5% (mean  $\pm$  SD). Isolated hepatocytes were then plated onto collagen-coated plastic culture dishes (60 mm in diameter) at a density of  $5 \times 10^4$  cells/cm $^2$  in Williams' medium E containing 10% FBS. The plates were then placed in a 5% CO $_2$  incubator for 3 h at 37°C, after which the medium was changed to FBS-free Williams' medium E. After an additional 30 min, ethanol, SP600125 and 4-methylpyrazole (4-MP) were added at various concentrations to the dishes, which were then immediately sealed with Parafilm. The cells were then incubated for 0-180 min at 37°C.

### Cell lysis and quantification

After incubation, cells were rinsed twice with ice-cold phosphate-buffered saline, followed by the addition of lysis buffer comprising 20 mmol/L HEPES (pH 8.8), 136 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 1% Triton X-100, 10 mmol/L KCl, 2 mmol/L MgCl $_2$ , 1 mmol/L phenylmethylsulfonyl fluoride, 1 mmol/L sodium orthovanadate, 1 mmol/L dithiothreitol, 1 mmol/L benzamidine, 10 mmol/L  $\beta$ -glycerophosphate, 10  $\mu\text{g}/\text{mL}$  aprotinin, 10  $\mu\text{g}/\text{mL}$  leupeptin, and 1  $\mu\text{g}/\text{mL}$  pepstatin A. The cell lysates were then sonicated for 5 min using a Vibra Cell ultrasonic processor (Sonics and Materials, Danbury, USA). After centrifugation of the sonicated samples at 12000  $\times g$  for 10 min at 4°C, the supernatants were

**Figure 1** Time course of effects on the IGF-I system, JNK1/2 activity, and cell viability induced by ethanol in primary cultured rat hepatocytes (mean  $\pm$  SD). The cells were exposed to 200 mmol/L ethanol for 0, 60, 120 and 180 min. **A:** P-JNK1/2, t-JNK1/2, and IGF-IR activities; **B:** IGF-I concentration; **C** and **D:** IGF-I mRNA expression; **E:** Cell viability.  $\beta$ -actin (**A**) and GAPDH (**C**) were used as loading controls. The mRNA expression (as indicated by a band at 180 bp, **C**) was determined by densitometric analysis (**D**) of the amplification products. Data represent percentages relative to control. The cell viability (**D**) was determined by the MTT assay.  $^aP < 0.05$ ,  $^bP < 0.01$  vs control ( $n = 6$ ).

collected, and the protein concentrations were estimated using a bicinchoninic acid (BCA) protein assay kit (Pierce, Bonn, Germany).

#### Western blot

Cell lysates containing equal amounts of protein (20–30  $\mu$ g) were fractionated by 10% SDS-polyacrylamide gel electrophoresis, after which the proteins were transferred to a PVDF membrane (Bio-Rad, Hercules, CA, USA) and then washed with 25 mmol/L Tris (pH 7.4) containing 137 mmol/L NaCl and 0.1% Tween-20. The membrane was then blocked with 25 mmol/L Tris (pH 7.4) containing 137 mmol/L NaCl and 0.1% Tween-20 containing 5% nonfat dry milk for 2 h at room temperature. The blots were then incubated with antibodies against p54/46 JNK1/2 and IGF-IR overnight at 4°C, after which they were incubated with antirabbit and antimouse horseradish peroxidase. After being washed, the blots were developed using an ECL kit and exposed to X-ray film to allow detection of the protein bands.

#### Cell viability

Standard MTT assay as described in literature was used with slight modification (2). MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H-tetrazolium bromide] (Sigma Co., MO, USA) was dissolved in isotonic

phosphate buffer (IPB, pH 7.4) solution at 5 mg/mL and filtered to sterilize and remove insoluble residues. Hepatocytes were cultured in containing Williams' medium E containing 10% FBS and incubated for 4 h at 37°C in serum free Williams' medium E. Cell survival was assayed by measuring the conversion of yellow, water-soluble tetrazolium MTT to blue, water-insoluble formazan. The absorbance was measured at 570 nm.

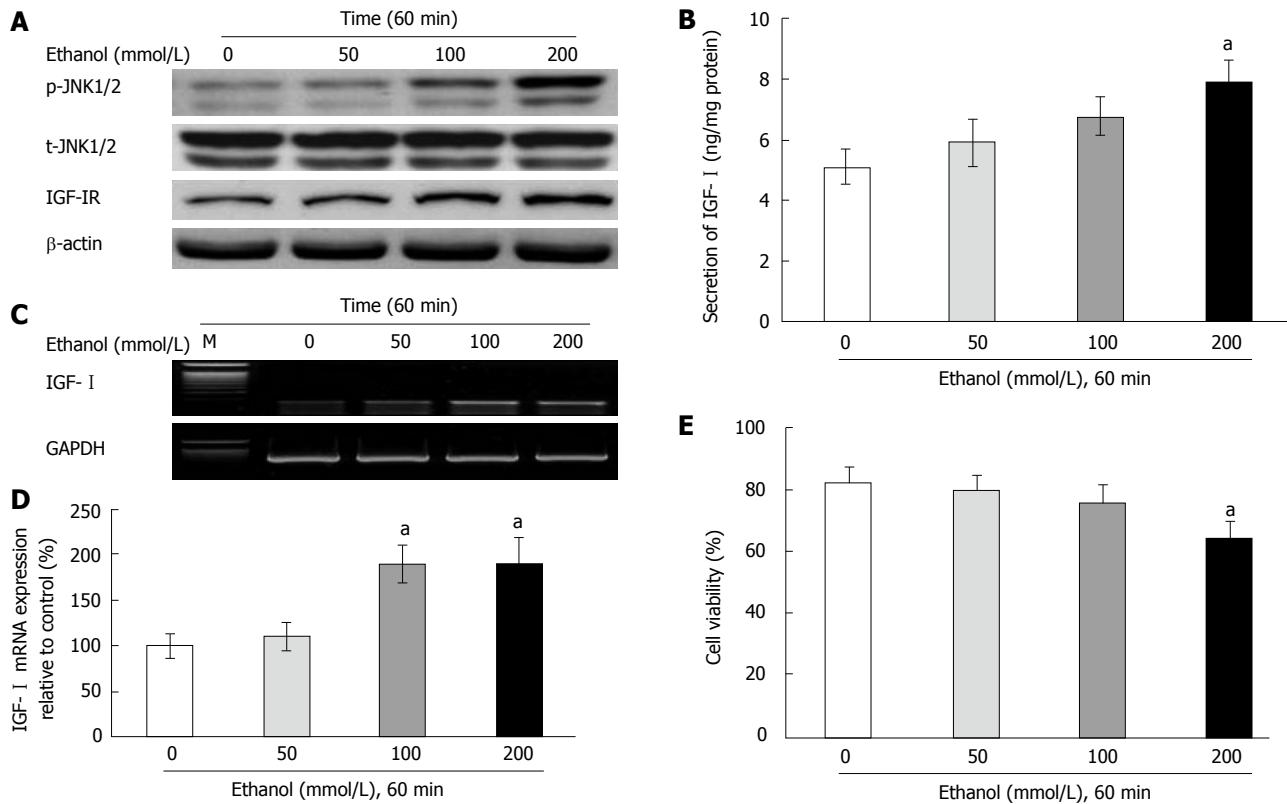

#### Statistical analysis

The statistical significance of differences between groups was determined using a Student's *t* test, with a probability value of  $P < 0.05$  being considered to be indicative of statistical significance. All experiments were performed at least six times.

## RESULTS

#### Time course of the effects of ethanol on the IGF-I system, cell viability, and JNK1/2 activity

To evaluate the time course of the effects of exposure to ethanol on the IGF-I system, cell viability, and JNK1/2 activity, primary cultured rat hepatocytes were exposed to 200 mmol/L ethanol for different times (1, 60, 120 and 180 min). The activity of p-JNK1/2 was observed at 60 and 120 min, and was decreased relative to control at 180 min by ethanol exposure (Figure 1A). However, the total (t)-JNK1/2 activity

**Figure 2** Effects of ethanol on the IGF-I system, JNK1/2 activity, and cell viability at different concentrations (0, 50, 100 and 200 mmol/L) in primary cultured hepatocytes (mean  $\pm$  SD). The cells were exposed to ethanol at different concentrations for 60 min. **A:** P-JNK1/2, t-JNK1/2, and IGF-IR activities; **B:** IGF-I concentration; **C** and **D:** IGF-I mRNA expression; **E:** Cell viability.  $\beta$ -actin (**A**) and GAPDH (**C**) were used as loading controls. The mRNA expression (as indicated by a band at 180 bp, **C**) was determined by densitometric analysis (**D**) of the amplification products. Data represent percentages relative to control. The cell viability (**D**) was determined by the MTT assay.  $^aP < 0.05$ , vs control ( $n = 6$ ).

was not affected. In addition, IGF-IR activity was also observed at 60 min, and it was decreased at 180 min (Figure 1A). The effects of ethanol on the secretion and mRNA expression of IGF-I were similar to changes in p-JNK1/2 activity, which increased at 60 (IGF-I secretion:  $7.11 \pm 0.59$  ng/mg vs  $4.91 \pm 0.51$  ng/mg protein; mRNA expression:  $150.2\% \pm 10.2\%$  vs  $101.5\% \pm 11.3\%$ ,  $P = 0.045$ ) and 120 min and then decreased at 180 min (IGF-I secretion:  $3.89 \pm 0.25$  ng/mg vs  $5.4 \pm 0.54$  ng/mg protein; mRNA expression:  $41.5\% \pm 10.4\%$  vs  $84.7\% \pm 12.1\%$ ,  $P = 0.04$ ; Figure 1B-D). The effects of ethanol on cell viability significantly decreased over time from 60 min onwards (at 60 min:  $66.7\% \pm 5.12\%$  vs  $80.45\% \pm 5.21\%$ ,  $P = 0.035$ ; Figure 1E).

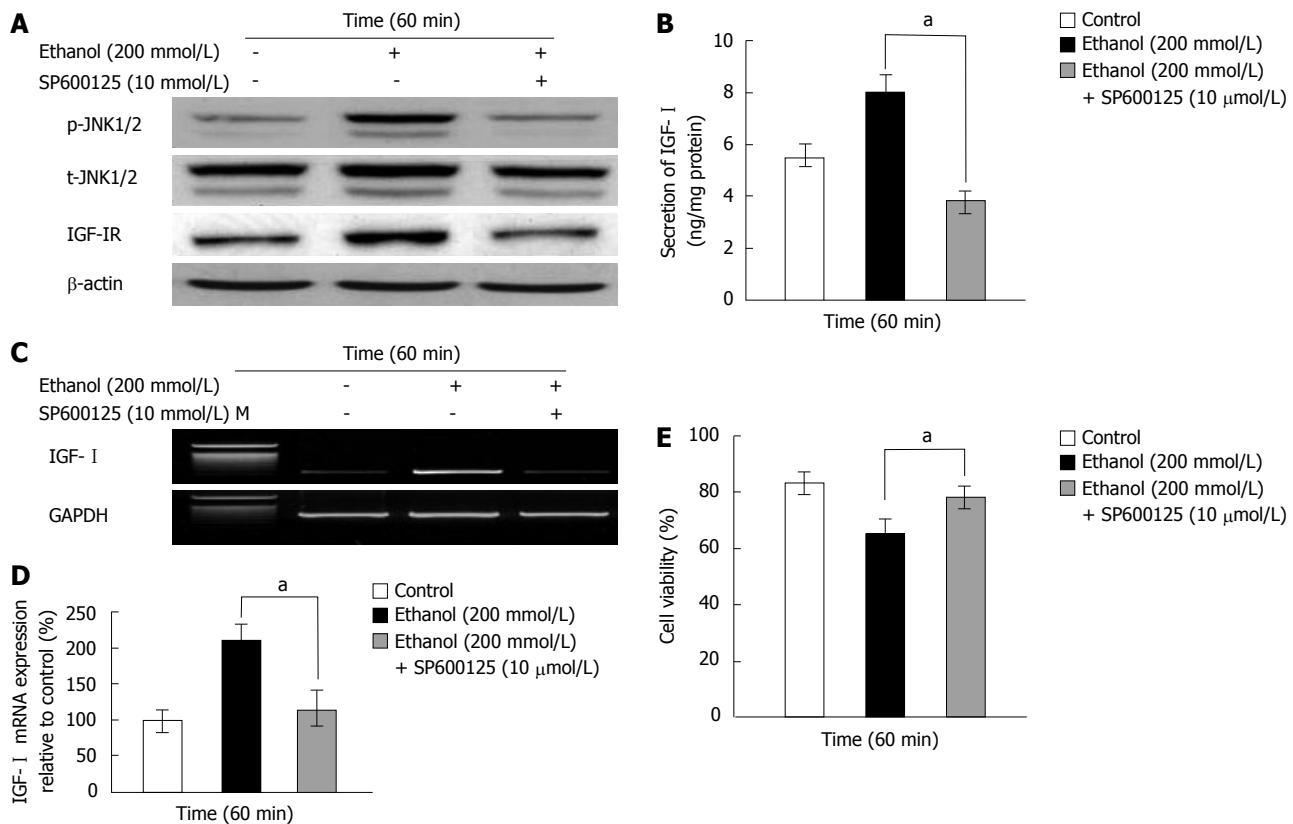

#### Dose-dependent effects of ethanol on the IGF-I system, cell viability, and JNK1/2 activity

To investigate the dose-response effects of ethanol on the IGF-I system and JNK1/2 activity, the cells were exposed to ethanol at different concentrations (0, 50, 100 and 200 mmol/L) for 60 min. The effects of ethanol on the p-JNK1/2 activity increased in a dose-dependent manner (Figure 2A). In addition, the activity of p-JNK1/2 relative to control was maximal in response to exposure to 200 mmol/L ethanol, whereas the t-JNK1/2 activity was not affected (Figure 2A). Furthermore, the changes in IGF-I secretion, mRNA expression, and IGF-IR activity were increased by ethanol in a dose-

dependent manner (Figure 2A-C). The treatment with 200 mmol/L ethanol showed significantly decrease of IGF-I secretion, mRNA expression and IGF-IR activity when compared with the control (IGF-I secretion:  $7.89 \pm 0.71$  ng/mg vs  $5.09 \pm 0.56$  ng/mg protein, mRNA expression:  $191.5\% \pm 27.4\%$  vs  $100\% \pm 13.1\%$ ,  $P = 0.032$ ; Figure 2A-D). These results were similar to those of the ethanol-induced p-JNK1/2 activity. However, cell viability was significantly decreased by exposure to 200 mmol/L ethanol ( $65.2\% \pm 4.9\%$  vs  $83.2\% \pm 4.2\%$ ,  $P = 0.024$ ; Figure 2E).

#### Relationships between ethanol-induced activation of JNK1/2, the IGF-I system, and cell viability

The JNK1/2 inhibitor SP600125 was used to determine if ethanol-induced activation of p-JNK1/2 (at 60 min) was related to the IGF-I system and cell viability. The ethanol-induced activations of p-JNK1/2 and IGF-IR were blocked by treatment with  $10^{-5}$  mol/L SP600125 (Figure 3A). In addition, the temporary increases in secretion ( $8.02 \pm 0.67$  ng/mg protein) and mRNA expression ( $208.8\% \pm 23.4\%$ ) of IGF-I induced by ethanol were also blocked by SP600125 (IGF-I secretion:  $3.78 \pm 0.42$  ng/mg protein, mRNA expression:  $113.87\% \pm 27.5\%$ ,  $P = 0.024$ ; Figure 3B-D), whereas t-JNK1/2 activity was not affected (Figure 3A). The ethanol-induced decrease in cell viability ( $64.2\% \pm 5.5\%$ ) was recovered by SP600125 ( $77.6\% \pm 4.1\%$ ,  $P =$

**Figure 3** Effects of JNK1/2 inhibitor on the IGF-I system, cell viability, and activity of JNK1/2 induced by ethanol at 60 min in primary cultured rat hepatocytes (mean  $\pm$  SD). The cells were pretreated with 10  $\mu$ mol/L SP600125 30 min before being exposed to 200 mmol/L ethanol for 60 min. **A:** p-JNK1/2, t-JNK1/2, and IGF-IR activities; **B:** IGF-I concentration; **C** and **D:** IGF-I mRNA expression; **E:** Cell viability.  $\beta$ -actin (**A**) and GAPDH (**C**) were used as loading controls. The mRNA expression (as indicated by a band at 180 bp, **C**) was determined by densitometric analysis (**D**) of the amplification products. Data represent percentages relative to control. The cell viability (**E**) was determined by the MTT assay.  $^aP < 0.05$  vs control ( $n = 6$ ).

0.045; Figure 3E). These results together demonstrate that the transient changes in the ethanol-induced IGF-I system and the decreased cell viability were related to p-JNK1/2 activity.

#### Relationships between ADH and decreased changes in the IGF-I system by ethanol-induced JNK1/2 activity

To determine the effects of ADH (alcohol dehydrogenase) on the ethanol-induced inactivation of p-JNK1/2 in the IGF-I system and decreased cell viability at 180 min, cells were exposed to 200 mmol/L ethanol after being pretreated with the ADH inhibitor 4-MP (200  $\mu$ mol/L). The ethanol-induced inactivation of p-JNK1/2 and IGF-IR was recovered by 10<sup>-5</sup> mol/L 4-MP, whereas the t-JNK1/2 activity was not affected (Figure 4A). The ethanol-induced decreases in the secretion (4.54  $\pm$  0.52 ng/mg protein) and mRNA expression (24.5%  $\pm$  17.1%) of IGF-I and cell viability (50.3%  $\pm$  5.5%) were also recovered by pretreatment with 4-MP (IGF-I secretion: 10.3  $\pm$  0.79, mRNA expression: 109.4%  $\pm$  21.8%, cell viability: 77.2  $\pm$  7.2,  $P = 0.035$ ; Figure 4B-E). These results together indicate that the decreases in ethanol-induced p-JNK1/2 activity, IGF-I system and cell viability were related to the ADH.

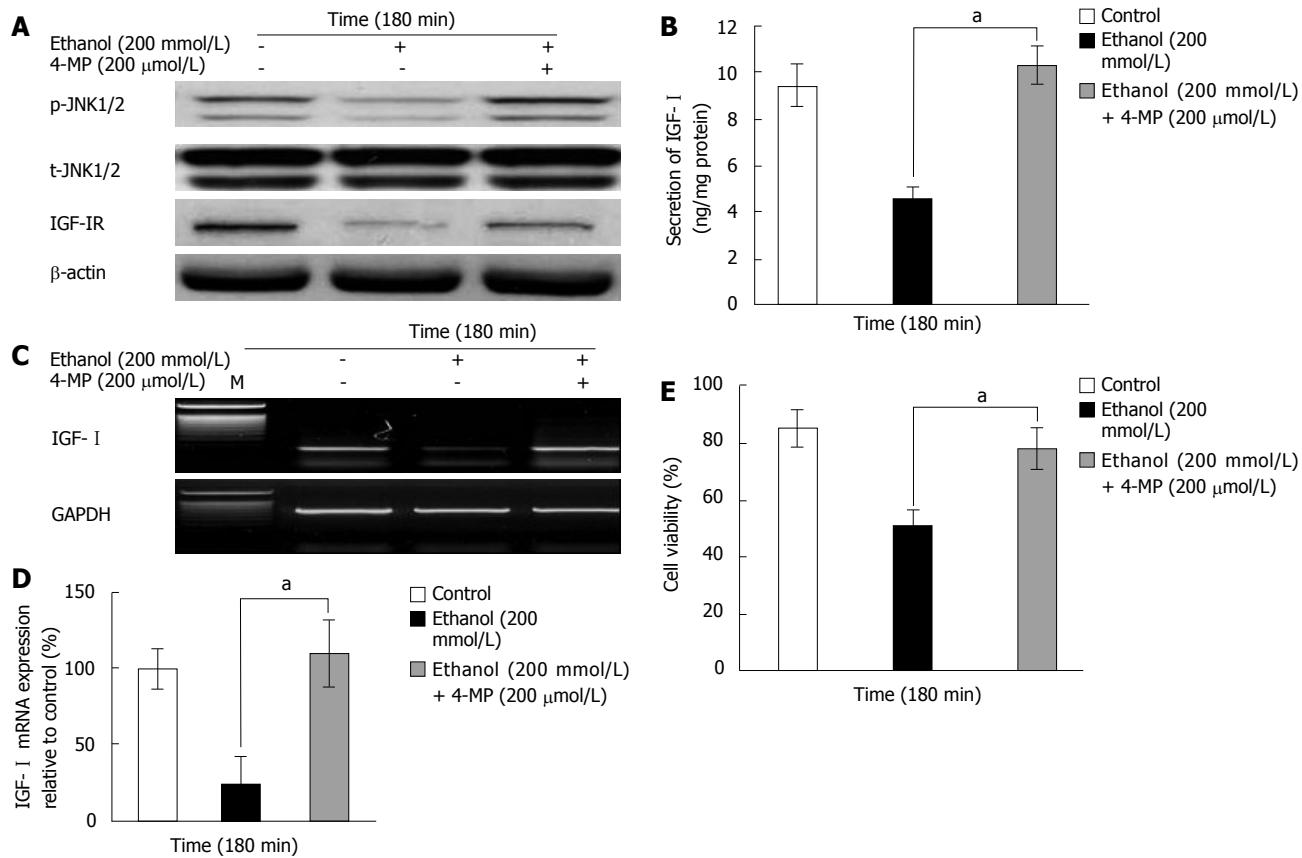

## DISCUSSION

Ethanol exerts toxic effects on almost all organs,

particularly liver and brain. The liver is a major metabolic organ in which most IGF-I is produced and secreted, and its mediators are responsible for alcohol-induced liver injury<sup>[14]</sup>.

In the present study, we showed that ethanol transiently increased p-JNK1/2 activity at 60 min and then decreased it at 180 min. It has been reported that ethanol activates MAPKs<sup>[1,2]</sup>, and acute exposure of primary cultured rat hepatocytes to ethanol for 60 min increases the activities of p42/44 MAPK and p-JNK1/2, with both activities gradually decreasing thereafter<sup>[15]</sup>. Exposure to ethanol has been shown to cause prolonged activation of p-JNK1/2; however, this response was attenuated in hepatocytes obtained from rats chronically exposed to ethanol for 6 wk<sup>[16]</sup>. Our result is similar with those of previous studies mentioned above, in which exposure time to ethanol causes activation and inactivation of p-JNK1/2 activation in rat hepatocytes.

The activation of p-JNK1/2 normally occurs in response to growth stimuli and is involved in cell proliferation<sup>[17]</sup>. This is also related to apoptosis and antiapoptosis, and is activated by cytokines or stress stimuli such as osmotic shock, UV light, and heat<sup>[9,18]</sup>. IGF-I system has been reported to protect against a variety of chemical cellular injuries that induce apoptosis<sup>[19]</sup>. We previously showed that ethanol decreased the synthesis and secretion of IGF-I and the activity of IGF-IR, an effect that is related to cell

**Figure 4** Effects of ADH inhibitor on the IGF-I system, cell viability, and JNK1/2 activity induced by ethanol at 180 min in primary cultured rat hepatocytes (mean  $\pm$  SD). The cells were pretreated with 200  $\mu$ mol/L 4-MP 30 min before being exposed to 200 mmol/L ethanol for 180 min. **A:** p-JNK1/2, t-JNK1/2, and IGF-IR activities; **B:** IGF-I concentration; **C** and **D:** IGF-I mRNA expression; **E:** Cell viability. β-actin (**A**) and GAPDH (**C**) were used as loading controls. The mRNA expression (as indicated by a band at 180 bp, **C**) was determined by densitometric analysis (**D**) of the amplification products. Data represent percentages relative to control. The cell viability (**D**) was determined by the MTT assay. <sup>a</sup> $P < 0.05$  vs control ( $n = 6$ ).

proliferation and differentiation<sup>[11]</sup>. In the present study, ethanol-induced transient activation of p-JNK1/2 increased in the IGF-I system, but this decreased when p-JNK1/2 was inactivated. Furthermore, IGF-IR activity also regulates ethanol-induced secretion and synthesis of IGF-I. These results are consistent with our previous study that ethanol-induced p42/44 activity was related to the secretion and synthesis of IGF-I in primary cultured rat hepatocytes<sup>[11]</sup>. In our previous study, although there were different doses (5%-20%), chronic ethanol treatment caused dose-dependent decreases in the secretion and synthesis of IGF-I in liver and blood *in vivo*<sup>[8]</sup>.

We also used a JNK1/2 inhibitor to verify whether the ethanol-induced transient activation of p-JNK1/2 may alter the IGF-I system. The results reported here confirmed that the effects of ethanol on p-JNK1/2 activation, the IGF-I system, and cell viability were recovered by an inhibitor of the JNK1/2 activity. We suggest that acute exposure to ethanol affects not only p42/44 MAPK but also p-JNK1/2 activities, which in turn alter the IGF-I system. It has been reported that ethanol-induced transient activation of p-JNK1/2 indicates pro-apoptosis, while a prolonged activation induces anti-apoptosis in hepatocytes<sup>[20]</sup>. Hepatocytes express two JNK genes (JNK1 and JNK2) and bile acids

cause activation of both JNK1 and JNK2, but JNK1 activation causes apoptosis whereas JNK2 activation protects against apoptosis<sup>[21]</sup>. It has been reported that ethanol causes more pronounced activation of JNK 1 compared to JNK 2, suggesting a role for this preferential activation of JNK 1 in ethanol-induced apoptosis of hepatocytes<sup>[15]</sup>.

Interestingly, we found that cell viability is always decreased by ethanol. However, there was a transient activation of p-JNK1/2 and the subsequent inactivation of p-JNK1/2 in parallel with changes of the IGF-I system. These results suggest that transient activation of p-JNK1/2 with increment of the IGF-I system lead to pro-apoptotic events and transient resistance of hepatocytes. Also, the ethanol-induced inactivation of p-JNK upon decrease of the IGF-I system indicate that the cells have already passed the threshold for proliferation or survival against the ethanol-induced toxicity.

The ADH is an enzyme involved in ethanol metabolism that appears to provide the link between the effects of ethanol-induced p-JNK1/2 activity on the IGF-I system and cell viability at 180 min but not at 60 min (data not shown). It has been reported that the level of 4-MP decreased by approximately 90% in rat hepatocytes following exposure to ADH and ethanol<sup>[22]</sup>.

Ethanol rapidly activates p-JNK1/2, which is associated with the response of the endoplasmic reticulum to stress, which in turn causes inhibition of ADH<sup>[23]</sup>. Acute exposure to 200 mmol/L ethanol may also activate p-JNK1/2 via acetaldehyde-dependent<sup>[15]</sup> and acetaldehyde-independent<sup>[24]</sup> pathways in rat hepatocytes. It was reported that acetaldehyde produced by ethanol oxidation activates p42/44 MAPK and p-JNK1/2 in rat hepatocytes<sup>[1,2,15]</sup>. We previously reported that ethanol-induced changes of the IGF-I system are related to ADH activity<sup>[11]</sup>. These results suggest that the decrease in p-JNK1/2 activity induced by exposure to ethanol for 180 min regulates the decrease of IGF-I system and cell viability, with these effects being related to ADH. However, the effects of the ethanol-induced transient activation of p-JNK1/2 on the increment of IGF-I system were not due to ADH.

In conclusion, this study suggest that ethanol-induced p-JNK1/2 activation is related to changes in the IGF-I system and cell viability in hepatocytes. Furthermore, ethanol-induced inactivation of p-JNK1/2 is involved in the IGF-I system and cell viability via ADH. These findings might be helpful to understand the pathogenesis of liver damage induced by ethanol, and may lead to a rational therapeutic intervention against ethanol toxicity.

## COMMENTS

### Background

Ethanol-induced liver damage is unavoidable upon exposure to alcohol. Moreover, enhanced c-Jun N-terminal kinase (JNK1/2) and alcohol dehydrogenase (ADH) activity have been linked to the ethanol induced hepatotoxicity. Insulin-like growth factor-I (IGF-I) system has been reported to protect against a variety of chemical cellular injuries that induce apoptosis; however it has not been well defined whether the IGF-I system is associated with the ethanol-induced JNK and ADH activity.

### Research frontiers

It was reported that acetaldehyde produced by ethanol oxidation activates p42/44 MAPK and p-JNK1/2 in rat hepatocytes. We previously reported that ethanol-induced changes of the IGF-I system are related to p42/44 activity. To investigate the importance of IGF-I system via JNK and ADH, we performed this study using specific inhibitors.

### Innovations and breakthroughs

We found that there was increase and then decrease in the IGF-I secretion and mRNA expression during ethanol treatment. The activity of JNK was also temporary increased and then decreased by ethanol. However, cell viability was monotonically decreased. Both JNK and ADH inhibitors blocked ethanol-induced changes of IGF-I system and cell viability.

### Applications

The present study evaluated the changes of the IGF-I system indicating that the potential value of IGF-I system for patients with ethanol-induced liver damage. Moreover, this study demonstrates that ethanol-induced IGF-I system is involved in the activities of JNK1/2 and ADH.

### Terminology

IGF-I system has been reported to protect against a variety of chemical cellular injuries and promote proliferation of hepatocytes. The liver is a major metabolic organ in which most IGF-I is produced and secreted, and its mediators are responsible for alcohol-induced liver injury.

### Peer review

This manuscript describes the activation of JNK1/2 activity by ethanol treatment of rat hepatocytes and subsequent changes in IGF expression and secretion as well as changes in proliferation. These effects could be inhibited by the specific inhibitors of JNK1/2 as well as an inhibitor of ADH. This manuscript is well-written, clear and concise with a thorough results section.

### Abstract

**AIM:** To investigate the effects of prednisolone on cell membrane bleb formation, calpain  $\mu$  activation and talin degradation during hepatic ischemia-reperfusion injury in rats.

**METHODS:** The hilar area of the left lateral and median lobes of rat liver (68%) was clamped for 60 min and followed by 120 min reperfusion. Prednisolone was administered at 1.0, 3.0, or 10 mg/kg at 30 min before ischemia. In addition to biochemical and microscopic analyses, activation of calpain  $\mu$  was determined using specific antibodies against the intermediate (activated) form of calpain  $\mu$ . Degradation of talin was also studied by Western blotting.

**RESULTS:** In the control and prednisolone (1.0 mg/kg) groups, serum aspartate transaminase (AST) and alanine transaminase (ALT) level were elevated, and cell membrane bleb formation was observed after 120 min of reperfusion. Moreover, calpain  $\mu$  activation and talin degradation were detected. Infusion of prednisolone at 3.0 or 10 mg/kg significantly suppressed serum AST and ALT, and prevented cell membrane bleb formation. At 10 mg/kg, prednisolone markedly suppressed calpain  $\mu$  activation and talin degradation.

**CONCLUSION:** Prednisolone can suppress ischemia-reperfusion injury of the rat liver. Its cytoprotective effect is closely associated with the suppression of calpain  $\mu$  activation and talin degradation.

### INTRODUCTION

Hepatic ischemia-reperfusion injury is a serious complication but unavoidable problem in liver surgery including liver transplantation and hepatic resection<sup>[1]</sup>. The most important consequence of this pathological process is multiple organ failure with a high mortality rate. Therefore, there is a considerable interest in the prevention of hepatic ischemia-reperfusion injury. Steroid therapy suppresses liver injury by a variety of mechanisms, including increased tissue blood flow and suppression of oxygen free radicals, arachidonic acid derivatives, lysosomal proteases (cathepsins) and cytokine production<sup>[2-5]</sup>. However, the exact intracellular mechanisms of steroid action on hepatic ischemia-reperfusion injury remains unknown.

Exposure of hepatocytes to hypoxia or oxidative stress is thought to result in a rise in intracellular Ca<sup>2+</sup> concentrations ([Ca<sup>2+</sup>]<sub>i</sub>), initiating cell membrane bleb formation, an early event leading to cell death<sup>[6,7]</sup>. Although the molecular mechanisms of bleb formation are unknown at present, Ca<sup>2+</sup>-dependent disruption of the cytoskeleton is considered to play an important role in the blebbing of plasma membrane<sup>[8,9]</sup>. Calpain  $\mu$ , a Ca<sup>2+</sup>-sensitive form of Ca<sup>2+</sup>-activated neutral protease (EC 3, 4, 22, 17), has been shown to degrade various cytoskeletal proteins such as talin,  $\alpha$ -actinin and

filamin<sup>[10-14]</sup>.

Steroids are the most potent anti-inflammatory and immunosuppressive agents<sup>[15]</sup>. They inhibit the synthesis of almost all known cytokines and cell surface molecules required for immune function, and suppress the activity of nuclear factor kappa B (NF-κB)<sup>[16]</sup>. This inhibition is mediated by the induction of IκBα inhibitory protein, which traps activated NF-κB in inactive cytoplasmic complexes. On the other hand, inflammatory cytokines, such as interleukin-1β and tumor necrosis factor-α, are involved in the pathophysiology of hepatic ischemia-reperfusion injury<sup>[17]</sup>. The liver also plays a central role in the metabolism of these acute reactant cytokines. In the liver, these mediators are produced in large amounts by Kupffer cells or endothelial cells<sup>[18]</sup>, and are released rapidly under various insults like hypoxia<sup>[17]</sup>.

In the present study, we investigated the cytoprotective mechanisms of prednisolone using an experimental model of ischemia-reperfusion injury of rat liver, with special emphasis on the activation of calpain μ and degradation of talin.

## MATERIALS AND METHODS

### Animals

Thirty-seven adult male Wistar (Aburabi Laboratory, Shiga, Japan) rats weighing 220-260 g were used in the study. All procedures were carried out in accordance with the guidelines set forth in the Animal Welfare Act and the Guide for the Care and Use of Laboratory Animals by the National Institutes of Health. Rats were anesthetized by an interperitoneal injection of pentobarbital sodium (50 mg/kg body weight), and underwent laparotomy. Before vascular clamping, heparin sodium (50 units) was intravenously injected to prevent blood coagulation.

### Prednisolone

A highly potent antagonist of prednisolone was obtained from Shionogi Pharmaceutical Co., Japan. Its molecular formula is C<sub>25</sub>H<sub>31</sub>NaO<sub>8</sub> and molecular weight is 482.51 (Figure 1). Animals were divided into two groups: rats treated with 0.9% normal saline solution were assigned as the control group ( $n = 10$ ), and those treated with intravenous injection of prednisolone (1.0, 3.0, or 10 mg/kg) as the prednisolone group ( $n = 27$ ) (1.0, 3.0 and 10 mg/kg) (Figure 2).

### Partial liver ischemia

An intravenous catheter was placed in the tail vein, through which prednisolone was infused at 30 min before vascular clamping. Partial (68%) hepatic ischemia was induced by clamping the branches of the portal vein, and hepatic artery feeding the left lateral and median lobes, the branches of the right lateral (24%) and caudate (8%) lobes were not clamped<sup>[13,14]</sup>. In this condition, intestinal congestion or other complications did not occur throughout the experiment (Figure 3).

Chemical Name: monosodium 11 β, 17, 21-trihydroxy-1, 4-pregnadiene-3, 20-dione 21-succinate  
Molecular Formula: C<sub>25</sub>H<sub>31</sub>NaO<sub>8</sub>  
Molecular Weight: 482.51

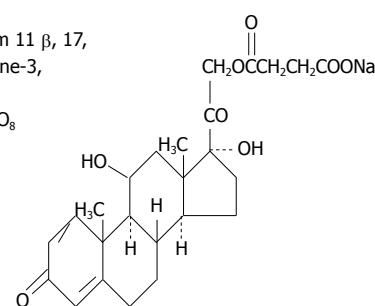

Figure 1 Structure of prednisolone.

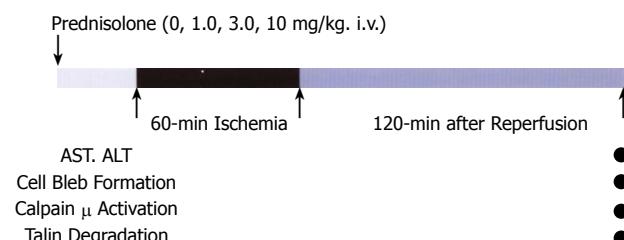

Figure 2 Experimental model.

### Measurement of serum aspartate transaminase (AST) and alanine transaminase (ALT)

Blood samples were collected at 120 min after declamping, and serum samples were stored at -80°C until biochemical analysis. Serum AST and ALT concentrations were determined by a Spot Chem kit (Spotchem Co., Kyoto, Japan).

### Cell membrane bleb formation

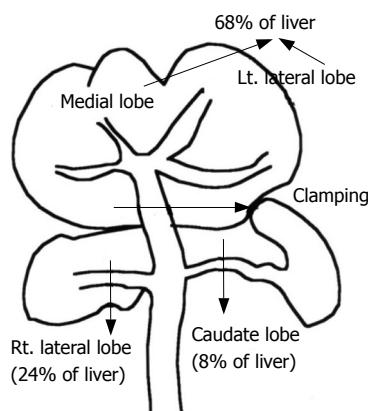

In a separate set of experiments similar to those described above, tissue samples were obtained for histological examination after *in situ* perfusion and fixation with 0.1% glutaraldehyde and 4% paraformaldehyde, which were infused via the portal vein. Biopsy specimens were also processed for routine histopathologic examination<sup>[13,14]</sup>.

### Antibodies against intermediate (activated) form of calpain μ

The preparation and characteristics of an antibody that specifically recognizes the N-terminal peptide of intermediate (activated) (NH<sub>2</sub>-AQVQKQC-COOH) form of calpain μ (78 kDa) have been described previously<sup>[13,14]</sup>.

### Western blot analysis

Liver tissues were immediately frozen by liquid nitrogen and stored at -80°C for 3 d. For Western blot analysis, samples were homogenized in an ice-water bath using a radioimmune protein assay buffer [1.0% Nonidet P-40 (Iwai Kagaku Co Ltd, Tokyo, Japan); 0.1% deoxycholic acid; 150 mmol/L sodium chloride; 50 mmol/L Tris hydrochloride; 1.0 mmol/L phenylmethylsulfonyl fluoride, pH 7.5] containing 5 mmol/L ethylene glycol-bis (β-aminoethyl ether)-N, N, N', N'-tetra acetic acid (EGTA) and 5 μmol/L leupeptin. After centrifugation

**Figure 3** Partial liver ischemia by clamping hilar area of left lateral and medial lobes without causing intestinal congestion. Lt.: Left; Rt.: Right.

at 3000 r/min for 20 min at 4°C, the supernatant (25 µg of protein) was subjected to Western blot analysis using an antibody against the intermediate form of calpain µ or an anti-talin antibody (Sigma Chemical Co., St. Louis, MO). The amount of these polypeptides was determined by a densitometric analysis.

#### Statistical analysis

Data were expressed as means  $\pm$  SD. Differences in transaminase levels, calpain µ activation and talin degradation among various groups were tested for statistical significance using the Student's *t* test and Dunnett's multiple comparison test. A *P* value of less than 0.05 denoted the presence of a statistically significant difference.

## RESULTS

### Serum AST and ALT

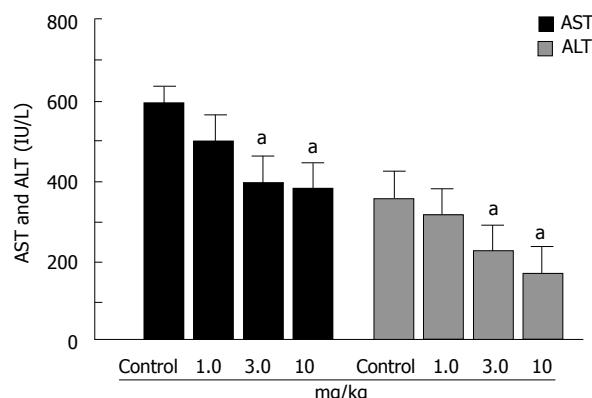

Serum AST and ALT concentrations were increased at 120 min after declamping in the control group. Prednisolone reduced the concentration of both transaminases in a dose-dependent manner. Differences between control and prednisolone levels were significant at prednisolone dose of 3.0 and 10 mg/kg (Figure 4).

### Histological findings

To further investigate the cytoprotective effect of prednisolone, liver tissues were examined histologically (Figure 5). In the control group, at 120 min after declamping, the cell structure of hepatocytes was not clear due to membrane bleb formation. Furthermore, numerous membrane microparticles were present in the sinusoidal space. In contrast, membrane blebbing was rarely seen and the cell structure was well preserved in prednisolone-treated (3.0 and 10 mg/kg) rats.

### Activation of calpain µ

Using a specific antibody to the intermediate (78 kDa) form of calpain µ, Western blotting was performed to examine the relationship between calpain µ activation and cell injury of the liver (Figure 6). The activated form

**Figure 4** Effects of prednisolone on the AST and ALT levels in animals with 60 min of partial hepatic ischemia. \**P* < 0.05.

of calpain µ appeared in all groups at 120 min after vascular declamping. However, prednisolone inhibited calpain µ activation in a dose-dependent manner. The difference in calpain µ activation was significant between control and high dose prednisolone (10 mg/kg) rats.

### Degradation of talin

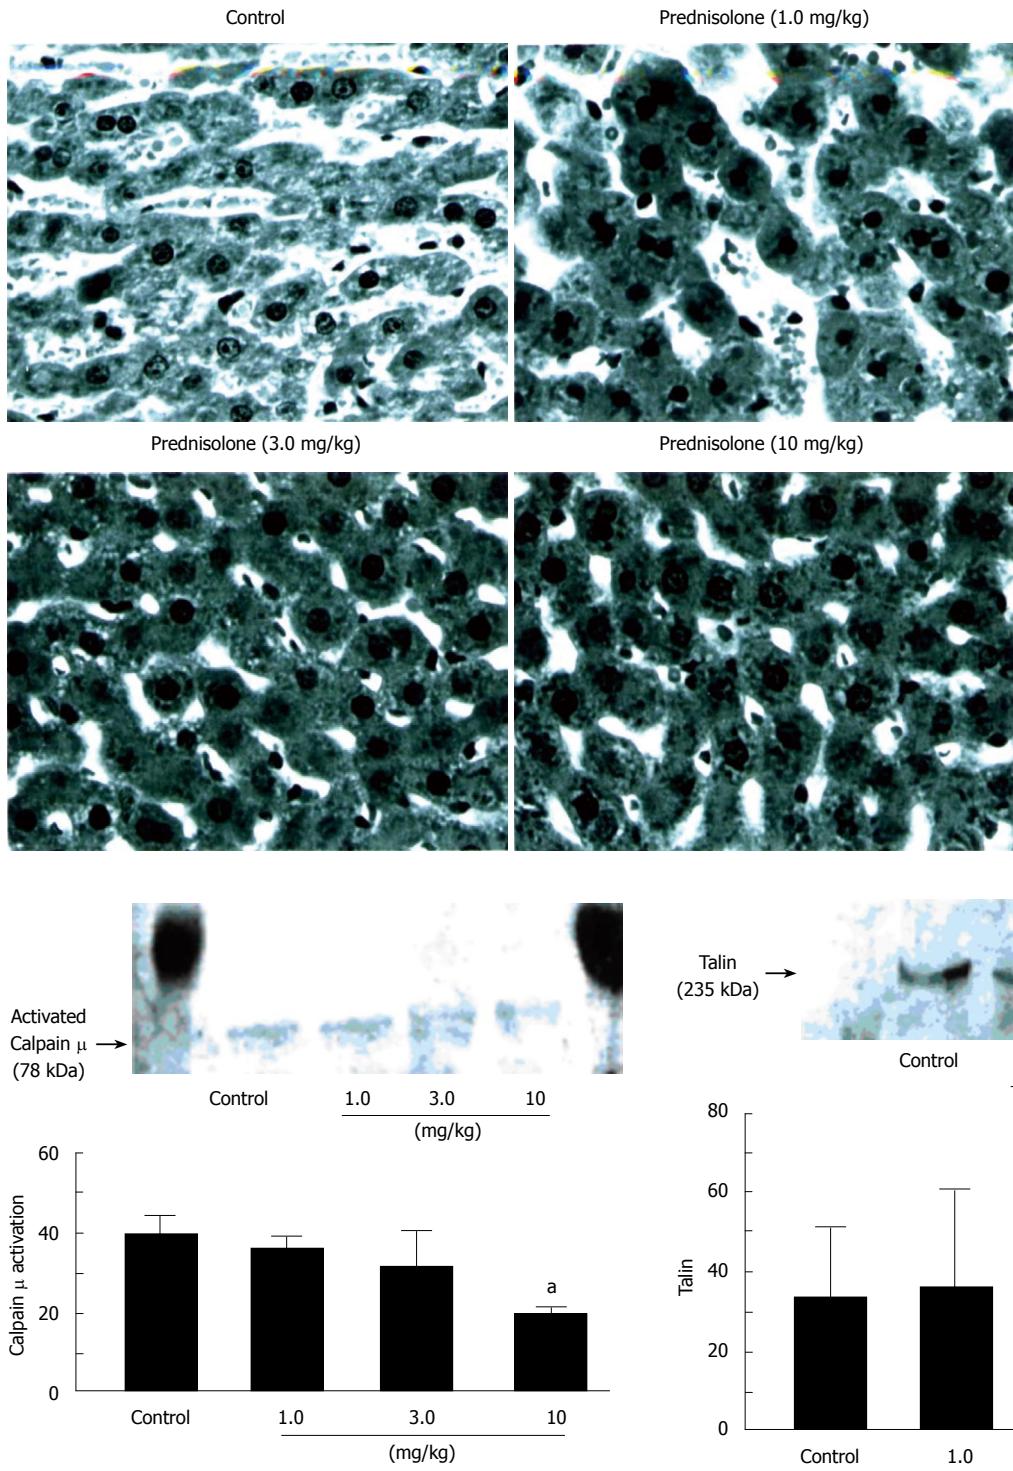

Proteolysis of talin, a favorable intracellular substrate of calpain µ was also investigated by Western blotting (Figure 7). Talin was markedly degraded in control and low-dose prednisolone (1.0 mg/kg) rats 120 min after vascular declamping. However, at 3.0 and 10 mg/kg, prednisolone significantly suppressed talin degradation, compared to the control group.

## DISCUSSION

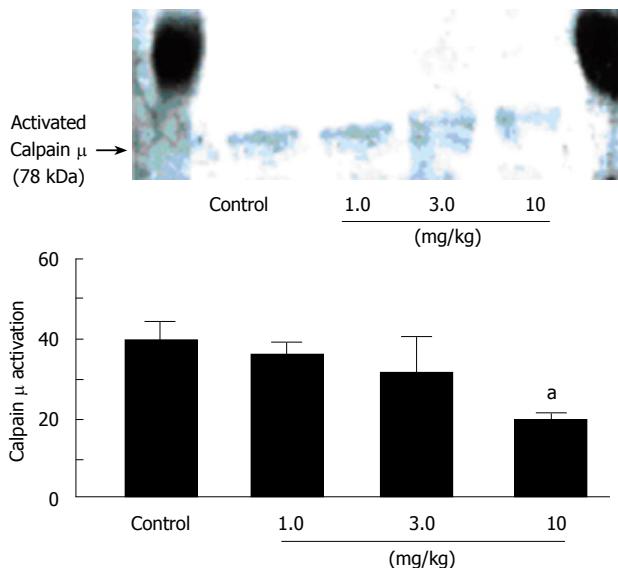

The major findings of our study were that prednisolone inhibited calpain µ activation in ischemia-reperfusion injury of the rat liver and that the degree of calpain µ activation closely correlated to the morphological changes in hepatocytes, i.e., cell membrane bleb formation. Furthermore, we also showed that prednisolone reduced the level of talin degradation in ischemic liver tissues. These changes were associated with improved overall liver function as reflected by lowering of serum AST and ALT concentrations, relative to the control.

Calpain µ is a major  $\text{Ca}^{2+}$ -dependent cytosolic protease so far described<sup>[13,14]</sup> and is activated following increased  $[\text{Ca}^{2+}]_i$  in hepatocyte injury. Since cell membrane bleb formation is an irreversible phenomenon leading to cell necrosis, the role of calpain activation in cell membrane blebbing through the proteolysis of cytoskeletal proteins<sup>[15]</sup> is considered to be particularly important. Furthermore, we have previously reported that talin and  $\alpha$ -actinin were degraded simultaneously with calpain µ activation in oxidative stress-induced hepatocyte injury, and that all these events were suppressed by a specific calpain inhibitor, calpeptin<sup>[10-14]</sup>. Thus, the beneficial effects of prednisolone on hepatic ischemia-reperfusion injury may be at least due to inhibition of calpain µ activation.

Recent studies have demonstrated that hepatocyte

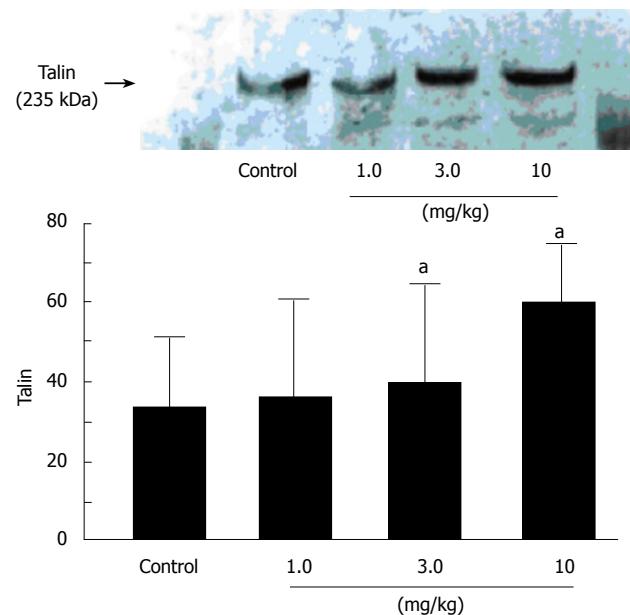

**Figure 5** Effects of prednisolone on histopathological findings in animals with 60 min partial hepatic ischemia. T (HE,  $\times 400$ ).

**Figure 6** Effects of prednisolone on calpain  $\mu$  activation in animals with 60 min of partial hepatic ischemia.  $^aP < 0.05$ .

injury is initiated by a rise in  $[Ca^{2+}]_i$ , which results from  $Ca^{2+}$  release from the internal storage sites and  $Ca^{2+}$  influx<sup>[7,11,12]</sup>, and is closely correlated with the magnitude of ischemic insult. On the other hand, the pathogenesis of hepatic ischemia-reperfusion injury is complex and multifactorial. Various factors such as the reactive oxygen species<sup>[19]</sup>, platelet-activating factor<sup>[20]</sup>, thromboxane A<sub>2</sub><sup>[21]</sup>, leukotriene B<sub>4</sub><sup>[22]</sup> and endothelin-1<sup>[23]</sup> have been identified. In addition, inflammatory cytokines like interleukin-1 $\beta$  and tumor necrosis factor- $\alpha$  also

**Figure 7** Effects of prednisolone on the degradation of talin in animals with 60 min of partial hepatic ischemia.  $^aP < 0.05$ .

play an important role in hepatic ischemia-reperfusion injury<sup>[17]</sup>. All these substances induce a rise in  $[Ca^{2+}]_i$ . These findings indicate that in addition to prostaglandin E1 and prostacyclin<sup>[13]</sup> which directly suppress the rise in  $[Ca^{2+}]_i$ , other agents like corticosteroids may inhibit hepatic ischemia-reperfusion injury by suppressing the production of these extracellular mediators. In fact, corticosteroids have been shown to inhibit the generation of oxygen free radicals<sup>[24]</sup>, and reduce

hepatic ischemia-reperfusion injury<sup>[25]</sup>. In the present study, we demonstrated that at a dose of 10 mg/kg, prednisolone inhibited degradation of talin, as well as calpain  $\mu$  activation in the ischemic liver. Since the increase in  $[Ca^{2+}]_i$  induces calpain  $\mu$  activation, inhibition of calpain  $\mu$  activation by prednisolone suggests a possible suppression of increased  $[Ca^{2+}]_i$  in hepatocytes. Therefore, it is possible that prednisolone inhibits hepatic ischemia-reperfusion injury by suppressing the generation of extracellular mediators with subsequent abrogation of the rise in  $[Ca^{2+}]_i$ .

Consistent with the beneficial effects on extra- and intracellular mediators, these findings suggest that preoperative administration of glucocorticoids may prevent hepatic ischemia-reperfusion injury and subsequent systemic reactions. However, the inhibitory effect of prednisolone on the calpain  $\mu$  activation was not completely similar to the results of the serum transaminase levels, and membrane bleb formation. From the clinical point of view, a complete inhibition of hepatic ischemia-reperfusion injury may be an ultimate goal in liver surgery. To accomplish this, treatment with a combination of several agents that inhibit various steps of hepatic ischemia-reperfusion injury is probably necessary since all agents reported so far produce only a partial inhibitory effect. The multiplicity approach for hepatic ischemia-reperfusion injury (e.g. prostaglandin E1 and prednisolone) is now under investigation.

In conclusion, we demonstrated in the present study that prednisolone suppressed ischemia-reperfusion injury of the rat liver. Its cytoprotective effect was partial, but was closely associated with inhibition of calpain  $\mu$  activation and suppression of talin degradation. The effects of a combination of two or more agents of different inhibitory mechanisms should be examined in the future to reduce the complications encountered during hepatic surgery.

## COMMENTS

### Background

Hepatic ischemia-reperfusion injury is a serious complication but unavoidable problem in liver surgery including liver transplantation and hepatic resection. The most important consequence of this pathological process is multiple organ failure with a high mortality rate. Steroid therapy suppresses liver injury by a variety of mechanisms, including increased tissue blood flow and suppression of oxygen free radicals, arachidonic acid derivatives, lysosomal proteases (cathepsins) and cytokine production. In this study, authors investigated the cytoprotective mechanisms of prednisolone using an experimental model of ischemia-reperfusion injury of rat liver, with special emphasis on the activation of calpain  $\mu$  and degradation of talin.

### Research frontiers

Steroids are the most potent anti-inflammatory and immunosuppressive agents. They inhibit the synthesis of almost all known cytokines and cell surface molecules required for immune function, and suppress the activity of nuclear factor kappa B (NF- $\kappa$ B). This inhibition is mediated by the induction of I $\kappa$ B $\alpha$  inhibitory protein, which traps activated NF- $\kappa$ B in inactive cytoplasmic complexes. On the other hand, inflammatory cytokines, such as interleukin-1 $\beta$  and tumor necrosis factor- $\alpha$ , are involved in the pathophysiology of hepatic ischemia-reperfusion injury. The liver also plays a central role in the metabolism of these acute reactant cytokines. In the liver, these mediators are produced in large amounts by Kupffer cells or endothelial cells, and are released rapidly under various insults like hypoxia.

### Innovations and breakthroughs

Recent studies have demonstrated that hepatocyte injury is initiated by a rise in  $[Ca^{2+}]_i$ , which results from  $Ca^{2+}$  release from the internal storage sites and  $Ca^{2+}$  influx, and is closely correlated with the magnitude of ischemic insult. On the other hand, the pathogenesis of hepatic ischemia-reperfusion injury is complex and multifactorial. All these reactive oxygen species induce a rise in  $[Ca^{2+}]_i$ . This study found that at a dose of 10 mg/kg, prednisolone inhibited degradation of talin, as well as calpain  $\mu$  activation in the ischemic liver.

### Applications

In this research, authors found calpain  $\mu$  is an important enzyme related to hepatic ischemia-reperfusion injury. The mechanism of calpain  $\mu$  is first reported in living organism in this research.

### Peer review

The study deals with protective effect of prednisolone antagonist on ischemia-induced liver injury. The authors have shown that the compound used offered protection for the liver. This is a well written and interesting study.

## INTRODUCTION

*Clostridium difficile* associated diarrhoea (CDAD) is the most common cause of healthcare-associated diarrhoea and results in a wide spectrum of disease severity ranging from asymptomatic carriage to life-threatening enterocolitis and death<sup>[1-5]</sup>. Recently, a new epidemic strain producing higher levels of toxin has emerged in Canada and the US<sup>[5-8]</sup> as well as in some European countries which results in CDAD with higher morbidity and mortality<sup>[9-13]</sup>. Many studies have investigated risk factors for infection with *Clostridium difficile* (*C. difficile*) and subsequent development of CDAD. Thus, advanced age, severe comorbidity<sup>[14]</sup>, hospitalisation<sup>[15]</sup>, antibiotic exposure, immunosuppressive therapy<sup>[16,17]</sup> and treatment with motility influencing or acid-suppressive drugs have all been reported as risk factors for CDAD<sup>[18-21]</sup>. In contrast, less is known about risk factors associated with a severe course of CDAD in hospitalized patients.

## MATERIALS AND METHODS

We conducted a retrospective analysis of CDAD in hospitalized patients to identify possible risk factors for a severe clinical course. Our institution is a community hospital treating approximately 19 000 in-patients per year. Using a computer-based search, we identified 186 positive stool tests for *C. difficile* toxin B from 142 patients who fulfilled the case definition for CDAD between October 2003 and August 2006. After chart review 18 cases were excluded: 5 patients had multiple admissions and only the first admission was included, 5 patients were younger than 18 years and in 8 patients

## Abstract

**AIM:** To investigate risk factors for severe *Clostridium difficile* associated diarrhoea (CDAD) in hospitalized patients.

**METHODS:** We analysed risk factors for severe CDAD (associated with systemic signs of hypovolemia) in 124 hospitalized patients by retrospective chart review.

**RESULTS:** Severe CDAD was present in 27 patients (22%). Statistical analysis showed a significant association with a higher 30-d mortality (33% vs 4%,  $P < 0.001$ ) and a higher proportion of longer hospital stay exceeding 14 d (74% vs 52%,  $P = 0.048$ ). Charlson co-morbidity score (OR 1.29 for 1 point increment,  $P < 0.05$ ) and serum C-reactive protein at diagnosis (OR 1.15 for 10 mg/L increment,  $P < 0.001$ ) were independent predictors of severe CDAD.

**CONCLUSION:** Patients with a severe level of co-morbidity and high serum C-reactive protein levels at the time of diagnosis should receive particular attention.

<sup>1</sup>Data are given as median (range) or number (percentage).

data were incomplete, leaving 124 patients for further analysis. We recorded patient age, sex, nursing home residency, comorbidity to calculate the Charlson comorbidity score<sup>[22,23]</sup> previous and concomitant medication (systemic antibiotic treatment within 6 wk preceding diagnosis, continuation of the initial antibiotic therapy after diagnosis of CDAD, use of opioids or laxatives), predisposing medical or surgical procedures (endoscopy, percutaneous gastrostomy, nasogastric tubes, chemotherapy or radiotherapy) as well as vital signs (heart rate, blood pressure and body temperature) and laboratory parameters (white blood cells, C-reactive protein, sodium, potassium, creatinine) at the time of diagnosis. In addition, we recorded the length of hospital stay, the period until beginning therapy for CDAD after the onset of diarrhoea, whether a specific antibiotic therapy for CDAD was instituted or not and the 30-d mortality after initial diagnosis of CDAD.

Patients with more than three loose stools per day on more than two consecutive days with a positive stool test for *C. difficile* toxin were diagnosed as CDAD<sup>[16,24]</sup>. Hospital-acquired CDAD was assumed if the onset of diarrhoea was > 72 h after hospital admission or if there had been a hospital admission for CDAD within the previous 6 wk. Severe CDAD was defined as profuse diarrhoea associated with a positive shock index (heart rate bpm/systolic blood pressure mmHg > 1.5) at initial diagnosis<sup>[10]</sup>. All other patients were classified as non-severe CDAD.

Comparisons between the two groups of severe and

White blood cell count (G/L)	15.3 ± 9.9	21.6 ± 10.4	< 0.01
C-reactive protein (mg/L)	109 ± 79	223 ± 92	< 0.001
Creatinine (mg/L)	14 ± 13	24 ± 17	< 0.01
Sodium (mmol/L)	135 ± 5	133 ± 7	
Potassium (mmol/L)	3.6 ± 0.5	3.4 ± 0.5	

non-severe CDAD were performed by Student *t* test for normally distributed data, proportions were analysed by  $\chi^2$  or *F* test as appropriate. A two-sided error level of *P* < 0.05 was considered statistically significant. Variables significantly associated with severe CDAD in univariate analysis together with risk factors reported in the literature were entered into a multivariate analysis. Statistical analysis was computed with SPSS version 14.0 (SPSS, Inc., Chicago, IL, USA).

## RESULTS

### Demographics and results of initial evaluation

Patient characteristics are summarised in Table 1. Many patients had a comorbidity resulting in a median Charlson comorbidity score of 4. The majority of patients had hospital-acquired CDAD, 27 patients (22%) had severe CDAD, the overall 30-d mortality was 10% (13/124); all patients who died were >70 years.

### Analysis of possible risk factors

Univariate analysis for comparison of patients with non-severe (*n* = 97) and severe CDAD (*n* = 27) revealed that immunosuppressive therapy, laxative use, body temperature  $\geq 38^\circ\text{C}$ , length of hospital stay > 14 d, 30-d mortality, Charlson comorbidity score, white blood cell count, serum levels of C-reactive protein and creatinine were all significantly associated with severe CDAD (Table 2).

**Table 3 Multivariate analysis of possible risk factors for severe CDAD**

Variable (unit)	P	OR; 95% CI
Charlson's score (points; 1-point increments)	< 0.05	1.39; 1.06-1.83
Body temperature $\geq 38^{\circ}\text{C}$		1.15; 0.35-3.83
Immunosuppressive therapy		1.84; 0.45-7.49
Acid-suppressive therapy		1.28; 0.39-4.21
Opioid use		2.50; 0.80-7.84
Laxative use		2.66; 0.79-8.97
C-reactive protein (mg/L; 10 mg/L increments)	< 0.01	11.2; 10.3-12.1
White blood cell count (G/L; 1 G/L increments)		1.01; 0.96-1.06
Creatinine level (mg/L; 10 mg/L increments)		12.5; 9.2-16.8
Reduced Model		
Charlson's score (points; 1-point increments)	< 0.05	1.29; 1.02-1.61
C-reactive protein (mg/L; 10 mg/L increments)	< 0.001	1.15; 1.08-1.22

A borderline statistically significant association was found for comedication with acid-suppressive therapy or opioids. By contrast, severe CDAD was not associated with nursing home residency, presence of hospital-acquired CDAD, continuation of the initial antibiotic therapy after diagnosis or increasing age. Multiple logistic regression analysis confirmed a significant association of severe CDAD and Charlson comorbidity score (OR 1.29 for 1 point increment,  $P < 0.05$ ) and levels of serum C-reactive protein (OR 1.15 for 10 mg/L increment,  $P < 0.001$ ; Tables 2 and 3).

## DISCUSSION

The major findings in this retrospective analysis were a 22% rate of severe CDAD significantly associated with relatively high 30-d mortality (33% vs 4%,  $P < 0.001$ ) and a higher proportion of a hospital stay exceeding 14 d (74% vs 52%,  $P < 0.05$ ). In addition, comorbidity assessed by the Charlson comorbidity score ( $P < 0.05$ ) and serum C-reactive protein at the time of diagnosis ( $P < 0.001$ ) were identified as independent risk factors for severe CDAD in multivariate analysis.

The rate of severe CDAD and associated 30-d mortality in this study are relatively high. Infection with the recently emerging strain BI/NAP1 associated with severe courses of CDAD<sup>[2,8-11]</sup> is an unlikely explanation, since this strain had not been documented in Germany at the time of our retrospective analysis<sup>[25]</sup>. Therefore the most likely explanation are advanced age (median 76 years) and high comorbidity (median Charlson score of 4) of our cohort. The observed association of disease severity with comorbidity assessed by the Charlson comorbidity score is in line with reports on an association of severe CDAD with cognitive impairment<sup>[16]</sup>, number of chronically affected organ systems<sup>[26]</sup>, cardiac disease, malignancy, chronic obstructive pulmonary disease, pre-existing renal failure and other severe disease<sup>[27,28]</sup>. Our data support the hypothesis that comorbidity is an important risk factor for severe CDAD and the Charlson comorbidity

score, which includes most of these conditions, might be a useful tool to identify patients at particular risk for severe CDAD. We also identified serum levels of C-reactive protein as independently associated with severe CDAD. In fact, serum C-reactive protein was a far better predictor of severe CDAD than white blood cell count, which has been described by others<sup>[28,29]</sup>. Thus, at the median Charlson comorbidity score of our cohort (4 points) a C-reactive protein level of 250 mg/L at diagnosis predicted a higher than 50% probability for severe CDAD. Perhaps more sensitive markers of inflammation such as procalcitonin might be even more useful in the evaluation of disease severity.

Other known risk factors for CDAD<sup>[2,18,30]</sup> might also be relevant for severe CDAD. In line with these data we found comedication with laxatives, opioids and acid-suppressive therapy associated with severe CDAD in univariate analysis although these risk factors could not be confirmed in multivariate analysis. In contrast, a variety of other putative risk factors for severe CDAD could not be confirmed. Thus, we did not detect an association of severe CDAD with increased age<sup>[27,30]</sup>, which is probably due to the already advanced median age of our cohort. Moreover, prolonged antibiotic use *per se*, continuation of the antibiotic therapy after the diagnosis of CDAD, gastrointestinal procedures or surgery, which have all been reported as risk factors for *C. difficile* colonisation and CDAD<sup>[2,17]</sup> were not associated with severe disease in this study.

In conclusion, comorbidity and serum levels of serum C-reactive protein were identified as predictors of severe CDAD. Patients with strong comorbidity and high serum C-reactive protein levels at the time of diagnosis should be treated with particular attention.

## ACKNOWLEDGMENTS

## COMMENTS

### Background

*Clostridium difficile* associated diarrhoea (CDAD) is the most common cause of healthcare-associated diarrhoea. It results in a wide spectrum of disease severity ranging from asymptomatic carriage to life-threatening enterocolitis and death with associated health care costs.

### Research frontiers

A variety of studies has investigated risk factors for the development of CDAD. Thus, advanced age, severe comorbidity, hospitalisation, antibiotic exposure, immunosuppressive therapy as well as treatment with motility influencing or acid-suppressive drugs were identified as risk factors for CDAD. However, little is known about risk factors for associated with a severe course of CDAD in hospitalized patients.

### Innovations and breakthroughs

The major findings reported are a 22% rate of severe CDAD which was significantly associated with relatively high 30-d mortality and a higher proportion of a hospital stay exceeding 14 d. Moreover, comorbidity assessed by the Charlson comorbidity score and levels of serum C-reactive protein at the time of diagnosis were identified as independent risk factors for severe CDAD

in multivariate analysis.

### Applications

The major findings of this study should help to identify hospitalized patients with a particular risk for a severe course of CDAD. An early identification of patients at risk would allow a more timely intervention probably improving both morbidity and mortality.

### Peer review

The paper describes important risk factors for a severe course of CDAD in hospitalized patients which have a potential for everyday clinical practice. It's an interesting paper.

Efficacy of 6-mercaptopurine treatment after azathioprine hypersensitivity in inflammatory bowel disease. *World J Gastroenterol* 2008; 14(27): 4342-4346 Available from: URL: <http://www.wjnet.com/1007-9327/14/4342.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4342>

### Abstract

**AIM:** To investigate the efficacy of 6-mercaptopurine (6-MP) in cases of azathioprine (AZA) hypersensitivity in patients with inflammatory bowel disease.

**METHODS:** Twenty nine previously confirmed Crohn's disease (CD) ( $n = 14$ ) and ulcerative colitis (UC) ( $n = 15$ ) patients with a known previous (AZA) hypersensitivity reaction were studied prospectively. The 6-MP doses were gradually increased from 0.5 up to 1.0-1.5 mg/kg per day. Clinical activity indices (CDAI/CAI), laboratory variables and daily doses of oral 5-ASA, corticosteroids, and 6-MP were assessed before and in the first, sixth and twelfth months of treatment.

**RESULTS:** In 9 patients, 6-MP was withdrawn in the first 2 wk due to an early hypersensitivity reaction. Medication was ineffective within 6 mo in 6 CD patients, and myelotoxic reaction was observed in two. Data were evaluated at the end of the sixth month in 12 (8 UC, 4 CD) patients, and after the first year in 9 (6 UC, 3 CD) patients. CDAI decreased transiently at the end of the sixth month, but no significant changes were observed in the CDAI or the CAI values at the end of the year. Leukocyte counts ( $P = 0.01$ ), CRP ( $P = 0.02$ ), and serum iron ( $P = 0.05$ ) values indicated decreased inflammatory reactions, especially in the UC patients at the end of the year, making the possibility to taper oral steroid doses.

**CONCLUSION:** About one-third of the previously AZA-intolerant patients showed adverse effects on taking 6MP. In our series, 20 patients tolerated 6MP, but it was ineffective in 8 CD cases, and valuable mainly in ulcerative colitis patients.

### INTRODUCTION

5-aminosalicylate is usually ineffective in the maintenance treatment of steroid induced remission in idiopathic inflammatory bowel (IBD) diseases, i.e. ulcerative colitis (UC) and Crohn's disease (CD)<sup>[1]</sup>. In the vast majority of cases immunosuppressive treatment is necessary to maintain the remission. Azathioprine (AZA) has been advised in the treatment of UC and CD since the middle of 1960's<sup>[2]</sup>. It is worth starting if the patient is corticosteroid resistant (the effective dose does not lead to remission) or dependent (discontinuation of the corticosteroid causes relapse)<sup>[3]</sup>. Azathioprine and its first metabolite 6-mercaptopurine are effective immunomodulators, but contrary to the corticosteroids, purine analogues have a late onset of action<sup>[4]</sup>. Their maximum effect can only be expected after 3-6 mo<sup>[5]</sup>. Azathioprine is offered as first choice, but it can cause early hypersensitivity reaction (fever), or gastrointestinal side effects (nausea, vomiting, and diarrhoea) in the first two weeks in 5%-10% of patients. In these cases, 6-mercaptopurine (6-MP) may be effective without side effects<sup>[6]</sup>. However, there are few data about the clinical efficacy of changing the AZA to 6-MP therapy in cases having hypersensitivity reactions after the first AZA medication.

### MATERIALS AND METHODS

Between 2002 and 2005, 29 IBD patients (15 women and 14 men) were treated with 6-mercaptopurine due to azathioprine hypersensitivity. The drug Purinethol, 50 mg (Laboratoire GlaxoSmithKline) was approved by the National Institute of Pharmacy. The mean age of the

**Table 1** The number of IBD patients in the three groups, according to extents, fistulas and surgeries

Disease	No. of patients	A	B	C	D	E	F
Group1 UC	7	1	2	4	-	-	-

Group2 CD	8	3	2	2	1	8	16
Group3 UC	8	1	-	7			1
Group3 CD	4	-	3	1	-	4	4
	29	4	9	14	1	12	21

UC-A: Distal; UC-B: Left sided; UC-C: Pancolitis; CD-A: Small bowel only; CD-B: Colon only; CD-C: Small bowel + colon, CD-D: Upper GI + small bowel + colon; CD-E: Number of fistulas; CD-F: Number of surgeries.

patient's was 40.1 years (range 19-66 years), and mean time to 6-MP treatment from the IBD diagnosis was 5.4 years (range 0.1-16.4 years). Fifteen patients had UC and 14 patients had CD. Table 1 contains the number of IBD patients in the 3 groups, according to extents, fistulas and surgeries. 6-MP test dose (50 mg/d for 7-10 d) was administered first. The therapy had to be discontinued in the first two weeks because of the same or similar hypersensitivity reactions as taking azathioprine during the initial doses in 9/29 patients (7/9 UC, 2/9 CD). Among the 9 patients, 4 had hypersensitivity reactions, including fever, and 5 were intolerant due to GI side-effects. During the very short interval (7-10 d) between the AZA start and the appearance of adverse events, we did not observe side-effects, such as leucopenia, abnormal LFTs or pancreatitis. Medication had to be suspended in 8/20 patients during the first 6 mo because it was ineffective. Decreasing the CDAI score not more than 70, and at least 3 score values in the CAI, was considered to be a treatment failure. All of them were CD patients; their treatment was continued by methotrexate and/or infliximab, if required.

Twelve patients tolerated 6-mercaptopurine without side-effects for more than six months with clinical efficiency. Four of 12 had Crohn's disease, 8/12 had UC. During the study 9 patients (6 UC, 3 CD) were treated for more than a year. The initial dose of 6-MP was 50 mg/d and it was increased, if possible, up to 1.5 mg/kg per day. The clinical activity, 6-MP and corticosteroid (prednisolone, methylprednisolone, separately) as well as the laboratory variables of acute inflammatory process were recorded. The medication was initiated at the first visit, and follow-up visits after the first, third, and sixth, twelfth months after the initial therapy. Crohn's Disease Activity Index (CDAI) and Clinical Activity Index of Ulcerative Colitis (CAI) were scored and calculated at each visit. According to the calculated values, the actual activity was grouped as inactive (1), mild (2), moderate (3) or severe (4). The following blood chemistry variables were determined, erythrocyte sedimentation rate, hematocrit, white cell and platelet counts, blood iron level, CRP, and fibrinogen.

STATA V8 program was used for statistical analysis. The repeated measurements of ANOVA and correlation analysis were used. Associations of variables between

activity groups were analyzed by one way method of ANOVA.

## RESULTS

The baseline means  $\pm$  SD of CDAI/CAI, CRP, ESR, WBC, platelets, and the changes over time demonstrated decreased inflammatory reactions (Table 2). Relationships between time (at six months and one year), activity, and laboratory variables are presented in Table 3. Results of the analysis corresponded to 12 patients at 6 mo (8 UC, 4 CD), and 9 mo (6 UC, 3 CD) at the end of the first year (repeated measurement of ANOVA). CDAI decreased significantly only at the end of the sixth month in 4 of the 12 patients in whom 6-MP treatment was successful, but a similar decrease could not be demonstrated in the CAI of UC. At the end of the year, such an alteration could not be detected in any of the activity indices. CRP, referring to the severity of the inflammation, decreased and the iron level increased significantly at the end of the year (Table 3). Correlation between the calculated activity index numeric values (CDAI, CAI) and laboratory variables (correlation analysis) is presented in Table 4. The laboratory variables associated with the numeric values of the activity revealed a decrease in the inflammatory reaction in UC, but not in CD, due to the small number of CD cases. Besides the amelioration of the inflammatory reaction, the direct suppressive effect on the bone marrow may also be associated with reductions in the numbers of leukocytes and platelets. Treatment had to be discontinued temporarily in 1 case because of leukopenia at the end of the year. In another case, a significant bone marrow depression developed, necessitating surgical intervention (ileal-pouch anal anastomosis - IPAA) after drug cessation. Hepatotoxic side-effects and pancreatitis were not observed during the year. Table 5 shows the correlation between the activity groups - inactive (1), mild (2), moderate (3), severe (4) - and the values of laboratory variables in UC and CD patients (one way ANOVA). The laboratory variables correlated substantially better with the group classification than with the activity index numeric values.

The average doses of 6-MP and corticosteroids administered at the time of the visits is presented as mg/kg (Figure 1). Prednisolone treatment could be omitted and the dose of methylprednisolone could be tapered to one third at the end of the year. At the end of the first year 5/9 patients (3 UC, and 2 CD) became steroid free.

## DISCUSSION

Systemic corticosteroid treatment is often needed in relapses of idiopathic inflammatory bowel diseases (UC, CD)<sup>[7]</sup>. The dose depends on the activity of the disease with severe cases treated intravenously<sup>[8]</sup>. If the patient responds to the intravenous regime, treatment should be switched to oral administration, and oral doses should be tapered gradually and finally terminated. If

the patient proves to be steroid resistant, or dependent, immunosuppressive treatment is suggested<sup>[9]</sup>. Azathioprine is recommended first, where it is the most frequently used immunosuppressive drug for IBD<sup>[10]</sup>. An oral dose of 1.5-2.5 mg/kg per day is usually effective, but requires monitoring<sup>[11]</sup>. Therapeutic effects and side-effects of AZA show great variability among the patients due to the various concentrations of the therapeutic and toxic metabolites<sup>[12]</sup>. The application is hampered in 9%-25% of the patients due to its toxic effects. Hypersensitivity reactions (fever), or gastrointestinal side effects (nausea, diarrhea), can occur during the first weeks of the treatment<sup>[13]</sup>. According to McGovern *et al*, imidazole that is cleaved off the AZA molecule can be responsible for the development of this process<sup>[14]</sup>. AZA is a pro-drug that is converted to 6-MP through a non-enzymatic step. Further metabolism of 6-MP depends on three competing enzyme pathways. Hepatotoxic 6-methylmercaptopurine (6-MMP) is produced by thiopurine methyltransferase (TPMT), a key enzyme of toxic and therapeutic metabolites. Measurement of its activity helps determine individual doses<sup>[14,15]</sup>. Catabolism, *via* xanthine oxidase (XO), forms inactive 6-thiouric acid which is eliminated through the urine. Metabolism, *via* hypoxanthin-guanine phosphoribosyl

**Figure 1 Changes of the 6-MP and oral steroid mean doses.**

transferase (HPRT), leads to the formation of cytoactive 6-thioguanine nucleotide (6-TGN) that binds to the DNA and RNA, and is the active molecule responsible for the late side-effects in a dose-dependent manner. The proportion of these three enzymes determines the effective 6-TGN level. In case of low TPMT activity (due to enzyme polymorphisms) metabolism shifts to the production of 6-TGN, where high concentrations are associated with efficacy, but above a certain level ( $> 450$  pmol/108 erythrocyte), 6-TGN has a myelotoxic effects<sup>[16]</sup>. Bone marrow depression that is a late toxic reaction usually occurs in the first three months<sup>[17]</sup>. Other mechanisms participate in the development of this process as well since this side-effect is noticed with normal and high TPMT activity. During the occurrence of immunosuppressor activity in IBD, a decrease in the number of lamina propria plasma cells and altered function of the lymphocytes and killer cells is detected. According to previous studies that need further

confirmation, the therapeutic effect of AZA is explained by its apoptosis inducing property that is independent from 6-TGN. Tiede *et al* showed that azathioprine and its 6-thioGTP metabolite alters apoptosis of T cells<sup>[18]</sup>. The activity of certain genes in the cells is repressed by the metabolite which induces apoptosis in a mitochondrial manner.

In the view of the clinical efficacy, results achieved by 6-MP treatment can be compared with azathioprine. Considering bioequivalence, 6-MP shows the same efficacy as half (0.75-1.5 mg/kg per day) of the daily dose of AZA (1.5-2.5 mg/kg per day)<sup>[19]</sup>. There are few data about the clinical use of 6-MP<sup>[20]</sup> and only some investigated treatment results of 6-MP in AZA-intolerant patients suffering from IBD. Boulton-Jones *et al* reported a cohort of 19 patients who had failed AZA therapy. Ten had CD and 9 UC<sup>[21]</sup>. The AZA dose prior to discontinuation ranged from 50 to 150 mg. Eleven of 19 patients were able to tolerate 6-MP in a dose ranging from 50 to 100 mg (median 100 mg). Two of 8 patients developed fever; other adverse events were vomiting, leucopenia, skin rash, headache, and abdominal pain. The treatment could be continued in 6 patients from the 11 in the study performed by Bowen *et al* and were successful only in 4 cases<sup>[22]</sup>. McGovern *et al* achieved steroid independent remission in 15 of 29 patients<sup>[23]</sup>. Similar results were achieved by Doménech *et al*<sup>[24]</sup>.

In our CD patients, favourable effects were attained only in 4/14 cases, at the end of the first 6 mo with 6-MP (average: 0.75 mg/kg per day). Eight CD patients were withdrawn due to ineffective therapy within the same time. Later, at the end of the first year, the benefit of the therapy was lost in all patients. In these cases, higher doses (more than 1.5 mg/kg per day) might increase the response and perhaps the number of adverse events<sup>[25]</sup>. Decreased inflammatory reactions were more significant in UC. The efficacy of the drug was indicated by the improvement of biological parameters associated with inflammation, which permitted a gradual reduction in the steroid. It is worth mentioning that clinical activity indexes (CDAI and CAI) were less sensitive than the laboratory variables at presenting decreased inflammation<sup>[26]</sup>. The correlation between activity groups and the laboratory variables showed substantially better statistical association. Considering the efficacy in case of our patients without 6-MP intolerance, it should be mentioned that more significant improvement could be achieved by using higher doses (mainly in CD). Measurement of the 6-TGN and 6-MMP metabolites and TPMT activity is recommended for the safe dosage of thiopurine analogues, and to avoid the development of late toxic effects, although none of these parameters ensure total safety<sup>[27]</sup>. In patients with early AZA intolerance treated with 6-MP thereafter, our results showed wide individual variation of 6-MP doses and responses. Patients on effective doses may develop adverse reactions at any time; therefore, blood counts and liver function tests have to be checked in every second week at the beginning, then every month, and later on in every third month. Because of the

potential for life-threatening side-effects, the drug is recommended in cooperating patients only<sup>[28]</sup>.

AZA and 6-MP have been accepted as maintenance therapies in IBD, but controversy exists regarding optimal dosing and benefits of therapeutic drug monitoring of metabolites<sup>[29]</sup>. The AZA baseline dose (1.7 mg/kg per day) proved to be effective in maintaining remission in a French cohort of CD patients, which was lower than the dose used in clinical trials (2.5 mg/kg per day). Nielsen *et al* in their review in the year 2001, suggested a  $0.25 \pm 0.5$  mg/kg daily initial (AZA equivalent) dose for the 6-MP, increasing to  $1.0 \pm 1.5$  mg/kg daily<sup>[30]</sup>. Su and Lichtenstein, three years later, advocated "the optimal dose for the treatment of active CD is generally considered 2.5 mg/kg per day for azathioprine and 1.5 mg/kg per day for 6-MP"<sup>[17]</sup>. In our AZA intolerant patients, the initial dose was 50 mg/d with a stepwise increase after the third and sixth month with 25 or 50 mg/d up to 1.5 mg/kg per day according to the tolerability of the patients. The low dose and the step up policy may play a role in the poor therapeutic response, especially in very active Crohn disease patients in the second group.

It is worth starting with 6-MP therapy in patients with hypersensitivity reactions to AZA. One third of the patients will be intolerant, and another third will not gain any benefit, especially those who had serious active CD. However, patients with mild or moderate UC/CD might have the advantage of being able to tolerate the daily dose of more than 1 mg/kg.

## INTRODUCTION

Gastric adenocarcinoma (GC) is the second most common cause of cancer-related mortality and a major public health problem worldwide<sup>[1]</sup>. GC has a distinct geographical distribution with the highest incidence rates in Asia and South America and the lowest incidence in western countries<sup>[1-3]</sup>.

The Epstein-Barr virus (EBV) is a ubiquitous virus, with carcinogenic properties, which has been linked to the development of several malignancies including nasopharyngeal carcinoma and Burkitt's lymphoma<sup>[4]</sup>. It has been estimated that over 90% of the population worldwide has been exposed to EBV, although, not all infected individuals develop EBV-related disease<sup>[4]</sup>. After infection, EBV remains in a latent state in B-cell lymphocytes, at a rate of 1 in 10<sup>6</sup> circulating cells. The reason why it is difficult to identify EBV is perhaps due to the fact that expression of only a small number of viral proteins allows the maintenance and control of cell proliferation<sup>[5,6]</sup>.

EBV is a common co-infection in several diseases and some authors have suggested that it may represent a late event in the GC carcinogenesis, after *H pylori* infection<sup>[7]</sup>. However, there is lack of specific information implicating EBV in the pathogenesis of GC. The worldwide occurrence of EBV positive GC is estimated at >50 000 cases/year, although, it remains unclear whether the presence of EBV is the cause or a consequence of GC<sup>[8]</sup>.

## Abstract

**AIM:** To examine the possible role of the Epstein-Barr Virus (EBV) in the development of gastric adenocarcinoma (GC). It is unclear whether EBV is involved in GC development or is a consequence of gastric inflammation secondary to immunosuppressive treatments.

**METHODS:** A systematic review was carried out of all published observational studies on the temporal association between EBV and GC, with a view to determine a causal relationship.

**RESULTS:** The present study showed that the worldwide crude prevalence of EBV in gastric adenocarcinoma was 8.29%. The prevalence varied from 7.08% for intestinal type and 9.82% for diffuse type of GC. It was observed that Western and Central Asian countries had a significantly higher frequency of EBV positive cases compared to South-Eastern countries. America had the highest EBV-GC prevalence whereas Europe had the lowest.

**CONCLUSION:** The present review has demonstrated a high prevalence of EBV in gastric adenocarcinoma. However, studies designed to assess a temporal relationship and histological association using sensitive techniques should be carried out to establish the role of EBV in GC carcinogenesis.

Therefore, we carried out a systematic analysis of all observational studies on EBV and GC with a view to assess a possible temporal and statistical association.

## MATERIAL AND METHODS

### Articles search

All studies included in the present review ( $n = 494$ ) were selected from the Medline database using the following subject headings: (1) EBV or Epstein-Barr or “EBV-associated membrane antigen, Epstein-Barr virus” [Substance Name] or “Epstein-Barr Virus Infections” [MeSH] or “Epstein-Barr viral capsid antigen” [Substance Name] or “Epstein-Barr virus early antigen” [Substance Name]; (2) virus OR (“Viruses” [MeSH] or “Virus Activation” [MeSH] or “DNA Tumor Viruses” [MeSH] or “Tumor Virus Infections” [MeSH]); (3) gastric or stomach or (“Stomach” [MeSH] or “Stomach Diseases” [MeSH]); (4) cancer or neoplasms OR “Neoplasms” [MeSH]. Furthermore, we also searched the reference list of all published articles.

### Inclusion/exclusion criteria

All original published studies in English, French, Spanish and Portuguese on EBV infection and gastric carcinoma were included in the analysis ( $n = 494$ ). Studies were excluded for the following reasons (Figure 1): studies referring to other types of cancer ( $n = 140$ ); use of languages such as Russian, Chinese, Japanese or Italian ( $n = 30$ ); articles other than those containing research data, such as reviews, letters to the editor and case-reports ( $n = 155$ ); *in vitro* and *in vivo* experiments ( $n = 81$ ); and studies referring to histological types other than gastric adenocarcinoma ( $n = 44$ ).

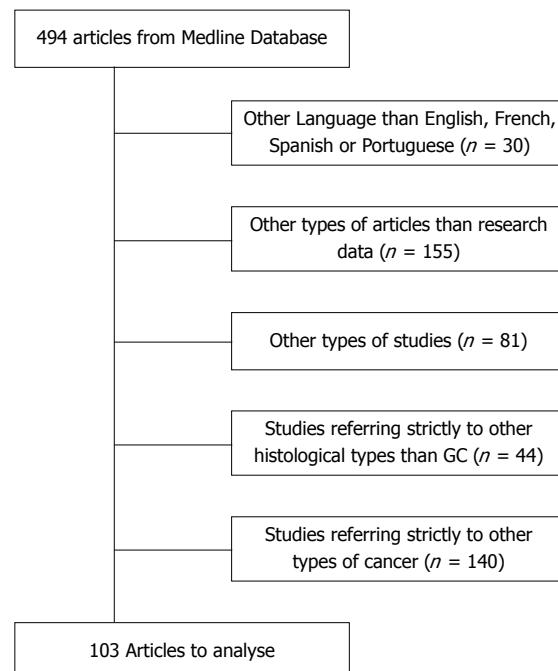

### Data extraction and statistical analysis

The studies included in the present analysis ( $n = 103$ ) were reviewed by all the authors, in order to obtain the necessary information, such as: design of study (case-control or retrospective), source of tissue sample (formalin embedded tissues, fresh tissues or peripheral blood samples), study population, geographical distribution, histological type of the lesion and EBV diagnostic methodology (*in situ* hybridization, Polymerase Chain Reaction, immunohistochemistry and PCR followed by Enzyme Linked Immunoassay). Pooled frequencies were estimated by country, region and continent and were adjusted for the type of cancer, sample source and EBV diagnostic methodology.

## RESULTS

### General observations

Our study included a total of 103 published articles which analysed the frequency of EBV in GC in 21 different countries: 9 from Asia (China, India, Japan, Taiwan, Korea, Papua New Guinea, Pakistan, Kazakhstan and Turkey), 7 from Europe (UK, France, Germany, Italy, Netherlands, Poland and Russia) and

**Figure 1** Application of Inclusion/exclusion criteria.

5 from America (USA, Mexico, Brazil, Chile and Colombia).

### Study design

Our study material consisted of 96 retrospective studies, 6 prospective studies and one case-control study.

### Sample source

The study samples comprised of the following: 92 studies were conducted on formalin embedded tissues, 10 on fresh tissues and one on peripheral blood samples.

### EBV diagnostic methodology

The most common methodology used for the diagnosis of EBV was *In Situ* Hybridization (ISH) for EBER1 ( $n = 88$ ), followed by Polymerase Chain Reaction (PCR) for the BamHI-W region of EBV ( $n = 6$ ), PCR for EBNA1 ( $n = 3$ ), immuno-histochemistry for LMP1 ( $n = 2$ ), PCR followed by Enzyme Immunoassay (PCR-EIA) for BamHI-W, and ISH for BamHI-W in one study each. In two studies, it was not possible to determine the methodology used for EBV detection.

### Statistical analysis

A total of 114 studies, comprising of 33471 cases were evaluated. The great majority of studies were conducted in Asian countries ( $n = 77$ ) with a total of 29076 individuals, followed by Europe ( $n = 18$ ) with 2296 individuals and America ( $n = 19$ ) with 2099 individuals (Table 1). With respect to the diffuse type of GC, a total of 5846 cases were analyzed, of which 4862 individuals were from Asian countries, 173 from Europe and 811 from America (Table 1). By contrast, intestinal type of GC was reported in 7786 cases, including 6367 individuals from Asia, 338 from Europe and 1082 from

Distribution of EBV association with Gastric Adenocarcinoma.

America (Table 1).

The largest sample size for gastric adenocarcinoma was obtained from South-east Asia (28760 cases), followed by Central Europe (1938 cases) and South America (927 cases). With respect to the intestinal and diffuse types of GC, the largest sample was from South-east Asia (6290 and 4665 cases respectively), followed by South America (503 and 381 studies respectively) and Central Europe (325 and 154 studies, respectively).

Table 1 shows the crude and adjusted frequency of positive EBV results in different countries considering the world as a discrimination factor. The worldwide crude EBV positive prevalence was 8.29% for gastric adenocarcinoma, with 7.08% for intestinal type and 9.82% for diffuse type. The corresponding adjusted prevalence was estimated as 9.67%, 5.88% and 12.1%, respectively. The adjustment of EBV positive prevalence resulted in minor changes from the crude estimates. America registered the highest adjusted EBV positive prevalence for both gastric adenocarcinomas and the diffuse type of GC (11.3% and 15.3%, respectively). On the other hand, Europe had the lowest adjusted EBV

positive prevalence for gastric adenocarcinoma, and intestinal and diffuse types of GC (7.96%, 2.94%, and 7.83%, respectively).

## DISCUSSION

As a Group I carcinogenic agent, EBV has been intensively studied over the past 40 years<sup>[9]</sup>. It has been demonstrated consistently that EBV has an association with nearly 100% of gastric lymphoepithelioma-like carcinomas<sup>[10-12]</sup>, which are believed to have similar pathogenic mechanism as nasopharyngeal carcinoma<sup>[7]</sup>.

Despite the presence of several hundred published studies demonstrating an association between EBV and GC, the pathogenic role of EBV in gastric carcinogenesis remains to be established<sup>[7]</sup>. Nevertheless, there is strong evidence to directly implicate EBV in GC development: presence of EBV in all cancer cells detected by *in situ* hybridization of EBER1, but not in the surrounding epithelial cells<sup>[13]</sup>; monoclonality of the viruses in neoplastic cells as judged by the analysis of single terminal repeats of EBV DNA<sup>[14]</sup>; and elevation of immunoglobulin A and B antibodies against viral

capsid antigen several months before the clinical presentation of the disease<sup>[15]</sup>.

The pathogenic mechanism of EBV-GC is not well understood. EBV is transmitted through the saliva, and primary infection occurs at the oropharyngeal mucosa, with the involvement of the Waldeyer's ring followed by infection of naive B-cells as they circulate near the infected cells<sup>[16]</sup>. After infection, EBV establishes a persistent state in the B-cells, and is maintained *ad eternum*. From time to time, the infected B-cells become activated as a result of immune suppression of the host, and the infected cells are able to enter other tissues<sup>[16]</sup>. Since the main receptor (CD21/CR2, the receptor for the C3d component of complement) for EBV is normally absent from gastric epithelial cells<sup>[17,18]</sup>, EBV infection has been suggested to be accomplished by the binding of EBV particles with IgA antibodies which are then engaged by gastric epithelial cells<sup>[7,19]</sup>. Once inside the gastric cells, EBV activates its latency state by expressing latency proteins which induce cell proliferation and viral maintenance. Recent studies have shown that in gastric carcinoma, EBV expresses a different pattern of proteins than those seen in Burkitt's lymphoma and nasopharyngeal carcinoma, suggesting a different oncogenic mechanism in gastric carcinoma<sup>[20,21]</sup>.

The development of gastric carcinoma is a multistep event, progressing from normal to preneoplastic lesions to highly malignant tumours<sup>[20]</sup>. Despite strong evidence implicating *H pylori* as the main etiological factor for GC development, several other environmental and genetic co-factors have been reported<sup>[22]</sup>. At present, it is generally accepted that EBV infects gastric cells depending on a permissive environment and a genetically susceptible host, upon an inflammatory state of gastric epithelium, which is in agreement with the findings that EBV-GC are monoclonal tumours<sup>[22]</sup>. Moreover, there are clinico-pathological features that are seen consistently in EBV-GC, such as: higher prevalence in males, with no impact on stromal invasion or survival<sup>[11,12,23]</sup>; tumour histology varying from moderately differentiated tubular to poorly differentiated solid type<sup>[17,24-29]</sup>; and a predisposition for the upper two-thirds of the stomach.

By performing a systematic review of all published studies worldwide, we have attempted to analyze the role of EBV in GC development, by estimating and comparing the worldwide occurrence of EBV-GC and by elucidating their temporal relationship and statistical association.

Our study included 103 published reports from 21 different countries distributed over 3 continents (Europe, Asia and America). Gastric adenocarcinoma is the second most common cause of cancer-related mortality worldwide and is the 14th overall cause of death<sup>[2]</sup>. Worldwide, there are widespread differences in gastric cancer rates, with the highest rates seen in Japan, China and South America, and much lower rates in Western Europe and the United States<sup>[2,22]</sup>. As expected, the great majority of studies were conducted in Asian countries, with 80 general reports on EBV and gastric adenocarcinoma, 20 on diffuse type and 21 on intestinal

type of GC. The crude frequency of EBV positive cases in Asian countries was 8.07%, 9.13% and 6.73% for GC, diffuse type and intestinal type, respectively. Moreover, western and central Asian countries had significantly higher frequency of EBV positive cases than south-eastern countries.

Despite these studies, the exact association between EBV and GC remains to be established. Moreover, recent data reinforces the importance of the differences in the association of EBV with gastric carcinoma among different ethnic communities<sup>[30,31]</sup>, with respect to temporal relationship, histological association and the application of sensitive methodologies for EBV diagnosis in GC. Nevertheless, the present review emphasizes the need for further studies designed to elucidate EBV-GC carcinogenesis model.

## COMMENTS

### Background

Gastric adenocarcinoma is a major public health problem worldwide. Epstein-Barr Virus (EBV) infects over 90% of population worldwide and has been linked as a late event in the gastric carcinogenesis process, after *H pylori* infection.

### Research frontiers

Despite evidence to suggest the existence of biological plausibility, there is lack of information about the role of EBV in gastric cancer, either as a risk factor for the development of cancer or as a predictive marker for major outcomes after medical therapy.

### Innovations and breakthroughs

A systematic review was conducted on 103 studies from 21 different countries representing 33471 cases of cancer. Most of the studies ( $n = 96$ ) were retrospective and used formalin embedded tissues ( $n = 92$ ) and used In Situ Hybridization (ISH) for EBER1. The adjusted prevalence of EBV was 9.67%, 5.88% and 12.1%, for gastric adenocarcinoma, intestinal type and diffuse type, respectively. America registered the highest adjusted EBV prevalence (11.3% and 15.3%, respectively) for both gastric adenocarcinomas and diffuse type. By contrast, Europe had the lowest adjusted EBV prevalence (7.96%, 2.94%, and 7.83%, respectively), for gastric adenocarcinoma, intestinal and diffuse type.

### Applications

Differences in EBV prevalence may provide further insight into research on gastric carcinogenesis and the natural history of this disease.

### Peer review

The present study is relevant as it emphasizes the lack of prospective studies and the absence of methodologies that can discriminate past from current viral infection. The focus of research and clinical application may become relevant in future studies.

## ACKNOWLEDGMENTS

The authors would like to thank Professor Joseph S. Pagano, from the Comprehensive Cancer Centre of the University of North Carolina USA, for his constructive criticisms on an earlier draft of this manuscript. We would also like to acknowledge the Portuguese League Against Cancer (*Liga Portuguesa Contra o Cancro-Nucleo Regional do Norte*) and Portuguese Ministry of Health Research Grant 2005.

## Abstract

**AIM:** To study the influence of tumor removal on the serum level of IgG antibodies to tumor-associated Thomsen-Friedenreich (TF), Tn carbohydrate epitopes and xenogeneic  $\alpha$ Gal, and to elucidate on the change of the level during the follow-up as well as its association with the stage and morphology of the tumor and the values of blood parameters in gastrointestinal cancer.

**METHODS:** Sixty patients with gastric cancer and 34 patients with colorectal cancer in stages I -IV without distant metastases were subjected to follow-up. The level of antibodies in serum was determined by the enzyme-linked immunosorbent assay (ELISA) using synthetic polyacrylamide (PAA) glycoconjugates. Biochemical and haematological analyses were performed using automated equipment.

**RESULTS:** In gastrointestinal cancer, the TF antibody level was found to have elevated significantly after the removal of G3 tumors as compared with the preoperative level ( $\mu = 278.5, P < 0.05$ ). After surgery, the TF and Tn antibody level was elevated in the majority of gastric cancer patients (sign test, 20 vs 8,  $P < 0.05$ , and 21 vs 8,  $P < 0.05$ , respectively). In gastrointestinal cancer, the elevated postoperative level of TF, Tn and  $\alpha$ Gal antibodies was noted in most patients with G3 tumors (sign test, 22 vs 5,  $P < 0.01$ ; 19 vs 6,  $P < 0.05$ ; 24 vs 8,

$P < 0.01$ , respectively), but the elevation was not significant in patients with G1 + G2 resected tumors. The postoperative follow-up showed that the percentage of patients with G3 resected tumors of the digestive tract, who had a mean level of anti-TF IgG above the cut-off value (1.53), was significantly higher than that of patients with G1 + G2 resected tumors ( $\chi^2 = 3.89$ , all patients;  $\chi^2 = 5.34$ , patients without regional lymph node metastases;  $P < 0.05$ ). The percentage of patients with a tumor in stage I, whose mean anti-TF IgG level remained above the cut-off value (1.26), was significantly higher than that of patients with the cancer in stages III-IV ( $\chi^2 = 4.71$ , gastric cancer;  $\chi^2 = 4.11$ , gastrointestinal cancer;  $P < 0.05$ ). The correlation was observed to exist between the level of anti-TF IgG and the count of lymphocytes ( $r = 0.517, P < 0.01$ ), as well as between the level of anti-Tn IgG and that of serum CA 19-9 ( $r = 0.481, P < 0.05$ ). No positive delayed-type hypersensitivity reaction in skin test challenges with TF-PAA in any of the fifteen patients, including those with a high level of anti-TF IgG, was observed.

**CONCLUSION:** The surgical operation raises the level of anti-carbohydrate IgG in most patients, especially in those with the G3 tumor of the gastrointestinal tract. The follow-up demonstrates that after surgery the low preoperative level of TF antibodies may be considerably increased in patients with the carcinoma in its early stage but remains low in its terminal stages. The stage-and morphology-dependent immunosuppression affects the TF-antibody response and may be one of the reasons for unresponsiveness to the immunization with TF-antigens.

## INTRODUCTION

Cancer immune surveillance is considered to be important in the anti-tumor protection of the host. However, immunity not only protects the host from cancer but also may promote tumor growth, creating an immuno-resistant cancer cell phenotype ("cancer immunoediting"). In the advanced stages of cancer, tumor escapes the immune control under the immunosuppressive conditions<sup>[1]</sup>. The removal of the tumor appears to disturb the immunoediting process and may reverse immunosuppression. The suppressed antigen-specific antibody responses in tumor-bearing mice may be reversed after the surgical removal of the primary tumor even in the existence of a disseminated metastatic disease<sup>[2]</sup>.

Mucin-type tumor-associated carbohydrate antigens (TACA), the Thomsen-Friedenreich (TF) antigen and its precursor, Tn, are frequently expressed in malignant tumor cells. They deserve to be studied as targets for active specific immunotherapy<sup>[3]</sup>. Human blood serum contains natural TF- and Tn antibodies whose subpopulations may bind the corresponding antigens on human tumor cell lines<sup>[3-5]</sup>. It is not yet clear which role antibodies play in the natural anti-cancer defense system. The level of TF- and Tn antibodies was significantly decreased in the serum of primary (not operated) patients with cancer, including patients with the disease in its early stage<sup>[6-9]</sup>. Furthermore, the low level of anti-TF IgG was associated with a lower differentiated carcinoma and advanced gastric cancer that suggests an implication for antibodies in the progression and pathology of the tumor<sup>[10]</sup>. The high level of anti-TF IgG in the serum of primary patients with gastric cancer is closely associated with survival<sup>[11]</sup>. The dynamic changes of the level of TF- and Tn-antibodies in the serum of patients with cancer and its association with survival have been insufficiently studied. Investigations have mainly focused on clinical trials of antigen-specific immunotherapy<sup>[12,13]</sup>. The authors have undertaken a long-term follow-up of cancer patients to determine changes in the postoperative level of TF- and Tn antibodies, as well as to elucidate the association of this level with the progression of cancer, and survival. For comparison, the level of xenoreactive antibodies to the  $\alpha$ Gal epitope was determined. In humans, the  $\alpha$ Gal epitope is absent because the  $\alpha$ 1-3 galactosyltransferase gene was inactivated in evolution, but approximately 1% of immunoglobulins have an anti- $\alpha$ Gal specificity<sup>[14]</sup>.

In this work, the influence of the surgical removal of the tumor on the level of antibodies and its change during the follow-up was investigated. The association of the

level of antibodies with the stage and morphology of the tumor, as well as values of blood parameters was studied. Also, the delayed-type hypersensitivity reaction to TF-PAA conjugates in skin testing was examined.

## MATERIALS AND METHODS

### Subjects

The investigation was carried out in accordance with the ICH GCP Standards and approved by Tallinn Medical Research Ethics Committee. Informed consent was obtained from subjects under study. The follow-up study was undertaken of patients with a verified diagnosis of gastric ( $n = 60$ ) and colorectal cancer ( $n = 34$ ) of stages I-IV by using the pTNM system<sup>[15]</sup>. Patients with distant metastases of the cancer or those who received chemo- and X-ray therapy were not subjected to study. The median age of the patients was 60 years (the age ranging from 30 to 75 years). The venous blood samples were taken before and after surgery at intervals from three to sixteen months, with a further follow-up during two to twelve years. The extended D2 gastrectomy with lymphadenectomy or, additionally, with the splenectomy in gastric cancer, as well as the resection of local lesions of colorectal cancer was performed. In advanced cancer regional lymph node metastases were also removed. In some patients concomitant diseases were documented. Breast cancer was diagnosed in three, benign diseases, in five, anaemia and diabetes mellitus, in two cases. The other sporadic manifestations were Parkinson's disease, carcinoma of the uterus and chronic hepatitis.

### Glycoconjugates

Synthetic polyacrylamide (PAA) glycoconjugates with a single reiterated epitope were used in comparative immunoassays<sup>[16]</sup>. The homogeneity of PAA-conjugates enables a precise detection of epitope-specific antibodies. The following PAA-conjugates were used: the TF disaccharide, Gal $\beta$ 1-3GalNAc $\alpha$ ; T $\beta$  $\beta$ , Gal $\beta$ 1-3GalNAc $\beta$ ; Tn, GalNAc $\alpha$ ;  $\alpha$ Gal or a B-blood group disaccharide, Gal $\alpha$ 1-3Gal $\beta$ ; SiaLe<sup>a</sup> (CA 19-9 tetrasaccharide), Neu5Ac $\alpha$ 2-3Gal $\beta$ 1-3 (Fuc $\alpha$ 1-4) GlcNAc $\beta$ . Tris-PAA, tris (hydroxymethyl) aminomethane-PAA, was used as a negative control because of its low background and good reproducibility in immunoassay<sup>[8]</sup>. The TF-PAA as a substituted PAA containing 0.1 mol of TF per 1 mol of PAA was used because of its elevated binding to human IgG antibodies. The rest of the polyacrylethanolamide-conjugates had 0.2 mol of a saccharide per 1 mol of PAA. All PAA-conjugates were received from Lectinity, Russia.

### The determination of the level of epitope-specific IgG antibodies in sera by enzyme-linked immunosorbent assay (ELISA)

The method has been described elsewhere<sup>[8]</sup>. The dilution of serum was 1:50-1:200. The antibody levels were calculated as a ratio  $A_{\text{test}}/A_{\text{control}}$  where  $A_{\text{test}}$  is the absorbance with PAA-glycoconjugate and  $A_{\text{control}}$ , with Tris-PAA. The variation coefficient was 3%. To diminish

<sup>1</sup>Values of the postoperative (the first analysis after surgery) minus preoperative antibody level; <sup>2</sup>The number of patients having the positive or negative difference.

the variation of the test, the serum samples taken before and after surgery were analyzed using the same plate.

### Clinical analysis of blood samples

Biochemical and hematological analyses were performed at the Oncological Centre of the North-Estonian Regional Hospital. The following automatic equipment was used: a Hitachi 912 and Elecsys 2010, Roche Diagnostics; a Sysmex XE-2100, Sysmex Corporation.

Blood samples were taken before and after surgical operation during the planned visits to the physician for health control. The antibody levels were correlated with those of the C-reactive protein (CRP), tumor markers (CA19-9, CEA), the alanine aminotransferase, glucose, haemoglobin, circulating red blood cells (count), leukocytes (count), neutrophils (%), monocytes (%), lymphocytes (%), platelets (count) and eosinophils (%). The concentration of CRP was determined by a turbidimetric method and that of tumor markers, by an electrochemiluminescence immunoassay.

### Skin test

Antigens: TF-PAA, *Mr* 30 and 1000 ku; T $\beta\beta$ -PAA, *Mr* 1000 ku. The antigens (50-100  $\mu$ g) were injected intradermally and the delayed-type hypersensitivity reaction was monitored twice: through 24 and 48 h. The reaction was considered positive if erythema > 5 mm was developed.

### Statistical analysis

The Mann-Whitney (U-test), the sign test with a null hypothesis (median = 0) for a paired-sample comparison, the Chi-squared test and the regression analysis were used in the study. The differences were considered significant when *P* < 0.05. The graphs were plotted by means of a SigmaPlot 2000 program and Statgraphics Plus 5.1.

## RESULTS

### The influence of the removal of the tumor on antibody levels

To investigate the effect of the surgical removal of the

tumor on antibody levels, the serum samples taken before and after surgery were analyzed. The subtracted values of the postoperative minus preoperative level of antibodies varied and showed an abnormal distribution, however, were mostly positive. The median of differences was also positive (Tables 1 and 2). A sign test for a paired-sample comparison showed the postoperative level of TF- and Tn antibodies to have significantly increased in patients with gastric cancer. Patients with gastric cancer, whose postoperative level of TF- and Tn antibodies was higher than the preoperative one, predominated significantly over those having a lower postoperative level (Table 1, *P* < 0.05). In gastrointestinal cancer, the TF antibody level was found to have elevated significantly after the removal of G3 tumors as compared with preoperative level (median 1.42 and 1.23, respectively, *n* = 278.5, *P* < 0.05). The elevation of the level of anti-Tn and  $\alpha$ Gal IgG after surgery was not significant in U-test owing to the variation in levels. However, the paired-sample sign test demonstrated a significant (more than 75%) predominance of patients having a postoperative elevation of TF, Tn or  $\alpha$ Gal antibody level over those having a lower postoperative level after resection of G3 tumors. These differences were not significant in patients with G1 and G2 resected tumors (Table 2). The level of all three antibodies was increased after surgery in 12% (mainly patients having G3 tumors) and reduced in 4% of patients with gastrointestinal cancer. The change of antibody levels was not associated with the transfusion of erythrocytes after surgery.

### The postoperative follow-up

The clustered distribution of the combined pre- and postoperative level of antibodies was observed. The clusters were separated with the following cut-off values: TF 1.26, 1.53; Tn 1.88, 2.38;  $\alpha$ Gal 2.18; 2.80. Patients whose level of antibodies was higher than the first cut-off value were considered responders. The follow-up showed that the percentage of patients with G3 resected tumors of the digestive tract, whose individual mean level of anti-TF IgG remained above the cut-off value, exceeded significantly the percentage of patients with G1 + G2 resected tumors (Table 3). In the case of the other antibodies these differences were not observed.

In gastric or gastrointestinal cancer, the percentage of anti-TF IgG responders was significantly higher in stage I than in stages III-IV (Table 4). In gastric cancer without metastases (N0 in stages I-II vs N1 + N2) the percentage of anti-TF IgG responders tended to increase. The proportion of Tn- or  $\alpha$ Gal-responders was not increased in stage I vs stages III-IV of the disease.

It was established that despite the elevation of anti-TF IgG level after surgery of patients with advanced cancer, its level during the follow-up varied only slightly, remaining mostly low (Figure 1).

### The relation of antibody levels to the values of blood parameters

Linear regression analysis showed an existing correlation

**Table 2** Postoperative changes of the level of antibodies in gastrointestinal tumor of different grades

Grade <sup>1</sup>	Detection of antibodies	Mean ± SD	Increase	Median of difference	Difference	P (sign test)
					+	-
G1 + G2 (n = 24)	TF, preoperative	2.03 ± 2.04				
	postoperative	2.43 ± 2.86	19.7%	0.05	15	9
G3 (n = 27)	TF, preoperative	1.84 ± 1.71				
	postoperative	3.03 ± 3.20	64.7%	0.29	22	5
G1 + G2 (n = 30)	Tn, preoperative	2.46 ± 1.80				
	postoperative	2.99 ± 2.45	21.5%	0.12	18	12

	postoperative	3.15 ± 2.92	28.6%	0.42	19	6
G1 + G2 (n = 32)	αGal, preoperative	4.10 ± 2.55				
	postoperative	4.62 ± 3.20	12.7%	0.17	20	12
G3 (n = 32)	αGal, preoperative	5.09 ± 3.34				
	postoperative	6.61 ± 3.70	29.9%	1.20	24	8

<sup>1</sup>G1+G2-well-and moderately-differentiated carcinomas.

**Table 3** The percentage of patients with the mean level of anti-TF IgG above the cut-off value (1.53) by histological grading: The postoperative follow-up study

Cancer	G1 + G2		G3		$\chi^2$	P
	n	> cut-off	n	> cut-off		
Gastric, all	22	9.1%	38	26.3%	2.58	0.108
Gastric, without metastases (N0)	16	6.2%	22	31.8%	3.64	0.056
Gastrointestinal, all	47	8.5%	47	23.4%	3.89	0.049
Gastrointestinal (N0)	35	5.7%	26	26.9%	5.34	0.021

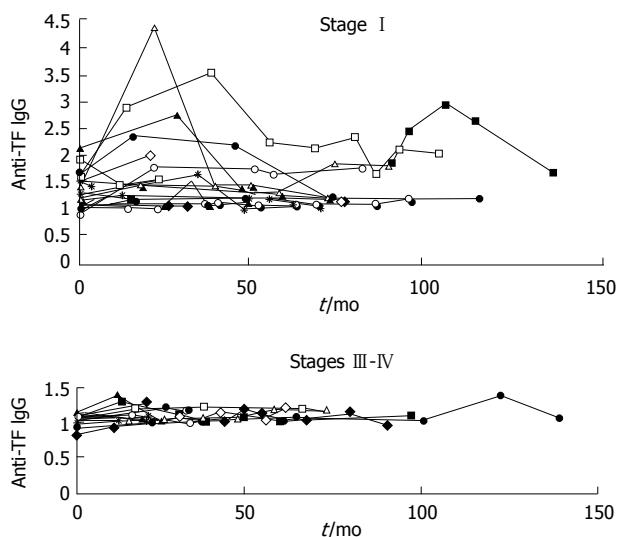

**Table 4** The percentage of patients with the mean level of anti-TF IgG above the cut-off value of 1.26 (responders) in relation to cancer progression: The postoperative follow-up study

Cancer	n	> cut-off	$\chi^2$	P
Gastric, N0	38	39.5%	2.92	0.088
Gastric, N1 + N2	22	18.9%		
Gastric, stage I	24	41.7%	4.71	0.03
Gastric, stages III-IV	18	11.1%		
Gastrointestinal, stage I	29	37.9%	4.11	0.043
Gastrointestinal, stages III-IV	28	14.3%		

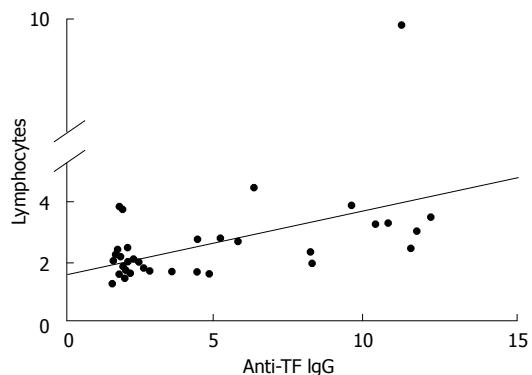

between the level of anti-TF IgG and the count of lymphocytes (Figure 2). As well, the correlation between the level of anti-Tn IgG and the serum level of tumor marker CA 19-9 was established:  $r = 0.481$ ,  $P = 0.011$ ,  $n = 27$  (Tn-responders);  $r = 0.495$ ,  $P = 0.002$ ,  $n = 36$  (all patients). No correlation between the level of antibodies and the values of other biochemical or hematological parameters was established.

### Skin test

No positive delayed-type hypersensitivity reaction in skin test challenges with TF-PAA in any of the fifteen patients, including those with a high level of anti-TF IgG, was observed. In some cases the weak erythema did not exceed 3 mm. Neither side effects nor complications were recorded.

**Figure 1** Changes of the level of anti-TF IgG in gastric cancer in stages I and III-IV during follow-up.

**Figure 2** The correlation between the level of anti-TF IgG and the count of lymphocytes ( $10^9/L$ ) in gastrointestinal cancer patients, whose anti-TF IgG level exceeded a cut-off value of 1.53.  $r = 0.517$ ,  $P = 0.001$ ,  $n = 37$ ,  $y = 0.215x + 1.380$ .

### DISCUSSION

The investigation of the level of serum IgG antibodies to tumor-associated carbohydrate epitopes (TF, Tn) and xenogeneic for human αGal epitope has been carried out earlier. The preoperative level of TF and Tn antibodies

was significantly lower in patients with gastrointestinal cancer, including stage I, than in blood donors, whereas the difference in the level of  $\alpha$ Gal IgG between cancer patients and blood donors was not significant<sup>[8]</sup>. The preoperative level of anti-TF IgG antibodies in patients with gastric carcinoma having regional lymph node metastases was found to be significantly lower than that in patients without metastases<sup>[10]</sup>.

In gastrointestinal cancer the level of TF antibodies in responders with regional metastases was increased after surgery but the follow-up showed the percentage of TF-responders to be significantly higher among patients with cancer in stage I (Table 4). This is due to a minor and short-term postoperative elevation of the antibody level in the serum of patients with lymph node metastases in stages III-IV of the disease. The level of anti-TF IgG in the serum of five patients with gastrointestinal cancer in stages II-IV, which was high prior to surgery rose even more after surgery and remained high for a long time (not shown). However, in most patients the TF IgG immune response in the terminal stages of the disease was suppressed whereas in stage I both the stimulation and suppression of the immune response took place (Figure 1). Since with cancer progression no significant differences were observed in the level of Tn and  $\alpha$ Gal antibodies, the immunosuppression associated with advanced cancer concerns TF antibodies mainly. In this study, the level of  $\alpha$ Gal antibodies was determined because their low level may be indicative of humoral immunodeficiency disorders<sup>[17]</sup>. However, the immunosuppression associated with advanced gastrointestinal cancer appeared not to affect the level of  $\alpha$ Gal antibodies. In gastric cancer the higher level of anti- $\alpha$ Gal IgG was observed in patients with a larger tumor<sup>[10]</sup>. In patients with pancreatic cancer, who often suffer from severe immunosuppression<sup>[18]</sup>, a high level of anti- $\alpha$ Gal IgG was observed as well.

The positive correlation between the level of TF antibodies and the count of lymphocytes in TF-responders ( $n = 57$ ,  $r = 0.400$ ,  $P = 0.002$ ) appeared to reflect the adaptive immune response and provided a further explanation for the involvement of anti-TF IgG in cancer-associated immunosuppression. In patients whose level of anti-TF IgG was higher than the second cut-off value (1.53, Figure 2) this correlation was more pronounced. However, during the follow-up of some patients no such correlation was observed. This is indicative of the existence of a complex relationship between both the parameters which depend on pathological conditions. A decreased preoperative count of lymphocytes and postoperative surgery-related lymphocytopenia occurred in patients with gastrointestinal cancer. Besides, the T helper deficiency was more frequently observed in patients with regional nodal metastases<sup>[18]</sup>.

The above findings are supportive of the idea that patients with a disease of an early stage and its minimal residue after surgery are more responsive to active immunotherapy. The pre- and postoperative level of TF-antibodies, the pattern of TF-expression in tumor, and the individual profile of immune response to the immunization with TF-antigen should be taken into

account when selecting the contingent for immunotherapy.

The postoperative elevation of the level of carbohydrate-specific antibodies, viz. Forssman antibodies, has been documented earlier<sup>[19,20]</sup>. In our study, the postoperative elevation of antibody levels was found to be related to the low-differentiated carcinoma. Thus, the levels of all carbohydrate-specific antibodies, including those investigated earlier<sup>[21]</sup>, were elevated in most patients after the surgical removal of G3 tumors, while in patients with G1 and G2 resected tumors, the differences in antibody levels before and after surgery were insignificant (Table 2).

In the preoperative examination of patients with gastrointestinal cancer, significant differences were established in the level of anti-TF IgG between them, namely, its lower level was associated with a lower-differentiated carcinoma in stages I-II<sup>[10]</sup>. These lower levels were increased significantly after surgery as shown in the present study. Moreover, the significant preponderance of patients with an elevated postoperative level of anti-TF IgG in the case of G3 resected tumors over those with G1 + G2 resected tumors was observed during the follow-up.

In general, the study shows that in most patients with the low-differentiated carcinoma the lower preoperative level of TF antibodies increases after surgery and has a tendency to remain elevated in the early stages of the cancer.

Taken together, the above results may be interpreted as follows: (1) A specific suppressive influence of the tumor on the production of TF antibodies is associated with the stage and grade of the tumor; the surgical removal of the primary tumor (especially G3 tumors) with lymphadenectomy may reverse the suppression of TF antibodies in the early stage of the disease; (2) The mainly low-differentiated carcinoma has an unspecific suppressive influence on the production of anti-carbohydrate antibodies. This influence may also be reversed by the removal of the tumor.

The specificity of human anticarbohydrate antibodies and their natural targets have been poorly studied. Natural anti-carbohydrate immunoglobulins are mostly antibodies of IgM-class. The high level of anti-TF and Tn IgG observed in some patients with cancer may be a sign of an acquired immune response which is indicative of the switching of antibody to the IgG-class. The anti-TF and anti-Tn IgG were affinity-purified from the serum of patients by using synthetic TF- and Tn-PAA sorbents<sup>[22,23]</sup>. TF antibodies demonstrated a high activity of binding to mucins isolated from human malignant tumors, but only in 15% of tumor extracts, whereas the high activity of Tn antibodies was not observed. The analysis of the specificity of purified anti-TF IgG, the mutual and complete inhibition of serum antibodies by TF $\alpha$  and TF $\beta$  conjugates, and a good correlation between the levels of anti-TF $\alpha$  and anti-TF $\beta$  IgG in sera manifest that human anti-TF IgG is specific to both TF $\alpha$  and  $\beta$  anomers, with preference to the latter<sup>[23]</sup>. In this respect, antibodies resemble human monoclonal antibodies, which are able to bind different carcinoma cell lines and immunostained

mucin-related tumor tissues<sup>[24]</sup>.

The level of anti-Tn IgG is correlated with that of CA 19-9 in the serum. This seems to be unusual because the CA 19-9 antigen (SiaLe<sup>a</sup>) differs structurally from Tn and contains no GalNAc residues. The correlation is not due to the cross-reactivity of antigens because the affinity-purified anti-Tn IgG did not react with SiaLe<sup>a</sup>-PAA in the ELISA. This correlation may be explained by a similar relationship between both independent parameters and pathological conditions. Cancer progression or disorders of excretion (cholestasis and other disorders) may provoke the elevation of the level of CA 19-9<sup>[25]</sup> and Tn antibodies, respectively. Since the tumor marker CA 19-9 is a prognostic factor in colorectal cancer<sup>[26]</sup>, the correlation between parameters may be indicative of the possible prognostic significance of antibodies as well.

Synthetic TF and Tn glycoconjugates deserve to be studied from a viewpoint of development of anti-cancer vaccines<sup>[12,13]</sup>. Synthetic PAA-glycoconjugates may be promising preparations because they have been described well and can be modified by epitope density or supplemented with the amplifier of immune response and synthesized in necessary quantities. The results of the skin test performed by the authors show the TF-PAA to be a safe and non-toxic glycoconjugate. The lack of the delayed-type hypersensitivity reaction indicates that the TF antibody response took place through the T-cell independent mechanism, which is typical of carbohydrate antigens.

The high preoperative level of anti-TF as well as anti-MUC1 IgG was closely associated with the survival of patients with gastric cancer<sup>[11]</sup>. However, the possible protective mechanism of TF antibodies in cancer has yet remained unclear. The TF antigen seems to play a crucial role in the adhesion of cancer cells to the endothelium through the interaction of galectin-3<sup>[27,28]</sup>. We suppose that even if TF antibodies are not cytotoxic for TF-expressed tumor cells, they may exhibit an anti-adhesive effect by blocking the TF- galectin-3 mediated metastatic spread. Whether anti-TF and anti-Tn IgG are prognostic factors and how their level in the follow-up is associated with survival will be shown by further investigations.

## ACKNOWLEDGMENTS

We are grateful to Professor N Bovin for consultations and for providing us with synthetic glycoconjugates, to Dr. A Lipping for providing us with histological data, to R Syld for correcting the English and to A Kull for technical assistance.

## COMMENTS

### Background

Tumor-associated carbohydrate antigens (TACA), the Thomsen-Friedenreich (TF) antigen and Tn are frequently expressed in malignant tumors. Human blood serum contains TF- and Tn antibodies but it is not yet clear which role antibodies play in the natural anti-cancer defense system. The TF antigen seems to play a crucial role in the metastatic mechanism due to adhesion of cancer cells to the endothelium. The high level of TF antibodies in the serum may be favourable if antibodies could block the TF- mediated metastatic spread. The level of TF- and

Tn antibodies is significantly decreased in the serum of primary (not operated) patients with cancer. The high level of anti-TF IgG in the serum of primary patients with gastric cancer is closely associated with survival.

### Research frontiers

The relationship of the immune system with the tumor is far from a clear understanding. Cancer immune surveillance is considered to be important in the anti-tumor protection of the host. The growing tumor escapes the immune control under the immunosuppressive conditions. The surgical removal of the tumor may reverse the immunosuppression.

### Innovations and breakthroughs

The dynamic changes of the level of TF- and Tn-antibodies in the serum of patients with cancer have been insufficiently studied. Investigations have mainly focused on short-term clinical trials of antigen-specific immunotherapy. Authors have undertaken a long-term follow-up of cancer patients to determine changes in the postoperative level of TF- and Tn antibodies, as well as to elucidate the association of this level with the progression of cancer, and survival. The association of the level of antibodies with the stage and morphology of the tumor, as well as values of blood parameters was studied. Also, the delayed-type hypersensitivity reaction to TF- polyacrylamide (PAA) conjugates in skin testing was examined.

### Applications

The patients with a disease of an early stage may be more responsive to TF-specific active immunotherapy. Synthetic TF and Tn glycoconjugates deserve to be studied from a viewpoint of development of anti-cancer vaccines and in diagnostic aims.

### Terminology

The epitope is an antigenic determinant, viz. saccharide. The PAA glycoconjugate is a polymeric molecule with covalently bound saccharide. The anomer ( $\alpha$  or  $\beta$ ) is a spatial structure of saccharides.

### Peer review

This is interesting and provocative work. The authors present most of their results in terms of changes in antibody levels. It would be important for them to state what the basal level of these antibodies is, and to give us some idea of what percentage change is represented.

analogue score greater than 5.5. Factors related to the development of severe pain were (1) standing position during upper endoscopy, (2) specific posture/habit during endoscopic procedures, and (3) multiple symptomatic areas. Finger pain was more common in beginners, whereas shoulder pain was more common in experienced endoscopists. Sixteen percent of symptomatic endoscopists have modified their practice or reduced the number of endoscopic examinations. Only a few symptomatic endoscopists had sought professional consultation with related specialists.

**CONCLUSION:** The prevalence of musculoskeletal pain in endoscopists is very high. The location of pain was different between beginners and experienced endoscopists. Measures for the prevention and adequate management of endoscopy-related musculoskeletal symptoms are necessary.

### Abstract

**AIM:** To determine the prevalence and risk factors of work-related musculoskeletal disorders in gastrointestinal endoscopists in Korea.

**METHODS:** A survey of musculoskeletal symptoms, using a self-administered questionnaire, was conducted on 55 endoscopists practicing in general hospitals or health promotion centers.

**RESULTS:** Forty-nine (89.1%) endoscopists reported musculoskeletal pain on at least one anatomic location and 37 (67.3%) endoscopists complained of pain at rest. Twenty-six (47.3%) endoscopists had severe musculoskeletal pain defined as a visual

### INTRODUCTION

Muscle and joint pains are common complaints in individuals whose job requires repetitive isometric maneuvers or awkward body positions<sup>[1]</sup>. Musculoskeletal pains have been reported in individuals with different occupations such as bus drivers, unskilled laborers,

musicians, physical therapists, and computer keyboard operators<sup>[1-7]</sup>. Recently, ergonomic mechanisms related to the development of work-related musculoskeletal disorders (MSD) have drawn substantial interest<sup>[8-10]</sup>.

Work-related musculoskeletal symptoms are common in certain medical specialists such as laparoscopic surgeons and dentists<sup>[11,12]</sup>. However, there are very few studies on MSD in gastrointestinal endoscopists. The incidence of musculoskeletal injuries has been variously reported from as low as 13% for neck pain<sup>[13]</sup> to as high as 57% for back pain<sup>[14]</sup>. To the best of our knowledge, a detailed study in endoscopists' on the severity of musculoskeletal symptoms, symptom-related risk factors, and doctor's response to their own symptoms has not been performed in eastern countries. The purpose of the present study was to assess the prevalence, severity, risk factors, and clinical impact of work-related MSD in gastrointestinal endoscopists in Korea.

## MATERIALS AND METHODS

From June 2006 to September 2006, 55 endoscopists practicing in 4 general hospitals and 2 health promotion centers were included in the present study. Endoscopists expressed their willingness to participate and completed a self-reported questionnaire. The questionnaire was largely structured; although some questions were kept open. Data were collected on the age, gender, duration of endoscopy practice, underlying musculoskeletal disease, and postures and habits during endoscopy. Workload parameters included total duration of endoscopy practice, weekly working hours and monthly number of endoscopic procedures. The areas of musculoskeletal pain were marked on a figure of the human body, and the severity of pain at each site was expressed using a 100 mm visual analogue scale (VAS), a standard measurement tool in pain research. The presence of severe pain was defined as a VAS value greater than 55 mm<sup>[15,16]</sup>. The participants were also asked as to whether their symptoms affected their ability to perform endoscopic procedures, how they managed their symptoms, and whether they had endoscopy-related symptoms other than MSD.

Continuous data were expressed as mean  $\pm$  standard deviation (SD) or median with range. Categorical data analysis was conducted using the chi-square test. Continuous data were analyzed using the independent *t* test. All *P* values were 2-tailed and *P* values less than 0.05 were considered statistically significant.

## RESULTS

### General characteristics of the endoscopists

Fifty-five endoscopists (male 37, female 18) participated in the study. The median age was 39 years (range, 28-47 years), and the median duration of practicing endoscopy was 39 mo (range, 1-228 mo). The average procedure time per week was  $19.5 \pm 7.7$  h. The average number of endoscopies performed per month was  $270.2 \pm 153.2$ .

Eighty-three percent of the endoscopists reported possible endoscopy-related non-musculoskeletal symptoms, such as decreased visual acuity (63.6%), chronic fatigue (60%), depressive mood (18.2%), dizziness (14.5%), headache (12.7%), and skin allergy (1.8%).

### Prevalence of musculoskeletal pain among the endoscopists

Forty-nine (89.1%) endoscopists reported musculoskeletal pain on at least one anatomic location. The average number of symptomatic areas was  $3.9 \pm 2.8$ . Forty endoscopists (72.7%) had pain at more than one anatomic location. Thirty-seven endoscopists (67.3%) had pain at rest. The VAS value of the most painful area was  $5.4 \pm 2.2$ . The musculoskeletal pain developed at  $27.5 \pm 37.9$  mo (range, 1-156 mo) after starting endoscopy.

The location and incidence of musculoskeletal pain during endoscopic procedures or at rest are shown in Figure 1A. The most commonly reported painful area during endoscopic procedures was right shoulder, followed by left shoulder and left finger. There was little difference in the overall distribution of the painful areas at rest. However, neck pain and upper back pain were relatively frequent.

The most painful site during endoscopic procedures was the left finger (16.4%), followed by left shoulder and right wrist (14.5%), left wrist (9.1%) and right shoulder (7.3%). The left and right shoulder (12.7%) were the most painful areas at rest, followed by neck (9.1%), right upper back and lower back (5.5%).

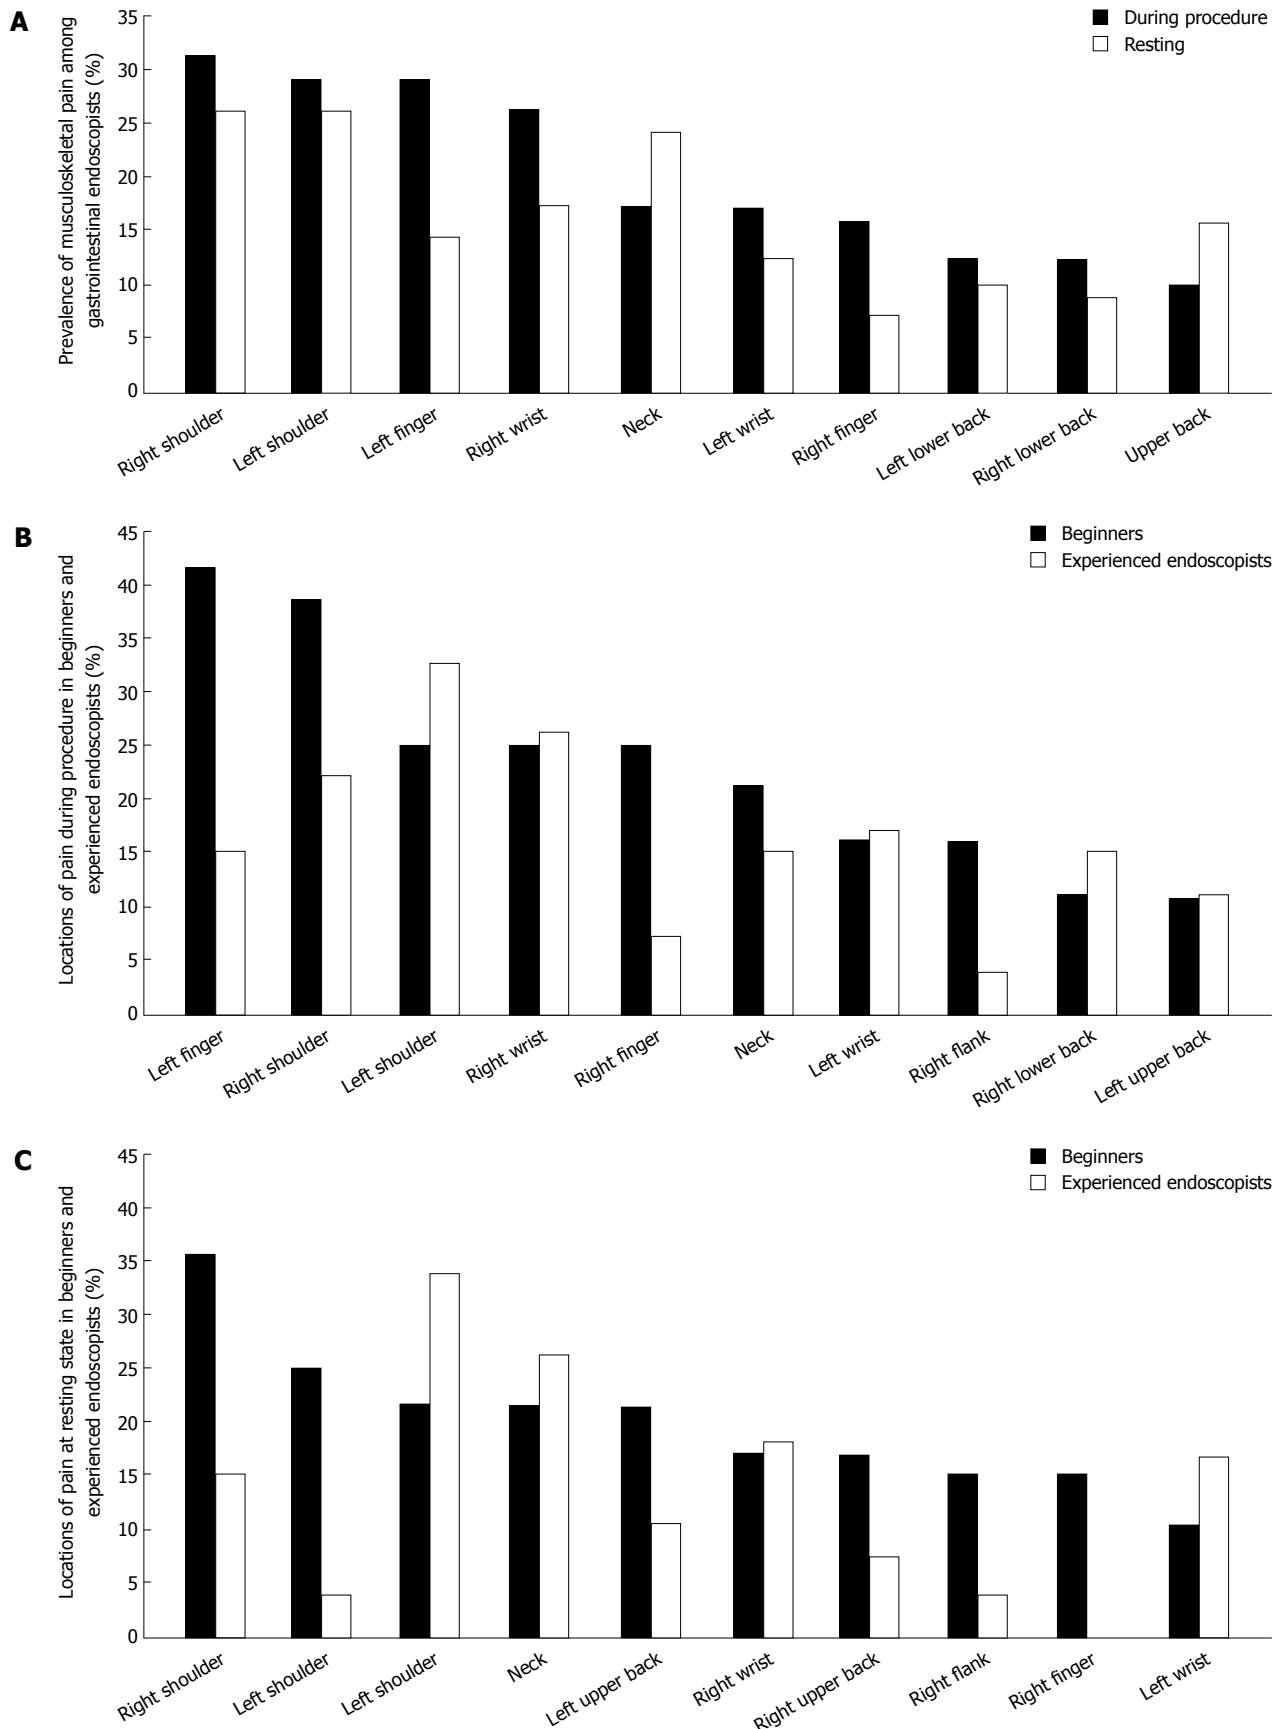

### Risk factors associated with severe musculoskeletal pain

Twenty-six endoscopists (47.3%) had severe musculoskeletal pain with a VAS value greater than 55 mm<sup>[15,16]</sup>. Three factors were statistically related to the development of severe musculoskeletal pain: (1) standing position during upper endoscopic procedures, (2) specific posture or habit during endoscopic procedures, and (3) multiple symptomatic areas (Table 1). The proportion of endoscopists with severe musculoskeletal pain was slightly higher in female than in male endoscopists (61.1% and 40.5%, respectively; *P* = 0.152).

### Comparison between beginners and experienced endoscopists

Endoscopists were divided into two groups (beginner versus experienced) by the total duration of practicing endoscopy (39 mo, Table 2). In the beginner group, the weekly procedure time was longer and the number of endoscopic examinations was greater. However, there was no significant difference in the prevalence of musculoskeletal pain, number of symptomatic areas, and VAS value of the most painful area between the two groups.

By contrast, the location of pain was different between the two groups (Figure 1B and C). During a

**Figure 1** A: Prevalence of musculoskeletal pain in gastrointestinal endoscopists in Korea. Right shoulder pain was the most common symptom both during endoscopic procedures and at rest; B: Prevalence of musculoskeletal pain in beginners and experienced endoscopists during endoscopic procedures ( $^aP < 0.05$ ); C: Prevalence of musculoskeletal pain in beginners and experienced endoscopists at rest.

procedure, the left finger was the most commonly reported painful area in beginners (42.9%, 12/28), whereas the

VAS: Visual analogue scale.

left shoulder was the most commonly reported painful area by experienced endoscopists (33.3%, 9/27) (Figure 1B). The distribution of the most painful area during endoscopic procedures was also different in the two groups. The most painful area was the left finger (21.4%, 6/28) in beginners, followed by right wrist (10.7%, 3/28), left shoulder (7.1%, 2/28) and left wrist (7.1%, 2/28). However, the most painful locations in experienced endoscopists were the left shoulder (22.2%, 6/27), followed by right wrist (18.5%, 5/27), left finger (11.1%, 3/27) and left wrist (11.1%, 3/27). The distribution of pain and the most painful areas at rest were very similar in the two groups (data not shown).

#### **Response of endoscopists to the musculoskeletal pain**

Among endoscopists with musculoskeletal pain, 16.3% (8/49) reported that they had modified their practice or reduced the number of the endoscopic procedures. A majority (81.6%) of endoscopists with musculoskeletal pain managed their symptoms by themselves using stretching (67.3%), exercising (8.2%) and rest (6.1%). Fourteen endoscopists (28.6%) reported the use of medications such as nonsteroidal anti-inflammatory drugs or topical analgesic patches.

Only 14.3% (7/49) of symptomatic endoscopists had sought advice from specialists on musculoskeletal

disorders or had undergone a specific diagnostic work-up. Three endoscopists were diagnosed to have a sprain ( $n = 1$ ) or a cervical intervertebral disk herniation ( $n = 2$ ). In the two endoscopists with herniated disc, one required a 4-wk sick leave until the symptoms improved and the other had modified the practice and reduced the number of endoscopic procedures.

#### **DISCUSSION**

Work-related MSDs or overuse syndrome are a group of diseases resulting from repetitive action at the work place<sup>[17]</sup>. Collagen failure and connective tissue damage results in inflammation, pain, and further weakening of the tissues. Such a vicious cycle can lead to permanent injury and disability if the tissues are not allowed to heal properly<sup>[13]</sup>. Work-related injury is an important cause of missed workdays and impaired performance at work.

We observed that MSD is very prevalent in gastrointestinal endoscopists in Korea. A majority of endoscopists experienced pain at multiple anatomic areas (72.7%) and two-third (67.3%) complained of the pain at rest. The prevalence of MSD observed in the present study is higher than that noted in previous reports by other groups<sup>[13,14]</sup>. One possible explanation is that the endoscopic workload of the doctors in the present study

was very high. In this regard, a previous study reported that the endoscopic volume measured in terms of hours per week, number per week, or percentage of working time was strongly associated with the development of musculoskeletal injuries among endoscopists<sup>[13]</sup>. Workload-associated factors such as the number or duration of work were also related to the prevalence of MSD in other occupations<sup>[1,3,18]</sup>.

In the present study, 26 (47.3%) endoscopists complained of severe musculoskeletal pain, defined as a VAS value greater than 5.5 (Table 1). Endoscopists with severe pain were more likely to have multiple painful areas than those without severe pain. Contrary to our expectations, there was no significant difference in the endoscopic workload between them. This may be due to the small number of participants of the present study. However, ergonomic factors like bad posture during the procedure may be important in the development of endoscopy-related musculoskeletal symptoms. With respect to this hypothesis, we observed that ergonomic factors, such as specific posture/habit during the procedure and standing position in upper gastrointestinal endoscopy, correlated significantly with the development of severe musculoskeletal pain.

In the present study, the experience level of endoscopists was not related to the prevalence of musculoskeletal pain, the number of symptomatic areas, and the severity of the most painful regions. However, there were differences in the distribution of the symptomatic areas (Figure 1B and C). For example, finger pain was more common in beginners, whereas shoulder pain was more common in experienced endoscopists. This was especially true when the endoscopist was performing a procedure. The exact reason of this difference is unclear, but muscles and/or joints frequently used during an endoscopic procedure may differ with the experience of the endoscopist. In this respect, it should be noted that beginners tend to depend more on the movement of the knob during endoscopy.

The best approach to MSD must be preventive. As noted in a previous report<sup>[13]</sup>, endoscopists in the present study tended to neglect or tried to alleviate their symptoms by themselves without resorting to professional help. However, we found that a small proportion (16.3%) of symptomatic endoscopists modified the procedure patterns or reduced the number of endoscopic procedures. The overall efficacy of an endoscopy unit may be negatively influenced by these factors. Measures for the prevention of work-related MSD may improve the productivity of healthcare institutions. The importance of ergonomics in work-related MSDs has been studied in a certain fields<sup>[19,20]</sup>. Endoscopists should also take advantage of such studies.

A major limitation of our study was that it was difficult to determine whether a particular symptom was related to endoscopy or not. This was related to our study design using a self-administered questionnaire without an objective assessment of the symptoms. However, we presumed that a great proportion of

the symptoms in the present study were endoscopy-related. Another limitation was that the participants were working in either general hospitals or health promotion centers, where the volume of endoscopic procedures exceeds the average endoscopic workload. About one-half of endoscopies, in general, were performed under sedation, the proportion of upper to lower endoscopy was approximately three to two, and that of therapeutic endoscopies was almost twenty percent, although this aspect was not investigated in the present survey. Finally, there was no follow-up data in the present study. Large-scaled follow-up studies in various clinical settings are needed.

In conclusion, the prevalence of musculoskeletal symptoms in endoscopists is very high, and the majority of symptomatic endoscopists do not seek professional consultation. The pattern of musculoskeletal pain among beginners and experienced endoscopists was different, suggesting multiple ergonomic mechanisms for symptom development. Measures for the prevention and adequate management of endoscopy-related musculoskeletal symptoms are necessary.

## COMMENTS

### Background

Work related musculoskeletal disorder (MSD) is a common problem in individuals whose job requires repetitive isometric maneuvers or awkward body positions. However, the prevalence of MSD among endoscopists is not well known. The present study was designed to investigate the prevalence and risk factors of work-related MSD in gastrointestinal endoscopist in Korea.

### Research frontiers

We investigated the incidence, severity, location and clinical impact of work-related MSD during endoscopic procedures and at rest in gastrointestinal endoscopists. The present study is the first detailed study designed to investigate MSD in gastrointestinal endoscopists in eastern countries.

### Innovations and breakthroughs

We used a self reported questionnaire in 55 endoscopists practicing in 4 general hospitals and 2 health promotion centers. The severity of MSD was assessed by the visual analogue scale, a standard measurement tool in pain research.

### Applications

In the present study, the prevalence of musculoskeletal symptoms among endoscopists was very high, and the majority of symptomatic endoscopists did not seek professional consultation. The pattern of musculoskeletal pain in beginners and in experienced endoscopists was different, suggesting multiple ergonomic mechanisms for symptom development. We hope the present study would lead to interest in work-related MSD and ergonomics in gastrointestinal endoscopists.

### Peer review

The present study has shown that the development of severe pain in gastrointestinal endoscopists is related to ergonomic factors, such as specific posture/habit and the standing position during endoscopic procedures. The study suggests that endoscopists need to focus on teaching a beginner about proper posture and manipulation techniques in order to prevent musculoskeletal symptoms.

## Abstract

**AIM:** To study and determine the resting energy expenditure (REE) and oxidation rates of glucose, fat and protein in severe chronic hepatitis B patients.

**METHODS:** A total of 100 patients with liver diseases were categorized into three groups: 16 in the acute hepatitis group, 56 in the severe chronic hepatitis group, and 28 in the cirrhosis group. The REE and the oxidation rates of glucose, fat and protein were assessed by indirect heat measurement using the CCM-D nutritive metabolic investigation system.

**RESULTS:** The REE of the severe chronic hepatitis group ( $20.7 \pm 6.1$  kcal/d per kg) was significantly lower than that of the acute hepatitis group ( $P = 0.014$ ). The respiratory quotient (RQ) of the severe chronic hepatitis group ( $0.84 \pm 0.06$ ) was significantly lower than that of the acute hepatitis and cirrhosis groups ( $P = 0.001$ ). The glucose oxidation rate of the severe hepatitis group (39.2%) was significantly lower than that of the acute hepatitis group and the cirrhosis group ( $P < 0.05$ ), while the fat oxidation rate (39.8%) in the severe hepatitis group was markedly higher than that of the other two groups ( $P < 0.05$ ). With improvement of liver function, the glucose oxidation rate increased from 41.7% to 60.1%, while the fat oxidation rate decreased from 26.3% to 7.6%.

**CONCLUSION:** The glucose oxidation rate is signifi-

## INTRODUCTION

The liver plays a pivotal role in controlling carbohydrate metabolism by maintaining glucose concentrations in the normal range, as well as in protein and fat metabolism. This is achieved by a tightly regulated system of enzymes and kinases that regulate nutrient breakdown and synthesis in hepatocytes. Many studies have shown that cirrhotic patients have nutrient and energy metabolism imbalance, which lead to malnutrition and seriously affect their prognosis<sup>[1,2]</sup>. On multivariate regression analysis, the Child-Pugh's score is a good independent predictor of malnutrition. With respect to energy metabolism, there is no consensus on energy expenditure, but there is a consensus that respiratory quotients are lower in liver cirrhosis patients than in healthy subjects. Therefore, resting energy expenditure (REE), calorie intake, and energy balance should be routinely assessed in cirrhotic patients in order to identify hypermetabolic and hypometabolic patients. The nutritional and metabolic parameters in these patients are indispensable for design-

ing and prescribing personalized nutritional strategies for the treatment of muscle malnutrition, which can thus improve their morbidity and mortality rates<sup>[3]</sup>. Protein-energy malnutrition is frequently observed in liver cirrhosis patients; disorders of protein metabolism and energy metabolism are closely correlated with protein-energy malnutrition. It has been shown that, in protein metabolism disorders, the synthesis and degradation rates of albumin decreased and the serum half-life of albumin became longer<sup>[4]</sup>. These changes are closely correlated with the prognosis of cirrhosis patients. Therefore, it is important for clinicians to identify and treat metabolic disorders in liver cirrhosis patients. Currently, it is thought that supplementation with branched-chain amino acids (BCAAs) is useful for improving protein metabolism disorders, and that a late evening snack (LES) improves the catabolic state of advanced liver cirrhosis patients. Long-term oral supplementation with a BCAA mixture was found to be better than an ordinary diet<sup>[5,6]</sup>. Recently, it was shown that the ingestion of a 200 kcal rice LES can improve nutritional metabolism in cirrhosis patients. Furthermore, a short course of recombinant human growth hormone (rhGH) and insulin-like growth factor-I (IGF-I) raised albumin levels and tended to improve energy metabolism in liver cirrhosis patients. The exogenous administration of IGF-I has hepatoprotective and antifibrogenic actions in experimental liver cirrhosis<sup>[7-11]</sup>. Therefore, proper nutritional support is very important in promoting the recovery of liver disease patients. However, the characteristics of the energy metabolism of severe chronic hepatitis patients are not clear. Thus, the aim of the present study was to explore the characteristics of the energy metabolism of severe chronic hepatitis patients so as to provide data that could be used for optimal nutritional support.

## MATERIALS AND METHODS

### Subjects

One hundred patients with liver diseases were enrolled from July 2006 to September 2007. They were categorized into 3 groups according to their disease recovery stage: acute hepatitis group ( $n = 16$ ); hepatitis A,  $n = 10$ ; hepatitis E,  $n = 6$ ), severe chronic hepatitis B-related hepatitis group ( $n = 56$ ), and hepatitis B-related cirrhosis group ( $n = 28$ , Table 1). Of the severe chronic hepatitis B-related hepatitis patients, 14 patients (10 males, 4 females), whose status changed from the acute severe stage to the recovery stage within 8 wk, were randomly selected for assessment twice. The patients' average age was 42.5 years (range, 36-62 years). The patients all met the diagnostic criteria of the "Symposium on Viral Hepatitis and Liver Diseases in 2000"<sup>[12]</sup>. Briefly, the severe chronic hepatitis was defined based on the following inclusion criteria: (1) a history of chronic hepatitis or liver cirrhosis; (2) severe asthenia and a serum total bilirubin more than 171  $\mu\text{mol/L}$ ; and (3) prothrombin time activity (PTA) less than 60%. All enrolled patients had not received nutritional support and rational regime treatment, anti-viral agents

and steroid. The study was explained to the patients and/or their relatives, and written informed consent was obtained. The study was approved by the Ethics Committee of the Beijing You'an Hospital of Capital Medical University.

### REE and glucose, protein and fat oxidation rates

The REE and the carbohydrate, protein and fat oxidation rates were determined by indirect heat measurement. The REE was determined using the CCM-D nutrition metabolism investigation system (Medgraphics Company, United States). The average  $\text{O}_2$  amount consumed and the  $\text{CO}_2$  amount produced per minute by the subjects were used to calculate the actual REE using the Weir formula; subsequently, the respiratory quotient, the ratio of the average  $\text{O}_2$  amount consumed to the  $\text{CO}_2$  amount produced per minute by the subjects, was calculated. Twenty-four-hour urine samples were collected from all subjects for the determination of the urea nitrogen level using the HITACHI7170 automatic biochemistry analyzer (Japan). The protein oxidation rate, non-protein-respiratory quotient (npRQ), the carbohydrate (CHO) and the fat oxidation rates were calculated from the collected data using a computer program. The predicted REE value was calculated using the Harris-Benedict formula based on the subject's height, weight and age.

The subjects were required to fast for at least 8 h prior to testing. In order to avoid muscle activation; they stayed in bed in the morning for at least 30 min. The room temperature was kept between 24°C and 26°C, with a humidity of 45%-60%. The volume and gas were calibrated for the CCM-D nutrition metabolism investigation system; and the subject's data on height, weight, gender and age were put into the system. The value of energy metabolism may be related to body weight. Therefore, the REE/kg of all patients were also evaluated.

### Liver function assessment

Serum samples were collected from all subjects, and the following liver function indices were determined by the HITACHI7170 automatic biochemistry analyzer (Japan): alanine transaminase (ALT), aspartate transaminase (AST), total bilirubin (TBIL), albumin (ALB), proalbumin (PA), cholinesterase (CHE), and cholesterol (CH).

### Statistical analysis

The data is presented as mean  $\pm$  SD. The means were compared between groups using variance analysis. Data from severe virus hepatitis patients in the severe stage and the recovery stage were compared using the paired *t* test. SPSS 10.0 statistical software was used for all analyses.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Energy metabolism characteristics

The REE of the severe chronic hepatitis group and the

Group 1: Acute hepatitis group; Group 2: Chronic severe hepatitis group; Group 3: Cirrhosis group. <sup>a</sup>*P* < 0.05, 2 vs 1 and 3 vs 1.

**Figure 1** Oxidation rates of protein, carbohydrate and fat in the severe hepatitis group, the acute hepatitis group, and the cirrhosis group. <sup>a</sup>*P* < 0.05, the acute hepatitis group vs the cirrhosis group. There is no significant difference between groups of severe hepatitis and liver cirrhosis.

acute hepatitis group was not significantly different from that of the cirrhosis group. However, the REE per kg (REE/kg) of the acute hepatitis group was significantly higher than that of the chronic severe hepatitis group and the cirrhosis group (*P* = 0.014), but the difference in the REE/kg between the chronic severe hepatitis group and the cirrhosis group was not significant. The respiratory quotient of the severe chronic hepatitis group (0.84 ± 0.06) was significantly lower than that of the acute hepatitis group and the cirrhosis group (*P* = 0.001). The respiratory quotients of the chronic hepatitis group (0.90 ± 0.05) and the cirrhosis group (0.88 ± 0.08) were not significantly different (Table 2).

The proportion of energy supplied by the three major substrates (carbohydrate, fat and protein) differed among the groups. Protein oxidation rates were not significantly different among the groups; they ranged from 21.0% to 22.2%. The carbohydrate oxidation rate of the severe hepatitis group (39.2%) was significantly lower than that of the acute hepatitis group and the cirrhosis group (*P* = 0.048). The fat oxidation rate of the severe hepa-

titis group (39.8%) was significantly higher than that of the acute hepatitis group and the cirrhosis group (*P* = 0.01). The carbohydrate and fat oxidation rates of the acute hepatitis group and the cirrhosis group were not significantly different (*P* = 0.472). Energy supplied by carbohydrate oxidation accounted for 50% or more of the total energy supplies (Figure 1). The actual consumptions per kg weight per day of protein and fat did not differ significantly among the three groups. However, the carbohydrate consumption per kg weight per day was highest in the acute hepatitis group and lowest in the chronic severe hepatitis group; there were significant differences among the groups in carbohydrate consumption (*P* < 0.0001, Table 2).

#### Energy metabolism differences between severe hepatitis patients at severe and recovery stages

The energy metabolism of the 14 patients with severe chronic hepatitis whose disease improved from the severe stage to the recovery stage was assessed twice. Four of these patients had been given growth hormone (4.5 IU/d for 2 wk). Significant improvement in the biochemical indices was seen in the patients at the recovery stage: ALT decreased from 561.2 ± 818.5 U/L to ALT 35.7 ± 9.37 U/L, T-Bil decreased from 17.4 ± 5.5 mg/dL to 5.3 ± 2.7 mg/dL, and PTA increased from 38.2% ± 29% to 72.7% ± 35.9%. After the improvement of liver function, the REE was not significantly changed compared to that obtained prior to the improvement; there was no significant change in the REE per kg weight. However, the carbohydrate oxidation rate increased from 41.7% to 60.1%, while the fat oxidation rate decreased from 26.3% to 7.6%. There was a non-significant trend for the respiratory quotient (RQ) value to increase (*P* = 0.105, Table 3).

#### DISCUSSION

The liver plays a unique role in carbohydrate metabolism by maintaining glucose concentration levels in the normal

**Table 3** Dynamic determination of REE and oxidation rates in severe chronic hepatitis patients ( $n = 14$ , mean  $\pm$  SD)

Patient	REE (kcal/d)	REE/kg (kcal/d per kg)	RQ	CHO (%)	Fat (%)	Protein (%)
Severe stage	1366.1 $\pm$ 140.7	19.1 $\pm$ 3.3	0.86 $\pm$ 0.05	41.7 $\pm$ 18.3	26.3 $\pm$ 27.2	32.1 $\pm$ 24.8
Recovery stage	1306.7 $\pm$ 497.8	17.9 $\pm$ 6.2	0.91 $\pm$ 0.06	60.1 $\pm$ 11.7	7.6 $\pm$ 38.6	32.3 $\pm$ 30.9
P value	0.761	0.638	0.105	0.075	0.232	0.990

range. This is achieved by a tightly regulated system of enzymes and kinases that regulate glucose breakdown and synthesis in hepatocytes. This process is under the control of glucoregulatory mediators, of which insulin plays a key role. Therefore, the liver is the major organ of substrate and energy metabolism. It has recently been noted that the energy metabolism of patients with end-stage liver diseases, such as cirrhosis, was altered compared to normal controls, they showed evidence of malnutrition, a high metabolism, a lower RQ value, and a relatively higher fat oxidation rate<sup>[2,4,6,11]</sup>. Long-term oral supplementation with a BCAA mixture is better than ordinary food taken as a late evening snack for improving the serum albumin level and the energy metabolism of cirrhosis patients<sup>[5,10]</sup>.

Severe chronic hepatitis is a severe liver disease in which extended liver tissue necrosis caused by chronic viral hepatitis or hepatitis cirrhosis may lead to liver failure. Nutritional support is an important component of comprehensive therapy. However, the characteristics of the energy metabolism of severe chronic hepatitis patients have never been previously reported. The present study found that the energy metabolism of patients with severe chronic hepatitis had several unique characteristics.

First, the REE of severe chronic hepatitis patients was not significantly different from that of acute hepatitis and cirrhosis patients, who did not have increased energy metabolism. The REE per kg weight was similar in the severe chronic hepatitis group to that in the cirrhosis group, and both were lower than that in the acute hepatitis group. This may be due to the fact that the REE/kg value in the severe chronic hepatitis patients was lower than that in normal controls. This is different from the high energy metabolism condition found in cirrhosis patients, which is widely acknowledged. Tajika<sup>[2]</sup> found that energy metabolism was normal in 58% patients, and only 12% of patients had low energy metabolism. This can be related to the high energy metabolism of acute hepatitis patients. Plauth<sup>[6]</sup> showed that chronic hepatitis C patients had a high energy metabolism related to their viral load; and their high energy metabolism resolved with anti-viral treatment. Therefore, it is likely that high energy metabolism is related to the presence of acute hepatitis.

Second, severe the chronic hepatitis group had a notably higher fat oxidation rate than the acute hepatitis group and the cirrhosis group, and a lower glucose oxidation rate than the acute hepatitis group and the cirrhosis group. There was no difference in the protein oxidation rate among the three groups.

Third, the REE before and after liver function improvement in the severe hepatitis patients was compared. The REE of these patients was not changed, but they had a lower fat oxidation rate and a higher carbohydrate oxidation rate; however, these differences were not statistically

significant, perhaps as a result of the small sample size. Recently, Plauth<sup>[6]</sup> showed that TIPS could improve energy metabolism and malnutrition in cirrhosis patients. Growth hormone treatment can improve the liver function and energy metabolism of severe hepatitis patients. From these results, it would appear that severe chronic hepatitis patients cannot utilize carbohydrate. With a notable decrease in the glucose oxidation rate, they can only obtain energy by increased fat utilization. Glucose utilization returns to normal when the patients recover. The inability to use glucose may be due to insulin resistance in chronic liver disease patients<sup>[8]</sup>. An increase in the RQ value can be used as a marker of recovery in these patients. Tajika<sup>[2]</sup> also found that, in cirrhosis patients, the non-protein respiratory quotient (npRQ) was an independent risk factor for survival; and patients with a lower npRQ had a worse prognosis.

In the present study, substrate and energy metabolism of cirrhosis patients was not significantly different from that of acute hepatitis patients. This may be related to patient selection. The cirrhotic patients selected were in Child grade A or B, resulting in no significant difference between the cirrhosis patient group and the acute hepatitis group. Multivariate regression analysis confirmed that the Child-Pugh's score is a better independent predictor of malnutrition than the other variables. However, the REE, TEE, calorie intake and energy balance need to be routinely assessed in cirrhotic patients in order to identify hypermetabolic and hypometabolic patients, which account for approximately 30% of patients. In these patients, the nutritional and metabolic parameters are indispensable for designing and prescribing personalized nutritional strategies for the treatment of the patients' muscle malnutrition, thus improving their morbidity and mortality rates.

In conclusion, in the present study, severe chronic hepatitis patients had a lower resting energy metabolism per kg weight than acute hepatitis patients, but similar to cirrhosis patients. Severe chronic hepatitis patients had a significantly higher fat oxidation rate and a significantly lower glucose oxidation rate than acute hepatitis and cirrhosis patients. As the severe chronic hepatitis patients' condition improved, the glucose oxidation rate increased. An increase in the RQ value can be used as a marker of recovery in these patients. The REE and the oxidation rates of various substrates determined by indirect heat measurement can be used to determine the optimal nutritive support therapy for severe liver disease patients.

## COMMENTS

### Background

The liver plays a pivotal role in glucose, fat, protein and energy metabolism.

Many studies have shown that patients with liver cirrhosis have nutrient and energy metabolism imbalance, which lead to malnutrition and seriously affect their prognosis. However, the characteristics of the glucose, fat, protein and energy metabolism in patients with severe chronic hepatitis are not clear.

### Research frontiers

It has recently been noted that the energy metabolism of patients with end-stage liver diseases such as cirrhosis was altered compared to normal controls. They showed evidence of malnutrition, a high metabolism, a lower respiratory quotient (RQ) value, and a relatively higher fat oxidation rate. Long-term oral supplementation with a branched-chain amino acids (BCAA) mixture is better than ordinary food taken as a late evening snack for improving the serum albumin level and the energy metabolism of cirrhotic patients. Severe chronic hepatitis, which extended hepatic cell necrosis caused by chronic viral hepatitis B, leads to liver failure. Nutritional support is an important component of comprehensive therapy. However, the characteristics of the glucose, fat, protein and energy metabolism in patients with severe chronic hepatitis remain unclear.

### Innovations and breakthroughs

The characteristics of the energy metabolism of severe chronic hepatitis patients have not been previously reported. The authors studied the disturbed homeostasis of energy, carbohydrate, fat and protein metabolism in severe chronic viral hepatitis B patients, and found that these patients had increased fat oxidation and reduced carbohydrate metabolism, which intended to improve when the liver function became normal. An increase in the RQ value can be used as a marker of recovery in these patients.

### Applications

The measurement of resting energy expenditure (REE) and the oxidation rates of various substrates can be used to determine the optimal nutritive support therapy for severe liver disease patients. This research is expected to warrant a large clinical trial to assess the optimal nutritive support therapy for severe liver disease patients.

### Peer review

The authors have estimated REE and RQ of patients with severe chronic hepatitis B. And most of energy consumed by these patients is provided by fat, not carbohydrate. The study is interesting and valuable.

## Abstract

**AIM:** To compare post-orthotopic liver transplantation (OLT) survival between patients with recurrent hepatocellular carcinoma (HCC) after partial hepatectomy and those who received *de novo* OLT for HCC and to assess the risk factors associated with post-OLT mortality.

**METHODS:** From July 2003 to August 2005, 77 consecutive HCC patients underwent OLT, including 15 patients with recurrent HCC after partial hepatectomy for tumor resection (the rescue OLT group) and 62 patients with *de novo* OLT for HCC (the *de novo* OLT group). Thirty-three demographic, clinical, histological, laboratory, intra-operative and post-operative variables were analyzed. Survival was calculated by the Kaplan-Meier method. Univariable and multivariable analyses were also performed.

**RESULTS:** The median age of the patients was 49.0 years. The median follow-up was 20 mo. Three patients (20.0%) in the rescue OLT group and 15 patients (24.2%) in the *de novo* OLT group died during the follow-up period ( $P = 0.73$ ). The 30-day mortality of OLT was 6.7% for the rescue OLT group vs 1.6% for the *de novo* OLT group ( $P = 0.27$ ). Cox proportional hazards model showed that pre-OLT hyperbilirubinemia, the requirement of post-OLT transfusion, the size of the tumor, and family history of HCC were significantly associated with a higher hazard for mortality.

**CONCLUSION:** There are no significant differences

in survival/mortality rates between OLT as *de novo* therapy and OLT as a rescue therapy for patients with HCC. Pre-OLT hyperbilirubinemia, post-OLT requirement of transfusion, large tumor size and family history of HCC are associated with a poor survival outcome.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. An estimated number of 372000 new cases of HCC are diagnosed each year, constituting 4.6% of all new cancers (6.3% in men, 2.7% in women)<sup>[1,2]</sup>. Endemic areas include the Far East and Africa. The number of patients with HCC in China comprises approximately 40%-50% of all HCC patients of the world and HCC is the 2nd leading cause of death among cancer mortalities in the country<sup>[3]</sup>. While the etiology and pathogenesis of HCC are not entirely clear, the major contributing factors for the high prevalence of HCC in the country include chronic hepatitis B infection and dietary contamination of aflatoxin<sup>[4]</sup>.

Partial hepatectomy with tumor resection and orthotopic liver transplantation (OLT) are the two commonly used surgical modalities for HCC treatment. Partial hepatectomy with tumor resection may be performed as a definitive or bridging therapy. Post-operative recurrence of HCC is common in patients undergoing hepatectomy, affecting long-term outcome. For patients with recurrent HCC after partial hepatectomy, rescue treatment options include percutaneous ethanol injection (PEI), trans-catheter

arterial chemoembolization (TACE), and surgical resection of recurrent tumor<sup>[5,6]</sup>. In addition, OLT appears to be a valid rescue option for these patients<sup>[7]</sup>. Poon *et al*<sup>[7]</sup> reported that OLT as a salvage operation is feasible and effective in patients with transplantable small HCC (solitary ≤ 5 cm, or 2 or 3 tumors ≤ 3 cm) who initially had primary resection and had preserved liver function. However, OLT has not been routinely performed in patients with recurrent advanced HCC<sup>[8]</sup>. In our clinical practice, we found that these patients with recurrent HCC, even at an advanced stage, might still benefit from OLT as a rescue operation. We hypothesized that OLT as a rescue operation for patients with recurrent HCC after initial resection surgery may have a similar outcome to these patients with HCC who had *de novo* OLT. The aims of the study were to compare post-OLT survival rates between patients who have recurrent HCC and those who have no history of resection surgery, and to evaluate the risk factors associated with postoperative mortalities.

## MATERIALS AND METHODS

### Patients

This is an historical cohort study involving 77 consecutive patients who underwent OLT for HCC from July 2003 to August 2005 in Eastern Hepatobiliary Surgery Hospital, Shanghai, China, a tertiary referral center specializing in surgical treatment of HCC and a variety of other liver disorders. The data were extracted from a prospectively maintained database for OLT which was approved by the Institutional Ethics Committee. The 77 eligible patients were divided into two groups: the study group with OLT performed as a rescue operation for recurrent HCC after initial partial hepatectomy for tumor resection (the rescue OLT group,  $n = 15$ ) and the control group with OLT performed as the 1st line *de novo* therapy for HCC (the *de novo* OLT group,  $n = 62$ ).

### Inclusion and exclusion criteria

The inclusion criteria were patients aged > 18 years and those with HCC who underwent OLT. The exclusion criteria were patients who had OLT for etiologies other than HCC and patients who had OLT combined with transplantation of other organ(s).

### Criteria for diagnosis and selection

The diagnosis of HCC was based on a combined assessment of clinical presentations, history of HBV infection and liver cirrhosis, imaging data (ultrasound, CT scan, and/or MRI), preoperative laboratory evaluation (alpha-fetoprotein), and pre- and/or postoperative histopathology. Patients considered to be candidates for OLT met the following criteria: (1) primary or recurrent HCC met Shanghai Criteria for OLT<sup>[9]</sup>, i.e., tumor size ≤ 9 cm, number of tumors ≤ 3, the absence of macrovascular tumor embolism, and the absence of extrahepatic metastasis; (2) the ability to take anti-rejection medications after OLT; and (3) the absence

of significant comorbidities. Written informed consent was obtained from all patients before the surgery.

### Demographic and clinical variables

A panel of demographic and clinical variables were evaluated, including age, sex, excessive alcohol use, tobacco use, family history of HCC, HBV and/or hepatitis C infection, liver cirrhosis, diabetes, cardiopulmonary diseases, renal insufficiency, the time from the tumor detection to OLT, donor source, preoperative blood biochemistry, pre-OLT Child-Pugh scores<sup>[10]</sup>, post-OLT pTNM tumor staging (UICC, International Union Against Cancer, 1953), intraoperative variables, postoperative histopathology and postoperative course.

### Clinical outcomes

The primary outcomes were estimated based on the 30-d postoperative mortality, overall survival, and tumor-free survival, and the secondary outcomes were risk factors associated with the mortality.

### Statistical analysis

Descriptive statistics were computed for all factors. These include medians and percentiles for continuous factors and frequencies for categorical factors. Time of follow-up is defined as either months from OLT to death, or months from OLT to last follow-up visit. A Kaplan-Meier plot was used for graphical representation of survival probabilities by recurrence of the liver cancer. Univariable and multivariable Cox proportional hazards models were used to estimate the hazard rates for several factors of interest. A stepwise selection method was used to choose the final multivariable model using a 0.50 and 0.25 significance criterions for entering and remaining in the model, respectively. A significance level of 0.05 was considered for all analyses. SAS version 9.1 software (SAS Institute, Cary, NC) and R 2.0.1 software (The R Foundation for Statistical Computing) were used to perform all analyses.

## RESULTS

### Procedure

In a median waiting period of 2 mo (ranging from 4 d to 3 mo), all 77 patients underwent cadaver OLT. Two patients (13.3%) in the rescue OLT group and 11 patients (17.7%) in the *de novo* OLT group underwent TACE or PEI therapy before OLT operation. As a part of our routine clinical protocol, end-to-end anastomoses of the inferior vena cava, portal veins, hepatic arteries, and bile ducts of the donors and recipients were performed. At anhepatic phase, 4000 units of hepatitis B immunoglobulin (HBIG) were injected intramuscularly. At the completion of the operation, methylprednisolone 500 mg was infused intravenously. As a part of the post-OLT protocol, 74 patients (96.1%) received one to three 6-d courses of intravenous 5-fluorouracil 500 mg on post-operative day 1 and day 4, mitomycin 2 mg

<sup>1</sup>Statistics presented are medians (Q25, Q75).

on post-operative day 2 and day 5, and carboplatin 100 mg on postoperative day 3 and day 6. Post-operative anti-rejection regimens included tacrolimus, methylprednisolone, and mycophenolate mofetil. The blood levels of tacrolimus were maintained at 10-15 ng/mL for 3 mo after OLT and 5-10 ng/mL thereafter. Intravenous methylprednisolone was started on postoperative day 1, at 50 mg per 6 h, and tapered to 20 mg per day. On discharge from the hospital, intravenous methylprednisolone was switched to oral prednisone 15 mg per day with tapering. Prednisone was discontinued at 3 mo post-operatively.

Table 1 summarizes descriptive statistics for all 77 patients in the rescue OLT (*n* = 15) and *de novo* OLT (*n* = 62) groups.

### Clinical data on the rescue OLT group

Table 2 presents detailed information about the tumor, at the time of tumor resection in the study group. All patients in the rescue OLT group underwent radical tumor resection because of the lack of a donor liver, even though the patients met Shanghai Criteria for OLT. The patients had partial hepatectomy with a tumor-free margin of  $\geq 1.5$  cm which was confirmed by postoperative histopathologic evaluation. The majority of patients underwent postoperative adjunctive therapy, including TACE in 12 (80.0%) patients and PEI in 2 (13.3%) patients.

### Survival data

range: 14–29 mo), 18 (23.4%) patients died: 3 (20%) in the rescue OLT group and 15 (24.2%) in the *de novo* OLT group. One patient from each group died in 30 d of OLT (6.7% vs 1.6%) because of disseminated intravascular coagulation and pneumonia, respectively. One patient in the control group died of graft-versus-host disease 2 mo after OLT. The main cause of the death was recurrent tumor and metastasis, and 15 patients died more than 30 d after OLT.

### Risk factors associated with survival outcome

Table 3 presents univariable hazard rates for the association between several factors of interest and overall survival rate. Younger age, pre-operative hyperbilirubinemia, large tumor size, family history of liver cancer, and tumor microembolism were found to significantly influence the hazard for post-OLT mortality. Figure 1 presents the Kaplan-Meier curves of overall survival and tumor-free survival by the two groups, respectively. Interaction between time and the study groups was verified as the two curves cross each other suggested non-proportionality of the hazards; but this was not found statistically significant.

Table 4 shows the results of the multivariable Cox proportional hazards model. Total bilirubin, the requirement for post-operative transfusion, the size of the largest tumor, family history of HCC, and microembolisms remained in the final model. Recurrence of HCC was kept in the final model because of clinical importance, even though it was not found significantly associated with survival rate. The hazard of dying after OLT increases by 1% for every 1 unit increase in total bilirubin. Also, for every 1 L increase in

**Figure 1** Probability of overall survival and tumor-free survival after orthotopic liver transplantation- Kaplan-Meier curves. **A:** Interaction between time and groups was verified as the two curves cross each other suggest non-proportionality of the hazards but this is not found statistically significant ( $P = 0.98$ ); **B:** Interaction between time and groups was verified as the two curves cross each other suggest non-proportionality of the hazards, but not statistically significant ( $P = 0.66$ ).

the amount of post-OLT blood transfusion, the hazard of dying increases by 40%. In addition, the hazard of dying increases by 30% for every 1 cm increase in the size of the largest tumor. Finally, subjects with a family history of HCC have 7.7 times of the hazards of dying that of those without a family history of HCC.

## DISCUSSION

Partial hepatectomy and OLT are effective treatment modalities for HCC patients with underlying cirrhosis<sup>[11–13]</sup>. The surgical outcome of the two approaches appeared to be comparable, with each of the treatment modalities having its advantages and disadvantages. For example, operative mortality was lower for partial hepatectomy which may be preferably applied to HCC patients with a well compensated cirrhotic liver, while OLT can be performed selectively in patients with tumor recurrence and/or decompensated liver. Although the decision of choice on partial hepatectomy and OLT can be difficult to make<sup>[14–16]</sup>, it appears that the latter treatment modality may have a survival advantage<sup>[17,18]</sup>. The main barrier for the routine application of OLT in the patient population has been the availability of a donor organ. On the other hand, partial hepatectomy can be offered as a sole surgical treatment or as a bridging procedure for OLT. However,

**Table 3** Univariable Cox proportional hazards models

	Factor	Hazard ratio (95% CI)	P
Demographic	Age	0.92 (0.88-0.97)	< 0.001
	Gender (male vs female)	1.6 (0.36-6.9)	0.54

Microembolism (yes vs no)	3.4 (0.85-13.5)	0.08

partial hepatectomy can be associated with a short-term risk for postoperative hepatic failure with a 5%-10% mortality and a 30%-50% morbidity<sup>[19,20]</sup> and with a long-term risk for tumor recurrence, affecting 80% of the patients at 5 years<sup>[21-24]</sup>. Since the recurrence of the tumor after partial hepatectomy is common, rescue medical, radiographic, and surgical therapies are often needed.

There are scanty data on the clinical outcome of OLT as a rescue operation for patients with recurrent HCC after the initial tumor resection. We evaluated 77 consecutive patients with OLT, of whom 15 patients had rescue OLT for recurrent HCC. All the 15 patients had concomitant liver cirrhosis. These patients all had postoperative single or multiple sessions of TACE and/or PEI. We found no difference in the overall and tumor-free survivals between the rescue OLT and *de novo* OLT groups, suggesting that OLT may be a valid option for patients with recurrent HCC after the tumor resection.

In addition to its application in advanced stage HCC, OLT can also be a valid treatment option for

patients with early stage tumors if partial hepatectomy is not amenable<sup>[25]</sup>, even though the survival advantage of OLT over partial hepatectomy in these patients has not been confirmed<sup>[26,27]</sup>. When compared with partial hepatectomy, OLT for resectable HCC may offer a survival benefit in a subset of patients as long as the donor organ is available within 6-10 mo<sup>[16]</sup>.

OLT has increasingly been performed for HCC where reported 1- and 2-year cumulative survival rates were 90.0% and 65.6%, and the disease-free survival rates were 77.5% and 62.5%, respectively<sup>[28]</sup>. The 3-year survival reached 77%-80%<sup>[29,30]</sup>. Poon *et al*<sup>[7]</sup> reported that a 5-year overall survival and tumor-free survival of OLT for patients with recurrent small HCC (diameter ≤ 3 cm) after initial tumor resection were 48% and 0%, respectively. The 5-year survival rate of 422 HCC patients with OLT was 44.4%, and histologic grade of HCC and tumor size (> 5 cm) were found associated with tumor-free survival<sup>[31]</sup>. Multiple factors may have contributed to the improvement in survival in HCC patients after OLT, including appropriate selection of candidate patients, the application of surgical techniques minimizing the risk for intraoperative tumor spread, and postoperative adjunct medical therapy.

The most commonly used criteria for transplantation for HCC patients are the Milan criteria: solitary tumor ≤ 5 cm in diameter or 2 or 3 tumor nodules with the largest diameter ≤ 3 cm and the absence of macroscopic vascular invasion or extrahepatic metastasis<sup>[11]</sup>. In the current study, we used the Shanghai Criteria<sup>[9]</sup>, i.e., tumor size ≤ 9 cm, number of tumors ≤ 3, the absence of macrovascular tumor embolism(s), and the absence of

extrahepatic metastasis. The main difference between the Milan Criteria and Shanghai Criteria was the tumor size with cut-off 5 cm vs 9 cm.

A variety of factors were reported to be associated with a poor surgical outcome after OLT, including large tumor size<sup>[13,28,31,32]</sup>, the presence of vascular invasion<sup>[13]</sup>, the presence of portal vein thrombosis<sup>[28]</sup>, and poor histologic differentiation<sup>[31]</sup>. In the current study, the risk factor associated with a poor survival were pre-OLT hyperbilirubinemia, the requirement of post-OLT blood transfusion, large tumor size, family history of liver cancer, and the presence of tumor microembolism. The recurrence of HCC after the tumor resection as an indication of OLT was not found associated with a poor survival outcome after OLT. Therefore, OLT appears to be a valid option as rescue operation for recurrent HCC after tumor resection.

Post-operative corticosteroid use may be associated with a high risk for tumor recurrence in patients with OLT. Mazzaferro *et al*<sup>[11,33]</sup> reported that discontinuation of corticosteroid use for 3-6 mo in HCC patients with OLT had a lower risk for tumor recurrence and post-operative long-term corticosteroid use had a 4-fold increase in tumor recurrence after OLT. In addition, post-operative corticosteroid use appears to pose a higher risk for post-operative infection and metabolic side effects. It appears that post-operative immunosuppression with omission of cortisosteroid use may be safe<sup>[34]</sup>. In our study protocol, all patients had corticosteroid tapering and discontinued the agent at one month after OLT.

There are some limitations to the study. First, this is not a randomized trial with a small sample size in the rescue OLT group ( $n=15$ ), which would have been subjected to a type II error. Second, longer follow-up would be needed. Finally, the study was conducted in a tertiary care center specializing in surgical treatment of HCC and other liver disorders and there might have been a selection bias.

In conclusion, there are no significant differences in survival/mortality rates between OLT as a *de novo* therapy and OLT as a rescue therapy for patients with HCC. Pre-OLT hyperbilirubinemia, post-OLT requirement of transfusion, large tumor size, and family history of HCC are associated with a poor survival outcome.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. Liver transplantation (LT) appears to be a valid rescue option for these patients. However, LT has not been routinely performed in patients with recurrent advanced HCC. Meanwhile, the risk factors of orthotopic liver transplantation (OLT) for HCC patients are unclear. So we hypothesized that OLT as a rescue operation for patients with recurrent HCC after initial resection surgery may have a similar outcome to these patients with HCC who had *de novo* OLT. The aims of the study were to compare post-OLT survival rates between patients who have recurrent HCC and those who have no history of resection surgery; and to evaluate risk factors associated with postoperative mortalities.

### Research frontiers

Liver transplantation is one of the hotspots in researches on liver tumors. But

few studies have tried to find the risk factors of OLT for HCC using the statistical method.

### Innovations and breakthroughs

No significant differences were found in survival/mortality rates between OLT as a *de novo* therapy and OLT as a rescue therapy for patients with HCC in this study. And Pre-OLT hyperbilirubinemia, post-OLT requirement of transfusion, large tumor size, and family history of HCC were found associated with a poor survival outcome.

### Applications

This study shows that there were no significant differences in survival/mortality rates between OLT as a *de novo* therapy and OLT as a rescue therapy for patients with HCC. And pre-OLT hyperbilirubinemia, post-OLT requirement of transfusion, large tumor size, and family history of HCC were associated with a poor survival outcome. The main limit in this research are the biology and genetics of tumors.

### Peer review

The authors described excellent results of the OLT for HCC patients using statistical methods. This article identified that recurrent HCC was not a risk factor of OLT. Meanwhile, pre-OLT hyperbilirubinemia, post-OLT requirement of transfusion, large tumor size, and family history of HCC play important roles in the prognosis of OLT. The findings are potentially important for planning of further studies.

the mirtazapine group and the lightest ( $11.39 \pm 1.45$  g) in the fluoxetine group ( $F_{(2,12)} = 11.43, P < 0.01$ ). The behavioral test on d 7 showed that the horizontal and vertical activities were significantly increased in the mirtazapine group compared with the fluoxetine and control groups ( $F_{(2,18)} = 10.89, P < 0.01$ ). These effects disappeared in the mirtazapine and fluoxetine groups during 2-6 wk. The grooming activity was higher in the mirtazapine group than in the fluoxetine group ( $10.1 \pm 2.1$  vs  $7.1 \pm 1.9$ ) ( $t = 2.40, P < 0.05$ ) in the second week. There was no significant difference in tumor volume and tumor weight of the three groups.

**CONCLUSION:** Mirtazapine and fluoxetine have no effect on the growth of pancreatic tumor. However, mirtazapine can significantly increase food intake and improve nutrition compared with fluoxetine in a pancreatic cancer mouse model.

Effect of antidepressants on body weight, ethology and tumor growth of human pancreatic carcinoma xenografts in nude mice. *World J Gastroenterol* 2008; 14(27): 4377-4382 Available from: URL: <http://www.wjnet.com/1007-9327/14/4377.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4377>

## INTRODUCTION

Pancreatic adenocarcinoma is the fourth leading cause of cancer-related death in the United States<sup>[1]</sup>. However, its incidence has increased steadily in China in recent years. At the time of diagnosis, 80% of patients present with either locally advanced or metastatic disease. In recent years, although gene therapy and biological targeting therapy can significantly inhibit the growth of pancreatic cancer in animal experiments, there is no satisfactory

therapy for pancreatic cancer patients to extend their median survival time and improve their quality of life. The overall five-year survival rate is less than 5%<sup>[2]</sup>.

The stress associated with the diagnosis and treatment of pancreatic cancer can cause significant psychiatric morbidity. It was reported that pancreatic cancer patients have the highest rate of major depression compared with other cancer patients<sup>[3]</sup>. Depression occurs in 47%-71% of patients with pancreatic cancer<sup>[4,5]</sup>. Unfortunately, depression adversely affects many clinical oncology outcomes. It can prolong hospital stay, augment the complication of therapy, decrease the ability to care oneself, reduce the compliance with medical treatment, lead to a poorer quality of life, and even shorten survival time<sup>[6-8]</sup>. Antidepressant medications not only improve depressive symptoms of patients with cancer but also reverse these adverse impacts<sup>[9]</sup>.

Clearly, antidepressant treatment constitutes one of the new strategies of cancer adjuvant therapy. However, data on treatment of depression with antidepressants in cancer patients are relatively scarce. The effect of different agents on distressing symptoms of cancer patients is still a subject for discussion. At present, selective serotonin reuptake inhibitor (SSRI) antidepressants are recommended as the first-line therapy for major depressive patients. Furthermore, mirtazapine is a new noradrenergic and specific serotonergic antidepressant (NaSSA), which stimulates 5-HT<sub>1</sub> receptors, but blocks serotonin 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors and histamine H<sub>1</sub> receptors<sup>[10]</sup>, which may be associated with increasing appetite and weight gain. Recent studies have shown that serotonin has been extensively implicated in the regulation of ingestive behavior<sup>[11,12]</sup>.

Therefore, we performed experiments using fluoxetine and mirtazapine as representatives of SSRI and NaSSA, respectively. The aim of the study was to study the effects of oral mirtazapine and fluoxetine on body weight, food intake, locomotion and tumor growth in a subcutaneous pancreatic tumor model.

## MATERIALS AND METHODS

### **Drugs and reagents**

Mirtazapine was kindly provided by Organon, Oss, the Netherlands. Fluoxetine was purchased from Eli Lilly & Co (Indianapolis, IN). RPMI1640 and fetal bovine serum were purchased from Gibco (Grand Island, NY).

### **Experimental animals**

BALB/c nu/nu male and female mice (5 wk old, weighing 17-20 g) of SPF class were purchased from the Experimental Animal Center, Guangzhou University of Chinese Medicine. The mice were housed under pathogen-free conditions in the Animal Center of Sun Yat-Sen University (4-5 mice per cage at 22 ± 1°C room temperature) with free access to water and standard rat chow, in a 12 h light-dark cycle.

### **Pancreatic cancer cell line and culture conditions**

Human pancreatic cancer cell line SW1990 was a kind

gift from the Second Affiliated Hospital of Sun Yat-Sen University. The cell line was maintained in RPMI 1640 supplemented with 10% fetal bovine serum (FBS). Monolayer cultures were maintained on a culture flask and incubated in a mixture of 50 mL/L CO<sub>2</sub> and 950 mL/L oxygen at 37°C. Trypsinization was terminated with a medium containing 10% FBS and the cells were washed once with a serum-free medium and resuspended in Hank's balanced salt solution. Only single-cell suspensions displaying greater than 90% viability were used for injection.

### **Establishment of subcutaneous xenograft model**

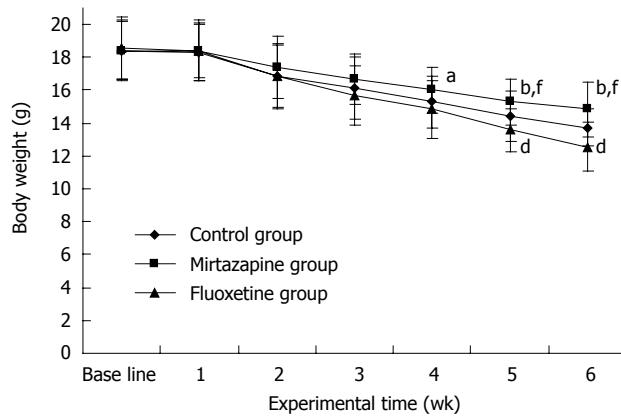

To produce SW1990 donor tumors, 3 × 10<sup>6</sup> cells per animal in a total volume of 0.2 mL were inoculated subcutaneously into the right flank of a nude mouse. Tumor size was measured *via* calliper. When the subcutaneous solid tumor reached approximately 1 cm in diameter and was aseptically removed from the donor animals. Macroscopically necrotic tissues and the remaining healthy tumor tissues were cut with scissors and minced into approximately 1 mm<sup>3</sup> pieces in Hanks' balanced salt solution containing 100 units/mL penicillin and 100 µg/mL streptomycin. A small incision was then made through the right dorsal flank and a tumor tissue piece was implanted subcutaneously beneath the dorsal flank skin of a nude mouse. We established a subcutaneous pancreatic cancer model as previously described<sup>[13]</sup> with certain modifications.

### **Experimental design**

After tumor transplantation, the mice were randomly assigned into three groups (7 mice each group). Treatment was initiated one day after tumor transplantation as the first day experiment. The first group received an equivalent normal saline solution as control. The second and third groups received 10 mg/(kg·d) mirtazapine and 10 mg/(kg·d) fluoxetine, respectively<sup>[14]</sup>, once a day for 42 d. Oral application was chosen as it is the standard application of antidepressants. For the study, the treated mice were closely monitored for any side effects and sacrificed on d 43. The transplanted tumor sizes were measured with a caliper, twice a week, and the tumor volume was calculated using the formula<sup>[15]</sup>: V = W<sup>2</sup> × L/2, where W is the width and L is the length of the tumor. Body was weighed biweekly and food intake was expressed as daily consumption in gram per animal weekly.

### **Open field test (OFT)**

OFT is a widely used test to evaluate the emotion and locomotor activity in rodents. As a test of spontaneous (unconditioned) behavior, it allows the animal to exhibit a wide range of behaviors and is therefore highly suitable for the study of complex phenomena such as anxiety or depression<sup>[16]</sup>. The open field apparatus used is a rectangular chamber (35 cm × 35 cm × 20 cm) made of plexigal, which was built from black walls and white floor. The floor of the open field was divided into 25 identical squares by 4 × 4 black lines<sup>[16]</sup>). A video camera

**Figure 1** Effects of antidepressants on body weight of nude mice. Data are represented as mean  $\pm$  SD. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs fluoxetine group, <sup>c</sup> $P < 0.01$  vs control group, <sup>d</sup> $P < 0.01$  vs control group.

was placed 1.5 m above the apparatus. After each trial, the apparatus was cleaned with water containing 0.1% acetic acid. The behavioral parameters registered during the first 5 min exposure to the open field apparatus were horizontal activity (the number of squares an animal entered), rearing known as vertical activity (the number of times an animal was standing on its hind legs with forelegs in the air or against the wall), grooming activity (the number of paws or tongues used to clean or scratch the body), which could reflect a stable individual trait "nonspecific excitability level". The OFT was performed weekly between 13:00 and 15:30. Any abrupt loud noise could markedly inhibit locomotion and even induce prolonged immobility of the mice. Therefore, the testing room was comprised merely of the background noise.

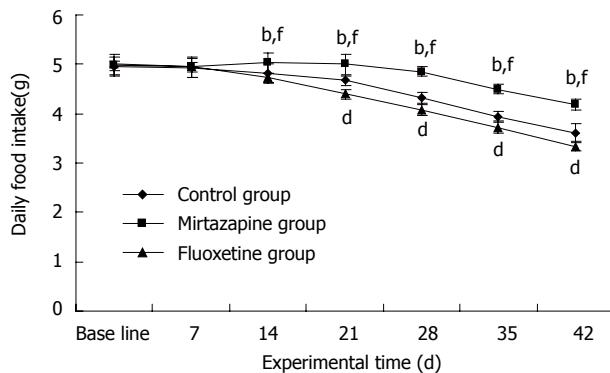

### Statistical analysis

Statistical analysis was performed with the SPSS 13.0 for Windows. Data were expressed as mean  $\pm$  SD. Pancreatic tumor weight, tumor volume and behavioral parameters were compared using one-way ANOVA. Significant differences in body weight and food intake were determined by two-way ANOVA and the Student-Newman-Keuls test for multiple comparisons between groups.  $P < 0.05$  was considered statistically significant based on a two-tailed test.

## RESULTS

### Effects of long-term antidepressant treatment on body weight

The change in body weight during the treatment is shown in Figure 1. The mice had a progressive weight loss. The body weight of mice in the three groups was very close in the first week. In the first 3 wk of treatment, the body weight of mice in the mirtazapine group was greater than that of mice in the other groups. However, no significant difference was observed. In wk 4, the body weight of mice was significantly greater in the mirtazapine group ( $16.00 \pm 1.41$  g) than in the fluoxetine group ( $14.86 \pm 1.77$  g) ( $F_{(2,12)} = 4.2$ ,  $P < 0.05$ ). The effect of mirtazapine lasted until the end of experiment. Nevertheless, the body

**Figure 2** Effects of antidepressants on food intake of mice. Data are represented as mean  $\pm$  SD. <sup>b</sup> $P < 0.01$  vs fluoxetine group, <sup>c</sup> $P < 0.01$  vs control group, <sup>d</sup> $P < 0.01$  vs control group.

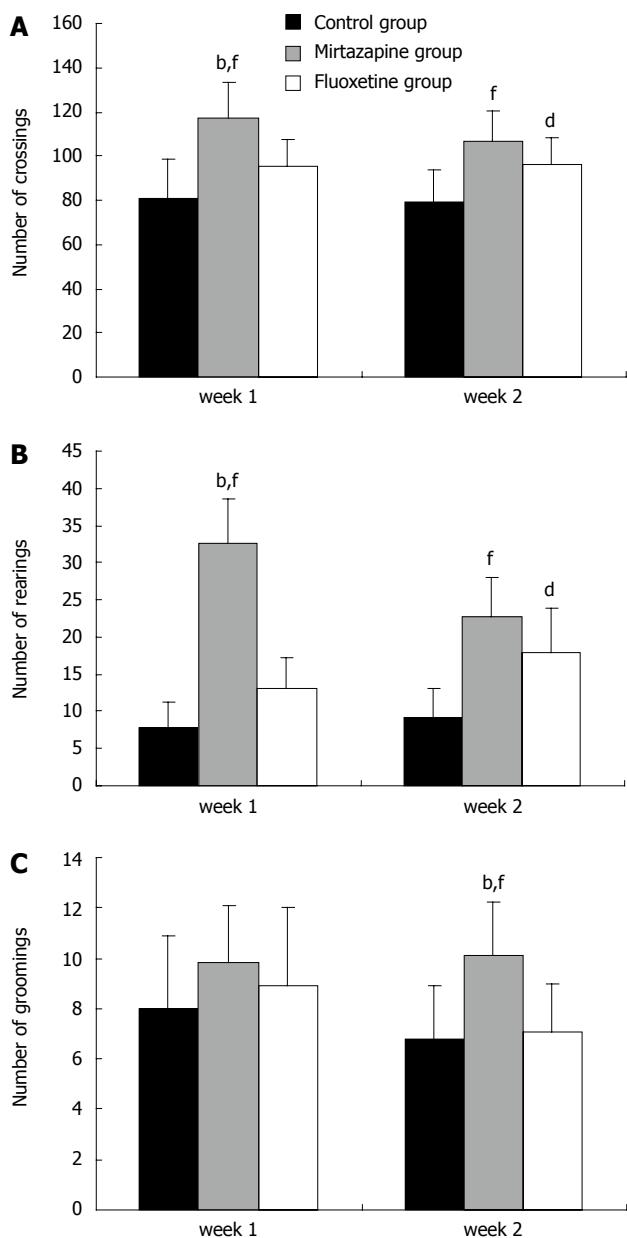

weight was significantly decreased in the fluoxetine group in week 5-6 compared with the control group ( $P < 0.01$ , Figure 1). The body weight of mice after removal of the tumor was also significantly increased in the mirtazapine group ( $13.66 \pm 1.55$  g) but decreased in the fluoxetine group ( $11.39 \pm 1.45$  g) compared with the control group ( $12.56 \pm 1.29$  g) ( $F_{(2,12)} = 11.43$ ,  $P < 0.01$ ).

### Effects of antidepressants on mice ingestive behaviour

Daily food intake of the tumor-bearing mice was gradually reduced over the whole treatment period (Figure 2). At initiation of the study, no difference was observed in ingestive behavior of mice in different groups. On day 14, food consumption of mice was significantly increased in the mirtazapine group ( $5.03 \pm 0.16$  g) compared with the fluoxetine ( $4.73 \pm 0.11$  g) and control groups ( $4.79 \pm 0.16$  g) ( $F_{(2,12)} = 23.31$ ,  $P < 0.01$ ). Mirtazapine exerted its effect to the end of experiment. However, fluoxetine treatment significantly decreased food consumption of mice compared with the control group from day 21 to 42 ( $P < 0.01$ , Figure 2).

### Locomotor behavior in open-field apparatus

Mirtazapine and fluoxetine significantly increased the locomotor activity of mice in the OFT. In the first week of behavioral test, the horizontal activity and vertical activity were significantly increased in the mirtazapine group ( $117.3 \pm 16.4$ ,  $95.3 \pm 13.6$ ) compared with the fluoxetine group ( $95.3 \pm 13.6$ ,  $13.0 \pm 4.2$ ) and control group ( $80.6 \pm 18.0$ ,  $7.9 \pm 3.4$ ) ( $F_{(2,18)} = 10.89$ ,  $F_{(2,18)} = 97.09$ ,  $P < 0.01$ , Figure 3A and B). There was no difference in grooming activity among the three groups. However, the grooming activity was significantly higher in the mirtazapine group ( $10.1 \pm 2.1$ ) than in the fluoxetine group ( $7.1 \pm 1.9$ ) ( $F_{(2,18)} = 4.90$ ,  $P < 0.01$ , Figure 3C) in the second week. Meanwhile, the horizontal and vertical activities were significantly increased in the mirtazapine and fluoxetine groups compared with the control group ( $P < 0.01$ , Figure 3A and B). Nevertheless, these parameters obtained from the mice treated with mirtazapine did not differ from those treated with fluoxetine during week 3-6.

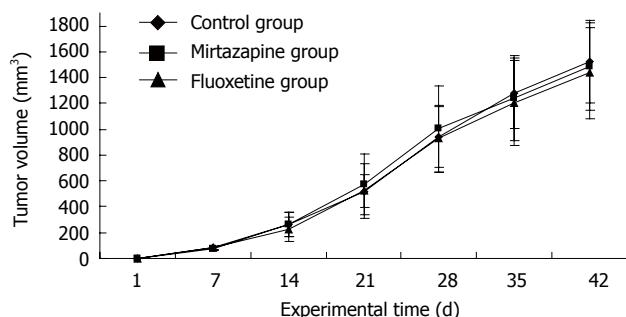

**Figure 3** Horizontal (A), vertical (B) and grooming (C) activity in pancreatic tumor-bearing mice in the OFT. Data are represented as mean  $\pm$  SD. <sup>b</sup> $P < 0.01$  vs fluoxetine group, <sup>d</sup> $P < 0.01$  vs control group, <sup>f</sup> $P < 0.01$  vs control group.

#### Effects of antidepressants on growth of pancreatic cancer *in vivo*

As shown in Figure 4, the tumor xenograft grew very rapidly with the prolongation of experiment. Nevertheless, no significant difference was observed in tumor volume of each group at any time point during the whole experiment. After 6-wk treatment, the animals were killed when the tumors were removed and weighed. However, no significant difference in tumor weight was detected in the mirtazapine group ( $1.18 \pm 0.20$  g), fluoxetine group ( $1.20 \pm 0.28$  g) and control group ( $1.23 \pm 0.34$  g) ( $F_{(2,18)} = 0.06$ ,  $P > 0.05$ ).

#### DISCUSSION

The results of the present study show that daily oral mirtazapine (10 mg/kg) could significantly increase

**Figure 4** Effect of antidepressants on the growth of pancreatic cancer xenografts. Data are represented as mean  $\pm$  SD.

food consumption and attenuated the rate of weight loss. However, treatment with fluoxetine (10 mg/kg) significantly suppressed food intake and promoted weight loss. Mirtazapine and fluoxetine showed their effects on the regulation of food intake and body weight to the end of experiment, suggesting that there is an extensive implication between serotonin and food intake. One explanation for the effects may be that the plasma half life of the two drugs is very long. It was reported that pharmacological agents that increase the levels of 5-HT in the central nervous system (CNS) suppress food intake, whereas drugs that antagonize the actions of 5-HT increase food intake<sup>[17]</sup>. Mirtazapine is a potent antagonist at postsynaptic 5HT<sub>2</sub> and 5HT<sub>3</sub> receptors which may potentially increase the appetite and body weight<sup>[18-20]</sup>. However, fluoxetine augments serotonergic activity by selectively inhibiting the reuptake of neurotransmitter, and reduces food intake and body weight in both animals<sup>[21, 22]</sup> and human beings<sup>[23]</sup>, and is thus used in the treatment of obesity<sup>[24]</sup>.

We examined the behavioral effects of mirtazapine and fluoxetine in the OFT. The horizontal activity fully reflected the animal activity, rearing the degree of curiosity to the novel surroundings, and grooming the level of alert against the novel environment. Mirtazapine and fluoxetine significantly increased the locomotor activity of pancreatic tumor-bearing mice compared with the control group. In the initial behavioral test, the horizontal activity was significantly increased in the mirtazapine group compared with the fluoxetine and control groups. Rearings were also significantly increased in the mirtazapine group compared with the fluoxetine and control groups (Figure 3A and B). Grooming activities increased earlier in the mirtazapine group than in the fluoxetine group. The results of the present study are consistent with the reported data<sup>[25, 26]</sup>, showing that antidepressants increase locomotor activity in a depressed model of normal rats. Nevertheless, mirtazapine adapted faster to the new environment and elevated earlier the alert of tumor-bearing mice against the novel environment. These findings indicate that mirtazapine is better than fluoxetine to tolerate the stress associated with the diagnosis and treatment of pancreatic cancer.

To our knowledge, the effect of mirtazapine and fluoxetine on the growth of pancreatic cancer in nude mice has not been reported. In the present study, the

tumor volume at any time points and tumor weight were not significantly different in the three groups. Interestingly, a previous study demonstrated that fluoxetine is neither a complete carcinogen nor a tumor promoter<sup>[27]</sup>, which is in agreement with our results obtained from pancreatic tumor-bearing mice. Moreover, Abdul *et al*<sup>[28]</sup> reported that the growth of subcutaneous PC-3 xenografts in athymic nude mice is significantly inhibited by antidepressants. Mirtazapine and fluoxetine also did not exhibit any toxicity throughout the whole treatment, suggesting that mirtazapine and fluoxetine can be safely used in the treatment of depression in pancreatic cancer patients.

Pancreatic cancer patients have not only distressing symptoms such as appetite loss, nausea, vomiting, weight loss, sleep disturbances and pain, but also psychiatric comorbidities such as adjustment disorder, depression frequently accompanying the disease process. It was reported that patients with pancreatic cancer have a weight loss of 83%-87% and approximately 30% of the patients have a weight loss of over 10%<sup>[29]</sup>.

In summary, mirtazapine as an adjuvant therapy is beneficial to the pancreatic cancer patients with depression<sup>[30]</sup>. Mirtazapine as the first-line therapy for depressed patients with advanced pancreatic cancer has a bright future. Nevertheless, further investigation and evaluation of mirtazapine are needed before it is widely used in clinical practice.

## COMMENTS

### Background

The treatment of pancreatic cancer remains a great challenge. The majority of patients with pancreatic cancer develop major depression. Depression adversely affects many clinical outcomes. Antidepressant treatment has been accepted as one of the new strategies in cancer adjuvant therapy. However, systemic studies on the treatment of depression in patients with cancer have not been well documented. The effect of different antidepressants on distressing symptoms of cancer patients is a subject for further evaluation.

### Research frontiers

At present, fluoxetine is one of the selective serotonin reuptake inhibitor (SSRI) antidepressants which are recommended as the first-line therapy for depression. Mirtazapine belongs to a new family of noradrenergic and specific serotonergic antidepressants (NaSSA) used in the treatment of major depression.

### Innovations and breakthroughs

On the basis of previous data, this was the first study examining the effects of mirtazapine and fluoxetine on the growth of pancreatic cancer in nude mice. The results of the present study show that mirtazapine could significantly increase food intake and attenuate the rate of weight loss in experimental mice. However, fluoxetine could significantly suppress food intake and promote weight loss in tumor-bearing mice.

### Applications

To summarize the actual application values, mirtazapine neither inhibits nor promotes pancreatic tumor growth according to the findings from this study. The results support the hypothesis that mirtazapine as an adjuvant therapy is superior to fluoxetine for pancreatic cancer patients with depression.

### Peer review

The title accurately reflects the major contents of the article. On the basis of

previous researches, this paper is an original research article on the effect of mirtazapine and fluoxetine on the growth of human pancreatic carcinoma in nude mice. The findings are of great interest and provide a foundation for their application in clinical practice. The conclusions are reliable and valuable.

category ( $\chi^2 = 30.82, P < 0.001$ ) and MLR ( $\chi^2 = 69.39, P < 0.001$ ) independently influenced the prognosis. A linear correlation between MLR and the 5-year survival was statistically significant based on the multiple linear regression ( $\beta = -0.63, P < 0.001$ ). Hypothetically, the 5-year survival would surpass 50% when MLR was lower than 10%.

**CONCLUSION:** The MLR is an independent prognostic factor for patients with advanced gastric cancer from the cardia and fundus. The decrease of MLR due to adequate number of total resected lymph nodes can improve the survival.

## Abstract

**AIM:** To investigate the prognostic impact of the metastatic lymph node ratio (MLR) in advanced gastric cancer from the cardia and fundus.

**METHODS:** Two hundred and thirty-six patients with gastric cancer from the cardia and fundus who underwent D2 curative resection were analyzed retrospectively. The correlations between MLR and the total lymph nodes, positive nodes and the total lymph nodes were analyzed respectively. The influence of MLR on the survival time of patients was determined with univariate Kaplan-Meier survival analysis and multivariate Cox proportional hazard model analysis. And the multiple linear regression was used to identify the relation between MLR and the 5-year survival rate of the patients.

**RESULTS:** The MLR did not correlate with the total lymph nodes resected ( $r = -0.093, P = 0.057$ ). The 5-year overall survival rate of the whole cohort was 37.5%. Kaplan-Meier survival analysis identified that the following eight factors influenced the survival time of the patients postoperatively: gender ( $\chi^2 = 4.26, P = 0.0389$ ), tumor size ( $\chi^2 = 18.48, P < 0.001$ ), Borrmann type ( $\chi^2 = 7.41, P = 0.0065$ ), histological grade ( $\chi^2 = 5.07, P = 0.0243$ ), pT category ( $\chi^2 = 49.42, P < 0.001$ ), pN category ( $\chi^2 = 87.7, P < 0.001$ ), total number of retrieved lymph nodes ( $\chi^2 = 8.22, P = 0.0042$ ) and MLR ( $\chi^2 = 34.3, P < 0.001$ ). Cox proportional hazard model showed that tumor size ( $\chi^2 = 7.985, P = 0.018$ ), pT

## INTRODUCTION

At present, patients with advanced gastric cancer from the cardia and fundus still have a poor prognosis despite some therapeutic modalities. Lymph node metastasis is considered one of the most important prognostic factors<sup>[1-3]</sup>. And lymphadenectomy is fundamentally critical in radical surgery. Its standardization highly depends on the accuracy of prognosis evaluation according to the classification of lymph node metastasis. The current American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) TNM system (1997) has established the classification

system based on the number of metastatic lymph nodes. D2 curative resection, which includes gastrectomy and D2 lymphadenectomy, required dissection of all the Group 1 and Group 2 nodes classified by anatomical location. However, with the development of D2 lymphadenectomy, larger lymph nodes dissected may enable to find larger metastatic lymph nodes, which induces a migration in the staging system. The ratio of the number of metastatic lymph nodes over the total number of resected lymph nodes is introduced to prognosis evaluation. It was reported that metastatic lymph node ratio (MLR) can minimize the stage migration effect caused by increasing total dissected lymph nodes, also can help refine the current TNM stage system<sup>[4,5]</sup>. Though many studies on the prognostic significance of MLR in gastric cancer have been carried out, relevant researches on advanced gastric cancer from the cardia and fundus are still rare. Therefore, the aim of this retrospective study was to discuss the clinical impact of MLR in patients with gastric cancer from the cardia and fundus, and provide further evidence for rational lymphadenectomy.

## MATERIALS AND METHODS

### Materials

Two hundred and thirty-six cases, diagnosed as primary gastric cancer from the cardia and fundus were treated with curative resection at the Department of Oncology, Affiliated Union Hospital of Fujian Medical University, Fuzhou China, between January 1996 and June 2002. The surgical procedure was defined as curative when no grossly visible tumor tissue (metastasis or lymph node involvement) remained after the resection and the resection margins were histologically normal. There were 197 male (83.5%) and 39 female (16.5%) patients aged from 30 to 79 years with a mean of  $58.8 \pm 9.8$  years. All patients received a D2 or more extended dissection of all the Group 1 and Group 2 lymph nodes or more according to the Japanese Classification of Gastric Carcinoma (JCGC)<sup>[6]</sup>. Among the 236 patients, total gastrectomy (TG) was performed in 190 patients, and proximal subtotal gastrectomy (PSG) in 46. Lymph nodes were meticulously dissected from the en bloc specimens, and the classification of the dissected lymph nodes was determined by specialized surgeons who reviewed the excised specimens after surgery based on the JCGC. Clinical and histopathologic data of each patient were collected and recorded in a specifically designed data collection form. The histopathologic spectrum included papillary adenocarcinomas (47/236, 20%), tubular adenocarcinomas (101/236, 43%), mucinous adenocarcinomas (29/236, 12%), poorly differentiated adenocarcinomas (36/236, 15%), undifferentiated carcinomas (8/236, 3%) and others (15/236, 6%) according to the World Health Organization classification system. Based on the 5th Edition of UICC TNM system<sup>[7]</sup>, T category is defined as follows: T2: tumor invades muscularis propria or submucosa; T3: tumor penetrates serosa without invasion of adjacent structure; T4: tumor invades adjacent structures. N

category is defined as follows: N0: no regional lymph node metastasis; N1: metastasis in 1 to 6 regional lymph nodes; N2: metastasis in 7 to 15 regional lymph nodes; N3: metastasis in more than 15 regional lymph nodes. Among our patients, there were 25 at stage pT2, 118 at pT3 and 93 at pT4, respectively, while there were 42 pN0, 97 pN1, 68 pN2 and 29 pN3 respectively. Finally, 48 cases (20%) were categorized as stage II, 128 (54%) as stage III and 60 (25%) as stage IV. All the patients received postoperative chemotherapy, using 5-FU as the dominant agent. No patient received postoperative radiotherapy. The follow-up was carried out by specialized investigators, who were trained about the follow-up system for clinical observation. The median follow-up for the entire cohort was 44 mo (range: 1-136 mo). A total of 222 cases were followed up with a rate of 94.0%.

### Methods

All calculations were performed using the SPSS 11.5 statistical package. Correlation analysis was made to find the relationship between MLR and the total lymph nodes, positive nodes and the total lymph nodes. Cumulative survival was determined via the Kaplan-Meier method, with univariate comparisons between groups through the log-rank test. Covariates that remained significant through the univariate analysis were selected for multivariate analysis. Cox regression was used for multivariate analysis, with a forward stepwise elimination model. A multiple linear regression model to correlate MLR with 5-year survival was obtained based on Kaplan-Meier 5-year survival estimates for each MLR interval, using midpoint of MLR interval as the independent variate. Significance of differences was assumed at  $P$  values of less than 0.05.

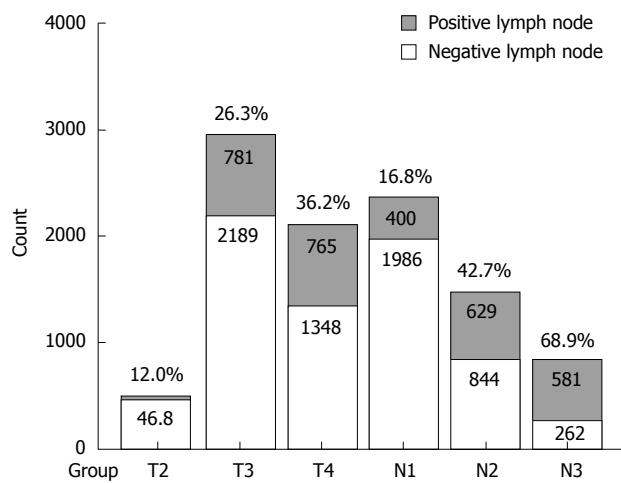

## RESULTS

### MLR of different pT/pN subcategories

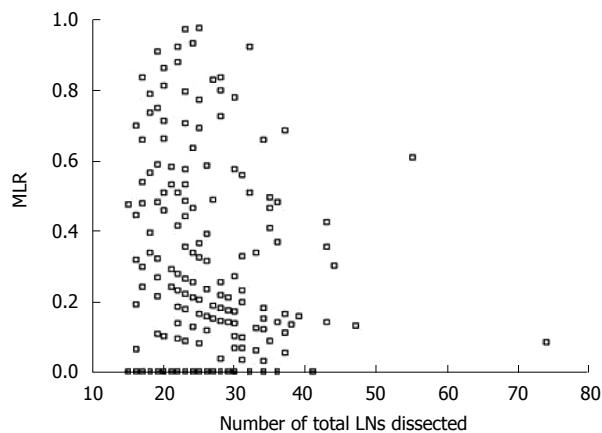

From the 236 cases, a total of 5615 lymph nodes were picked up and histologically examined, with 1610 positive and 4005 negative. The median total LN number was 23 (range 7-74, mean  $23.8 \pm 8.8$  per patient), the median number of positive LNs was 5 (range 0-44, mean  $6.8 \pm 6.8$  per patient), and that of negative LNs was 16 (range 0-48, mean  $16.9 \pm 9.3$  per patient). The MLRs were 12.0%, 26.3% and 36.2% in cases with pT2, pT3 and pT4, ( $\chi^2 = 138.9$ ,  $P < 0.001$ ), and 16.8%, 42.7% and 68.9% in cases with pN1, pN2, and pN3, respectively ( $\chi^2 = 820.7$ ,  $P < 0.001$ ). Figure 1 shows a trend of MLR according to different pT/pN subcategories. The MLR ascended as the invasion deepened, or the number of metastatic nodes increased.

### Correlation analysis between MLR and total lymph nodes, positive lymph nodes and total lymph nodes

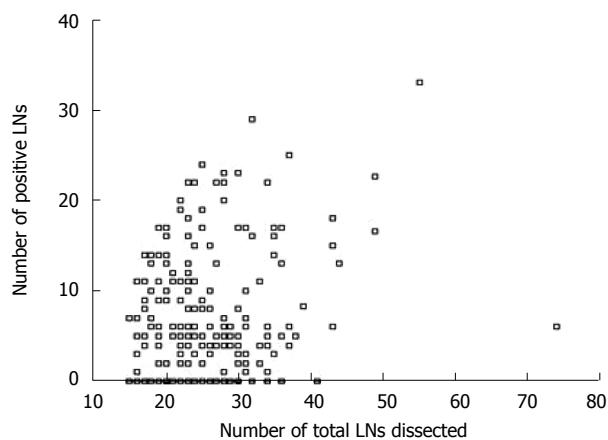

The MLR did not correlate with the total lymph nodes dissected ( $r = -0.093$ ,  $P = 0.057$ ), whereas positive lymph nodes did ( $r = 0.173$ ,  $P = 0.008$ ). Figures 2 and 3 show the scatters of these two groups. The results revealed that, in the same extent of lymphadenectomy, MLR

**Figure 1** MLR of different pT/pN subcategories.

**Figure 2** Scatter of MLR and total LNs dissected.

**Figure 3** Scatter of positive LNs and total LNs dissected.

would not increase with the number of total lymph nodes, but the number of positive lymph nodes would.

#### Univariate survival analysis

The 5-year overall survival rate of the entire cohort was 37.5%. The clinicopathological variables tested in the univariate analysis are shown in Table 1. Factors influencing the 5-year survival rate were patient gender

**Table 1** Univariate survival analysis of MLR and clinicopathological characteristics in 236 patients undergoing curative surgery

Characteristics	n	Median survival (mo)	5-yr survival (%)	$\chi^2$	P

<sup>1</sup>Borrmann's type: Macroscopic appearances of primary tumor, classified as Type I : polypoid tumors; Type II: ulcerated carcinomas with demarcated and raised margins; Type III: ulcerated carcinomas without definite limits, infiltrating into the surrounding wall; Type IV: diffusely infiltrating carcinomas.

( $P = 0.0389$ ), tumor size ( $P < 0.001$ ), Borrmann type ( $P = 0.0065$ ), histological grade ( $P = 0.0243$ ), pT category ( $P < 0.001$ ), pN category ( $P < 0.001$ ), total number of dissected lymph nodes ( $P = 0.0042$ ) and MLR ( $P < 0.001$ ). Patient age ( $P = 0.2777$ ) and type of gastrectomy ( $P = 0.0844$ ) had no significant influence on the survival.

#### Multivariate survival analysis

Multiple survival analysis was calculated by the Cox's proportional hazard regression model. In order to confirm the influence of MLR, the prognostic factors considered at univariate analysis were analyzed first by stepwise regression, including gender, tumor size, Borrmann type, histological grade, pT category, pN category and total number of dissected lymph nodes except MLR. As a result, there were four independent, statistically significant prognostic parameters: tumor

**Table 2 Multiple stepwise regression analysis with Cox proportional hazards model**

Characteristics	$\beta$	Wald	$P$	RR	95% CI for RR	
					Low	High
MLR excluded						
Tumor size		6.665	0.039			
3-6 cm vs < 3 cm	0.222	1.938	0.164	1.249	0.913	1.707
> 6 cm vs < 3 cm	0.501	6.636	0.010	1.650	1.127	2.414
pT category		27.747	0.002			
pT3 vs pT2	0.761	9.184	0.000	2.140	1.308	3.499
pT4 vs pT2	1.286	24.369	0.000	3.617	2.171	6.026
pN category		65.066	0.000			
pN1 vs pN0	0.618	9.792	0.002	1.855	1.260	2.733
pN2 vs pN0	1.224	30.727	0.000	3.402	2.206	5.244
pN3 vs pN0	2.156	57.470	0.000	8.639	4.947	15.090
Num of total LNs	-0.682	10.684	0.001	0.506	0.336	0.761
MLR included						
Tumor size		7.985	0.018			
3-6 cm vs < 3 cm	0.307	3.863	0.049	1.359	1.001	1.845
> 6 cm vs < 3 cm	0.512	7.353	0.007	1.668	1.152	2.415
pT category		30.821	0.000			
pT3 vs pT2	0.772	9.940	0.002	2.165	1.339	3.500
pT4 vs pT2	1.343	26.759	0.000	3.832	2.303	6.375
MLR	2.569	69.390	0.000	13.06	7.134	23.900

size ( $P = 0.039$ ), pT category ( $P = 0.002$ ), pN category ( $P < 0.001$ ) and total number of dissected lymph nodes ( $P = 0.001$ ). When MLR was included in the Cox's regression, the overall fit of the Cox model increased (likelihood ratio test with and without MLR: 397 and 305, respectively). Tumor size ( $P = 0.018$ ), pT category ( $P < 0.001$ ) and MLR ( $P < 0.001$ ) were remained to be independent prognostic factors, with MLR being the most significantly independent factor. The risk ratios and their 95% confident interval are listed in Table 2.

#### MLR impact on overall survival

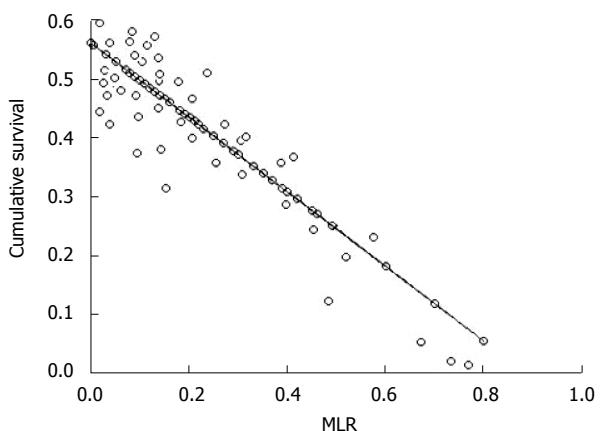

Linear trend test found that tumor size and MLR both had a linear correlation to the 5-year overall survival rate, and the correlation coefficients ( $r$ ) were  $-0.157$  ( $P = 0.019$ ) and  $-0.655$  ( $P < 0.0001$ ), respectively. Obviously, MLR showed a much stronger correlation than tumor size. Despite tumor size and overall survival related, only MLR can reach statistically significant differences according to the multiple linear regressions ( $P < 0.0001$ ). As shown in Table 3, the regression equation of the assumed statistically linearity was  $y = -0.63x + 0.56$ . Figure 4 presents a regression line of this calculated MLR effect on the 5-year survival. The hypothetical baseline 5-year survival (based on the  $y$ -intercept, i.e. MLR 0%) was 56%. For every 10% added to MLR, the calculated 5-year survival rate decreased by 6.3%. Hypothetically, the 5-year survival would surpass 50% when MLR was lower than 10%.

## DISCUSSION

Over the last few decades, the rising trends in incidence rates for upper third gastric cancer have been reported by many investigators around the world<sup>[8,9]</sup>. Cancer of the gastric cardia and fundus is commonly found in late

**Table 3 Estimation based on multiple linear regression model (stepwise method)**

Parameters	$\beta$	$t$	$P$	95% CI for $\beta$

MLR	-0.63	-10.4	0.000	-0.71 to -0.51
Intercept (constant)	0.56	19.0	0.000	0.48 to 0.59

**Figure 4** Regression line of MLR impact on the 5-year survival rate.

or the advanced stage at the initial diagnosis<sup>[10,11]</sup>. It was warranted to link the poor prognosis to lymph node metastases for cancer of this anatomical location reported with a higher frequency of perigastric lymph nodes and higher proportion of overall lymph node metastasis<sup>[12,13]</sup>. A prospective study conducted by de Manzoni *et al*<sup>[14]</sup> showed that 56.9% of patients with types II and III cardia cancer had nodal spread. Di *et al*<sup>[15]</sup> set up a research on lymph node involvement in gastric cancer for different sites, showing an involvement in 80.4% of cases for upper third cancers. In the present study, 82.2% of cases were found to have lymph node metastasis. And the overall MLR was 28.7%. These data confirmed the cited reports.

Lymph node metastasis is one of the most important prognostic factors for gastric cancer after curative resection. Methods of metastatic lymph nodes evaluation are still under investigation and being continuously improved, including some immunohistochemical methods, in order to predict the prognosis and guide the therapy. But few special proteins expressed in gastric cardia cancer, compared with non-cardia cancer. For example, with regard to the mucin phenotype, MUC1 and MUC5AC expression was less frequent in cardia carcinomas than in non-cardia carcinomas<sup>[16]</sup>. Therefore, lymph node status mainly depends on routine pathological examinations, previously based on the anatomical station of metastatic lymph nodes, and is classified by the number of metastatic regional lymph nodes<sup>[17-19]</sup>. The problem of lymph node classification based on number of metastatic ones is the stage migration, induced by larger lymph nodes dissected. Researches on prognostic impact of MLR have been done in patients with colon cancer, pancreatic cancer, breast cancer and other carcinomas<sup>[20-23]</sup> to find its advantage

in predicting survival outcome after curative resection. MLR was introduced as a more reliable prognostic factor for gastric cancer<sup>[24,25]</sup>. In our study, a greater MLR was associated with poorer survival by univariate analysis. Multivariate analysis further identified that the MLR was a most important independent prognostic factor among the other factors evaluated, including pN category. This phenomenon was in agreement with those reported by some other investigators. It may be a superior indicator for lymph node classification system. Relevant data were reported about the grouping of patients with gastric cancer with lymph node metastasis ratios. By imitating the pN category of UICC/AJCC, most researchers selected three or four different groups. Different N ratio cutoffs have been proposed<sup>[26-29]</sup>, such as 0%, 1% to 9%, 10% to 25%, > 25%; 0%, < 25%, < 50%, > 50% and so on. Many authors did not describe a specific method for the selection of the reported cutoffs. Hyung *et al*<sup>[30]</sup> discovered that the cutoff values were 10% for T3N1M0 and 25% for T3N2M0 by analysis of the prognosis according to MLR. In the present study, we found the 5-year survival would surpass 50% when MLR was lower than 0.10.

Our study also showed that MLR can reflect the number of LNs examined and the quality of LN dissection. Curative resection was the determining factor to improve the 5-year survival in this type of tumor<sup>[31]</sup>. Although D2 radical resection for patients with cancer of gastric cardia and fundus is widely accepted<sup>[32]</sup>, how many lymph nodes should be removed to accurately predict clinical outcome has not been determined. Barbour *et al*<sup>[33]</sup> suggested patients with Siewert types II and III adenocarcinoma of the GEJ should undergo adequate lymphadenectomy to permit examination of  $\geq 15$  lymph nodes allowing the accurate identification of prognostic variables. Removal of  $\geq 15$  lymph nodes is associated with more accurate survival estimates for patients with advanced disease. Gee *et al*<sup>[34]</sup> stated that preferably 20-25 lymph nodes were necessary for determining prognosis and treatment for tumors of the gastroesophageal junction. In the present study, MLR did not correlate with the total lymph nodes while the number of metastatic LNs did. This finding indicated that the extent of lymphadenectomy was adequate when MLR value did not fluctuate with the resected number of lymph nodes. Obviously, it requires a certain amount of lymph nodes to be dissected. McKee *et al*<sup>[35]</sup> pointed out, MLR may be confounded by the small number of nodes examined from each patient, it should not be used for prognostic information in patients with fewer than 15 nodes examined. The median total LN number was 23 (mean  $23.8 \pm 8.8$  per patient) in this study, so we suggested D2 lymphadenectomy in order to ensure adequate dissection.

In conclusion, MLR has advantages in providing a more precise prognostic evaluation. We should pay attention to the clinical impact of MLR on prognosis of gastric cancer located in cardia and fundus when performing a D2 radical resection. It is warranted to make efforts to reduce MLR, preferably lower than 10%, in order to achieve better therapeutic efficiency.

## COMMENTS

### Background

The incidence rates of gastric cancer located in cardia and fundus have increased in recent years. Though the staging system of gastric cancer refines step by step, staging techniques never stop updating. So far, few studies have investigated the relative contribution of metastatic lymph node (LN) ratio to the prognosis evaluation with advanced gastric cancer from cardia and fundus.

### Research frontiers

Some researches have shown that metastatic lymph node ratio (MLR) is an excellent predictor for survival outcome in patients with colon cancer, pancreatic cancer, breast cancer and other carcinomas. Some related studies on gastric cancer also found the potential of the MLR on prognostic evaluation, but without a consensus on stratification cutoffs, especially lack of data for advanced gastric cancer located in cardia and fundus.

### Innovations and breakthroughs

The authors retrospectively reviewed 236 patients with gastric cancer from cardia and fundus who were treated with D2 radical resection in a hospital in Fujian between 1996 and 2002, to investigate the validity of metastatic LN ratio as a prognostic factor. The study not only divided MLR into some different grades for survival analysis, but also set up a regression to discover the relation between MLR and survival.

### Applications

The authors suggest that metastatic LN ratio can provide more dependable and accurate information on the extent of LN metastasis and lymphadenectomy for advanced gastric cancer located in cardia and fundus. Moreover, it is an important prognostic factor and can provide further evidence for rational lymphadenectomy.

### Peer review

This is an interesting and well-done study investigating the prognostic role of MLR in cancer of gastric cardia and fundus. This is a well-written and significant paper.

of sarcomatoid carcinoma remain speculative. To the best of our knowledge, this is the first report of co-existence of sarcomatoid carcinoma and invasive adenocarcinoma with tubulovillous adenoma; all stages represented within the same tumor. This observation supports the "monoclonal theory" of pathogenesis with an adenoma-sarcoma progression with or without an intermediate stage of carcinoma.

## Abstract

Sarcomatoid carcinomas of the colorectum are rare tumors that display both malignant epithelial and stromal components. Clinically, they are aggressive tumors with early metastasis. Due to their infrequent occurrence, the pathogenesis is poorly understood. We report a case of a 52-year-old woman who presented with a rectal mass and intermittent hematochezia. Superficial biopsies during colonoscopy revealed a tubulovillous adenoma with high-grade dysplasia. Endoscopic ultrasound confirmed an invasive nature of the mass, and deeper biopsies revealed the presence of neoplasm with mixed histological components. The surgically-excised specimen demonstrated the presence of poorly differentiated spindle cells underneath the tubulovillous adenoma and an intermediate stage of invasive adenocarcinoma. Based on the histological appearance and immunohistochemical studies, a diagnosis of sarcomatoid carcinoma was made. Only nine cases of sarcomatoid carcinomas of the colorectum have been reported to date. As a result, the terminology and pathogenesis

## INTRODUCTION

Sarcomatoid carcinoma is a rare malignant tumor characterized by a combination of epithelial and mesenchymal elements. Over the past 100 years, sarcomatoid carcinomas have been increasingly recognized at different anatomic locations including the head and neck, respiratory tract, and female reproductive organs<sup>[1-3]</sup>. Within the gastrointestinal tract, the oropharynx and esophagus are the most commonly affected areas<sup>[1,4-7]</sup>. To our knowledge, sarcomatoid carcinomas rarely occur in the colon, with only nine cases reported in the English literature<sup>[8-12]</sup>. A possible reason is likely due to their marked similarity to malignant mesenchymal tumors, such as gastrointestinal stromal tumors, malignant fibrous histiocytoma, and leiomyosarcoma<sup>[12-16]</sup>. As a result, the natural history, pathogenesis, and treatment of these unusual tumors are poorly understood. In general, sarcomatoid carcinoma of the colon has been described as an aggressive neoplasm with an associated poor prognosis.

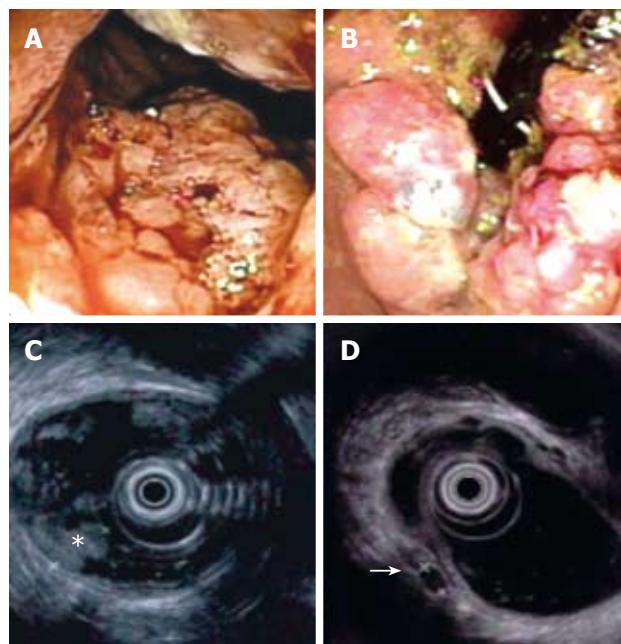

First described by Virchow in 1864, a variety of terms

have been used to describe sarcomatoid carcinomas. They include carcinosarcoma, pseudosarcomatous carcinoma, carcinoma with mesenchymal stroma, and spindle cell carcinoma<sup>[17]</sup>. These varied terminologies for sarcomatoid carcinomas reflect the uncertainty of its histogenesis and classification. Several theories have been proposed to explain the histopathogenesis of sarcomatoid carcinoma; however, these theories remain speculative.

We report an unusual case of a mixed rectal tumor containing a superficial tubulovillous adenoma with deeper areas of high-grade malignant spindle cells and an invasive adenocarcinoma; all stages represented within the same tumor. This could support an adenoma-to-sarcomatoid progression either directly or indirectly via an intermediate stage of adenocarcinoma. In addition, we discuss the basis of pathologic diagnosis, proposed theories regarding its histopathogenesis and review the clinical features of this heterogenous tumor.

## CASE REPORT

A 52-year-old white female presented to the emergency department with a prolapsed rectal mass and intermittent rectal bleeding over the past 10 years. Until presentation, she had attributed her symptoms to hemorrhoidal disease and had performed digital reduction of the prolapsed ‘mass’ from time to time. Increased bleeding and frequency of prolapse made her seek medical attention. Her past medical history was unremarkable; however, there was a family history of colon cancer in her father. Physical examination revealed a large, firm, ulcerated mass that prolapsed from her rectum. Serum levels of carcinoembryonic antigen (CEA) and carbohydrate antigen (CA) 19-9 were not elevated. Colonoscopy confirmed the presence of a large sessile exophytic rectal growth with a velvety, multi-lobulated surface, just proximal to the dentate line (Figure 1A and B). Several biopsies were performed using a jumbo forceps, which revealed a tubulovillous adenoma with high-grade dysplasia. However, the possibility of an adjacent invading tumor beneath the tubulovillous adenoma could not be ruled out given the lack of depth from the biopsy. An extensive staging workup including a CT scan of the chest and abdomen showed no signs of distant metastasis. To further evaluate the tumor for any presence and extent of local invasion, a rectal endoscopic ultrasound (EUS) was performed. At EUS, the invasive nature of the mass became apparent as the tumor invaded into the lamina propria and into the muscularis mucosa (Figure 1C, star). Additionally, an 8-mm hypoechoic well-defined malignant-appearing lymph node was found adjacent to the mass, suggestive of lymphatic metastasis (Figure 1D, arrow). During this procedure, a 1-cm × 1-cm piece of the tumor was snared off to obtain deeper sections of the mass for further histopathological diagnosis, and which demonstrated a neoplasm with mixed histological components consisting of tubulovillous adenoma (Figure 2A and B) and poorly differentiated spindle cells (Figure 2C to E). Subsequently, the patient underwent an abdominoperineal resection of this mass. *Ex-vivo* pathologic analysis of the surgically re-

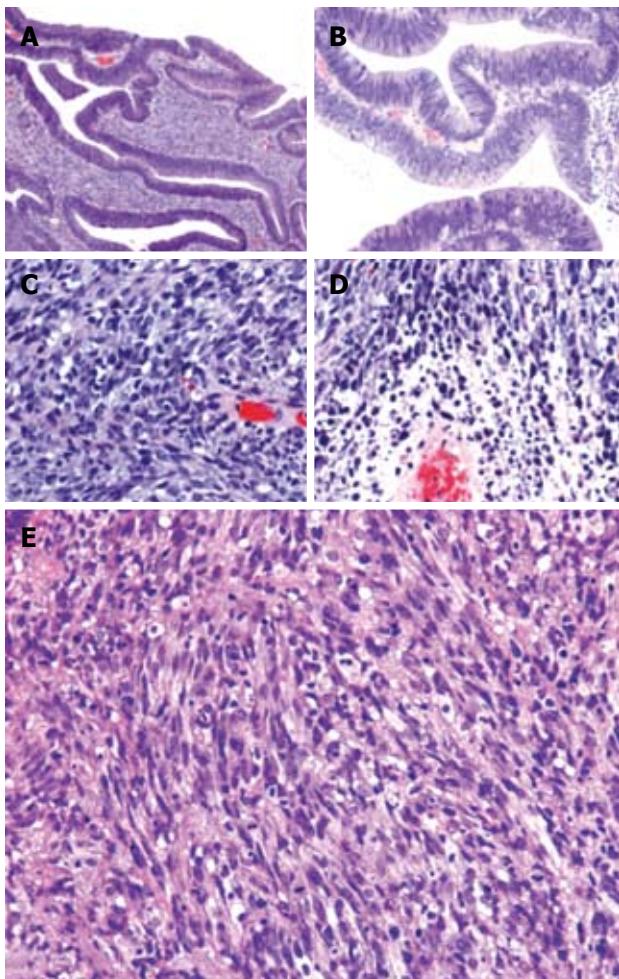

**Figure 1** Colonoscopy demonstrates. **A:** Large sessile polypoid growth with velvety surface and superficial ulceration in the rectum (forward view); **B:** Multilobulated, smooth surfaced exophytic nature of the tumor upon retroflexion. Sonographic images at rectal EUS showing; **C:** An infiltrative mass with invasion of the muscularis mucosa (star); **D:** An 8-mm hypoechoic lymph node suspicious for lymphatic metastasis (arrow).

moved rectum showed a superficial layer of tubulovillous adenoma with high-grade dysplasia arising just proximal to the dentate line and extending 6.2 cm proximally (Figure 3A and B). Its deeper sections featured islands of intermediate stage invasive adenocarcinoma with poorly organized glandular structures (Figure 3C) within a background of poorly differentiated sheets of spindle cells. Immunohistochemical studies showed strong positivity for cytokeratin in both epithelial and stromal components of the tumor (Figure 3D). Histological analysis of all 41 lymph nodes showed no evidence of metastasis including the 8-mm hypoechoic lymph node seen on EUS. Based on the histological appearance and immunohistochemical studies, a diagnosis of sarcomatoid carcinoma was made. The disease was clinically staged according to the American Joint Committee on Cancer as a Stage I (T1N0M0) colorectal cancer. The patient’s postoperative course was uneventful and she remains free of tumor recurrence or metastasis after an 8-mo follow up.

### Case tissue

Tissue from the rectal tumor was fixed in 10% neutral buffered formalin, embedded in paraffin wax, sectioned at 4 µm in thickness, floated onto positively charged slides, and dried overnight at 70°C. From each block, 5 micron thick sections were cut and stained with haematoxylin and eosin (HE). For immunohistochemical analysis, the avidin-biotin complex method was used with the following antibodies: pancytokeratin (Figure 3D), vimentin (Figure 3E), smooth muscle actin (SMA), S100, Bcl-2, CD34, smooth muscle myosin (SMMS), p53 (Figure 4A), CD117 (Figure 4B), desmin, and PDGFR-alpha

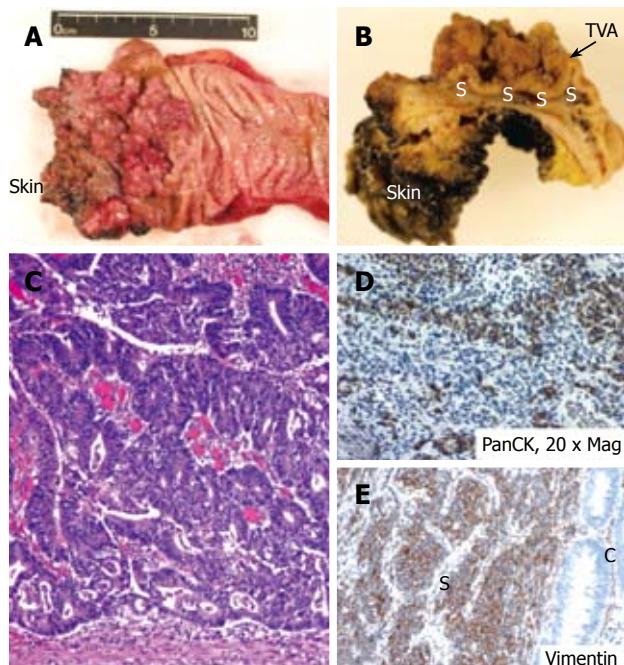

**Figure 2** Histology of the rectal biopsy using HE stains. **A:** Tubulovillous adenoma and underlying spindle cell tumor. The aggressive spindle cell lesion infiltrates directly underneath the adenoma ( $\times 10$ ). **B:** A higher magnification view of the adenomatous component ( $\times 20$ ). High-grade spindle cell lesion ( $\times 40$ ) showing: **C:** Cigar shaped nuclei, nuclear pleomorphism, a high nucleus/cytoplasm ratio within the deeper sections; **D:** Tumor necrosis; **E:** Smooth muscle-like spindle sheets of cells in the sarcomatoid component ( $\times 40$ ).

(Figure 4C). The immunohistochemical profile is listed in Table 1. Appropriate positive and negative control tissues were incubated in parallel with the case slides to confirm the specificity of each antibody.

### Gross findings

The surgical specimen consisted of a sigmoid and rectal segment measuring about 36.5 cm in length with a luminal diameter varying from about 4.8 cm at the proximal end to 8.0 cm at the distal end (Figure 3A and B). Located at the distal end of the specimen was an exophytic, circumferential, and fungating mass measuring about 5.5 cm in length along the gastrointestinal tract, rising approximately 1.3 cm from the luminal surface, with a greatest diameter of 6.2 cm. Just distal to the fungating mass was a squamous anal mucosa measuring about 0.8 cm in length. The remainder of the colonic mucosa was covered by small papules, which were slightly whiter than the gray mucosal background and measured about 0.1-0.3 cm in greatest dimension. These papules covered about 80% of the total surface of the colon and were most prominent in the

**Figure 3** Gross appearance of the surgically-removed rectosigmoid mass (**A** and **B**). **A:** The luminal side view demonstrates the proximity to the dentate line; anal skin is labeled for orientation; **B:** Upon sectioning the sample through the sagittal plane, the lateral view identifies the sarcomatoid smooth component (marked as S) underneath the velvety tubulovillous adenoma component (marked as TVA); **C:** Invasive adenocarcinoma with high nucleus/cytoplasm ratio within the deeper sections; **D:** Pancytokeratin was diffusely positive in both epithelial and mesenchymal components ( $\times 20$ ); **E:** Vimentin showed expression in the sarcomatous (S) component only, with no staining in the carcinoma (C) portion.

**Table 1 Antibodies used for histological evaluation of the tumor, and a summary of the results**

Antibody	Concentration	Company	Result
Smooth muscle actin (SMA)	1:2	Dako	Negative
S100	1:1000	Zymed	Negative
Bcl-2	1:60	Dako	Negative
CD34	1:30	Becton Dickinson	Negative
PDGFA- $\alpha$	1:120	Santa Cruz Biotechnology	Non-contributory
Smooth muscle myosin (SMMS)	1:100	Dako	Negative
CD117	1:150	Dako	Negative
Desmin	1:100	Dako	Negative
Vimentin	1:100	Dako	Negative
p53	1:100	Dako	Positive
Pancytokeratin	1:100	Zymed AE1/AE3 Becton Dickinson Cam 5.2	Patchy positive

distal area near the fungating mass. No ulcers or strictures were noted. Forty-one lymph nodes were isolated from the adipose tissue surrounding the bowel wall and were negative for any evidence of metastasis.

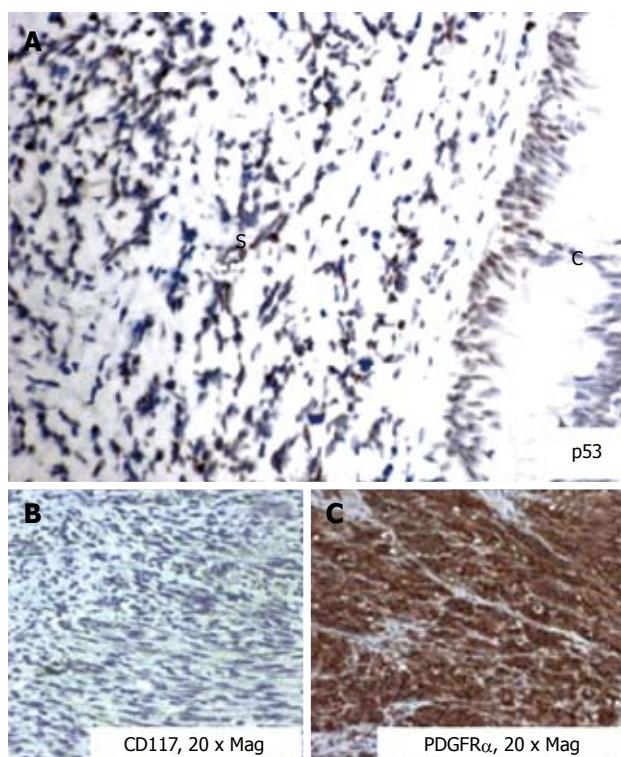

### Histological findings

The initial superficial biopsies from the large rectal mass showed a tubulovillous adenoma with high-grade dysplasia; however, the possibility of adjacent invasive tumor could not be ruled out given the lack of depth from the

**Table 2 Summary of demographics and outcome of cases reported in the English literature with the diagnosis of colorectal sarcomatoid carcinoma**

Case	Author, yr	Age (yr)	Sex	Site	Distant metastasis	Outcome
1	Weidner, 1986	73	M	Sigmoid	On follow up	4 yr, DOD
2	Chetty, 1993	72	F	Cecum	On initial visit	3 mo, DOD
3	Roncaroli, 1995	71	F	Rectum	On follow up	6 mo, DOD
4	Isimbaldi, 1996	86	F	Ascending colon	None	2 yr, disease free

DOD: Died of disease.

**Figure 4** Immunohistochemical characteristics of the resected tumor showed. **A:** p53 was expressed in both carcinomatous (C) and sarcomatous (S) components within the tumor, with a relative increase in the latter; **B:** Staining for CD117 was negative; **C:** PDGFR stained diffusely positive in both the components (x 20).

biopsies. Subsequently, a larger piece of tumor tissue, obtained during a EUS procedure, revealed a neoplasm with mixed histological components consisting of high-grade spindle cells and a tubulovillous adenoma (Figure 2). The high-grade spindle cell tumor showed cigar shaped nuclei, nuclear pleomorphism, a high mitotic rate, a high nucleus/cytoplasm ratio, and central necrosis (Figure 2C-E). The spindled cells appear to infiltrate from the deep aspect of the biopsy into the mucosa and surround the adenomatous glands in an aggressive fashion. The tubulovillous adenoma, similar to the previous biopsy, contained abundant dysplastic epithelial glands with very few mucus.

The surgical specimen of the sigmoid colon and rectum revealed an invasive well-differentiated adenocarci-

noma in a background of a large tubulovillous adenoma (Figure 3C). In addition, there was a focal sarcomatous component consisting of high-grade spindle cells. The carcinoma was composed of neoplastic epithelial cells, arranged in nests forming glandular structures with increased nuclear/cytoplasmic ratio and prominent nucleoli. The invasive carcinoma was confined to the submucosa (pT1) without gross or microscopic evidence of muscular invasion. Surgical margins were free of tumor and there was no evidence of metastasis in all 41 lymph nodes. According to the TNM classification, the pathological stage was pT1N0.

#### Immunohistochemistry

Immunohistochemical analysis revealed focal, but strong staining for pancytokeratin (Figure 3D), focal staining for vimentin (Figure 3E), smooth muscle actin, and patchy cell clusters of desmin in the spindle cell component of our specimen. Although staining for p53 revealed immunoreactivity in both the epithelial and sarcomatous components, it was relatively increased in the sarcomatous component (Figure 4A). In addition, the sarcomatous component was weakly positive for CD34 and Bcl-2, but negative for CD117 (Figure 4B). The epithelial component was diffusely immunoreactive to pancytokeratin and negative to smooth muscle actin, desmin, CD34, CD117, and Bcl-2. Since there is a subset of gastrointestinal stromal tumors that are negative for CD117 and positive for PDGFR- $\alpha$ , we performed an immunohistochemical staining for PDGFR- $\alpha$ , which stained diffusely positive in both the spindle and epithelial cells of the overlying tubulovillous adenoma (Figure 4C). Taken together, the strong cytokeratin staining and the focal positivity for smooth muscle markers, the tumor adjacent to the tubulovillous adenoma was diagnosed as sarcomatoid carcinoma rather than a carcinosarcoma or CD117-negative GIST.

#### DISCUSSION

Sarcomatoid carcinoma of the colon is a rare clinical and pathological entity. To the best of our knowledge, only nine cases of colonic sarcomatoid carcinoma have been reported in the English literature (Table 2), the present case being the tenth. Histologically, sarcomatoid carci-

nomas of the colon contain both epithelial and mesenchymal components. The epithelial component of these tumors mainly consists of high-grade adenocarcinoma, while the accompanying sarcomatous component often demonstrates a spindled appearance with varying degrees of mesenchymal-like differentiation.

The nomenclature of these bi-differentiated tumors has been a matter of debate despite the advent of immunohistochemistry and electron microscopy. In the past, the term pseudosarcoma was used to describe the condition in which the epithelial component was malignant and spindle cells were benign<sup>[17-19]</sup>. Later, Matsusaka *et al* showed that pseudosarcoma and sarcomatoid carcinoma were histologically and clinically the same conditions<sup>[20]</sup>. Moreover, several reports have used carcinosarcoma interchangeably to describe sarcomatoid carcinoma, further confusing the diagnosis and classification of these tumors<sup>[13,16,21]</sup>. Rosai J explained that when the sarcomatous component is mainly composed of spindle cells but still identifiable as epithelial ones morphologically or immunohistochemically, the diagnosis should be called sarcomatoid carcinoma<sup>[22]</sup>. However, when sarcomatous components reveal typical specialized differentiation such as obvious striation of rhabdomyosarcoma or osteoid produced by malignant neoplastic cells, the diagnosis should be called carcinosarcoma<sup>[22]</sup>. For cases without any histologically-identifiable differentiation, immunostaining for cytokeratin or other epithelial markers may help in determining whether the neoplasm matches the qualifications for sarcomatoid carcinoma or carcinosarcoma. The common denominator of all sarcomatoid carcinomas is the immunoreactivity of epithelial markers such as cytokeratin for both the sarcomatous and epithelial components. However, if sarcomatous elements do not express epithelial markers, the term carcinosarcoma is the preferred diagnosis<sup>[17,23]</sup>. In our case, both the sarcomatous and epithelial components were immunoreactive to pancytokeratin, confirming our diagnosis of sarcomatoid carcinoma.

The histogenesis of sarcomatoid carcinoma remains unclear and controversial despite more than a century of conjecture. Proposed explanations of the bi-differentiated appearance include the multiclonal hypothesis on one hand, and on the other hand the "collision theory", suggesting that the two tumor components are derived from separate and distinct malignant cell clones<sup>[5,24]</sup>. Other investigators suggest a clonal origin (monoclonal hypothesis) of the tumor since common characteristics have been seen between the different cellular populations as well as an observed transitional population<sup>[25,26]</sup>. For example, the presence of cytokeratin in spindle cells within sarcomatoid carcinomas of various anatomical locations supports the epithelial origin of these cells<sup>[17,19,27,28]</sup>. The observed characteristics in the monoclonal hypothesis could either be due to a malignant transformation of a pluripotent stem cell capable of epithelial and mesenchymal differentiation or the sarcomatous element arising from a metaplastic transformation of the carcinomatous element. Some postulate that this sarcomatous transition from carcinomatous cells could be related to retrovirus infection<sup>[29]</sup>. Sarcomatoid carcinomas demonstrated very rarely to be

"collision tumors" with sharply defined sarcomatous and carcinomatous components without any shared or transitional features. There is, however, strong molecular evidence that supports the monoclonal origin of most sarcomatoid carcinomas<sup>[30]</sup>. Several genetic studies involving loss of heterozygosity (LOH) with microsatellite markers and pattern of X chromosome inactivation have demonstrated a common origin of the admixed components<sup>[31,32]</sup>. In addition, Delahunt *et al* described progressive accumulation of p53 proteins in the phenotypic conversion of carcinoma into sarcomatoid phenotype, thus indicating an increasing clonal dominance of dedifferentiated tumor cells carrying p53 mutations<sup>[33]</sup>.

In our case, the surgically removed rectal tumor demonstrated both tubulovillous adenoma and adenocarcinoma adjacent to each other with sarcomatous elements right beneath the tubulovillous adenoma. This histological finding strongly suggests that the two components originated from a multipotent epithelial cell, and that the sarcomatous components originated with differentiation from adenoma to sarcomatoid phenotype during tumor progression through an intermediate stage of adenocarcinoma. To further support a monoclonal origin and a possible tumor progression sequence in our case, immunohistochemistry for p53 protein showed increasing accumulation of p53 from tubulovillous adenoma to adenocarcinoma and finally to the sarcomatous area (Figure 4A). The adenoma-to-carcinoma sequence is well known; however little is known whether the sarcomatous phenotype is part of this tumor progression sequence. To our knowledge, this is the first case that demonstrates a clear histological adenoma-adenocarcinoma-sarcomatoid phenotype sequence progression all in one image.

Clinical features of all ten cases (including our present report) showed a mean age of 68 years (range 41-86) and a slight predilection for females (Table 2). Sarcomatoid carcinomas can be located anywhere in the large bowel, but a preference for the distal colon (including the descending colon, sigmoid colon, and rectum) is seen in most cases. Lymph nodes and distant sites of metastasis disclose a predominance of the malignant epithelial component. However, only one case has shown metastasis from the sarcomatous element, indicating the aggressive nature of the epithelial component<sup>[13]</sup>. Despite radical surgery, chemotherapy, or radiotherapy, prognosis for sarcomatoid carcinoma of the colon remains poor. Seven cases revealed distant metastasis either at initial or follow-up visit, and six of the ten cases died within five years of diagnosis. Due to the rarity of cases, no specific conclusions can be made regarding prognostic factors.

Treatment for sarcomatoid carcinomas of the colon should follow similar guidelines for colonic adenocarcinomas, as no specific treatment guidelines are available for the management of this tumor. In addition, extensive follow-up should be warranted given the poor prognosis associated with this rare clinical entity. Nine of the ten reported cases (including ours) of colonic sarcomatoid carcinomas have undergone resection of the primary tumor; however, only two of the ten cases have survived over the

past two years despite adjuvant therapy. In a recent 8-mo follow-up, our patient is still alive with no evidence of metastasis after surgical resection of the primary tumor.

In summary, sarcomatoid carcinoma of the colon is a highly aggressive neoplasm that leads to a poor patient outcome despite clinical intervention. Endoscopic biopsy specimens containing lesions with spindle cell morphology should raise the differential diagnosis of sarcomatoid carcinoma with immunostaining for cytokeratin to help confirm the diagnosis. The histogenesis of sarcomatoid carcinoma is still unclear; however, the morphological appearance and immunohistochemical analysis of our case strongly suggests an adenoma-carcinoma-sarcomatoid phenotype sequence progression as the likely pathogenesis of this rare tumor. Clinical management should follow the diagnostic and therapeutic guidelines for colorectal adenocarcinomas given the paucity of cases. Further studies and collection of cases are needed to establish proper therapeutic interventions.

## Abstract

Plasmablastic lymphoma (PBL) is a rare form of diffuse large B-cell lymphoma characterized by weak/absent expression of conventional B-cell markers and strong expression of plasma cell markers. It is strongly associated with human immunodeficiency virus (HIV) and Epstein Barr virus infection, and shows an unusual tropism to the oral cavity. Herein we describe a patient with AIDS who presented with weight loss and dysphagia owing to a large gastroesophageal mass. His radiographic and endoscopic findings and long history of cigarette consumption suggested carcinoma. Biopsy demonstrated a poorly differentiated tumor stained negatively to routine lymphoid markers including CD20. However, gene rearrangement studies confirmed a B-cell process and a more detailed immunohistochemical analysis revealed the cells stained positively for CD138 (plasma cell antigen). These findings were diagnostic of PBL. Our report reviews the wide differential diagnosis of PBL and underscores the importance of a broad array of viral and molecular studies needed to establish this diagnosis.

## INTRODUCTION

An increasingly large number of HIV-infected patients are developing HIV-associated, but not AIDS-defining neoplasms including esophageal cancer, head and neck malignancies, lung cancer, liver and anal neoplasms and renal cell carcinoma<sup>[1]</sup>. The pathogenesis of these tumors is complex and is in part related to alcohol and cigarette consumption, the consequences of chronic inflammation including hepatitis C virus (HCV)-associated cirrhotic liver disease and the presence of oncogenic viruses such as human papilloma virus, Epstein Barr virus (EBV) and hepatitis B virus (HBV). Many of these patients are receiving highly active anti-retroviral therapy (HAART) and are no longer destined to die from AIDS-related complications.

Plasmablastic lymphomas (PBLs) were originally described in HIV-infected patients as an aggressive variant of diffuse large B-cell lymphoma (DLBCL), with a peculiar tropism for the oral cavity<sup>[2]</sup>. PBLs are composed of rapidly growing, large neoplastic cells displaying some degree of plasma cell differentiation. Phenotypically, PBLs display an unusual immunohistochemical profile characterized by weak or absent expression of conventional B-cell markers

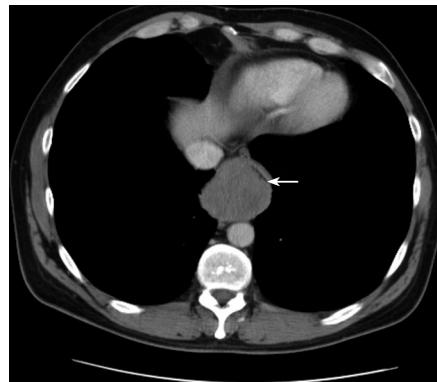

coupled with strong expression of plasma cell markers. Recent reports have identified this neoplasm in extra oral sites in both HIV seropositive and seronegative individuals.

Herein, we describe the clinical course of a patient with AIDS who presented with a constrictive and ulcerating esophageal mass which was thought initially to be a poorly differentiated carcinoma, but after a more detailed immunohistochemical evaluation, proved to be PBL. We emphasize the unusual clinical features of this rare form of non-Hodgkin's lymphoma (NHL) and the diagnostic challenges associated with its identification.

## CASE REPORT

A 40-year-old Caucasian male with a 25-pack-year history of cigarette consumption but no alcohol or illicit drug use, sought medical attention. He had lost 20 lbs over a period of 2 mo, and complained of loss of appetite and progressive odynophagia (solids > liquids). He also experienced low-grade fevers and drenching night sweat that was not ameliorated by acetaminophen. His past medical history was significant for HIV and chronic active HBV co-infection, diagnosed a year earlier when, while homeless, he presented with muscle weakness and altered mental status. His initial CD4+ count was < 50 cells/ $\mu$ L and his HIV viral load was > 100 000 copies/mL. Neurological evaluation led to a diagnosis of AIDS-associated encephalopathy and myelopathy. He was transferred to a skilled nursing facility where he received rehabilitatory care along with once daily HAART consisting of a fixed dose coformulation of tenofovir 300 mg and emtricitabine 200 mg, ritonavir 100 mg and atazanavir 300 mg. His condition gradually improved and 6 mo later his CD4+ count increased to 180 cells/ $\mu$ L and his HIV viral load fell to < 75 copies/mL.

On physical examination he appeared disheveled and emaciated with dry mucous membranes, proximal muscle wasting but no hairy leukoplakia or oral candidiasis. There was no lymphadenopathy or hepatosplenomegaly, and his myelopathy-associated spastic gait and lower extremity hyperreflexia were stable. Laboratory tests included: white blood count 7600 cells/mm<sup>3</sup>; hemoglobin 12.1 mg/dL; platelet count  $303 \times 10^3/\mu$ L; total protein 7.2 mg/dL; albumin 4 mg/dL; lactate dehydrogenase 496 IU/L (normal range, 125-243 IU/L); normal electrolyte and hepatic transaminase levels; positive HBV surface antigen and HBV e antigen; HBV DNA 9360 copies/mL and negative Hepatitis A virus and HCV serologies. His CD4+ count had dipped to 103 cells/ $\mu$ L, but his HIV viral load remained non-detectable. A chest roentgenogram demonstrated a retrocardiac soft tissue density. Chest and abdominal computed tomogram (CT) further showed the density to be a 4.9 cm × 5.1 cm concentric distal esophageal mass associated with extensive gastric wall thickening (Figure 1). The dominant mass corresponded to an area of intensely increased metabolic activity (SUV = 40.3) and was associated with right iliac adenopathy

**Figure 1** CT scan of chest highlighting the large distal esophageal mass. Note the impressive constriction of the esophageal lumen (arrow).

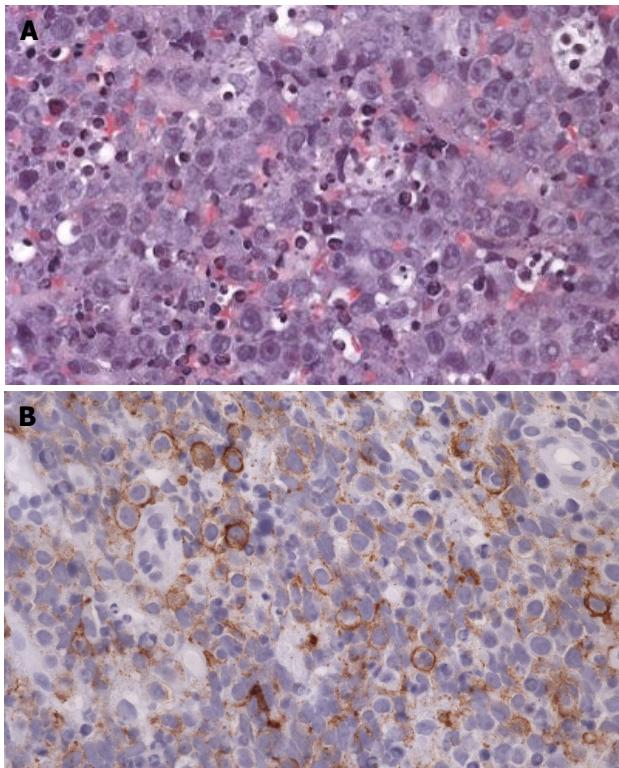

**Figure 2** Whole body PET scan demonstrates intensely increased metabolic activity corresponding to the large esophagogastric mass. There is also focal increased activity in a right iliac node.

**Figure 3** Upper Endoscopic evaluation shows esophageal mass with ulcerative features which extended into the gastric fundus.

(SUV = 40.6) on a whole body F-18 Fluorodeoxyglucose positron emission tomography (PET) scan (Figure 2).

Upper endoscopic evaluation revealed that the mass constricted 40% of the esophageal lumen and extended into the proximal stomach where a large ulcerative lesion was identified (Figure 3). Biopsies of the tumor showed a poorly differentiated, malignant neoplasm composed of irregular sheets of cells, which in many areas were largely necrotic. Cells were cytologically atypical with somewhat eccentric vesicular nuclei and prominent nucleoli (Figure 4A). On initial review of the biopsy, a poorly differentiated carcinoma of gastroesophageal origin was favored. However, immunohistochemical evaluation showed that the tumor cells stained negatively

**Figure 4** **A:** HE image shows a poorly differentiated, malignant neoplasm composed of irregular sheets of cells. Cells are cytologically atypical with somewhat eccentric vesicular nuclei and prominent nucleoli ( $\times 40$ ). **B:** Immunohistochemistry shows patchy but strong staining of tumor cells for CD138 ( $\times 40$ ).

for epithelial markers (cytokeratin), lymphoid markers (CD20, CD3, CD30 and PAX-5) and melanocytic markers (HMB-45, melan-A and S100). Based on these inconclusive results, additional immunohistochemical stains for markers of lymphoid and plasmacytoid differentiation was performed. The tumor cells were stained strongly positive for CD-45 (leukocyte common antigen) and CD-138 (plasma cell marker) and weakly positive for CD-79a (pan B-cell marker) (Figure 4B). Tumor cells were also positive for the B-cell transcription factors Bob-1 (focal) and Oct-2 (focal weak). In situ hybridization studies were positive for EBV but negative for human herpes virus type-8 (HHV-8, Table 1). A clonal rearrangement of the immunoglobulin heavy chain gene was identified on polymerase chain reaction analysis.

Following a diagnosis of PBL, the patient was treated with combined chemotherapy consisting of liposomal doxorubicin, cyclophosphamide and etoposide (LACE regimen) in addition to HAART<sup>[3]</sup>. He tolerated the therapy well, with mild nausea with each treatment cycle, alopecia and a single episode of culture negative neutropenic fever. A follow-up CT scan taken after the second treatment cycle showed dramatic improvement with just mild residual wall thickening of the distal esophagus. After completing a total of six cycles of chemotherapy, his dysphagia and weight loss resolved and a CT-PET scan showed complete resolution of the abnormal activity in esophagus and right iliac region.

**Table 1** Immunohistochemical findings of esophagogastric mass

Type	Antigen	Immunoreactivity
Epithelial markers	Cytokeratin 35BH11	Negative
	EMA	Diffusely positive
	BER-EP4	Negative
Lymphoid markers	CD-45	Positive
	CD-3	Negative
	CD20	Negative
	CD79a	Equivocally positive in some cells
	PAX-5	Negative
	CD30	Negative
	CD138	Positive (patchy, strong)
B-cell transcription factors	Bob-1	Positive
	Oct-2	Positive
Melanocyte markers	Melan-A	Negative
	HMB-45	Negative
	S100	Negative
Viral markers	HHV-8	Negative
	EBV ( <i>in situ</i> hybridization)	Positive

EMA: Epithelial membrane antigen; PAX-5: Paired box gene-5; HHV-8: Human Herpes Virus type-8; EBV: Epstein Barr virus.

His post-chemotherapy upper endoscopic evaluation did not reveal persistent NHL and 6 mo later, he remains in remission.

## DISCUSSION

In 1997, Delecluse and colleagues were the first to describe in HIV-infected patients, the occurrence of a high-grade malignant lymphoma subtype named PBL which exclusively involved the oral cavity<sup>[2]</sup>. These tumors possessed a unique immunohistochemical phenotype characterized by their failure to express common lymphoid markers while stained positively for plasma cell markers<sup>[4]</sup>. Over the past decade, the clinical spectrum of this NHL has expanded to include extra oral involvement in patients with and without HIV infection. Unusual sites of PBL involvement have included the skin, nasal and paranasal sinuses, long bones, lungs, stomach, anorectum, omentum, testes, spermatic cord, bone marrow, sacrococcygeal cysts and central nervous system<sup>[5-10]</sup>.

PBL accounts for 2.6 % of all AIDS-related NHLs, and rarely represents the sentinel manifestation of AIDS<sup>[11-13]</sup>. In HIV-negative individuals, PBL is often associated with iatrogenic immunosuppression such as seen with organ transplantation<sup>[14]</sup>. It has also been reported in association with Azathioprine and Infliximab therapy for management of inflammatory bowel disease<sup>[15,16]</sup>. PBL has been diagnosed in children as young as age 7, but the majority of the reported cases involve middle-aged adults.

Patients with PBL can be divided into three distinct categories<sup>[17-20]</sup>. The first and the more common PBL variant is localized to the oral mucosa, although the tumor may also involve nodal or extranodal sites. Histologically, this variant is characterized by a

**Table 2** Differential diagnosis of PBL

Tumor subtype	Carcinoma	PBL	Common DLBCL	BL	Plasmacytoma
Tumor cell size	Large	Large	Large	Intermediate	Intermediate
CD20	-	- to ±	+	+	-
CD45	-	Variable	+	+	-
CD138	-	+	-	-	+
VS38c	-	+	- to ±	-	+
MUM1	-	+	-	-	+
EBV	-	+	-	+	-
HHV-8	-	Variable	-	-	-

PBL: Plasmablastic lymphoma; DLBCL: Diffuse large B cell lymphoma; BL: Burkitt's lymphoma; CD: Cluster of differentiation; MUM-1: Multiple myeloma oncogene-1-protein; EBV: Epstein Barr virus; HHV-8, human Herpes Virus type-8; +: Expression of the antigen in the majority of cells; -: Absence of antigen expression; ±: Weak antigen expression.

monomorphic population of immunoblasts with no or minimal plasmacytic differentiation. The second PBL category is distinguished by its plasmacytic differentiation and extra oral presentation. The tumor cells are composed predominantly of immunoblasts, plasmablasts and mature plasma cells. The third variant of PBL has also been reported in association with HHV-8 and multicentric Castleman's disease. Patients typically present with lymphadenopathy and splenomegaly, often with plasmablasts circulating in the peripheral blood.

Despite morphologically resembling B-cell immunoblasts, PBL is associated with plasma cell immunophenotype, with loss of B cell markers (CD20) and surface immunoglobulin, and acquisition of plasma cell surface markers [VS38c, CD38 (syndecan-1), MUM-1, CD-138]. The plasmablasts are variably immunoreactive for CD45 and CD-79a<sup>[6,11,15]</sup>. They usually lack Bcl-6, the germinal center-associated B-cell antigen and PAX-5/BSAP, a nuclear factor that is present from the precursor B-cell stage and in all mature B cells but lost in terminal differentiation to plasma cells<sup>[11,17]</sup>. Newer B-lineage markers like the transcription factors OCT-2 and BOB-1 may be helpful to confirm the B-cell origin of these tumors<sup>[20]</sup>.

EBV infection is strongly associated with PBL. *In situ* hybridization for EBV Encoded RNA in tumor specimens has reportedly ranged from 60% to 100%, suggesting that EBV plays an important role in PBL pathogenesis<sup>[9,15,17,21]</sup>. In contrast, HHV-8 is not consistently associated with PBL, although rare cases have identified HHV-8 in conjunction with HIV infection, PBL and multicentric Castleman's disease<sup>[9,15,17,22,23]</sup>. Patients with chronic HBV infection are more likely to develop NHLs, but specific cases of PBL have not been documented in this population<sup>[24]</sup>.

The differential diagnosis of PBL may overlap with a variety of other clinicopathologic entities (Table 2). When PBL presents as an oral lesion, it may be confused with periodontal disease like odontogenic cellulitis, KS or melanoma<sup>[12]</sup>. Carcinomas can be distinguished from PBLs based on presence of immunoreactivity for epithelial markers such as cytokeratin. Primary effusion lymphoma, as opposed to PBL, usually presents with

serous effusions without detectable tumor masses, and is strongly associated with both HHV-8 and HIV infection. The presence of serum monoclonal proteins, and/or bone involvement with radiographically evident lytic lesions, favors the diagnosis of plasma cell myeloma rather than PBL<sup>[25]</sup>.

In the pre-HAART era, HIV-infected patients with PBL were destined to die from their disease shortly after their NHL diagnosis. In the initial report by Delecluse and colleagues, 9 of 11 patients with long-term follow-up had a median survival of 6 mo<sup>[2]</sup>. In the HAART era, patient prognosis appears better and prolonged survival is the goal of treatment. Among six patients treated with anthracycline-based multiagent chemotherapy in conjunction with HAART, five were alive and disease free with a median follow-up of 22 mo<sup>[15]</sup>. The importance of an intact immune system in preventing or controlling PBL is underscored by reports of tumor regression with HAART alone and in the absence of chemotherapy<sup>[26-28]</sup>. Ironically, the early phase of immune reconstitution may be a fertile ground for NHL development. Our patient's diagnosis of lymphoma within 1 year of HAART initiation, and in the context of a rapidly improving CD4+ cell count and non-detectable HIV viral load may be another example<sup>[29]</sup>.

Finally, our patient's complaint of dysphagia in the setting of a large esophagogastric mass, together with his long-standing history of smoking was disconcerting for carcinoma. Though the history of fever, night sweat and an elevated LDH raised the possibility of a lymphoma, the finding of poorly differentiated tumor cells stained negatively for routine lymphoid markers of B and T-cell differentiation did not support this diagnosis. But the subsequent demonstration of the plasma cell antigens, which are not typically part of the routine immunohistochemical panel, in conjunction with a broader array of viral and molecular studies helped us to establish the diagnosis of PBL.

### INTRODUCTION

Mesalamine is a well-known treatment for ulcerative colitis. Drug reactions to mesalamine are uncommon, and most often include skin rash and hypereosinophilia<sup>[1]</sup>. Severe reactions to mesalamine products are rarely seen in pediatric patients. Cardiac complications have been reported as a rare extraintestinal manifestation of inflammatory bowel disease (IBD) and mainly manifest as pericarditis<sup>[2-4]</sup>. However, cardiac complications may be associated as a very rare drug reaction to 5-aminosalicylic acid (5-ASA) products<sup>[1,5,6]</sup>. The difficulty lies in distinguishing between these two etiologies. We herein report a case of a 12-year-old boy with ulcerative colitis who had a severe cardiovascular reaction to a mesalamine product, Asacol.

### CASE REPORT

This is a 12-year-old boy with a past medical history significant for ulcerative colitis (UC) diagnosed at 9 years of age, along with psoriasis and arthritis. He was initially placed on steroids and Pentasa when he was first diagnosed. The Pentasa was discontinued after he developed a rash. It was difficult to distinguish his psoriasis from a potential drug reaction as a cause of the rash. He was subsequently weaned from his steroids after approximately 2 mo.

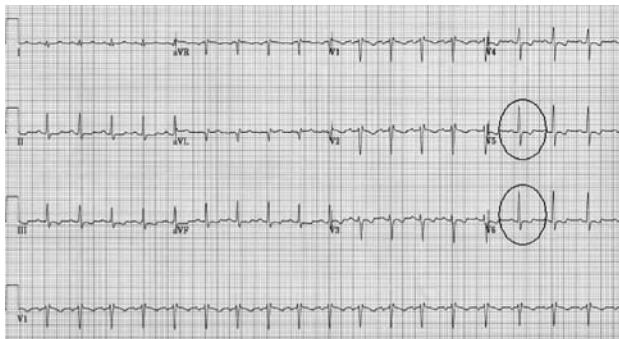

He presented to the hospital three years after his initial diagnosis with a two-month history of exacerbation of his UC. His symptoms continued to progress. He had 6-8 bloody stools per day 2 wk prior to hospital admission. Colonoscopy 6 wk into the flare revealed pancolitis. He was started on Asacol 800 mg three times per day and prednisone 20 mg once a day for his UC flare. The patient was subsequently admitted for worsening abdominal pain, bloody diarrhea as well as fever, fatigue, myalgia, and extremity pain. He also complained of new onset of severe chest pain progressively worsening since

### Abstract

Severe reactions to mesalamine products are rarely seen in pediatric patients. We report a case of a 12-year-old boy who had a severe cardiac reaction to a mesalamine product Asacol. Past medical history is significant for ulcerative colitis (UC) diagnosed at 9 years of age. Colonoscopy one week prior to admission revealed pancolitis. He was treated with Asacol 800 mg three times per day and prednisone 20 mg/d. He was subsequently admitted to the hospital for an exacerbation of his UC and started on intravenous solumedrol. He had improvement of his abdominal pain and diarrhea. The patient complained of new onset of chest pain upon initiating Asacol therapy. Electrocardiogram (ECG) revealed non-specific ST-T wave changes with T-wave inversion in the lateral leads. Echocardiogram (ECHO) revealed low-normal to mildly depressed left ventricular systolic function. The left main coronary artery and left anterior descending artery were mildly prominent measuring 5 mm and 4.7 mm, respectively. His chest pain completely resolved within 24-36 h of discontinuing Asacol. A repeat echocardiogram performed two days later revealed normal left ventricular function with normal coronary arteries (< 3.5 mm). Onset of chest pain after Asacol and immediate improvement of chest pain, as well as improvement of echocardiogram and ECG findings after discontinuing Asacol suggests that our patient suffered from a rare drug-hypersensitivity reaction to Asacol.

starting Asacol therapy. The chest pain was not related to exercise and not associated with palpitations, shortness of breath, syncope, pallor, cyanosis or altered by changes in posture or breathing.

On admission, his vitals included a temperature of 38°C, pulse rate of 126 beats per minute, respiratory rate of 18 breaths per minute and a blood pressure of 107/65 mmHg. He was started on intravenous solumedrol 8 mg every 6 h with subsequent improvement of his abdominal pain and diarrhea. Chest pain, however, persisted and the chest pain worsened shortly after ingesting Asacol. Electrocardiogram (ECG) was performed and revealed non-specific ST-T wave changes with T-wave inversion in the lateral leads (Figure 1). Troponin T, CK-MB, Brain Natriuritic Peptide, and CRP levels were ordered to evaluate for possible pericarditis or a myocardial abnormality. The results of this lab work were normal. Echocardiogram (ECHO) revealed low-normal to mildly depressed left ventricular systolic function. Calculated shortening fraction was 26% and left ventricular size was within normal limits. The left main coronary artery and left anterior descending artery were mildly prominent measuring 5 mm and 4.7 mm, respectively (Figure 2). The ECHO also revealed trivial circumferential pericardial effusion that was hemodynamically insignificant (Figure 3). A spiral CT scan ordered to evaluate for possible pulmonary embolism in the setting of an elevated d-dimer was unremarkable except for a small amount of pericardial fluid.

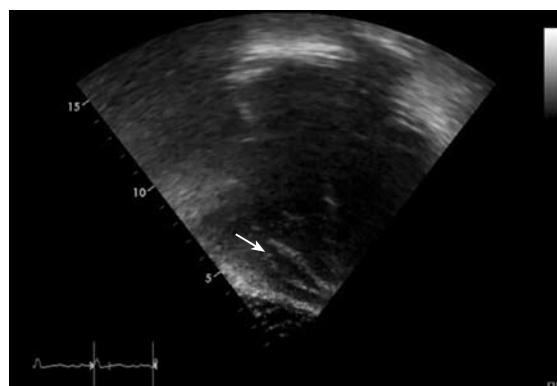

The patient's chest pain completely resolved within 24 h after discontinuation of Asacol. A repeat echocardiogram performed two days later revealed normal left ventricular function with a shortening fraction of 33%, normal coronary arteries (< 3.5 mm) and a trivial pericardial effusion. The patient was subsequently discharged from the hospital on prednisone and methotrexate. His UC remained in remission upon follow-up by his pediatric gastroenterologist 2 mo after hospital discharge. An ECHO and ECG were also repeated in the follow-up 2 mo after hospital discharge, revealing continued resolution of coronary artery dilation (Figure 4). The ECG was normal without the S-T wave abnormality noted 2 mo earlier.

## DISCUSSION

Mesalamine has been found to be a beneficial medication in the treatment of patients with ulcerative colitis. The

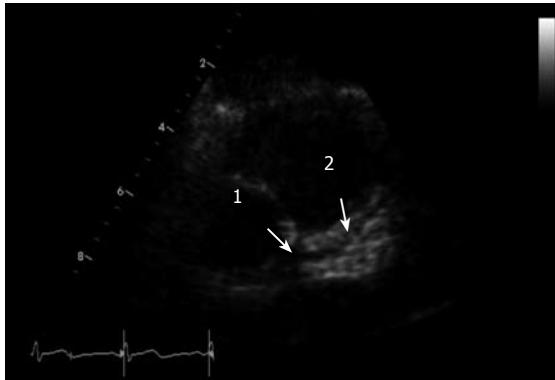

**Figure 2** Echocardiogram-parasternal short-axis view showing mildly dilated left main coronary artery (1), left anterior descending artery (2), left circumflex coronary artery (3).

**Figure 3** Echocardiogram-4-chamber view showing pericardial effusion (arrow).

mechanism of action of mesalamine is unknown; however, it is thought to exert its action topically as opposed to systemically. Mucosal production of arachidonic acid metabolites, through both the cyclo-oxygenase and the lipoxygenase pathways, is thought to be increased in patients with inflammatory bowel disease. Mesalamine acts by a variety of mechanisms which include blocking cyclo-oxygenase thereby inhibiting prostaglandin synthesis, reducing antioxidant and pro-inflammatory cytokine synthesis, reducing lymphocyte metabolism and reducing expression of adhesion molecules. All these work to decrease inflammation in the colon<sup>[7,8]</sup>.

Chest pain along with electrocardiographic and echocardiogram findings in a pediatric patient on a 5-ASA product should alert the physician to the possibility of drug reaction. We have presented a pediatric patient with ulcerative colitis who developed cardiac signs and symptoms associated with pericarditis soon after starting a 5-ASA product. Determining the etiology of pericarditis in this setting can be complex as this presentation has been reported as a rare extraintestinal manifestation of inflammatory bowel disease<sup>[2-4]</sup>. Chest pain may be associated with other more common gastrointestinal conditions such as gastroesophageal reflux disease (GERD). Chest pain in IBD may also be caused by respiratory infection and pleural inflammation which were ruled out in our patient. Patients with IBD have a higher propensity to develop pulmonary embolism (PE) and patients often

**Figure 4** Echocardiogram-parasternal short-axis view showing normal left main coronary artery (1), normal left anterior descending artery (2).

present with acute onset of chest pain<sup>[4]</sup>. The normal spiral chest CT ruled out PE in our patient.

In our case, there was a temporal relationship between the onset of the chest pain and the administration of Asacol. The characteristics of the chest pain were not typical of pericarditis but the ST-T wave changes and the pericardial effusion which resolved after discontinuation of the Asacol were suggestive of the diagnosis. Normal troponin and CKMB levels do not support the diagnosis of myocarditis, although there was a mild but clear change in ventricular systolic function which also resolved after the Asacol was stopped. It is unclear why the coronary arteries were mildly prominent at the time of the diagnosis, which would suggest a vasculitis process such as Kawasaki disease.

This case illustrates the importance of eliciting a

thorough medical history and being aware of the timing when new medications are started. It is imperative that any new onset of chest pain, especially in this setting, should be evaluated via cardiac enzymes, EKG and echocardiogram to quickly diagnose any complication caused by either the inflammatory bowel disease itself or a rare adverse drug reaction.

## INTRODUCTION

Intentional or unintentional insertion of rectal foreign bodies is not uncommon and often poses a serious challenge on the clinician. Objects can be inserted for diagnostic or therapeutic purposes, or self-treatment of anorectal disease, by criminal assault and accident or, most commonly, for sexual purposes. Most patients with rectal foreign bodies present to the emergency room usually after efforts to remove the object at home. Many endoscopic and surgical techniques to remove rectal foreign bodies have been described in the literature and the reported variety in foreign bodies is as large as the number of techniques used to remove them<sup>[1-46]</sup>. The descriptions in the available literature are anecdotic and consist largely of case reports or case series<sup>[1-46]</sup>.

In this report, a novel endoscopic technique to remove rectal foreign bodies using a pneumatic dilatation balloon normally used in achalasia patients is presented. In addition, a systematic review of the literature was performed for non-operative methods to remove foreign bodies from the rectum. These results are summarized, presented as a practical at-a-glance overview and a flow chart is offered to guide the clinician in treatment decisions.

## CASE REPORT

A 19-year-old man presented at the emergency department, 12 h after insertion of a high pressure container with tanning spray into his rectum. A plain abdominal radiograph (Figure 1) showed the container in the rectosigmoid region. There were no signs of perforation. A flexible sigmoidoscopy was performed under conscious sedation. The object was located just above the rectosigmoid junction. The container could not be extracted by bimanual manipulation. An attempt to remove the object with conventional endoscopic instruments, such as polypectomy snares, was unsuccessful.

The sigmoidoscope could be passed alongside the foreign body to its proximal end. A guide wire was left behind with the sigmoidoscope removed. Subsequently, a 40 mm pneumatic dilatation balloon (Rigiflex®, Boston Scientific), normally used in achalasia patients, was inserted over the guide wire and inflated just above the container (Figure 2). For safety purposes, the sigmoidoscope was reintroduced alongside the catheter of the balloon to allow endoscopic visual control of

## Abstract

A number of techniques have been described to remove rectal foreign bodies. In this report, a novel endoscopic technique using a pneumatic dilatation balloon normally used in achalasia patients is presented. In addition, a systematic review of the literature was performed for non-operative methods to remove foreign bodies from the rectum. These results are summarised, presented as a practical at-a-glance overview and a flow chart is offered to guide the clinician in treatment decisions. The design of the flow chart was based on the aims to treat the patient preferably on an outpatient basis with minimally invasive techniques and if possible under conscious sedation rather than general anaesthesia.

the distal end of the container in the rectum. Gentle traction was exerted on the balloon catheter, and the container was successfully removed under fluoroscopic and endoscopic control (Figure 3).

## DISCUSSION

A large number of surgical and non-surgical techniques have been described to remove rectal foreign bodies<sup>[1-46]</sup>. Our case illustrates that for removal of foreign bodies retained in the rectosigmoid, extraction with a pneumatic dilatation balloon, inflated above the foreign body, may be an elegant and safe alternative when conventional techniques fail. Our technique has not been described before as revealed by a systematic review of the literature. We performed a systematic PubMed search from 1966 to present, using the search terms 'rectal', 'rectum', 'colorectal', 'foreign', 'bodies' and 'endoscopic'. Only reports in English were included. The results of the systematic search of the literature, specified for the type of foreign body, are summarized in Table 1<sup>[1-36]</sup>. Table 1 also summarizes endoscopic techniques and non-endoscopic techniques for removing foreign bodies. In addition to the reports presented in the Table 1, several case series have been published without detailed information on the techniques used to remove various foreign bodies<sup>[18,22,25,37-46]</sup>.

An algorithm was provided to guide the clinician in his or her treatment decisions, partly based on the methods presented in the Table 1 (Figure 4). We included only those methods most commonly used and excluded rare treatment variants.

The first step in the evaluation is that one should

**Figure 4** Algorithm for the removal of a colorectal foreign body.

always be aware of the possibility of a large bowel perforation and perform radiological investigations. Plain abdominal radiography or water soluble contrast enemas may be helpful. An abdominal X-ray will also provide information on the localization of the foreign body, whether it is below or above the rectosigmoid junction. If perforation of the bowel has occurred, immediate laparotomy is warranted. If there are no signs of perforation, several management approaches can be tried. Our aim was to treat the patient on an outpatient basis with minimally invasive techniques and preferably under conscious sedation instead of general anaesthesia.

First, digital removal of the object should be attempted, if necessary with the patient at different positions. If this approach fails, one can try bimanual manipulation. The next step is the insertion of an endoscope with subsequent attempts to grasp the foreign body with regular endoscopy accessories like polypectomy snares. When this fails, it may be helpful to

use devices that can be inflated in the rectosigmoid, such as a Foley catheter or an achalasia balloon. Such a device prevents a vacuum that might develop upon extraction of the foreign body and may also be directly used to remove the object.

If these interventions fail, we refer the patients to the operating theatre. Full relaxation of the anal sphincter muscles can be achieved by local, spinal or general anaesthesia. Sometimes, bimanual manipulation of the relaxed abdominal wall under spinal or general anaesthesia may evade surgery. Patients should be consented for a laparotomy prior to general anaesthesia should the manual or endoscopic removal fail.

Finally, when conservative measures fail, laparoscopic or laparotomic approaches are indicated. After removal, sigmoidoscopy is generally recommended to rule out perforations. In the largest series of patients with rectal foreign bodies described thus far ( $n = 93$ ), it was found

that objects retained for more than 2 days, those larger than 10 cm and those located proximal to the rectum increase the likelihood of surgery<sup>[37]</sup>.

In conclusion, many techniques are available for the extraction of rectal foreign bodies. If possible, patients should be treated with minimally invasive techniques and preferably on an outpatient basis under conscious sedation.

## INTRODUCTION

Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of non-Hodgkin's lymphoma (NHL) accounting for about 40% of all NHLs<sup>[1,2]</sup>. Tumors may be localized or confined to one side of the diaphragm in 20% to 40% of cases (Stage I or II). Stage IV or disseminated disease is observed in approximately 40% of patients and is usually characterized by extranodal extramedullary infiltration<sup>[3,4]</sup>. Sites of extranodal involvement in DLBCL can include the stomach/gastrointestinal system among others<sup>[5-7]</sup>. In this report, we describe a patient with a stage IV DLBCL infiltrating the stomach diagnosed at endoscopic examination and an excellent response after 6 cycles of chemotherapy.

## CASE REPORT

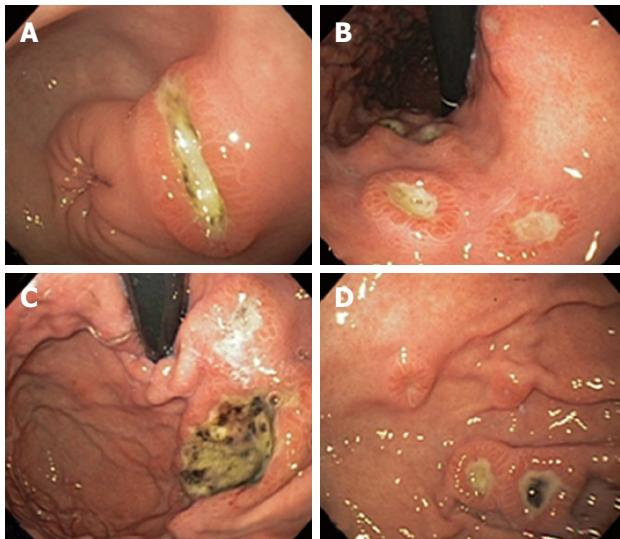

A 39-year-old female was referred for an upper endoscopy because of melena, weight loss and a retroperitoneal mass. She had a 6-mo history of lumbar and left upper quadrant pain. Two months before admission she presented with nausea, early satiety, and intermittent episodes of melena and malaise. At admission she also reported a 5 kg weight loss and nocturnal diaphoresis. Physical examination revealed bilateral supraclavicular lymphadenopathy, hepatosplenomegaly and a palpable tender epigastric mass. A computer tomography (CT) scan showed cervical and mediastinal lymphadenopathy, bilateral pleural effusion, two pulmonary nodules in the upper right lobe, hepatosplenomegaly and a retroperitoneal

## Abstract

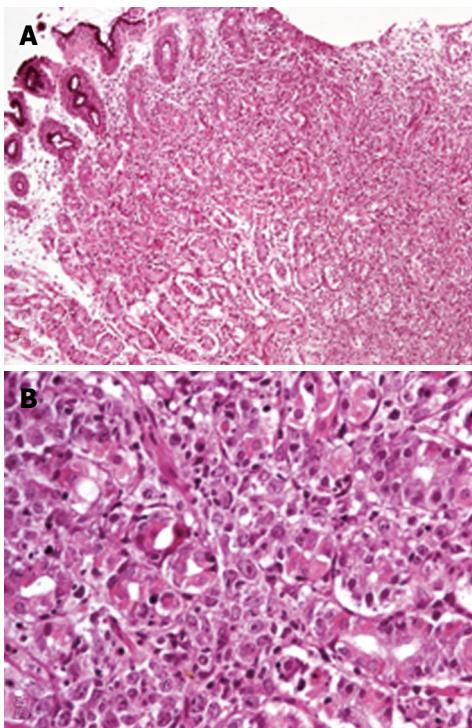

Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of the non-Hodgkin's lymphoma (NHL) accounting for about 40% of all NHLs. This is a case report about the endoscopic appearance of a DLBCL with infiltration to the stomach in a 39-year-old female. She had a 6-mo history of lumbar and left upper quadrant pain with intermittent episodes of melena. A computer tomography (CT) scan showed mural thickening of the gastric antrum. Endoscopic examination revealed multiple gastric ulcers. Definite diagnosis could be made by endoscopic biopsies and the patient had a good response to chemotherapy. This response correlated well with a further endoscopic follow-up. A follow-up endoscopic examination could be considered to evaluate a good response to chemotherapy in DLBCL patients with secondary gastric dissemination.

**Key words:** Diffuse large B-cell lymphoma; Non-Hodgkin's lymphoma; Gastric infiltration

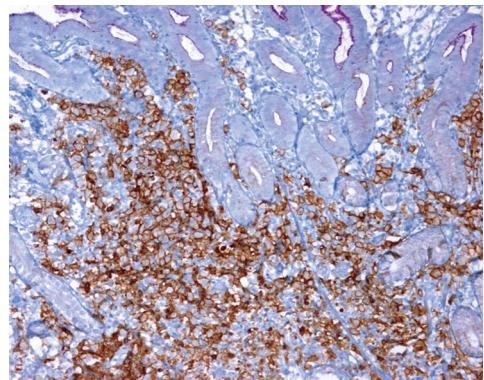

**Figure 1** Endoscopic appearance of DLBCL infiltration of gastric antrum (A), lesser curvature (B), fundus (C), and body (D).

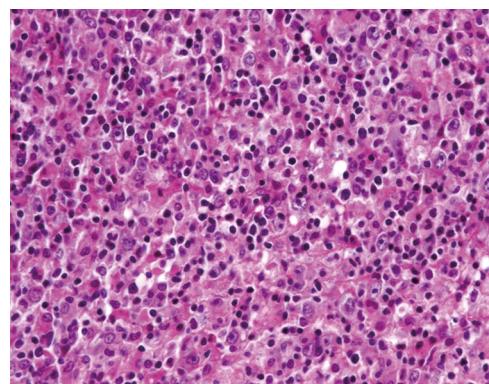

**Figure 2** Gastric mucosa biopsy showing diffuse infiltration of lamina propria with distortion of the glandular architecture (A) and diffuse infiltration by large lymphoid cells (centroblast-type) that surround and destroy the gastric glands (B).

mass with mural thickening of the gastric antrum. A cervical lymph node biopsy was obtained and the patient underwent an upper endoscopic examination. At endoscopy, we observed multiple gastric ulcers without active bleeding. The ulcers had elevated margins, ranging from 5 to 15 mm in diameter and their base was covered by fibrin and/or necrotic material. The margins of the ulcers showed a characteristic erythematous, congestive, mosaic-like pattern suggestive of infiltration (Figure 1). Multiple biopsies were taken from the ulcer margins. Histopathologic analysis revealed a centroblastic DLBCL

**Figure 3** Gastric biopsy showing infiltration by atypical lymphoid cells in the gastric mucosa with intense positivity for CD20 at immunohistochemical analysis.

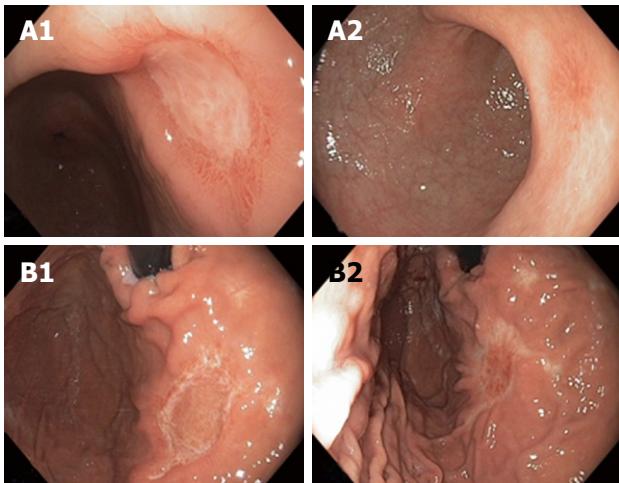

**Figure 4** Lymph node biopsy showing neoplastic lymphocytes with fine nuclear chromatin, some of which have 2 or 3 peripheral nucleoli (centroblast type) and others have prominent central nucleoli (immunoblastic type).

positive for CD20 at immunohistochemical analysis (Figures 2 and 3). The histologic results from the lymph node biopsy confirmed the diagnosis (Figure 4). The patient received rituximab, cyclophosphamide, adriamycin, vincristine and prednisone (R-CHOP) chemotherapy and omeprazole (20 mg *po* twice a day). Her clinical symptoms improved dramatically after 2 cycles of chemotherapy. After 3 cycles of chemotherapy she underwent a follow-up upper endoscopy (6 wk after the first endoscopy) that showed the presence of scarring tissue in majority of the ulcer sites and improvement at the sites where the ulcers with a bigger size were located. A final upper endoscopy performed after 6 cycles of chemotherapy (12 wk after the first endoscopy), showed almost complete resolution of the lesions (Figure 5). She denied early satiety or pain and had no signs of gastrointestinal hemorrhage.

## DISCUSSION

Disseminated DLBCL (stage IV) is seen in approximately 40% of patients and the gastrointestinal tract is the most common site of extranodal NHL accounting for 20% to 60% of newly diagnosed cases<sup>[8-10]</sup>. Disseminated nodal disease requires systemic chemotherapy as opposed to localized primary gastric NHL that is potentially curable

**Figure 5** Endoscopic appearances of gastric antrum (A1, A2) and fundus (B1, B2) after 3 and 6 cycles of chemotherapy respectively.

with local radical treatment<sup>[11]</sup>. Thereby, it is crucial to make an early and reliable identification of the disease to initiate a correct therapy. The characteristics of the lesions at endoscopic examination can differ between primary and secondary gastric NHL. Kolve *et al*<sup>[12]</sup> described the endoscopic differences between 176 patients with primary NHL and 29 with secondary NHL, the lesions had macroscopical polypoid or exulcerative infiltrating changes. Primary low-grade gastric NHL was mainly characterized by diffuse infiltration and unifocal growth pattern with bulky disease in 80% of the cases with high-grade malignancy, whereas the lesions with secondary involvement showed a multifocal growth pattern in 66% of cases with bulky disease in 35%<sup>[12]</sup>. Our case showed a multifocal pattern of ulcerative lesions with elevated margins. Infiltrative disease was suspected on the basis of her clinical presentation, the number of ulcers and the erythematous mosaïc-like pattern at margins of the lesions. Biopsies taken at the margin sites were diagnostic. This description of gastric infiltration by this specific type of neoplasia could help the endoscopist to suspect or identify this entity since appearance of the ulcers at endoscopic examination was very characteristic. The reason to perform the second endoscopic examination was to correlate the endoscopic findings with the improvement in the clinical picture and the radiological follow-up. Obviously, omeprazole treatment could also improve gastric ulcers, but we consider that in such a short period of time and considering the nature of the disease, it is highly improbable that without chemotherapy, we

would have observed the same results. This shows that a follow-up endoscopic examination could also be taken into consideration to evaluate a good response to chemotherapy in DLBCL patients with secondary gastric dissemination.

### Abstract

We report a rare case of duodenal perforation caused by an ingested 12-cm long toothbrush handle. A 22-year-old female presented with intermittent epigastric pain for 6 d after swallowing a broken toothbrush. The swallowed toothbrush could not be removed from the second portion of the duodenum by endoscopy. Laparotomy revealed a perforation in the anterior wall of the duodenal bulb. The toothbrush was removed *via* the perforation which was debrided and closed. There were no postoperative complications.

### INTRODUCTION

Ingestion of various types of foreign bodies, such as toothpicks, fish or meat bones, screws, coins, metal clips,

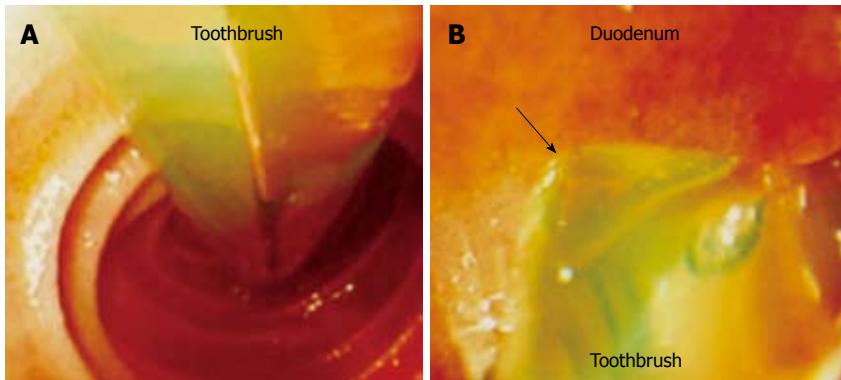

teeth, dental prosthesis, and spoon handles, has been reported<sup>[1-3]</sup>. Most ingested foreign bodies pass through the gastrointestinal tract spontaneously without causing untoward effects. However, sometimes these foreign bodies cause obstruction or perforation of the gastrointestinal tract necessitating surgical intervention<sup>[2-5]</sup>. Here, we report a rare case of duodenal perforation resulting from an ingested toothbrush.

### CASE REPORT

A 22-year-old female presented with intermittent epigastric pain for 6 d. Eight days prior to hospitalization, she experienced nausea and foreign body sensation in the throat. She attempted to induce vomiting by irritating the pharynx with the distal end of a toothbrush handle. The toothbrush broke at the junction of the handle and the brush head. Unfortunately, she accidentally swallowed the handle of the broken toothbrush, which was 12 cm long. She had no passage of tarry noted after swallowing the foreign body. However, she experienced epigastralgia 2 d after ingesting the toothbrush. Endoscopy was performed twice at another hospital. However, the swallowed toothbrush could not be removed. The patient denied any history of excessive alcohol consumption or illicit drug use. Her medical history was otherwise unremarkable.

Upon admission, the patient was afebrile, and her vital signs were normal. Mild tenderness but no rebound pain was noted in the upper abdomen. Laboratory values were as follows: 10.0 g/dL hemoglobin, 30.5% hematocrit, 7100/mm<sup>3</sup> white blood cells (WBC), 30 U/L aspartate aminotransferase (AST), 32 U/L alanine aminotransferase (ALT), and 72 U/L alkaline phosphatase. Chest and plain abdominal X-ray examinations were unremarkable. Endoscopic examination revealed a broken toothbrush handle in the second portion of the duodenum (Figure 1A). The blunt end of the toothbrush faced distally and the broken end, proximally against the duodenal wall (Figure 1B). There was an ulcer on the anterior wall of the duodenal bulb. Endoscopic removal of the toothbrush was reattempted but failed.

Surgery was performed on the second day of hospitalization. Laparotomy revealed a perforation in the anterior wall of the first portion of the duodenum. The perforation had necrotic edges and was sealed off by the infundibulum of the gallbladder. The toothbrush was removed through this perforation which was debrided and then closed primarily with interrupted silk sutures rein-

**Figure 1** A toothbrush handle found in the second portion of the duodenum (A) and the pointed broken end (arrow) of the toothbrush handle impinged on the wall of the duodenal bulb (B).

forced with an omental patch. The patient's postoperative course was uneventful. The patient resumed oral intake on the fourth postoperative day and was discharged from the hospital 7 d after surgery.

## DISCUSSION

Several factors are associated with the ingestion of foreign bodies. Children usually swallow foreign bodies because of carelessness. In adults, poor vision, mental disease, drug addiction, wearing of dentures, and rapid eating have been implicated as the etiologic factors of foreign body ingestion<sup>[2-5]</sup>. In addition, excessive alcohol intake and extremely cold fluids may dull the sensitivity of the palatal surface and increase the risk of swallowing foreign bodies<sup>[6]</sup>. The majority of ingested foreign bodies pass uneventfully through the gastrointestinal tract<sup>[2-5]</sup>. However, in some patients, the ingested foreign body may cause impaction, perforation, or obstruction. Perforation of the gastrointestinal tract may be associated with a considerably high mortality and morbidity. Gastrointestinal tract perforation may cause peritonitis, abscess formation, inflammatory mass formation, obstruction, fistulae, and hemorrhage<sup>[2,6]</sup>. In addition, foreign body perforation of the gastrointestinal tract may involve adjacent structures such as the kidneys, psoas muscle, and inferior vena cava<sup>[7,8]</sup>. Rare cases of foreign body migration to the pleura, heart, kidneys, or liver have been reported<sup>[9-12]</sup>. Most deaths in patients with foreign body perforation of the gastrointestinal tract are due to fulminant sepsis<sup>[2,13,14]</sup>. Therefore, efforts should be made to remove the ingested foreign bodies if they cannot pass through the gastrointestinal tract spontaneously.

In this case, the broken toothbrush handle was entrapped in the duodenal sweep and resulted in perforation of the duodenum. Intestinal injury resulting from an ingested foreign body tends to occur in areas of acute angulation but it may occur in all segments of the gastrointestinal tract<sup>[6]</sup>. The retroperitoneal, relatively immobile, and rigid nature of the duodenum as well as its deep transverse rugae and sharp angulations make it a common site for the entrapment of long and sharp-ended objects. Furthermore, the properties of foreign bodies determine the degree of complications caused by them. Thin and sharp foreign bodies such as chicken and fish bones, toothpicks, and straightened paperclips carry

a higher risk of perforation. Long, slender, sharp-ended items have difficulty in traversing the tortuous gastrointestinal tract<sup>[2,3]</sup>. In a review of 31 cases of toothbrush ingestion, no episodes of spontaneous passage were reported<sup>[15]</sup>. Complications related to pressure necrosis, including gastritis, mucosal tears, and perforations, occurred in several of these cases.

Although a conservative approach toward foreign body ingestion is justified, early endoscopic removal of the ingested foreign body from the stomach is recommended<sup>[2,4,15]</sup>. Ertan *et al*<sup>[16]</sup> reported the first case of successful removal of a swallowed toothbrush. Other authors found the endoscopic approach unsuccessful due to the size and shape of the ingested toothbrush<sup>[17,18]</sup>. Esophageal perforation during the endoscopic extraction of a toothbrush has been reported<sup>[6]</sup>. In addition, objects longer than 6-10 cm have difficulty in passing the duodenal sweep<sup>[19]</sup>. Therefore, in cases of unsuccessful removal of gastric foreign bodies that are longer than 6.0 cm, surgical removal of them should be considered. Wishner and Rogers<sup>[18]</sup> reported a case of successful laparoscopic removal of a toothbrush from the stomach. Laparotomy in this case is justified because it is difficult to remove a toothbrush from the duodenum *via* a laparoscopic approach.

In conclusion, an ingested toothbrush cannot pass spontaneously through the gastrointestinal tract. Early removal of the ingested toothbrush is advised to avoid impaction of the toothbrush at the duodenum and to minimize morbidity. Endoscopic removal should be performed by a skilled endoscopist. If this is not possible or unsuccessful, a surgical approach is recommended.

### INTRODUCTION

Although exacerbation of ulcerative colitis (UC) usually poses a little diagnostic dilemma, physicians should remain cognizant to the possibility of an alternative cause for patient symptoms.

### CASE REPORT

A 54-year-old practicing physician, native of Brazil who immigrated to Israel 20 years ago, was hospitalized in the Neurology Department with severe cluster headache attack, which responded to oral dexamethasone at 16 mg/d. History was also notable for left-sided UC controlled by 5-aminosalicylates (5-ASA) over the past 11 years. In the previous 2 years, the patient was lost to follow-up but reported he was in clinical remission. Two weeks after his hospital discharge from the Neurology Department, he presented again with non-bloody diarrhea, abdominal pain and muscle pain.

Upon examination a fever of 37.7°C was noted, and right abdominal tenderness was appreciated. The rest of the physical examination was unremarkable. Complete blood count showed that his white blood cell count was 8.4 K/mcl, with a normal differential count. Hemoglobin level was 14.6 g/dL. Chemistry results were all normal except for an albumin of 2.6 g/dL. Urinalysis showed leukocyturia and urine culture-yielded *E.coli*. Abdominal plain film showed small fluid levels.

Although the patient's abdominal pain and diarrhea suggested a possible UC flare-up, the lack of rectal bleeding, the right-sided abdominal tenderness and the muscular complaints raised the suspicion of a superimposed infectious process in addition to a urinary tract

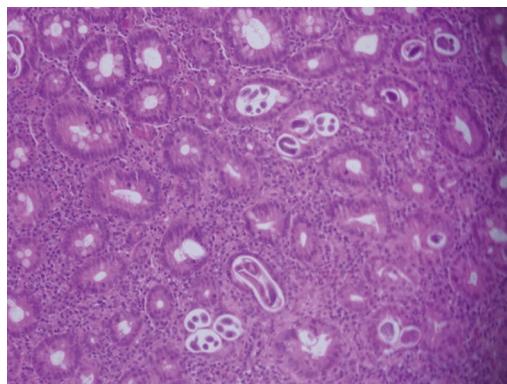

### Abstract

Super-imposed infection with intestinal organisms can mimic a flare-up of underlying disease in patients with inflammatory bowel disease (IBD). We report a case of patient with long standing ulcerative colitis (UC), who presented with abdominal pain, diarrhea and low-grade fever after receiving systemic corticosteroids for an unrelated disorder. Despite a negative stool examination, a peripheral eosinophilia reappeared upon tapering down of a corticosteroid dose. Subsequently, duodenal biopsies showed evidence for Strongyloides, presumably acquired 20 years ago when the patient was residing in Brazil. The patient fully recovered following anti-helminthic therapy. This case underscores the importance of considering Strongyloides in the work-up of flaring-up IBD patients, even if a history of residing or traveling to endemic areas is in the distant past.

infection. Steroid myopathy causing muscles' pain was also considered. Prednisone was tapered to 5 mg over 4 d and ofloxacin was started, but the patients' symptoms persisted and a fever up to 38°C was noted. Stool culture, examination for ova & parasites and *C. difficile* toxin assay were all negative. Following steroid tapering, an elevation of eosinophil count to 15.5% of white blood cells was noted, with an absolute count of 980/mcl. Re-inspection of the blood count obtained in the Neurology Department before initiation of dexamethasone revealed peripheral eosinophilia (1240/mcl), which went unnoticed. The patient underwent gastroduodenoscopy, which showed a hyperemic edematous duodenal wall. Colonoscopy showed edematous mucosa and punctate submucosal hemorrhages extending along the colon from the descending colon to the cecum. The rectum appeared relatively spared.

Histology from the colon revealed chronic eosinophilic inflammation and formation of eosinophilic abscesses. Duodenal histology revealed *Strongyloides* larva (Figure 1). CMV PCR in blood and tissue CMV immunohistochemistry were negative.

Ivermectin at a dose of 12 mg once daily was initiated with prompt resolution of all symptoms. During the 4-year follow-up, the patient was well, but experienced several mild flare-ups of UC, controlled with 5-ASA therapy. Repeat colonoscopies showed left sided colitis, and histology was compatible with UC. Two subsequent gastroduodenoscopies with biopsies did not disclose evidence of *strongyloides*.

## DISCUSSION

*Strongyloides stercoralis* is endemic in tropic and sub-tropic areas of the world, but has also been reported in residents of certain regions of the US and in coal miners in non-endemic areas<sup>[1,2]</sup>. Most cases present with pulmonary and/or upper gastrointestinal symptoms<sup>[3]</sup>. However, *Strongyloides*-associated colitis can occur as part of hyperinfestation following altered host immune status<sup>[4,5]</sup>. In this situation, larvae traveling down from the duodenum penetrate the colon wall rather than continue to be excreted in the stool<sup>[4]</sup>. The ensuing

eosinophilic-predominant colitis may mimic new onset of UC<sup>[2,4]</sup>. Alternatively, it can emerge after corticosteroid treatment of a patient with well established UC, and can be mistaken for a refractory exacerbation<sup>[1,3,6]</sup>.

The diagnosis of *Strongyloides* is often problematic. Stool examination is negative in 50%-70%<sup>[7,8]</sup> of patients. Eosinophilia was present in 84% of patients in one series<sup>[7]</sup>, but in only 32% of corticosteroids-treated patients in another series<sup>[9]</sup>. Our patient had eosinophilia upon his prior admission to the Neurology Department that went unnoticed. Serology testing for *Strongyloides*-specific antibodies is also helpful, although not widely available. Upper endoscopy usually reveals hyperemic edematous duodenal mucosa with white villi<sup>[10]</sup> and colonoscopy may show mucosal edema, erosions and ulcerations<sup>[11]</sup>, but none of these findings is specific. Duodenal aspirates and/or biopsy can assist the diagnosis, but are dependent upon worm burden and amenable to sample error<sup>[7]</sup>. Moreover, even when larvae are present in the intestinal or colonic wall, the diagnosis can be over-looked by the inexperienced or unsuspecting pathologist<sup>[1,12]</sup>, or may be mistaken for eosinophilic gastroenteritis<sup>[13]</sup>.

*Strongyloides* can persist in the host for his or her entire life-time<sup>[14]</sup>. Indeed, in our patient, infection was probably acquired in Brazil, twenty years prior to clinical presentation. Thus, albeit rare, the potential fatal consequences of untreated strongyloidiasis, make it imperative to consider this diagnosis in flaring inflammatory bowel disease (IBD) patients with even a distant history of residence or travel in endemic areas, or in patients failing to respond to standard therapy<sup>[15]</sup>. Eosinophilia should be excluded before initiation of immunosuppression, given the hazards of over-looking a dormant parasitic infection.

### Abstract

Lamivudine has a high rate of antiviral resistance. Sequential treatment of anti-hepatitis B virus (HBV) is commonly used for lamivudine resistance. We report 4 cases of patients with rapid redetection of HBV mutants during the lamivudine retreatment. The four patients received lamivudine as an initial treatment of HBV and adefovir and lamivudine as a rescue therapy consecutively. HBV-DNA level, YMDD mutations and adefovir -resistant mutations (RFMP) were tested every 3 mo during the sequential treatment. All the patients showed YMDD mutations during the initial lamivudine therapy. After adefovir therapy for lamivudine resistance, they showed viral breakthrough. Adefovir was switched to lamivudine, however, it did not induce viral suppression at all, rather increased HBV-DNA with rapid reemergence of the YMDD mutations. All the patients had ALT flares, and hepatic decompensation occurred in two patients. After switching to adefovir combined with entecavir or lamivudine for a rescue therapy, the patients had reduction in HBV-DNA and ALT improvement. These cases demonstrated that lamivudine retreatment of patients with preexposed lamivudine resistance leads to rapid reemergence of YMDD mutation with significant viral rebounds and subsequent hepatic decompensation. Sequential administration of lamivudine in patients with a prior history of YMDD mutation should be abandoned.

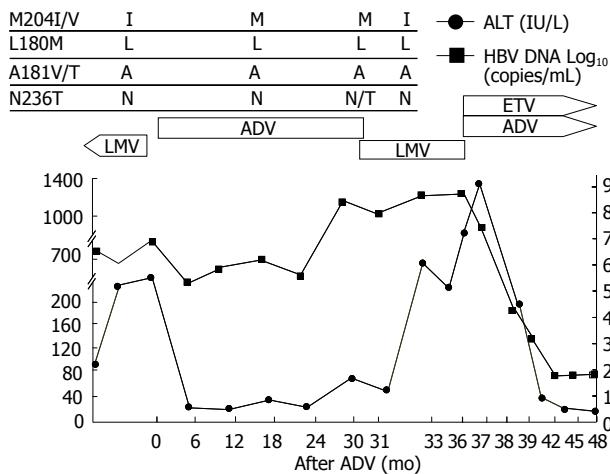

### INTRODUCTION

Lamivudine has been commonly used in the treatment of chronic hepatitis B as a first-line antiviral agent. Long-term lamivudine therapy can usually suppress hepatitis B virus (HBV) replication, however, prolonged monotherapy leads to the emergence of lamivudine-resistant HBV mutants<sup>[1-3]</sup>. The emergence of rtM204I/V (YMDD) mutation of HBV polymerase gene is associated with rebounds in serum HBV DNA and flares of transaminase level<sup>[4]</sup>.

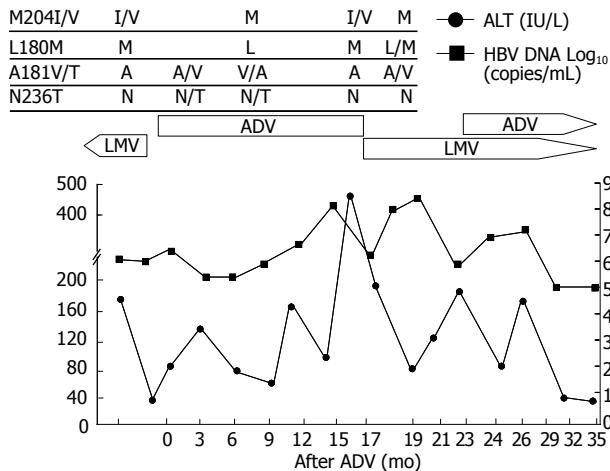

Adefovir dipivoxil is an effective rescue therapy for lamivudine-resistant HBV<sup>[5,6]</sup>. However, adefovir resistance occurs more frequently in second-line treatment of lamivudine-resistant patients than in naïve patients<sup>[7]</sup>. It is well known that sequential monotherapy with antiviral agents induces the sequential occurrence of viral mutations<sup>[8]</sup>. We here report the rapid redetection of YMDD mutants and hepatic decompensation in patients with prior lamivudine resistance during lamivudine retreatment.

### CASE REPORTS

Patient 1 (Figure 1) was a 46-year-old man with HBeAg-positive chronic hepatitis B. Lamivudine was started initially and good virological and biochemical responses were observed in the patient. However, HBV-DNA increased and rtM204I mutation was detected by restriction fragment length polymorphism (RFMP) assay<sup>[9]</sup> after 2 years of lamivudine therapy.

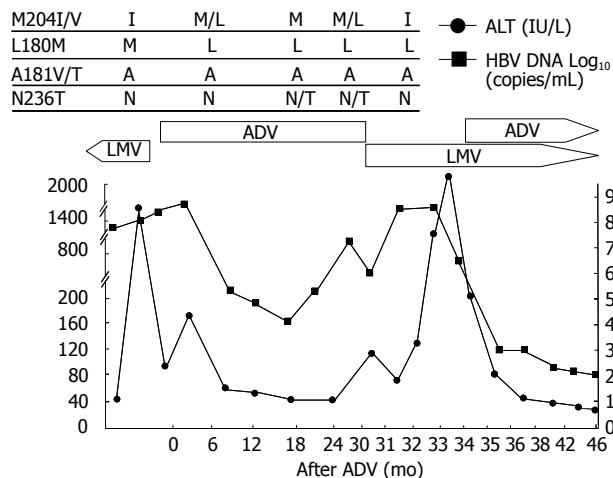

**Figure 1** Viral responses and clinical courses in a 46-year-old man with chronic hepatitis (patient 1). The underline represents sequential evolution of lamivudine- or adefovir- resistant genotypic mutations in HBV polymerase gene. LMV: Lamivudine; ADV: Adefovir; ETV: Entecavir; ALT: Alanine aminotransferase.

**Figure 2** Viral responses and clinical courses in a 49-year-old man with compensated cirrhosis (patient 2). The underline represents sequential evolution of lamivudine- or adefovir- resistant genotypic mutations in HBV polymerase gene. LMV: Lamivudine; ADV: Adefovir; ALT: Alanine aminotransferase.

After lamivudine was switched to adefovir, HBV-DNA dropped by 2 logs with ALT normalization. Viral breakthrough (defined as a  $\geq 1 \log_{10}$  increase in HBV DNA from nadir after initial viral response) and rtN236T mutation developed after 30 mo of adefovir therapy. Lamivudine was restarted with discontinuation of adefovir. After lamivudine was restarted, the rtM204I mutation reemerged and rtN236T adefovir-resistant mutants disappeared 1 mo after the treatment. He showed persistently high levels of HBV-DNA, ALT and total bilirubin. Lamivudine was changed to adefovir and entecavir combination treatment as a rescue therapy. After the combination treatment, HBV-DNA and ALT dropped significantly.

Patient 2 (Figure 2), a 49-year-old man with cirrhosis, showed the similar response to lamivudine retreatment as shown in patient 1. Viral breakthrough with YMDD mutation developed after 15 mo of the

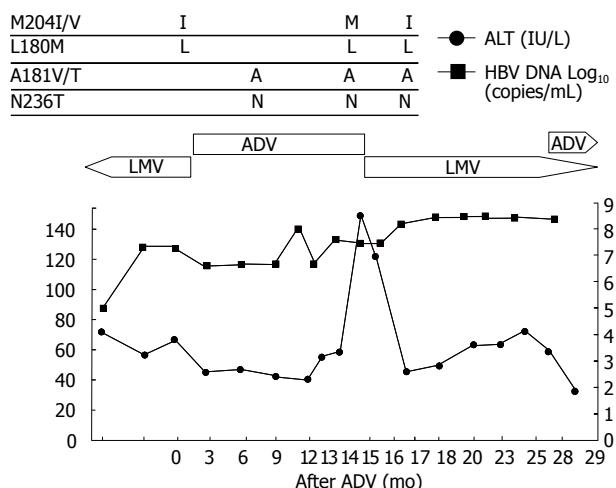

**Figure 3** Viral responses and clinical courses in a 50-year-old woman with decompensated cirrhosis (patient 3). The underline represents sequential evolution of lamivudine- or adefovir- resistant genotypic mutations in HBV polymerase gene. LMV: Lamivudine; ADV: Adefovir; ALT: Alanine aminotransferase.

initial lamivudine treatment. Lamivudine was switched to adefovir, however, there was no decrease in HBV-DNA level but ALT elevation. After reintroduction of lamivudine for adefovir resistance, ALT level decreased without a significant drop in HBV-DNA level initially. Adefovir-resistant mutant was replaced by wild type, however, reemergence of the rtM204I/V mutation followed by HBV-DNA rebound and ALT fluctuation were observed. Adefovir was added to the ongoing lamivudine therapy.

Patient 3 (Figure 3), a 50-year-old woman, had cirrhosis and received lamivudine as an initial treatment. After 16 mo of lamivudine therapy, she had elevated HBV-DNA followed by hepatic decompensation. Mutation profile showed rtM204I and rtL180M at the time of viral breakthrough. Lamivudine was switched to adefovir, and HBV-DNA decreased and her liver function was restored. Viral breakthrough occurred after 27 mo of adefovir treatment and rtN236T mutation was detected at this time. Lamivudine monotherapy was reintroduced consecutively. Rapid increase in HBV-DNA with the rtM204I mutants 2 mo after the lamivudine retreatment and ALT flare with jaundice and ascites occurred subsequently. The rtN236T mutation changed to wild type after the LMV treatment. Adefovir was added to lamivudine as a rescue therapy, and a rapid drop in HBV-DNA and ALT level was observed. The bilirubin decreased from the peak level of 18.7 to 1.6 mg/dL 6 mo after the combination treatment.

Patient 4 (Figure 4), a 50-year-old man with cirrhosis, received lamivudine for 14 mo. He had viral breakthrough with mild elevation of ALT, therefore lamivudine was changed to adefovir. However, he had no viral response though he showed a normal ALT level during the adefovir treatment. Adefovir was switched to lamivudine due to the high viral load. The ALT level was stable despite no decrease in HBV-DNA. After 2 mo

**Figure 4** Viral responses and clinical courses in 50-year-old man with compensated cirrhosis (patient 4). The underline represents sequential evolution of lamivudine- or adefovir- resistant genotypic mutations in HBV polymerase gene. LMV: Lamivudine; ADV: Adefovir; ALT: Alanine aminotransferase.

of lamivudine retreatment, HBV-DNA rebound with ALT flare developed. HBV mutation rtM204I was reappeared at this time. Adefovir was added to the ongoing lamivudine treatment.

All the patients were positive for HBeAg and had no seroconversion of HBeAg during the sequential antiviral treatment except for patient 3. Patient 3 had HBeAg loss after the lamivudine/adefovir combination therapy. No death occurred, however, two of them showed hepatic decompensation following the reemergence of YMDD mutations and viral breakthrough.

## DISCUSSION

These cases showed that reintroduction of lamivudine could induce rapid reemergence of lamivudine-resistant mutations in chronic hepatitis B patients with prior lamivudine resistance. Lamivudine is well tolerated and significantly reduces HBV-DNA level<sup>[10]</sup>. However, lamivudine resistance associated with mutations in the polymerase gene, particularly in rtM204I/V known as YMDD mutant, occurs at a rate of 14%-30% annually<sup>[3,4]</sup>. Development of lamivudine resistance is associated with high baseline HBV-DNA level, duration of lamivudine treatment, precore variant, insufficient serum HBV-DNA suppression and elevated serum ALT level during treatment<sup>[11-13]</sup>. All the cases had positive HBeAg and high viral load at the time of lamivudine resistance. The high viral replication status may predispose to develop antiviral resistant mutations and subsequent viral breakthrough.

Adefovir is an effective rescue therapy for lamivudine-resistant HBV and significantly improves biochemical, virological, and histological features of lamivudine-resistant patients<sup>[5,6]</sup>. Compared with lamivudine, adefovir is associated with a low rate of antiviral resistance<sup>[14]</sup>. However, adefovir resistance occurs more common in patients with preexisting lamivudine resistance<sup>[7]</sup>. Among our cases, rtN236T mutation was detected in two

patients at the time of viral breakthrough after adefovir rescue therapy. The other two showed no virologic response, and rtA181V was found in one patient.

YMDD mutations, mainly rtM204I in our cases, disappeared after the adefovir treatment, suggesting that cessation of antiviral therapy leads to disappearance of drug-resistant mutations. However, it was reported that lamivudine-resistant HBV mutants reappear rapidly after reintroduction of lamivudine<sup>[15]</sup>. Once antiviral-resistant HBV mutants have been selected, the mutants are archived even if treatment is stopped. In our cases, YMDD mutation reemerged within 3 mo after reintroduction of lamivudine, suggesting that re-treatment to which the virus has been previously resistant has a limited efficacy even after wild-type YMDD has restored. It could not be excluded that the adefovir-resistant mutations may affect the rapid emergence of lamivudine-resistant mutation.

The emergence of lamivudine resistance can result in viral breakthrough, flares of hepatitis and worsening of the initial histological improvement<sup>[1,2]</sup>. In patients with cirrhosis, severe exacerbation of hepatitis may result in hepatic failure<sup>[16]</sup>. It was reported that patients with YMDD mutations experience a higher rate of hepatitis flares than those without YMDD mutations<sup>[17]</sup>, which is possibly because the YMDD locus takes part in cellular immune response in some cases.

Serum HBV DNA level was higher than baseline in the cases after emergence of the YMDD mutant before exacerbation occurred. Two patients experienced a very rapid deterioration of hepatic function accompanying the reemerging YMDD mutants only a few months after lamivudine reintroduction. These findings clearly demonstrate that sequential monotherapy, particularly retreatment with the antiviral agent to which the HBV has been previously resistant, should be avoided.

Combination therapy with adefovir and lamivudine or other antiviral agents could be a better option to prevent the emergence of antiviral-resistant mutations in patients with lamivudine- or adefovir -resistance. Combination therapy is not likely to improve virologic response, but rather decrease the rate of viral resistance<sup>[18,19]</sup>. Unfortunately, combination therapy could not be commonly used in Korea so far because of the high cost of antiviral agents. Other antiviral agents, such as tenofovir or pegylated interferon, could be promising agents for multi-drug resistant HBV<sup>[20,21]</sup>. All the patients in this study received combination therapy with adefovir and lamivudine or entecavir as a rescue therapy for lamivudine resistance. After the combination treatment, the HBV DNA and ALT level dropped and hepatic function was restored. It was reported that entecavir has a potent antiviral efficacy against naïve HBV and lamivudine-refractory HBV<sup>[22]</sup>. Case 1 received adefovir and entecavir as the rescue therapy. These two agents have antiviral activity on wild type or YMDD mutants without cross resistance. The other three patients received adefovir and lamivudine combination treatment. Case 3 showed a rapid reduction in HBV DNA level and HBeAg seroconversion soon after the combination

therapy. Long-term data are not available from cases 2 and 4. However, they showed a significant decrease in HBV DNA level and improvement in hepatic function after combination therapy.

Taken together, lamivudine retreatment may induce rapid reemergence of the YMDD mutation and significant viral rebound and subsequent hepatic flare in patients with preexposed YMDD mutants. Sequential lamivudine treatment of those with a prior history of YMDD mutation should be abandoned.

### Abstract

Nutritional therapy for active Crohn's disease (CD) is an underutilized form of treatment in adult patients, though its use is common in the paediatric population. There is evidence that nutritional therapy can effectively induce remission of CD in adult patients. Enteral nutrition therapy is safe and generally well tolerated. Meta-analysis data suggest that corticosteroids are superior to nutritional treatment for induction of remission in active CD. However, the potential side effects of such pharmacotherapy must be taken into consideration. This review examines the evidence for the efficacy of elemental and polymeric diets, and the use of total parenteral nutrition in active CD.

### TO THE EDITOR

Nutritional therapies studied for the induction of remission in active Crohn's disease (CD) include enteral

nutrition (EN), and total parenteral nutrition (TPN). EN by means of a polymeric diet can be given via the nasogastric or per oral route. Compliance tends to be greater with polymeric nutrition support than with an elemental diet, as the feed is considered more palatable. Polymeric diets provide nitrogen in the form of whole protein, and carbohydrates as hydrolysates of starch. Fat is most often provided as medium chain fatty acids. Fiber is commonly added to polymeric feeds though there is little evidence to suggest that it has a substantial positive or negative effect in hospitalized patients<sup>[1]</sup>. Elemental diets contain nutrients in simple forms (such as amino acids, simple carbohydrates, fats, vitamins and minerals) requiring little or no digestion to take place prior to absorption.

The theory behind the mechanism of action of an elemental diet is multi-factorial. Malnutrition can have effects on immune function and wound healing, as well as psychological and cognitive effects. Improvements in wound healing by ensuring a good nutritional status would theoretically lead to enhanced mucosal healing. Increased gut permeability has been implicated in the pathophysiology of CD. This is thought to relate to abnormalities in the tight junctions between enterocytes allowing an increase in luminal antigen uptake-potentially a factor contributing to increased inflammatory activity<sup>[2]</sup>. Treatment with an elemental diet has been shown to decrease intestinal permeability<sup>[3]</sup>. The incidence of CD dramatically increased in the twentieth century<sup>[4]</sup>. This coincides with many changes in our daily lives, including changes in our dietary intake. As elemental diets involve the ingestion of specific substances, it may be that pro-inflammatory antigens are avoided. The normal commensal bacterial population of the gut may play a role in the development of inflammation in CD, though the mechanism is unclear. In experimental animal models, inflammation does not develop in mice reared in a sterile environment<sup>[5]</sup>. An early study suggested the amount of bacteria per gram of faeces was reduced in patients on an elemental diet, though there is no consensus on this issue<sup>[6]</sup>. The constituents of an elemental diet are primarily absorbed in the proximal small bowel-proximal to the most commonly affected sites of inflammation in CD. The reduction in the workload of digestion and absorption, and a reduction in peristalsis and digestive tract secretions may also play a role<sup>[7]</sup>. In general, elemental diets contain a low proportion of fat compared to polymeric or normal diets. A recent Cochrane review concluded that there is a non-significant trend towards greater efficacy with

very low fat and long-chain triglyceride elemental diets compared to standard elemental diet regimes<sup>[8]</sup>.

High quality randomised controlled trials looking at the use of nutritional therapy for the management of acute CD are difficult to perform. There have been very few studies where the remission rate with nutritional therapy is as low as that seen in the placebo arm of drug trials in active CD. So, if we accept that nutritional treatments have an effect, then the question arises as to the magnitude of this effect. According to some studies, remission rates may be as high as 84% with the use of an elemental diet<sup>[9]</sup>. The Cochrane review (2007) of enteral feeding in active CD provides us with very useful meta-analysis data<sup>[8]</sup>. As found in previous meta-analyses, the Cochrane review concluded that steroids have superior efficacy to enteral nutrition in inducing remission<sup>[8]</sup>. The exact role of enteral nutrition (EN) in adults to treat active CD is therefore undefined.

## TRIALS COMPARING ELEMENTAL DIET TO CORTICOSTEROIDS

A number of studies have been conducted looking into the efficacy of elemental diets in CD patients. Riordan *et al*<sup>[9]</sup> studied 136 patients with active CD. An elemental diet was introduced and all other CD treatments discontinued. The intention was to give an elemental diet for 2 wk, though 31% of the patients did not tolerate the diet for more than 1 wk. Of the 78 remaining patients, 84% achieved disease remission after a 14-d treatment course. The group was then split into 38 patients receiving a tapered course of prednisolone and advice on healthy eating, and 40 patients receiving placebo instead of steroid—this ‘diet’ group was asked to introduce one new food each day and exclude foods that worsened symptoms. There was a median remission of 3.8 mo in the steroid group compared to 7.5 mo in the diet group.

Gorard *et al*<sup>[10]</sup> compared 22 patients given an elemental diet (4 wk treatment) to 20 patients receiving prednisolone (0.75 mg/kg daily for 2 wk followed by reducing doses). All participants were CD patients requiring hospitalisation for an acute flare of the disease. Nine of the twenty-two patients (41%) in the diet arm of the trial withdrew because of intolerance. Disease activity was measured using a simple disease activity index. The reduction in disease activity was similar between the diet (score of 4.8 reducing to 1.7) and prednisolone (score of 5.3 reducing to 1.9) groups. In addition to this, similar reductions in C-reactive protein, and increases in serum albumin concentration were found. The probability ratio of remaining patients in remission was, however, much lower in the diet group. At 6 mo, this probability was 0.67 after steroid compared to 0.28 after elemental diet.

## TRIALS COMPARING POLYMERIC DIET TO CORTICOSTEROIDS

Many trials involving polymeric and enteral diets in CD

have been conducted in children, due to the perceived need to avoid corticosteroids, to alleviate the additional risk of growth failure. Day *et al*<sup>[11]</sup> looked at 27 children with active CD (15 new diagnoses, 12 with known disease). They gave a polymeric feed as the exclusive source of nutrition for 6–8 wk either per oral or via a NG tube. No other medical therapy was used at that time. Twenty-four of the twenty-seven children completed the 6–8 wk course, while the other three did not tolerate enteral feeding. At the end of the treatment period, 80% of the newly diagnosed patients and 58% of the known-CD patients had entered remission. The CD remained inactive in all of the newly diagnosed patients with entered remission, over the mean 15.2-mo follow-up period.

Borrelli *et al*<sup>[12]</sup> conducted a trial comparing polymeric diet to corticosteroids in 37 children with active treatment in naïve CD patients. The study period was 10 wk, and after this time 15 of the 19 children (79%) receiving a polymeric diet had remission compared to 12 of the 18 patients in the corticosteroid group (67%). The differences were not statistically significant. An additional interesting aspect of this trial was that mucosal healing was assessed by endoscopy with histology at weeks 0 and 10. The proportion of children with mucosal healing was significantly higher in the polymeric diet group (74%) than in the corticosteroid group (33%).

The use of a polymeric diet in adult patients with CD has also been studied. Gonzalez-Huix *et al*<sup>[13]</sup> conducted a randomised controlled trial comparing adults with acute CD receiving 1 mg/kg per day prednisolone ( $n = 17$ ) followed by a reducing course, to those on a polymeric diet and no medication ( $n = 15$ ). The polymeric feed was given via a fine-bore NG tube and no other nutrition allowed. The polymeric diet patients went back to a normal diet after clinical remission was achieved. Of the seventeen patients in the steroid group, fifteen entered remission after a mean time of 2 wk. One patient had an intestinal perforation requiring surgery, and the others entered remission after being started on a polymeric diet. Of the 15 patients in the polymeric diet group, 12 entered remission after a mean time of 2.4 wk. Of the 3 treatment failures, one improved when steroids were given, and the other two were said to have failed as they did not enter remission after 4 wk on the polymeric feed. Patients from both arms of the trial were started on oral 5-ASA preparations prior to discharge. The cumulative probability of relapse during the follow-up period was higher after steroid treatment than after polymeric diet though this did not reach a statistical significance.

There is some evidence to suggest that the amount and type of fat in polymeric feeds may have an impact on its efficacy in CD patients. Gassull *et al*<sup>[14]</sup> hypothesised that a polymeric diet rich in monounsaturated fatty acids (MUFA) would be more effective in inducing remission in active CD patients than an identical diet but with polyunsaturated fatty acids (PUFA)-precursors of some inflammatory cytokines. They randomised 62 patients with active CD to either one of these diets for no longer

than 4 wk, or to 1 mg/kg per day prednisolone. The steroid group reacted as expected from previous studies with a 79% remission rate. However, the diet group did not fare as well. Only 20 % in the MUFA group entered remission, while 52% in the PUFA group achieved this target. These results were quite the opposite of those expected. Leiper *et al*<sup>[15]</sup> conducted a randomised trial in 54 patients with active CD. They received a polymeric diet with either high or low long-chain triglyceride (LCT) content. A staggering 39% of patients withdrew from the trial within 3 wk because of an inability to tolerate the diet, which was offered by either the oral or nasogastric route. Of those completing the trial, the response rate was 46% for the low LCT group and 45% for the high LCT group, respectively, thereby demonstrating no significant difference in efficacy with differing fat composition.

## COCHRANE COLLABORATION REVIEW OF ENTERAL NUTRITION THERAPY FOR THE INDUCTION OF REMISSION IN ACTIVE CD

There have been four meta-analyses looking at the use of enteral nutrition therapy in comparison to steroids to induce remission in active CD patients. Overall, each of these meta-analyses showed steroids to be more effective than enteral nutrition strategies. However, when two large trials were excluded because of the concomitant use of other medicines in the steroid arm, both enteral nutrition and steroids were seen to have an equal efficacy. A recent review from the Cochrane Collaboration studied the results from trials comparing different types of enteral nutrition (EN) to each other, and trials comparing the use of EN to steroids<sup>[8]</sup>. When looking at differences between diet formulations used to treat patients with acute CD, they performed a meta-analysis which included data from 188 adult patients treated by elemental diet and 146 patients given a polymeric diet. No significant difference was found in the results achieved between elemental and polymeric diets.

Sub-group analysis showed no difference between formulae with high fat *versus* low fat content. Differences in the amount of fat in the form of high *versus* low long-chain triglyceride were also shown not to be significant. Meta-analysis of trials comparing enteral feeding to corticosteroids compared data from 192 enteral nutrition patients *versus* 160 patients treated with steroid, which revealed a pooled odds ratio of 0.33 favouring steroid treatment.

## TOTAL PARENTERAL NUTRITION AS A TREATMENT FOR ACTIVE CD

Controlled trials of total parenteral nutrition (TPN) in CD patients are few and far between. Greenberg *et al*<sup>[16]</sup> conducted a trial in 51 patients with active CD. They were

randomised to either TPN and nil by mouth ( $n = 17$ ), partial parenteral nutrition (PPN) and supplementary nutrition with a liquid feed of a defined formula *via* a NG tube ( $n = 19$ ), or PPN and supplementary normal food ( $n = 15$ ). Remission occurred in 71% of patients on TPN, in 58% of patients on the PPN/defined formula diet, and in 60% of patients on PPN/normal diet. Of those achieving remission, the chance of successfully remaining in remission at one year was 42%, 55%, and 56%, respectively. The differences were found not to be significant. The total bowel rest achieved through TPN was therefore not thought to be of importance.

## DISCUSSION

There is a disappointing lack of quality studies on the use of TPN in active CD patients. It is difficult to find a place for TPN as a treatment for active CD. The efficacy of TPN does not seem to be greater than that suggested by other trials of EN or steroids. TPN is known to be associated with an increased risk of adverse events, such as sepsis, although perhaps it has a place in patients intolerant to both EN and steroids. The value of TPN in malnourished patients with intestinal failure due to CD is beyond doubt.

There would seem no logical reason to choose EN over steroids for the vast majority of our patients. The European Society for Parenteral and Enteral Nutrition published guidelines in 2006 on the use of enteral nutrition in gastroenterology<sup>[17]</sup>. They suggested that a role could be found for EN in active CD in the following circumstances: steroid intolerance, patient refusal of steroids, EN in combination with steroids in undernourished individuals, and in patients with an inflammatory stenosis of the small intestine.

EN plays a greater role in children with active CD. In this group of patients, EN has been shown to have an efficacy equal to steroids. Therefore, it would seem perfectly reasonable to prescribe EN instead of steroids in the hope of avoiding steroid side-effects, including deleterious effects upon growth and development of children. The use of corticosteroids increases the risk of permanent growth failure in children, and 20%-30% will become adults with an abnormally short stature whether or not they are exposed to prolonged courses of steroids<sup>[18]</sup>.

The nutritional status in those with acute CD is important. Differences are seen between patients in an active phase of disease and those in remission. Weight loss is found in up to 75% of patients hospitalized with an exacerbation of CD, with a negative nitrogen balance present in more than 50%, whereas the majority of patients in remission are of normal nutritional status<sup>[17]</sup>. The role of nutritional therapy in the maintenance of a good nutritional status in CD patients is important, especially as the condition itself will predispose to malnutrition.

When EN is to be used, the type of formula does not make any difference to the efficacy. Polymeric diets are less expensive and more palatable than elemental

diets, and therefore it would seem reasonable to suggest that there is no place for the elemental diet.

## Meetings

### Events Calendar 2008-2009

FALK SYMPOSIA 2008  
January 24-25, Frankfurt, Germany  
Falk Workshop: Perspectives in Liver Transplantation

International Gastroenterological Congresses 2008  
February 14-16, Paris, France  
EASL-AASLD-APASL-ALEH-IASL Conference Hepatitis B and C virus resistance to antiviral therapies  
[www.easl.ch/hepatitis-conference](http://www.easl.ch/hepatitis-conference)

February 14-17, Berlin, Germany  
8<sup>th</sup> International Conference on New Trends in Immunosuppression and Immunotherapy  
[www.kenes.com/immuno](http://www.kenes.com/immuno)

February 28, Lyon, France  
3<sup>rd</sup> Congress of ECCO - the European Crohn's and Colitis Organisation Inflammatory Bowel Diseases 2008  
[www.ecco-ibd.eu](http://www.ecco-ibd.eu)

February 29, Québec, Canada  
Canadian Association of Gastroenterology  
E-mail: general@cag-acg.org

March 10-13, Birmingham, UK  
British Society of Gastroenterology Annual Meeting  
E-mail: BSG@mailbox.ulcc.ac.uk

March 14-15, HangZhou, China  
Falk Symposium 163: Chronic Inflammation of Liver and Gut

March 23-26, Seoul, Korea  
Asian Pacific Association for the Study of the Liver  
18<sup>th</sup> Conference of APASL: New Horizons in Hepatology  
[www.apaslseoul2008.org](http://www.apaslseoul2008.org)

March 29-April 1, Shanghai, China  
Shanghai-Hong Kong International Liver Congress  
[www.livercongress.org](http://www.livercongress.org)

April 05-09, Monte-Carlo (Grimaldi Forum), Monaco  
OESO 9<sup>th</sup> World Congress, The Gastro-esophageal Reflux Disease: from Reflux to Mucosal Inflammation-Management of Adeno-carcinomas  
E-mail: robert.giuli@oeso.org

April 9-12, Los Angeles, USA  
SAGES 2008 Annual Meeting - part of Surgical Spring Week  
[www.sages.org/08program/html/](http://www.sages.org/08program/html/)

April 18-22, Buenos Aires, Argentina  
9<sup>th</sup> World Congress of the International Hepato-Pancreato Biliary Association  
Association for the Study of the Liver  
[www.ca-ihpba.com.ar](http://www.ca-ihpba.com.ar)

April 23-27, Milan, Italy

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London, The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

#### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjnet.com](mailto:submission@wjnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express  $t$  test as  $t$  (in italics),  $F$  test as  $F$  (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as  $r$  (in italics), degree of freedom as  $v$  (in Greek), sample number as  $n$  (in italics), and probability as  $P$  (in italics).

## Units

Use SI units. For example: body mass,  $m$  (B) = 78 kg; blood pressure,  $p$  (B) = 16.2/12.3 kPa; incubation time,  $t$  (incubation) = 96 h, blood glucose concentration,  $c$  (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration,  $p$  (CEA) = 8.6 24.5  $\mu$ g/L;  $CO_2$  volume fraction, 50 mL/L  $CO_2$ , not 5%  $CO_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities:  $t$  time or temperature,  $c$  concentration,  $A$  area,  $l$  length,  $m$  mass,  $V$  volume.

Genotypes:  $gyrA$ ,  $arg\ 1$ ,  $c\ myc$ ,  $c\ fos$ , etc.

Restriction enzymes:  $EcoRI$ ,  $HindII$ ,  $BamHI$ ,  $KhoI$ ,  $KpnI$ , etc.

Biology:  $H\ pylori$ ,  $E\ coli$ , etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903  
Ocean International Center, Building D  
No. 62 Dongsihuan Zhonglu  
Chaoyang District, Beijing 100025, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>  
Telephone: +86-10-59080039  
Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

<b>EDITORIAL</b>	4429 New insights into calcium, dairy and colon cancer <i>Holt PR</i>
	4434 Molecular basis of the potential of mesalazine to prevent colorectal cancer <i>Stolfi C, Pellegrini R, Franzè E, Pallone F, Monteleone G</i>
	4440 Thrombosis and inflammatory bowel disease-the role of genetic risk factors <i>Tsiolakidou G, Kourtroubakis IE</i>
<b>TOPIC HIGHLIGHT</b>	4445 Hepatocellular carcinoma: Defining the place of surgery in an era of organ shortage <i>Bartlett A, Heaton N</i>
<b>CLINICAL RESEARCH</b>	4454 Clinical significance of NOD2/CARD15 and Toll-like receptor 4 gene single nucleotide polymorphisms in inflammatory bowel disease <i>Rigoli L, Romano C, Caruso RA, Lo Presti MA, Di Bella C, Procopio V, Lo Giudice G, Amorini M, Costantino G, Sergi MD, Cuppari C, Calabro GE, Gallizzi R, Salpietro CD, Fries W</i>
<b>BASIC RESEARCH</b>	4462 Metabolomic changes in fatty liver can be modified by dietary protein and calcium during energy restriction <i>Pilvi TK, Seppänen-Laakso T, Simolin H, Finckenberg P, Huotari A, Herzog KH, Korpela R, Orešić M, Mervaala EM</i>
	4473 Lysophosphatidic acid induced nuclear translocation of nuclear factor- $\kappa$ B in Panc-1 cells by mobilizing cytosolic free calcium <i>Arita Y, Ito T, Oono T, Kawabe K, Hisano T, Takayanagi R</i>
<b>RAPID COMMUNICATION</b>	4480 Comparison of esophageal capsule endoscopy and esophagogastroduodenoscopy for diagnosis of esophageal varices <i>Frenette CT, Kuldau JG, Hillebrand DJ, Lane J, Pockros PJ</i>
	4486 Association between <i>calcium sensing receptor</i> gene polymorphisms and chronic pancreatitis in a US population: Role of <i>serine protease inhibitor Kazal 1 type</i> and alcohol <i>Muddana V, Lamb J, Greer JB, Elinoff B, Hawes RH, Cotton PB, Anderson MA, Brand RE, Slivka A, Whitcomb DC</i>
	4492 Folic acid supplementation inhibits recurrence of colorectal adenomas: A randomized chemoprevention trial <i>Jaszewski R, Misra S, Tobi M, Ullah N, Naumoff JA, Kucuk O, Levi E, Axelrod BN, Patel BB, Majumdar APN</i>
	4499 CT colonography after incomplete colonoscopy in subjects with positive faecal occult blood test <i>Sali L, Falchini M, Bonanomi AG, Castiglione G, Ciatto S, Mantellini P, Mungai F, Menchi I, Villari N, Mascalchi M</i>

**Contents**

**World Journal of Gastroenterology**  
**Volume 14 Number 28 July 28, 2008**

- 4505** Development of hepatorenal syndrome in bile duct ligated rats  
*Pereira RM, dos Santos RAS, Oliveira EA, Leite VHR, Dias FLC, Rezende AS, Costa LP, Barcelos LS, Teixeira MM, Simões e Silva AC*
- 4512** Effects of microalgae chlorella species crude extracts on intestinal adaptation in experimental short bowel syndrome  
*Kerem M, Salman B, Pasaoglu H, Bedirli A, Alper M, Katircioglu H, Atici T, Perçin EF, Ofluoglu E*
- 4518** Risk factors of thrombosis in abdominal veins  
*Dutta AK, Chacko A, George B, Joseph JA, Nair SC, Mathews V*
- 4523** Laryngopharyngeal reflux in patients with reflux esophagitis  
*Lai YC, Wang PC, Lin JC*
- 4529** Macro-regenerative nodules in biliary atresia: CT/MRI findings and their pathological relations  
*Liang JL, Cheng YF, Concejero AM, Huang TL, Chen TY, Tsang LLC, Ou HY*
- 4535** Celecoxib-related gastroduodenal ulcer and cardiovascular events in a randomized trial for gastric cancer prevention  
*Feng GS, Ma JL, Wong BCY, Zhang L, Liu WD, Pan KF, Shen L, Zhang XD, Li J, Xia HHX, Li JY, Lam SK, You WC*
- 4540** Radiofrequency ablation as a treatment for hilar cholangiocarcinoma  
*Fan WJ, Wu PH, Zhang L, Huang JH, Zhang FJ, Gu YK, Zhao M, Huang XL, Guo CY*
- 4546** Delayed ethyl pyruvate therapy attenuates experimental severe acute pancreatitis via reduced serum high mobility group box 1 levels in rats  
*Yang ZY, Ling Y, Yin T, Tao J, Xiong JX, Wu HS, Wang CY*
- 4551** Programmed death-1 expression is associated with the disease status in hepatitis B virus infection  
*Ye P, Weng ZH, Zhang SL, Zhang JA, Zhao L, Dong JH, Jie SH, Pang R, Wei RH*
- 4558** Effect of admission hypertriglyceridemia on the episodes of severe acute pancreatitis  
*Deng LH, Xue P, Xia Q, Yang XN, Wan MH*
- 4562** Correlation between expression and differentiation of endocan in colorectal cancer  
*Zuo L, Zhang SM, Hu RL, Zhu HQ, Zhou Q, Gui SY, Wu Q, Wang Y*
- 4569** Diagnosis and treatment of spontaneous colonic perforation: Analysis of 10 cases  
*Yang B, Ni HK*

**CASE REPORT**

- 4573** Anabolic steroid abuse causing recurrent hepatic adenomas and hemorrhage  
*Martin NM, Abu Dayeh BK, Chung RT*
- 4576** Cerebral venous thrombosis and heparin-induced thrombocytopenia in an 18-year old male with severe ulcerative colitis  
*Thorsteinsson GS, Magnusson M, Hallberg LM, Wahlgren NG, Lindgren F, Malmborg P, Casswall TH*
- 4580** Septic thrombophlebitis of the porto-mesenteric veins as a complication of acute appendicitis  
*Chang YS, Min SY, Joo SH, Lee SH*

**Published online:** July 28, 2008

increasing dramatically in the rest of the world. In the United States, colorectal cancer is the second most common cause of cancer deaths, with an incidence of around 130 000 cases a year and a mortality rate of approximately 55-60 000<sup>[1]</sup>. The World Health Organization statistics for colorectal cancer incidences worldwide in 1996 showed about 875 000 cases with a mortality of over 500 000. The incidence of this tumor in the less well developed countries of the world is increasing dramatically so that the death rate for this tumor far exceeds the 7.2% of all cancer deaths reported by the WHO. Incidence and mortality rates differ markedly across countries with the highest rates reported from Australia and Northern Great Britain and the lowest rates in Southern Africa. This 30-fold difference in incidence underscores the importance of environmental factors in inducing this cancer.

Although the treatment of established colorectal cancer has improved remarkably over the last half century, mortality rates still are high, particularly in our aging population. Therefore, a major focus of the management of this tumor has been in the area of cancer prevention which is better termed "cancer risk reduction". There are three modalities of cancer prevention; tertiary prevention is when efforts are made to lower the risk of a second cancer once a primary tumor has been diagnosed. A good example of this is the use of tamoxifen for risk reduction of breast cancer in women who have had one breast cancer and the use of retinoid acting agents to lower the risk of second squamous cancers of the aero-digestive tract. Secondary prevention involves the abolition of pre-cancerous neoplastic lesions, thus lowering the risk of the later development of cancer. For the colorectum, secondary prevention by detection of neoplastic colorectal adenomas and adenoma polypectomy has become an established preventive technique and has been demonstrated to be effective in lowering the incidence of this tumor<sup>[2]</sup>. Primary prevention aims to reduce the development of a cancer before tissue pre-neoplastic changes occur. This is the approach where calcium and dairy products appear to have an important role in lowering the risk of colorectal cancer. It must be emphasized that in order to advocate a primary cancer prevention modality which is likely to be applied to large numbers of the population, it must have an excellent benefit to risk ratio. The term "chemoprevention" which is better called "risk reduction" has been applied to these approaches. Chemoprevention involves the use

### Abstract

This paper is to review recent information about the relationship of calcium and dairy foods to colon cancer. The review focuses on primary prevention, discusses the potential components in dairy foods that might be anti-neoplastic, reviews the epidemiologic information and describes intervention studies demonstrating efficacy of calcium and vitamin D in reducing colorectal polyp recurrence. Since vitamin D is important in cancer prevention, pertinent data is discussed and potential mechanisms of actions presented. Calcium and vitamin D are important agents for the primary prevention of colorectal neoplasia.

### INTRODUCTION

Colorectal cancer is a common and lethal disease in the Western World and the incidence and mortality is

of an agent to slow the progress, to reverse or inhibit the process of carcinogenesis. Such agents may act at different levels modulating cancer production at the level of the cell, at the molecular level, at the whole tissue level or potentially at the whole patient clinical level.

There are many components of dairy foods that have been shown experimentally to have protective effects against colon cancer. These components include calcium and vitamin D for which there is most evidence and (which will be discussed below), conjugated linoleic acid<sup>[5]</sup>, sphingolipids<sup>[4]</sup> and the potential of butyric acid formed by colonic lactobacilli from milk products. Clearly if one includes bacterial cultures, i.e. probiotics added to dairy products, there is an increasingly important literature that suggests that such agents may be beneficial in reducing the risk of colorectal neoplasia<sup>[5]</sup>.

## EPIDEMIOLOGY

There have been numerous epidemiologic studies that have suggested that calcium or dairy products may lower the risk of colorectal neoplasia. The data for many of these have been reviewed recently<sup>[6]</sup>. An important prospective epidemiologic study was performed in over 45 000 Swedish men, aged 45 to 79 years<sup>[7]</sup>. In this study, calcium intake was determined from food frequency questionnaires and there was a mean follow up of between 6 and 7 years. The data on colorectal cancer incidence, when analyzed for the highest versus the lowest quartile for calcium intake, showed a statistically significant reduction in colon cancer development with a mean odds ratio of 0.68 and for dairy intake a mean odds ratio of 0.46. Using multivariate analysis, the data from this study suggested that there might be a threshold effect at about 1200 mg to 1400 mg of calcium per day<sup>[7]</sup>.

## CALCIUM

At the present time, the gold standard for measuring risk reduction by an intervention in colorectal cancer uses determination of the incidence of recurrence of adenomatous polyps following removal of all colonic polyps by polypectomy. This approach was originally developed by Baron JA (Baron JA, Beach M, Mandel JS, van Stolk RU, Haile RW, Sandler RS, Rothstein R, Summers RW, Snover DC, Beck GJ, Bond JH, Greenberg ER. Calcium supplements for the prevention of colorectal adenomas. Calcium Polyp Prevention Study Group. *N Engl J Med* 1999; 340: 101-107) and his co-workers to analyze the beneficial effects of calcium for adenomatous polyp reduction<sup>[8]</sup>. Subsequent analyses have evaluated reduction of total adenomatous polyps and reduction of advanced polyps as defined by size and the presence of severe dysplasia. Calcium supplementation of 1200 mg per day reduced total adenomas by approximately 20%<sup>[8]</sup>, but advanced adenomas by about 45%<sup>[9]</sup>. If one translates these data into numbers of adenomas that would be reduced

in the United States by increased calcium intake this would total approximately 26 000 cases of adenomas with a more important impact on the advanced lesions. Subsequent analyses by Baron's group showed that most of the effect of calcium in lowering the incidence of recurrent adenomas occurred in individuals who had baseline levels of serum 25 hydroxy vitamin D above the median (about 29 ng per mL) with little effect in individuals with lower levels<sup>[10]</sup>. These data strongly suggest that it is the combination of calcium and vitamin D which is important in altering adenoma recurrence. A prospective US national study is ongoing to examine the relative effects of calcium, vitamin D or the combination of calcium plus vitamin D on colorectal adenoma recurrence. In a further recent publication, Baron JA and coworkers have followed calcium supplemented subjects for ten years after completing the ongoing study<sup>[11]</sup>. These data suggested that the beneficial effect of calcium upon adenoma recurrence persisted for five years even in subjects who were not taking supplemental calcium after stopping the formal study and showed 40% less adenoma recurrence when compared to control placebo treated subjects. After 5 years after no further beneficial effect of calcium administration was demonstrated<sup>[11]</sup>.

The classical hypothesis for the beneficial effects of calcium derived from an original physiochemical hypothesis by Newmark and colleagues in which they suggested that fatty acids and bile acids in the colon may be detrimental to the epithelium and important in the initial steps of colorectal carcinogenesis and that calcium could bring bile acids and fatty acids out of solution in the colonic lumen and, thus, reduce the cytotoxicity of these agents<sup>[12]</sup>. A number of studies by Van der Meer's group subsequently were consistent with this hypothesis even in *in-vivo* studies<sup>[13,14]</sup>.

However, calcium is known to have manifold cellular effects in colonic epithelial cells suggesting that these must be important in the action of this compound upon colorectal carcinogenesis. Two recent areas of research suggest that other mechanisms may well be crucial in the cellular effects of calcium. The human parathyroid calcium sensing receptor which senses minor changes in extra-cellular calcium concentrations is expressed in differentiated cells of the human colonic crypt. The receptor is partially or completely lost during colon carcinogenesis<sup>[15]</sup>. The calcium sensing receptor has two promoters with vitamin D response elements. *In vitro*, calcium and vitamin D stimulate the calcium sensing receptor promoter activity in colonic cells to reduce E-cadherin expression and inhibit TCF4. Thus, this receptor may function to regulate epithelial differentiation and be anticarcinogenic<sup>[15]</sup>. In addition, evidence suggests that the cardiac L-type calcium channel is present in colon tissue and may play a role in determining calcium influx into colonic epithelial cells<sup>[16]</sup>.

Vitamin D stores of the body derive from photolysis of 7 dehydrocholesterol in the skin to form pre-vitamin D<sub>3</sub>, which rapidly isomerizes at body temperature to form vitamin D<sub>3</sub> and then passes into the circulation.

Dietary vitamin D<sub>2</sub> and vitamin D<sub>3</sub> is absorbed from the intestinal lumen in micellar form and after transfer into intestinal lymph passes into the circulation where it is bound to a vitamin D binding protein. Vitamin D from both cutaneous and intestinal sources is taken up by the liver and converted to 25 hydroxy vitamin D (25 OHD<sub>3</sub>). The circulating levels of serum 25 OHD<sub>3</sub> reflect the body stores of this vitamin. 25 OHD<sub>3</sub> is transported to the periphery and converted to calcitriol, (1,25 dihydroxy vitamin D3 1,25 (OH)<sub>2</sub>D<sub>3</sub>), mainly in the kidney but also in many peripheral tissues by the action of the enzyme 1 alpha hydroxylase (CYP 27 B2). 1,25 (OH)<sub>2</sub>D<sub>3</sub> is bound to vitamin D receptors present in many tissues and has pleiomorphic actions in bone, the gastrointestinal tract and uterus, etc.

Epidemiologic studies of vitamin D effects upon human health have included evaluation of effects of sunlight (ultraviolet) exposure, analysis of dietary and supplemental vitamin D intake as well as measurement of serum 25 hydroxy vitamin D levels.

There is abundant epidemiologic data to show that exposure to sunlight results in a reduction in the incidence of many cancers, but most clearly reduced colorectal cancer. The original observations of Cedric Garland<sup>[17]</sup> which followed upon a forgotten report in 1941<sup>[18]</sup> showed a distinct North to South latitude difference in colorectal cancer development. More recently, several studies have shown not only a lowering of colorectal cancer incidence, but also that for breast, ovary and prostate<sup>[19]</sup> accompanied by the expected increased non-melanoma skin cancer formation. Other studies have also pointed to beneficial changes of sunlight in esophageal, renal and bladder cancer as well as non-Hodgkins lymphoma<sup>[20]</sup>.

Many investigators have analyzed the relationship of colorectal cancer prevalence with vitamin D body stores, i.e. measurement of circulating 25 OHD<sub>3</sub>. A metanalysis of vitamin D intake studies using dose response gradient analysis showed a reduction in colorectal cancer of approximately 20%<sup>[21]</sup>. In 2006, Garland analyzed positive and negative studies comparing serum 25 OHD levels and the development of colorectal, breast and prostate cancer. Six of seven studies of colorectal cancers showed a significant reduction of cancer and one was borderline, whereas for breast cancer only one was significant and one showed no effect with similar negative results for prostate cancer<sup>[22]</sup>. Further evidence for the beneficial effect of higher levels of 25 OHD were shown in the distal colon of older women (OR = 0.45)<sup>[23]</sup> and in black men<sup>[24]</sup>, because of lower action of sunlight in pigmented skin to form this vitamin. A prospective 7.75 year study of serum levels of vitamin D showed a 55% reduction in cancer development in the highest compared to the lowest quartile<sup>[25]</sup>.

## MECHANISMS OF ACTION OF VITAMIN D

The cellular activity of vitamin D is dependent on the

action of calcitriol principally through interaction with a high affinity binding protein (VDR). VDR is a member of the steroid receptor superfamily ligand dependent transcription factor and the binding of calcitriol to VDR induces a configurational change in the receptor. The receptor then heterodimerizes with the retinol receptor (RxR) and the VDR-RxR complex binds to vitamin D response elements in the nucleus. This interaction induces gene transcription which results in cell cycle arrest through the regulation of CDK2, p21, p27, p53, KI67 and E-cadherin. In addition there are effects on differentiation and apoptosis, the latter through changes in Bcl-2, Bcl-x<sub>L</sub>, Mcl-1, etc. Furthermore, there are non-receptor dependent actions of vitamin D upon the cell which include activation of calcium channels at least in the small intestine and colon<sup>[26]</sup>.

The clinical effects of vitamin D are also dependent on polymorphisms in the vitamin D receptor. Such polymorphisms can occur at the 3' end of the receptor and includes Bsm1, Taq1 and at the 5' end FoK1. It is known that such polymorphisms are functionally associated with differences in bone density and in serum calcitriol levels, but whether they affect the action of vitamin D upon the colon is unclear<sup>[27]</sup>. However, high dairy intake effects upon colon adenoma recurrence has been restricted to individuals with the Apal aA/AA genotype<sup>[28]</sup>.

One small, but unique study has described the effects of 6 mo supplemental calcium (1200 mg) plus vitamin D (400 IU) to subjects with adenomatous polyps which were transected with one half tattooed and left *in situ*. Calcium plus vitamin D reduced proliferation indices in the remaining polyps and flat mucosa, but also dramatically down-regulated polyp mucin 5AC (MUC5AC)<sup>[29]</sup>. These data suggest that the combination alters important cellular processes both in the adenoma and the flat colorectal mucosa.

Turning to other studies of dairy products upon colon neoplasia formation, Cho *et al* (Cho E, Smith-Warner SA, Spiegelman D, Beeson WL, van den Brandt PA, Colditz GA, Folsom AR, Fraser GE, Freudenheim JL, Giovannucci E, Goldbohm RA, Graham S, Miller AB, Pieninen P, Potter JD, Rohan TE, Terry P, Toniolo P, Virtanen MJ, Willett WC, Wolk A, Wu K, Yau SS, Zeleniuch-Jacquotte A, Hunter DJ. Dairy foods, calcium, and colorectal cancer: a pooled analysis of 10 cohort studies. *J Natl Cancer Inst* 2004; 96: 1015-1022) published pooled data of dairy product intake from 10 cohort studies and reported a 12% reduction in colon cancer risk with each 500 mL increase in milk intake. There also was a significant and 17% reduction in colorectal cancer incidence with the ingestion of ricotta cheese greater than 25 mg per day<sup>[30]</sup>. An important study that has received a large amount of attention was the Women's Health Initiative Dietary modification study (WHI study) in which women 50-79 years of age received supplemental 1100 mg calcium plus 400 IU vitamin D with meals. Some of these women also participated in a study of the effects of estrogen replacement therapy upon colon cancer development.

This prospective study had a mean follow up of  $7.0 \pm 1.4$  years and had colorectal cancer as an end point<sup>[31]</sup>. There was no significant difference between the development of colorectal cancer in women taking the calcium plus vitamin D when compared to controls (OR = 1.08) (0.86-1.34). There clearly were a number of issues related to this study which have resulted in some considerable criticism. Such issues included the fact that the mean age of the women in the study was 62 and the increase in colon cancer in women occurs only after age 60, they had a high basal dietary intake of calcium of approximately 1100 mg to 1200 mg per day and relatively adequate vitamin D intake approaching 400 IU per day. There was low compliance with the intervention with only 70% of subjects consuming more than 50% of the pills and in addition the subjects were permitted to continue to take calcium and/or vitamin D supplements separately from study drugs. It also was felt that the duration of the study was too short for a cancer end point and the amount of vitamin D provided in the intervention was relatively low. Importantly however, women who showed a low serum 25 hydroxy vitamin D level at base line demonstrated a 2.5 fold increased risk of colorectal cancer compared to the top quartile of serum 25 hydroxy vitamin D levels ( $P < 0.02$ )<sup>[31]</sup>.

## VITAMIN D AND CANCER MORTALITY

A unique study by Lappe prospectively evaluated the development of any cancer in approximately 1200 postmenopausal women who received calcium 1500 mg/d with or without vitamin D 1100 IU per day. The unadjusted relative risk for the development of any cancer with calcium administration was 0.53 and for vitamin D plus calcium 0.40. Serum 25 hydroxy vitamin D also was a significant predictor of decreased cancer development<sup>[32]</sup>. A recent meta-analysis of 18 studies of effects of vitamin D on overall mortality by Philippe Autier showed an 8% reduction in overall mortality in subjects who received vitamin D<sup>[33]</sup>.

## ANIMAL STUDIES

Over the past decade Martin Lipkin's group have been evaluating the effects of a Western style diet (WD) relatively high in fat content (20%) and relatively low in vitamin D and calcium upon carcinogenic changes in the colon of mice. This represented the first demonstration of diet-induced colorectal tumor formation in the absence of a carcinogen<sup>[34]</sup>. When folic acid also was reduced in the WD over a period of 18-24 mo, adenomas and carcinomas developed with increases in both the percent of mice developing tumors as well as in tumor frequency. The addition of calcium and vitamin D to the diet dramatically reduced or eliminated most of these tumors<sup>[35]</sup>. It also is of interest that this Western style diet in mice produced hyperproliferation in mammary duct epithelial cells<sup>[36]</sup>, pancreatic epithelial cells<sup>[37]</sup> and prostate cells<sup>[38]</sup> and that calcium and vitamin D suppressed such hyperproliferation. The molecular

underpinnings of these observations are presently under study.

## CONCLUSION

Epidemiologic intake and intervention studies have shown that calcium administration lowers colorectal adenomatous polyps as well as cancer rates and this effect may be prolonged. Most evidence suggests that the effect of calcium is dependent or partially related to simultaneous vitamin D intake. Vitamin D may also reduce colon cancer risk independent of the presence of increased amounts of calcium or dairy products in the diet. Few studies have been performed with dairy products alone, but the data generally supports the positive effects shown with calcium and vitamin supplementation as well. Understanding the cellular effects of calcium and vitamin D in humans' *in-vivo* is crucial to make further progress in this field.

### INTRODUCTION

Patients with ulcerative colitis (UC) and Crohn's disease (CD), the major forms of inflammatory bowel disease (IBD) in humans, are at increased risk of developing colorectal cancer (CRC)<sup>[1,2]</sup>. Chronic inflammation is believed to be the driving force for neoplastic transformation, and clinical factors that increase the risk include disease duration > 10 years, extensive disease, severity of colitis, a positive family history of sporadic CRC, and the concomitant presence of primary sclerosing cholangitis<sup>[3-5]</sup>.

While in sporadic CRC, the dysplastic precursor is usually the adenomatous polyp, dysplasia in IBD patients can be both polypoid and flat, localized or diffuse. Detection of dysplasia during programmed screening and surveillance colonoscopy is the goal of the current strategy for CRC prevention in IBD patients. When dysplasia or CRC is identified, proctocolectomy is performed to remove the at-risk organ<sup>[6]</sup>. However, no evidence exists that screening for colonic dysplasia and cancer with surveillance colonoscopy prolongs survival in IBD patients. Indirect evidence also suggests that this is a cost-effective approach<sup>[7,8]</sup>. Therefore, gastroenterologists have recently shifted their attention towards alternative strategies of chemoprevention, and particular interest has been given to the possibility of reducing the risk of IBD-related CRC by using mesalazine or 5-aminosalicylic acid (5-ASA). Mesalazine is widely used in the maintenance of remission and in the treatment of mild flare-ups of IBD, and recent epidemiological studies have suggested that this drug is chemopreventive for CRC development in UC patients<sup>[9-11]</sup>, even though some studies have documented no benefit<sup>[12]</sup>. The mechanisms behind the antineoplastic effect of mesalazine are incompletely understood, but it is likely that they are mostly dependent on the ability of the drug to attenuate ongoing mucosal inflammation. Indeed, it is well known that mesalazine can modulate various inflammatory pathways (e.g. production of inflammatory cytokines, activity of inducible nitric oxide synthase, activation of nuclear factor- $\kappa$ B) that are

### Abstract

Patients with ulcerative colitis (UC) and Crohn's disease (CD) are at increased risk for developing colorectal cancer (CRC), and this is believed to be a result of chronic inflammation. Although conclusive evidence is still missing, both epidemiological and experimental observations suggest that certain drugs used to treat inflammation, such as mesalazine, can reduce the incidence of colitis-associated CRC. Therefore, in recent years, several studies have been conducted to dissect the mechanisms by which mesalazine interferes with CRC cell growth and survival. This review summarizes the current information on the molecular mechanisms that underlie the antineoplastic action of mesalazine.

relevant to CRC initiation and progression<sup>[13-16]</sup>. There is also evidence that mesalazine inhibits the formation of reactive oxygen species (ROS) from polymorphonuclear leukocytes<sup>[17]</sup>, which leads to a decrease or complete inhibition of DNA damage, a phenomenon that has been involved in colon carcinogenesis. More recently, it has also been shown that mesalazine can directly target CRC cells and interfere with biological pathways that control their growth and survival<sup>[18]</sup>. The object of this article is to summarize recent data that elucidate the basic mechanisms of the antineoplastic effect of mesalazine.

## MESALAZINE HAS DIRECT INHIBITORY EFFECTS ON CRC CELL GROWTH AND SURVIVAL

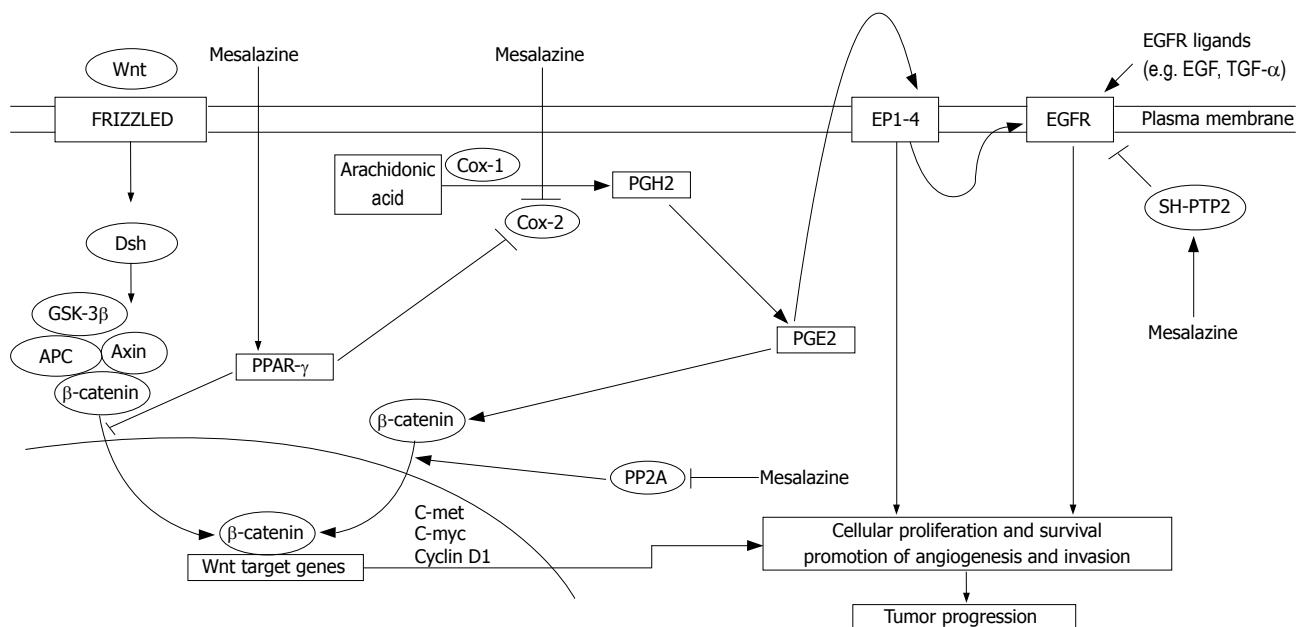

Carcinogenesis is a complex and multistage process that involves interactions between genes and environmental insults which ultimately affect cell proliferation and apoptosis. Apoptosis progressively decreases and proliferation increases in the sequential stages from normal colonic mucosa to dysplastic and CRC tissue. Therefore, strategies that inhibit cell proliferation and/or restore cell susceptibility to apoptosis have been shown to be effective in interfering with CRC initiation and/or progression.

Accumulating evidence indicates that mesalazine can block growth and promote apoptosis of CRC cells. This was initially suggested by *ex vivo* studies in patients with colonic adenoma. In particular, Reinacker-Schick *et al* have analyzed the effect of orally administered mesalazine on apoptosis and proliferation of colorectal mucosa in 21 patients with sporadic polyps. An increase in the apoptotic rate and decrease in cell proliferation were seen 1 and 3 d, respectively, after the initiation of treatment with mesalazine<sup>[19]</sup>. Bus *et al* have demonstrated that 2 wk treatment with 4 g/d mesalazine enema in patient with sporadic CRC resulted in enhanced apoptosis of tumor cells, while no change was seen in the normal mucosa that surrounded the tumor lesion. Moreover, the cellular proliferation rate as assessed by means of Ki-67 expression was unchanged in both the tumor and normal tissue<sup>[20]</sup>. Studies in rodent models of CRC showed that mesalazine inhibits tumor growth and reduces the number of aberrant cryptic foci<sup>[21,22]</sup>. Moreover, in a mouse model of colitis-associated CRC, Ikeda *et al* have shown that mesalazine, given in the remission stage of colitis, markedly suppresses the number and size of neoplasms. Notably, mesalazine treatment reduces the rate of proliferation of tumor cells, which leaves the proliferation of normal epithelial cells unaltered<sup>[23]</sup>. These observations have been reinforced by *in vitro* studies that show that mesalazine inhibits the growth and enhances apoptosis of several cultured CRC cell lines, in a time- and dose-dependent manner<sup>[18,24]</sup>. Altogether, these later findings

indicate that mesalazine has direct effects on CRC cells. This novel information has boosted new research aimed at dissecting the molecular mechanisms by which mesalazine interferes with CRC development/growth.

## EFFECTS OF MESALAZINE ON REPLICATION FIDELITY

Many of the molecular alterations that are believed to play a major role in the development of sporadic CRC are also seen in IBD-associated CRC tissue. For instance, both these types of CRC are characterized by a very similar frequency of the two main types of genomic instability, namely chromosomal instability (CIN, 85%) and microsatellite instability (MSI, 15%)<sup>[25]</sup>. CIN results in abnormal segregation of chromosomes and abnormal DNA content (aneuploidy). As a result, loss of chromosomal material often occurs, which contributes to the loss of function of important tumor suppressor genes [e.g. adenomatous polyposis coli (*APC*) and *p53*]. The MSI pathway involves the primary loss of function of genes that usually repair DNA base-pair mismatches that occur during the normal process of DNA replication in dividing cells. During this process, frameshift mutations, called microsatellites, tend to accumulate. Since microsatellites are mainly located in intronic DNA sequences, microsatellite mutations generally result in no gene function alteration. However, if microsatellites are located in exonic gene regions, the mutations can lead to a shift in the codon reading frame and changes in the amino acid sequence during mRNA translation. The introduction of an early stop codon can eventually cause protein truncation, and this is generally associated with a loss of protein function<sup>[26]</sup>. Recently, Gasche and colleagues, using an assay based on a stable transfection of a plasmid carrying a microsatellite sequence into HCT-116 cells, have shown that mesalazine improves replication fidelity in cultured CRC cell lines by reducing frameshift mutations at microsatellites. Since the effect of mesalazine is seen in mismatch repair-deficient CRC cells, it is highly likely that mesalazine acts on replication fidelity independently of post-replication mismatch repair. The molecular mechanism by which mesalazine inhibits the generation of frameshift mutations has not yet been characterized. However, studies by the same group have shown that mesalazine can interact with cellular machinery involved in cell-cycle progression<sup>[28]</sup>. In particular, it has been shown that mesalazine can slow down DNA replication and cell division, thus allowing cells to either repair DNA damage or undergo apoptosis. Analysis of cell-cycle phases has revealed that CRC cells are arrested in S-phase when treated with mesalazine for 24-48 h. Such results are, however, somewhat different from those published by Reinacher-Schick *et al* that have shown that CRC cells are arrested in G2-M phase when exposed to mesalazine<sup>[18]</sup>. The

**Figure 1** Some putative molecular mechanisms that underlie the antineoplastic activity of mesalazine. Mesalazine inhibits COX-2, thereby blocking synthesis of PGH2, an intermediate that is metabolized into various prostaglandins, including PGE2. PGE2 binds to its cell surface cognate receptors (EP1-4) and sustains various functions of tumor cells, including proliferation, survival, angiogenesis and invasion. These are mediated through the transactivation of EGFR or activation of other intracellular pathways. The antineoplastic effects of mesalazine rely also on its ability to inhibit Wnt/β-catenin, through inactivation of PP2A (and downstream down-regulation of β-catenin), and EGFR pathways. Moreover, mesalazine activates PPAR-γ, thus leading to inactivation of the Wnt/β-catenin pathway and down-regulation of COX-2.

reasons for these discrepancies remain unclear, but it is likely that they are due to differences in the culture systems used by these investigators.

### THE ANTI-MITOGENIC EFFECT OF MESALAZINE IS NOT STRICTLY DEPENDENT ON CYCLOOXYGENASE (COX)-2 INHIBITION

COX-2 is a major target of CRC chemopreventive programs, as it is highly expressed in both sporadic and familial CRC, and activation of COX-2 is known to trigger and/or amplify biological pathways that sustain CRC growth<sup>[29-32]</sup>. COX-2 is also over-expressed in IBD-related CRC tissue<sup>[33]</sup>. Since mesalazine inhibits COX-2 in inflammatory cells, it is hypothesized that the antineoplastic effect of this drug is strictly dependent on the inhibition of COX-2 in CRC cells. In this context, we have recently shown that mesalazine inhibits the growth of HT-115, a CRC cell line that expresses a functionally active COX-2, and that the anti-mitogenic effect of mesalazine is associated with a marked down-regulation of COX-2 at the protein and mRNA level<sup>[34]</sup>. Consistently, treatment of HT-115 cells with mesalazine causes a significant reduction in secretion of prostaglandin (PG) E2, a product of COX-2 activity that positively regulates CRC cell growth (Figure 1). However, exogenously added PGE2 does not abrogate the inhibitory effect of mesalazine on HT-115 cell growth. Moreover, mesalazine blocks the growth of DLD-1, a CRC cell line that does not express COX-2,

which suggests that the effect of this drug on CRC cell growth is partially independent of inhibition of the COX-2/PGE2 axis.

### MESALAZINE INHIBITS BOTH THE WNT/β-CATENIN AND EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR) SIGNALING PATHWAYS IN CRC CELLS

An intriguing hypothesis that has emerged from the available experimental data is that mesalazine may act on one or more pathways that are both early and common in colorectal carcinogenesis. A potential candidate is the wingless and integration site growth factor (Wnt)/β-catenin pathway, since it is constitutively activated in the majority of CRC<sup>[35-37]</sup>. In this pathway, Wnt binds to the transmembrane Frizzled receptor, which leads to activation of the cytoplasmic disheveled (Dsh) protein. Dsh forms a complex with the β-catenin degradation complex, which consists of the APC gene product, glycogen synthase kinase-3β (GSK-3β), axin and β-catenin. The current model for the Wnt signaling pathway proposes that, in the absence of Wnt, GSK-3β phosphorylates β-catenin, thereby promoting ubiquitination and degradation of β-catenin<sup>[38]</sup>. In response to Wnt signals, β-catenin is no longer targeted for degradation and accumulates to high levels in the cytoplasm<sup>[39]</sup>. The accumulated β-catenin translocates to the nucleus, associates with the transcriptional enhancers of the lymphoid enhancer-binding factor/Tcf family, and stimulates the expression of genes, such as *Myc*, that

play important roles in tumor progression<sup>[40,41]</sup>.

Elegant studies by Bos *et al* have shown that mesalazine inhibits the Wnt/β-catenin pathway in APC-mutated CRC cells with intact β-catenin (Figure 1)<sup>[42]</sup>. Consistent with this, mesalazine treatment reduces expression of nuclear β-catenin and Wnt/β-catenin target genes (e.g. *cyclin D1*, *c-met* and *c-Myc*), and increased β-catenin phosphorylation. Mesalazine fails to inhibit the expression of Wnt/β-catenin target genes in β-catenin mutant CRC cell lines, in which the Wnt/β-catenin pathway is not regulated by β-catenin phosphorylation. These observations suggest that inhibition of the Wnt/β-catenin pathway by mesalazine is dependent on increased phosphorylation of β-catenin. In line with this, pre-incubation of CRC cells with okadaic acid, a specific phospho-serine/phospho-threonine phosphatase inhibitor, prevents mesalazine-induced β-catenin phosphorylation. The precise mechanism by which mesalazine enhances β-catenin phosphorylation remains to be ascertained, even though Bos *et al* have demonstrated that mesalazine reduces the activity of protein phosphatase 2A (PP2A), a known regulator of the β-catenin phosphorylation status and Wnt/β-catenin pathway in CRC cells.

Another target of mesalazine is EGFR (Figure 1). This receptor is highly activated in CRC cells, in which it is supposed to trigger mitogenic and pro-survival signals<sup>[43,44]</sup>. Consistent, EGFR inhibitors, such as monoclonal antibodies or small molecules that inhibit tyrosine kinase activity, have been shown to be effective in patients with advanced CRC<sup>[45]</sup>. A very high percentage of IBD-associated CRC displays immunohistochemical positivity for EGFR. Expression of EGFR is frequent in IBD-associated intestinal cancer<sup>[46]</sup>. Expression occurs at an early stage (i.e. premalignant lesions), as described in sporadic CRC<sup>[47]</sup>, which suggests that blocking EGFR activity is useful for reducing the occurrence of IBD-related CRC<sup>[48,49]</sup>. We have shown that exposure of CRC cell lines to mesalazine results in a marked suppression of EGFR phosphorylation/activation, and that mesalazine-induced EGFR dephosphorylation is dependent on neither CRC cell death induction nor shedding of the receptor<sup>[50]</sup>. Moreover, mesalazine suppresses EGFR activation induced by exogenous EGF or TGF-α, thus excluding the possibility that dephosphorylation of EGFR in mesalazine-treated cells is secondary to inhibition of EGFR ligand synthesis. EGFR phosphorylation is a tightly controlled phenomenon, which is the net result of the action of tyrosine kinase and phosphatases (PTPs). Therefore, we have examined whether mesalazine-mediated inhibition of EGFR activation reflects changes in the expression/activity of PTPs, which have been reported to control the extent of EGFR activation<sup>[51]</sup>. Notably, treatment of CRC cells with mesalazine causes a significant increase in the activity, but not expression, of phosphorylated-EGFR-targeting PTPs, and pre-incubation of cells with PTP inhibitors largely reduces the inhibitory effect of mesalazine on EGFR activation. Among these PTPs, both SH-PTP1 and SH-PTP2 interact with EGFR upon

mesalazine treatment. However, targeted silencing of SH-PTP2, but not SH-PTP1 prevents mesalazine-induced EGFR dephosphorylation. Consistent with these data, mesalazine also attenuates EGFR phosphorylation in *ex vivo* organ cultures of human sporadic CRC explants.

## MESALAZINE ACTIVATES PEROXISOME PROLIFERATOR ACTIVATED RECEPTOR-γ (PPAR-γ) IN CRC CELLS

PPAR-γ is a nuclear receptor that is highly expressed in the colon, and plays a key role in bacteria-induced inflammation. Many factors can modulate the activity of PPAR-γ, but the most important activating factor in colon epithelial cells appears to be the luminal flora<sup>[52]</sup>. Activation of PPAR-γ also has anti-tumorigenic effects that are manifested as both anti-proliferative and pro-apoptotic activities<sup>[53, 54]</sup>, inhibition of the formation of aberrant cryptic foci<sup>[55]</sup>, and inhibition of CRC development<sup>[56]</sup>. It has also been shown that PPAR-γ suppresses tumor formation by interfering with the Wnt/β-catenin signaling pathway<sup>[57,58]</sup>. Recent *in vitro* and *in vivo* studies have shown that mesalazine can activate PPAR-γ (Figure 1). In particular, using HT-29 CRC cells, Rousseaux *et al* have shown that mesalazine enhances PPAR-γ expression, stimulates translocation of PPAR-γ to the nucleus, induces conformational changes in the PPAR-γ molecule, and increases the interaction between PPAR-γ and vitamin D3 receptor-interacting protein 205<sup>[59]</sup>. In competitive binding studies, mesalazine displaces rosiglitazone and the selective PPAR-γ ligand GW1929 from their binding sites on the PPAR-γ molecule<sup>[59]</sup>. In line with these *in vitro* findings, it has been shown that the antineoplastic effects of mesalazine are mediated by PPAR-γ in a model of CRC, in which SCID mice were engrafted with human CRC cells. In particular, in this model, locally administered mesalazine significantly reduced the growth of xenografts, and this effect was blocked by the selective PPAR-γ antagonist GW9662<sup>[60]</sup>.

## CONCLUSION

In recent years, there has been great interest in the possibility of chemoprevention of IBD-related CRC by mesalazine. Given the difficulty of performing double-blind, placebo-controlled, randomized clinical trials in patients, investigators have turned to experimental models of cancer, and indeed, the existing data suggest that mesalazine can reduce the risk of CRC by directly interfering with CRC cell biology, other than by simply controlling inflammation. However, definitive conclusions from experimental findings are not always completely correct, and therefore, future studies will be necessary to ascertain whether data generated from studies with cultured cells or animal models of CRC can be generalized to IBD-associated dysplasia or CRC.

Another important issue that needs further investigation regards the dosage/concentration of

mesalazine required to interfere with CRC cell growth and survival. *In vitro* studies have indicated that the antineoplastic effect of mesalazine is seen with relative high drug dosages (e.g. 10-50 mmol/L), which are not always reached within the colonic tissue under standard oral treatment. In this context, it is also relevant to take into consideration mesalazine metabolism, for instance, mesalazine oxidation and acetylation, which could differ considerably between *in vitro* and *in vivo* circumstances, and limit the amount of biologically active compound.

### Abstract

Thromboembolism is a significant cause of morbidity and mortality in patients with inflammatory bowel disease (IBD). Recent data suggest thromboembolism as a disease-specific extraintestinal manifestation of IBD, which is developed as the result of multiple interactions between acquired and genetic risk factors. There is evidence indicating an imbalance of procoagulant, anticoagulant and fibrinolytic factors predisposing in thrombosis in patients with IBD. The genetic factors that have been suggested to interfere in the thrombotic manifestations of IBD include factor V Leiden, factor II (prothrombin, G20210A), methylenetetrahydrofolate reductase gene mutation (MTHFR, 677T), plasminogen activator inhibitor type 1 (PAI-1) gene mutation and factor X III (val34leu). In this article we review the current data and future prospects on the role of genetic risk factors in the development of thromboembolism in IBD.

### INTRODUCTION

Inflammatory bowel disease (IBD) is associated with an increased risk of vascular complications<sup>[1-4]</sup>. The most important of these complications are arterial and venous thromboembolisms, which represent a significant cause of morbidity and mortality in IBD patients. Thromboembolism is a disease-specific extraintestinal manifestation of IBD<sup>[5]</sup>, which is developed as the result of multiple interactions between acquired and genetic risk factors. Several studies have shown an imbalance of procoagulant, anticoagulant and fibrinolytic factors predisposing in thrombosis in patients with IBD<sup>[6-9]</sup>. The incidence of thromboembolism in IBD ranges between 1% and 7.7% in clinical studies<sup>[1,10,11]</sup>, rising to 39%-41% in postmortem studies<sup>[12]</sup>.

The most common thrombotic manifestations in IBD are deep vein thrombosis, usually in the leg, and pulmonary embolism. The latter may be fatal. Thrombotic events occur less frequently in other sites, such as the cerebrovascular system, portal vein, mesenteric veins, and retinal vein. Arterial thrombotic complications occur less frequently than venous thromboembolism in patients with IBD, and most occur after surgery. An increased atherosclerotic risk in patients with IBD has also been suggested<sup>[13]</sup>. This could be associated with the elevated levels of C-reactive protein and plasma sCD40L, which are features of the IBD<sup>[14,15]</sup>. Common carotid artery intima-media thickness has been found significantly higher in IBD patients compared with healthy controls<sup>[16]</sup>. Premature atherosclerosis with lower extremity arterial occlusions has been reported in young patients with Crohn's disease<sup>[17]</sup>. An increased risk of cardiovascular arterial thromboembolic diseases in both Crohn's disease and ulcerative colitis and an increase in cerebrovascular arterial thromboembolic diseases in Crohn's disease recently have been reported<sup>[18]</sup>. IBD patients have been found to develop thromboembolisms earlier in life than non-IBD thrombotic patients<sup>[19]</sup>. Furthermore, many IBD patients with thromboembolic disorders either have active disease or have undergone recent major abdominal surgery<sup>[2]</sup>. Conversely, thromboembolisms may also occur in quiescent IBD<sup>[1]</sup>. It has been suggested that the extent of colonic disease is correlated with thromboembolic risk. Extensive ulcerative colitis and colonic involvement of Crohn's disease was significantly associated with the development of thromboembolism<sup>[2]</sup>. The risk of recurrence of thromboembolism in IBD patients has been

reported to be 10%-13% despite medical therapy for the thromboembolic event<sup>[2]</sup>. The mortality from this complication in IBD has been reported to be 8%-25% during the acute episode<sup>[1,2]</sup>. The etiology of thrombosis in IBD is multifactorial. Thrombosis is a complex event in which several mechanisms and causal factors, inherited and acquired, are implicated, complicating the identification of its causes<sup>[20,21]</sup>. Several acquired prothrombotic risk factors are frequently observed, such as the inflammatory process per se, prolonged immobilization, use of corticosteroids, surgical treatment, fluid depletion, central venous catheters, hyperhomocysteinemia, vitamin deficiencies, smoking and use of oral contraceptives<sup>[4]</sup>. Importantly, approximately half of the patients with inflammatory bowel disease that develop a thromboembolic event have no identifiable risk factor<sup>[10]</sup>. Genetic factors may also play a role in thrombosis of patients with IBD. Based on the unraveling of the biochemistry and cell biology of the coagulation system, major advances in the understanding of genetics of thrombosis have been applied also in IBD complicating by thrombosis. The most common genetic variants that have been found to affect the risk of thrombosis are: factor V Leiden, factor II (prothrombin, G20210A), methylenetetrahydrofolate reductase gene mutation (MTHFR, 6777T), plasminogen activator inhibitor type 1 (PAI-1) gene mutation and factor XIII (val34leu). This review focuses on the role of genetic risk factors in the development of thromboembolism in IBD.

## EVALUATING GENETIC RISK OF THROMBOSIS IN INFLAMMATORY BOWEL DISEASE

Genetic risk factors have been suggested to predispose to thromboembolism in IBD. Several genetic markers located in coagulation genes have been examined in an attempt to document whether these markers are associated with increased thrombotic risk in IBD. Genetic studies of vascular complications of IBD pose enormous challenges, including resolution of immense genotypic and phenotypic heterogeneity, and gene-environment and gene-gene interactions. Past efforts to identify thrombosis-related genes in IBD have utilized population-based association methods, but the substantial progress that has been made recently with the strategy of using positional cloning of genes based on linkage studies is expected to apply to this field. These methods focus on measuring quantitative traits that are correlated with the risk of disease.

### **Factor V Leiden**

Factor V Leiden (FVL), an arginine to glutamine missense mutation in the factor V (FV) gene at position 506<sup>[22]</sup>, is the most prominent risk factor for venous thromboembolism<sup>[23,24]</sup>. The amino acid substitution in the activated protein C (APC) cleavage site of FV leads to increased thrombin generation due to decreased APC-mediated inactivation of FV, and due to decreased FV cofactor activity for FVIIIa inactivation<sup>[25]</sup>. Factor V Leiden is found in approximately 5% of Caucasians, and

increases the risk of thrombosis five- to eightfold for heterozygous carriers and 50- to 80-fold for homozygous carriers. The prevalence of FVL ranges from 20% to 30% in unselected patients with venous thrombosis. Genetic studies determining the prevalence of the FVL allele in IBD mostly have shown no difference in allele frequency between IBD patients and healthy controls<sup>[26-30]</sup>. The prevalence of FVL in thrombotic IBD patients was significantly higher than in IBD patients without thrombosis<sup>[31-33]</sup>. It is noteworthy that the FVL allele was associated mainly with venous thrombosis<sup>[33]</sup>. In addition, the prevalence of FVL in IBD patients with previous thromboembolism appears not to differ from that found in non-IBD patients with thromboembolism<sup>[33,34]</sup>. On the other hand, an Italian study showed a very low prevalence of FVL allele in thrombotic IBD patients<sup>[35]</sup>. The discrepancies between these results may be due to the different characteristics of the populations studied (genetic background, previous history of thrombosis, and small sample sizes). Furthermore, in a recent study of experimental colitis, the FVL allele had no effect in murine colitis and thus, the authors question the role of activated blood coagulation in IBD<sup>[36]</sup>. Although somewhat conflicting, these genetic studies suggest that the FVL as a risk factor for thrombosis in IBD patients matches that of the general population. Furthermore, FVL is not associated with IBD per se, but when present it increases the risk of thromboembolism<sup>[37]</sup>. Finally, it is important to realize that homozygous carriers of the FVL allele are rare and that all genetic studies are performed using heterozygotes, which have a milder thrombotic phenotype.

### **G20210A prothrombin gene mutation**

The G20210A mutation is a genetic variation of the prothrombin (Factor II) gene consisting of a single nucleotide change (guanine to adenine) at position 20210 of the 3'-untranslated region. The G20210A mutation is the second most frequent genetic prothrombotic mutation after FVL. It is present in approximately 2% of Caucasians, leads to greater prothrombin plasma levels (heterozygous carriers have about 30% higher PT levels than healthy controls), and increases the risk of venous thrombosis about threefold<sup>[38]</sup>. However, no definite association between this gene mutation and IBD has been detected in several studies<sup>[30,33-35,39]</sup>. Presence of this mutation is found at a similar prevalence in IBD patients as well as in IBD patients with thrombosis<sup>[27,32-33]</sup>. This mutation has only been studied in a limited number of thrombotic IBD patients so firm conclusions cannot be drawn.

### **Methylenetetrahydrofolate reductase C677T gene mutation**

Methylenetetrahydrofolate reductase is a critical enzyme involved in the remethylation pathway of homocysteine metabolism. A common mutation (C677T) has been identified in the MTHFR gene. This variant leads to 10%-20% increases in homocysteine plasma levels in homozygous carriers, which are found in around 10% of

the population. The effect of MTHFR 6777T carriership on the risk of thrombosis varies among studies, and a recent meta-analysis found a weak effect (10%-20% risk increase)<sup>[40-43]</sup>. Studies of the prevalence of C677T homozygosity in IBD have found discordant results<sup>[34]</sup>, probably because of regional and ethnic variations in the prevalence of polymorphism in the general population. In a recent population-based case-control study<sup>[50]</sup>, although some differences were observed among patients with IBD and healthy controls in the prevalence of MTHFR 6777T (decrease in mutant allele carriership in UC), these did not explain an excess risk of thrombosis. The prevalence of C677T homozygosity between IBD thrombotic patients and non-IBD thrombotic patients showed no significant difference<sup>[32,33]</sup>.

### **Factor X<sub>III</sub> gene mutation**

A common variant in subunit A of factor X<sub>III</sub>, usually indicated by the amino acid position and change (val34leu), is associated with a greater FXIII activation rate and leads to a 20%-40% reduction of the risk of venous thrombosis for homozygous carriers. These are found in approximately 10% of the population<sup>[44,45]</sup>. This variant, which is protective against thrombosis, has been evaluated in IBD patients<sup>[46]</sup>. Available data suggest that the prevalence of this polymorphism is similar in patients with IBD compared to the general population<sup>[47,48]</sup>. A slightly greater prevalence of factor X<sub>III</sub> mutation carriership in CD has been found in a recent population-based study<sup>[30]</sup>, but this could not explain the greater risk of venous thrombosis in CD. Finally, the prevalence of X<sub>III</sub> (val34leu) was similar in IBD patients with vascular complications and non-IBD thrombotic patients<sup>[33]</sup>.

### **Plasminogen activator inhibitor type 1 gene mutation**

Plasminogen activator inhibitor type 1 (PAI-1) is considered as inhibitor of fibrinolysis. The 4G/4G genotype is associated with an overexpression of PAI-1, which may cause a decreased fibrinolysis and, therefore, a hypercoagulability state contributing to the development of vascular complications. Several studies have demonstrated that the 4G/4G genotype is associated with an enhanced PAI-1 expression<sup>[49]</sup> and contributes as an additional risk factor to the development of myocardial infarction<sup>[50]</sup>, arterial thrombosis<sup>[51]</sup>, and deep venous thrombosis<sup>[52]</sup>. However, the evidence regarding the relationship between an elevated PAI-1 plasma level or PAI-1 genetic polymorphism and the risk of venous thromboembolism is rather conflicting. The allelic frequency of PAI-1 4G has been reported higher in IBD patients than in the reference population<sup>[53]</sup>. Moreover, a recent study showed a significantly higher allelic frequency of PAI-1 4G in IBD patients with vascular complications compared with IBD and healthy controls. However, the prevalence of this genotype does not differ in thrombotic IBD patients compared to non-IBD thrombotic patients<sup>[33]</sup>.

### **Janus kinase 2 gene mutation**

Janus kinase 2 (JAK2) mutations have been described in

several Philadelphia-negative myeloproliferative disorders (MPD)<sup>[54]</sup>. The point mutation in JAK2 encodes a valine to phenylalanine change at position 617 (JAK2 V617F) and confers constitutive tyrosine kinase activity<sup>[55]</sup>. It has been suggested that thrombosis in MPD may be due to JAK2 mutation. JAK2 is also important in vascular diseases, such as atherosclerosis, in which inflammation plays an important role. JAK2 V617F mutation has been found, in the absence of overt MPD, highly associated with splanchnic vein thrombosis and sporadically with cerebral thrombosis. A recent study investigated the role of JAK2 V617F mutation in 48 IBD patients with thrombotic complications, but no case with the JAK2 V617F mutation was found<sup>[56]</sup>. The small number of cases with splanchnic vein thrombosis in this series (but also in other IBD series) that are mainly associated JAK2 V617F mutation could be also an explanation of this finding.

### **Other genetic factors**

The role of the well recognized inherited thrombophilic states such as deficiencies of plasma antithrombin III, protein C, and protein S has been examined in several studies. Although deficiency of the proteins C and S in IBD patients have been proposed by some studies<sup>[20]</sup>, other studies failed to confirm these data<sup>[21]</sup>. These factors are rare (< 1% of the population) and are considered to play a less important role in the thrombosis, and therefore it is not surprising that their results in IBD are rather contradictory.

### **Future prospects**

We are entering a new era in genetic studies of venous thrombosis. It is believed that, combined, all the known mutations account for about the half of the genetic thrombosis risk. There is every reason to believe that additional genetic causes of thrombosis remain to be discovered. As a complex disease, thrombosis is considered to be the result of flexible combinations of variations of multiple genes that interact with lifestyle or other environmental factors to produce the disease. Future studies should investigate these interactions. Moreover, in IBD we need collection of large case-control series of patients complicating with venous thrombosis. This will provide the high quality clinical information related both to IBD and thrombosis that forms the basis of any genetic project. On the other hand, large-scale DNA analysis systems are now becoming available, which will allow us to study in the setting of IBD the genetics of venous thrombosis down to the single nucleotide level. As an example, we recently have reported a multigenetic analysis of polymorphisms of thrombophilic and vasoactive genes in a group of IBD patients with vascular complications compared with IBD patients without vascular complications and both thrombotic and healthy controls<sup>[33]</sup>. This approach, in a multicenter basis with a large number of patients, will give more insight into the genetic architecture of thrombotic risk in IBD. The final aim is personalized thrombosis prediction and appropriate management in a patient with IBD.

## CONCLUSION

Epidemiological data suggest that IBD is associated with an increased risk of thromboembolic complications. However, the cause for this strong association remains unclear. It can be speculated that gene mutations may underlie the greater risk for thromboembolic complications in IBD patients. Thus, several studies have investigated the role of genetic defects in the development of vascular complications in IBD. The most common genetic variants that affect the risk of thrombosis are factor V Leiden, factor II (prothrombin, G20210A), MTHFR (6777T) and factor XIII (val34leu). Furthermore, the role of other thrombophilic and vasoactive genes has been evaluated with the occurrence of thromboembolism in IBD. The available data in the literature have shown that genetic risk factors are generally not found more often in IBD patients than others. However, when they occur, those with IBD compared to healthy controls are more likely to suffer thromboembolic complications. The screening for genetic coagulation defects appears justified in all IBD patients with a history of thrombosis or a family history of venous thromboembolic events. Future multicentre studies with large number of cases and further investigation of the interaction between genetic and environmental factors might increase our understanding of the mechanisms of pathogenesis of thrombotic complications in IBD. Using the new large-scale DNA sequencing techniques that are becoming available and enable many genes to be studied in a single individual, we could expect an in-depth insight into how genetic risk factors are involved in thrombosis in IBD.

### INTRODUCTION

Liver resection (LR) has been the only potentially curative treatment available for hepatocellular carcinoma (HCC). With the advent of liver transplantation (LT) as a clinical modality patients with HCC were preferentially placed on the waiting list for transplantation<sup>[1]</sup>. To date, there have been no randomised clinical trials comparing LR to LT in patients with potentially resectable HCC (Child-Pugh A, wedged hepatic venous pressure < 10 mmHg)<sup>[2]</sup>. The decision of whether to resect or transplant is often determined by centre experience and the availability of LT. Unfortunately, the majority of patients have extensive tumours at presentation and are not candidates for either LT or LR. The use of neoadjuvant therapies to downstage the disease has recently been shown to be effective in a small number of selected cases. The results of newer tumour specific therapies that are currently being developed are awaited and may expand the number of potentially resectable cases. If livers for LT were freely available, a case could be made for transplanting all patients with HCC confined to the liver. However, there are insufficient numbers of grafts to transplant even good risk candidates. Determining which patients should be managed by resection or transplantation remains a subject of much debate.

### LIVER RESECTION

For the majority of patients with HCC, eligibility for LR is not only dependant upon anatomical location, but also on the extent of the underlying liver disease<sup>[3]</sup>. Consequently, only 15%-30% of patients with HCC are candidates for LR at the time of presentation<sup>[4]</sup>. Although the advantages of LR over LT are not clear-cut, patients with well-preserved liver function (Child-Pugh A) with small solitary (< 5 cm) HCCs should be considered for LR. The presence of hepatic decompensation (Child-Pugh C) is a contraindication to surgical LR, due to the high peri-operative mortality. The more difficult patients

### Abstract

Liver resection (LR) and transplantation offer the only potential chance of cure for patients with hepatocellular carcinoma (HCC). Historically, all patients were treated by hepatic resection. With the advent of liver transplantation (LT) patients with HCC were preferentially placed on the waiting list for LT. However, early experience with LT was associated with a high rate of tumour recurrence and poor long-term survival. The increasing scarcity of donor livers resulted in restrictions being placed on tumour size, and an improvement in patient survival. To date there have been no randomised clinical trials comparing LR to LT. We review the evidence supporting LR and/or LT for HCC and discuss the role of neoadjuvant therapy. The decision of whether to resect or transplant remains debatable and is often determined by centre experience, availability of LT and donor organs.

are those with Child-Pugh B cirrhosis or those with large ( $> 5$  cm) or multiple tumours.

The natural history of HCC has been studied in small series 20–30 years ago. Those patients with a solitary small ( $< 3$  cm) tumour have good three-year survival irrespective of treatment modality. Of those that undergo LR approximately 70% will develop intrahepatic tumour recurrence within 5 years of resection<sup>[5]</sup>. This represents either tumour that was present, but not detected at the time of LR (synchronous), or a new tumour that has arisen in the diseased liver remnant (metachronous). The results of LR for HCC in some recent publications are summarised in Table 1.

A number of different clinico-pathological staging systems have been proposed to help predict survival outcomes for patients with HCC to assist clinicians in deciding whether patients are suitable for LR. The Barcelona Clinic Liver Cancer (BCLC) group stratifies patients with HCC into 4 categories (early, intermediate, advanced and terminal) and recommends different treatment options for each category<sup>[6]</sup>. Accordingly, LR is only indicated in patients with early stage HCC, that is; a single nodule  $\leq 5$  cm or up to 3 nodules

$\leq 3$  cm; Okuda stage 1 or 2<sup>[7]</sup>; Child-Pugh A or B<sup>[8]</sup>; Performance score of 0<sup>[9]</sup>; with no portal hypertension and a normal serum bilirubin level. The role of LR for BCLC group intermediate-stage HCC (single nodule  $> 5$  cm or multinodular tumours) in the presence of preserved liver function (Okuda stage 1 or 2; Child-Pugh A; Performance score 0–2) remains controversial. Patients with large ( $> 5$  cm) HCCs are not suitable for ablative therapies and are excluded from LT if the Milan criteria are used for patient selection. These patients are often deemed too high-risk to undergo LR due to the extent of the resection. The American Association for Study of Liver Diseases (AASLD)<sup>[10]</sup> and the European Association for Study of Liver (EASL)<sup>[11]</sup> guidelines state that LR is contraindicated for tumours  $> 5$  cm due to the high incidence of vascular invasion and the associated poor prognosis. However, a number of centres have reported acceptable outcomes for patients with resected HCC greater than 5 cm or even 10 cm. A multicentre study of 300 patients with HCC  $> 10$  cm reported a 5-year overall survival rate of 26.9%<sup>[12]</sup>. Poon *et al* reported a 5-year actual survival rate of 20.6% for 58 patients resected for tumours  $> 10$  cm<sup>[13]</sup>.

Much of the improvement in patient outcome following LR has been due to the adoption of a multidisciplinary approach to managing these patients with stringent preoperative evaluation of hepatic function and liver manipulation by selective portal vein or hepatic artery embolization. This has been borne out by nationally representative data which has shown inpatient mortality to be 40% less in high-volume hospitals compared to low-volume hospitals (odds ratio 0.60;  $P = 0.02$ )<sup>[14]</sup>. Supporting the concept that patients requiring hepatectomy, particularly in the presence of chronic liver disease, should be managed in high-volume centres.

Multi-focal HCC is associated with a poor outcome, due to the high rate of recurrence and is considered a relative contraindication to LR. A recent audit of LR in 380 patients with large and multifocal HCC and small ( $< 5$  cm) single nodules ( $n = 404$ ), revealed similar peri-operative morbidity and mortality rates between the two groups, but the three-year survival that was significantly better for small solitary HCC (76% vs 50%)<sup>[15]</sup>. Despite this the authors stated that survival of patients with multifocal HCC after LR was better than that achieved with trans-arterial chemoembolization (TACE), and suggested that if functional reserve was acceptable they should be considered for LR provided all identifiable tumour is able to be resected<sup>[15]</sup>.

Patients with early Child-Pugh B cirrhosis without evidence of significant portal hypertension should be considered for minor LRs. The difficulty is objectively assessing liver function and the extent of LR likely to be tolerated. The indocyanine green (ICG) clearance test<sup>[16,17]</sup> has been well validated and the Model of End Stage Liver Disease (MELD) also appears to predict peri-operative mortality following LR. A MELD score of  $\geq 9$  had a peri-operative mortality rate of 29%, whilst a score of  $< 9$  had no mortality<sup>[18]</sup>. However, no technique has been shown to be superior to that of the judgement of an experienced clinician.

The aim of LR is to achieve local control of the index tumour, accepting that new or unrecognised tumours may subsequently appear. Thirty-nine percent of patients with a solitary HCC  $< 5$  cm on preoperative cross sectional imaging are found after LT to have other lesions on histologic examination of the explanted liver<sup>[19]</sup>. Although preoperative imaging has improved, less than one third of HCCs  $< 1$  cm can be identified using either contrast enhanced computer tomography (CT) or magnetic resonance imaging (MRI)<sup>[19]</sup>. This suggests that progression of established disease present at the time of LR accounts for a significant proportion of tumour recurrences post resection.

Parenchymal preservation is important in preserving hepatic function and reducing the risk of small for size syndrome<sup>[3]</sup>. However, HCC has a propensity for vascular invasion resulting in intrahepatic metastases. Anatomical (segmental) LR, results in resection of a greater volume of liver parenchyma, leads to the *en bloc* resection of the primary tumour and all the potentially tumour-bearing portal tributaries. In support of this, anatomical resection for solitary HCC has been shown

to be associated with a lower rate of disease recurrence and improved overall survival<sup>[20-22]</sup>. In a retrospective study of 321 patients who underwent curative LR for solitary HCC  $< 5$  cm, patients with preserved synthetic function (Liver damage group A) that underwent anatomical LR had improved overall and recurrence free 5-year survival compared to those treated by non-anatomical LR (87% vs 76%,  $P = 0.02$  and 63% vs 35%,  $P < 0.01$ , respectively)<sup>[21]</sup>. Similarly, a recent retrospective analysis of 158 consecutive patients undergoing either anatomical ( $n = 95$ ) or non-anatomical ( $n = 63$ ) LR for HCC, demonstrated improved disease-free and long-term survival after anatomical LR, despite having larger tumours and higher prevalence of vascular invasion<sup>[22]</sup>. However, anatomical LR cannot always be performed due to limited hepatic reserve. The only option in these patients is a more limited (non-anatomical) LR or local ablative therapy. Patients with moderately impaired (Liver damage group B) synthetic function who underwent non-anatomical LR had significantly better 5-year overall and recurrence free survival compared to those treated by anatomical LR (72% vs 48%,  $P < 0.01$  and 43% vs 28%,  $P = 0.01$ , respectively)<sup>[21]</sup>. Although the reason for this dichotomy remains speculative, it is possible that non-anatomical LR is associated with less physiological stress, which is better tolerated by patients with limited hepatic reserve.

More recently ablative therapies, such as radiofrequency ablation (RFA) or percutaneous ethanol injection (PEI), have been shown to offer similar outcomes to LR for small tumours ( $< 4$  cm) without the associated operative morbidity. In a randomised controlled trial comparing PEI and RFA for HCCs  $< 3$  cm, 4-year local recurrence and survival rates were 1.7% and 74%, respectively<sup>[23]</sup>. This was achieved despite a 63% incidence of disease recurrence elsewhere within the liver. Outcome appears to be operator dependent, both in terms of patient selection and technique, with rates of complete ablation varying from 20% to 96%. In a trial comparing PEI with RFA in HCCs  $\leq 4$  cm, RFA achieved initial complete ablation in 96% of lesions<sup>[24]</sup>. Looking at explant pathology, Lu *et al* reported complete necrosis in 83% of HCCs  $< 3$  cm<sup>[25]</sup>. The higher failure rate of RFA compared to LR in larger lesions may be due to the presence of vascular invasion, which is present in 10%-15% and 46%-50% of 2 cm and 3-4 cm HCCs, respectively<sup>[26]</sup>. LR has the advantage of removing unrecognised regional metastases contained within the resected specimen and is supported by the finding of less intrahepatic recurrence after anatomical compared to non-anatomical LR<sup>[20]</sup>.

## INCREASING RESECTABILITY

Attempts to improve resectability include down staging the primary tumour and reducing the extent of surgery or increasing the size of the future liver remnant. Several techniques have been used to 'down-size' the tumour or to increase the size of the future liver remnant. Pre-operative portal vein embolization allows extensive resections to be performed by decreasing the likelihood

of post-operative liver insufficiency. This is achieved by embolizing the lobe of liver that is to be resected 6 wk prior to surgery, inducing hypertrophy in the future liver remnant. An increase of 40% to 60% in the size of the non-embolized liver is observed in non-cirrhotic livers.

TACE as a down-staging procedure in irresectable tumors has been shown to result in necrosis in 40%-100% of tumors with a three-year survival rate of 77%<sup>[26]</sup>. There is no clear evidence currently that chemoembolization is more effective than embolization alone<sup>[27]</sup>; however, combination of local ablative therapy with systemic chemotherapy or biological agents appears to increase resection rates in patients with compensated liver disease.

## ADJUVANT TREATMENT FOLLOWING LIVER RESECTION

Several strategies have been employed in an attempt to reduce tumour recurrence following LR for HCC, including systemic chemotherapy, regional chemotherapy and internal radiotherapy. Intra-arterial 131-iodine labelled lipiodol has been shown to increase disease-free and overall survival in randomised controlled trials<sup>[27]</sup>. These findings have subsequently been confirmed in a retrospective analysis, where the 3-year disease-free survival rates were 68.4% and 41.5% in those that did and did not receive 131-iodine labelled lipiodol, respectively<sup>[28]</sup>. A large randomised study is awaited to confirm these results. More recently, menatetrenone, a vitamin K2 analogue with known anti-proliferative effects against hepatoma cell lines, reduced tumour recurrence and improved patient survival in patients with HCC following LR or local ablative therapy<sup>[29]</sup>. Sorafenib (Nexavar, Bayer Pharmaceuticals Corporation), an oral multi-kinase inhibitor, has been shown in a phase III placebo-controlled randomised trial to improve overall survival by 44% in patients with stage IV HCC (Hazard Ratio = 0.69, P = 0.0006)<sup>[30]</sup>. Whether this will translate into an improvement in survival in patients following LR or ablation remains to be tested.

## LIVER TRANSPLANTATION

LT is theoretically the best option for treating HCC as it allows for both radical resection of the primary tumour and treatment of the underlying liver disease, thus eliminating the risk of developing new HCCs and progression to end-stage liver failure. For many patients LR is not feasible because of tumour size, anatomical location or poor liver function, and LT is the only surgical option.

Early experience with LT for HCC was associated with a high rate of tumour recurrence and poor long-term survival<sup>[31]</sup>. Improving results for LT and the increasing scarcity donor grafts resulted in restrictions on tumour size as a 20%-40% survival at 5-years was deemed unacceptable. Bismuth<sup>[32]</sup> proposed and Mazzaferro<sup>[33]</sup> popularised the Milan criteria (single HCC

$\leq 5$  cm or up to 3 nodules  $\leq 3$  cm in diameter) for LT in patients with HCC to restrict access and to improve long-term outcome<sup>[33]</sup>. In many centres this has become the 'gold-standard' in determining eligibility for LT; however, some consider these criteria as too restrictive. Yao *et al* analyzed the outcome of 70 patients with HCC undergoing LT and found that patients with a single lesion  $\leq 6.5$  cm, 2 to 3 nodules with the largest  $\leq 4.5$  cm or a total tumor diameter  $\leq 8$  cm had a 75% 5-year survival<sup>[34]</sup>. Patients exceeding these University of California at San Francisco (UCSF) criteria, however, had a 1-year survival rate of 50% following LT<sup>[34]</sup>. Onaca *et al*, in an analysis of 1206 patients that underwent LT, found that patients with 2-4 tumours  $\leq 5$  cm or a solitary HCC  $\leq 6$  cm had tumour free survival similar to those that were within the Milan criteria<sup>[35]</sup>. Despite these encouraging reports adopting expanded criteria, a recent a retrospective study found that patients meeting the Milan criteria pre-transplant had a 5-year survival rate of 60% compared to 45% for those exceeding the Milan criteria, but meeting the UCSF criteria<sup>[36]</sup>. Although the difference was not statistically different, such a clinical difference warrants further examination. The results from a multi-center audit being undertaken by the 'Mazzaferro' group looking at the preoperative number and size of tumours and outcome is awaited<sup>[37]</sup>.

Vascular invasion has been shown to be predictive of tumour recurrence and poor long-term survival in patients with HCC<sup>[38]</sup>. Vascular invasion is more common in large HCCs; however a significant proportion of tumours  $> 5$  cm do not have histological evidence of vascular invasion<sup>[38]</sup>. Using size as a surrogate marker of biological behaviour may, therefore, result in patients with large well-differentiated HCC, who would potentially benefit from LT being excluded, and include small poorly differentiated tumours that are at high risk of recurrence<sup>[34]</sup>. An alternative method of assessing the risk of tumour recurrence is undertaking preoperative percutaneous biopsies, which places the patient at potential risk of local and hematogenous recurrence. Studies have demonstrated that percutaneous biopsy impairs the chance of curative resection. A retrospective review of 85 HCCs resected over 12 years found that preoperative biopsy resulted in the 5-year disease-free survival rate falling from 52% to 24%<sup>[38]</sup>. A recent review estimated the risk of needle tract seeding as being less than 2%, but acknowledged that biopsy carries a risk of hematogenous dissemination, but considered the degree of risk as speculative<sup>[39]</sup>. Further studies are needed to evaluate using histological criteria from biopsy for patients with tumours exceeding standard criteria. It is likely histological and other molecular analyses of tissue samples will increasingly be used preoperatively to characterise the biological behaviour of HCC.

As a consequence of donor shortage, live donor LT (LDLT) has become increasingly utilized for patients with end-stage liver disease. Despite the initial enthusiasm, the number of LRLT performed in the United States has fallen since 2002 as a consequence of

the realisation of donor risk and the implementation of the MELD system for organ allocation, which gave greater priority to patients with HCC. Out of necessity the number of LDLT undertaken in Asian countries, where cadaveric donation is not routinely available, has increased dramatically over the last decade.

For patients with early HCC for whom a suitable donor is available, LDLT offers a number of benefits. It can be performed in a timely manner eliminating the risk of waiting list dropout due to disease progression. LDLT does not rely upon cadaveric donation that is dependent upon equitable allocation for all patients with end-stage liver disease. Consequently, there have been a number of studies looking at LDLT using extended criteria, where the size and number of lesions is not limited<sup>[40,41]</sup>. The largest study reviewed 125 patients that underwent LDLT, 55 of which had tumours that exceeded Milan criteria<sup>[41]</sup>. Patients that exceeded Milan criteria, but had ≤ 10 tumours, all of which were ≤ 5 cm in diameter, had a 5-year recurrence rate similar to those that were within the Milan criteria (7.3% and 9.7%, respectively;  $P = 0.89$ ). Multivariate analysis also demonstrated a preoperative des-gamma-carboxy prothrombin (PIVKA-II; protein induced by vitamin K antagonist-II) value of > 400 mAU/mL as strongly associated with disease recurrence, and a level of < 400 mAU/mL be included in the selection criteria<sup>[41]</sup>. Similarly, Soejima *et al* reported on 60 patients that underwent LDLT for HCC, and found that there were no recurrences in those that were within the Milan Criteria. Multivariate analysis identified only tumour diameter of > 5 cm and PIVKA-II of > 300 mAU/mL as strongly associated with disease recurrence<sup>[40]</sup>. Although these studies are small and have short follow-up, they suggest that expansion of the current tumour size and number with the use of preoperative PIVKA-II, may be associated with acceptable outcomes in patients undergoing LDLT.

## LOCAL ABLATIVE THERAPIES AS A BRIDGE TO LIVER TRANSPLANTATION

RFA and TACE have been used by many centres to downstage and/or prevent disease progression in patients with HCC. Currently there are no prospective randomised trials evaluating the effect of these therapies prior to LT.

RFA is operator dependent, both in terms of patient selection and technique, with rates of complete ablation varying from 20% to 96%<sup>[25]</sup>. Most studies have demonstrated a reduction in the dropout rate compared to historical controls. A study of 60 consecutive HCCs in 50 patients on the waiting list for LT treated by percutaneous and laparoscopic RFA demonstrated a 0% dropout rate and a 8% morbidity at a mean time to LT of 9.5 mo<sup>[42]</sup>. This compares favourably to an historical dropout rate of 10%-30% with waiting times of 6-12 mo<sup>[43]</sup>. More recently, a study of 52 patients treated by preoperative RFA reported a dropout rate of 5.7% at a mean of 12.7 mo with no evidence of tumour

recurrence post-transplant<sup>[44]</sup>. Although there remains a potential risk for needle track dissemination and its efficacy has not been demonstrated in large HCC, RFA should be considered in patients on the waiting list with small (< 3 cm) solitary tumours and reasonable synthetic function (Child-Pugh A, and selected B).

A number of cohort studies have evaluated the efficacy of TACE, alone or in combination with systemic chemotherapy prior to LT<sup>[45,46]</sup>. The results are conflicting, and a recent meta-analysis of TACE as a bridge to LT found that there was insufficient evidence to support the use of neoadjuvant TACE prior to LT as it did not improve long-term survival, allow for the expansion of selection criteria or reduce the dropout rates on the waiting list<sup>[47]</sup>. TACE has been proposed as a method of selecting patients with favourable tumour biology. In a study of 96 consecutive patients with HCC, 62 of whom exceeded Milan criteria, tumour recurrence was influenced by the response to pre-transplant TACE. Patients who had a sustained response to TACE pre-transplant ( $n = 39$ ) had a 5-year tumour free recurrence rate of 94.5%, whereas patients who had disease progression had a tumour free recurrence rate of 35.4% ( $P = 0.0017$ )<sup>[48]</sup>. Similarly, in a smaller study there were only 2 recurrences in 19 patients with tumours > 3 cm that had decreased the sum of two diameters by > 50% following pre-transplant TACE<sup>[49]</sup>.

The current practice guidelines from the American Association for the Study of Liver Diseases (AASLD) state that local ablation, RFA and TACE, are safe and effective in patients who are not suitable for LR, or as a bridge to LT if the waiting list time exceeds 6 mo<sup>[10]</sup>.

## SALVAGE LIVER TRANSPLANTATION

Salvage LT has been promoted as a way of managing patients with HCC in an era of organ shortage. LR is performed as the primary procedure, keeping LT in reserve for those who develop further intrahepatic tumours or decompensation. The strategy offers a number of potential benefits. With increasing waiting times for LT patients with HCC face the prospect of disease progression beyond transplant criteria whilst waiting for a suitable donor. Overall, 5 year survival decreases by 10%-20% (from 81%-58% to 62%-47%) for waiting times of 6-12 mo, and dropout rates range from 10%-30%<sup>[43]</sup>. Undertaking LR in the first instance allows one to observe the natural history of the disease and allow those patients with aggressive disease to declare extrahepatic disease, thus avoiding inappropriate LT and eliminating the risk of disease progression beyond transplant criteria while on the waiting list. In addition, the potential exists to reduce the number of patients requiring LT. In the medium term, disease-free survival for patients undergoing LR with early stage HCC has been shown to be comparable to that of primary LT. LR also allows for histological analysis of the tumour and those with poor prognostic criteria, such as macroscopic vascular invasion or poor differentiation, should be excluded from LT due to the high likelihood

of tumour recurrence, while resected patients who had solitary well-differentiated tumours without vascular invasion can be managed by surveillance and offered LT only if there is tumour recurrence or hepatic decompensation.

Salvage LT for HCC relies upon the principal that patients that have tumour recurrence following LR are still amenable to LT. Tanaka *et al* found that 8% of patients who underwent LR within the Milan criteria had tumour recurrence that exceeded Milan criteria<sup>[50]</sup>. Conversely, only 22% of patients undergoing LR for tumours outside the Milan criteria develop post-resection recurrence that is within Milan criteria<sup>[50]</sup>. Multivariate analysis identified size of the primary tumour and degree of differentiation as risk factors for recurrence exceeding Milan criteria<sup>[50]</sup>. Others have identified the presence of portal vein invasion in the resected liver specimen as the most important predictor of tumour recurrence<sup>[51]</sup>. A number of molecular indices have been examined to try to predict tumour recurrence. A high level of telomerase activity is reported as an independent predictor for tumour recurrence<sup>[52]</sup>. However, no marker has been confirmed to predict the risk of tumour recurrence reliably.

Salvage LT appears to have higher morbidity and mortality and an increased incidence of tumour recurrence compared to primary LT<sup>[53]</sup>. Of 18 patients that underwent salvage LT at Mount Sinai following LR, 2 died peri-operatively (11%), and 7 subsequently developed tumour recurrence (44%)<sup>[19]</sup>. Similarly, of 17 patients that underwent salvage LDLT, bleeding complications were more common, and the peri-operative mortality rate (5.9%) was significantly higher than after primary LT<sup>[54]</sup>. In contrast, Belghiti *et al* reported that LR prior to LT did not significantly increase the operative difficulty of the procedure<sup>[55]</sup>. Furthermore, they did not find any difference in disease-free or overall survival between primary and salvage LT. Patients who underwent salvage LT had a mean 20 mo disease-free interval before listing for LT<sup>[55]</sup>. The long-term outcome of these strategies is awaited.

## EFFECT OF IMMUNOSUPPRESSION ON TUMOUR RECURRENCE

Calcineurin inhibitors, cyclosporine and tacrolimus, are currently the mainstay of immunosuppression in LT recipients. Sirolimus, a novel immunosuppressive drug that inhibits the mammalian target of rapamycin has been shown *in vitro* to allow for the maintenance of tumour immunosurveillance, and may theoretically offer survival benefit in patients transplanted for HCC. In a study of 70 patients transplanted for HCC receiving *de novo* sirolimus and low dose calcineurin inhibitor for 6-12 mo and either a short course (3 mo) or no steroids, tumour free survival at a median of 49 mo was comparable to that achieved with conventional immunosuppression<sup>[56]</sup>. However, 50% of patients had at least one episode of rejection and 34% developed

an incisional hernia. A better understanding of tumour biology and particularly the role of immunosuppression and tumour growth will provide further improvement in the treatment of HCC.

## DIRECT COMPARISONS: RESECTION VERSUS TRANSPLANTATION

The oncological advantage of LT compared to LR has not been universally demonstrated. For large tumours LR is not often possible and LT is the only potential treatment modality. Numerous retrospective studies from the 1990s have demonstrated that the results of LT for large HCCs are poor in relative terms, with 5-year survival rates of < 20%-30%<sup>[31,57,58]</sup>. In contrast the best therapeutic modality for small tumours (< 5 cm) is debatable. A retrospective analysis of 102 patients treated by LT ( $n = 50$ ) and LR ( $n = 52$ ) showed no difference in 3-year survival or recurrence rate for tumours < 5 cm<sup>[57]</sup>. In contrast, Bismuth found that LT was superior to LR for small (< 3 cm) tumours<sup>[32]</sup>. The 3-year survival rate for patients with tumours < 3 cm with 1 to 2 nodules was 83% and 41% for LT and LR, respectively<sup>[32]</sup>. The difference could be attributed to lower peri-operative mortality and tumour recurrence in the LT recipients. The operative mortality for LR for HCC varies from 0.5% and 21.5% and reflects the incidence of hepatic insufficiency-associated with underlying liver disease<sup>[59]</sup>. In addition, the rate of 'recurrent' disease is significantly higher after LR compared to LT with a 3-year recurrence-free survival rate of 83% and 18%, respectively<sup>[32]</sup>. Taken together, it is apparent that in the presence of chronic liver disease, LT offers the greatest chance of long-term survival for patients with small (< 5 cm) tumours. In the present climate of donor organ scarcity it is difficult to justify LT for large and/or advanced HCC.

## CONCLUSION

Currently, in the absence of large randomised clinical trials, the treatment strategy for patients with HCC remains a matter of choice depending upon the interpretation of retrospective studies, anecdotal evidence, unit experience, and availability of therapeutic options.

To date, we have relied upon radiological criteria as a surrogate marker of tumour behaviour. What is needed is an accurate predictor of the biological behaviour of the tumour at the time of presentation. The molecular analysis of tumour biopsies has yet to deliver, and is associated with a risk of needle track recurrence. Less invasive markers that can accurately predict the risk of tumour recurrence are needed to help stratify patients for appropriate therapy.

One of the confounding factors in comparing the outcome of different treatment modalities for HCC is the lack of a uniform staging system. A large multicentre trial examining the commonly used staging systems, found that the American Joint Committee

on Cancer/Union Internationale Contre le Cancer AJCC/UICC (sixth edition) staging system provides the best stratification of prognosis following LR or LT<sup>[60]</sup>. Adoption of a uniform staging system by all centres would help to provide a better comparison of therapeutic modalities in the future.

Although there is no consensus as to the best treatment for patients with HCC, it is apparent that LR appears to be the most appropriate treatment for patients with small (< 5 cm) solitary HCC with well-preserved synthetic function (Child-Pugh A) and normal portal pressures (hepatic vein wedge pressure < 10 mmHg). On account of the high rate of complete ablation that can be achieved in small tumours (< 3 cm), with a similar rate of local control compared to LR, it is hard to justify LR for patients with HCCs < 3 cm, especially if they have significant co-morbidities. Given the scarcity of donor organs and the lack of prospective data demonstrating an acceptable outcome in extending the current criteria, LT should be reserved for early stage HCC (solitary < 5 cm; ≤ 3 lesions 3 cm) that cannot be treated by LR. Medical treatments currently have limited efficacy, and their role, as a surgical adjuvant to LR and LT is yet to be determined.

nificant difference was found between UC patients and control group ( $P > 0.05$ ). In CD and UC patients, no significant association with G908R variant was found. L1007finsC SNP showed an association with CD (9.8%) compared with controls (2.9%,  $P = 0.002$ ) and UC patients (2.3%,  $P = 0.01$ ). Moreover, in CD patients, G908R and L1007finsC mutations were significantly associated with different phenotypes compared to CD wild-type patients. No association of IBD with the TLR4 SNPs was found in either cohort (allele frequencies: D299G-controls 3.9%, CD 3.7%, UC 3.4%,  $P > 0.05$ ; T399I-controls 2.9%, CD 3.0%, UC 3.4%,  $P > 0.05$ ). **CONCLUSION:** These findings confirm that, in our IBD patients selected from Southern Italy, the NOD2/CARD15, but not TLR4 SNPs, are associated with increased risk of CD.

## Abstract

**AIM:** To evaluate the role of genetic factors in the pathogenesis of Crohn's disease (CD) and ulcerative colitis (UC), we investigated the single nucleotide polymorphisms (SNPs) of NOD2/CARD15 (R702W, G908R and L1007finsC), and Toll-like receptor 4 (TLR4) genes (D299G and T399I) in a selected inflammatory bowel disease (IBD) population coming from Southern Italy.

**METHODS:** Allele and genotype frequencies of NOD2/CARD15 (R702W, G908R and L1007finsC) and TLR4 (D299G and T399I) SNPs were examined in 133 CD patients, in 45 UC patients, and in 103 healthy controls. A genotype-phenotype correlation was performed.

**RESULTS:** NOD2/CARD15 R702W mutation was significantly more frequent in CD (9.8%) than in controls (2.4%,  $P = 0.001$ ) and in UC (2.3%,  $P = 0.03$ ). No sig-

## INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are

idiopathic chronic inflammatory bowel disease (IBD). The molecular basis of their pathogenesis is not completely clear, but contributing factors may include persistent bacterial infection, a defective mucosal barrier, and an imbalance in the regulation of the intestinal immune response<sup>[1]</sup>.

Animal models of IBD support the concept that genetic factors, environmental triggers, and immune dysregulation may have a potential role in developing uncontrolled intestinal inflammation that determines the typical endoscopic manifestations and mucosal lesions compatible with CD or UC<sup>[1-4]</sup>.

Over the last decade, multiple genome-wide linkage searches have delineated numerous genomic regions containing putative IBD risk factors. In studies performed on unselected populations, an average of 8%-10% of CD patients and 6%-8% of UC patients have at least one relative affected by some type of IBD. However, these values vary from study to study and percentages of CD familial aggregation of less than 4% and more than 20% have been reported<sup>[2]</sup>.

Moreover, studies on twins demonstrate a greater genetic influence for CD compared with UC; combined study concordance rates for monozygotic twins are 36% for CD and 16% for UC<sup>[5]</sup>.

Recently, an association between CD and mutations in the NOD2/CARD15 gene located on chromosome 16q12 (IBD1) has been reported. NOD2/CARD15 acts as an intracellular receptor in monocytes for bacterial components, triggering activation of NF $\kappa$ B and thus leading to subsequent activation of the inflammatory response. Within the NOD2/CARD15 gene, three mutations have been identified as being associated with CD: two missense mutations (Arg702Trp in exon 4 and Gly908Arg in exon 8) and an insertion mutation of a C in exon 11 (1007finsC), the latter resulting in a truncated NOD2/CARD15 protein. These NOD2/CARD15 variants alter the structure of either the leucine-rich repeat (LRR) domain of the protein or the adjacent region. The activating function of nuclear factor NF $\kappa$ B is regulated by the carboxy-terminal LRR domain, which has an inhibitory role and also acts as an intracellular receptor for components of microbial pathogens. These observations suggest that the NOD2/CARD15 gene can confer susceptibility to CD by altering the recognition of these components and/or by over-activating NF $\kappa$ B in monocytes<sup>[6-9]</sup>. The question arises as to how NOD2/CARD15 mutations and impaired NF $\kappa$ B activation can confer susceptibility to CD. It has been suggested that the answer most likely lies within the leucine-rich repeats (LRR) of the NOD2/CARD15 gene and the family of Toll-like receptors (TLRs). These receptors, a family composed of at least 10 mammalian homologs of Drosophila Toll, serve as pattern recognition receptors for various microbial products and can mediate production of proinflammatory cytokines<sup>[10]</sup>. Toll-like receptor 4 (TLR4) functions as the main receptor for lipopolysaccharide (LPS) of Gram-negative bacteria<sup>[11]</sup>. After the recognition of pathogen-associated molecular patterns, the TLRs activate signal transduction pathways

of the innate immune response genes including inflammatory cytokines and the NF $\kappa$ B signalling pathway<sup>[12]</sup>. TLR4 is expressed in macrophages, dendritic cells, endothelial cells, and, less abundantly, in intestinal epithelial cells, which are partly tolerant to LPS, thereby preventing an exaggerated immune response caused by the large number of bacteria in the intestinal lumen<sup>[13]</sup>.

Mutations of the TLR4 gene are known to abolish responses to endotoxin in mice, as shown for the mice strains C3H/HeJ and C57BL/10SeCr<sup>[14]</sup>. Therefore, the ability to recognize bacterial wall products and to activate proinflammatory mechanisms by TLRs may be of great importance for immune reactions in the intestinal mucosa. The recently characterised D299G and T399I single nucleotide polymorphisms (SNPs) of TLR4 gene are probably associated with impaired LPS signalling and increased susceptibility to Gram negative infections<sup>[15]</sup>.

In this study, we investigated the frequencies of the three NOD2/CARD15 gene mutations (Arg702Trp, Gly908Arg and 1007finsC) and of the TLR4 gene D299G and T399I SNPs in a group of 178 Italian adult patients affected by IBD: 133 patients with CD and 45 with UC. The allele frequencies of the NOD2/CARD15 and TLR4 genes were evaluated, and a detailed genotype-phenotype correlation was performed.

## MATERIALS AND METHODS

### **Study population**

The study population was comprised of 133 patients with CD (70 males, 63 females; mean age,  $43.5 \pm 10.7$  years), 45 with UC (27 males, 18 females; mean age,  $43.2 \pm 11.0$  years) and 103 healthy, unrelated controls (68 males, 35 females; mean age,  $46.6 \pm 9.8$  years). Patients were consecutively recruited from Department of Paediatrics and Department of Medicine, University Hospital of Messina, Italy. All patients were from Eastern Sicily and Calabria (Southern Italy). Informed consent was obtained from each participant.

Diagnosis of CD and UC was established according to accepted clinical, endoscopic radiological, and histological criteria<sup>[16]</sup>. A detailed clinical questionnaire concerning different features of the disease was employed. The Vienna classification was used for CD phenotypes<sup>[17]</sup>, while localization was defined based on the largest extent of the disease, according to X-ray, endoscopy, or surgical reports.

The following data of patients with CD and UC were collected: age, age at diagnosis, gender, familial or spontaneous disease (familial disease was considered if one first or second-degree relative had IBD), disease localization, disease behaviour, extraintestinal manifestations (arthritis, affections of eyes or skin, primary sclerosing cholangitis), type and site of surgery. Disease localization was defined as the maximum extent of digestive tract involvement at the latest follow-up.

Patients were eligible if IBD was confirmed, and they had undergone full colonoscopy with biopsy and/or surgical resection.

A group of 103 healthy, unrelated subjects coming from the Sicily and Calabria regions (mainly students, blood donors and hospital employees) were selected as controls.

#### DNA extraction

Genomic DNA was isolated from 1 mL of peripheral blood anticoagulated with EDTA as previously described<sup>[18]</sup>. DNA samples of the patients and control subjects were analyzed for the variants of NOD2/CARD15 and TLR4 genes by melting curve analysis.

#### Genotyping of the NOD2/CARD15 mutations

To detect the R702W, G908R, and L1007finsC mutations, we performed a polymerase chain reaction (PCR) using 0.5 U of Taq polymerase (Eurotaq, Euroclone Life Sciences Division, UK), 400 μmol/L dNTPs, and 0.1 μmol/L of each primer in a total volume of 25 μL. After an initial denaturation for 5 min at 95°C, PCR was performed by 35 cycles of denaturing at 95°C for 30 s, annealing at 65°C for 40 s, primer extension at 72°C for 30 s. The final extension was performed at 72°C for 7 min. PCR reactions were carried out using a GeneAmp PCR system 2700 (Applied Biosystem, CA, USA).

Genotyping of each SNP was performed by enzymatic digestion at 37°C, overnight. After enzymatic digestion, the fragments were separated and visualized by gel electrophoresis (3% NuSieve® GTG agarose gel BMA, Rockland, ME, USA).

The specific primers PCR and the restriction enzymes (New England Biolabs, Ipswich, MA) for each SNP are given in Table 1.

Wild-type/mutant genotype was confirmed by automatic sequencing using the ABI-PRISM Big Dye™ Terminator v. 3.0 Cycle sequencing Ready Reaction Kit (Applied Biosystems, CA, USA). The sequencing products were purified using DyeEx Spin Kits (Qiagen) and visualized on an ABI-PRISM 310 Genetic Analyzer (Applied Biosystems, CA, USA).

#### Genotyping of the TLR4 polymorphisms

The two D299G and T399I SNPs of the TLR4 gene were determined by PCR-RFLP.

We performed PCR using 0.5 U of Taq polymerase (Eurotaq, Euroclone Life Sciences Division, UK), 400 μmol/L dNTPs, and 0.1 μmol/L of each primer in

a total volume of 25 μL.

For D299G SNP, cycle conditions were an initial denaturation for 5 min at 95°C, followed by 32 cycles of denaturing at 95°C for 30 s, annealing at 51°C for 30 s, primer extension at 72°C for 30 s, followed by a final extension at 72°C for 7 min. For T399I SNP, cycle conditions were an initial denaturation for 5 min at 95°C, followed by 35 cycles of denaturing at 95°C for 45 s, annealing at 55°C for 30 s, primer extension at 72°C for 45 s, followed by a final extension at 72°C for 7 min.

The specific primers PCR and the restriction enzymes for each SNP are given in Table 1.

The amplified samples of TLR4 gene D299G and T399I SNPs were digested at 37°C, overnight, with the *Bsa*BI and *Hinf*I restriction enzymes (New England Biolabs, Ipswich, MA, USA), respectively.

After enzymatic digestion, the fragments were separated and visualized by gel electrophoresis (3% NuSieve® GTG agarose gel BMA, Rockland, ME, USA).

As previously described here, the results of enzymatic digestion were confirmed by DNA sequence analysis of representative samples of each SNP.

#### Statistical analysis

Data are given as mean ± SD. Allele and genotypes frequencies in patients and in controls were compared by  $\chi^2$  test or Fisher exact test, when an expected value was < 0.5; *P* values were considered significant at a level of < 0.05. Odds ratio (OR) and *P* values were calculated using a standard package (StataCorp. Stata Statistical Software: Release 8.0 College Station. TX: Stata Corporation 2001).

Allele frequencies were tested for the Hardy-Weinberg equilibrium. Cases and controls were compared using Pearson's  $\chi^2$  test.

## RESULTS

#### Allele frequencies in IBD patients NOD2/CARD15 gene SNPs

In CD patients, the frequency of R702W mutation was significantly higher (9.8%) than in controls (2.4%, *P* = 0.001; OR, 4.09; 95% CI, 1.5-11.9) and in UC (2.3%, *P* = 0.03; OR, 4.49; 95% CI, 1.02-19.8; Table 2). No significant difference of the G908R mutation allele frequency was found

No patients homozygous for NOD2/CARD15 gene R702W, G908R and L1007finsC SNPs were found in this study population; No patients homozygous for TLR4 gene D299G and T399I SNPs were found in this study population. <sup>1</sup>CD patients vs control group; <sup>2</sup>CD patients vs UC patients. NS: No significance.

between CD (4.5%) and the control group (4.3%; P > 0.05; OR, 1.01; 95% CI, 0.3-3.5), and between CD and UC patients (4.4%, 0.05; OR, 0.90; 95% CI, 0.28-2.92; Table 2).

The frequency of the frameshift mutation L1007finsC was significantly higher in CD patients (9.8%) compared with controls (2.9%, P = 0.002; OR, 3.92; 95% CI, 1.55-9.95) or patients with UC (2.3%, P = 0.01; OR, 5.22; 95% CI, 1.19-22.98; Table 2).

In UC patients, the allele frequencies of the R702W, G908R, and 1007finsC mutations were not significantly different from the control group (R702W: P > 0.05; OR, 0.91; 95% CI, 0.17-4.88 and G908R: P > 0.05; OR, 1.01; 95% CI, 0.3-3.5 and L1007finsC: P > 0.05; OR, 0.75; 95% CI, 0.15-3.88).

No homozygous carriers of the three NOD2/CARD15 mutations were found in the study and control populations.

The NOD2/CARD15 allele frequencies were in Hardy-Weinberg equilibrium in all patients and in control subjects.

### TLR4 gene SNPs

The results of the genotype analyses in 133 patients with CD, in 45 patients with UC and in 103 control individuals, with regard to the TLR4 D299G and T399I SNPs are shown in Table 2.

In CD patients, the frequency of the D299G SNP (3.7%) was not significantly different from the controls (3.9%, P > 0.05; OR, 0.96; 95% CI, 0.37-2.54) or from UC patients (3.4%, P > 0.05; OR, 0.87; 95% CI, 0.23-3.35; Table 2). The T399I SNP allele frequency was not significantly different between CD patients (3.0%) and control group (2.9%, P > 0.05; OR, 1.15; 95% CI, 0.28-4.64); or between CD (3.0%) and UC patients (3.4%, P > 0.05; OR 1.11, 95% CI 0.28-4.40; Table 2). No significant difference was found between UC patients and control group as regards the D299G SNP (P > 0.05;

OR, 0.84; 95% CI, 0.21-3.36) or the T399I SNP (P > 0.05; OR, 1.15; 95% CI, 0.28-4.64).

No homozygous carriers of the two SNPs were found in the study and control populations.

The TLR4 allele frequencies were in Hardy-Weinberg equilibrium in all patients and in the control group.

### Genotype-phenotype correlations

When the contribution of each SNP of the NOD2/CARD15 gene was investigated, the major support to the genotype-phenotype correlation could be ascribed to the G908R and the L1007finsC alleles (Table 3). In particular, in CD patients, the occurrence of one risk allele of G908R was associated with stenosing phenotype (P = 0.03) and resective surgery (P = 0.003).

An increased frequency of ileal localization (80.7%, P = 0.001) and resective surgery (53.9%, P = 0.01) was found in CD L1007finsC heterozygotes compared with CD patients with wild-type NOD2/CARD15 gene (ileum 36.8% and resective surgery 26.4%, respectively).

Moreover, the clinical features of all CD patients were analysed with respect to the presence of one or two risk alleles of each SNP (heterozygous or compound heterozygous) of any NOD2/CARD15 variants (Table 3).

By univariate analysis, the presence of one risk allele was significantly associated with ileal localization (P = 0.04) and resective surgery (P = 0.03). These significant associations increased in the compound heterozygotes (P = 0.03 and P < 0.0001, respectively). Moreover, the presence of two risk alleles was significantly associated with stenosing disease (P = 0.02, Table 3).

In CD patients, TLR4 D299G and T399I SNPs were not found to be associated with age at diagnosis, sex, localization, disease type, resective surgery and extraintestinal manifestations.

Similarly, in UC patients, these TLR4 gene SNPs were not associated with any studied clinicopathological parameter.

**Table 3** Genotype-phenotype correlations in CD patients

Total CD patients (n = 133)	CARD15 no risk alleles (n = 68, 51.1%)	R702W 1 risk allele (n = 26, 19.6%)	G908R 1 risk allele (n = 13, 9.7%)	L1007finsC 1 risk allele (n = 26, 19.6%)	CARD15 at least 1 risk allele (n = 65, 48.8%)	CARD15 compound heterozygous (n = 48, 36.1%)

## DISCUSSION

In our study, we investigated the prevalence of NOD2/CARD15 and TLR4 genetic variants in CD and UC patients. Moreover, we compared the results with clinical phenotype characteristics of IBD of our patients to identify a possible genotype-phenotype association.

There are several controversial data about the role of the SNPs of the NOD2/CARD15 (R702W, G908R and L1007finsC), and TLR4 genes (D299G and T399I) in the pathogenesis of CD. Indeed, there are significant phenotypic differences that exist among populations.

The NOD2/CARD15 mutations are absent in Asian CD populations and controls<sup>[19-21]</sup>. In this case, the findings indicate that the NOD2/CARD15 is not a major contributor to CD susceptibility in the Japanese population. Similar data have been found in Turkish patients with IBD<sup>[22]</sup>.

The highest recorded frequencies are reported in a small study of 55 paediatric patients in Europe with two thirds of the patients having at least one NOD2/CARD15 mutation<sup>[23]</sup>. Within Europe, there is evidence of a north-south gradient with lower allele frequencies in the Celtic and Scandinavian countries compared to Southern Europe<sup>[23]</sup>.

To our knowledge, this is the first study in a large series of sporadic IBD patients coming from Eastern Sicily and Calabria. Indeed, previous reports regarded a Sicilian, small town population in which a familial study was performed<sup>[24]</sup>. Other studies have examined a group of sporadic Sicilian IBD patients, but the number of cases was smaller than in our study<sup>[25]</sup>.

In our study, the reported rates of 48.8 % of patients carrying at least one NOD2/CARD15 mutation in CD and 19.4% in controls are consistent with previously reported rates of 30%-50% in CD and 7%-20% in controls from other European regions<sup>[26-31]</sup>. Moreover, 36.1% had two mutations (compound heterozygotes). Recently,

Renda *et al* examined a group of 182 CD patients coming from Western Sicily and they found that 56 patients (30%) had at least one mutation of the NOD2/CARD15 gene<sup>[32]</sup>. This percentage was lower in respect to our data (48.8%). This difference may be ascribed to a different ethnic background. Indeed, the patients of our study coming both Eastern Sicily and Calabria. Today, populations genetically similar to that of the Northern Italy (as well as of the Northern Africa) are present in the Eastern Sicily. This heterogeneous population, during the middle age, might explain the genetic differences in the patient CD samples of the Eastern in respect to Western Sicily<sup>[33]</sup>.

The allele frequencies of the R702W (9.8%) and L1007finsC (9.8%) mutations were significantly higher in CD patients compared to UC patients and controls, whereas the frequency of the G908R (4.5%) mutation was similar in CD and UC patients, and in the control group. Collectively, our study confirmed previous studies, which reported increased mutation carrier frequencies of one of the three variant alleles in CD patients compared to UC patients or healthy controls<sup>[2,28,32,34-36]</sup>.

We also found that different risk alleles might be associated with different clinical features: in particular, the G908R allele seems to be associated with stenosing phenotype and need for surgery. The L1007finsC seems to correlate with ileal localization and resective surgery. These data suggest a more aggressive course of the disease in carriers of risk alleles. The strongest observed effect for ileal location is consistent with the proposed involvement of ileal Paneth cells in the pathophysiology of NOD2/CARD15-mediated disease susceptibility<sup>[30,36,37]</sup>. NOD2/CARD15 mutations may, thus, abrogate normal Paneth cell behaviour, explaining preferential involvement of the terminal ileum<sup>[26]</sup>.

Moreover, in our study, the risk of developing CD with a more aggressive course was increased in compound heterozygotes. In other populations, stronger associations

have been reported for homozygotes and compound heterozygotes than for simple heterozygotes. One copy of the risk alleles confers a 2-4-fold risk for developing CD, whereas double-dose carriage increases the risk by 20-40-fold<sup>[23]</sup>. Our study is in agreement with such a gene-dosage effect, although at lower levels.

In our IBD patients, we also examined the allele frequencies of the TLR4 D299G and T399I SNPs and the possible genotype-phenotype correlation.

With regard to the role of the TLR4 gene in the pathogenesis of IBD, several studies have been conducted leading to divergent results<sup>[23]</sup>. The allele frequency of the D299G mutation ranges between 8%-13% in CD, 0%-10% in UC and 3%-15% in healthy controls<sup>[38]</sup>. This TLR4 SNP was associated with CD and UC in a Belgian study<sup>[39]</sup>. This association was replicated in Dutch, German, Australian and Greek populations with CD, and an association with colonic disease has been described<sup>[8,34,35,40]</sup>. In one German cohort, an association was demonstrated between UC and the TLR4 T399I SNP<sup>[41]</sup>. However, there is substantial heterogeneity between populations, and no association was noted in Scottish CD patients<sup>[30]</sup>.

In our study, we found no difference in the prevalence of these mutations in our CD and UC patients, and controls. Recently, other studies have failed to find the association of the D299G and T399I SNPs of TLR4 gene<sup>[24,42-45]</sup>. In a retrospective German and Hungarian cohort study, patients with CD and UC were genotyped for the presence of the CD14 c.1-260C>T promoter variant and the TLR4 D299G variant. In this study, in German and Hungarian populations, IBD appears to be associated with the CD14 c.1-260C>T promoter variant, but not with the TLR4 D299G variant<sup>[45]</sup>. Recent data suggest that neither of these 2 variants is causal, but they may be in linkage disequilibrium with, as yet unidentified, causal variants<sup>[46-48]</sup>.

We examined also whether the TLR4 D299G and T399I SNPs could be related to particular CD or UC phenotypes. Detailed analysis did not show any association of the examined TLR4 gene variants with either CD or UC patient subgroups. In other studies, in CD patients, an association has been reported between D299G SNP and ileal localization and structuring phenotype<sup>[49]</sup>. Our data are similar to those previously reported<sup>[28]</sup>. These contrasting results can be ascribed to the different ethnic background of the various IBD populations studied.

Although several studies have been performed, further research is warranted to clarify the role of the genetic variants of NOD2/CARD15 and TLR4, and to investigate whether these genetic risk factors might be confirmed and considered clinically relevant. Indeed, an eventual goal in the genomic study of IBD is to identify these biologically relevant genotype-phenotype associations and to apply them to clinical practice.

## COMMENTS

### Background

Crohn's disease (CD) and ulcerative colitis (UC) are idiopathic inflammatory

bowel disease (IBD) with genetic risk factors. There is evidence that NOD2/CARD15 and Toll-like receptor 4 (TLR4) genes may be involved in their pathogenesis.

### Research frontiers

In our study, we found that some single nucleotide polymorphisms (SNPs) of the NOD2/CARD15 gene, but not of the TLR4 gene, were significantly more frequent in CD patients. Therefore, it is possible that the NOD2/CARD15 gene plays an important role in the pathogenesis of IBD.

### Innovations and breakthroughs

We evaluated the allele and genotype frequencies of the more frequent SNPs of NOD2/CARD15 and TLR4 genes in a selected IBD population coming from Eastern Sicily and Calabria (Southern Italy), a geographical area for which very few data exist.

### Applications

Genotyping of patients with CD could be an important diagnostic tool in clinical practice for identifying high-risk patients with specific diagnostics and therapeutic needs.

### Peer review

This study underlines the association of the NOD2/CARD15 genotype with the behaviour and location of CD also in patients coming from Eastern Sicily and Calabria (Italy). Moreover, the CD patients carrying at least one major variant of NOD2/CARD15 gene had an aggressive clinical course. Test strategies with NOD2/CARD15 variations to predict the clinical course of CD could lead to the development of new therapeutic paradigms.

analyses were performed using the UPLC/MS based lipidomic platform and the HPLC/MS/MS based primary metabolite platform.

**RESULTS:** ER on both diets significantly reduced hepatic lipid accumulation and lipid droplet size, while only whey + Ca diet significantly decreased blood glucose ( $P < 0.001$ ) and serum insulin ( $P < 0.01$ ). In hepatic lipid species the biggest reduction was in the level of triacylglycerols and ceramides while the level of cholesterol esters was significantly increased during ER. Interestingly, diacylglycerol to phospholipid ratio, an indicator of relative amount of diabetogenic diglyceride species, was increased in the control ER group, but decreased in the whey + Ca ER group ( $P < 0.001$ , vs obese). ER on whey + Ca diet also totally reversed the obesity induced increase in the relative level of lipotoxic ceramides ( $P < 0.001$ , vs obese;  $P > 0.05$ , vs lean). These changes were accompanied with up-regulated TCA cycle and pentose phosphate pathway metabolites.

**CONCLUSION:** ER-induced changes on hepatic metabolomic profile can be significantly affected by dietary protein source. The therapeutic potential of whey protein and calcium should be further studied.

### Abstract

**AIM:** To characterise the effect of energy restriction (ER) on liver lipid and primary metabolite profile by using metabolomic approach. We also investigated whether the effect of energy restriction can be further enhanced by modification of dietary protein source and calcium.

**METHODS:** Liver metabolomic profile of lean and obese C57BL/6J mice ( $n = 10/\text{group}$ ) were compared with two groups of weight-reduced mice. ER was performed on control diet and whey protein-based high-calcium diet (whey + Ca). The metabolomic

### INTRODUCTION

Obesity is closely associated with different components of metabolic syndrome<sup>[1]</sup>. However, not all obese

individuals develop metabolic syndrome and not all individuals with metabolic syndrome are obese. It has recently been suggested that fat accumulation in the liver is the key feature distinguishing those individuals who develop metabolic syndrome from those who do not<sup>[2]</sup>. The mechanisms leading to hepatic fat accumulation are not fully understood and, hence, the means of preventing and treating this condition are limited. Once fat has accumulated, the liver is insulin resistant and overproduces major cardiovascular risk factors, such as C-reactive protein, very low density lipoprotein and plasminogen activator inhibitor-1<sup>[3]</sup>. At the moment, improving insulin resistance through energy restriction and subsequent weight loss remains the cornerstone of therapy for non-alcoholic fatty liver disease<sup>[4]</sup>.

Lipids are a highly diverse class of molecules, which have important roles as signalling and structural molecules in addition to serving as energy storage. Therefore, it is crucial to identify the variety of lipid species accumulating in the liver in order to understand the complex process of hepatic insulin resistance. The level of triacylglycerides (TAG) and diacylglycerides (DAG) has been shown to be increased in non-alcoholic fatty liver disease in humans, while total amount of phosphatidylcholines is decreased<sup>[5]</sup>. Similar changes in liver lipids have been detected in ob/ob mice with up-regulation of TAG and DAG, diacylphosphoglycerols and specific ceramide species and down-regulation of sphingomyelins<sup>[6]</sup>. Interestingly, a recent human study revealed that a high level of liver fat is also associated with changes in the lipidomic profile of subcutaneous adipose tissue<sup>[7]</sup>. Increased adipose tissue ceramides, SM, ether phospholipids and long-chain TAG were associated with higher liver fat level. Hence, the accumulation of ceramides and TAG also in the subcutaneous adipose tissue seems to reflect the development of fatty liver. However, more studies are needed to support the findings of fatty liver lipidomics.

Even though weight loss is the main therapeutic way to reduce liver fat, the information on the effect of energy restriction on liver lipidomic profile is scarce. Also the beneficial effect of different dietary components on liver fat species is nearly an unexplored area<sup>[8]</sup>. High intake of dairy products is related to lower risk of insulin resistance<sup>[9]</sup>, type two diabetes<sup>[10,11]</sup> and metabolic syndrome<sup>[12-15]</sup>, but the mechanism of action has not been established. The increased intake of dairy products or calcium has also been shown to augment weight loss both in humans and mice<sup>[16-19]</sup>. Although part of the effect of dairy products on weight loss can be attributed to calcium, it has been repeatedly demonstrated that the anti-obesity effect of dairy is superior to that of calcium alone<sup>[18,20]</sup>. It has been suggested that the whey protein fraction of milk is a source of bioactive peptides or other compounds capable of regulating adipose tissue metabolism, energy expenditure or satiety signals<sup>[21]</sup>. In our previous study, we showed that whey protein in combination with calcium attenuates weight gain<sup>[22]</sup>, but the effects of whey protein during energy restriction

have not been reported. Also, the effect of whey protein containing high-calcium diet on hepatic lipid profile has not been previously described.

The aim of this study was to characterise the effect of high-fat diet-induced obesity and the subsequent ER on liver lipidomic and primary metabolite profile in C57Bl/6 mice, a widely studied model of diet induced obesity. In addition we investigated whether the effect of ER may be significantly improved by modulating the protein source and calcium content of the weight loss diet.

## MATERIALS AND METHODS

### Animals and diets

Eight-week old male C57Bl/6J mice ( $n = 40$ ) were purchased from Harlan (Horst, The Netherlands). The mice were housed five in a cage in a standard experimental animal laboratory, illuminated from 6:30-18:30, temperature  $22 \pm 1^\circ\text{C}$ . The protocols were approved by the Animal Experimentation Committee of the University of Helsinki, Finland and the principles of laboratory animal care (NIH publication no. 85-23, revised 1985) were followed. The mice had free access to feed and tap water during the experiment. After a one-week acclimatisation period on a normal chow diet (Harlan Tekland 2018, Harlan Holding, Inc, Wilmington, DE, USA) thirty mice ( $25.5 \text{ g} \pm 0.3 \text{ g}$ ) were put on a high-fat diet (60% of energy from fat, D05031101M, Research Diets Inc., New Brunswick, NJ, USA) for 14 wk. Ten remaining mice continued on normal chow diet (*ad libitum*) throughout the study and served as a lean control group. After the weight gain period on high-fat diet one group of mice (obese group,  $n = 10$ ) was sacrificed, and the remaining mice were put on a calorie restriction diet for 7 wk. During the calorie restriction period, the mice were given 70% of the energy they ate during the *ad libitum* feeding. In the beginning of the calorie restriction period, the body weight matched mice were divided into two groups: whey + Ca group and control group. Whey + Ca group received high-fat diet (D05031104M, Research Diets Inc., New Brunswick, NJ, USA) with 1.8%  $\text{CaCO}_3$  and all protein (18% of energy) from whey protein isolate (Alacen™ 895, NZMP, Auckland, New Zealand). The control group continued with the same high-fat diet (D05031101M) as during the weight gain period. The powdered diets were moistened with tap water (200 mL/kg in whey + Ca, 110 mL/kg in control and 700 mL/kg in normal chow diet) using industrial dough mixer, packed in one-day portions and stored at  $-20^\circ\text{C}$ .

The body weight was monitored weekly during the weight gain period, and twice per week during the calorie restriction period using a standard table scale (Ohaus Scout™ Pro, SP4001, Nänikon, Switzerland). The consumption of feed was monitored daily using the same table scale. The body fat content was analysed by dual-energy X-ray absorptiometry (DEXA, Lunar PIXImus, GE Healthcare, Chalfont St. Giles, UK) at the end of the weight gain and calorie restriction periods.

### **Calorimetry and metabolic performance**

The dietary protein-induced differences in metabolic performance, energy expenditure, physical activity and drinking and feeding behaviour were analysed by housing an additional group of animals ( $n = 4$ /whey group and  $n = 3$ /casein group) in a home cage-based monitoring system for laboratory animals (LabMaster®, Bad Homburg, Germany). The instrument consists of a combination of highly sensitive feeding and drinking sensors for automated online measurement. The calorimetry system is an open-circuit system that determines  $O_2$  consumption,  $CO_2$  production, and respiratory quotient ( $RQ = VCO_2/VO_2$ , where  $V$  is volume), respiratory exchange rate and heat. A photobeam-based activity monitoring system detects and records every ambulatory movement, including rearing and climbing movements in every cage. The sensors for detection of movement operate efficiently in both light and dark phases, allowing continuous recording. All of the parameters were measured continuously and simultaneously in all animals over the subsequent 7 d after 5 d of adaptation in identical training cages.

### **Fecal fat excretion**

For the collection of feces, the mice were housed in metabolic cages for 72 h at the end of the weight gain and weight reduction periods. The intake of feed and drink was monitored daily and feces collected at the end of the 72 h period. The feces were weighed and stored in -70°C until assayed. The fat content of the fecal samples was determined by SBR (Schmid-Bondzynski-Ratzlaff) method modified for fecal sample analysis<sup>[23]</sup>. The apparent fat absorption was calculated from the amount of feed consumed and the amount of fat excreted during the housing in metabolic cages. Apparent fat absorption (%) was determined as  $100 \times (\text{fat intake-fecal fat})/(\text{fat intake})$ . To estimate the effect of fat excretion on energy absorption during the whole study period, we calculated the apparent cumulative energy absorption from fat using the cumulative energy intake data (apparent fat absorption %  $\times$  cumulative energy intake from fat) as described previously<sup>[24]</sup>.

### **Blood glucose and serum insulin**

Blood glucose and was analysed from the blood samples taken at the termination of the animals. Blood glucose was determined by glucometer (Super Glucocard™ II, GT-1630, Arkray Factory Inc., Shiga, Japan). Serum insulin was analysed from frozen serum samples by ELISA kit for mouse insulin (Ultra sensitive Mouse Insulin ELISA kit 90080, Crystal Chem Inc., IL, USA).

### **The sample preparation**

At the end of the treatment period, the mice were rendered unconscious with  $CO_2/O_2$  (95%/5%; AGA, Riihimäki, Finland) and decapitated. The blood samples were taken into chilled plastic tubes, and the serum was separated by centrifugation at 4°C for 15 min. The livers and subcutaneous, epididymal, abdominal and perirenal

fat pads were removed, washed with saline, blotted dry and weighted. The tissue samples for lipidomic and primary metabolite analysis were snap-frozen in liquid nitrogen and stored at -80°C until assayed. The samples for oil red O-staining were frozen in isopentane (-38°C) and stored at -80°C until further processed. The samples for histology were fixed in 40 g/L formaldehyde and embedded in paraffin with routine techniques.

### **Liver histology and Oil Red O staining**

For histological evaluation of the liver samples 4  $\mu\text{m}$  sections of the paraffin embedded samples were cut with a microtome, stained with H&E and examined with a light microscopy. The severity of the observed lesions was graded as previously described<sup>[25]</sup>.

In order to determine the relative amount of lipids in the liver samples, frozen sections (4  $\mu\text{m}$ ) were stained with Oil Red O, mounted and photographed. From the obtained microscopic images, the amount of Oil Red O-positive staining was determined with AnalySIS Pro-software (Soft Imaging System, Münster, Germany).

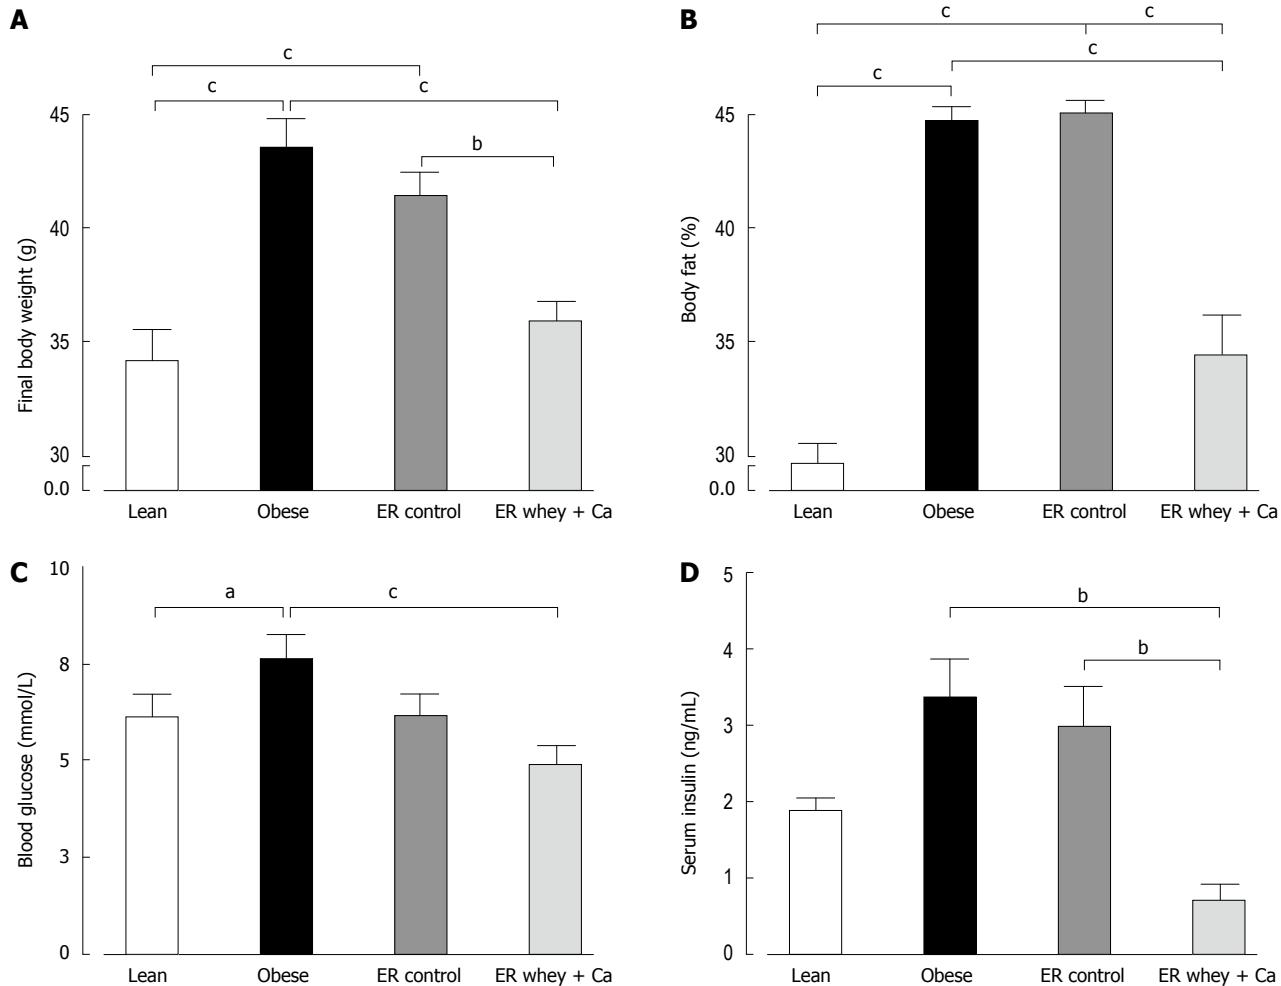

### **Lipidomics**

The lipidomic analysis of liver tissue samples ( $n = 10/\text{group}$ ) was performed as described previously described<sup>[26]</sup>. Liver tissue lipid extracts were examined by a Q-ToF Premier mass spectrometer by introducing the sample through an Acquity UPLCTM system equipped with an Acquity UPLCTM BEH C18 1 mm  $\times$  50 mm column with 1.7  $\mu\text{m}$  particles. The compounds were detected by using electrospray ionization in positive ion mode (ESI+). Data was collected at  $m/z$  300-1200 with a scan duration of 0.2 s. Data was processed using MZmine software version 0.60<sup>[27,28]</sup>, and metabolites were identified using internal spectral library or with tandem mass spectrometry as previously described<sup>[6,29]</sup>.

### **Primary metabolites**

Twenty mg of frozen liver tissue ( $n = 10/\text{group}$ ) was weighed into Eppendorf tubes and 200  $\mu\text{L}$  of methanol (-80°C) and 10  $\mu\text{L}$  of  $^{13}\text{C}$  labeled internal standard was added. Sample was homogenized with Micro Dismembrator S (Sartorius, Germany) by using glass beads (0.5-0.75 mm) and 3000 r/min for 3 min. Homogenized samples were boiled immediately in 80°C for 3 min and at 10000 r/min for 5 min. Supernatant was collected and evaporated to dryness under a stream of nitrogen. Samples were reconstituted in 100  $\mu\text{L}$  of ultra pure water.

The liver extracts were analyzed with HPLC-MS/MS method for quantitative analysis of phosphorous and TCA-cycle compounds. The system consisted of HT-Alliance HPLC (Waters, Milford, MA, USA) working at high pH. The analytes were resolved by anion exchange chromatography combined with post column ASRS Ultra II 2 mm ion suppressor (Dionex, Sunnyvale, CA) and detected with Quattro Micro triple quadrupole mass spectrometry (Waters, Milford, MA, USA) operating in electrospray negative ion mode. The analytical column

**Figure 1** A: The body weight of C57Bl/6J mice at the end of the study; B: The body fat content of C57Bl/6J mice measured by DEXA at the end of the study; C: The blood glucose of C57Bl/6J mice at the end of the study; D: The serum insulin of C57Bl/6J mice at the end of the study. Data is presented as mean  $\pm$  SE. The letters denote a significant difference between the groups (<sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.001$ ;  $n = 10/\text{group}$ ).

was IonPac AS11 (2 mm  $\times$  250 mm, Dionex, Sunnyvale, CA) and guard column IonPac AG11 (2 mm  $\times$  50 mm, Dionex, Dionex Sunnyvale, CA). Flow rate was 250  $\mu\text{L}/\text{min}$  and injection volume 5  $\mu\text{L}$ . The temperature of the column was 35°C and autosampler 10°C.

The compounds were detected in Multiple Reaction Monitoring mode for optimal sensitivity and selectivity. Mass spectrometric parameters, cone voltage and collision energy were optimized for each component. A small aliquot of <sup>13</sup>C-labelled metabolites from yeast-fed batch cultivation was used as an internal standard for both calibration standards and samples. Hexose phosphates (glucose-6-phosphate, fructose-6-phosphate, mannose-6-phosphate and 6-glucose-1-phosphate), pentose phosphates (ribose-5-phosphate and ribulose-5-phosphate), fructose bisphosphate, glycerate-2-phosphate and glycerate-3-phosphate, phosphoenolpyruvate, 6-phosphogluconate, succinate, malate,  $\alpha$ -ketoglutarate, oxaloacetate, citrate, iso-citrate, glyoxylate and pyruvate were quantitatively measured with this method. Data was processed with MassLynx 4.1 software and internal calibration curves were calculated based on response of <sup>12</sup>C analyte and <sup>13</sup>C labelled analogue.

### Statistical analysis

Data are presented as mean  $\pm$  SEM. Statistically significant difference in mean values were tested by ANOVA followed by Tukey's test. The data were analysed using GraphPad Prism, version 4.02 (GraphPad Software, Inc., San Diego, CA, USA). Statistical analyses of metabolomics data were performed using R statistical software ([www.r-project.org](http://www.r-project.org)).

## RESULTS

### Weight and fat loss and fat absorption during ER

The body weight of the high-fat fed mice increased significantly during the 14 wk ad libitum feeding. At the end of the weight gain period the high-fat fed mice weighed significantly more than the chow fed control mice (Figure 1A). The obese mice also had significantly more fat tissue than the lean controls (Figure 1B). The 7-week ER reduced the body weight in the whey + Ca group, to the level of lean controls, but the decrease in body weight was not statistically significant in the control group. Whey + Ca also reduced the fat pad weights more than the weight loss on control diet

**Table 1** Fat pad weights (g)

	Lean	Obese	ER		ANOVA P value
			Control	Whey + Ca	
Subcutaneous fat	0.4 ± 0.1 <sup>c</sup>	1.6 ± 0.1	1.4 ± 0.1 <sup>d,e</sup>	1.0 ± 0.1 <sup>c,d</sup>	< 0.0001
Epididymal fat	1.4 ± 0.1 <sup>a</sup>	1.9 ± 0.1	1.8 ± 0.1 <sup>f</sup>	1.3 ± 0.05 <sup>b</sup>	0.0006
Perirenal fat	0.7 ± 0.1 <sup>c</sup>	1.3 ± 0.1	1.4 ± 0.1 <sup>d,f</sup>	0.9 ± 0.1 <sup>b</sup>	< 0.0001

Data is presented as mean ± SE ( $n = 10$ /group). <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.001$ , vs obese, respectively; <sup>d</sup> $P < 0.001$  vs lean; <sup>e</sup> $P < 0.05$ , <sup>f</sup> $P < 0.01$  vs whey + Ca, respectively.

**Table 2** Incidences of the observed histopathological lesions in liver samples

	Lean	Obese	ER	
			Control	Whey + Ca
Number of samples	8	10	10	10
No abnormalities detected	8	0	0	0
Macrovesicular fatty change (total)	0	10	10	10
Severe	0	1	0	0
Marked	0	1	0	0
Moderate	0	5	5	4
Slight	0	3	5	5
Minimal	0	0	0	1
Infiltration of inflammatory cells, minimal	0	1	1	3
Focal hepatocyte necrosis, total	0	2	0	2
Slight	0	1	0	0
Minimal	0	1	0	2

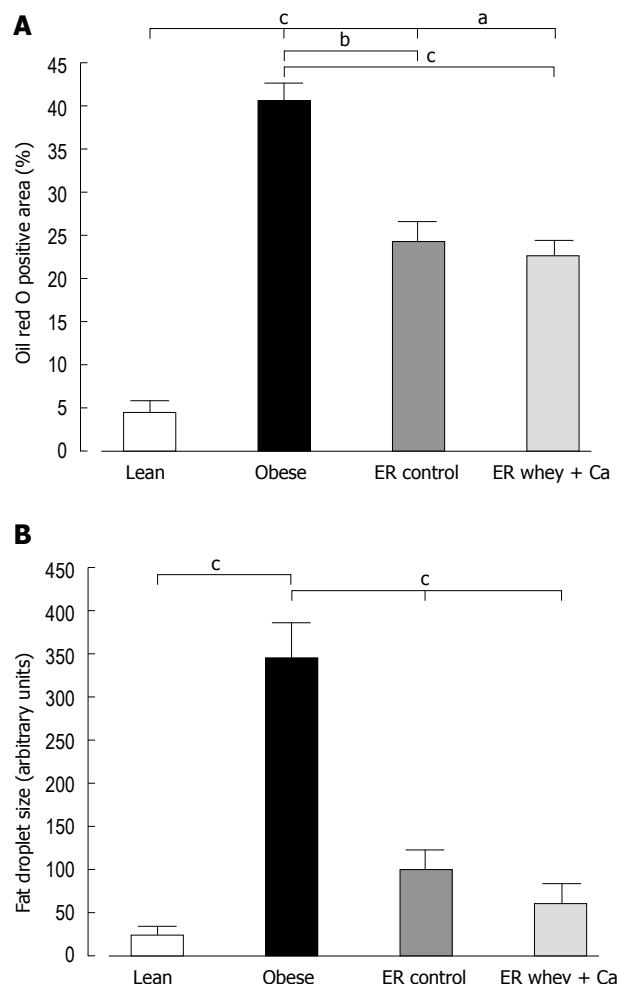

(Table 1). Apparent fat absorption was reduced in the whey + Ca group in comparison with the control diet ( $96.9\% \pm 0.3\%$  vs  $98.4\% \pm 0.1\%$  in whey + Ca and control diet, respectively;  $P = 0.0004$ ).

#### Blood glucose, serum insulin and liver histology

ER on both diets reduced the blood glucose to the level of lean controls, but the decrease was statistically significant only in the whey + Ca group (Figure 1C). Also the serum insulin was significantly decreased only in the whey + Ca group (Figure 1D). In the obese group, the liver histology showed an evident macrovesicular fatty change of diffuse pattern, with severity ranging from slight to severe (Table 2). In the ER groups, the observed fatty change was less severe. The fat droplets were smaller and mainly present in the perivenular regions. Minimal foci of inflammatory cells and necrotic hepatocytes were occasionally noted, but fibrosis was absent. Oil Red O-staining demonstrated that ER on control and whey + Ca diet significantly reduced hepatic lipid accumulation and lipid droplet size (Figure 2), but the amount of fat did not reach the level observed in the lean mice.

#### The effect of protein source on metabolic performance

In order to investigate whether the more pronounced weight loss effect in the whey protein fed mice was a result of differences in drinking and feeding behaviour, increased activity or changes in metabolic performance,

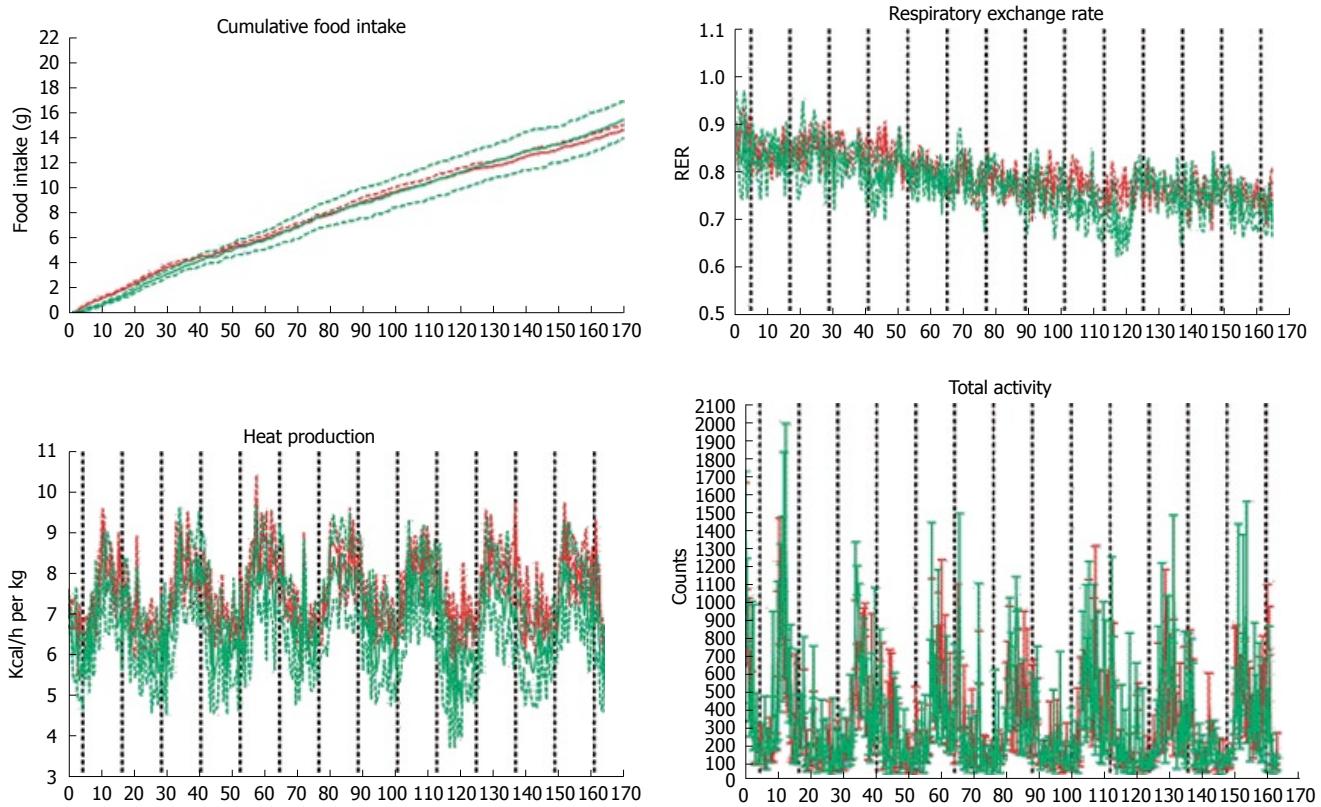

**Figure 2** **A:** The Oil Red O positive area of paraffin embedded liver samples of C57Bl/6J mice at the end of the study; **B:** The mean fat droplet area (arbitrary units) of paraffin embedded liver samples of C57Bl/6J mice at the end of the study. Data is presented as mean ± SE. The letters denote the significant difference between the groups (<sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.001$ ;  $n = 10$ /group).

an additional group of mice were housed in a home cage based monitoring system. A 7-day monitoring did not reveal differences in cumulative feed or water intake, respiratory exchange rate, heat production,  $O_2$  consumption,  $CO_2$  production, total or rearing activity or ambulatory movements during the observation period (Figure 3).

#### The effect of ER on liver lipid profile

Of the total 2498 hepatic lipid peaks detected, 391 major peaks were identified and included in further analysis. The reduction of lipids was mainly seen in the level of triacylglycerols (TAG) and ceramides and ER on whey + Ca diet even restored the level of ceramides to the level of lean mice (Figure 4). The amount of cholesterol esters was significantly increased in both ER groups. The TAG to phospholipid ratio, which reflects the relation of membrane lipids to storage lipids, was significantly reduced only in whey + Ca group, but it was still higher than in the lean controls (Figure 5A). Interestingly, diacylglycerol (DAG) to phospholipid ratio was increased in the control ER group, but decreased in

**Figure 3** A: Cumulative food intake over 7 d analyzed by LabMaster system. The cumulative total food intake was similar between the groups; B: LabMaster analysis of respiratory exchange rate (RER); C: Heat production measured by LabMaster; D: Total ambulatory movement did not differ between the groups. In all figures data is presented as mean  $\pm$  SE,  $n = 4$  in casein group (red) and  $n = 3$  in whey group (green).

the whey + Ca ER group (Figure 5B). ER on whey + Ca diet also totally reversed the obesity-induced increase in the ceramide to sphingomyelin ratio (Figure 5C). Phosphatidic acid (GPA) and phosphatidylglycerol (GPGro) peaks could not be uniquely distinguished by our method. The level of GPA/GPGro, phosphatidylcholines and lysophosphatidylethanolamines was not affected by obesity or ER.

The most significantly changed lipids are presented in Figure 6. Interestingly TAG (58:3) and TAG (58:2) were at higher level in the control weight loss group even though they were already increased as a result of obesity, and so was the level of TAG (50:8) in the whey + Ca group. Weight loss further increased the level of GPCho (32:2) even though its level was already over 10 times higher in the obese group than in the lean mice. On the other hand, the level of TAG (52:0) decreased during ER even though its level was already lower in obese than in the lean animals.

The most distinct features of whey + Ca ER group were the significant increases in the level of total phosphatidylserines, phosphatidylethanolamines and sphingomyelins (Figure 6). It is also of note that the level of certain phosphatidylcholine species was significantly decreased during ER on control diet whereas there was no change in whey + Ca group. Whey + Ca specifically affected certain ceramide species [Cer (d18:0/22:5), Cer (d18:0/22:6), Cer (d18:1/23:3), Cer (d18:1/23:5), Cer (d18:1/26:4)], whose level was reduced to the level of

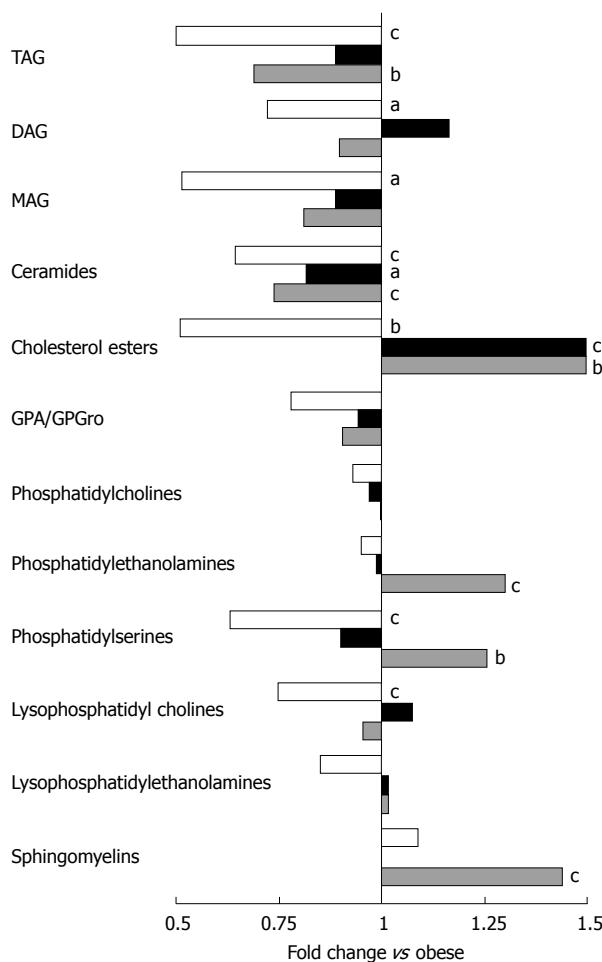

lean mice, whereas their level was unaffected by ER on control diet. Cer (d18:1/25:4) was even increased by ER on control diet while its level did not differ between lean, obese and whey + Ca group.

#### The effect of ER on primary metabolites

The primary metabolite analysis led to identification of 13 metabolites (glucose-6-phosphate, fructose-6-phosphate, mannose-6-phosphate, fructose bisphosphate, glycerate-3-phosphate, ribose-5-phosphate, succinate, malate, citrate, pyruvate, phosphoenolpyruvate, 6-phosphogluconate and fumarate). The high-fat diet feeding and subsequent obesity led to reduction of glycolytic metabolites, such as glucose-6-phosphate, fructose-6-phosphate and pyruvate (Table 3, Figure 7). ER with whey + Ca diet was associated with significant increases of succinate, which belongs to the TCA cycle and of ribose-5-phosphate, which is a product of pentose phosphate pathway. Whey + Ca diet also decreased the level of glycolytic metabolites glucose-6-phosphate, fructose-6-phosphate and fructose bisphosphate in contrast with ER on control diet, which did not affect the level of these metabolites.

#### DISCUSSION

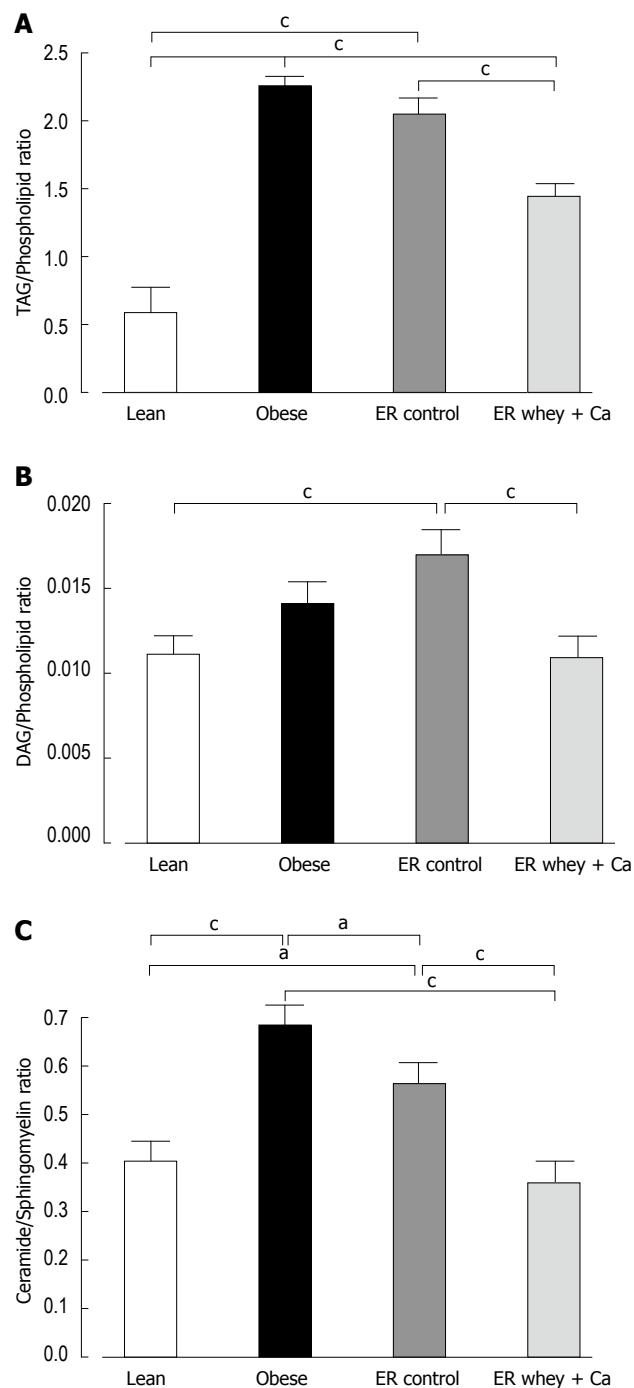

In this study, we showed that decreasing liver fat by ER significantly modulates the overall profile of liver

**Figure 4** Mean fold changes in lipid classes in lean (white), ER control (black) and ER whey + Ca (grey) groups in relation to the obese group ( $n = 10/\text{group}$ ). The letters denote a significant difference in comparison with the obese group ( $^{\circ}P < 0.05$ ,  $^{\circ}P < 0.01$ ,  $^{\circ}P < 0.001$ ).

lipid species. The main finding of the study was that the protein source and calcium content of the diet had a significant effect on the ER-induced hepatic lipid changes. Even though the histological analysis did not reveal significant differences in the amount of liver fat between the ER groups, the metabolomic data demonstrated that ER on whey + Ca diet was able to reduce the relative level of potentially diabetogenic ceramides and diacylglycerols to the level observed in lean animals. This finding is in accordance with the decreased level of serum insulin in this group. These changes were accompanied by a decrease in glycolytic metabolites while the metabolites from the pentose phosphate pathway and TCA cycle were increased together with a shift towards gluconeogenesis.

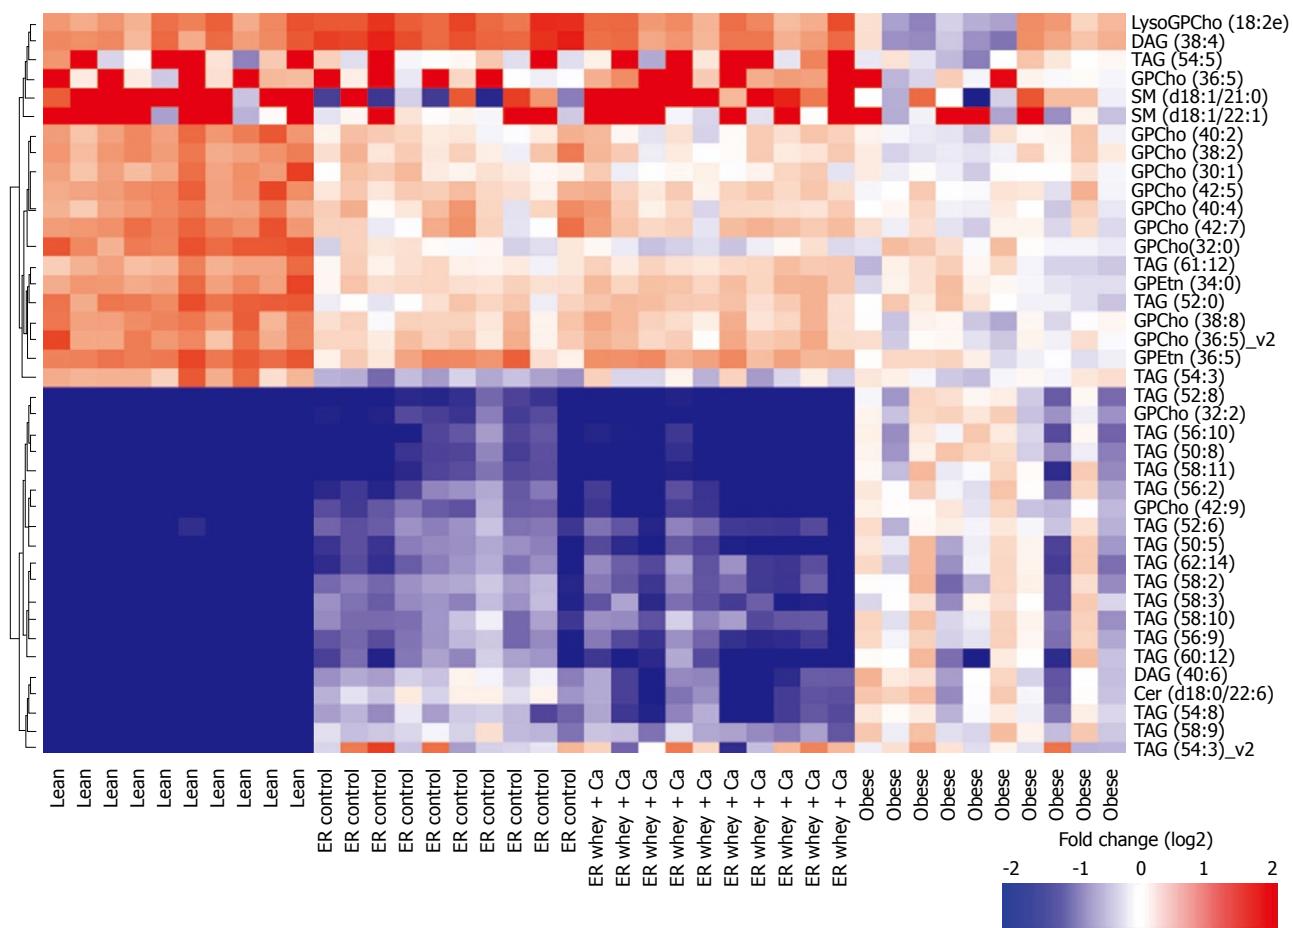

The UPLC/MS based lipidomics platform and the HPLC/MS/MS based primary metabolite platform techniques were used to characterise the hepatic lipid and primary metabolite changes in this study. These techniques provide an overview of key metabolites involved in energy metabolism, including a broad profile covering all major lipid classes present in liver as well as key metabolites of the central carbon metabolism. Traditional analyses of lipids have been generally limited

**Figure 5** A: The liver TAG/Phospholipid ratio; B: The liver DAG/Phospholipid ratio; C: The liver Ceramide/Sphingomyelin ratio. Lipids measured by UPLC/MS. Data is presented as mean  $\pm$  SE. to investigations of lipid class- or fatty acid-specific changes<sup>[30]</sup>. These new analytical methods combined with information technology provide extremely sensitive tools to measure the extended metabolome, and may help to explore the mechanisms of many complex diseases<sup>[31,32]</sup>. However, one evident shortcoming of the method is that a major part of the spectral peaks are still unidentified.

To our knowledge this is the first study to demonstrate the effect of ER on fatty liver lipidomic and primary metabolite profile in diet induced obese mice. In

**Figure 6** Twenty most significantly up- and down-regulated lipids between obese and lean group. Fold change for each individual mouse within each group as a log<sub>2</sub> ratio between the lipid concentration in individual sample and the median lipid concentration in the obese group. Hierarchical clustering using Ward linkage was applied.

Data is presented as mean  $\pm$  SE ( $n = 10$ /group). <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.001$  vs obese, respectively; <sup>d</sup> $P < 0.05$ , <sup>e</sup> $P < 0.01$ , <sup>f</sup> $P < 0.001$  vs lean, respectively; <sup>g</sup> $P < 0.05$ , <sup>h</sup> $P < 0.01$ , <sup>i</sup> $P < 0.001$  vs whey + Ca, respectively.

accordance with previous studies on lipidomic profile of non-alcoholic fatty liver disease, we also found increased levels of TAG, DAG and specific ceramide species and down-regulation of sphingomyelins in the obese group<sup>[6]</sup>. Interestingly, only ceramides were significantly decreased by ER on control diet, while the level of DAG increased non-significantly and sphingomyelins stayed un-changed.

However, ER on whey + Ca diet significantly increased the level of sphingomyelins and decreased the level of DAG changing the ceramide/sphingomyelin and DAG/phospholipid ratios to the level of lean animals. The accumulation of both ceramides and DAG in peripheral tissues contribute to insulin resistance<sup>[33-35]</sup> and, therefore, the decrease of these lipids can be considered

**Figure 7** Primary metabolite profiles for each individual mouse as a log<sub>2</sub> ratio between the metabolite concentration in individual samples and the median metabolite concentration in the obese group. Hierarchical clustering using Ward linkage was applied.

particularly beneficial.

Additionally an increase in liver cholesterol ester level, which was seen in both of the ER groups, has been demonstrated to occur also as a result of acute 24 h food deprivation<sup>[36]</sup>. One of the main functions of cholesterol is maintaining of membrane fluidity by interacting with other membrane lipid components such as phosphatidylcholines and sphingomyelin<sup>[37]</sup>. However, only cholesterol esters were found to be increased as a result of ER in the control group.

The level of primary metabolites was particularly affected in the whey + Ca group. Energy restriction in normal weight, healthy mice, is known to enhance hepatic gluconeogenesis<sup>[38,39]</sup> and suppress glycolysis<sup>[40]</sup>. This effect was particularly pronounced in the whey + Ca group as indicated by the striking decrease of fructose bisphosphate, the key regulator of gluconeogenesis, and significant decrease of glycolytic intermediates glucose-6-phosphate and fructose-6-phosphate. An increased level of ribose-5-phosphate in the whey + Ca group indicates enhanced flux through pentose phosphate pathway, which is known to be triggered by low concentrations of fructose-2,6-bisphosphate<sup>[41]</sup>. ER on whey + Ca diet also decreased the level of succinate to the level of lean animals, whereas the level of succinate did not change in the ER control group. The significance of the decrease of mannose-6-phosphate in whey + Ca groups remains to be elucidated.

One of the few dietary components which are known to influence the liver fat profile during ER is the type and amount of dietary fat<sup>[8]</sup>. In this study there were no differences in either the type or amount of dietary fat between the ER groups. However, the apparent fat absorption was decreased in the whey + Ca group. Calcium preferentially binds saturated fatty acids in the intestine<sup>[42]</sup>, and therefore, also the quality of the absorbed fat might have been influenced in the whey + Ca group.

Even though these findings may help to understand why increased dairy calcium intake may lower the risk of metabolic syndrome, the molecular mechanism by which whey protein and calcium modulate the liver lipid profile remain unanswered. Whey protein consists of several

small protein types, including alfa-lactalbumin, beta-lactoglobulin, bovine serum albumin, lactoferrin and other minor peptides<sup>[43]</sup>. In order to investigate the possible effects of whey protein on energy expenditure and food intake, we measured the metabolic performance of mice fed either casein or whey based diet in a calorimetry system, but did not see any differences between the proteins. The principal question regarding the mechanism is whether the beneficial effect is derived only from the amino acids or if bioactive peptides are formed during the digestion and absorption of the protein.

The present study demonstrates that ER-induced changes in fatty liver are significantly affected by dietary protein source and calcium. Reducing liver fat by ER is currently the main treatment for non-alcoholic fatty liver disease and therefore, it is crucial to understand which dietary factors have significant effects on the outcome of ER in liver. These results indicate that whey protein and calcium could be beneficial in the dietary treatment of fatty liver, and are likely contribute to the inverse relationship between dairy intake and the risk of insulin resistance. The therapeutic potential of whey protein and calcium in clinical setting, and the mechanism of action remain to be elucidated.

## COMMENTS

### Background

Fatty liver is considered to be an important link between obesity and the development of metabolic syndrome and insulin resistance. Liver fat can be reduced by weight loss, but the effect of weight loss on the quality of hepatic lipid profile is currently not well established.

### Research frontiers

Some dietary factors, like the quantity and quality of fat during weight loss have been shown to have an effect on liver fat. However, the importance of dietary protein source and calcium content has not been investigated previously.

### Innovations and breakthroughs

This study characterises the changes in hepatic lipid profile during energy

restriction in a mouse model of diet induced obesity. The effect of protein source and calcium content of the weight loss diet is also studied. This study demonstrates for the first time that dietary protein source may beneficially modulate the lipid profile of fatty liver during energy restriction.

### Applications

Weight loss by life style changes is the main therapeutic approach to reduce liver fat. Therefore, it is crucial to identify dietary components which may improve the outcome of weight loss in the level of hepatic lipid profile. These results indicate that whey protein and calcium beneficially modulate the hepatic lipid profile targeting specifically the lipotoxic diacylglycerol and ceramide species.

### Peer review

The study is well conducted and has important information about the pathophysiology of fatty liver.

kinase C inhibitor, attenuated translocation of NF- $\kappa$ B induced by LPA.

**CONCLUSION:** These findings suggest that protein kinase C is activated endogenously in Panc-1, and protein kinase C is essential for activating NF- $\kappa$ B with cytosolic calcium and that LPA induces the nuclear translocation of NF- $\kappa$ B in Panc-1 by mobilizing cytosolic free calcium.

## Abstract

**AIM:** To clarify whether Lysophosphatidic acid (LPA) activates the nuclear translocation of nuclear factor- $\kappa$ B (NF- $\kappa$ B) in pancreatic cancer.

**METHODS:** Panc-1, a human pancreatic cancer cell line, was used throughout the study. The expression of LPA receptors was confirmed by reverse-transcript polymerase chain reaction (RT-PCR). Cytosolic free calcium was measured by fluorescent calcium indicator fura-2, and the localization of NF- $\kappa$ B was visualized by immunofluorescent method with or without various agents, which effect cell signaling.

**RESULTS:** Panc-1 expressed LPA receptors, LP<sub>A1</sub>, LP<sub>A2</sub> and LP<sub>A3</sub>. LPA caused the elevation of cytosolic free calcium dose-dependently. LPA also caused the nuclear translocation of NF- $\kappa$ B. Cytosolic free calcium was attenuated by pertussis toxin (PTX) and U73122, an inhibitor of phospholipase C. The translocation of NF- $\kappa$ B was similarly attenuated by PTX and U73122, but phorbol ester, an activator of protein kinase C, alone did not translocate NF- $\kappa$ B. Furthermore, the translocation of NF- $\kappa$ B was completely blocked by Ca<sup>2+</sup> chelator BAPTA-AM. Thapsigargin, an endoplasmic reticulum Ca<sup>2+</sup>-ATPase pump inhibitor, also promoted the translocation of NF- $\kappa$ B. Staurosporine, a protein

## INTRODUCTION

Lysophosphatidic acid (LPA) is the smallest and structurally simplest of all glycerophospholipids, and exists in serum at concentrations between 1-5  $\mu$ mol/L<sup>[1]</sup>. LPA is mainly released by activated platelets<sup>[2]</sup>, and immediately complexes with high affinity to serum albumin<sup>[3]</sup>. It is well known that LPA exhibits hormone- and growth factor-like activities<sup>[4,5]</sup>. LPA represents a major bioactive constituent of serum. LPA increases [<sup>3</sup>H]-thymidine incorporation, inositol phosphates, intracellular calcium, and protein kinase C activities<sup>[4,5]</sup>. Indeed, LPA acts on a large number of cells to achieve a broad range of immediate and long lasting effects. Specific responses to LPA include changes in cell shape and tension, chemotaxis, proliferation and differentiation<sup>[6,7]</sup>. LPA binds to putative G protein-coupled receptors found on nearly all cell types, including cancer cell lines. Numerous other cellular

and biochemical responses to LPA have also been documented<sup>[8]</sup>.

The molecular actions of LPA have been characterized best in rodent fibroblasts, where LPA stimulates phosphoinositide hydrolysis<sup>[4]</sup> and promotes the Rho-dependent formation of stress fibers and focal adhesions<sup>[9]</sup>. The stimulation of phosphoinositide hydrolysis is thought to occur through the GTP-binding regulatory protein (G protein) Go or Gq. The formation of stress fibers and focal adhesions is consistent with activation of Rho through G<sub>i0</sub> or G<sub>i1</sub><sup>[8]</sup>. Whether G proteins are sufficient for this action is unclear, but the sensitivity of the phenomenon to pertussis toxin (PTX) implies that G<sub>i0</sub> represents at least one necessary input. Receptors that recognize LPA have been identified that conform to the seven-transmembrane domain motif characteristic of G protein-coupled receptors, and identified as LP<sub>A1</sub>/Edg-2, LP<sub>A2</sub>/Edg-4, LP<sub>A3</sub>/Edg-7<sup>[10]</sup>.

On the other hand, nuclear factor-κB (NF-κB) is the prototype of a family of dimers whose constituents are members of the Rel family of transcription factors<sup>[11]</sup>. In most types of cells, NF-κB is present as a heterodimer comprising p50 (NF-κB1) and p65 (RelA). NF-κB is normally retained in the cytosol in an inactive form through interaction with I κB inhibitory proteins. Release of NF-κB for translocation to the nucleus and interaction with cognate DNA sequences is accomplished through a signal-induced phosphorylation and subsequent degradation of I κB. Originally described as a necessary element for expression of the immunoglobulin gene in mature B cells, NF-κB is now recognized to be an important transcriptional regulatory protein in a variety of cell types.

It is reported that LPA translocates NF-κB to the nucleus in fibroblasts<sup>[12]</sup>, lymphocytes<sup>[13]</sup>, breast cancer cells<sup>[14]</sup>, colon cancer cells<sup>[15]</sup>, prostate cancer cells<sup>[16]</sup>, and ovarian cancer cells<sup>[17]</sup>. However, until now it is not clear whether LPA translocates NF-κB in pancreatic cancer cells or not. In this study, we demonstrate for the first time that LPA induces translocation of NF-κB to nucleus in the pancreatic cancer cell line, Panc-1, by mobilizing cytosolic free calcium.

## MATERIALS AND METHODS

### Materials

The human pancreatic cancer cell line, Panc-1 (ATCC CRL 1469), was obtained from American Type Culture Collection (MD, USA). Media and supplements were from GIBCO BRL (New York, USA). Fetal bovine serum and fetal calf serum were from Hyclone (Utah, USA). Glass-bottomed chambers were from Costar (Massachusetts, USA). LPA and fatty-acid free albumin were from Sigma (Montana, USA). PTX, staurosporine, genistein and PD98059 were from Calbiochem (California, USA). U73122, U73343 and Fura-2/AM were from Seikagakukogyo (Tokyo, Japan). Rabbit anti-human NF-κB p65 polyclonal antibody was obtained from Upstate Biotechnology (New York, USA); and rhodamine-conjugated donkey anti-rabbit polyclonal

antibody and normal donkey serum from Chemicon International (California, USA), respectively.

### Methods

**Cell culture:** Panc-1 was maintained in Dulbecco's modified Eagle medium (DMEM) supplemented with penicillin (50 units/mL), streptomycin (50 units/mL), and 10% fetal bovine serum (FBS). Panc-1 was maintained in DMEM without FBS for 48 h prior to use for the following experiments.

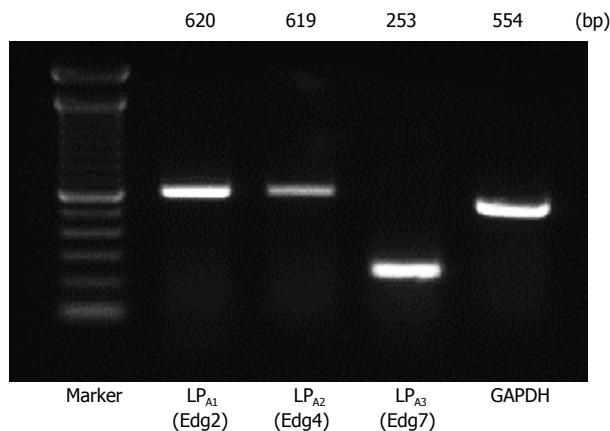

**Total RNA extraction and reverse-transcription polymerase chain reaction (RT-PCR) analysis for detection of LPA receptors:** Total RNA was extracted from Panc-1 using ISOGEN (Nippon Gene, Tokyo, Japan). The first strand cDNA synthesis was carried out using the SuperScript™ First-Strand Synthesis System for RT-PCR (Invitrogen™ life technologies, California, USA). One hundred nanogram of the synthesized first strand cDNA was subjected to PCR using Platinum® Taq DNA Polymerase (Invitrogen™ Life Technologies, California, USA). The first strand cDNA was then amplified with specific primers; GAPDH (as an internal control), Edg-2, Edg-4, and Edg-7. The PCR primers and conditions are listed in Table 1. In all cases after the RT step the templates were heated at 94°C for 30 s, annealed for another 30 s, and finally subjected to a 72°C extension for 60 s. The PCR products were separated in 2% agarose gel and visualized under UV illumination.

**Measurement of cytosolic free calcium:** Cytosolic free calcium concentration was measured as previously described<sup>[18]</sup>. Confluent monolayers of Panc-1 cells grown in 175 cm<sup>2</sup> flasks were harvested by incubation in 0.9% (w/v) NaCl, 0.02% (w/v) EGTA and 10 mmol/L Hepes, pH 7.2. Cells were washed twice with PBS, resuspended to a density of 1 × 10<sup>6</sup> cells/mL, and then incubated with 6 μmol/L fura-2/AM for 1 h at room temperature. Aliquots of this suspension were washed twice with Krebs-Ringer's HEPES buffer in a stirred fluorimetry cuvette at 37°C. Fluorescence of fura-2 was measured with Shimazu RF-5000 luminescence spectrometer (alternate excitation wavelengths of 340 nm and 380 nm; emission wavelength, 505 nm). R<sub>max</sub> was determined by the addition of 0.1% Triton X-100, then R<sub>min</sub> was estimated using 4 mmol/L EGTA.

**Immunofluorescence:** Panc-1 cells were cultured on glass-bottomed culture dishes, and experiments were conducted as described above. Panc-1 cells were washed twice with ice-cold PBS and fixed with methanol for 5 min, permeabilized with 0.2% Triton X-100. Once the dishes had air-dried, the cells were incubated in 10% FCS for 2 h to block nonspecific antibody binding. The cells were then incubated with rabbit anti-human NF-κB p65 polyclonal antibody (1:50) in PBS containing 0.2% BSA for 6 h at room temperature. The dishes were then washed three times in PBS with 0.2% BSA for 5 min at room temperature. Cells were then incubated with rhodamine-conjugated donkey anti-rabbit polyclonal

**Table 1** The PCR primers and conditions for detection of LPA receptors

	Sense primer	Antisense primer	Temperature (°C)	Size (bp)
GAPDH	5'-AATGCATCCCTGCACCACCAACTGC-3'	5'-GGAGGCCATGTAGGCCATGAGGTC-3'	59	554

Edg-7	5'-GCTGGAATTGCCTCTGCAAC -3'	5'-ACCACAAACGCCCTAAGAC -3'	62	253

**Figure 1** Expression of LPA receptors in Panc-1 cells. LPA-specific receptors LP<sub>A1</sub>/Edg-2, LP<sub>A2</sub>/Edg-4, and LP<sub>A3</sub>/Edg-7 are expressed in PANC-1 cells. Total mRNA of PANC-1 cells was extracted and used for RT and PCR using primers designed from the sequence of LP<sub>A1</sub>, LP<sub>A2</sub>, and LP<sub>A3</sub>, and GAPDH. PCR products were separated by electrophoresis in 2.0% agarose gel. The molecular size of the amplification products is inferred from the electrophoretic migration of the DNA markers.

antibody (1:100) in PBS containing 0.2% BSA for 1 h at room temperature. The dishes were then washed three times in PBS containing 0.2% BSA for 5 min at room temperature and mounted with glass coverslips using Vectashield mounting medium from Vector Laboratories (California, USA). Immunofluorescence was observed by using an LSM410 Confocal Laser Scanning Microscope from Carl Zeiss, Inc. (Oberkochen, Germany).

**Treatment of Panc-1 cells:** Panc-1 cells were treated with various agents before measuring cytosolic free calcium or detecting translocation of NF- $\kappa$ B. For PTX-pretreatment, monolayers of Panc-1 cells were cultured in DMEM with 100 ng/mL PTX overnight, and then washed twice with PBS. Panc-1 cells were treated with other agents; 10  $\mu$ mol/L U73122 for 10 min, 10  $\mu$ mol/L U73343 for 10 min, 10  $\mu$ mol/L BAPTA for 15 min, 10 nmol/L staurosporine for 10 min, 50  $\mu$ g/mL genistein for 1 h, and 10 nmol/L PD98059 for 1 h before stimulation of LPA.

#### Statistical analysis

The Student's *t*-test was used to determine significant differences between the groups.

## RESULTS

### Panc-1 cells express LP<sub>A1</sub>, LP<sub>A2</sub>, and LP<sub>A3</sub> mRNA

The expression of LP<sub>A1</sub>/Edg-2, LP<sub>A2</sub>/Edg-4, and LP<sub>A3</sub>/

Edg-7 receptors was determined by RT-PCR in Panc-1 cells. As shown in Figure 1, a significant expression of mRNA encoding LP<sub>A1</sub>/Edg-2, LP<sub>A2</sub>/Edg-4, and LP<sub>A3</sub>/Edg-7 was observed, as judged from the appearance of unique cDNA bands of the expected size.

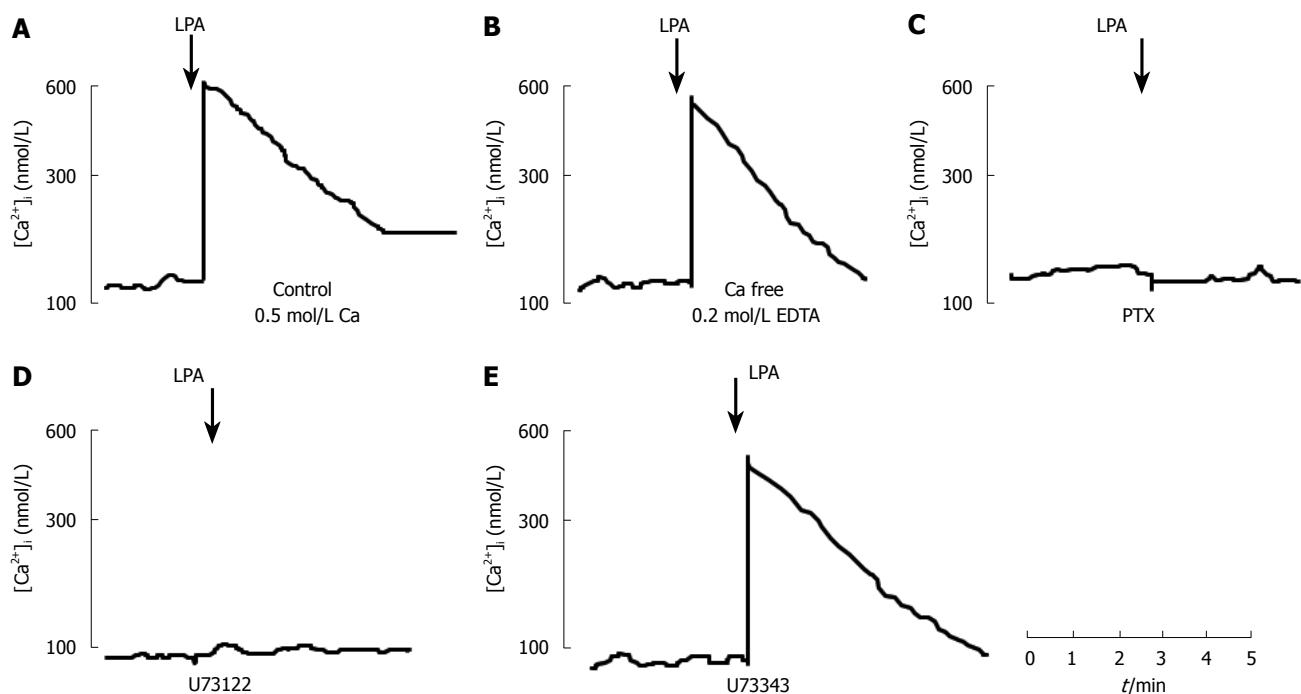

### LPA elevates [Ca<sup>2+</sup>]<sub>i</sub> by mobilizing Ca<sup>2+</sup> from intracellular stores

LPA, at concentration of 10  $\mu$ mol/L, elevated [Ca<sup>2+</sup>]<sub>i</sub> by  $600 \pm 45$  nmol/L ( $n = 5$ ) above a resting [Ca<sup>2+</sup>]<sub>i</sub> of  $108 \pm 30$  nmol/L within 20 s of addition to intact fura2-loaded Panc-1 cell suspension (Figure 2A). This increase in [Ca<sup>2+</sup>]<sub>i</sub> was followed by a return to near resting levels within 3 min. The elevation of [Ca<sup>2+</sup>]<sub>i</sub> by LPA in Panc-1 cells was concentration-dependent, with an EC<sub>50</sub> of 870 nmol/L (Figure 3). Responses to LPA were dependent upon the presence of fatty acid-free BSA (0.1% w/v), without which [Ca<sup>2+</sup>]<sub>i</sub> increases were a quarter-maximal. Fatty acid-free BSA itself did not cause a significant increase in [Ca<sup>2+</sup>]<sub>i</sub> for 30 min (data not shown), as other researchers previously reported<sup>[4]</sup>. LPA-induced elevation of [Ca<sup>2+</sup>]<sub>i</sub> resulted predominantly from mobilization of intracellular [Ca<sup>2+</sup>]<sub>i</sub> store. In the condition of Ca<sup>2+</sup>-free with 0.2 mmol/L EDTA, LPA increased [Ca<sup>2+</sup>]<sub>i</sub> with a similar potency and maximal effect to the condition with extracellular Ca<sup>2+</sup> (Figure 2B). After overnight treatment with PTX (100 ng/mL), LPA did not evoke [Ca<sup>2+</sup>]<sub>i</sub> in Panc-1 cells (Figures 2C and 3). Treatment of Panc-1 cells with a phospholipase C inhibitor, U73122, at a concentration of 10  $\mu$ mol/L for 10 min, abolished LPA-induced increase in [Ca<sup>2+</sup>]<sub>i</sub> (Figure 2D and 3). Pretreated with U73343, an inactive analogue of U73122, at a concentration of 10  $\mu$ mol/L for 10 min had no effect on LPA-induced elevation of [Ca<sup>2+</sup>]<sub>i</sub> in Panc-1 cells (Figure 2E). These findings suggest that LPA induces elevation of [Ca<sup>2+</sup>]<sub>i</sub> by mobilizing Ca<sup>2+</sup> from Ca<sup>2+</sup> store through PTX-sensitive G-protein (Gi or Go) and phospholipase C. Treatment of Panc-1 cells with thapsigargin, the endoplasmic-reticulum Ca<sup>2+</sup>-ATPase pump inhibitor, at a concentration of 500 nmol/L caused a slow increase in [Ca<sup>2+</sup>]<sub>i</sub> followed by a sustained plateau (data not shown).

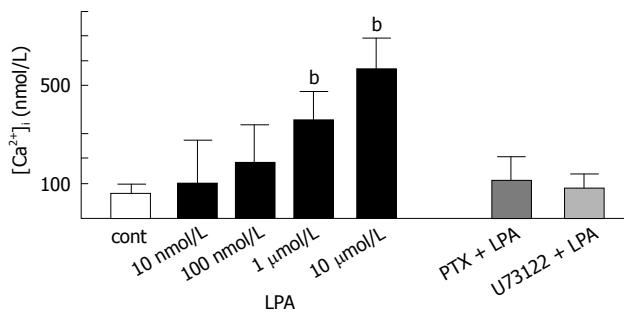

### Effect of LPA on translocation of NF- $\kappa$ B to nuclei in Panc-1 cells

It has been reported that LPA activates NF- $\kappa$ B in fibroblasts<sup>[19]</sup> and endothelial cells<sup>[20]</sup>. We, therefore, investigated the possibility that LPA activates the transcription factor NF- $\kappa$ B in Panc-1 cells.

NF- $\kappa$ B is normally retained in the cytosol in an inactive form in Panc-1 cells (Figure 4A). LPA, at a

**Figure 2** Effect of LPA on cytosolic free calcium concentration  $[Ca^{2+}]_i$  in Panc-1 cells. **A:** Representative  $Ca^{2+}$  signal was evoked by 10  $\mu\text{mol/L}$  LPA in Panc-1 cells; **B:** Effect of chelation of extracellular  $Ca^{2+}$  by addition of 0.2 mmol/L EDTA on LPA-induced increases in  $Ca^{2+}$ ; **C:** PTX-sensitive effect of LPA on cytosolic free calcium. Panc-1 cells were pretreated with 100 ng/ml of PTX for overnight and loaded with fura-2/AM; **D:** Effect of U73122, a phospholipase C inhibitor, on LPA-induced increases in cytosolic free calcium in Panc-1 cells. Panc-1 cells were treated with U73122 at a concentration of 10  $\mu\text{mol/L}$  for 10 min, and then stimulated by 10  $\mu\text{mol/L}$  LPA; **E:** Effect of U73343, an inactive analogue of U73122, on LPA-evoked increases in cytosolic free calcium in Panc-1 cells.

**Figure 3** Effect of LPA on cytosolic free calcium in Panc-1. LPA evoked cytosolic free calcium in concentration-dependent manner. PTX-treatment at a concentration of 100 ng/ml for overnight abolished 10  $\mu\text{mol/L}$  LPA-induced mobilization of  $[Ca^{2+}]_i$ . Pretreatment of U73122 (10  $\mu\text{mol/L}$ ) for 10 min also abolished LPA-induced mobilization of  $[Ca^{2+}]_i$ . <sup>b</sup> $P < 0.01$ .

concentration of 10  $\mu\text{mol/L}$ , translocated NF- $\kappa$ B to the nucleus within 30 min (Figure 4B). NF- $\kappa$ B was re-established in the cytosol after 3 h (data not shown).

After Panc-1 cells were preincubate with 100 ng/ml PTX, LPA did not translocate NF- $\kappa$ B to nuclei (Figure 5A). A phospholipase C inhibitor, U73122, also abolished the translocation induced by LPA (Figure 5B). Pretreatment of Panc-1 with BAPTA-AM, an intracellular calcium chelator, at a concentration of 10  $\mu\text{mol/L}$  for 15 min, completely abolished NF- $\kappa$ B translocation (Figure 5C). Thapsigargin is known to block a  $Ca^{2+}$ -ATP pump of calcium stores, and elevates cytosolic free calcium slowly. In the present study, thapsigargin alone caused NF- $\kappa$ B translocation in Panc-1 cells at a concentration of 500 nmol/L (Figure 5D). These data suggest that elevation of

cytosolic free calcium is necessary for activation of NF- $\kappa$ B in Panc-1 cells.

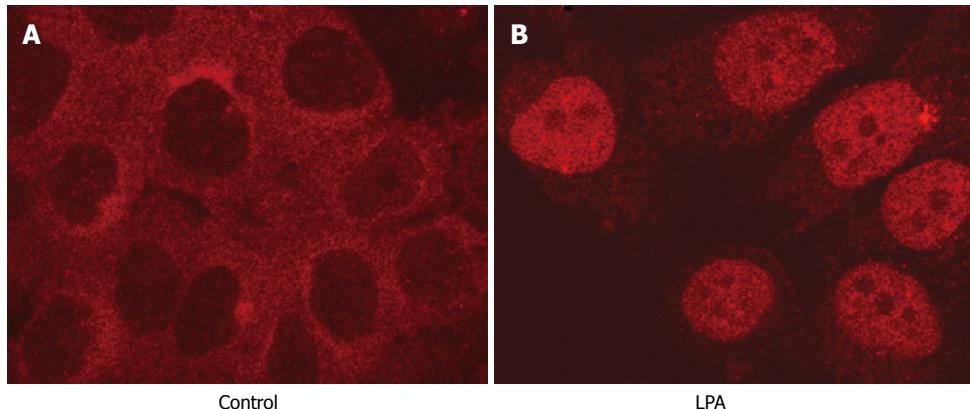

Phorbol myristate, which is well known to be a potent activator of protein kinase C, alone failed to induce the translocation at a concentration of 100 nmol/L (Figure 5E). On the other hand, staurosporine, a protein kinase C inhibitor, attenuated translocation of NF- $\kappa$ B induced by LPA (Figure 5F). These findings suggested that protein kinase C is activated endogenously in cancer cells, such as Panc-1, and that protein kinase C is essential for activating NF- $\kappa$ B with cytosolic calcium. It is reported that PMA could activate NF- $\kappa$ B in some types of cells including rat pancreatic acinar cells. However, the present data revealed that cytosolic calcium might have a more crucial role in activating NF- $\kappa$ B than protein kinase C in Panc-1 cells.

A tyrosine kinase inhibitor genistein or a MEK inhibitor PD98059 did not have significant effects on the translocation of NF- $\kappa$ B induced by LPA (data not shown).

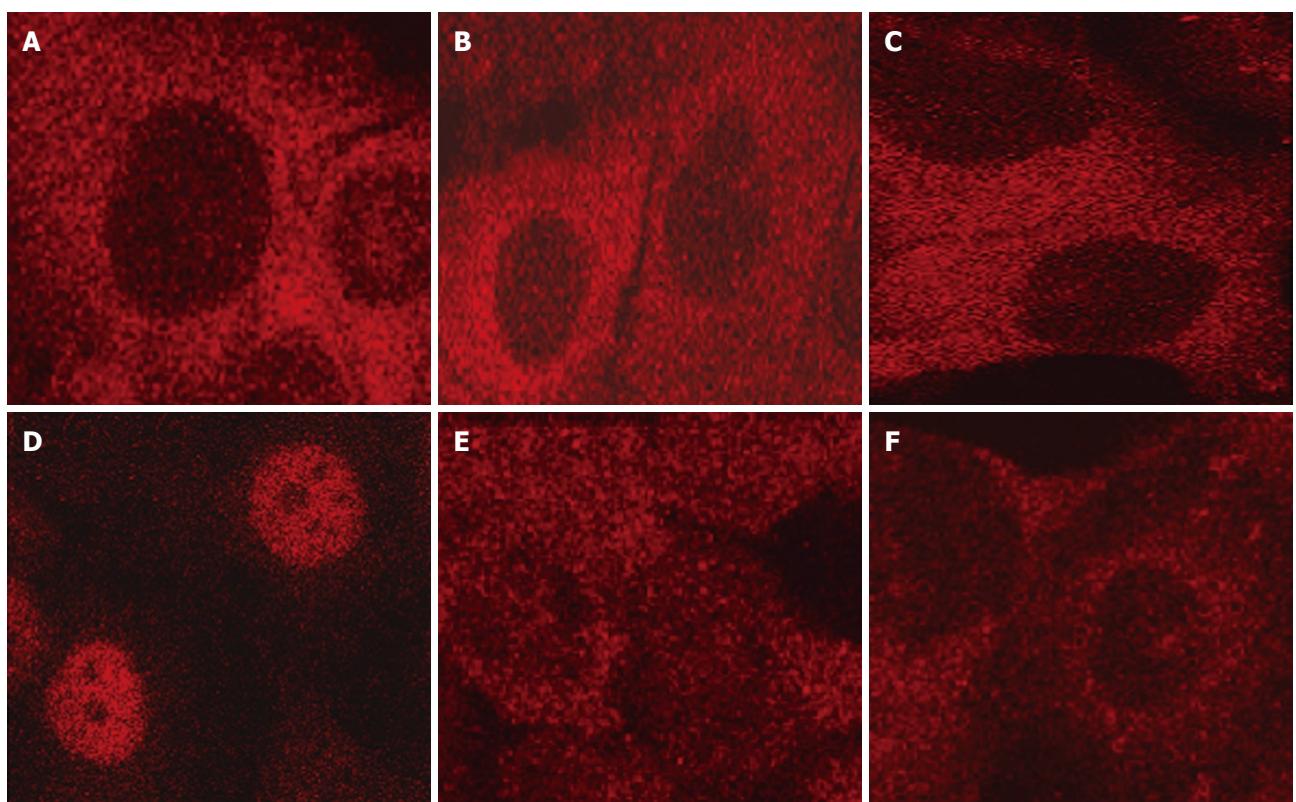

## DISCUSSION

In the present study, we first confirmed that Panc-1 cells express LPA receptors, and then showed that LPA induced  $Ca^{2+}$  mobilization and translocation of NF- $\kappa$ B into the nucleus.

LPA acts as an intercellular messenger molecule bound to serum albumin<sup>[3]</sup>. LPA exerts multiple biological functions through G protein-coupled receptors. It has been identified a new family of

**Figure 4** Effect of LPA on nuclear translocation of NF-κB. LPA-induced nuclear translocation of p65 in Panc-1 cells. Localization of p65 was visualized by indirect immunofluorescence staining using rabbit anti-p65 polyclonal antibodies (1:50) which only recognized NF-κB p65. Donkey anti-rabbit antibodies (1:100) conjugated to rhodamine was performed, and visualized under a confocal microscope. **A:** Cytosolic localization of p65 in an inactive form in unstimulated Panc-1 cells; **B:** Nuclear localization of p65 in Panc-1 cells after treatment of 10  $\mu$ mol/L LPA was observed at 60 min.

**Figure 5** Localization of NF-κB p65 in Panc-1 cells. **A:** PTX-treatment prevented nuclear translocation of NF-κB p65 induced by LPA in Panc-1 cells at 1 h. Panc-1 cells were preincubated with 100 ng/mL PTX, and then stimulated with 10  $\mu$ mol/L LPA; **B:** U73122-treatment prevented nuclear translocation of NF-κB p65 induced by LPA in Panc-1 cells at 1 h. Panc-1 cells were pretreated with 10  $\mu$ mol/L U73122 for 10 min before adding 10  $\mu$ mol/L LPA; **C:** Nuclear translocation of p65 induced by LPA was reduced by an intracellular calcium chelator, BPTA-AM at 1 h. Panc-1 cells were treated with 10  $\mu$ mol/L BAPTA-AM for 15 min and then stimulated with 10  $\mu$ mol/L LPA; **D:** Thapsigargin alone caused nuclear translocation of p65 at 1 h. Panc-1 cells were treated with 500 nmol/L thapsigargin; **E:** Phorbol myristate (PMA) alone failed to mobilize p65 into nuclei at 1 h. Panc-1 cells were treated with 100 nmol/L PMA; **F:** Staurosporine reduced nuclear localization of p65 induced by LPA at 1 h. Panc-1 cells were treated with 10 nmol/L staurosporine for 10 min and then stimulated with 10  $\mu$ mol/L LPA.

receptor genes for LPA. Members of this family include at least three G-protein-coupled receptors belonging to the endothelial differentiation gene (Edg) family, Edg-2/LP<sub>A1</sub>, Edg-4/LP<sub>A2</sub>, and Edg-7/LP<sub>A3</sub><sup>[10]</sup>. Recent investigation has revealed that Panc-1 cells also express functionally active LPA receptors (LP<sub>A1</sub>/Edg-2, LP<sub>A2</sub>/Edg-4, LP<sub>A3</sub>/Edg-7)<sup>[21]</sup>. LPA has a major

role in migration of Panc-1 cells via phosphorylation of ERK<sup>[21]</sup>, but was reported to not act as mitogen in pancreatic cancer cell lines, Panc-1 cells and Bx-PC cells<sup>[21]</sup>. LPA also mobilized cytosolic calcium in Panc-1 cells as neuropeptides including neuropeptidin, bombesin, cholecystokinin, and vasopressin<sup>[22]</sup>. However, it is still unclear of roles of calcium mobilization in Panc-1 cells.

Some researchers have tried to identify which subtype of LPA receptors is crucial for calcium mobilization. An investigation using human-recombinant G protein has suggested that LP<sub>A1</sub>/EDG-2 transduces Ca<sup>2+</sup> mobilization largely through PTX sensitive G<sub>i/o</sub> proteins<sup>[18]</sup>. LP<sub>A2</sub>/Edg-4 was supposed to be linked with G<sub>q</sub> and phospholipase C<sup>[18]</sup> and cooperated with other G proteins<sup>[19]</sup>. Another study, using a knock-out technique, revealed that nearly all PLC activation in response to LPA is dependent on endogenous expression of LP<sub>A1</sub> and LP<sub>A2</sub><sup>[20]</sup>.

The results presented in this paper show that PTX and U73122 attenuated LPA-induced calcium mobilization in Panc-1 cells, which suggests that LPA evokes cytosolic calcium via PTX-sensitive G protein and inositol phosphate production. We have not yet determined which subtypes of LPA receptors have a major role in mobilizing cytosolic calcium in Panc-1 cells. It is likely that LP<sub>A1</sub> or LP<sub>A2</sub> might have a major role in mobilization of cytosolic calcium in Panc-1 cells.

The present data suggests that LPA-induced cytosolic calcium mobilization is necessary for activation of NF-κB. PTX and U73122 attenuated both cytosolic calcium mobilization and nuclear translocation of NF-κB induced by LPA. Thapsigargin exerted more potent and long lasting actions than those achieved by LPA. PMA alone failed to stimulate the nuclear translocation of NF-κB. This result suggests that evoked cytosolic calcium concentration is crucial for this translocation, and that a resting level of cytosolic calcium might be insufficient for activation of NF-κB by phorbol ester-stimulated protein kinase C.

Activation of NF-κB by LPA may function as a counterpart to proliferative signaling. It is well known that activation of NF-κB is related to resistance to apoptosis. Recent studies have revealed that chemosensitivity of human pancreatic cancer cells, including Panc-1, is enhanced by I-κBα super-repressor<sup>[23]</sup> and that NF-κB has a major role in tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) resistance of pancreatic cancer cell lines<sup>[24]</sup>.

LPA is supposed to utilize G proteins to achieve its activation of NF-κB. The fact that PTX attenuates activation of NF-κB would suggest a role for G<sub>i/o</sub>. NF-κB can be activated by oncogenic Ras<sup>[25]</sup>, and both Ras and ERKs are activated by LPA through pathways partly sensitive to PTX<sup>[20]</sup>. Cummings *et al* has shown that protein kinase C is also related with activation of NF-κB, which was coupled to G<sub>i/o</sub> and G<sub>12/13</sub> proteins<sup>[25]</sup>.

G<sub>i/o</sub> might have a major role in the activation of NF-κB<sup>[25]</sup>. It is conceivable that low concentrations of LPA activates G<sub>i/o</sub> and that higher concentrations activates G<sub>q</sub>. G<sub>q</sub> protein may be responsible for the activation of protein kinase C and mobilization of Ca<sup>2+</sup> of sufficient magnitude or duration to bring, together with signals from G<sub>i/o</sub>, activation of NF-κB<sup>[26]</sup>.

In conclusion, our results show for the first time that LPA induces nuclear translocation of NF-κB in Panc-1 cells by mobilizing cytosolic free calcium. This effect might be caused by activation of phospholipase C via PTX-sensitive G protein.

## ACKNOWLEDGMENTS

The authors thank Mr. SE Rife and Mr. H Matsuo for their contribution to this article.

## COMMENTS

### Background

Lysophosphatidic acid (LPA) is a growth factor that exerts a number of biological actions on some cancer cell lines. However, the effect of LPA on pancreatic cancer cells has not been well estimated. In the present study, the authors investigate the effects of LPA on cytosolic calcium and translocation of NF-κB in Panc-1 cells.

### Research frontiers

The article focuses on the relationship of cytosolic calcium mobilization and NF-κB in Panc-1 cells induced by LPA.

### Innovations and breakthroughs

The present study shows that LPA-induced cytosolic calcium mobilization is necessary for activation of NF-κB in pancreatic cancer cells, and that a resting level of cytosolic calcium might be insufficient for activation of NF-κB by phorbol ester-stimulated protein kinase C. It is suggested that protein kinase C is activated endogenously in Panc-1, and protein kinase C is essential for activating NF-κB with cytosolic calcium and that LPA induces the nuclear translocation of NF-κB in Panc-1 by mobilizing cytosolic free calcium.

### Applications

It is known that LPA represents a major bioactive constituent of serum, and that activation of NF-κB is related to resistance to apoptosis. By knowing the mechanism of action of LPA, it can be used that target apoptosis in pancreatic cancer cells.

### Peer review

The authors investigated the effect of LPA on calcium mobilization, and localization of the transcription factor, NF-κB in the pancreatic cell line, Panc-1. This is an interesting paper. They demonstrated that LPA stimulates calcium mobilization from intracellular stores via PTX sensitive G proteins and PLC.

Comparison of esophageal capsule endoscopy and esophagogastroduodenoscopy for diagnosis of esophageal varices. *World J Gastroenterol* 2008; 14(28): 4480-4485 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4480.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4480>

## Abstract

**AIM:** To investigate the utility of esophageal capsule endoscopy in the diagnosis and grading of esophageal varices.

**METHODS:** Cirrhotic patients who were undergoing esophagogastroduodenoscopy (EGD) for variceal screening or surveillance underwent capsule endoscopy. Two separate blinded investigators read each capsule endoscopy for the following results: variceal grade, need for treatment with variceal banding or prophylaxis with beta-blocker therapy, degree of portal hypertensive gastropathy, and gastric varices.

**RESULTS:** Fifty patients underwent both capsule and EGD. Forty-eight patients had both procedures on the same day, and 2 patients had capsule endoscopy within 72 h of EGD. The accuracy of capsule endoscopy to decide on the need for prophylaxis was 74%, with sensitivity of 63% and specificity of 82%. Inter-rater agreement was moderate ( $\kappa = 0.56$ ). Agreement between EGD and capsule endoscopy on grade of varices was 0.53 (moderate). Inter-rater reliability was good ( $\kappa = 0.77$ ). In diagnosis of portal hypertensive gastropathy, accuracy was 57%, with sensitivity of 96% and specificity of 17%. Two patients had gastric varices seen on EGD, one of which was seen on capsule endoscopy. There were no complications from capsule endoscopy.

## INTRODUCTION

Cirrhosis affects 3.6 out of every 1000 adults in North America. A major cause of cirrhosis-related morbidity and mortality is the development of variceal hemorrhage, a direct consequence of portal hypertension. The reported prevalence of esophageal varices in patients with chronic liver disease varies from 24% to 81%<sup>[1-3]</sup>. Variceal hemorrhage occurs in 25%-40% of patients with cirrhosis, and is associated with a mortality rate of up to 30%<sup>[1,2]</sup>. Accurate identification of patients with an increased risk of bleeding allows for primary prophylaxis to prevent variceal bleeding. Prophylactic use of beta-blockers has been shown to decrease the incidence of first variceal bleeding and death in patients with cirrhosis, and is currently the standard of care in patients who are at high risk for variceal hemorrhage<sup>[4,5]</sup>. Factors predictive of variceal hemorrhage include location of varices, size of varices, appearance of varices, clinical features of the patient, and variceal pressure<sup>[6]</sup>.

Esophagogastroduodenoscopy (EGD) is the standard of care for evaluation of varices. An EGD is currently recommended at diagnosis of cirrhosis, and

then yearly screening for patients with no varices on initial EGD for patients with progression of their liver disease or every two years for those who remain stable<sup>[5]</sup>. In patients with small varices, endoscopy should be performed every year to assess for a change in size<sup>[7]</sup>.

Currently, there is no universally accepted grading system for varices. Reliability of endoscopy is affected by inter-observer variability<sup>[8,9]</sup>. The subjective grading, invasiveness, risks of sedation, and cost of EGD has prompted a search for other alternatives. As of yet, no alternative had proven to be as accurate as EGD.

Several pilot studies have been published comparing capsule endoscopy (CE) to EGD for variceal screening. Eisen *et al* studied 32 patients, and found an overall concordance rate of 96.9% for the diagnosis of esophageal varices and 90.6% for the diagnosis of portal hypertensive gastropathy<sup>[10]</sup>. Lapalus *et al* performed unsedated EGD and capsule endoscopy in 21 patients, with an accuracy of 84.2% for the presence or absence of esophageal varices<sup>[11]</sup>.

Herein, we report the results of a study designed to assess the ability of capsule endoscopy to correctly identify the presence of esophageal varices and related features of portal hypertension in patients undergoing screening or surveillance endoscopy, and to determine the need for treatment or prophylaxis of esophageal varices.

## MATERIALS AND METHODS

All patients enrolled were from the patient population of Scripps Clinic, La Jolla, California. Patients were eligible if they were scheduled to undergo EGD for screening or surveillance of esophageal varices. Screening was performed in patients with either biopsy-proven cirrhosis, or biochemical and imaging studies consistent with cirrhosis. Surveillance was performed in patients who had previously been diagnosed with esophageal varices *via* EGD and were repeating the test to assess for progression of varices. Patients who had previously undergone banding of esophageal varices were included in the study if they were stable and had not had a variceal hemorrhage for  $\geq 6$  mo. Consecutive patients scheduled for EGD as screening or surveillance of esophageal varices were screened for eligibility to participate. All patients were age  $> 18$  years, able to give informed consent, and hemodynamically stable.

Exclusion criteria included dysphagia, known Zenker's diverticulum, the presence of cardiac pacemaker or other implantable electro-medical devices, pregnancy, or a scheduled MRI within 7 d after capsule ingestion. Patients also were excluded if they had a history of or risk for intestinal obstruction, including any prior abdominal surgery of the gastrointestinal tract other than uncomplicated cholecystectomy or appendectomy.

All patients who consented underwent capsule endoscopy and EGD on the same day or within 72 h. The endoscopies were performed under moderate sedation by three staff hepatologists at Scripps Clinic. The hepatologists were blinded to the results of the capsule endoscopy, but not to the patient's prior history or

previous endoscopy findings. Photographs were taken of any pertinent findings at endoscopy and grading of varices was agreed to by all three physicians after unblinding.

EGDs and CEs were both graded by the following scale: F0, no varices; F1, small straight varices; F2, tortuous varices and  $< 50\%$  of esophageal radius; F3, large and tortuous varices with or without red spots<sup>[6,12]</sup>. Presence or absence of high risk stigmata, defined as neovascularization or red or white spots was noted separately. Each observer decided whether or not treatment was indicated based on presence of F2 or F3 varices or the presence of high risk stigmata on any size varix. Portal hypertensive gastropathy (PHG) was graded on the following scale: none, mild (mucosal mosaic pattern), moderate (mosaic mucosal pattern with occasional red spots), or severe (mosaic mucosal pattern, extensive red or black spots, active oozing)<sup>[13,14]</sup>. Portal hypertensive gastropathy was diagnosed on capsule endoscopy *via* photographs of any area of the gastric mucosa as it was not possible to assess the location of the visualized area. The presence or absence of gastric varices was noted separately, as well as other findings unrelated to portal hypertension such as esophagitis, gastritis (defined as erythema or erosions of gastric lining), peptic ulcer disease, or duodenal lesions.

Capsule endoscopy was administered in the following manner in all patients. After imbibing 100 mL of water with 0.6 mL of simethicone, patients lay supine and then ingested the pill with 5 mL of water without raising their head. Any difficulty with ingestion was recorded by the administrator, and patients were instructed not to speak after pill ingestion. After 2 min supine, they were raised to a 30 degree incline. After another 2 min they were raised to 60 degrees, and after 1 min at 60 degrees the patient imbibed a sip of water. They then sat up completely and imbibed another sip of water, at which time they were placed in the left lateral decubitus position in order to improve visualization of the fundus. Three minutes after being placed on their left side the patients were instructed to sit up or walk around for the remaining 12 min of the examination.

Capsule endoscopies were read by two separate investigators, who were blinded to EGD findings, patient medical history, and reading of the other investigator. Both capsule readers had prior experience in endoscopic evaluation and diagnosis of esophageal varices. Prior to the study, both readers underwent training as recommended by the capsule manufacturer, consisting of review of a CD Rom and participation in an online course, which included review of 10 cases of capsule endoscopy. Each CE was read twice by each investigator on two separate occasions at least 60 d apart. Capsule images were evaluated for the presence and grade of esophageal varices, the presence and grade of PHG, the presence of gastric varices, and any other findings. Esophageal transit time and time spent reading each examination was recorded.

One week after capsule ingestion, each patient was contacted by telephone to assess for symptoms of capsule retention. At that time, patient satisfaction was

assessed. Patients were asked if they would be willing to undergo CE or EGD again, and which study they preferred.

Statistical analysis was performed to assess sensitivity, specificity, and accuracy of CE versus EGD in determining need for prophylaxis or treatment. A weighted kappa scale was used to determine agreement of variceal grade by CE compared to EGD, as well as inter- and intra-observer agreement<sup>[14-17]</sup>. Inter-observer agreement was defined as comparing results from Reader 1 to results from Reader 2. Intra-observer agreement measured results from the first read and results from the second read of each reader independent of the other reader. The sample size of 50 was chosen because with these numbers one typically will expect a standard deviation of 0.10 and coefficients of variation of 15% or less.

The study was approved by the local institutional review board.

## RESULTS

Fifty-five patients were screened to participate in the study. Five patients were not included: 2 patients refused, 1 patient had a history of an esophageal stricture, and 2 patients had history of surgery on the gastrointestinal tract. Fifty patients successfully underwent EGD and esophageal capsule endoscopy. In most cases, patients underwent CE on the same day as and just prior to EGD. There were two patients who underwent CE on a different day but within 72 h and two patients who underwent CE immediately after EGD. Median esophageal transit time was 249.5 s (range, 1-352 s). The esophageal transit times were as follows: 2 capsules 0-5 s, 15 capsules 5-60 s, and 33 capsules 60-352 s. Five patients (10%) had a mild amount of difficulty swallowing the capsule, and four patients (8%) had a moderate amount of difficulty, one of whom had to swallow it in a sitting position.

**Figure 1** Sensitivity, specificity and accuracy of esophageal capsule endoscopy compared to EGD for two separate blinded investigators. The error bars represent 95% confidence intervals.

Demographics of the patients can be seen in Table 1. Thirteen patients (26%) were undergoing surveillance of varices and had a history of previous variceal banding; the remainder were undergoing screening examinations. The patients who were undergoing surveillance had not been banded for at least 6 mo, and previously had been obliterated. All patients had undergone banding in the past for history of variceal bleeding. Based on EGD findings, prevalence of esophageal varices was 66%: 17 patients had no varices, 16 patients with F1 varices, 15 patients with F2 varices, and 2 patients with F3 varices. 5 patients underwent banding at the time of EGD.

In determining need for prophylaxis using EGD as the gold standard, sensitivity of CE was 63% (95% CI, 0.40-0.83; SD, 0.04), specificity was 82% (95% CI, 0.63-0.94; SD, 0.03), and accuracy was 74% (95% CI, 0.59-0.85; SD 0.04; Figure 1). The accuracy was not improved when patients with prior banding were excluded or when patients with difficulty swallowing the capsule were excluded. Positive predictive value in this population was 73% (95% CI, 0.48-0.91; SD, 0.04) and negative predictive value was 74% (95% CI, 0.55-0.88; SD, 0.04). There was no association between time of esophageal transit of the capsule and accuracy of the results, assessed by splitting the group at the median time of 249 s and comparing the two groups. Inter-rater reliability for need for prophylaxis was 0.56 (moderate agreement). Intra-rater reliability was 0.61 (good) for Reader 1 and 0.41 (moderate) for Reader 2. For grade of varices, agreement between EGD and CE was 0.53 (moderate). Inter-rater reliability for grade of varices was 0.77 (good), and intra-rater reliability was 0.76 (good) for Reader 1 and 0.69 for Reader 2.

Two patients (4%) had gastric varices. One of these patients had gastric varices suspected on CE by Reader 2, and neither of the patients had large esophageal varices requiring primary prophylaxis. It was not possible to gauge the location of the varices based on the capsule photographs.

Forty-five patients (90%) had portal hypertensive gastropathy: 28 patients with mild disease and 17 patients with moderate disease. In determining the presence or absence of PHG, sensitivity was 96% (95% CI, 0.78-0.99) and specificity was 17% (95% CI, 0.05-0.39). Accuracy was 57% (95% CI, 0.41-0.71). Inter-rater reliability for presence of PHG was 0.61 (good).

Seventeen patients (34%) had other findings seen on

EGD. Seven patients had gastritis seen on EGD, two of which were detected by CE. Two patients had Barrett's esophagus; one was detected by Reader 1 and one was detected by Reader 2. Two patients had esophagitis seen on EGD but not on CE. One patient had gastric polyps and one had duodenal polyps seen on EGD, and neither was detected on CE. One patient had an esophageal ring seen on EGD that was also detected on CE by Reader 2. One patient had scarring from prior banding that was seen on EGD but not CE. 11 patients underwent biopsy at time of EGD: 10 to rule out *H pylori* and one for diagnosis of Barrett's esophagus.

There were no complications from either CE or EGD. Thirty-six patients (72%) were satisfied equally with EGD and CE. Thirteen (26%) preferred CE to EGD, and one patient preferred EGD to CE. There were no instances of capsule retention.

## DISCUSSION

Complications of portal hypertension remain one of the major causes of morbidity and mortality in patients with cirrhosis. Up to 33% of cirrhotics will experience bleeding from varices, and 70% of these will be plagued with recurrent variceal bleeding<sup>[1,2,6]</sup>. In 1998, an AASLD single-topic symposium on portal hypertension devised the following current recommendations for variceal screening: EGD at time of diagnosis of cirrhosis, and if no varices were present, on a biyearly basis if liver function is stable, or yearly if liver function worsens, and yearly if small varices were present on initial screening<sup>[7]</sup>. Numerous studies have demonstrated the efficacy of beta-blocker therapy for reduction of risk of variceal bleeding and related mortality, decreasing the risk of variceal bleeding by 50%<sup>[18-20]</sup>. Recent data have suggested that variceal banding is also effective as primary prevention of variceal bleeding in patients with high risk varices<sup>[18-21]</sup>. Despite these recommendations, compliance with screening has been quite poor. Arguedas *et al* in 2001 reported that just 46% of cirrhotic patients underwent variceal screening by EGD prior to referral for liver transplantation, despite having a diagnosis of cirrhosis for a median duration of 3 years<sup>[22]</sup>. Results of a survey of practicing gastroenterologists suggested an even lower screening rate of 39%<sup>[23]</sup>.

Alternative methods to EGD have been studied for variceal screening, including transnasal endoluminal ultrasound<sup>[24]</sup>, platelet count/spleen diameter ratio<sup>[25]</sup>, multidetector computed tomography esophagography<sup>[26]</sup>, and esophageal capsule endoscopy<sup>[10,11,27]</sup>. To date, no method has proven accurate enough to replace EGD.

The results of our study are different from the two published pilot studies, showing a lower sensitivity, specificity, and accuracy for esophageal capsule endoscopy. Because there is known variability in grading of varices by EGD<sup>[8,9]</sup>, the accuracy of capsule endoscopy when measured against EGD may be wrong. We attempted to decrease this effect by verification of variceal grade diagnosed at endoscopy after unblinding by all physicians involved in the study, through

inspection of photographs. Other possible reasons that our study results may vary include the small size of prior studies compared to ours. Our trial size was still somewhat small, but we balanced that expectation with the recognition that a much larger trial would be needed for confirmation of this as a pilot trial. Other confounders for the data could include the absence of complete industry funding in our study as opposed to the prior ones, and our relative lack of expertise with capsule endoscopy or other technical difficulties.

Concern has been raised regarding the utility of capsule endoscopy in patients who have previously undergone banding of esophageal varices. Patients were included in our study if they had not undergone banding for at least 6 mo. We chose to include these patients because we felt that varices would still be able to be diagnosed at esophageal capsule endoscopy. When patients with previous banding were excluded from analysis, our accuracy did not improve significantly. A total of 5 patients out of 13 who were undergoing surveillance for esophageal varices required repeat banding at the time of EGD. This underscores a limitation of capsule endoscopy: that patients with varices seen at diagnosis may then have to undergo EGD for therapy.

There has been some concern about the mixed results of capsule endoscopy use for evaluation of esophageal pathology, such as varices, Barrett's esophagus, or esophagitis<sup>[27-29]</sup>. It is thought that the mixed results of capsule endoscopy may have to do with deviations from the standard ingestion procedure recommended by the manufacturer<sup>[30]</sup>. We note that in our study, all patients were able to successfully swallow the capsule, with only 9 patients having some difficulty, including two patients that needed to lift their heads from the supine position and one patient that had to ingest the pill in the sitting position. We feel that there is little chance these deviations influenced our results. When we looked at patient history of banding, time of esophageal transit, and reader experience/learning curve, none of these factors significantly changed the results of our study. We, therefore, feel that the accuracy reported here may be more reflective of what can be expected with capsule endoscopy use in community gastroenterology practice.

Esophageal capsule endoscopy has been designed specifically to look at the esophagus; there is no way to ensure that full inspection of the gastric mucosa and duodenum will occur, as it would with EGD. When screening for varices, this usually is not an issue. However, as in our study, there are patients who have gastric varices in the absence of significant esophageal varices that would require pharmacologic prophylaxis against bleeding. These patients may be missed if screening was done solely with capsule endoscopy. In addition, capsule endoscopy had poor accuracy for diagnosis of portal hypertensive gastropathy. Capsule endoscopy limits the patient to diagnosis only. In 11 of our patients, biopsies were performed for diagnosis of *H pylori* or Barrett's esophagus. Obviously, these biopsies would not have been able to be performed if capsule endoscopy was the only diagnostic method used.

Given our results for capsule endoscopy, we are uncertain if its routine use can replace EGD at this time as a screening tool. It may be useful for those patients who are unable or unwilling to undergo upper endoscopy, but clinicians need to be cognizant of the possibility of a false negative result. At this time, we would recommend use of esophageal capsule endoscopy only in the setting of a clinical trial.

In conclusion, we feel that capsule endoscopy has a limited role in deciding which patients would benefit from EGD with banding or beta-blocker therapy in early cirrhosis, as well as for determining the specific grade of esophageal varices, PHG, or gastric varices. More data is needed to assess accuracy for staging esophageal varices, PHG, and the detection of gastric varices. Clinicians who choose to employ capsule endoscopy as part of their routine clinical practice should be cognizant of the lower accuracy for esophageal variceal screening.

## COMMENTS

### Background

Esophageal varices are found in up to 81% of patient with cirrhosis, and results in significant gastrointestinal bleeding in up to half of patients. In order to prevent variceal bleeding, screening is recommended with upper endoscopy every 1-3 years, with prophylaxis given to those patients with large varices. Esophageal capsule endoscopy is a new device designed to image the esophagus in a noninvasive way. The utility of esophageal capsule endoscopy in the diagnosis of esophageal varices is not known.

### Research frontiers

To date, two pilot studies have been published regarding the use of esophageal capsule endoscopy for the diagnosis of esophageal varices. These initial studies were performed in 32 and 21 patients, respectively, and showed high concordance and accuracy for the diagnosis of esophageal varices with capsule endoscopy (96.9% and 84.2%, respectively).

### Innovations and breakthroughs

In this publication, 50 patients underwent upper endoscopy and esophageal capsule endoscopy. The capsule endoscopies were independently read by two blinded investigators. The accuracy of capsule endoscopy for diagnosis of esophageal varices was found to be 74% in determining the need for prophylaxis based on the presence of large varices. The sensitivity was 63% and the specificity was 82%. Inter-rater reliability was moderate for determining the need for prophylaxis. Intra-rater reliability was moderate for one reader and good for the other reader. 34% of patients studied had other findings seen at upper endoscopy that were not reliably diagnosed with capsule endoscopy, including gastric varices, gastric and duodenal polyps, esophagitis, and Barrett's esophagus. Accuracy for diagnosis of portal hypertensive gastropathy was poor at only 57%.

### Applications

Currently, the use of capsule endoscopy for variceal screening cannot be routinely recommended. Refinements to the capsule procedure may improve the accuracy in the future. Further studies are needed to verify these results.

### Peer review

This paper details the use of esophageal capsule endoscopy for the diagnosis of esophageal varices. Two pilots studies suggested that capsule endoscopy may be useful for detection of large varices. In this largest cohort to date, we found that capsule endoscopy has a poor sensitivity in detecting large varices requiring prophylactic therapy. In addition, there is also poor inter- and intra-observer agreement when using this method for grading esophageal varices. Finally, since three quarters of all patients do not prefer one method over the other, it appears that capsule endoscopy would have a limited role in diagnosis of esophageal varices.

alcohol are necessary co-factors in its etiology.

**METHODS:** Initially, 115 subjects with pancreatitis and 66 controls were evaluated, of whom 57 patients and 21 controls were predetermined to carry the high-risk *SPINK1* N34S polymorphism. We sequenced *CASR* gene exons 2, 3, 4, 5 and 7, areas containing the majority of reported polymorphisms and novel mutations. Based on the initial results, we added 223 patients and 239 controls to analyze three common nonsynonymous single nucleotide polymorphisms (SNPs) in exon 7 (A986S, R990G, and Q1011E).

**RESULTS:** The *CASR* exon 7 R990G polymorphism was significantly associated with CP (OR, 2.01; 95% CI, 1.12-3.59;  $P = 0.015$ ). The association between *CASR* R990G and CP was stronger in subjects who reported moderate or heavy alcohol consumption (OR, 3.12; 95% CI, 1.14-9.13;  $P = 0.018$ ). There was no association between the various *CASR* genotypes and *SPINK1* N34S in pancreatitis. None of the novel *CASR* polymorphisms reported from Germany and India was detected.

**CONCLUSION:** Our United States-based study confirmed an association of *CASR* and CP and for the first time demonstrated that *CASR* R990G is a significant risk factor for CP. We also conclude that the risk of CP with *CASR* R990G is increased in subjects with moderate to heavy alcohol consumption.

### Abstract

**AIM:** To test the hypothesis that calcium sensing receptor (*CASR*) polymorphisms are associated with chronic pancreatitis (CP), and to determine whether *serine protease inhibitor Kazal 1type* (*SPINK1*) N34S or

## INTRODUCTION

Chronic pancreatitis (CP) is a debilitating, inflammatory disease of the pancreas, characterized by progressive organ destruction and fibrosis. CP results in profound exocrine and endocrine insufficiency and, in many cases, intractable, chronic pain. As a complex disorder, CP can develop from a variety of etiologies with multiple pathological pathways<sup>[1]</sup>. For several years, alcohol abuse has been considered the most likely causative agent for CP in Western countries, although etiologies including toxic, metabolic (hypercalcemia, hyperlipidemia), genetic mutations, autoimmune, and duct obstruction, have also been implicated<sup>[2,3]</sup>.

Consistent experimental evidence links elevated acinar cell calcium levels with acute pancreatitis in association with premature trypsinogen activation to trypsin<sup>[4]</sup>. Recurrent acute pancreatitis (RAP), as illustrated in patients with hereditary and sporadic pancreatitis, can lead to CP<sup>[5-7]</sup>. Hypercalcemia itself has been associated with the development and complications of CP<sup>[2]</sup>. Recent studies from Germany and India have reported that novel *calcium sensing receptor* (*CASR*) gene mutations in combination with the presence of *serine protease inhibitor Kazal 1 type* (*SPINK1*) N34S increased the risk of CP<sup>[8-10]</sup>. The *SPINK1* N34S "high-risk haplotype" is strongly associated with CP, but only a limited portion of mutation carriers develop CP during their life time, suggesting that additional factors are necessary to develop this complex disorder<sup>[11,12]</sup>.

*CASR* is a member of the G-protein-coupled receptor (GPCR) superfamily<sup>[13]</sup>. *CASR* plays an important role in calcium homeostasis, as is reflected in its expression by cells of the parathyroid gland and renal tubules that are involved in calcium metabolism. *CASR* has been identified in both human pancreatic acinar and ductal cells, as well as in various non-exocrine cells<sup>[14]</sup>, although its functional significance in the pancreas has not been determined.

The human *CASR* gene is located on chromosome 3q 13.3-21<sup>[15,16]</sup>. *CASR* possesses a coding region of 3234 base pairs (bp) which is contained within 6 of the seven exons that make up the gene. One hundred and twelve functional mutations (40 activating and 72 inactivating) have been described in the *CASR* mutation database related to familial hypocalciuric hypercalcemia (FHH), neonatal severe primary hyperparathyroidism (NSHPT), and autosomal dominant hypocalcemia (ADH) families as well as in *de-novo* disease<sup>[17]</sup>. In addition, single activating or inactivating *CASR* mutations may cause hypercalcemic or hypocalcemic disorders<sup>[18,19]</sup>.

We hypothesized that *CASR* polymorphisms are associated with the development of CP and that *SPINK1* N34S mutations or alcohol may be important co-factors in its etiology. We tested this hypothesis by evaluating subjects with RAP, CP and healthy controls with known *SPINK1* genotypes and alcohol intake for common and novel *CASR* polymorphisms in exons 2, 3, 4, 5 and 7.

## MATERIALS AND METHODS

### Study population

Subjects were recruited from the North American

Pancreatic Study2 (NAPS2). The NAPS2 study is a multicenter, molecular epidemiology study designed to evaluate the genetic and environmental factors predisposing to recurrent acute pancreatitis (RAP) and CP. Detailed description of methods are presented elsewhere<sup>[20]</sup>. The subjects were stratified into alcohol categories based on self-reported average number of drinks consumed per week during the period of heaviest lifetime drinking. Alcohol categories were defined based on the drinking pattern as: (1) abstainers: no alcohol use or < 20 drinks in lifetime; (2) light drinkers: ≤ 3 drinks/week; (3) moderate drinkers: 4-7 drinks/week for females; 4-14 drinks/week for males; (4) heavy drinkers: 8-34 drinks/week for females; 15-34 drinks/week for males; (5) very heavy drinkers: ≥ 35 drinks/week for both males and females. For analysis, alcohol drinking categories were combined into 3 groups based on their risk for causing CP: (1) abstainers and light drinkers were considered very low risk, (2) moderate and heavy drinkers were considered moderate risk, and (3) very heavy drinkers were considered substantial risk<sup>[20]</sup>.

One hundred and fifteen affected individuals and 66 controls were selected initially from four sites of the NAPS2 cohort. These subjects were selected based on the presence or absence of *SPINK1* N34S mutations, of which 57 patients and 21 controls were determined by previous genetic analysis to carry the high-risk *SPINK1* mutation. From the twenty site NAPS2 consortium, 219 affected subjects and 239 controls were later screened for the three common nonsynonymous single nucleotide polymorphisms (SNPs) seen in the coding region of the intracellular *CASR* tail in exon 7 which appeared to be the region of interest. These were A986S (rs # 1801725), R990G (rs # 1042636), and Q1011E (rs # 1801726).

### DNA preparation and mutation analysis

Genomic DNA was extracted from whole blood as described<sup>[20]</sup>. PCR primers were designed for *CASR* gene exons 2, 3, 4, 5 and 7, which contains most of the commonly seen activating and inactivating mutations as well as the novel mutations found in Germany and India (Table 1). Exons 4 and 7 were lengthy and thus were divided into 2 and 4 fragments respectively.

PCR was performed in a total volume of 25 μL; 200 nmol of forward and reverse primer, 200 μmol of dNTP and 1 × PCR Buffer II (ABI, CA) with 10 ng of DNA. Amplification settings were 95°C for 12 min × 1 cycle, 95°C for 30 s, annealing temperature (Table 1) × 20 s and 72°C × 20 s for 35 cycles and 72°C for 2 min × 1 cycle. Annealing temperatures and magnesium concentrations for different primers are shown in Table 1. PCR amplification products were purified with exonuclease I (NEB, Beverly, MA) and shrimp alkaline phosphatase (Roche Diagnostics, Indianapolis, IN) according to the manufacturer's recommendations. Cycle sequencing was performed using the ABI Prism Big Dye Terminator Sequencing Kit v3.1 diluted 1:8 (ABI, Foster City, CA) using the appropriate PCR primers. Products from the sequencing reaction were purified by ethanol EDTA precipitation. Sequence products were run on

CP: Chronic pancreatitis; RAP: Recurrent acute pancreatitis; SD: Standard deviation. Abstainers: No alcohol use or < 20 drinks in lifetime; Light: < 3 drinks/week; Moderate: 4-7 drinks/week for females, 4-14 drinks/week for males; Heavy: 8-34 drinks/week for females, 15-34 drinks/week for males; Very heavy: > 35 drinks/week.

an ABI Prism 3730 Genetic Analyzer and sequence data were analyzed using Sequencher 4.7 (Gene Codes Corp., Ann Arbor, MI)<sup>[5,21]</sup>.

### Statistical analysis

Genotype frequencies were assessed for Hardy-Weinberg equilibrium. The frequencies of genotypes among cases and controls were compared using Chi square test or the Fisher's exact test when appropriate. Odds ratio (OR) and 95% confidence intervals (95% CI) for genotypes were calculated using an autosomal dominant model. For all statistical comparisons, *P* < 0.05 was considered significant.

## RESULTS

Subject demographics and alcohol drinking patterns are given in Table 2. The proportion of subjects reporting a moderate or heavy alcohol drinking pattern was similar between patients and controls. Of the 334 patients with pancreatitis, 219 (66%) had CP and 115 (34%) had RAP.

The initial study consisted of 115 patients (CP = 82

and RAP = 33) and 66 controls, of which 57 patients (CP = 47 and RAP = 10) and 21 controls carried the *SPINK1* N34S high risk haplotype. Of the 58 patients without *SPINK1* N34S, 35 were diagnosed with CP and 23 had RAP.

The genotype frequencies were found to be in Hardy-Weinberg equilibrium. The R990G polymorphism (AGG → GGG transition) in exon 7 of the *CASR* gene, the G allele was more common among CP patients (*n* = 35) than controls (*n* = 45), but only in subjects without *SPINK1* N34S. In comparing CP patients (*n* = 47) and controls (*n* = 21) with *SPINK1* N34S, there was a non-significant trend towards an increased occurrence of the G allele in patients (OR, 4.03; 95% CI, 0.48-190.8, *P* = 0.255). One limitation of this study was the small number of *SPINK1* N34S subjects for comparison; Therefore, caution must be exercised before this association is either accepted or rejected.

From the 112 mutations reported previously, the following three mutations--E191E, Y440C and A746A were each observed once in CP patients with *SPINK1* N34S. Another mutation, P748P, was identified in two CP patients without *SPINK1* N34S. Recently identified novel *CASR* mutations from Germany and India seen in exons 3 (P163R), 4 (L173P, F391F, I425S, D433H), 5 (V477A) and 7 (E870E, R896E)<sup>[8-10]</sup> were not observed in either patients or controls. Two intronic polymorphisms 493-94 C>T and 493-134 T>C included in exon 4 amplicon occurred with similar frequency in CP patients and controls, both with and without *SPINK1* N34S polymorphisms.

Secondarily, 219 patients (137 CP and 82 RAP) and 239 controls from the NAPS2 study who did not carry *SPINK1* N34S were analyzed to test the association of *CASR* A990G and CP. This ancillary analysis confirmed that the R990G was significantly associated with CP, as shown in Table 3 (OR, 2.01; 95% CI, 1.12-3.59; *P* = 0.015). The frequencies of R990G among RAP patients and controls, with and without *SPINK1* N34S were similar. There was

A: Abstainer; L: Light; M: Moderate; H: Heavy; VH: Very heavy. Alcohol categories: Abstainers: No alcohol use or < 20 drinks in lifetime; Light drinkers: < 3 drinks/week; Moderate drinkers: 4-7 drinks/week for females, 4-14 drinks/week for males; Heavy drinkers: 8-34 drinks/week for females, 15-34 drinks/week for males; Very heavy drinkers: > 35 drinks/week. <sup>1</sup>Fisher's exact test.

no difference in A986S and Q1011E polymorphisms among RAP and CP patients, and controls.

To determine if the risk was modified with alcohol use we compared *CASR* R990G genotypes in subjects with moderate and heavy alcohol drinking pattern. CP was strongly associated with the *CASR* R990G in moderate and heavy alcohol drinkers, as is demonstrated in Table 4 (OR, 3.12; 95% CI, 1.14-9.13; P = 0.018). No association was observed with this particular polymorphism in abstainers or in subjects with self-reported light or very heavy alcohol drinking patterns.

## DISCUSSION

In the past, CP was commonly attributed to heavy alcohol consumption. More recent studies, however, suggest there is also a strong genetic basis for this illness<sup>[22]</sup>. Growing knowledge of complex gene-environment interactions has

provided fundamental insight into the pathophysiological mechanisms that result in fibrotic destruction of the pancreas<sup>[11,23-25]</sup>. Studies from Germany and India have recently identified 8 novel *CASR* mutations that were associated with *SPINK1* N34S in idiopathic and tropical CP subjects. Our study did not detect these novel *CASR* mutations. However, we were able to demonstrate and verify that *CASR* R990G confers significant risk for developing of CP especially when linked to moderate and heavy alcohol consumption.

Three common nonsynonymous SNPs are located in the region coding the intracellular tail of *CASR*<sup>[26]</sup> and play an important role in cellular signal transduction that alters serum ionized calcium level<sup>[27,28]</sup>. Previously, it was reported that individuals carrying the 990 variant G allele may experience very mild decrease in serum ionized calcium levels from 4.92 mg/dL to 4.84 mg/dL<sup>[28]</sup>. Although serum ionized calcium levels

alter the cytosolic calcium ion concentrations in acinar cells in a concentration-dependent manner, and may alter the risk of acute pancreatitis<sup>[29,30]</sup>, the *CASR* R990G allele associated with increased risk of CP should slightly reduce the risk of acute pancreatitis. Furthermore, the magnitude of change in serum calcium levels due to *CASR* R990G alone is small, and it is difficult to imagine that this small change would, by itself, significantly alter the risk of acute pancreatitis. Indeed, our data suggests that *CASR* R990G is associated with CP rather than RAP. Our speculation is that *CASR* R990G might induce direct changes in the acinar and ductal cells that increase the risk for CP. However, the mechanism remains unknown.

Interestingly, while 55%-80% of pancreatitis cases may be attributed to alcohol abuse, less than 5% of heavy alcohol users develop pancreatitis<sup>[31]</sup>. Alcohol abuse may not be the sole risk for the development of CP<sup>[32]</sup>; rather alcoholic CP is likely the result of an interaction of several co-factors<sup>[2]</sup>. It has been demonstrated that chronic alcohol consumption accelerates fibrosis in response to cerulein-induced CP in rats<sup>[33]</sup>. Alcohol metabolites in pancreatic acinar cells induce persistent cytosolic Ca<sup>2+</sup> signals in a concentration-dependent manner and depolarize mitochondria.

The discovery and characterization of a genetic cause of hereditary pancreatitis generated renewed interest in a possible genetic predisposition to alcoholic CP<sup>[34]</sup>. Several CP-related gene mutations have been described previously with *CFTR*, *PRSS1*, *SPINK1* and others<sup>[35]</sup>. Our study also demonstrates the association of *CASR* R990G with CP, especially with moderate and heavy alcohol consumption. The presence of *CASR* R990G alone doubled the risk of developing CP, while in those individuals reporting moderate and heavy alcohol consumption, the risk was increased by 3-fold. Our hypothesis for testing *CASR* R990G in subjects with moderate and heavy drinking patterns is that this group represented a "threshold" alcohol pancreatitis risk group in which the addition of another risk factor would increase the overall risk of developing CP. The risk of CP in subjects with *CASR* R990G but with minimal or no alcohol consumption would be lower, while very heavy drinkers would be at high risk, regardless of the *CASR* genotype. Our experimental findings support this hypothesis.

The novel *CASR* gene mutations that were identified in German and Indian populations appeared to be closely associated with the *SPINK1* N34S haplotype. We did not detect these, or other novel *CASR* mutations, and our study was not powered to demonstrate an interaction between *SPINK1* N34S and *CASR* R990G. On the other hand, it was not clear whether or not the German and Indian studies tested for an effect of alcohol in a "threshold" dose range. However, both studies suggest that the overall effect of *CASR* polymorphisms are relatively small, and become clinically significant in the presence of additional risk factors in an additive or multiplicative way. This is consistent with current concepts that CP is a complex syndrome.

The present study confirmed the association of *CASR* genetic variants with CP. Our genotyping results

in a US population were different from those reported from Germany and India. *CASR* R990G significantly increased the risk of developing CP and this effect was enhanced in subjects who consumed alcohol in a moderate to heavy dose range. Certain polymorphisms in the *CASR* gene may be considered risk factors for the development of CP, especially within the context of alcohol consumption. The relationship with *SPINK1* mutations warrants further study.

## ACKNOWLEDGMENTS

We thank physician members of the NAPS2 Consortium and associates who contributed sample and information for the final data set. These include Christopher Lawrence MD, Joseph Romagnuolo MD, Meredith Korneffel MD, Grace Elta MD, Krik-Gan Wamsteker MD, James Scheiman MD, Peter Banks MD, Michele Bishop MD, John Baillie MD, Paul Jowell MD, Malcom Branch MD, Stuart Sherman MD, Lee McHenry MD, Evan Fogle MD, Nahla Hasabou MD, Michel Goldberg MD, Stephen Amann MD, Nathan Schmulewitz MD, Syed Ahmad MD, Shailendra Chauhan MD, Jim DiSario MD, Frank Burton MD, Timothy Gartner MD, Andres Gelrud MD, Simon Lo MD, Mark DeMeo MD, Sri Komanduri MD, William Steinberg MD, Michael Kochman MD, Gregory Ginsberg MD, Babak Etemad MD, and Christopher Forsmark MD. We also thank Dr. Georgios I Papachristou for helpful comments.

## COMMENTS

### Background

Chronic pancreatitis is a highly morbid, complex disease whose development depends on the combination of genetic and environmental factors. Elucidating the genetic links to this illness is critical in diagnosis, treatment and risk assessment.

### Research frontiers

This study adds another gene to the growing number of genetic and other factors that confers increased risk of chronic pancreatitis. As new factors continue to be identified and confirmed, the emphasis will turn to integrating these risks, using systems approaches, as described in reference #1.

### Innovations and breakthroughs

This study is one of the first to consider the complexity of gene-environment and gene-gene interactive paradigms by evaluating alcohol consumption and serine protease inhibitor Kazal 1type (*SPINK1*) N34S variants with calcium sensing receptor (*CASR*) polymorphisms. The confirmation of *CASR* genetic variants as risk factors for chronic pancreatitis strengthens the importance of dysfunctional calcium regulating genes in the etiology of pancreatitis.

### Application

With the inclusion of associated *CASR* polymorphisms in comprehensive evaluation of selected patients, we may improve the accuracy of overall pancreatitis risk prediction and may be able to provide a target for preventive approaches and possible treatment options.

### Peer review

Our peer reviewers noted this brief manuscript to be well-developed and well-written. They felt that the abstract was clear and the hypothesis being tested and methodology were sound and well presented.

### Abstract

**AIM:** To determine whether folic acid supplementation will reduce the recurrence of colorectal adenomas, the precursors of colorectal cancer, we performed a double-blind placebo-controlled trial in patients with adenomatous polyps.

**METHODS:** In the current double-blind, placebo-controlled trial at this VA Medical Center, patients with colorectal adenomas were randomly assigned to receive either a daily 5 mg dose of folic acid or a matched identical placebo for 3 years. All polyps were removed at baseline colonoscopy and each patient had a follow up colonoscopy at 3 years. The primary endpoint was a reduction in the number of recurrent adenomas at 3 years.

**RESULTS:** Of 137 subjects, who were eligible after confirmation of polyp histology and run-in period to conform compliance, 94 completed the study; 49 in folic acid group and 45 in placebo group. Recurrence of adenomas at 3-year was compared between the two groups. The mean number of recurrent polyps at 3-year was 0.36 (SD, 0.69) for folic acid treated patients compared to 0.82 (SD, 1.17) for placebo treated subjects, resulting in a 3-fold increase in polyp recurrence in the placebo group. Patients below 70 years of age and those with left-sided colonic

adenomas or advanced adenomas responded better to folic acid supplementation.

**CONCLUSION:** High dose folic acid supplementation is associated with a significant reduction in the recurrence of colonic adenomas suggesting that folic acid may be an effective chemopreventive agent for colorectal neoplasia.

### INTRODUCTION

Colorectal cancer is the second most common cancer in the United States<sup>[1]</sup>. Although the etiology of this disease is related to genetic susceptibility, dietary factors such as vitamins and micronutrients are thought to influence carcinogenesis<sup>[2]</sup>. Considerable interest has recently been focused on the water soluble vitamin folic acid. Although the specific mechanism(s) by which folate deficiency enhances colorectal carcinogenesis have not been fully elucidated, it has been hypothesized that aberrations in DNA methylation may contribute to abnormalities in DNA synthesis and genomic instability<sup>[3]</sup>.

Several clinical trials have noted an inverse relationship between dietary folic acid and the development of colorectal cancer<sup>[4-7]</sup>. A folate deficient diet is thought to increase the risk of colonic neoplasia<sup>[8-11]</sup>, whereas supplementation of this nutrient may be chemopreventive<sup>[12-15]</sup>. However, the timing of folate supplementation may be particularly important since folate intervention after the establishment of microscopic neoplastic foci in the colorectal mucosa may promote

rather than suppress colorectal carcinogenesis<sup>[16]</sup>.

Accumulating data from murine studies have also supported a role for folic acid in the prevention of colon carcinogenesis. Folate deficient rats demonstrate an increased susceptibility to dimethylhydrazine induced colonic neoplasia as compared to folate replete animals<sup>[10]</sup>. In a similar model, folate supplementation protected against the development of colonic neoplastic lesions in a dose dependent manner<sup>[17]</sup>. We have previously demonstrated that folic acid supplementation can reduce the age-related susceptibility of murine colorectal mucosa to a colonic carcinogen<sup>[18]</sup>. In the azoxymethane-induced colon cancer rat model, supplemental folic acid has also been shown to decrease the formation of aberrant crypt foci, which are considered to be precursors of colorectal adenomas and carcinoma<sup>[19,20]</sup>. Additionally, *in vitro* studies have further demonstrated that supplemental folic acid greatly inhibits proliferation of colon cancer cells<sup>[21,22]</sup>. Although these studies suggest a chemopreventive role for folic acid in colorectal cancer, to the best of our knowledge, no conclusive long-term clinical trials have been performed to evaluate the efficacy of folic acid in preventing the recurrence of colorectal adenomas. The current 3-year placebo-controlled clinical trial was, therefore, undertaken to test the hypothesis that folic acid will inhibit the recurrence of colorectal adenomas.

## MATERIALS AND METHODS

### Objectives

The primary objective of this chemopreventive trial is to determine if supplementation of folic acid for 3 years will inhibit the recurrence of colorectal adenomas. The study was initiated in December, 1998 with a 2-year patient accrual followed by a 3-year treatment with folic acid (5 mg/d) or placebo. The study was completed in June, 2005. The study protocol was approved by the Human Investigation Committee of Wayne State University. All subjects provided written informed consent.

### Study subjects and treatment

Eligible subjects were male or female, from the age of 18-80 years. However, the youngest subject enrolled in this clinical trial was 44 years of age. All subjects underwent a colonoscopy for colon polyps noted on screening flexible sigmoidoscopy or as routine surveillance for a history of colon polyps at the Detroit VA Medical Center. Prior to colonoscopy, potential subjects agreed in advance to participate if they were found to have at least one adenoma (tubular, tubulovillous, villous) > 0.5 cm, and had no exclusionary factors including hyperplastic histology of the index polyp. The histology of all polyps was examined by a pathologist blinded to the sample coding.

At study entry, all patients completed a lifestyle questionnaire. Nutritional assessment was evaluated by a registered dietitian using a Block Dietary Data System for California, Berkley. Nutrient intakes were computed according to the composition values from the U.S. Department of Agriculture<sup>[23]</sup>, supplemented with other sources<sup>[24]</sup>.

Eligible participants underwent a complete colonoscopy and had all adenomas removed at colonoscopy (with at least one adenoma > 0.5 cm). They were then randomized in a double-blind trial to receive either a 5 mg folic acid tablet (Stanley Pharmaceutical, Toronto, Canada) or one identical placebo tablet (sucrose/fructose base) daily per oral with breakfast for 3 years. Compliance was monitored by both pill count and telephone contact. Patients were seen or contacted by telephone every 90 d by the study coordinator to obtain pill counts, assess adverse events and to renew a 90 d supply of study medication. Patients were required to take ≥ 90% of their prescribed study treatment. At the end of 3 years, a repeat colonoscopy was performed, and all identified polyps were removed endoscopically. Serum and RBC folate concentrations were monitored at baseline and every 6 mo. During the course of the trial all adverse events including deaths were reported to the Institutional Review Board (IRB).

### Choice of folic acid dose

A 5 mg dose of folic acid was chosen on the basis of the previous observations that diets high in folate protect against the development of colorectal neoplasia. Although lower doses of folic acid (0.4-1 mg) resulted in a reduced relative risk of neoplasia, the risk reduction did not achieve statistical significance<sup>[12,14]</sup>. Kim *et al* noted a significant increase in colonic mucosal and systemic folate concentrations in patients who were treated for 1 year with 5 mg folic acid<sup>[25]</sup>. Folate supplementation, even at a dose of 15 mg/d, has been rarely associated with gastrointestinal or CNS adverse effects<sup>[26]</sup>. In addition, the high prevalence of dietary supplementation of folic acid (up to 1 mg/d) in the general population would have been a confounding variable.

### Exclusion criteria

Subjects were excluded if they had any of the following criteria: severe co-morbid conditions, such as severe heart disease, cancer, or other diseases causing organ dysfunction or contraindications for colonoscopy and polypectomy. Subjects with gastrointestinal disorders that affect absorption or metabolism of folic acid, B12 deficiency, and hereditary predisposition to colorectal cancer were excluded. In addition, pregnant or nursing mothers were excluded. Sexually active females agreed to use an effective method of birth control. Patients who drank more than 2 alcoholic drinks daily or who were regularly ingesting or anticipating chronic therapy with vitamin, mineral or any other nutritional supplement, steroids and non-steroidal anti-inflammatory drugs (excluding cardiopreventive aspirin doses), antineoplastic agents or folate were also excluded. Patients were asked if they had a family history of familial colorectal cancer syndrome. This question was asked to exclude obvious known history of FAP or HNPCC.

### Placebo run-in

Subjects were supplied with a known number of placebo

**Table 1** Baseline characteristics of the subjects

Characteristics	Folate group (n = 80)	Placebo group (n = 97)	P
Age (yr)	60.36 ± 10.34	62.64 ± 9.59	NS
Sex (male, %)	93	92	NS
Race

NS: Not significant. Advance adenoma: ≥ 2 adenomas, large (> 1 cm) or adenoma with villous component or high grade dysplasia. Number of patients in placebo and folate group represents those who completed the baseline colonoscopy and satisfied the criteria for enrollment. Ninety-four subjects completed the 3-year study.

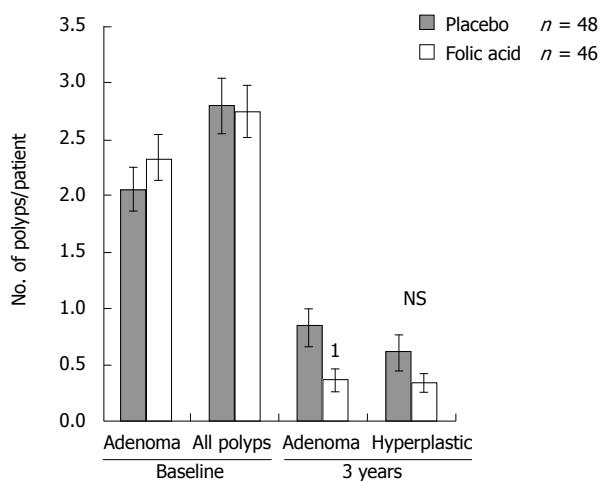

tablets to be taken daily during breakfast for 4 wk. Those who had taken ≥ 90% of their tablets were randomized.

### Randomization and stratification

Participants were randomized to the folic acid or placebo group using a stratified randomization block scheme. There were 3 stratification factors: number of adenomas (1, 2-5 and ≥ 6), size of the largest adenoma (≤ 1 cm, >1 cm) and history of polyps (no, yes). Block randomization was used in a block size of 8 to ensure that at no time during the study would there be a large imbalance between the intervention and control groups. Subject assignment was made in advance and recorded in sealed envelopes, numbered consecutively.

### Statistical analysis

The statistical analyses were all performed using the Statistical Package for Social Sciences (SPSS, version 8.0; 1997, Chicago, IL). All t-tests were two sided. Initially, the two treatment groups were compared across demographic information using independent t-tests for continuous data and Chi-Square analyses for categorical information. Treatment efficacy was assessed between intervention groups using independent t-tests across classifications of polyp morphology, lateralization, and age grouping. Logistic regression was utilized to assess the incidence of recurring polyps three years post-removal for individuals taking folic acid versus those

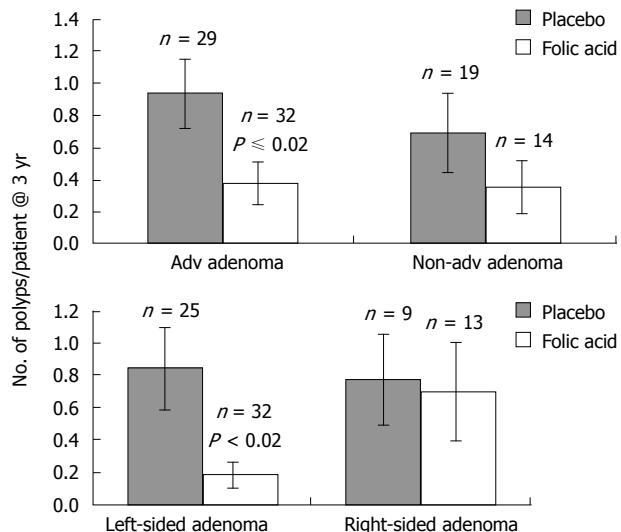

**Figure 1** Number of adenomas versus treatment. Histograms showing the number of adenomas or all types of polyps in folic acid and placebo-treated groups at baseline and 3 years after treatment.  $P = 0.02514$ , compared to the placebo-treated group. Each histogram represents the mean ± SD.

taking placebo. A contingency table was computed via Chi-Square analysis, and Odds Ratios were computed via logistic regression analysis.

## RESULTS

One hundred and thirty seven patients fulfilled the eligibility criteria. Ninety four completed the 3-year follow up colonoscopy and were included in this analysis. There were 43 subjects that dropped out from this study; of which 28 died from various causes unrelated to colon cancer and 15 subjects had geographic relocation precluding further participation. Of those who did not complete the study, there were no statistically significant differences (age, BMI, sex, NSAID/multivitamin, baseline adenoma, RBC folate, deaths) between those assigned to receive folic acid or placebo. Forty nine of the subjects who completed the 3-year follow-up received supplemental folic acid and 45 were given placebo tablets. At post-randomization, there was no statistical difference in the serum levels of folic acid between the two groups (Table 1). Demographic data and other baseline parameters were also comparable between these two groups (Table 1). At the 3-year follow-up colonoscopy, patients in the folic acid group showed a significantly lower number of adenomas per patient ( $0.36 \pm 0.69$ ) with a 64% lower risk ratio, compared to the placebo group ( $0.82 \pm 1.17$ ; odds ratio, 2.77;  $t = -2.26$ ,  $P = 0.02514$ , 95% CI, 0.06-0.84; Chi Square = 11.2,  $P = 0.00142$ ; Figure 1). The recurrence of adenoma at the 3-year follow-up was twice as high in the placebo group, compared to the folic acid group. There was no significant difference in the recurrence of hyperplastic polyps between the groups (folic acid:  $0.44 \pm 0.89$ , placebo:  $0.51 \pm 0.94$ ;  $P = 0.74$ ; 95% CI, 0.31-0.43).

Folic acid supplementation caused a significant reduction ( $P = 0.02335$ ) in the recurrence of adenomas in patients with advanced adenoma [large (> 1 cm)

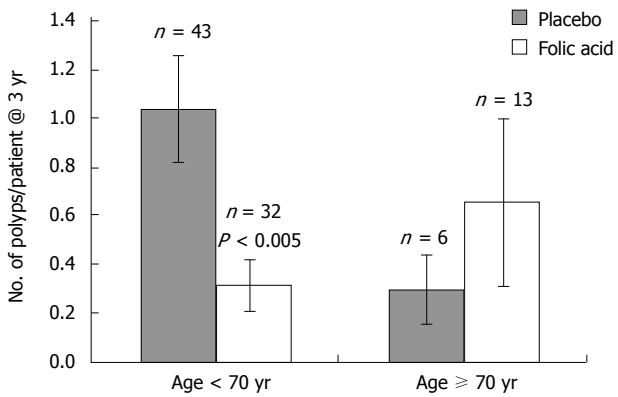

**Figure 2** Polyp characteristics and response to treatment. Recurrence of advanced [large ( $> 1$  cm) and polyps with villous component] or non-advanced adenomas (upper panel) as well as right or left-sided adenomas (lower panel) following 3 years of treatment with a high dose of folic acid. The numbers of subjects as well as the levels of significance between the two groups are shown.

adenoma or adenoma with villous component or high grade dysplasia], compared to the placebo-treated controls (Figure 2, upper panel). Those with non-advanced adenomas also showed a reduction in the recurrence of adenomas with folic acid, compared to placebo controls, but this was not statistically significant (Figure 2, upper panel). On further stratifications, it was noted that subjects with left-sided polyps had a significantly lower ( $P = 0.01964$ ) recurrence of adenomas than those with right-sided polyps in response to folic acid supplementation, when compared with the corresponding placebo-treated controls (Figure 2, lower panel).

Since colorectal cancer is an age-related disease, the data were analyzed to determine the age-related differences in responsiveness to folic acid. We observed that the younger subjects responded better than older subjects in that the recurrence of adenomas was significantly lower ( $P = 0.00496$ ) in younger patients, compared to older patients (Figure 3). This response was maintained until 70 years of age (Figure 3). However, patients older than 70 years of age failed to respond to folic acid supplementation demonstrating a higher recurrence rate of polyps as compared to the placebo group. This difference was not statistically significant (Figure 3). There were more deaths in the folic acid group, compared to the placebo-treated group, but this difference was not statistically significant (19 in folic acid vs 9 in placebo,  $P > 0.1$ ).

## DISCUSSION

Despite recent advances in medicine, the mortality from colorectal cancer, a leading cause of death in the USA and other Western countries, still remains unacceptably high. Therefore, the search for strategies to prevent the development and progression of colorectal cancer has

**Figure 3** The effect of age on the response to treatment. Recurrence of adenomas in response to 3 years of folic acid treatment in patients over or below 70 years of age is shown. The number of subjects in each group as well as the levels of significance is shown in the figure.

greatly intensified. Chemoprevention offers a viable option to block neoplastic inception or delay disease progression. Since colorectal cancer is an age-related disease, typically diagnosed after the age of 50, any delay in the onset and subsequent progression of this disease through the use of dietary agents is likely to have significant health benefits. Folic acid has recently emerged as a major contender in the repertoire of promising colorectal cancer prevention agents. A number of animal, as well as a few case controlled human studies, strongly support folic acid as a potentially efficacious chemopreventive agent with a negligible toxicity profile<sup>[3]</sup>. However, there have been no systematic conclusive studies to examine the effect of supplemental folic acid on recurrence of adenomas in the colon.

Our data, for the first time, show that the daily consumption of a high dose of folic acid over a period of 3 years prevents the recurrence of colorectal adenomas. This reduction could not be attributed to differences in diet or lifestyle. The patients completed a detailed lifestyle questionnaire and nutritional assessment with both study groups demonstrating statistically similar caloric, fiber, fat and protein intake as well as similar baseline BMI, folate, B12 and calcium status. Additionally, the groups were similar with regard to aspirin use and the number and type of adenoma at baseline. Most patients were male which is consistent with the Veterans Affairs based population. Interestingly, patients who had large adenomas or adenomas with a villous component (referred to as advanced adenomas) responded better to high dose folate supplementation, as evidenced by the significantly reduced number of recurrent adenomatous polyps. A similar phenomenon was also observed among patients with left-sided adenomas and those who were less than 70 years of age. Although the reasons for this are not fully understood, it is plausible that the increased responsiveness of these subjects could be a result of greater tissue accumulation of folic acid due to a better active folate transport system. The basis for this inference comes from the observations by Mennan *et al* which suggest that mucosal folate levels may be a determinant factor

in the development of adenomas<sup>[27]</sup>. They demonstrated that the levels of folate in adenoma, carcinoma as well as normal appearing adjacent mucosa are lower than the corresponding polyp-free controls<sup>[27]</sup>. Future studies analyzing folate levels in adjacent tissue near recurrent adenomas need to be completed.

Although several clinical trials have suggested a role for folic acid in the prevention of colorectal adenomas, there are no prospective controlled trials addressing this issue at the dose of 5 mg<sup>[5-8]</sup>. It has also been demonstrated that supplementation of a high dose of folic acid in animals with colonic neoplasia may accelerate the progression of carcinogenesis<sup>[16]</sup>. A more recent human study showed that supplemental folic acid may not reduce the incidence of colorectal adenomas and in some cases may actually increase the risk<sup>[28]</sup>. Although the reasons for these controversial issues are not fully understood, one possibility could be attributed to the dual modulatory effect of folic acid on carcinogenesis. It has been demonstrated that the timing and the dose of folate intervention has a promoting effect on the progression of established neoplasms, while it could have a chemopreventive effect if given in premalignant conditions. Data from our clinical trial clearly supports a chemopreventive role of folic acid since supplementation of this vitamin for 3 years inhibits the recurrence of colonic adenomas. More importantly, none of the patients in the folate treatment group were found to have histologically aggressive adenomas or carcinoma at final endoscopy.

The mechanisms by which folic acid exerts its chemopreventive role in colorectal carcinogenesis are becoming increasingly understood. Since folic acid plays a key role in DNA methylation and cellular homeostasis, folate deficiency may result in a variety of cellular consequences including misincorporation of uracil for thymidine during DNA synthesis resulting in an increased spontaneous mutation as well as chromosomal abnormalities and errors in DNA synthesis<sup>[29-33]</sup>. The restoration of DNA methylation status in patients with colorectal neoplasms treated with supraphysiological doses of folic acid lends further support to the hypothesis. In a recent study, we examined the changes in mutational status of APC, DCC and p53 genes in macroscopically normal appearing rectal mucosa at baseline and after 1 year of treatment with either folic acid or placebo<sup>[34]</sup>. We have observed that folate supplementation prevented the loss of heterozygosity (LOH) of the DCC gene in 5 out of 5 patients who demonstrated baseline heterozygosity, whereas 2 out of 4 placebo treated patients with baseline heterozygosity demonstrated complete allelic loss. Mucosal protein levels of DCC were also reduced in 70% of placebo treated patients compared to only 10% of folate treated patients<sup>[34]</sup>. Cell culture studies have further demonstrated that supplemental folic acid and its metabolite 5-methyltetrahydrofolate (5-MTF) inhibit EGF-receptor (EGFR) promoter activity in colon cancer HCT-116 cells by enhancing methylation<sup>[35]</sup>. Since EGFR is known to play a critical role in the development and progression of a wide variety of epithelial cancers,

including colorectal cancer<sup>[36,37]</sup>, the inhibition of basal as well as serum-stimulated EGFR promoter activity by folic acid and 5-MTF suggests that these changes may partly contribute to specific inhibition of growth-related processes in colorectal neoplasia. Supplemental folic acid may also attenuate the downstream events of EGFR signal transduction pathways that are critically involved in modulating growth-related processes. We have observed that in polypectomized patients, supplemental folic acid for 1 year leads to a decreased nuclear translocation of β-catenin<sup>[38]</sup>, which interacts with the T-cell factor 4 (TCF-4) transcription factor to induce expression of specific target genes, including cyclin D1, VEGF and c-myc, which promote cell growth and proliferation<sup>[39-42]</sup>.

The dose of folic acid supplementation may be important when considering the differing effects of supplementation. This has been more explored in the cardiovascular literature in attempting to modulate homocysteine levels where the VISP study showed greater efficacy at higher doses in lowering homocysteine levels<sup>[43]</sup>. A cogent example of this was the recently published large scale study interventional study of over 1000 men and women who were randomized to receive either 1mg folic acid or placebo. The endpoints were similar to our study, but the 3 year follow up data were very different in that no effect was seen for the dose used<sup>[28]</sup>. Of interest, there was no effect of gender in that study which may have important implications for our study in terms of applicability to the general population. The timing of supplementation may also be important<sup>[44]</sup>.

In summary, daily consumption of a high dose of folic acid over 3 years prevents the recurrence of colorectal adenomas. Patients below 70 years of age and those with left-sided colonic adenomas or advanced adenomas responded better to folic acid supplementation. We conclude that folic acid is an effective chemopreventive agent for colorectal adenomas, and more specifically for that category of adenomas which are believed to possess the highest risk of cancer progression.

## ACKNOWLEDGMENTS

The work was supported by grants to Dr. Majumdar from the Department of Veterans Affairs (VA Merit Review). The authors wish to thank Karen McGee and Angeline Carter for help in patient recruitment and record keeping, and to Drs. Irwin H Rosenberg and Joel Mason for their critical review.

## COMMENTS

### Background

Colorectal cancer is one of the major causes of cancer related deaths. In the US and the other developed countries, 50% of the subjects diagnosed with colon cancer die. Therefore, there is a need to prevent the development and progression of colon cancer using chemopreventive agents. Water soluble vitamins, such as folic acid, have shown to have chemopreventive potential for colon cancer. Aim of this investigation was to determine whether folic acid supplementation will reduce the recurrence of colorectal polyps, the precursors of colorectal cancer, we performed a double-blind placebo-controlled trial in patients with polyps.

## Research frontiers

Several clinical trials have noted an inverse relationship between dietary folic acid and the development of colorectal cancer. A folate deficient diet is thought to increase the risk of colonic neoplasia, whereas supplementation of this nutrient may be chemopreventive. However, the timing of folate supplementation may be particularly important since folate intervention, after the establishment of microscopic neoplastic foci in the colorectal mucosa, may promote rather than suppress colorectal carcinogenesis. A similar approach using aspirin and similar non-steroidal anti-inflammatory agents have shown promising activity in prevention of colon cancer after resection of colon polyps.

## Innovations and breakthroughs

This is a large randomized, single institution, double-blind placebo controlled trial demonstrating the efficacy of folic acid in secondary chemoprevention of colorectal cancer. This is the only study examining high dose supplementation over a period of three years further establishing safety and efficacy of large dose of folic acid. It should also be noted that the present study is the only study of its kind specifically targeting the US veteran population.

## Applications

Daily consumption of a high dose of folic acid over 3 years prevents the recurrence of colorectal adenomas. Particularly, patients below 70 years of age and those with left-sided colonic adenomas or advanced adenomas responded better to folic acid supplementation. We conclude that folic acid is an effective chemopreventive agent for colorectal adenomas, and more specifically for that category of adenomas which are believed to possess the highest risk of cancer progression.

## Peer review

This is an important study which, for the first time, demonstrates that daily consumption of a high dose folic acid over a prolonged period of time leads to a significant reduction in the recurrence of colonic adenomas. The results suggest that folic acid may be an effective chemopreventive agent for colorectal neoplasia.

surgery for colonic masses of indeterminate nature. Four subjects refused further examinations. CTC correctly identified 2 colonic masses and 20 polyps. PPV for masses or polyps greater than 9 mm was of 87.5%. Per-lesion and per-segment PPV were, respectively, 83.3% and 83.3% for polyps greater or equal to 10 mm, and 77.8% and 85.7% for polyps of 6-9 mm.

**CONCLUSION:** In the context of a screening program for CRC based on FOBT, CTC shows high per-segment and per-lesion PPV for colonic masses and polyps greater than 9 mm. Therefore, CTC has the potential to become a useful technique for evaluation of the non visualized part of the colon after incomplete colonoscopy.

### Abstract

**AIM:** To report our experience with computed tomography colonography (CTC) systematically performed in subjects with positive faecal occult blood test (FOBT) and an incomplete colonoscopy in the setting of a population-based screening for colorectal cancer (CRC). **METHODS:** From April 2006 to April 2007, 43290 individuals (age range 50-70) who adhered to the regional screening program for the prevention of CRC underwent immunochemical FOBT. FOBT was positive in 1882 subjects (4.3%). 1463 (77.7%) of these subjects underwent colonoscopy, 903 performed in a single center. Of 903 colonoscopies 65 (7.2%) were incomplete. Forty-two of these subjects underwent CTC. CTC was performed with a 16-MDCT scanner after standard bowel prep (polyethylene glycole) in both supine and prone position. Subjects whose CTC showed polyps or masses were referred to the endoscopist for repeat colonoscopy under sedation or underwent surgery. Per-lesion and per-segment positive predictive values (PPV) were calculated.

**RESULTS:** Twenty-one (50%) of 42 CTCs showed polyps or masses. Fifty-five of these subjects underwent a repeat colonoscopy, whereas 2 subjects underwent

### INTRODUCTION

Randomized clinical trials have demonstrated that screening with faecal occult blood test (FOBT) reduces mortality for colorectal cancer (CRC)<sup>[1]</sup>. Accordingly, population-based screening with FOBT is currently recommended by the European community health associations and has been applied in many countries, including Italy<sup>[2]</sup>.

Subjects with a positive FOBT are usually examined with a total colonoscopy which allows removal of polyps and histological diagnosis of the lesions. However, colonoscopy can be incomplete due to several reasons, including intolerance to the procedure, adhesions from previous surgery, redundant colon and the presence of stenosis. The reported rates of incomplete colonoscopy from various studies carried out in U.S. and Europe over the past 15 years range from 4% to 25%<sup>[3,4]</sup>.

In order to complete evaluation of the colon, radiological examinations can be performed such as double contrast barium enema (DCBE)<sup>[5]</sup> and computed tomography colonography (CTC). In particular, several studies have shown that CTC is a valuable tool to evaluate the proximal colon after incomplete colonoscopy<sup>[6-10]</sup>, and the American Gastroenterologists Association (AGA) recognized that CTC is indicated for adults with failed colonoscopy<sup>[11]</sup>.

We report the results of CTC systematically performed in subjects with positive FOBT and incomplete colonoscopy in the context of a population-based screening programme for CRC with FOBT.

## MATERIALS AND METHODS

### Subjects

This prospective study was approved by our institutional review board; informed consent was obtained in all subjects. A population-based screening program for CRC has been active in the Tuscany Region, Italy, since 1998. The screening protocol is directed to all subjects aged 50-70 living in the regional area who are invited via mail every second year to perform immunochemical FOBT. Subjects with negative FOBT are notified of their result by mail and advised to repeat screening after two years. Subjects with positive test are invited to perform colonoscopy<sup>[12]</sup>.

From April 2006 to April 2007, 43 290 asymptomatic individuals aged 50-70 years attended the FOBT-based Florence District screening program and were tested. FOBT was positive in 1882 (4.3%) subjects. These subjects were invited to undergo colonoscopy assessment: 1463 (77.7%) subjects underwent colonoscopy and 419 refused. 903 colonoscopies were performed in a single center by two experienced endoscopists.

According to the screening protocol, colonoscopy was performed without sedation. 838 (92.8%) colonoscopies were complete (i.e. the caecum was reached) and 65 (7.2%) were incomplete. The levels at which colonoscopy was interrupted were the sigmoid colon in 33 subjects, the descending colon in 21, the transverse colon in 8 and the ascending colon in 3. According to the endoscopist's report, presumptive reasons for incomplete colonoscopy were dolichocolon (14.8%), diverticular disease (23.1%), adherences due to previous abdominal surgery (16.4%) or intolerance to the procedure (12.1%).

Forty-two of these 65 subjects (17 males, 25 females; mean age 60.7 years; age range 51-70) agreed to complete colonic examination with CTC and constitute of the base for this report.

CTC was performed within 6 wk after incomplete colonoscopy (mean interval 16 d). In those subjects in whom endoscopic polyp removal was performed during the incomplete colonoscopy, CTC was delayed for at least 1 mo after polypectomy.

### CTC technique

All subjects underwent a standard bowel preparation for CTC with 4 L of a polyethylene glycole solution (Isocoloran; Giuliani, Milan, Italy) administered the day before the procedure and a low residue diet for 3 d. All subjects received intravenously 30 mg of scopolamine butylbromide (Buscopan; Boehringer Ingelheim, Florence, Italy) before air insufflation, in order to improve colonic distension<sup>[13]</sup>.

The subjects were placed on the right lateral decubitus and a 24 Fr rubber catheter, Foley type, with a small retention balloon (10 mL) was inserted into the rectum. After catheter positioning the patient was turned in supine position and colonic distension was obtained with manual insufflation of room air. Air was administered from an enema bag connected to the rectal tube with a maximum capacity of 2 L. Insufflation was performed by gently squeezing the enema bag during 3 to 5 min up to subject tolerance.

Both supine and prone CT scans were obtained in all subjects. Colonic distension was evaluated with an anterior-posterior scout view in both supine and prone position, and additional air was inflated using a manual bulb if distension was unsatisfactory. In one subject, unable to stay prone because of abdominal pain, a right lateral decubitus acquisition was obtained instead of the prone scan. Intravenous contrast medium was not used.

CTC was performed with a 16-MDCT scanner (Sensation 16; Siemens, Erlangen, Germany) using a detector configuration of 16 mm × 0.75 mm, 120 kVp, 50 effective mAs, tube rotation time of 500 ms and a pitch of 1.25. Data were reconstructed using a slice thickness of 1 mm with a reconstruction increment of 0.7 mm (30% overlap). For each acquisition CTDI<sub>vol</sub> was 4.15 mGy with a calculated equivalent dose of 3.5 mSv for females and 2.7 mSv for males (CT Patient Dosimetry Calculator, ImPACT; measures executed on MonteCarlo Phantom).

### CTC evaluation

The images of each study were transferred to a workstation equipped with CTC dedicated software (Syngo; Siemens, Erlangen, Germany). The software provides axial, multi-planar reformatted (MPR), endoluminal surface-shaded images and double-contrast-like reconstructions of the colon. All studies were interpreted on the workstation by two readers, one experienced gastrointestinal radiologist and one radiology resident, by consensus.

Preliminarily, the degree of colonic distension was evaluated on axial images. The colon was divided into six segments: caecum, ascending, transverse, descending, sigmoid and rectum (the different segments were evaluated both in supine and prone acquisitions). Distension for each segment was graded on a scale from 0 to 3, in

which a grade of 0 indicated complete collapse and a grade of 3 optimal distension<sup>[13]</sup>. The least-distended section of any individual segment was used to assign the overall distention score for that segment. Colonic distension was deemed clinically adequate if all segments had a score of 2 or 3 at least in supine or prone acquisition.

Moreover, we assessed the adequacy of preparation by evaluating the proportion of colonic segments containing residual faecal matter or fluid for each subject (no specific attempt was made to rank the amount of fluid or stool).

CTCs were evaluated with a primary 3D approach, using 2D for problem solving. In all cases, endoluminal navigation was performed from rectum to caecum and backwards for both supine and prone acquisitions. Then axial images were examined with an abdominal window (level 40 HU, width 350 HU), in order to discover areas of colonic wall thickening, and to look for extra-colonic findings.

All lesions detected at CTC were localized according to their segmental location in the colon. Each lesion was measured taking account of its maximum diameter on 2D images viewed with a bone window (level 400 HU, width 2000 HU).

### **Subjects management**

All subjects with CTC showing polyps were referred to the endoscopist to repeat colonoscopy under sedation. Also subjects with colonic masses were referred to the endoscopist who evaluated in agreement with the subject the opportunity of a repeat colonoscopy or a surgical consult.

The results of repeat colonoscopy and/or the pathological findings on surgical specimens were used as a gold standard for CTC performance assessment. Lesions were measured by open biopsy forceps at endoscopy and with ruler for pathological specimens.

CTC findings were classified as true-positive or false-positive results. A true-positive lesion at CTC was defined as a lesion that was confirmed at repeat colonoscopy or at surgery, a lesion that was in the same or an adjacent colonic segment, and a lesion for which the size correlated within 50% of the diameter. A lesion was defined as false positive if the lesion reported at CTC was not detected at repeat colonoscopy, was not in the same or an adjacent colonic segment or there was more than a 50% discrepancy in the lesion diameter. Endoscopic evidence of polyps or masses at repeat colonoscopy not detected at CTC was assumed as a false negative result for CTC.

Descriptive statistics were used to calculate per-lesion and per-segment positive predictive values (PPV) for polyps equal or greater than 10 mm, for polyps of 6–9 mm and for smaller lesions (< 6 mm). In per-segment analysis the colon was divided into six segments (caecum, ascending, transverse, descending, sigmoid and rectum) and the segments examined by initial colonoscopies were excluded from the evaluation.

Subjects with a negative CTC did not undergo further examination and were scheduled for standard follow-up according to the screening protocol<sup>[12]</sup>.

**Table 1** CTC results for polyps

	True positive	False positive	False negative	Per-lesion PPV (%)
Polyps < 6 mm	8	4	2	66.7
Polyps 6–9 mm	7	2	0	77.8
Polyps ≥ 10 mm	5	1	0	83.3
Total	20	7	2	

## **RESULTS**

Complete colonic distension was obtained in 36 (85.7%) of 42 subjects. Considering both supine and prone acquisitions, the rectum in one patient and the sigmoid colon in 5 patients were not adequately distended. Incomplete distension was mainly due to advanced diverticular disease. The mean overall bowel distension scores were  $2.75 \pm 0.37$  for supine position and  $2.84 \pm 0.23$  for prone position. Either fluid and faecal residua, or inadequate distension precluded evaluation of 14 (5.6%) of 252 colonic segments [rectum ( $n = 1$ ), sigmoid colon ( $n = 10$ ), descending colon ( $n = 3$ )].

Twenty one (50%) of 42 CTCs showed polyps or colonic masses of indeterminate nature. Fifteen patients with polyps at CTC underwent repeat colonoscopy under sedation. Two patients with colonic masses of indeterminate nature were referred to surgical consult and underwent colectomy. Four patients with CTC findings of polyps smaller than 6 mm did not undergo repeat colonoscopy because of medical problems or refusal.

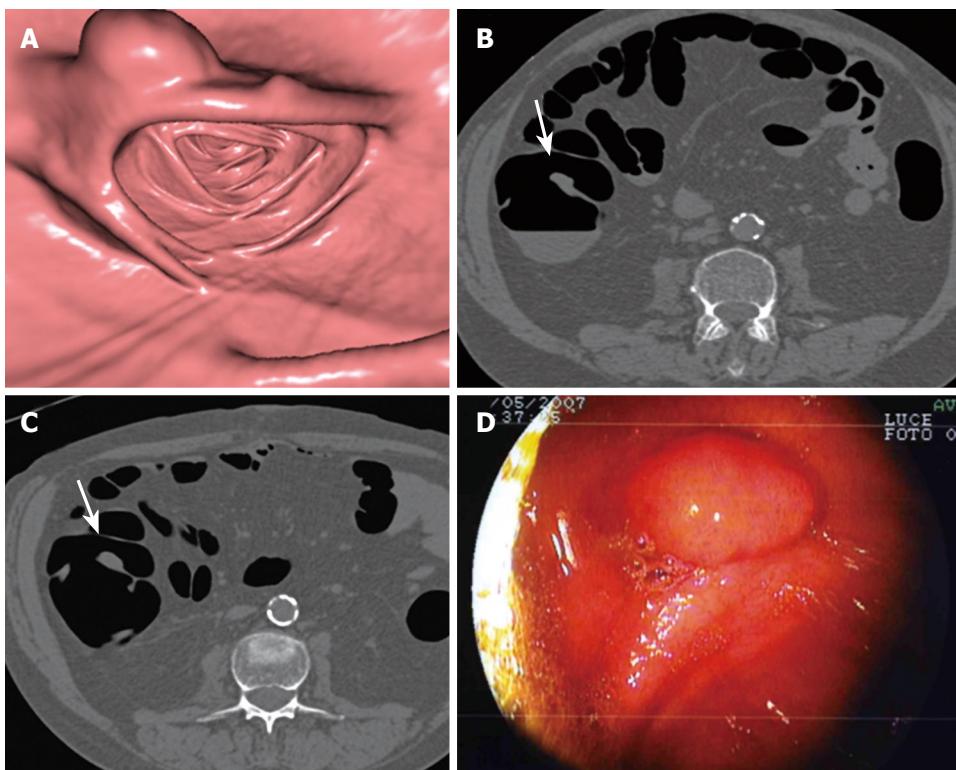

All repeat colonoscopic examinations were performed within a mean of 34 d after CTC (range 15 d to 6 mo) and were complete. No complications occurred after CTC or diagnostic and operative colonoscopy.

CTC correctly identified 20 polyps in segments not visualized at initial colonoscopy, and gave 7 false positive and 2 false negative results (Table 1). All polyps were endoscopically removed and histology was obtained (Figure 1). Of 20 polyps 11 were adenomas (2 tubulo-villous adenomas with high-grade dysplasia, 6 tubulo-villous adenomas, 3 tubular adenomas) and 9 hyperplastic or inflammatory polyps. No cancers were observed. The two false negative polyps not identified at CTC included one hyperplastic polyp and one tubular adenoma, both smaller than 6 mm. A total of 5 advanced adenomas were found at CTC and histologically proved.

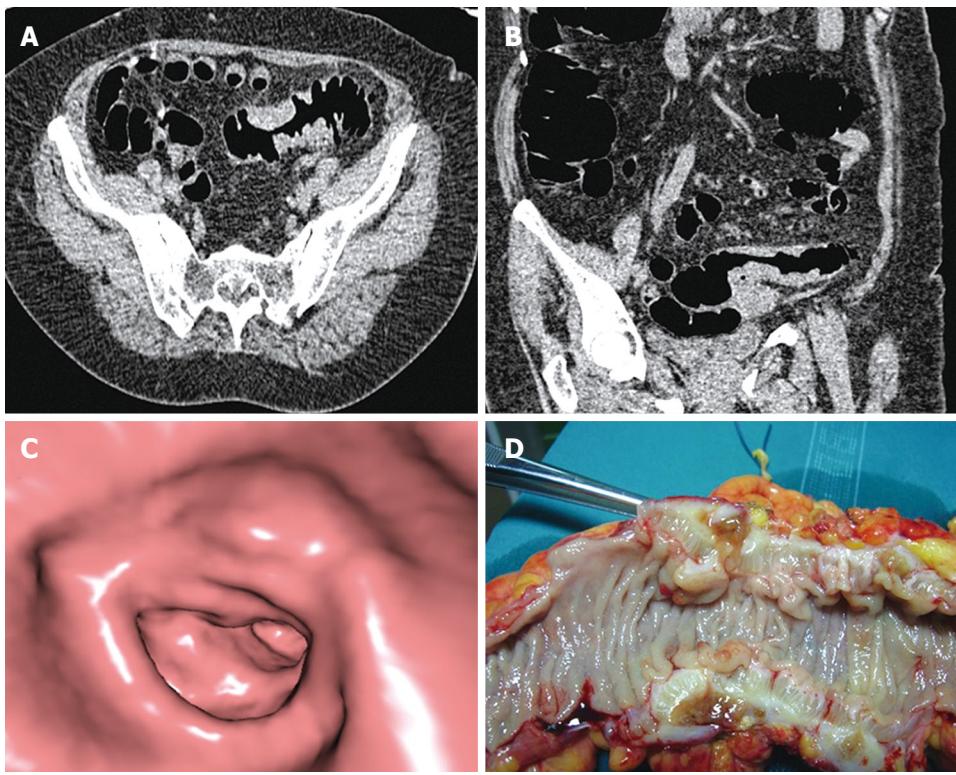

CTC correctly depicted two colonic masses of indeterminate nature at the level of the proximal sigmoid colon, which were found to be advanced diverticular disease complicated by stenosis at surgery (Figure 2). None of these patients had endoscopically visualized masses or adenomatous polyps at initial colonoscopy.

Per-segment analysis was performed on patients who completed repeat colonoscopy or underwent surgery ( $n = 17$ ). On a total of 102 colonic segments, 26 segments examined by initial colonoscopies were excluded, and the analysis was based on the remaining 76 segments.

CTC showed a PPV for masses or polyps greater than 9 mm of 87.5%. Per-lesion and per-segment PPV

**Figure 1** Adenomatous polyp of 13 mm of the ascending colon in a 61-year-old female with initial colonoscopy interrupted at the descending colon for severe discomfort. **A:** Endoluminal CT image of the ascending colon shows 13 mm sessile polyp lying on a fold; **B** and **C:** Axial CT images acquired in supine and prone position show the polypoid lesion (arrow) on a fold; **D:** Sessile polyp of 13 mm of the ascending colon found at repeat colonoscopy. Histology evaluation revealed adenomatous polyp.

**Figure 2** Stenosing mass of the proximal sigmoid colon in a 69-year-old female with initial colonoscopy interrupted at the distal sigmoid colon for diverticular disease. **A:** Axial CT image acquired in prone decubitus shows a stenosing lesion of the proximal sigmoid colon with CT findings suspicious for malignancy: eccentric wall thickening, "shoulder sign", absence of pericolonic fat stranding; **B:** Coronal oblique multiplanar reformation shows the lesion in the sigmoid colon; **C:** Endoluminal CT image shows the passage from the normal colonic wall to the stenosis; **D:** Surgical specimen from left hemicolectomy shows a stenosing lesion of about 5 cm in the proximal sigmoid colon with marked wall thickening due to advanced diverticular disease confirmed at histological evaluation.

were respectively 83.3% and 83.3% for polyps greater or equal to 10 mm, 77.8% and 85.7% for polyps of 6-9 mm, 66.7% and 50% for polyps smaller than 6 mm.

Diverticular disease was found in 20 subjects (47.6%) and 5 of these subjects (11.9%) showed signs of chronic diverticulitis such as diffuse wall thickening and pericolic fat stranding.

Major extra-colonic findings included aneurysm of the abdominal aorta ( $n = 1$ ), renal masses ( $n = 2$ ), he-

patic focal lesion other than cystic ( $n = 1$ ), splenomegaly ( $n = 1$ ) and pulmonary nodules ( $n = 2$ ).

## DISCUSSION

Due to its natural history CRC is an ideal candidate for screening<sup>[14]</sup>. In fact, most CRC originate from pre-existing adenomatous polyps that, in 10 to 15 years, undergo malignant transformation<sup>[15]</sup>. Likelihood for malignant

transformation is not the same for all adenomas. In particular adenomas equal or greater than 10 mm (advanced adenomas) tend to become malignant after an average of 5.5 years, whereas it is estimated that less than 1% of adenomas smaller than 10 mm contain a cancer<sup>[14]</sup>. Thus, advanced adenoma is a precancerous lesion and should be considered the main target of a screening test for CRC.

In the majority of screening programmes, subjects with positive FOBT are invited to undergo colonoscopy, which can be performed with or without sedation. Colonoscopies without sedation can be incomplete in up to 25% of the cases<sup>[4]</sup> and in our series incomplete colonoscopies were 7.2%. Before adoption of CTC in such cases, we previously performed DCBE.

Several studies showed that DCBE has a low accuracy in detecting colonic neoplasms, with sensitivity for adenomas greater than 9 mm in the range of 45%-50%<sup>[16]</sup>. CTC is more accurate in detecting colorectal neoplasms as shown in some meta-analyses in which the performance of CTC *versus* optical colonoscopy revealed sensitivity in the range of 85%-90% and specificity of about 95% for polyps greater than 9 mm<sup>[17,18]</sup>.

We evaluated the performance of CTC after incomplete colonoscopy in the setting of a large population based screening program with FOBT. In this context, CTC showed its potential for diagnostic assessment, identifying 2 colonic masses, 5 advanced adenomas and 6 smaller adenomas. CTC gave 7 false positive results which led to unnecessary repeat colonoscopy. One false positive was a polypoid lesion of 14 mm of the ascending colon that was visible only on the supine dataset. Four false positive results were for polyps smaller than 6 mm which should not be reported according to current recommendations<sup>[19]</sup>.

The possibility that diverticular disease simulates with colonic masses is well known, as is the fact that the differential diagnosis with cancer can be difficult with CT<sup>[20]</sup>. In our series, CTC detected two colonic masses of the proximal sigmoid colon which showed CT features suspicious for malignancy, but were demonstrated by pathology to be due to diverticular disease in absence of any malignancy. In both cases, initial colonoscopy was interrupted at distal sigmoid colon because of advanced diverticular disease. In the two cases, the endoscopist and the subject decided not to perform a repeat colonoscopy and the subjects were referred to the surgeon to undergo colectomy.

Colonic distension and cleansing were adequate for an accurate examination in the majority of our cases. In some cases, colonic collapse or repletion by fluid or faeces precluded evaluation of the rectum, sigmoid or descending colon. This limitation can be partially overcome by the fact that lower colonic segments are usually examined at initial colonoscopy. Indeed, segments examined by initial colonoscopies were excluded from per-segment analysis.

Almost 50% of 42 patients of our study had diverticular disease which represented an obstacle to complete conventional colonoscopy. Our series showed that

diverticular disease did not seriously compromise colonic distension and evaluation of the proximal colon at CTC.

Previous studies on CTC after incomplete colonoscopy have been conducted<sup>[6-10]</sup>. These studies were inhomogeneous regarding the patients' selection, because they included asymptomatic as well as symptomatic subjects. Our results in terms of PPV, acquired in a selected group of screening subjects, were comparable with those obtained in the largest study on CTC after incomplete colonoscopy conducted by Copel *et al*<sup>[10]</sup>. They reported per-lesion PPV of 91.7% for masses, of 70% for polyps of 10 mm or greater, and of 30.4% for polyps of 6-9 mm<sup>[10]</sup>. In our small group of subjects, we considered, altogether masses and polyps greater than 9 mm obtaining a similar result (PPV of 87.5%). Our better results for medium sized polyps (6-9 mm) with a per-lesion PPV value of 77.8% might be due to thinner collimation for CT scanning and double reading of the examinations we utilize.

We observed a significant number of false positive results which led to unnecessary repeat colonoscopy. The use of faecal tagging should reduce the number of false positive, enabling a better distinction between polyps and faecal residues, as showed in a series of CTC after incomplete colonoscopies<sup>[9]</sup>.

Our study had limitations. First, it was carried out on a small series of subjects. Second, repeat colonoscopy was conducted with segmental blinding, and this could have increased the number of false positive results of the CTC. Third, since subjects with negative CTC did not undergo further examinations, we could not evaluate sensitivity and specificity of CTC with respect to optical colonoscopy.

In conclusion, in the context of a population-based screening program for CRC based on FOBT, CTC showed a high per-segment and per-lesion PPV for colonic masses and polyps greater than 9 mm. Therefore, CTC has the potential to become a useful technique for evaluation of the non-visualized part of the colon after incomplete colonoscopy and should replace DCBE.

## ACKNOWLEDGMENTS

We thank Mr. Graziano Giannini, radiographer, for his collaboration in performing CTCs.

## COMMENTS

### Background

Colorectal cancer (CRC) is a relevant neoplastic disease for its high incidence and mortality. Due to its natural history CRC is suitable for screening. Screening with faecal occult blood test (FOBT) reduces mortality from CRC. Subjects with positive FOBT are usually examined by colonoscopy which can be incomplete.

### Research frontiers

Computed tomography colonography (CTC) is a non-invasive imaging technique with a high sensitivity and specificity in the diagnosis of colonic cancer and polyps equal or greater than 10 mm, which are the target for screening. Therefore, it might represent a second step examination before colonoscopy to examine subjects with positive FOBT.

### Innovations and breakthroughs

This study on CTC after incomplete colonoscopy was conducted in the frame of a population based screening program. Previous reports on this topic were car-

ried out in heterogeneous samples of symptomatic and asymptomatic subjects or patients with known colonic pathology.

### Application

In the context of a screening program with FOBT, CTC has high positive predictive value (PPV) for colonic masses or polyps equal or greater than 10 mm and should replace double contrast barium enema (DCBE) for evaluation of the non visualized part of the colon after incomplete colonoscopy.

### Terminology

CTC is a thin slice CT scan of the abdomen after adequate bowel preparation and colon insufflation in which data are reconstructed providing axial, multiplanar, and endoluminal views (virtual colonoscopy), in order to visualize colonic wall. Colonoscopy is the more accurate technique to evaluate colonic internal surface and it is performed passing a flexible tube with fiber optic through the anus. FOBT is a chemical test that can detect tiny traces of blood in the stool that may indicate the presence of CRC.

### Peer review

This paper shows the usefulness of CTC after insufficient colonoscopy in order to detect colorectal lesions. It was conducted as a part of population-based screening programme of CRC. It's an interesting study.

placed in metabolic cages and, at the end of the experiment, blood and urine samples were obtained. Histology and hydroxyproline content were analyzed in liver and renal tissue.

**RESULTS:** Rats with 2 wk of BDL increased free water clearance ( $P = 0.02$ ), reduced urinary osmolality ( $P = 0.03$ ) and serum creatinine ( $P = 0.01$ ) in comparison to the sham group. In contrast, rats at 6 wk of BDL showed features of HRS, including significant increase in serum creatinine and reductions in creatinine clearance, water excretion and urinary sodium concentration. Rats with 4 wk of BDL exhibited an intermediate stage of renal dysfunction. Progressive hepatic fibrosis according to post-procedure time was confirmed by histology. The increased levels of liver hydroxyproline contrasted with the absence of structural changes in the kidney, as assessed by histology and unchanged hydroxyproline content in renal tissue.

**CONCLUSION:** Our data show that BDL produced progressive renal dysfunction without structural changes in the kidney, characterizing HRS. The present model will be useful to understand the pathophysiology of HRS.

### Abstract

**AIM:** To evaluate in bile duct ligated rats whether there were progressive alterations of renal function without changes in histopathology.

**METHODS:** Male Wistar rats were submitted to sham-surgery or bile duct ligation (BDL) and divided according to the post-procedure time (2, 4 and 6-wk). To determine renal function parameters, rats were

### INTRODUCTION

Hepatorenal syndrome (HRS) has been defined as a progressive renal failure that occurs in patients with chronic liver disease and advanced hepatic failure in

the absence of any apparent clinical cause for renal insufficiency<sup>[1,2]</sup>. HRS represents the final stage of a process that gradually reduces the renal blood flow and the glomerular filtration rate (GFR) due to a marked renal vasoconstriction<sup>[1,4]</sup>. Despite the severity of renal failure, no significant histological abnormalities are found in the kidneys.

There are many experimental models to induce hepatic fibrosis<sup>[5]</sup>. However, none of them has been evaluated systematically as a model of hepatorenal syndrome. The two most frequently used experimental models of liver disease are the administration carbon tetrachloride, and the common bile duct ligation (BDL)<sup>[6]</sup>. The main advantage of BDL is to allow the study of renal function alterations in a short period of time with lower mortality rates than the administration of carbon tetrachloride<sup>[6]</sup>. In addition, this model mimics clinical conditions characterized by obstructive jaundice, such as biliary atresia and choledocal cysts<sup>[5,6]</sup>. In this study, we aimed to systematically evaluate renal function parameters, renal histology and tissue hydroxyproline content at different time-points of BDL.

## MATERIALS AND METHODS

### **Animals and experimental design**

Male Wistar rats weighing 220 to 300 g were maintained under temperature controlled conditions with an artificial 12-h light-dark cycle, and were allowed standard chow and water ad libitum. Hepatic fibrosis was induced by BDL. Briefly, the animals were anesthetized with intraperitoneal administration of 2.5% tribromoethanol (1 mL/100 g). A 1.5 cm midline incision was made and the common bile duct was located, double ligated with 4-0 silk and sectioned as previously described<sup>[7]</sup>. Our Ethics Committee approved all animal procedures.

### **Experimental protocol**

Animals were randomized into the following groups: sham-operated and those that underwent BDL. Sham-operated rats ( $n = 17$ ) underwent a midline incision and manipulation of the bile duct without ligation and were evaluated at various times following sham-surgery: 2-wk ( $n = 5$ ), 4-wk ( $n = 7$ ), and 6-wk ( $n = 5$ ). Bile duct ligated rats were also evaluated at the same post-procedure times: 2-wk ( $n = 8$ ), 4-wk ( $n = 7$ ) and 6-wk ( $n = 7$ ). Three days before blood sampling, all rats were placed in metabolic cages to measure urinary volume, water and food intake. At the end of the experiment, animals were weighed and blood samples were collected by decapitation to determine renal function parameters. Liver and renal tissue fragments were also obtained for histology and hydroxyproline determination.

### **Biochemical parameters**

Serum and urinary levels of creatinine (Jaffe method) were measured using Katal Kit and a semi-automatic analyzer BIO 2000. Urinary and serum osmolality were determined using a freezing point osmometer (Fiske

Osmometer, Fiske Ass. Inc., MA, USA). Serum and urinary levels of sodium and potassium were measured by flame photometry (Corning 400, Corning Inc., NY, USA).

### **Hydroxyproline determination**

Fragments (200 mg) of liver and renal tissue were removed for hydroxyproline determination as an indirect measure of tissue collagen content, as described by Reddy & Enwemeka<sup>[8]</sup>. Briefly, tissue fragments were homogenized in saline 0.9%, frozen and lyophilized. The assay was performed with 40 mg of the lyophilized tissue that was subjected to alkaline hydrolysis in 300  $\mu$ L plus 75  $\mu$ L NaOH 10 mol/L at 120°C for 20 min. An aliquot of 50  $\mu$ L of the hydrolysed tissue was added to 450  $\mu$ L of chloramine T oxidizing reagent (Chloramine T 0.056 mol/L, n-propanol 10% in acetate/citrate buffer pH 6.5) and allowed to react for 20 min. A hydroxyproline standard curve with the highest concentration of 400  $\mu$ g was prepared likewise. Colour was developed by the addition of 500  $\mu$ L of the Ehrlich reagent (p-dimethylaminobenzaldehyde, 1 mol/L) diluted in n-propanol/perchloric acid, 2:1 v/v). The samples then were centrifuged for 1500 g for 10 min at 4°C. An aliquot of 200  $\mu$ L of the supernatant was transferred to 96-well plates and the absorbance was read at 550 nm.

Five-micrometer sections of formalin-fixed and paraffin-embedded right liver lobes and kidney slices were processed routinely with hematoxylin-eosin, Masson's trichrome and ammoniac silver of Gomori. A single pathologist, blinded to experimental protocol, analyzed all liver and kidney fragments using light microscopy. The degree of liver fibrosis was measured based on the semi-quantitative scoring described by Ishak *et al*<sup>[9]</sup>.

### **Statistical analysis**

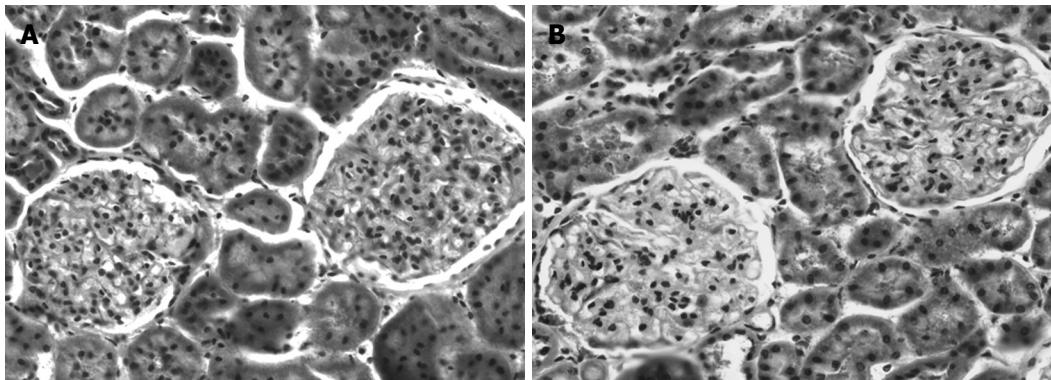

The data are expressed as mean  $\pm$  SD. Analysis of variance followed by Student Newman Keuls test was used to compare the differences between groups. Values of  $P < 0.05$  were considered significant.

## RESULTS

### **Morphological studies**

Because there did not appear to be any difference in the many variables studied in the sham group at two, four and 6 wk after sham operation, results from all the sham-operated groups were pooled for ease of presentation.

Hepatic fibrosis progressed over the time after BDL. Based on Ishak's score, the following score values for each group of BDL rats were obtained: sham operated rats scored 0 (normal hepatic architecture), 2-wk rats scored 3 (fibrous expansion of portal tracts with occasional portal-to-portal bridging), 4-wk rats scored 4 (fibrous expansion of portal tracts with marked portal-to-portal and portal-to-central bridging) and, at 6-wk, definite cirrhosis occurred (Score 6). In sharp contrast, as shown on Figure 1, no alterations in renal histology were observed in any bile duct ligated rats when compared to sham-operated animals.

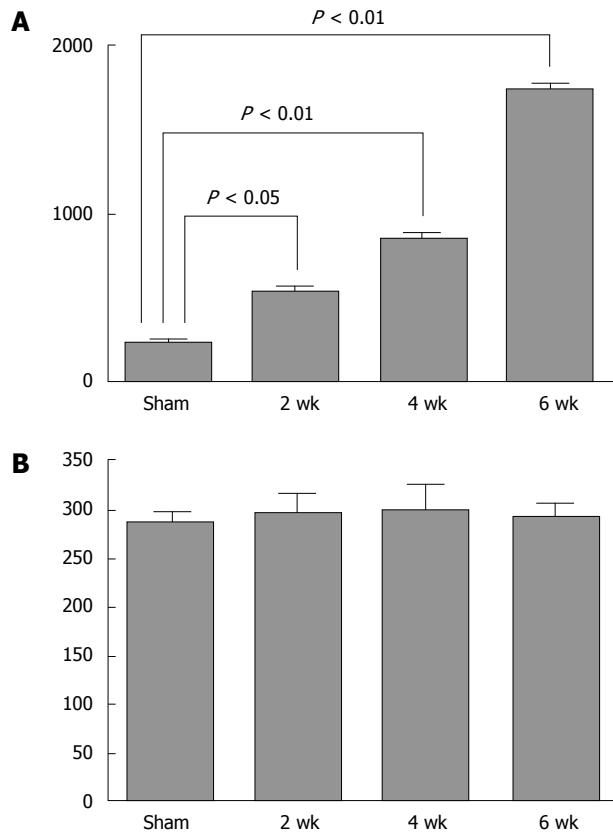

**Figure 1** Representative micrographs of the renal slices from bile duct ligated (BDL) and sham operated rats (HE,  $\times 100$ ). **A:** Sham operated rat with normal kidney; **B:** BDL rat at 6-wk also showing the absence of kidney histological alterations.

### Hydroxyproline determination

The progression of collagen deposition in liver tissue was also confirmed by the measurement of tissue hydroxyproline content at different time-points after bile duct ligation. Sham-operated rats represented the basal values of hydroxyproline content from a normal liver ( $235 \pm 45 \mu\text{g}/\text{mg}$  of liver tissue). As expected, according to the time after BDL, hydroxyproline content progressively increased in liver tissue, reaching values significantly higher than the control group in all time-points (2 wk:  $540 \pm 60 \mu\text{g}/\text{mg}$ ; 4 wk:  $863 \pm 57 \mu\text{g}/\text{mg}$ ; 6 wk:  $1735 \pm 73 \mu\text{g}/\text{mg}$ ;  $P = 0.0001$  for all comparisons, Figure 2A). The highest amount of liver hydroxyproline was detected in animals at 6 wk of BDL, indicating the significant degree of liver fibrosis (Figure 2A). Hydroxyproline content in renal tissue remained unchanged in sham-operated animals ( $288 \pm 31 \mu\text{g}/\text{mg}$  of kidney tissue) as well as in all groups of bile duct ligated rats (2 wk:  $298 \pm 55 \mu\text{g}/\text{mg}$ ; 4 wk:  $300 \pm 73 \mu\text{g}/\text{mg}$ ; 6 wk:  $294 \pm 39 \mu\text{g}/\text{mg}$ ;  $P > 0.05$  for all comparisons, Figure 2B). The results obtained with histological analysis and tissue hydroxyproline determinations showed the absence of structural changes in renal tissue during the development of liver fibrosis.

### Renal function parameters

Despite the well-preserved renal structure, important changes in renal function were clearly evidenced in bile duct ligated rats, as shown in Table 1 and Figure 3. As shown in Table 1, the 24-h urinary volume was significantly higher in animals with 4 and 6 wk of BDL compared to sham group. On the other hand, the 24-h urinary volume of 2 wk animals did not differ from sham group. Despite having the same urinary volume as sham-operated animals, rats with 2 wk of BDL exhibited an attempt to compensate the hydroelectrolyte imbalance produced by hepatic dysfunction. These animals significantly increased water excretion (Figure 3A,  $P = 0.02$ ), and reduced the urinary osmolality ( $P = 0.03$ ) and serum creatinine levels ( $P = 0.01$ ) in comparison to sham-operated rats (Table 1). An elevation in potassium excretion was also observed. However, the fractional excretion of this ion was unchanged in comparison with the sham group. Rats with 4 wk of BDL presented a progression in renal dysfunction as shown by a significant increase in serum creatinine ( $P = 0.01$ ) and a reduc-

tion in urinary sodium concentration ( $P = 0.02$ ) when compared to sham-operated animals (Table 1). Rats with 6 wk of BDL clearly developed hepatorenal syndrome as revealed by a complete deterioration in renal compensatory mechanisms. These animals presented high levels of serum creatinine, a pronounced decrease in creatinine clearance (Figure 3B,  $P = 0.01$ ), and an important impairment in water excretion (Figure 3A,  $P = 0.02$ ) when compared to sham operated and 2 wk of BDL animals ( $P < 0.05$  for all comparisons, Table 1). Rats with 4 and 6 wk of BDL also presented dilutional hyponatremia and an elevation of fractional excretion of potassium when compared to sham group and animals with 2-wk of BDL ( $P < 0.05$  for both comparisons, Table 1). It

should be pointed out that body weights were similar in all groups at the beginning of the experimental protocol and no differences were observed in water and food intake (data not shown). No ascites was observed in the rats at 2-wk after BDL. In contrast, animals at 4 wk and 6 wk clearly exhibited ascites, also indicating the presence of water retention.

## DISCUSSION

This study supports the concept that the progression of hepatic damage promotes the manifestation of HRS. Indeed, the duration of BDL was positively correlated with renal function disarrangement without alterations in renal histology.

Animals at 2 wk of BDL seemed to be in a compensated state of hepatic injury, without ascites and alterations in water balance. These rats exhibited well-preserved renal function, suggesting that the homeostatic compensatory mechanisms remained intact at this moment of hepatic damage. Of note, serum creatinine was reduced in this group even when compared to sham operated animals. The creatinine clearance was slightly higher than in sham group, but significantly increased when compared to rats at 6 wk of BDL. These animals were also able to excrete water by increasing free water clearance. For this reason, serum osmolality remained at normal range and urinary osmolality was reduced when compared to sham. It has been reported that, at early stages of hepatic injury, as observed in animals with 2 wk of BDL, renal compensatory mechanisms against fluid retention still remain operating<sup>[1,3,4]</sup>. However, the progression of the process culminates in a non-compensated state by compromising the negative feedback loops of different regulatory systems<sup>[1,3,4]</sup>. Consistent with this, 4 wk after BDL, the rats already presented ascites, changes in water balance and an initial disturbance in renal function, revealed by sodium retention and an increase of the serum creatinine levels. After 6 wk of BDL, the hepatic damage evolved into a non-compensated stage with features of HRS<sup>[1,3,4]</sup>, including reduction in creatinine clearance and an evident fluid retention associated with significant reductions of the serum osmolality and of the free water clearance.

Clinical studies have attempted to delineate the natural history of cirrhotic patients with ascites with

respect to the development of HRS. Factors predictive for the development of HRS include intense urinary sodium retention, dilutional hyponatremia, and increased activity of systemic vasoconstrictors<sup>[10]</sup>. These features were clearly evidenced in our bile duct ligated rats, mostly at 6 wk. However, some characteristics of bile duct ligated rats are not typically observed in HRS seen in clinical medicine. While patients with HRS are usually oliguric<sup>[1,3]</sup>, our bile duct ligated animals at 4 wk and 6 wk increased the urinary volume when compared to the sham-operated group. It should be mentioned that, despite the elevation in the urinary volume, these animals still presented water and sodium retention, according to the observed reductions in free water clearance and in urinary sodium concentration. The so-called polyuria was not enough to excrete the whole amount of water and sodium retained by rats with 4 wk and 6 wk of BDL. Indeed, most investigators have used the BDL model to study pathological sodium retention<sup>[6,11]</sup>, which occurs in liver disease. Another possible explanation for this apparently elevated urinary volume is the well-known effect of circulating bile acids in kidney function during obstructive jaundice<sup>[12,13]</sup>. Acute cholaemia may cause volume depletion by increasing urinary salt loss, which, in turn, may aggravate the direct nephrotoxicity of circulating bile compounds<sup>[12]</sup>. *In vitro* addition of bile acids or bilirubin at concentrations comparable to those found in the plasma of BDL rats, to a mixture of reactive enzymes strongly inhibited most, particularly mitochondrial oxidative phosphorylation<sup>[13]</sup>. Thus, high concentrations of these substances in the blood may explain the development of renal failure during liver disease, and its reversibility when liver function returns to normal<sup>[13]</sup>. It also should be noted that the normal kidney histology and the unchanged levels of renal hydroxyproline content also favors the existence of HRS, a syndrome characterized by functional rather than structural disarrangement of the kidneys in presence of progressive liver disease<sup>[1,4]</sup>. Despite the differences in renal parameters in HRS in our system and in HRS observed in humans, this model seems to be very useful to evaluate the progression of renal dysfunction in hepatic diseases, since BDL rats are normally able to maintain a residual diuresis, probably allowing their long-lasting survival<sup>[6]</sup>.

The pathophysiology of HRS is still poorly understood. Hypoperfusion of the kidney due to active renal vasoconstrictors has been considered the hallmark of HRS<sup>[1-4]</sup>. In this context, Ozdogan and co-workers<sup>[14]</sup> conducted an elegant study that evidenced the role of endothelin-1, a potent vasoconstrictor, in an experimental model of HRS, which was induced by endotoxin administration to carbon tetrachloride-treated rats. In addition, the renin-angiotensin system (RAS) and the sympathetic nervous system, some of the major systems with a vasoconstrictor effect in the renal circulation, have been suggested as potential mediators of renal vasoconstriction in HRS<sup>[4,11,15]</sup>. During hepatic damage, systemic vasodilation and hyperdynamic circulation have been observed<sup>[16]</sup>, which

in turn promote an increase in sympathetic nervous activity, plasma renin activity (PRA), angiotensin II and aldosterone levels, especially in the presence of HRS<sup>[3,4]</sup>. It is well known that angiotensin II is one of the most powerful regulators of sodium excretion, operating through extrarenal as well as intrarenal mechanisms<sup>[17-19]</sup>. Some authors believe that, at the early stages of hepatic injury, the renal effects of angiotensin II represent a compensatory mechanism against the drop in organ perfusion pressure<sup>[3,4]</sup>. However, the development of renal impairment leading to HRS would occur as a result of an uncontrolled activation of systemic vasoconstrictor factors such as angiotensin II, sympathetic nervous system, endothelin and others that could not be counteracted by vasodilators such as nitric oxide, prostaglandins, bradykinin and maybe angiotensin-(1-7)<sup>[3,4]</sup>.

In this regard, we recently have shown that bile duct ligated rats presented different profiles of circulating RAS expression according to the progress of hepatic damage<sup>[20]</sup>. At early stages (1 wk and 2 wk of BDL), animals exhibited an elevation of angiotensin II and angiotensin-(1-7) levels, without concomitant changes in PRA and angiotensin I. With the progression of liver fibrosis (4 wk and 6 wk of BDL), RAS profile changed toward an overall enhancement of the PRA and the circulating levels of angiotensin I, angiotensin II and angiotensin-(1-7)<sup>[20]</sup>. According to these data<sup>[20]</sup>, we hypothesize that not only angiotensin II, but also angiotensin-(1-7) may possibly participate in the regulation of renal blood flow, glomerular filtration, and tubular transport in liver diseases. However, we still do not know how angiotensin-(1-7) could affect renal function in BDL rats. It has been clearly demonstrated that angiotensin-(1-7) also exerts complex renal actions<sup>[19,21,22]</sup>. Our group and others detected *in vivo* and *in vitro* antidiuretic effects of angiotensin-(1-7) by increasing fluid reabsorption<sup>[23-26]</sup>. These renal actions could contribute to sodium and water retention observed in bile duct ligated rats. In contrast, other studies showed that angiotensin-(1-7) has natriuretic and diuretic effects by inhibiting sodium reabsorption<sup>[27,28]</sup>. In addition, angiotensin-(1-7) seems to be involved in renal hemodynamic regulation by opposing the vasoconstrictive effects of angiotensin II in glomerular vessels<sup>[29,30]</sup>. However, it is difficult to know if the changes in the components of the RAS preceded or were caused by the decline in renal function. The liver, or maybe also the kidney, could produce angiotensin peptides, which, in turn, act either as systemic hormones or as locally generated factors. Accordingly, Paizis *et al*<sup>[31]</sup> detected an up-regulation of angiotensin converting enzyme 2 (ACE2), the main enzyme responsible for angiotensin-(1-7) synthesis<sup>[22]</sup>, in liver tissue from cirrhotic patients and bile duct ligated rats. Herath *et al*<sup>[32]</sup> showed increased expression of angiotensin-(1-7) receptor, the Mas receptor<sup>[33]</sup>, in experimental biliary fibrosis, suggesting a role for ACE2-angiotensin-(1-7)-Mas axis in liver injury.

Finally, the overall state of sodium and water

balance and the effect of many circulating and/or local regulators may influence the direction of the observed renal actions in bile duct ligated rats. Further studies are necessary to clarify the mechanisms involved in the development of HRS in experimental cirrhosis. However, our data indicate that BDL emerges as a good model for the study of HRS.

## COMMENTS

### Background

Hepatorenal syndrome (HRS) has been defined as a progressive renal failure that occurs in patients with chronic liver disease and advanced hepatic failure in the absence of any apparent clinical cause for renal insufficiency. HRS corresponds to a functional alteration without histological changes in kidney tissue. There are many experimental models to induce hepatic fibrosis. However, none of them has been systematically evaluated as a model of hepatorenal syndrome.

### Research frontiers

In this study, we aimed to systematically evaluate in bile duct ligated rats at different post-procedure time-points, whether there were alterations of renal function without changes in histopathology.

### Innovations and breakthroughs

Renal dysfunction without histological changes occurred according to the duration of bile duct ligation (BDL) in the absence of any additional treatment. Animals at 2 wk of BDL exhibited a well-preserved renal function, suggesting that the renal homeostatic compensatory mechanisms remained intact at this moment of hepatic damage. However, the progression of the process culminates in a non-compensated state, as already shown by rats at 4 wk of BDL with ascites, changes in water balance, sodium retention and increased serum creatinine levels. After 6 wk of BDL, features of hepatorenal syndrome (HRS) became evident, including reduction in creatinine clearance and fluid retention without alterations in renal histology and renal tissue collagen content. Our data showed that BDL seems to be a helpful model for the study of HRS, since it mimics clinical conditions characterized by obstructive jaundice, such as biliary atresia and choledochal cysts.

### Applications

The mechanisms for the renal changes observed in BDL animals remain unclear; however, this study indicates that BDL emerges as a good model for further studies of HRS and its treatment.

### Peer review

This study is a well-designed experimental work, which tries to define an experimental model for hepatorenal syndrome.

citrulline levels in blood were studied.

**RESULTS:** In rats receiving CCE, villus lengthening, crypt depth, mucosal DNA and protein levels, intestinal proliferation, and serum citrulline, protein and albumin levels were found to be significantly higher than those in control group. Apoptosis in CCE treated rats was significantly reduced when compared to EN group rats.

**CONCLUSION:** CCE has beneficial effects on intestinal adaptation in experimental SBS.

## INTRODUCTION

Short bowel syndrome (SBS) is a clinical condition characterized by diarrhea, dehydration, electrolyte imbalance, malabsorption, and progressive malnutrition related to a wide resection of the small intestine<sup>[1-3]</sup>. In the pediatric population, necrotizing enterocolitis, gastroschisis, omphalocele, intestinal atresia and Hirschsprung disease, and in the adults mesenteric vascular occlusion, inflammatory bowel disease (IBD) and malignancies, are the most common reasons for performing extensive resection of the intestine<sup>[2]</sup>. Retaining intestinal autonomy depends on the length of remaining intestine and the adaptive capacity of the intestinal remnant. Some compensatory changes occur after massive intestinal resection in order to maintain adequate digestion. Restoration of the absorptive surface area and functional capacity result in morphologic and functional improvement. Structural adaptation after

## Abstract

**AIM:** To evaluate the effects of chlorella crude extract (CCE) on intestinal adaptation in rats subjected to short bowel syndrome (SBS).

**METHODS:** Wistar rats weighing 230-260 g were used in the study. After anesthesia a 75% small bowel resection was performed. Rats were randomized and divided into groups. Control group ( $n = 10$ ): where 5% dextrose was given through a gastrostomy tube, Enteral nutrition (EN) group ( $n = 10$ ): Isocaloric and isonitrogen EN (Altraq, Abbott, USA), study group ( $n = 10$ ): CCE was administrated through a gastrostomy tube. Rats were sacrificed on the fifteenth postoperative day and blood and tissue samples were taken. Histopathologic evaluation, intestinal mucosal protein and DNA levels, intestinal proliferation and apoptosis were determined in intestinal tissues, and total protein, albumin and

intestinal resection involves intestinal dilatation and elongation, villus lengthening, and increasing crypt cell proliferation. These changes result in a marked increase in the intestinal absorptive surface area<sup>[4]</sup>. The functional adaptation mechanism in the remnant intestine is still not entirely understood. Regulation of intestinal adaptation is an extremely complicated process influenced by many factors<sup>[5]</sup>. Some of these factors are nutrients, gastrointestinal secretions, hormones, and a variety of polypeptides stimulating growth capability<sup>[6]</sup>. The most important therapeutic objectives in the management of SBS are maintenance of the patient's calorie intake and nutritional status. Optimal intestinal rehabilitation should enhance the intestinal adaptation and shorten the period of intestinal recovery<sup>[7,8]</sup>; Yet, today no such optimal therapy exists. However, some enteral nutrition (EN) products are used for energy supports in order to reduce demand for total parenteral nutrition (TPN). The prospective, randomised and double blind clinical study of Byrne and colleagues<sup>[9]</sup> showed that glutamine, growth factor and optimum diet could reduce the length of TPN support. O'Dwyer and colleagues<sup>[10]</sup> emphasized that glutamine enriched TPN significantly improved the mucosal recovery and adaptation. New treatment alternatives to the current ones are still under research in experimental and clinical studies.

Chlorella is a species of green algae that grows in fresh water. The name Chlorella is taken from the Greek word meaning "small, fresh green", it contains the highest level of chlorophyll in the world when compared with all other nutrients. It has been consumed as a food source for centuries mainly in Japan and other Far East countries, and suggestion of its healing properties has enhanced consumption<sup>[11,12]</sup>. Biotechnological processing for single cell protein production is the most emphasized area of chlorella studies. Because of high protein ingredients, chlorella was considered to be a protein source in the beginning, but later it was seen as a "functional nutrient" first in Japan then Europe and America, and today it is accepted that chlorella is rich in nutritional ingredients<sup>[11,12]</sup>. Active ingredients of chlorella are: 61.6% protein, 12.5% fat, 13.7% carbohydrate, trace elements (Al, Ze, P, Ca, Mg, Mn, Ni, Se), vitamins (carotene, beta-carotene, thiamine, B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, C, D, E, K), nucleic acids (RNA and DNA), and various enzymes<sup>[12,13]</sup>. In our previous research, we showed that feeding with chlorella crude extract (CCE) has beneficial effects on malnourished rats which had undergone colon anastomosis<sup>[13]</sup>.

In the current study, we aimed to evaluate the efficacy of chlorella extract which is rich in amino acids, beta carotene, and trace elements on intestinal adaptation in SBS.

## MATERIALS AND METHODS

All procedures were conducted according to recommendations of the Animal Research Committee at Gazi University in Ankara, Turkey. Wistar rats weighing 230-260 g were used in the study. The rats were

maintained at 23°C in a 12 h light dark cycle, with free access to water and standard rat chow for a week. Eight hours prior to the start of experiments, rats were deprived of food while drinking water was available ad libitum. Animals were anesthetized by an intramuscular injection of 40 mg/kg ketamine (Ketalar®, Parke Davis, Eczacibasi, Istanbul, Turkey) and 5 mg/kg xylazine (Rompum®, Bayer AG, Leverkusen, Germany). Rats underwent central venous catheterization by inserting the catheter into the right external jugular vein, and were operated on under sterile conditions. A gastrostomy tube was placed for enteral feeding before the 75% small bowel resection. A 3 cm midline laparotomy was performed and intestinal transections were done 15 cm above the ileocecal junction and 5 cm from the duodenojejunal transition. Interrupted sutures of 7-0 PDS (Ethicon®, USA) were used for end to end bowel anastomosis. The venous catheter and the gastrostomy tube were tunneled subcutaneously through the dorsal cervical area, and attached with special apparatus (Swivel 56-1308; Harvard Apparatus, USA) which has a port and equipped with a spring system just beneath the skin. Before the closure of the abdominal cavity, 3 mL saline was administered intraperitoneally for the fluid resuscitation.

During the postoperative 3 d, rats received 60 kcal non-protein energy and 0.414 g nitrogen total parenteral nutrition (TPN). After postoperative day 4, rats were randomized and divided into the groups below: (1) Sham group: Laparotomy was performed; (2) Control group: 5% dextrose 12 mL/24 h was given to the rats by the gastrostomy tube with the infusion pump; (3) EN group: isocaloric (60 kcal/d) and isonitrogen (0.686 g/d) Alitraq (Abbott, USA) given to the rats through the gastrostomy tube with the infusion pump. Since, Alitraq is the EN product which has the highest amount of glutamine, and research clearly shows that glutamine has beneficial effect in SBS, Alitraq was used for enteral feeding in this study; (4) Study group: rats received CCE (60 kcal/d) through the gastrostomy tube by the infusion pump. In the sham, both EN and study group rats were not allowed to eat solid food, but were free to drink water.

Rats were anesthetized by intraperitoneal injection of 50 mg/kg sodium pentothal before laparotomy. The length of the small bowel was measured from the Treitz to the caecum. After withdrawal of blood samples from vena cava, rats were sacrificed by bleeding. Intestinal resection was quickly performed, and specimens were washed with cold saline. Histopathologic samples were taken from both the jejunal and ileal side of the anastomosis, and the rest of it was weighed.

### **Preparation of the algae extract, its ingredients and its use**

**Culturing and growth conditions:** Collection and isolation of microalgae were made in compliance with Rippka *et al*<sup>[14]</sup>. Microalgae were obtained from GUMACC (Gazi University Microalgae Culture Collection) *Chlorella* sp. C1 were expanded in number by culture in BG11 nutrition medium (blue-green medium 11) at less than 3000 lux light intensity, under illumination for 16 h

and under darkness for 8 h. Algae were harvested after approximately a 15-d production period.

**Preparation of the extracts:** Algal mass from an axenic exponential culture of the microalgae strains grown in BG11 were separated from the culture medium by centrifugation and pellets were dried at 60°C for 24 h. Methanol extracts were prepared according to the methods of Khan *et al*<sup>[15]</sup> and Vlachos *et al*<sup>[16]</sup>, from dry algal mass (ratio 1:15 g/mL) extracted throughout 24 h. After separating the extraction phase, all of the extracts were preserved at 4°C. The *chlorella sp.* extract was resuspended at 1 g/mL in 0.9% sterile saline.

**Ingredients of algae extract and its use:** The dose of algae extract used was 50 g/kg BW/d<sup>[13,15,16]</sup>. The suspension was given *via* oral gavage three times a day in equal doses (each dose was less than 5 mL).

### Biochemical analysis

Serum protein, albumin and blood sugar levels were analyzed from blood samples. The mucosal layers of the intestinal samples were brushed with slides and then weighed. After a homogenization process, mucosal DNA and protein levels were evaluated by the techniques of Chomczynski as described previously<sup>[17]</sup>.

### Serum citrulline levels

Serum citrulline levels were measured by the tandem mass spectrophotometric technique with isotope embedded amino acid standards. The results were expressed as mmol/L.

### Histopathology

Jejunal and ileal tissue samples were fixed in a 10% solution of formaldehyde, and embedded in paraffin wax from which 3-µm-thick sections were mounted on slides. The sections were stained with hematoxylin-eosin

(HE), and mucosal widening, villus length and crypt depth were evaluated.

### Enterocyte proliferation and apoptosis

Crypt cell proliferation was determined using 5-bromodeoxyuridine (BrdU). Twelve hours before sacrifice, 100 mg/kg BrdU was given intraperitoneally to the rats. Sections were stained with anti-BrdU antibodies. Every 10 crypts stained with positive BrdU were calculated as a proliferation index. The TUNEL technique was used for the determination of apoptotic cells.

### Statistical analysis

All values were expressed as mean ± SE and the results were compared by analysis of variance (one-way ANOVA) and Scheffe's post hoc analysis. P < 0.05 was considered statistically significant. Statistical evaluation was carried out using SPSS 11.5 software (SPSS, Chicago, IL, USA).

## RESULTS

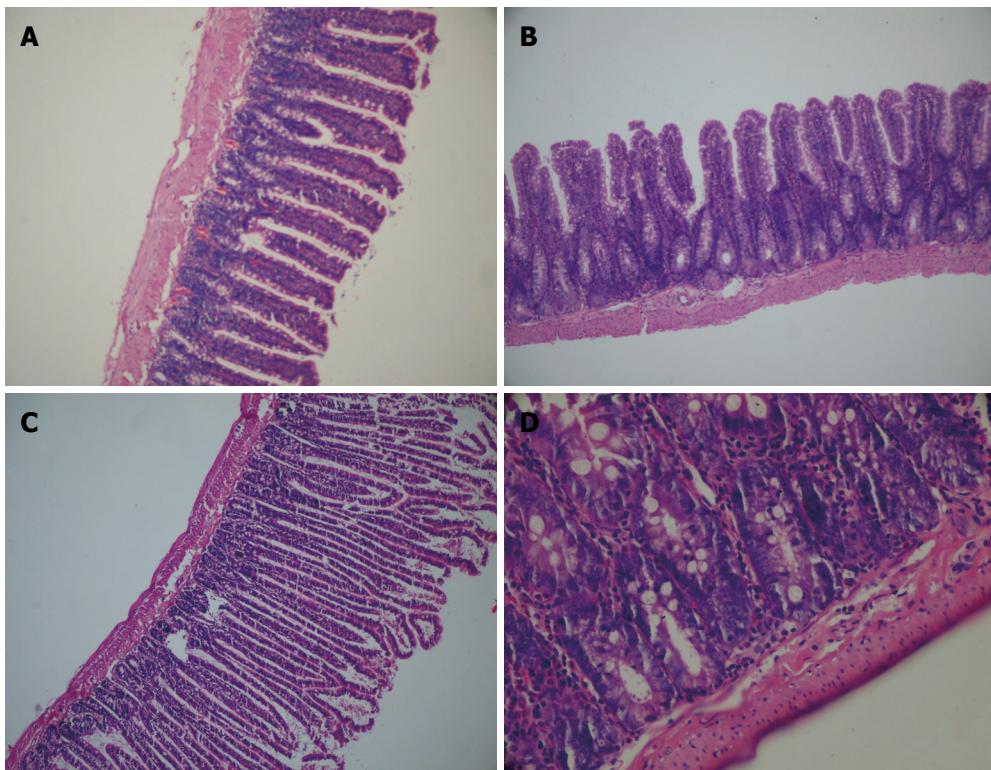

Three rats died during the creation of the SBS, and they were replaced with new ones.

### Weight lost

All rats subjected to SBS lost significant weight when compared with their original weight before the experiment. In the EN and study (CCE) groups, rats lost less weight than the control group (P < 0.05). When they were compared with each other, it was observed that in the CRE group rats lost significantly less weight than the EN group (P < 0.001, Table 1).

### Histopathologic evaluation

In the control group, mucosal widening, villous length, crypt depth and amount of mitosis markedly decreased

**Figure 1** Villi and crypts in the ileum of rats which underwent SBS (HE, x 100): Control group (**A**) and EN group (**B**); **C**: Significant elongation of villi in CCE group (ileum, HE, x 100); **D**: Significant mitotic figures in the crypts in the CCE group (ileum, HE, x 400).

when compared to sham, EN and CCE groups ( $P < 0.05$ ). Jejunal and ileal mitosis number in the EN and CCE groups were significantly higher than those at the control group ( $P < 0.05$ ). The amount of mitosis in both segments of intestine in the CCE group was markedly higher than those in the EN group. Villus length and mucosal widening were not significantly different between the EN and CCE groups, whereas crypt depth was remarkably increased in the CCE group over the others ( $P < 0.05$ , Table 1, Figure 1).

#### Mucosal DNA levels

Mucosal DNA levels significantly decreased in the control group when compared to the other groups. The mucosal DNA levels for EN and CCE groups were found to be remarkably higher than the sham and control groups. Moreover, the same parameters significantly increased in the CCE group when compared to the EN group ( $P < 0.05$ , Table 1).

#### Mucosal protein levels

Ileal mucosal protein levels were significantly higher in the CCE group than all other groups ( $P < 0.05$ ). The mucosal protein levels of the control group were markedly reduced when compared to the other groups ( $P < 0.05$ ). There was no difference between the EN and CCE groups ( $P < 0.05$ , Table 1).

#### Cell proliferation index

The jejunal and ileal cell proliferation indexes were significantly higher in the CRE group than all other

groups ( $P < 0.05$ ). The cell proliferation indexes in the control group were increased when compared to the sham group while they were significantly lower than the EN and CCE groups ( $P < 0.05$ , Table 1).

#### Apoptotic index

Apoptosis in the control group was markedly increased compared to other groups. The apoptotic index in subjects fed with CCE was significantly lower than those in the EN and control groups ( $P < 0.05$ ), and it was found to be insignificantly higher than the apoptotic indexes of the sham group ( $P < 0.05$ , Table 1).

## DISCUSSION

Loss of small bowel function caused by extended intestinal resection results in malabsorption and fluid and electrolyte imbalances<sup>[1]</sup>. In the early postoperative period the first priority of SBS treatment is adequate resuscitation of volume and electrolyte disturbances. When these parameters are stabilized, parenteral nutrition can be started<sup>[1-3]</sup>. Although parenteral nutrition causes a significant decrease in the mortality rates of SBS, the time required for optimal TPN therapy is too long and has many disadvantages and severe complications<sup>[4-7]</sup>. Searching for new treatment methods for increasing bowel adaptation mechanisms in order to reduce complications of SBS is an area which many recent studies concentrated on. The hormones; bombesin, growth factors, insulin like growth factors, ghrelin, leptin, and EN products; glutamine, fish oil (omega-3 fatty acids), immune

nutrients and fibers, have been investigated, and found to have beneficial effects on bowel adaptation mechanism in SBS<sup>[8-10,18]</sup>. We designed our research on the use of species of chlorella algae for healing effects because of its high protein, nucleic acid, antioxidant and fiber content<sup>[11,12]</sup>. In this study, it was observed that enteral feeding with CCE has beneficial effects on intestinal adaptation in rats with SBS. Lengthening of the intestinal villus, increasing crypt depth, intestinal proliferation, mucosal protein, DNA, serum citrulline, protein and albumin levels, and decrease of apoptosis were found in the study. This is the first study to demonstrate the healing effects of chlorella on SBS.

When we look at the current literature, we can find few trials of different algae species<sup>[19,20]</sup>. Tokida ameliorated murine chronic colitis through down-regulation of interleukin-6 production on colonic epithelial cells. Sakai *et al*<sup>[21]</sup> have also described that *Sargassum horneri*, a marine brown algae, increases Cl<sup>-</sup> absorption in isolated rat colon by activation of leukotrienes. In another study, it was shown that algae extract can reduce inflammation and ultrastructural changes in rats colitis induced by acetic acid<sup>[20]</sup>. Gonzalez *et al*<sup>[22]</sup>, demonstrated that intestinal myeloperoxidase enzyme levels remarkably decrease in response to algae extract. Dvir and colleagues<sup>[23]</sup> suggested that red algae can regulate intestinal physiology and lipid metabolism, it can also be used as a functional nutrient. The same investigators claimed that algae-derived polysaccharides can increase jejunal muscular hypertrophy, and algae fiber can lengthen both colon and small bowel and increase colonic transit time by 44% compared to control group. Significant increases in mucosal villous lengthening and crypt depth due to the effects of micro-algae were observed in the same study. Although it is very rare, we can see the use of algae for SBS in the literature.

To our knowledge, if fluid resuscitation is not subsequently provided following the surgery, mortality can be significantly high in animal models of SBS<sup>[1]</sup>. For this reason, we inserted an intravenous line in rats, before starting TPN, and we resuscitated them with iv fluid for a short period of time. After the third postoperative day, rats received dextrose in addition to EN and CCE. They were weighed daily until the end of the experiment. All rats subjected to SBS lost significant weight. However, weight lost in rats fed with EN and CCE was markedly less than the control group. Though both EN and CCE resulted in weight gain in rats, the CCE group rats gained more weight than the EN group. Both nutritional solutions have almost the same energy distribution, but CCE has higher nucleotide content, and better absorptive and adaptive capacity than the EN, so rats gained more weight in the CCE group than those in other groups. In our previous study, we observed that CCE increases weight gain in malnourished rats.

Recent articles feature the amino acid citrulline, the best marker of intestinal absorptive capacity in SBS due to massive intestinal resection<sup>[3-7]</sup>. The clinical study of Rhoads *et al*<sup>[24]</sup>, found that there was a correlation between serum citrulline levels and enteral tolerance, and

levels of serum citrulline could be used as a predictive test. In our study, fifteenth day serum citrulline levels were significantly lower than those in other groups. However, the CCE group serum citrulline levels were markedly higher than those in the control and EN groups. Another result of absorptive and adaptive responses was the significant increase in serum protein and albumin levels in CCE fed rats when compared to control rats. High amino acid and nucleotide levels in CCE could be responsible for these effects.

Mucosal DNA and BrdU proliferation index for evaluating intestinal proliferation rate were found significantly reduced in SBS rats when compared to control group rats. Mucosal DNA and intestinal proliferation index were markedly higher in CCE and EN groups than those in control group. These parameters also increased in the CCE group compared to the EN group. Excessive amount of nucleic acid, protein, vitamin and other substances in CCE may be responsible for these outcomes.

In conclusion, enteral administration of CCE increases intestinal adaptation and proliferation in experimental SBS. The current study provides preliminary data for future research. More studies are needed to investigate the use of algae species growing in water as a clinical nutrition product.

## COMMENTS

### Background

Chlorella is a species of green algae that grows in fresh water. The name chlorella is taken from the Greek word meaning "small, fresh green", it contains the highest level of chlorophyll in the world when compared with all other nutrients. It has been consumed as a food source for centuries mainly in Japan and other Far East countries, and suggestion of its healing properties has enhanced consumption. However, there is little data about the use of chlorella in disease, which is investigated in this experimental study.

### Research frontiers

Short bowel syndrome (SBS) which affects both children and adults is a generally seen disease. The basis of treatment for this disease is enteral and intravenous nutrition. Several enteral nutrition (EN) products have been used for SBS. The aim of this study is to evaluate the effect of chlorella in SBS in rats.

### Innovations and breakthroughs

In this study, positive effects of orally given chlorella were seen. This is the first study on this subject. It was seen that chlorella increased intestinal adaptation in SBS.

### Applications

This experimental study will guide new experimental and clinical studies. Chlorella is an algae which is widely found in both salt and fresh water. As a usage for EN, it can be used for acute pancreatitis, inflammatory bowel diseases, colitis studies and clinical studies.

### Peer review

In this experimental study about SBS, orally given CCE showed a positive effect on parameters of intestinal adaptation. Since it is the first study that shows positive effects of algae in SBS, this is an interesting study.

### Abstract

**AIM:** To estimate the prevalence of inherited and acquired thrombophilic risk factors in patients with abdominal venous thrombosis and to compare the risk factor profiles between Budd-Chiari syndromes (BCS) and splanchnic vein thrombosis (SVT).

**METHODS:** In this retrospective study, 36 patients with abdominal venous thrombosis were studied. The patients were divided into Budd-Chiari group (hepatic vein, IVC thrombosis) and splanchnic venous thrombosis group (portal, splenic, superior mesenteric veins) based on the veins involved. Hereditary and acquired thrombophilic risk factors were evaluated in all patients.

**RESULTS:** Twenty patients had SVT, 14 had BCS, and 2 had mixed venous thrombosis. Ten patients (28%) had hereditary and 10 patients (28%) acquired thrombophilic risk factors. The acquired risk factors were significantly more common in the SVT group (SVT vs BCS: 45% vs 7%,  $\chi^2 = 5.7$ ,  $P = 0.02$ ) while hereditary risk factors did not show significant differences between the two groups (SVT vs BCS: 25% vs 36%,  $\chi^2 = 0.46$ ,  $P = 0.7$ ). Multiple risk factors were present in one (7%) patient with BCS and in 3 patients (15%) with SVT. No risk factors were identified in 57% of patients with BCS and in 45% of patients with SVT.

**CONCLUSION:** Hereditary and acquired risk factors play an important role in the etiopathogenesis of abdominal venous thrombosis. Acquired risk factors

are significantly more common in SVT patients while hereditary factors are similar in both groups.

### INTRODUCTION

Abdominal venous thrombosis may present as Budd-Chiari Syndrome (BCS) (thrombosis of inferior vena cava and/or hepatic veins) or splanchnic venous thrombosis (SVT) (occlusion of portal, splenic, superior or inferior mesenteric veins). Hereditary and acquired risk factors have been implicated in the etiopathogenesis of abdominal venous thrombosis<sup>[1,2]</sup>. Hereditary risk factors for thrombophilia include Factor V Leiden gene mutation, prothrombin gene mutation, homozygous methyl tetrahydrofolate reductase (MTHFR) gene mutation, and deficiencies of coagulation inhibitor protein C, protein S and antithrombin III (AT III)<sup>[3-7]</sup>. Causes of acquired thrombophilia are myeloproliferative disorders, malignancy, surgery, antiphospholipid syndrome, pregnancy, oral contraceptives, and infection<sup>[8-11]</sup>. Identification of these risk factors may help in evaluation, planning therapy, or screening family members to evaluate an individual risk.

There are few studies from South Asian regions which have comprehensively evaluated prothrombotic risk factors in BCS and portal venous thrombosis (PVT)<sup>[12,13]</sup>. These studies did not assess risk factors in patients with mesenteric venous thrombosis. Other studies have evaluated individual risk factors or multiple risk factors in single venous thrombosis<sup>[14-17]</sup>. The aim

of the study was to analyse prothrombotic etiological profiles (hereditary and acquired) in patients with abdominal venous thrombosis and to compare the profiles of the BCS and SVT groups.

## MATERIALS AND METHODS

Patients admitted with abdominal venous thrombosis that had complete etiological work up during the period July 1997 to June 2006 were included in the study. Patients with incomplete evaluation (acute thrombosis or on anticoagulants) were excluded. Diagnosis of thrombosis was based on Doppler sonography, abdominal computed tomography (CT), or venography. For all selected patients, clinical information and laboratory data were collected by a standardized review of medical charts using uniform structured data forms. Details of acquired prothrombotic risk factors like abdominal surgery, oral contraceptives, pregnancy, liver cirrhosis, antiphospholipid syndrome, infection, or others were also obtained.

Genetic tests for mutation in Factor V Leiden gene (1691, G-A), *MTHFR* gene (677 C-T), and prothrombin gene (20210, G-A) were done in all the patients by PCR amplification of the respective gene segments<sup>[18-20]</sup>. The amplified products were subjected to restriction digestion fragment length polymorphism (RFLP) analysis. Protein C and AT III were assessed using chromogenic assays, done on the coagulation analyzer (Dade Behring's Sysmex CA 1500). Free protein S was estimated by an immunoassay (Chromogenix Coamatic Protein S Free, IL) done on the ACL Advance (Instrumentation Laboratory). The assays for protein C, protein S, and AT III were run concurrently with normal control and abnormal control (substrate present in low level simulating deficiency states) samples for validation as well as comparison with normal. The normal reference ranges of various tests were protein C: 50%-150% of normal; protein S: 50%-150% of normal; AT III: 80%-120% of normal. Patients were considered to have protein C, protein S, or AT III deficiency only if liver dysfunction was ruled out.

### Statistical analysis

Comparison between the BCS and the SVT group was done by Fischer's exact test for categorical variables and Mann Whitney U test for continuous variables. A *P* value of < 0.05 was considered significant. All analysis was performed in SPSS for Windows Version 11.

## RESULTS

Thirty-six patients with thrombosis of abdominal veins were studied. The mean age of the patients was 36.7 years (range: 3-69 years). There were 24 males (67%) and 12 females (33%). Abdominal pain, the commonest symptom, was seen in 16 (44%), hepatomegaly in 4 (11%), splenomegaly in 10 (28%), and ascites in 13 (36%) patients. Acute presentation was more common in SVT (40%) than in BCS (21%). Diagnosis of abdominal venous thrombosis was made by Doppler sonography in 21 patients (58%), CECT abdomen in 10 (28%), and

venography in 5 (14%) patients. Twenty patients had thrombosis of splanchnic veins (SVT), 14 had thrombosis of inferior vena cava and/or hepatic vein (BCS) and 2 had thrombosis in both splanchnic and IVC/hepatic veins.

The site of thrombosis along with details of hereditary and acquired risk factors in all patients studied is shown in Table 1. Hereditary risk factors were present in 10 (28%) patients and acquired risk factors in 10 (28%) patients. The most common hereditary risk factors were Factor V Leiden gene mutation (11%) and AT III deficiency (11%) followed by protein C deficiency (8%). None of the patients had a prothrombin gene mutation, protein S deficiency, or was homozygous for *MTHFR* gene mutation. *MTHFR* mutation (heterozygous) was seen in 22% patients, which is not considered a risk factor for thrombosis. In the BCS group (14 patients): IVC obstruction alone was present in 5 patients, hepatic vein (HV) obstruction alone in 6 patients, and IVC + HV obstruction in 3 patients. Hereditary risk factors were present in 5 (36%) patients and acquired risk factor in one (7%) patient. In SVT group (20 patients): portal vein (PV) obstruction alone was present in 4 patients, splenic vein (SV) obstruction alone in 2 patients, superior mesenteric vein (SMV) obstruction alone in 1 patient, PV + SMV obstruction in 3 patients, and PV + SV + SMV obstruction in 10 patients. Hereditary risk factors were present in 5 (25%) patients and acquired risk factors in 9 (45%) patients.

Comparison of risk factor profiles between the BCS and the SVT group is shown in Table 2. Hereditary risk factors were higher in the BCS group (BCS vs SVT: 36% vs 25%, *P* = 0.7), but this difference did not reach statistical significance. Acquired risk factors were significantly higher in the SVT group (SVT vs BCS: 45% vs 7%, *P* = 0.02). The prevalence of multiple risk factors in the BCS and the SVT group are shown in Table 3. More than one risk factor was seen in 1 (7%) patient in the BCS group and in 4 (20%) patients in the SVT group. No risk factor was identified in 57% of patients in the BCS group and in 45% of patients in the SVT group.

## DISCUSSION

This study evaluated hereditary and acquired risk factors in 36 patients with abdominal venous thrombosis. Hereditary risk factors were identified in 36% of patients with BCS and in 25% of patients with SVT. Acquired risk factors were detected in 7% of patients with BCS and in 45% of patients with SVT.

Prevalence of Factor V Leiden mutation (FVLM), the most common cause of inherited thrombophilia, is variable in different populations<sup>[21]</sup>. Risk of venous thrombosis is 5- to 8-fold in heterozygotes and 50- to 80-fold in mutation homozygotes<sup>[3]</sup>. Janssen *et al* showed that prevalence of FVLM in BCS (26%) and PVT (8%) was higher than in controls (3%) suggesting that FVLM is an important risk factor for BCS (OR 11.3) and PVT (OR 2.7)<sup>[22]</sup>. Mohanty *et al* also found FVLM to be an important risk factor in BCS (26%; OR 14.5) and in PVT (6%; OR 2.3)<sup>[12]</sup>. Bhattacharyya *et al* demonstrated FVLM mutation in 17% of BCS and in 3% of patients with

AT III deficiency	21.4%	5%	0.28
Acquired risk factors	7.1%	45%	0.02
No risk factor	57.1%	45%	0.70

<sup>1</sup>Fisher's exact test for categorical variables and Mann Whitney's U test for continuous variable.

PVT<sup>[13]</sup>. Koshy *et al* showed that the prevalence of FVLM was similar in patients with PVT (3%) and controls (1%) and suggested that FVLM is not associated with PVT in

**Table 3 Prevalence of multiple risk factors (inherited and acquired) among patients with BCS and SVT n (%)**

Number of risk factors	BCS (n = 14)	SVT (n = 20)	Total (n = 34)
0	8 (57)	9 (45)	17 (50)
1	5 (36)	7 (35)	12 (35)
2	1 (7)	3 (15)	4 (12)
3	-	1 (5)	1 (3)

India<sup>[14]</sup>. Similar observations were made by Sharma *et al* who demonstrated FVLM in 1.6% of patients with PVT and in 4% of controls<sup>[15]</sup>. In the present study, 14% of patients with BCS and 10% with SVT were heterozygotes, both higher than control data (1%-4%) reported earlier from India<sup>[12,14,15]</sup>. Though the numbers of patients in the study are small, results suggest that FVLM may be a risk factor in BCS and SVT.

Prothrombin gene mutation, a risk factor for venous thrombosis (homozygote: 10-fold; heterozygote: 2- to 4-fold) is rare in African and Asian populations compared to Caucasians<sup>[23]</sup>. None of the five Indian

studies have shown this gene mutation in cases or controls<sup>[12,13,15-17]</sup>. We also did not detect this mutation in any of our patients. Prevalence of heterozygote *MTHFR* gene mutation in patients with venous thrombosis is similar to healthy controls suggesting that this mutation is not an important prothrombotic factor<sup>[24]</sup>. It has been shown that homozygote *MTHFR* mutation, one of the causes of hyperhomocystinaemia (risk factor for vascular disease), is a risk factor for venous thrombosis<sup>[19,24]</sup>. None of the patients in the present study were homozygous for the *MTHFR* mutation. Three patients had heterozygote *MTHFR* mutation as the only abnormality. They were presumed to have idiopathic abdominal venous thrombosis as heterozygote *MTHFR* mutation alone is not considered a significant prothrombotic risk factor. Five heterozygous patients had additional hereditary or acquired risk factors. In a study from Northern India, Bhattacharyya *et al* investigated 57 BCS and 48 PVT patients, and reported none were homozygous for *MTHFR* gene mutation. Heterozygous mutations were seen in 24% of BCS and 21% of PVT patients<sup>[13]</sup>.

Indian and Western studies have shown that protein C deficiency is the second most common cause of inherited thrombophilia in patients with BCS and PVT<sup>[12,13,22]</sup>. Amarapurkar *et al* showed that protein C deficiency was the commonest hereditary risk factor (26%) in a study on 28 patients with mesenteric venous thrombosis<sup>[25]</sup>. Protein C was also the commonest risk factor (38% patients) in a series of 16 patients with mesenteric venous thrombosis reported by Harward *et al*<sup>[26]</sup>. In the present study, protein C deficiency was demonstrated in 7% of patients with BCS and in 10% of patients with SVT. Prevalence of protein S, and AT III deficiency as risk factors for inherited thrombophilia in patients with BCS and PVT were low in Indian and Western studies<sup>[12,13,22]</sup>. Protein S deficiency was not detected in any of our patients. AT III deficiency was higher in patients with BCS (21%) as compared to those with SVT (5%). Diagnosis of inherited deficiencies of protein C, protein S, and AT III, as a cause of abdominal venous thrombosis is difficult, because acquired deficiencies develop in liver failure, acute thrombosis, and during anticoagulant therapy<sup>[27]</sup>. None of the patients in the present study with protein C and AT III deficiency had liver failure or were on anticoagulant therapy.

Comparison of prothrombotic risk factor profiles between BCS and SVT showed a trend for hereditary risk factors to be more frequent in BCS (BCS *vs* SVT: 35.7% *vs* 25%; *P* = 0.7); two other Indian studies have made similar observations of hereditary factors being more frequent in BCS group compared to PVT group<sup>[12,13]</sup>. Studies on prevalence of acquired risk factors in abdominal venous thrombosis have shown variable results. Denninger *et al* and Janssen *et al* have shown that acquired risk factors are more frequent in PVT than in BCS<sup>[22,28]</sup>. Mohanty *et al* found the frequency of acquired risk factors to be similar in BCS and PVT<sup>[12]</sup>. In our study, acquired risk factors were significantly more common in the SVT group (BCS *vs* SVT: 7% *vs* 45%; *P* = 0.02) suggesting that SVT is a

heterogeneous disease where hereditary and local risk factors play important roles.

No risk factor was identified in 57% of BCS and 45% of patients with SVT. One possible reason may be the low prevalence of myeloproliferative disorders in our series (one patient). Myeloproliferative disorders (overt or latent) have been shown as an important risk factor in previous studies on abdominal vein thrombosis<sup>[28-31]</sup>. Tests for detecting latent myeloproliferative disorders (formation of "spontaneous" erythroid colonies in cultures of bone marrow progenitor cells in erythropoietin-poor medium<sup>[32,33]</sup>) were not performed on our patients. In a study from Western India, an etiological factor could be found in 59% of the BCS and 30% of the PVT patients<sup>[12]</sup>. Interestingly, in this study also, none had a myeloproliferative disorder.

Previous studies have suggested that venous thrombosis results from coexistence of several risk factors<sup>[28]</sup>. In the present study, ≥ 2 risk factors were detected in 7% of BCS and in 20% of patients with SVT.

Hereditary and acquired risk factors play an important role in etiopathogenesis of abdominal venous thrombosis. Acquired risk factors are significantly more common in patients with SVT while hereditary risk factors are similar in patients with BCS and SVT. Recognition and evaluation of these risk factors may help in therapy and prevention of disease progression. As a significant number of patients lack obvious etiology further research is required to identify as yet unrecognized risk factors.

## COMMENTS

### Background

Abdominal venous thrombosis may present as Budd-Chiari Syndrome (BCS) or splanchnic venous thrombosis (SVT). Hereditary and acquired risk factors are implicated in the etiopathogenesis of abdominal venous thrombosis. There are few systematic studies that have comprehensively evaluated both hereditary and acquired factors in BCS and SVT. Most studies have evaluated either a single prothrombotic risk factor or multiple risk factors in a single vein.

### Research frontiers

Concept of multifactorial theory of thrombogenesis suggests that thrombosis occurs by activation of a trigger factor (acquired) in a thrombophilic milieu (hereditary). The prevalence of inherited risk factors is variable between populations throughout the world. Possible reasons are small numbers of patients studied, non-standardized evaluation of parameters tested, and genetic differences between patient populations. Data need to be generated by good studies from different geographical areas in the world. Etiological factors for abdominal venous thrombosis were identified in 70%-80% of patients in Western studies. In Indian studies, no risk factor was identified in half the patients suggesting that other unknown hereditary/risk factors may be operating in these patients.

### Innovations and breakthroughs

The present study suggests that acquired risk factors which are preventable are important in etiopathogenesis of SVT. As no risk factors were identified in about half the patients, research needs to be ongoing to identify unknown hereditary/acquired risk factors operating in these patients.

### Applications

Abdominal venous thrombosis is a life threatening condition caused by single or multiple, hereditary or acquired prothrombotic risk factors. Prevention and therapy with non-invasive techniques and new anticoagulant drugs are now possible. Complete thrombophilia screening is, therefore, important for risk assessment, and therapy in patients with abdominal venous thrombosis. With continuing search for hereditary risk factors (genetic molecular defects), true

idiopathic thrombotic disease will become uncommon.

#### Peer review

This paper investigates genetic and acquired risk factors in patients with thromboembolism in abdominal veins. The authors make a difference between hereditary and acquired risk. It's a nice study.

## INTRODUCTION

Gastroesophageal reflux disease (GERD) has been known to be a common medical condition affecting approximately 35%-40% of the adult population in the Western world<sup>[1,2]</sup>. Forty-four of all Americans suffer from heartburn at least once per month, 20% at least once per week<sup>[3]</sup>. The role of GERD in causing extra-esophageal symptoms is also increasingly being recognized<sup>[4]</sup>. Chronic laryngeal signs and symptoms associated with GERD are often referred to as reflux laryngitis or laryngopharyngeal reflux (LPR)<sup>[5]</sup>. But, not all episodes of GERD are associated with LPR and not all patients with LPR have typical features of GERD<sup>[6]</sup>. Classic reflux symptoms (heartburn and regurgitation), which are referred to as "typical GERD," may be absent in more than half the patients presenting with extra-esophageal manifestations<sup>[7,8]</sup>. The "silent reflux" contributes to the difficulty in making a definite and correct diagnosis. The extra-esophageal manifestations of GERD provide the most challenging areas to perform good research<sup>[9]</sup>.

Furthermore, the prevalence of LPR in the patients with GERD has not been studied well in the past. The kind of patients with GERD who are more associated with LPR is still unknown. The cause-and-effect relationship between GERD and LPR remains elusive.

In patients with esophageal syndromes of GERD, reflux esophagitis (RE) is more easily diagnosed definitely by endoscopy than others. The objectives of our current study were to determine the prevalence of LPR in the patients with RE and to find out the factors that contribute to the development of LPR.

## Abstract

**AIM:** To assess the prevalence of laryngopharyngeal reflux (LPR) in patients with reflux esophagitis and disclose factors contributing to the development of LPR.

**METHODS:** A total of 167 patients who proved to have reflux esophagitis by endoscopy were enrolled. They received laryngoscopy to grade the reflux findings for the diagnosis of LPR. We used validated questionnaires to identify the presence of laryngopharyngeal symptoms, and stringent criteria of inclusion to increase the specificity of laryngoscopic findings. The data of patients were analyzed statistically to find out factors related to LPR.

**RESULTS:** The prevalence rate of LPR in studied subjects with reflux esophagitis was 23.9%. Age, hoarseness and hiatus hernia were factors significantly associated with LPR. In 23 patients with a hiatus hernia, the group with LPR was found to have a lower trend of esophagitis grading.

**CONCLUSION:** Laryngopharyngeal reflux is present in patients with reflux esophagitis, and three predicting factors were identified. However, the development of LPR might be different from that of reflux esophagitis. The importance of hiatus hernia deserves further study.

## MATERIALS AND METHODS

### Recruitment of patients

Consecutive patients who were diagnosed to have RE by gastroendoscopic examination due to various symptoms, such as epigastric pain, acid regurgitation, heartburn, nausea, abdominal fullness sensation, and so on, at the gastrointestinal clinic of Cathay General Hospital from September 2006 to October 2007 were enrolled. These qualified patients then were referred to the otorhinolaryngologic clinic for the further work-up of a laryngoscopic examination. Written, informed consent had to be provided by the participants before the endoscopic examination.

To improve the specificity of our study, the inclusion criteria of the patients were very strict. Patients were excluded from the study if they had a history of respiratory or gastrointestinal malignancy; radiation therapy to the head and neck, lung, or gastrointestinal tract; gastroesophageal surgery; use of H<sub>2</sub>-receptor antagonists or proton pump inhibitors in previous 1 mo; past or present smoker; excessive alcohol consumption; chronic cough attributable to known chronic pulmonary or tracheobronchial disease; professional voice users (e.g. singer, teacher); excessive voice use; exposure to occupational or environmental pollutants; history of seasonal allergic rhinitis; pharyngolaryngeal infection in the previous 3 mo; tracheal intubation in the previous 12 mo and use of inhaled corticosteroids<sup>[10,11]</sup>.

### Gastroendoscopic examination

All subjects received conventional endoscopic imaging, as well as imaging with the narrow-band imaging (NBI) system by using a video endoscope (GIF-H 260; Olympus Optical Co, Ltd, Tokyo, Japan). A group of experienced endoscopists performed the endoscopic examination. NBI is a novel, non-invasive optical technique that adjusts reflected light to enhance the contrast between the esophageal mucosa and the gastric mucosa<sup>[12]</sup>. The Los Angeles classification was used to grade esophagitis. A hiatus hernia was diagnosed if the hernia sac was more than 2 cm in length. We did not include patients suspected to have Barrett's esophagus due to diagnostic complexity.

### Questionnaire

The qualified participants needed to complete a questionnaire by answering "yes" or "no" with the aid of research nurses, right after the gastroendoscopic examination. It was used to identify the presence of any throat or reflux symptoms (cough, hoarseness, throat clearing, sore throat, thick drainage, globus sensation, bad taste in the mouth, swallowing problems, chest pain). Subjects were also asked to score the severity of each symptom based on a graded scale of 1 to 4 [1 = rare (once a month or less), 2 = occasional (2-3 times a month), 3 = frequent (several times a week); 4 = all the time (several times daily)]. The graded scales of more than 2 were considered significant, and the symptoms with such a scale could be included into the study<sup>[13]</sup>.

### Laryngoscopic examination

Each patient at the otorhinolaryngologic clinic underwent an endoscopic examination (Hopkins 70°C Telescope, Model 8706 CA, Karl Storz, Germany) of the larynx by two well-trained otolaryngologists, both with experience of over 10 years and good consensus, to grade the laryngoscopic findings. The otolaryngologists were not aware of the results of the questionnaire before the laryngoscopic examination. A reflux finding score (RFS) was obtained based on the laryngeal examination scoring system by Belafsky *et al*<sup>[14]</sup>. A RFS of > 7 was considered abnormal and to have LPR. Laryngeal signs suspected to be reflux-related were determined based on an agreement of the two experts.

### Statistical analysis

Statistical analyses were performed using the Stata 8.0 for Window (STATA Corp, College Station, TX). Patient characteristics were compared using the Student's *t* test and Pearson's  $\chi^2$  test for proportions. A logistic regression model was used to adjust for confounding covariates including, age, sex, BMI, disease (presence or absence), a hiatus hernia (presence or absence), and the grading of LA classification (A, B, C) *et al*. A two-tailed *P* value of less than 0.05 was taken to indicate statistical significance.

## RESULTS

Two hundred twenty-two patients with endoscopically proven RE initially were included in the study. However, 13 patients did not visit otorhinolaryngeal clinic due to personal reasons and 42 patients were excluded because they did not meet the strict inclusion criteria. Therefore, a total of 167 patients (80 males and 87 females) were enrolled in this study. The demographic characteristics of the studied subjects are listed in Table 1. 96.4% of the patients belonged to the groups of esophagitis grade A and B; only 3.6% were of grade C. A hiatus hernia was found in 13.8% of the patients.

Table 2 shows comparisons of demographic characteristics of patients with and without LPR. Among the 167 patients, 23.9% (40 cases) were diagnosed to have LPR. The difference in age between the patients with and without LPR was significant (45.2 *vs* 49.9 years, *P* = 0.04). The patients with LPR were younger than the ones without LPR. The presence of hoarseness symptom was significantly higher in the group with LPR (55.0% *vs* 26.8%, *P* = 0.001). In addition, a hiatus hernia was found more frequently in the group with LPR (27.5% *vs* 9.5%, *P* = 0.004).

If we combined the symptom of hoarseness and presence of a hiatus hernia together, the prediction of LPR was much higher (odds ratio increased up to 12.3, Table 3).

We also made a detailed analysis in the patients with a hiatus hernia. The distribution of esophagitis grading between the groups with and without LPR were compared. Of interest, in 23 patients with a hiatus hernia, the group with LPR (11 patients) had a relatively lower trend of esophagitis grading (LA grade A/B/C:

9, 81.8%/2, 18.2%/0, 0%), whereas the group without LPR (12 patients) had a higher trend of grading (LA grade A/B/C: 4, 33.3%/6, 50.0%/2, 16.7%). The difference was statistically significant ( $P = 0.04$ ).

## DISCUSSION

The association between LPR and GERD has not been firmly established yet<sup>[6]</sup>. Not all patients with GERD will develop LPR. On the other hand, it is estimated that 50%-60% of chronic laryngitis and difficult-to-treat sore throat may be related to GERD<sup>[8]</sup>. The causal association between acid reflux and laryngitis is highly plausible considering the close anatomical relationship. The vagally mediated reflexes (bronchospasm, laryngospasm and cough) stimulated by esophageal acid is also implicated in the pathogenesis of GERD-related extra-esophageal disorder<sup>[11,15]</sup>.

BMI: Body mass index; LPR: Laryngopharyngeal reflux; LA grade: The grade of Los Angeles classification of esophagitis. <sup>1</sup>P value is significant at the 0.05 level.

Currently, there is no “gold-standard” for the diagnosis of LPR. Ambulatory 24-h dual or triple probe pH-metry was once considered the best method for reflux testing<sup>[16]</sup> but the position of the probes makes the measurement not easy to interpret, and there is no consensus about the pathological reflux at the level of laryngopharynx<sup>[6]</sup>. Moreover, extra-esophageal reflux is also intermittent. A negative pH study does not rule out extra-esophageal reflux<sup>[17]</sup>. The empiric therapy with aggressive acid suppression, usually BID dosing of proton-pump inhibitors (PPIs), is currently recommended as the most practical and cost effective approach for the patients suspected with extra-esophageal presentations of GERD<sup>[16]</sup>. Nevertheless, this therapeutic trial for the diagnosis of LPR could not provide direct evidence of pathologic imaging changes of patients, about which most clinicians want to learn.

Laryngeal examination with special emphasis on the posterior location of tissue injury can be helpful for the diagnosis of LPR<sup>[18]</sup>. The severity of mucosal injury may be graded according to the RFS by Belafsky 2001<sup>[14]</sup>. The RFS is an 8-item clinical severity scale based on findings during fiberoptic laryngoscopy. However, this RFS system has been criticized to have high inter- or intra-observer variability and low specificity for reflux laryngitis<sup>[6,10,19]</sup>. Therefore, it is very important to exclude meticulously other potential etiologies that can lead to laryngeal irritation. In our study, we did a very stringent selection of the patients to avoid the secondary causes of chronic laryngitis, such as smoking, alcohol, excessive voice use, allergies, or asthma.

The NBI system we used on gastroendoscopic examinations could offer a better image of capillary patterns and, thus, enhance the contrast between the esophageal and gastric mucosa and facilitate the endoscopic evaluation of esophagitis<sup>[20,21]</sup>. The better depictions of small erosive foci improves the intra- and inter-observer reproducibility in the grading of esophagitis, especially

in the grading of class A or B esophagitis<sup>[12]</sup>, which was very helpful in our study.

In our study, LPR was present in 23.9% of the studied subjects with RE. In the past, Koufman described posterior laryngitis in 74% and laryngeal edema with erythema in 60% of all patients with GERD<sup>[16]</sup>. Tauber *et al* also reported 85% of GERD-positive patients had posterior laryngitis and 69% had laryngitis with an interarytenoid erythema and edema<sup>[22]</sup>. Our prevalence rate of LPR is much lower than theirs; the different sample size of patients and method of enrollment in our research must have influenced the results. Because we used very stringent criteria to enroll the patients, it was possible that we missed some cases and underestimated the prevalence rate of LPR. In fact, this kind of report is quite rare in the literature. Most papers dealt only with the prevalence rate of GERD (ranging 20%-50%) in patients with LPR<sup>[4,21,23,24]</sup>.

Our results indicated that age, hoarseness and a hiatus hernia could be the predicting factors of LPR in the patients with RE. However, gender, body mass index, and the severity of esophagitis were not associated. A large cohort study performed by Jaspersen *et al* reported female gender, higher age, severe esophagitis, longer duration of GERD and smoking were significantly related to the extra-esophageal disorder<sup>[25]</sup>. Their risk factors were not the same as ours, which might be caused by the recruitment method they used. Though the case number of their study was large, they did not exclude the patients strictly and included patients who smoked. The patients they studied did not receive a laryngoscopic examination, and solely relied on the "symptom questionnaire" for the diagnosis of extra-esophageal disorders, which could be another factor that would induce diverse outcomes.

Increased GERD severity due to degradation of the gastroesophageal junction and impaired esophageal clearance was found in the elderly<sup>[26]</sup>. Yet, age as a factor contributing to LPR seldom has been mentioned before. In the present study, the RE patients with LPR were of a younger age than the patients without LPR. This finding is contradictory to the result of Jaspersen's study, in which they noted higher age was a risk factor for the occurrence of extra-esophageal disorder<sup>[25]</sup>. The opposite results again might be attributed to the different recruitment and research methods. However, the drawback of our study was that we had fewer patients. According to our findings, higher age, which implies the probable longer duration of GERD, is not essential for the development of LPR. In addition, our study also indicated the severity of RE had nothing to do with the occurrence of LPR. Therefore, the existence of LPR seems to be not associated with the duration or severity of RE.

LPR may have several clinical symptoms. Among them, throat-clearing, persistent cough, globus and hoarseness are the most common complaints<sup>[24]</sup>. In our study, the prevalence of hoarseness in all the patients was 33.5%. When we made comparison between the patients with and without LPR, the rate of hoarseness became 55.0% vs 26.8%, which was statistically significant. Our result indicated that more than 50% of the RE

patients with LPR had the symptom of hoarseness. As for the other symptoms (globus, throat discomfort and persistent cough), we did not find significant differences between the two groups.

Hoarseness is a common complaint of the patients at the otorhinolaryngologic clinic. Underlying causes include malignancy, vocal cord palsy, polyps and nodules of the vocal cords, laryngitis and functional disorders. Acute laryngitis is usually infective, whereas chronic laryngitis may result from a spectrum of insults including cigarette smoking, dehydration, acid reflux and muscular imbalance<sup>[6]</sup>. Hoarseness is not specific for LPR. Therefore, we must exclude several other possible causes before we can make sure the laryngitis-related hoarseness is induced solely by acid reflux. In our patients with RE, an additional symptom of hoarseness might reflect that the acid reflux has gone beyond the upper esophageal sphincter and injured the vocal cord. Extra-esophageal manifestation of GERD, thus, might be incurred.

Hiatus hernias have a higher detection rate in Western populations, ranging between 14.5% and 22%<sup>[27]</sup>. In the Far East, the prevalence rate is much lower, 7% of 464 subjects in Taiwan<sup>[28]</sup>, 2.9% of 11943 subjects in Singapore<sup>[29]</sup>, and 17.5% of 6010 individuals in Japan were reported<sup>[30]</sup>. In a recent series in Taiwan, hiatus hernia was found in 18.8% of patients with erosive esophagitis<sup>[31]</sup>. In our research, it was 13.8% of the studied subjects, which was also higher than that of the normal population here.

A hiatus hernia can disrupt both the anatomy and physiology of the normal anti-reflux mechanism. It is associated with decreased esophageal peristalsis; it also increases the cross-sectional area of the esophago-gastric junction and acts as a reservoir allowing reflux from the hernia sac into the esophagus during swallowing. The presence of a hiatus hernia is associated with symptoms of gastroesophageal reflux, and increased prevalence and severity of RE<sup>[27]</sup>. Because the presence of a hiatus hernia would increase esophageal acid exposure, it is emerging as an important factor in the pathogenesis of GERD<sup>[27]</sup>.

In our study, a confirmed hiatus hernia was found to be a risk factor contributing to LPR in the patients with RE. Considering the possible mechanism of reflux-related extra-esophageal disorders, it will not be surprising to disclose the importance of a hiatus hernia in these patients. With the existence of a hiatus hernia, the acid reflux could be potentiated and would result in more mucosal injury up to larynx. Animal studies have shown that even minute amounts of gastric acid and pepsin on laryngeal mucosa can induce significant inflammation and edema<sup>[32,33]</sup>. Further work is still needed to understand how a hiatus hernia influences the progression of GERD and its complications. At present, a hiatus hernia is known to be a marker of severe GERD<sup>[27]</sup> and must have a contributing effect in the pathogenesis of LPR.

In our patients with a hiatus hernia, we also analyzed their grade of esophagitis. Between the groups with and without LPR, the result was quite interesting and surprising. In this category, the patients with LPR had

a milder form of esophagitis than the ones without LPR. This finding again supports the concept that the development of LPR is not related to the severity of RE. To the contrary, LPR can be seen more frequently in the patients with mild RE when a confirmed hiatus hernia is present. Of interest, Li *et al* just reported that a hiatus hernia was found to be associated with more severe esophagitis in patients with RE<sup>[34]</sup>. Therefore, the development of LPR must be different from that of simple RE without LPR. Moreover, our patients who coexisted with a hiatus hernia and hoarseness had a very high odds ratio for LPR. Combining these two factors clinically, we could predict the presence of LPR more accurately in the patients with RE.

Regrettably, we had only 6 patients (3.6%) with LA grade C esophagitis and no patient with grade D. Thus, in our research, several factors could not be viewed and studied with the entire esophagitis spectrum from grade A to D. Another drawback of our study is that we did not include patients suspected to have Barrett's esophagus or endoscopically suspected esophageal metaplasia, which could be another intriguing field to see the relationship between GERD and extra-esophageal syndromes.

In conclusion, our study revealed that age, hoarseness and a confirmed hiatus hernia were the factors related to LPR in the patients with RE. LPR could be associated with RE, but the definite cause-and-effect relationship is still unknown. Our research was only a hospital-based study; more case numbers and convincing data are necessary in the future. Based on the aforementioned findings, the development of LPR seems to be different from that of RE. The importance of a confirmed hiatus hernia in LPR deserves further study.

## ACKNOWLEDGMENTS

The authors would like to thank Miss Ya-Hui Chen for her help in the work of statistical analyses.

## COMMENTS

### Background

The role of gastroesophageal reflux disease (GERD) in causing laryngopharyngeal reflux (LPR) is being increasingly recognized, but the cause-and-effect relationship between them remains elusive.

### Research frontiers

This research is to assess the prevalence of LPR in the patients with reflux esophagitis (RE), and also to identify the factors contributing to the development of LPR.

### Innovations and breakthroughs

The prevalence rate of LPR in our studied subjects with RE was 23.9%. Age, hoarseness, and hiatus hernia were the factors significantly associated with LPR. In addition, the patients who coexisted with a hiatus hernia and hoarseness had a very high odds ratio (12.3) for LPR. Another interesting finding was that in 23 patients with a hiatus hernia, the group with LPR was incidentally revealed to have lower trend of esophagitis grading.

### Applications

LPR is present in patients with RE and three predicting factors could be identified. Combining the two factors of hoarseness and hiatus hernia together, we could predict the presence of LPR more accurately in the patients with RE. However, the development of LPR seems to be different from that of RE, based

on the findings of this research. The importance of hiatus hernia in LPR deserves further study.

### Peer review

In this study, the authors ascertained the association of LPR with GERD and analyzed the factors related to the development of LPR. The results could be very important because the readers could learn the newest knowledge and understand the future perspectives in this field.

### Abstract

**AIM:** To describe the radiological findings of a macro-regenerative nodule (MRN) in the liver of pre-transplantation biliary atresia (BA) patients and to correlate it with histological findings.

**METHODS:** Between August 1990 and November 2007, 144 BA patients underwent liver transplantation (LT) at our institution. The pre-transplantation computer tomography (CT) and magnetic resonance imaging (MRI) findings were reviewed and correlated with the post-transplantation pathological findings.

**RESULTS:** Nine tumor lesions in 7 patients were diagnosed in explanted livers. The post-transplantation pathological findings showed that all the lesions were MRNs without malignant features. No small nodule was detected by either MRI or CT. Of the 8 detectable lesions, 6 (75%) were in the central part of the liver, 5 (63%) were larger than 5 cm, 5 (63%) had intra-tumor tubular structures, 3 (38%) showed enhancing fibrous septa, 3 (38%) had arterial enhancement in CT, one (13%) showed enhancement in MRI, and one (13%) had internal calcifications.

**CONCLUSION:** Although varied in radiological appearance, MRN can be differentiated from hepatocellular carcinoma (HCC) in most of BA patients awaiting LT. The presence of an arterial-enhancing

### INTRODUCTION

Biliary atresia (BA), the congenital absence or destruction of the intra- or extra-hepatic biliary system<sup>[1]</sup>, affects about 5-10/100 000 live births<sup>[2]</sup>. Porto-enterostomy is typically performed as soon as possible in these children<sup>[3,4]</sup>. However, liver cirrhosis and its complications may develop in some patients even after a successful porto-enterostomy. Liver transplantation (LT) is, thus, beneficial to BA, and is the leading reason for LT in children<sup>[5]</sup>.

Macro-regenerative nodule (MRN), defined as a regenerating liver nodule > 0.5 cm in size, is occasionally encountered in cirrhotic livers<sup>[6]</sup> and may mimic a hepatocellular carcinoma (HCC)<sup>[7,8]</sup>. Differentiating this benign entity from HCC may be challenging, but is very important when considering patients for LT. Although the clinical importance of MRN in BA patients have been discussed<sup>[9]</sup>, further details of its computer tomography (CT) and magnetic resonance imaging (MRI) radiological appearances remain to be elucidated. The objective of this study was to describe the CT and MRI appearances of MRN in BA patients, and their radiological importance.

## MATERIALS AND METHODS

### **Patients**

We reviewed the images, medical records, and pathological reports of 144 BA patients who underwent LT from August 1990 to November 2007 in Chang Gung Memorial Hospital-Kaohsiung Medical Center, Taiwan, China. The diagnosis of BA was proven by surgical and pathological findings after porto-enterostomy in all patients. Of the 144 patients, routine liver CT angiography and MRI were not performed in 33 patients before September 2000 because no standard procedure was available. However, there were no liver masses described in the pathological reports in these 33 patients. A total of 111 patients were included in this study.

### **CT**

Preoperative imaging evaluation was performed in the 111 patients using Somaton plus 4 spiral CT scanner (Siemens, Erlangen, Germany). Sedation using intravenous propofol (0.5-1 mg/kg body weight) without tracheal intubation was given in uncooperative patients. The scanning protocol was 5-mm collimation and a 1:1.5 pitch. The images were subsequently reconstructed at a 4- or 5-mm interval with scanning range from lung base to liver edge. Non-contrast enhanced scanning was performed followed by contrast enhanced scans utilizing an intravenous contrast medium (1.5-2 mL/kg body weight) injected at 1.5 mL/s with an automated power injector via a 22- or 24-gauge intravenous catheter. The arterial phase acquisition started at 20-25 s, porto-venous phase at 60-70 s and equilibrium phase at 3-5 min after intravenous administration of a contrast medium.

### **MRI**

Seventy-nine of the 111 patients underwent MRI examination. We used a 1.5-T superconducting imager (Gyroscan Intera, Philips Medical system, Netherland B.V.) equipped with a phase-array body-coil. The liver was imaged in the axial planes with the following sequences: T1WI (GRE), T2WI (SENSE) and contrast-enhanced T1WI (GR). T1WI (GRE) was conducted using the following parameter: a repetition time/ echo time of 10/4.6 milliseconds. The T2WI (SENSE) was imaged using the following parameter: a repetition time/ echo time of 600/80 milliseconds.

For all the pulse sequences, a 5-8 mm thick slice was used with a 2 mm gap, 256 × 256 matrix size, echo train length of 1, number of average of 1 and a 35-40 field of view, depending on the size of the individual patient's liver.

A contrast medium was administrated using gadolinium-DTPA (0.1 mmole/kg body weight, Magnevist, Schering, Berlin, Germany) followed by a 20-mL saline flush. The delay for image acquisition timing was determined with a bolus tracking technique. Image reconstruction with 5-8 mm thickness was performed with source images at a MRI workstation.

### **Image interpretation**

Two radiologists experienced in reading abdominal

radiography retrospectively reviewed the images from the picture archiving and communicating system (PACS, GE medics) or from the patient's file storage (before 2002). Arterial, porto-venous and equilibrium phase images were interpreted conjointly. Preoperative assessment of the liver nodules included the number, location, size (the largest diameter in 3D orthogonal view), morphology, enhancing pattern, and signal intensity in MRI.

### **Histopathologic review**

All explanted livers were serially sliced at 0.5 cm intervals and carefully inspected to detect the focal lesions seen during preoperative imaging. The size and location of all visible nodules were recorded at gross inspection. All macroscopic nodules were examined microscopically for histological identification and differentiation. Representative sections of the liver were also examined.

### **Serum alpha-fetoprotein (AFP)**

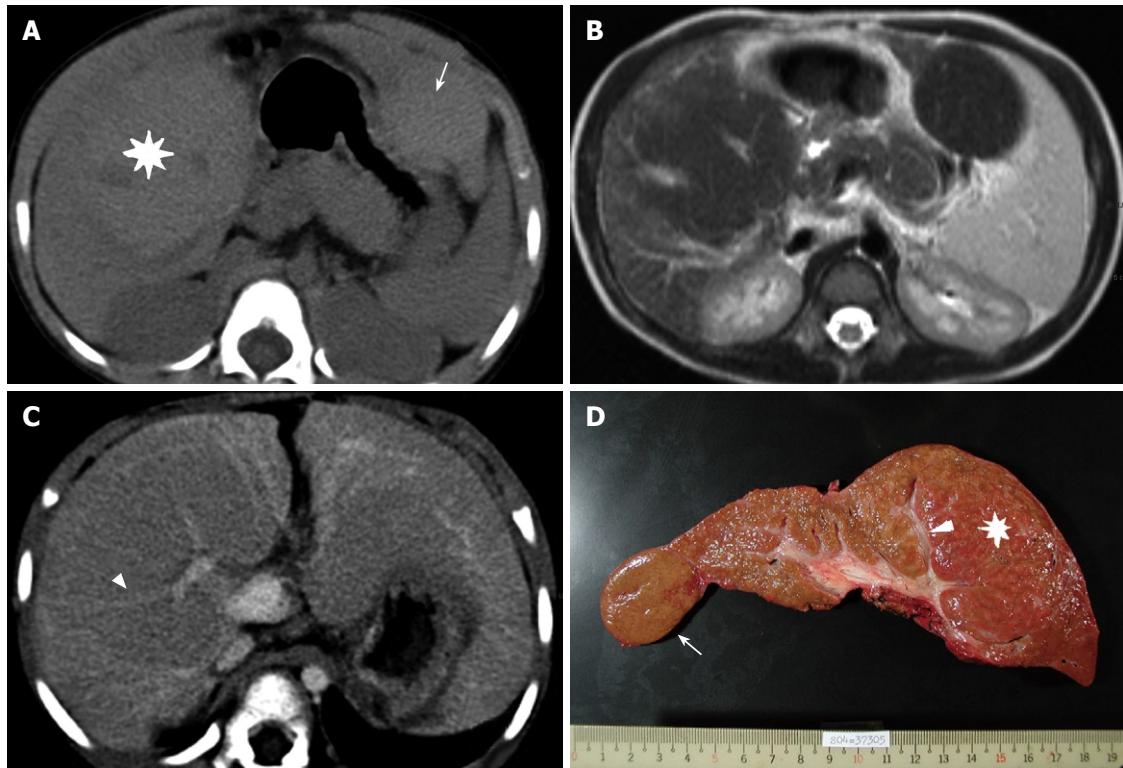

Serum AFP values were determined in all patients at the time of imaging or before transplantation.

## RESULTS

Nine MRN were detected in the explanted liver of 7 (4.8%) out of the 111 patients. The mean nodule diameter was 5.9 cm (range 1.6-9 cm). The MRN were located in the medial aspect (hepatic segments 4, 5, and 8) of 6 (67%) patients and in the lateral part of the liver (hepatic segments 2, and 6) of 3 (33%). The margin of the nodules was well-defined in all specimens. Of these 9 MRN, 7 were detected by CT and 7 by MRI. One was not detected by either MRI or CT, and one was found by MRI only. One patient with MRN did not undergo MRI. The CT and MRI findings of the 8 detectable MRN are listed in Table 1. At CT, the MRN were hyperdense compared with the surrounding liver parenchyma before contrast in 6 (75%) nodules (Figure 1A), the other 3 (38%) nodules were isodense (Figure 2A). After contrast medium enhancement, one nodule (13%) showed prominent enhancement both in arterial phase and in porto-venous phase, two nodules (25%) showed early enhancement and early wash-out pattern (Figure 3A), and four (50%) nodules showed no enhancement.

At MRI, the nodule was isointense to hyperintense on T1WI sequences and hypointense in T2WI in 5 (63%) nodules (Figure 1B) with one nodule showing T2WI central hyperintensity. Two nodules (25%) were hypointense on T1WI and hyperintense in T2WI (Figure 2B). After contrast enhancement, only one nodule showed enhancement. The other characteristic radiological findings in CT and MRI included stretching of intratumor tubular structures (5 lesions) (Figures 1C and 3B), fibrous septa in the periphery of the nodules (2 lesions), and internal calcifications (1 lesion). The septa were hypointense both before and after enhancement in T1WI.

Histopathology displayed that all lesions were MRN (Figures 1D and 3C), which were described as well-circumscribed liver cell nodules showing proliferating uniform liver cells bearing uniform round nuclei and

**Figure 1** A 3-year-old BA girl with segments 5-8 (asterisk) and segment 2 (arrow) MRN. **A:** The density of the MRN is slightly higher than that in the surrounding liver parenchyma during pre-enhanced phase of the CT; **B:** FSE/T2WI MRI shows a lower signal intensity in the MRN than in the surrounding liver; **C:** During portovenous phase of the CT, the tubular structure and splaying portal veins can be seen in the MRN (arrowhead); **D:** The explanted liver and intra-tumoral portal tract can be seen (arrowhead).

<sup>1</sup>This small nodule is not detected by either CT or MRI.

eosinophilic cytoplasm. No cellular atypia was found. The liver cells were arranged in one- to two-cell thick plates with intervening sinusoids (Figure 3D). No apparent sinusoidal capillarization was seen in the tumor lesion and no malignant foci were identified. Abortive portal tract formation was also noted. In all the seven MRN patients, the AFP level was < 3 ng/mL before LT.

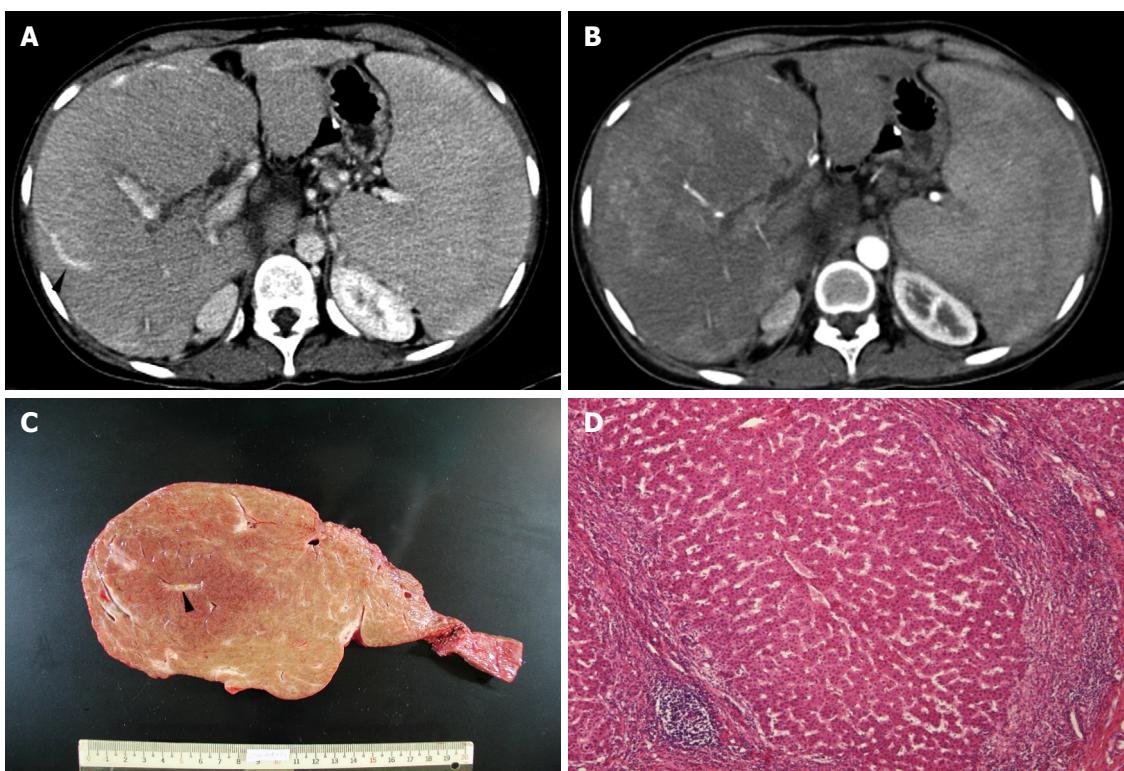

## DISCUSSION

Multi-acinar MRN, first described by Edmondson in

1976<sup>[10]</sup>, are sometimes seen in the cirrhotic liver. In 1996, an International Working Party defined MRN as “at least 5 mm regenerative nodules containing more than one portal tract”<sup>[10]</sup>. The reported prevalence in autopsy and explanted series varies from 14.2% in nodules > 1 cm in diameter to 37% in nodules > 0.5 cm in diameter<sup>[6,11,12]</sup>. It has been proposed that nodules > 2 cm in diameter in a background of cirrhosis are almost always dysplastic. However, these data were derived mainly from viral- or alcoholic-related cirrhotic livers. The smallest lesion found at gross pathology in our series was 1.6 cm in

**Figure 2** A 16-month-old BA girl with a 2.1 cm MRN in segment 8. **A:** During pre-enhanced phase of the CT, no nodule can be seen; **B:** The signal intensity is hyperintense on T2WI MRI.

**Figure 3** Patchy arterial enhancement within the mass in arterial phase of the CT (**A**), tubular structure (arrowhead) within the mass during portovenous phase of the CT (**B**), the explanted liver and intra-tumoral portal tract (arrowhead) (**C**), and microscopic examination (HE) showing uniform benign-looking liver cells arranged in one- to two-cell thick plates with intervening sinusoids and surrounding fibrous septa infiltrated with lymphocyte (**D**) in a 3-year-old BA girl with 13 cm MRN in right liver.

diameter and 56% (5/9) of the nodules were  $> 5$  cm in diameter (Figure 1A). In the literature, lesions  $> 10$  cm in diameter have been reported<sup>[13,14]</sup>.

MRN can be divided into siderotic and non-siderotic types<sup>[15]</sup> based on the presence of iron deposition within the mass. The presence of iron results in hypointense signal especially with longer TE MRI pulse sequences<sup>[16]</sup>. In this study, 63% (5/8) of the regenerating nodules fit this pattern (Figure 1B)<sup>[17,18]</sup>. In non-siderotic regenerating nodules (2/8), the patterns included T1 hypointensity and T2 hyperintensity (Figure 2B). These non-siderotic MRN are difficult to see on pre-enhanced CT due to their isodensity with the surrounding liver parenchyma (Figure 2A). Because of the retrospective

design of the current study, our methodology did not include histopathologic proof that the decreased signal intensity seen was caused by hepatic iron deposition. However, the same imaging techniques have been used to detect hepatic iron overload and siderotic regenerative nodules, and the results were confirmed with quantitative histopathologic measurements<sup>[19-21]</sup>.

In CT hepatic angiography, MRN have been characterized as non-enhancing nodules surrounded by enhancing fibrous septa<sup>[22]</sup>. However, in our study, this structural pattern was not easily seen. Only 25% (2/8) in our cases had broad vascular septa partially discernible by MRI. These septa were hypointense on T1W images, perhaps due to the fibrous component of the septum

itself. Enhancing septa were seen only in two nodules in this series after gadolinium-DTPA administration.

Fifty-three percent (5/8) of the MRN in our series had characteristic internal enhancing tubular structures during porto-venous phase. This was particularly true in the larger masses (Figures 1C and 3B). The enhancing tubular structures correlated with a distorted portal vein accompanying a bile duct on histopathology (Figures 1D and 3C). MRN virtually always contain some normal-appearing abortive portal tracts with complete portal veins, hepatic arteries and bile ducts<sup>[10]</sup>. Importantly, as a regenerative nodule progresses to become a dysplastic nodule or early HCC, one may notice the loss of visualization of these portal tracts and development of new arterial vessels, termed non-triadal arteries. These features are often used to differentiate MRN from adenoma or carcinoma pathologically. Therefore, the imaging appearance of these characteristic findings may be useful in diagnosing MRN during the pretransplant survey among BA patients awaiting LT.

Other useful imaging features used to differentiate MRN from HCC have been described elsewhere. First, a MRN is usually hyperdense to liver parenchyma in pre-enhanced study and often (but not always) does not enhance post contrast. A typical HCC is hypodense or isodense to liver parenchyma in pre-enhanced study and shows early arterial enhancement and early washout in porto-venous phase in dynamic-enhanced CT<sup>[23]</sup>. Second, the signal intensity of MRN in T2WI is often hypointense while malignant tumors are often hyperintense<sup>[23,24]</sup>. Third, MRN, especially larger ones, show splaying of intratumor portal veins while malignant tumors usually demonstrate displaced or obliterated portal veins. However, there are some overlapping features between MRN and HCC<sup>[25]</sup>. In a cirrhotic liver, early reports suggested that virtually all arterial-enhancing lesions are HCC. However, arterial enhancement may be seen in a regenerating nodule, non-tumor arterio-portal shunt, and aberrant venous drainage in a cirrhotic liver<sup>[8,26,27]</sup>. Our series demonstrated that arterial enhancement also occurred in MRN of BA patients.

A MRN has been presumed to be a precancerous lesion in virus-related or alcoholic-related liver cirrhosis because malignant foci are occasionally found in MRN<sup>[28,29]</sup>. Although rare, one case report has described a small HCC in a BA-related cirrhotic liver<sup>[30]</sup>. The possibility of early HCC could not be excluded in some of our pre-transplant imaging surveys of BA patients. According to the non-invasive diagnostic criteria for HCC proposed by the European Association for the Study of the Liver<sup>[31,32]</sup>, a diagnosis of HCC is established by the concomitant positive findings in two imaging techniques, or by a positive findings in one imaging technique with an AFP > 400 µg/L. The radiological interpretations for three arterial-enhancing tumor lesions (patient 2, 5 and 7) in this series were HCC initially (Figure 3A). Using the Barcelona Clinic Liver Cancer staging classification and treatment schedule, LT is considered for patients with three nodules < 3 cm in

diameter or with one tumor < 5 cm in diameter and liver function impairment<sup>[33]</sup>. LT may be precluded in patients 5 and 7 if the HCC diagnosis was made based solely on imaging. Furthermore, the AFP values for all cases were < 3 ng/mL. In such a situation, liver biopsy is necessary to confirm the nature of an arterial enhancing mass in order to exclude hepatic malignancy.

In conclusion, MRN are seen in about 5% of patients with BA awaiting LT. CT and MRI imaging features of MRN as described in this review can be useful in differentiating MRN from HCC in most of BA patients awaiting LT. The presence of an arterial-enhancing nodule should not imply that LT should be withheld solely on the basis of presumed malignancy by imaging studies, especially if the AFP value is incongruent with radiographic findings. Liver biopsy may be required in aid of diagnostic imaging to exclude malignancy in these cases.

## COMMENTS

### Background

End stage liver cirrhosis develops in some biliary atresia (BA) patients later in life. Liver transplantation (LT) is beneficial to such patients. Macro-regenerative nodules (MRNs) in cirrhotic liver are occasionally encountered in computer tomography (CT) / magnetic resonance imaging (MRI) and may be confused with hepatocellular carcinoma (HCC).

### Research frontiers

The authors described typical and atypical CT/MRI appearance of the MRN in BA patients, and the criteria for differentiation of MRNs from HCC. The strategy of managing atypical MRNs is also discussed.

### Innovations and breakthroughs

This study showed that the majority of MRNs can be easily differentiated from hepatocellular carcinoma by CT/MRI and unnecessary liver biopsy can be avoided.

### Applications

Using the radiographic features presented in this study will help manage BA patients awaiting LT properly.

### Terminology

MRN are defined as regenerative nodules larger than 0.5 cm in diameter in a cirrhotic liver. BA is a congenital absence or destruction of the intra- or extra-hepatic biliary system. It affects about 5-10/100 000 live births and is the leading cause for liver transplant in children especially in the oriental population.

### Peer review

The authors described the radiological findings of MRN in the liver of pre-transplantation BA patients and correlated it with histological findings. This is an interesting paper, which is informative to readers.

Published online: July 28, 2008

**METHODS:** From 2004 to 2006, a total of 1024 Chinese patients (aged 35 to 64 years) with severe chronic atrophic gastritis, intestinal metaplasia or dysplasia were randomly assigned to receive 200 mg of celecoxib twice daily or placebo in Linqu County (Shandong Province, China), a high-risk area of gastric cancer. All gastroduodenal ulcer and cardiovascular events occurred were recorded and the patients were followed up for 1.5 years after treatment. At the end of the trial, a systematic interview survey about other adverse events was conducted.

**RESULTS:** Gastroduodenal ulcer was detected in 19 of 463 (3.72%) patients who received celecoxib and 17 of 473 (3.31%) patients who received placebo, respectively (odds ratio = 1.13, 95% CI = 0.58-2.19). Cardiovascular (CV) events occurred in 4 patients who received celecoxib and in 5 patients who received placebo, respectively. Compared with those who received placebo, patients who received celecoxib had no significant increase in occurrence of CV events (hazard ratio = 0.84, 95% CI = 0.23-3.15). Among the adverse events acquired by interview survey, only the frequency of bloating was significantly higher in patients treated with celecoxib than in those treated with placebo.

**CONCLUSION:** Treatment of gastric cancer with celecoxib is not associated with increased risk of gastroduodenal ulcer and cardiovascular events.

### Abstract

**AIM:** To evaluate the long-term risk of gastroduodenal ulcer and cardiovascular events induced by celecoxib in a population-based, randomized, double-blind, placebo-controlled study.

## INTRODUCTION

Celecoxib, approved by the US Food and Drug Administration (FDA) in 1998 for osteoarthritis and rheumatoid arthritis, is a cyclooxygenase-2 (COX-2) inhibitor. Owing to the selective inhibition of COX-2, this drug provides similar anti-inflammatory effects and a reduced risk of gastrointestinal complications in osteoarthritis and rheumatoid arthritis patients compared with nonsteroidal anti-inflammatory drugs (NSAIDs)<sup>[1,2]</sup>, which inhibit both COX-1 and COX-2. In addition, celecoxib, a selective inhibitor of COX-2, can block tumor growth by its antiangiogenic and proapoptotic effects, suggesting that it can be used in the prevention and treatment of cancers<sup>[3-5]</sup>.

However, it was reported that rofecoxib, also a COX-2 inhibitor, is associated with gastrointestinal toxic effects and cardiovascular (CV) events<sup>[6,7]</sup>; But, it has no gastrointestinal toxicity<sup>[8]</sup>. The conflicting results have raised the concern about the safety of celecoxib<sup>[9,10]</sup>. In 2005, the FDA Advisory Committee concluded that the adverse events of celecoxib are less than those of rofecoxib<sup>[11]</sup>. Therefore, we studied the safety issue of celecoxib. Gastroduodenal ulcer and CV events induced by celecoxib are reported in this paper.

## MATERIALS AND METHODS

### **Study population**

In 2004, a total of 1024 subjects, randomly selected from 12 villages of Linqu County (Shandong Province, China), participated in this study. Their age was 35-64 years. All subjects received a brief physical examination and their medical history was recorded. Subjects were ineligible if they had a history of stroke within two years, angina or congestive heart failure or myocardial infarction within one year, neoplastic diseases in the previous 10 years, esophageal or gastric surgery, inflammatory bowel disease, or bleeding diathesis, paracetamol allergy or hypersensitivity to aspirin, or other life-threatening illness. The remainders received <sup>13</sup>C-urea breath test (<sup>13</sup>C-UBT) and gastroscopic examination with biopsies from 5 standard sites of the stomach. Only those who had *Helicobacter pylori* (*H pylori*) infection and a histological diagnosis of severe chronic atrophic gastritis (CAG), intestinal metaplasia (IM) or dysplasia (DYS) were enrolled in the intervention trial. A written informed consent was obtained from each participant and the trial was approved by the Institutional Review Board (IRB) of Peking University School of Oncology (PUSO).

### **Study design and randomization**

Subjects were randomly assigned to received antibiotics and/or celecoxib or their placebo in a 2 × 2 factorial design. Finally, the subjects were divided into four groups. Group 1 received anti-*H pylori* treatment in the first week followed by 200 mg celecoxib twice daily for 24 mo, group 2 received anti-*H pylori* treatment in the first week followed by a look-alike celecoxib placebo for 24 mo, group 3 received a look-alike anti-*H pylori*

placebo in the first week followed by celecoxib twice daily for 24 mo, group 4 received a look-alike anti-*H pylori* placebo in the first week followed by a look-alike celecoxib placebo for 24 mo. We only observed and evaluated the risk of cardiovascular and other adverse events in the celecoxib and placebo groups (Figure 1). Both the participants and investigators were blinded to the treatment. Randomization of treatment assignments was generated at Westat Inc. in the US after eligibility was determined.

From March 16 to 30, 2004, the eligible participants were given a triple therapy with 20 mg omeprazole, 1 g amoxicillin and 500 mg clarithromycin or placebo twice daily for 7 d to eradicate their *H pylori* infection. Then 200 mg of celecoxib or placebo twice daily was given orally from April 8, 2004 to May 6, 2006, except for April 2005 because of the interim gastroscopic examination.

### **Follow-up**

During the period of study, labeled pill bottles of celecoxib or placebo were distributed to participants in each village by PUSO staff and trained field staff each month. The field staff visited each participant twice a month to monitor treatment-related events and to promote pill compliance in the entire duration of the study. The staff counted and recorded the number of pills remaining in each bottle before the new pill bottles were distributed each month. If a subject was not at home during the staff visit, an evening visit was scheduled. A subject was considered compliant if the pill bottle was empty at the end of that month. If a subject was unable to be contacted at the time of counting pills, he or she was considered non-compliant.

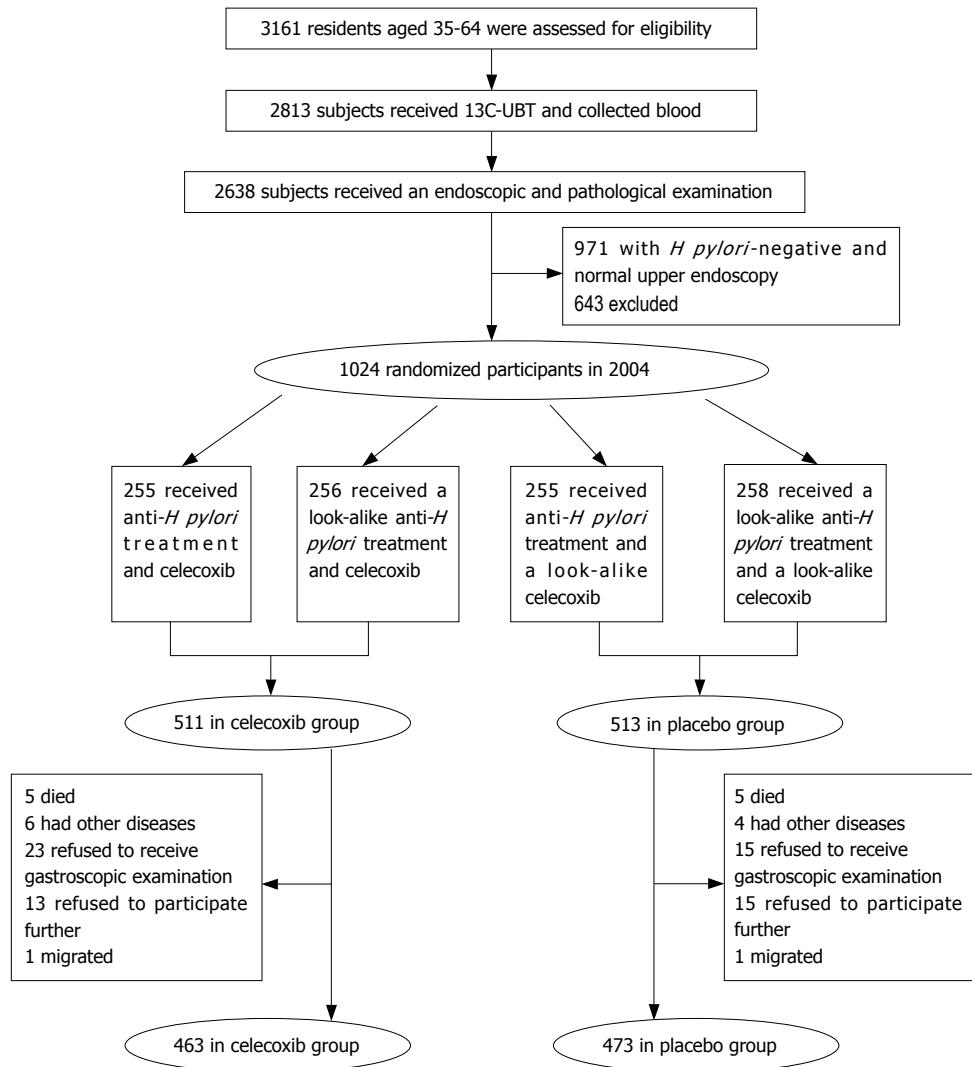

### **Adverse events**

Gastroduodenal ulcer was detected in 2005 and 2006 by the same group of PUSO physicians and gastroenterologists. Gastroscopic procedures, including biopsy samples taken from seven standard sites of stomach and histopathologic criteria, have been described elsewhere<sup>[12]</sup>. The gastroenterologist and pathologist were blinded to the subjects' intervention.

The CV events were defined as fatal or nonfatal myocardial infarction, ischemic and hemorrhagic stroke as previously described<sup>[13]</sup>. When visiting the participants, investigators recorded the CV events and other complaints of the participants. While investigators were absent, participants-reported symptoms were recorded by doctors in village clinics. All the CV events were diagnosed in local hospitals.

Other non-adjudicated adverse events were acquired by an interview among all the subjects at the end of the trial in May 2006. All the subjects' symptoms in the past two years were inquired and recorded by the trained interviewers, checked and categorized by two physicians in a blinded fashion after completion of the survey.

If the symptoms were related to treatment, PUSO physicians and field staff paid a close attention to the

**Figure 1** Trial profile.

subjects for at least 2 mo and these subjects received continuous treatment if the symptoms were aggravated.

### Statistical analysis

This study was designed to achieve a significant level of 95% ( $< 0.05$ ) and a power of 90% to detect a 20% regression of pre-malignant lesions, based on the background of 80% prevalence of gastric atrophy. At least 120 subjects were required in each group in order to detect a significant difference between the different treatment groups.

All data analyses were performed in a blinded fashion. The relative risks (with 95% confidence intervals) of gastroduodenal ulcer were analyzed using logistic regression by adjusting gender, age, smoking and drinking. The rate of CV events was determined and multivariate hazard ratio (HR) was calculated using the Cox proportional-hazard model. All  $P$  values were two-sided, and  $P < 0.05$  was considered statistically significant. All analyses were performed with SAS software, version 8.2.

## RESULTS

The 1024 participants were divided into celecoxib treatment group ( $n = 511$ ) and placebo treatment group ( $n = 513$ ). The baseline characteristics were balanced between the two groups (Table 1). During the two-year period of treatment, 88 participants who were relatively evenly distributed between the two groups withdrew from the study (Figure 1). The compliance rate was 90.61% in the celecoxib treatment group and 92.20% in the placebo treatment group, respectively.

From April 2004 to May 2006, gastroduodenal ulcer was detected in 19 of 463 (3.72%) participants of the celecoxib treatment group and in 17 of 473 (3.31%) participants of the placebo treatment group, respectively. The odds ratio (OR) was 1.13 (95% CI = 0.58-2.19, Table 2).

During the entire period of follow-up, CV events occurred in 4 participants of the celecoxib treatment group and in 5 participants of the placebo treatment group, respectively (Table 2). Compared with the placebo treatment group, the celecoxib treatment had no

Gastric spasmus	15 (3.24)	15 (3.17)	1.02 (0.49-2.12)
Headache	26 (5.62)	23 (4.86)	1.16 (0.65-2.07)
Heartburn	29 (6.26)	23 (4.86)	1.31 (0.75-2.30)
Loss of appetite	25 (5.40)	16 (3.38)	1.63 (0.86-3.10)
Muscle pain	55 (11.88)	70 (14.80)	0.78 (0.53-1.13)
Nausea	14 (3.02)	17 (3.59)	0.84 (0.41-1.72)
Pain in the chest	16 (3.46)	17 (3.59)	0.96 (0.48-1.92)
Palpitations	22 (4.75)	16 (3.38)	1.43 (0.74-2.75)

significant increase in occurrence of CV events (HR = 0.84, 95% CI = 0.23-3.15).

The main nonadjudicated side effects are listed in Table 2. Except for bloating (OR = 2.85, 95% CI = 1.19-6.84), there were no significant differences in the frequency of other nonadjudicated adverse events between the two groups.

## DISCUSSION

In this study, gastroduodenal ulcer and CV events occurred in the subjects who took 200 mg celecoxib twice daily.

Two previous trials addressed the possibility that celecoxib has a lower rate of gastrointestinal complications than NSAIDs<sup>[14,15]</sup>. It was reported that the annual incidence rate of upper gastrointestinal complications and symptomatic ulcers is significantly lower in the celecoxib treatment group than in the combined diclofenac and ibuprofen treatment group (2.08% vs 3.54%;  $P = 0.02$ ) after 6 mo of treatment<sup>[14]</sup>. It has been shown that the incidence rate of gastric ulcer in the celecoxib treatment group and diclofenac treatment group is 18% and 34%, respectively ( $P < 0.001$ ), and the incidence rate of duodenal ulcer is 5% and 11%, in the celecoxib treatment group and diclofenac treatment group, respectively ( $P < 0.009$ )<sup>[15]</sup>.

Although the distinct role of celecoxib in ulcer is still unclear<sup>[16]</sup>, most studies suggested that celecoxib is not associated with gastric or duodenal ulcer<sup>[17-19]</sup>. Our trial compared the effects of celecoxib and placebo on

gastroduodenal ulcer, and the risk of gastroduodenal ulcer was not increased after treatment with 200 mg celecoxib daily compared with placebo.

The association between celecoxib and CV events was still debatable in our study. It was reported that a single dose of 400 mg celecoxib daily and placebo does not induce excess CV risk<sup>[20]</sup>. However, it was reported that 800 mg celecoxib increases the risk of death due to cardiovascular disease, myocardial infarction, stroke, or heart failure<sup>[21]</sup>.

The mechanism underlying the potential cardiovascular risk of COX-2 inhibitors is not fully understood. Although the imbalance caused by COX-2 inhibitors suppressing the COX-2 dependent prostacyclin production in endothelial cells without affecting the synthesis of platelet-derived thromboxane A<sub>2</sub>, may promote thrombosis and increase the risk of CV events<sup>[22-24]</sup>, the extent of instability to serum thromboxane and platelet function can be influenced by many factors, such as different doses of COX-2 inhibitors, variability among patients<sup>[16]</sup>.

In this study, different dose-effects of celecoxib on cardiovascular risk were observed. The dose of 800 mg celecoxib daily could increase the CV risk. However, 400 mg celecoxib daily did not increase the CV risk, suggesting that it can be used in the treatment of gastric ulcer.

In the present study, the frequency of bloating was higher in the celecoxib treatment group than in the placebo treatment group. However, the CV events were mild and tolerable, and none of the participants withdrew from this trial.

In conclusion, increases in gastroduodenal ulcer and CV events do not occur in subjects who take 200 mg celecoxib twice daily for two years. Celecoxib can be used in prevention and treatment of gastric cancer.

## ACKNOWLEDGMENTS

The authors thank the residents, field staff, and governments of Linqu County for supporting this long-term trial.

## COMMENTS

### Background

Celecoxib, a cyclooxygenase-2 inhibitor, is widely used as an analgesic and anti-inflammatory agent. In addition, it can prevent cancer. However, it is necessary to evaluate the risk of gastroduodenal ulcer and cardiovascular events, particularly in population-based studies.

### Research frontiers

No increase in gastroduodenal ulcer and cardiovascular (CV) events were found in the subjects who took 200 mg celecoxib twice daily for two years.

### Innovations and breakthroughs

This paper firstly reports an assessment of celecoxib-related gastroduodenal ulcer and cardiovascular events in Chinese population.

### Applications

Celecoxib (200 mg twice daily for two years) can prevent and treat gastric cancer in Chinese population.

### Peer review

The authors documented the absence of adverse effects of prolonged celecoxib administration at gastroduodenal and cardiovascular level in Chinese patients. The study was well designed and the results are reliable.

### Abstract

**AIM:** To explore the role of radio-frequency ablation (RFA) as a treatment for hilar cholangiocarcinoma.

**METHODS:** Eleven patients with obstructive cholestasis underwent Computed Tomography (CT) examination, occupying lesions were observed in the hepatic hilar region in each patient. All lesions were confirmed as cholangioadenocarcinoma by biopsy and were classified as type III or IV by percutaneous transhepatic cholangiography. Patients were treated with multiple electrodes RFA combined with other adjuvant therapy. The survival rate, change of CT attenuation coefficient of the tumor and tumor size were studied in these patients after RFA.

**RESULTS:** In a follow-up CT scan one month after RFA, a size reduction of about 30% was observed in six masses, and two masses were reduced by about 20% in size, three of the eleven masses remained unchanged. In a follow-up CT scan 6 mo after RFA, all the masses were reduced in size (overall 35%), in which the most significant size reduction was 60%. The survival follow-up among these eleven cases was 18 mo in average. Ongoing follow-up showed that the longest survival case was 30 mo and the shortest case was 10 mo.

**CONCLUSION:** RFA is a microinvasive and effective treatment for hilar cholangiocarcinoma.

### INTRODUCTION

Hilar cholangiocarcinoma (also known as Klatskin Tumor) was first reported by Gerald Klatskin in 1965. Since then, many therapeutic methods have been established to treat this type of tumor. For those patients presenting with type I and type II tumors, surgical resection is good and has a high 5-year survival rate<sup>[1-5]</sup>. However, for those tumors classified as type III and IV tumors, the surgical prognosis is poor even when combined with local tumor resection and left or right hemi-lobectomy of the liver, which can itself lead to further complications<sup>[6-8]</sup>. Thus, finding a surgical approach for the treatment of type III and IV Klatskin tumors is problematic. Percutaneous image-guided radiofrequency ablation (RFA) has received increasing attention as a promising technique for the treatment of liver tumors. This technique permits the destruction of tumors without necessitating their removal, and in many cases, can be used in place of more invasive and expensive surgical treatment. Initial attempts at tissue ablation with radiofrequency have been limited to the 1.6-cm diameter coagulation necrosis obtained from a single conventional electrode<sup>[9]</sup>. In order to achieve larger thermal necrosis, internally cooled, single or

clustered electrode technique, as well as expandable needle techniques has been introduced. Hence, from May, 2003 to December, 2005, we applied RFA therapy to a group of 11 patients with pathologically confirmed, type III and IV cholangiocarcinoma after percutaneous transhepatic cholangic drainage (PTCD) in order to determine its safety, efficacy, and outcome.

## MATERIALS AND METHODS

### Patient demographics

Eleven patients enrolled in this study were all male, ranging in age from 42 to 74 years, with a mean of 52 years. All patients presented with jaundice, and underwent CT examination. Occupying lesions were observed in hepatic hilar region in all cases. All lesions were confirmed as cholangioadenocarcinoma by biopsy and were classified as type III a ( $n = 4$ ), type III b ( $n = 2$ ), type IV ( $n = 5$ ) tumors by percutaneous transhepatic cholangiography. The average dimensions of the tumor masses were 3.4–4.5 cm.

### Instruments

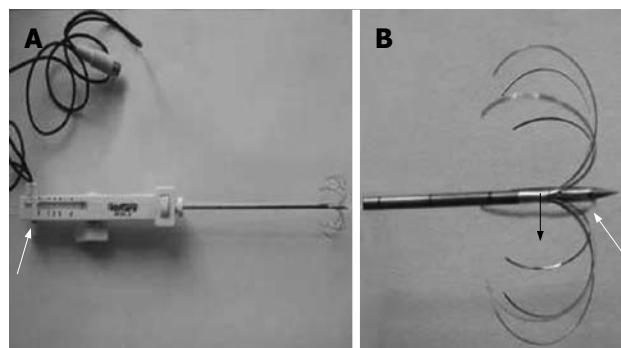

The Marconi CT-Twin flash, with the following parameters: volumetric scan with 5–10 mm thickness and pitch 1, WE7568 multiple electrode tumor RF ablator, 200W pulse output and 290 KHz pulse frequency, was applied (made by Beijing Welfare Electronic Co.). A temperature sensor was installed in the electrode to monitor the temperature and the sensor deviation was  $\pm 0.50^{\circ}\text{C}$ . A WHK-4 multiple electrode tumor RFA electrode with side holes ablation needle was applied. These systems deploy an array of multiple curved stiff wires in the shape of an umbrella from a single 14-gauge or 16-gauge canula (Figure 1). This array can produce zones of coagulation necrosis of up to 4–5 cm compared to the bipolar electrode. Furthermore, there are tiny side holes in the distal end of the central electrode, which make it possible for saline infusion during RFA in order to avoid charring and improve the ablation effect.

### Therapeutic strategy

All patients were hospitalized with proper blood analyses and preparations before synthetic interventional therapy. PTCD was performed for biliary drainage for 2 wk prior to RFA in order to preserve or improve hepatic function. The tumor size determined the number of sessions and duration of RFA.

### PTCD (percutaneous transhepatic cholangic drainage)

By using a 22 gauge Chiba needle, PTC was performed from the right middle axillary line to the most dilated intrahepatic biliary duct according to a prior CT scan. When the needle punctured the biliary duct, we fixed the needle and injected contrast media to perform cholangiography. The contrast media allowed better depiction of the stenotic segment and determined whether the left and right hepatic ducts were involved, allowing the tumor to be staged further. A unilateral

**Figure 1** **A:** The white arrow indicates the injection hole; **B:** The white arrow indicates the side hole, and the black arrow indicates hooked array radiofrequency needles

drainage catheter was applied for type III a and type III b. Bilateral kissing catheters were applied for type IV. The percutaneous drainage catheter was fixed onto the skin with stitches and connected with a drainage bag for daily observation of external bile drainage.

### RFA

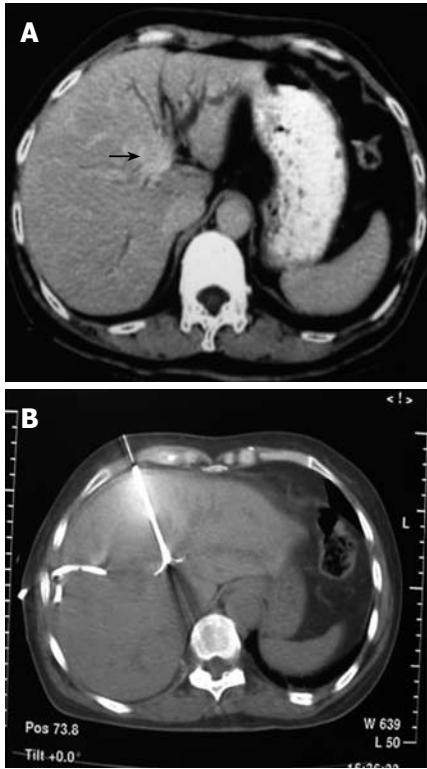

After 2 wk of biliary drainage, depending on the patient's general condition and improvement of the hepatic function, RFA was applied by percutaneous puncture into the tumor mass with an ablation electrode needle under CT guiding (a density survey of the tumor mass was performed before the procedure). After optimal tumor puncture, we delivered the electrodes in appreciable diameter. The electrodes were distanced from the drainage catheter during the RFA procedure, thereby protecting the catheters from mechanical puncture and thermal damage. The duration of ablation was dependant on the size of the tumor mass, with 10 min for those  $\leq 3$  cm, and 10–15 min for those around 3.1–4.0 cm. We prolonged the procedure time during which the temperature slowly increased. Injection of 1 mL of 10% saline from the side aperture of the needle every minute enhanced the excitement of ion vibrations, increasing the capability of the device. A CT scan was performed after delivering the electrodes to ensure that the entire lesion was fully covered within the region of RFA. This would provide complete tumor necrosis and eliminate the possible residual tumor infiltration in the adjacent area (Figures 2 and 3).

### Follow up

After RFA, regular monthly abdominal CT scans including a plain scan, double-phase scan and delayed image were performed with biochemical blood analysis in the first 6 mo. For the next 6 mo, follow-up work was every 2 mo, and 1 year after RFA, follow-up was every 3 mo.

### Evaluation of the therapeutic effect

One month after the RFA synthetic therapy, CT scans were compared to the baseline data. The treatment was counted as effective, in case where there was significant density attenuation of the tumor mass with no contrast

**Figure 2** A case with type IIIb Klatskin tumor. **A:** Plain CT scan reveals that the tumor is in the main trunk of left hepatic duct with dilatation of branches; **B:** The patient underwent RFA under CT guidance after internal and external drainage for two weeks.

enhancement, regardless of whether the tumor size was reduced or remained unchanged. Conversely, cases were counted as non-effective, if the tumor mass was enlarged and there was no significant density attenuation and inhomogeneous enhancement by IV contrast.

## RESULTS

### Quantification of tumor density change

The average density of the 11 tumor masses was 44.23 Hu before RFA therapy. One month after the therapy, it decreased to 21.6 Hu with the most marked case being a decrease of about 40 Hu.

### Quantification of tumor size

After RFA treatment, six masses had diminished in size by approximately 30%, two masses had been reduced by approximately 20% and no significant change in size was noted in three masses. These results were confirmed 1 mo later by a second CT scan. After 6 mo, the average size reduction in all the masses was approximately 35%. The most significant size reduction was 60%.

### Quantification of biochemical blood analysis

One month after PTCD, the direct and indirect bilirubin levels returned to their normal range (direct bilirubin  $\leq 8 \mu\text{mol/L}$  and indirect bilirubin  $\leq 15 \mu\text{mol/L}$ ) in nine cases. By 6 mo after RFA therapy, the bilirubin levels of all cases had returned to their normal range.

### Quantification of complications

No severe complications occurred during or after each procedure with the exception of fever post RFA.

### Survival analysis

The 11 patients were all alive at the end of the study. The survival period among these 11 cases was 18 mo on average. Ongoing follow-up showed that the longest survival case was 30 mo and the shortest case was 10 mo.

## DISCUSSION

Gerald Klatskin<sup>[10]</sup> first described the specific entities of adenocarcinoma as confined below, at or above the confluence of the common hepatic duct in 1965. Afterwards, Bismuth and Corlette<sup>[11]</sup> classified the tumor into four types: Type I: the lesion is confined to the common hepatic duct with no involvement of the left and right common ducts or confluence; Type II: confluence of the hepatic ducts is involved, but the lesion does not extend to the left and right intrahepatic biliary ducts; Type III a: the lesion spreads to the right hepatic duct; Type III b: the lesion spreads to the left hepatic duct; Type IV: involvement of the left and right hepatic ducts and confluence<sup>[12-18]</sup>.

For Type I and II tumors, surgical resection is the most effective form of therapy. Furthermore, a surgical approach is still possible in cases of local tumor recurrence<sup>[19,20]</sup>. However, for Type III tumors, radical resection is an aggressive procedure that might involve removal of the left or right hepatic lobe and caudate lobe of the liver. A mortality rate of up to 10% has been encountered, and survival after surgical resection on this type of tumor has been disappointing<sup>[12,14,21-24]</sup>. Palliative resection of Type IV tumor is still controversial, but doctors tend to perform liver transplantation. Transartery chemoembolization (TACE) is not an ideal treatment for Type IV tumors. Since the tumor mass is hypo-vascular, only a faint tumor contrast dye will be observed by DSA (Digital Subtraction Angiography) resulting in inadequate lipiodol staining. Chemotherapy either general or intra-arterial does not improve survival<sup>[25-27]</sup>. Based on these reasons, we propose that RFA therapy should be used for the treatment of type III and IV cholangiocarcinoma.

Due to the massive and wide range of invasion of the tumor, the majority of patients with Type III and IV Klatskin's tumor present with serious obstructive jaundice on admission. Therefore, with the aid of DSA, PTCD is the first step of the sequential interventional therapy since it anticipates jaundice and decompensates liver function by using an internal and external drainage. Two weeks following the drainage, until jaundice diminishes and hepatic function is amended, RFA is carried out and that is the most critical step of this sequential interventional therapy. RFA is becoming a widely used tool for treatment of liver metastatic tumors especially since Rossi *et al* introduced new needle

**Figure 3** A case with type IV Klatskin tumor. **A:** The plain CT reveals that the tumor is in the portal hepatic region with dilatation of the left and right hepatic ducts; **B:** The patient underwent RFA under CT guidance after internal and external drainage for 2 wk; **C:** The plain CT scan reveals a liquidized and necrotic region of the tumor in the portal hepatic region without contrast enhancement 2 mo after RFA.

electrodes capable of increasing the diameter of tissue necrosis to 4-5 cm<sup>[28,29]</sup>. The tissue necrosis should include 5 mm of normal tissue around the lesion for oncological clearance.

The basic principle of RFA therapy is described below. Under CT or sonographic guidance, the electrode percutaneously punctures and is placed into the tumor tissue with single or multiple electrode probes. The cluster of electrodes at the end of the probe will emit median to high-frequency electromagnetic wave energy that may induce ionic vibrating friction of the target tissue cells resulting in the generation of heat. As the local temperature increases up to 80°C-90°C, it is sufficient to cause coagulation necrosis of the tumor tissue, and eventually, liquefaction or fibrosis. Coagulation of the peripheral vessel and tissue around the tumor will form a reactive zone. Thus, the tumor blood supplies are interrupted contributing to the prevention of metastasis.

The tumor size determines the number of sessions and duration of RFA. Furthermore, extending the range of RFA to 0.5 cm out of the normal tissue margin where possible will effectively eliminate potential minimal tumor infiltration in the normal liver tissue. This creates a free margin and may reduce the likelihood of tumor relapse.

RFA has a tendency to injure the biliary system when the lesions are near the porta hepatis. This injury may be a bile fistula or an obstruction of the biliary tract. In our study, none of these complications occurred, since PTCD was performed in all of our cases before RFA. The advantages of PTCD before RFA are that: (1) the probability of biliary tract injury decreases due to remission of the obstruction and dilation of the biliary tract after PTCD; and (2) the drain pipe which was detained in the biliary tract during PTCD can be used as a localization mark during RFA.

There are several large vessels near the porta hepatis. Thus, serious hemorrhage will occur if the puncture of the needle injures the large vessels. Hemorrhage will also occur if the dissepiment necrosis of the vessels happens during the RFA procedure due to the entry of the electrode. RFA treatment of all 11 cases in our

study did not result in hemorrhagic complications. Our experience is that the radiologist who operates the RFA procedure must possess the imaging radiology and puncture technique, as well as being able to identify the large vessels in the porta hepatis and evade them. When the electrode enters the large vessels, the temperature remains low or the curve of the temperature offers crenate type and duty curve lasts high. At this time, the power source must be turned off immediately, and the location of the needle and electrode is adjusted. The cooling effect of the blood flow in the large vessels near the lesions results in lower efficacy in tumor necrosis. Our countermeasure is to inject 1 mL of 10% saline from the side aperture of the needle every minute to enhance ion vibration and excite the instrument to enhance the duty. It is also important to prolong the procedure time to ensure that the total time of effective temperature (higher than 70°C) lasts for 10-15 min.

Evaluation of the therapeutic effects of this treatment requires analysis of the changes in the density and size of the tumor mass by CT compared with base line data. One month follow-up after RFA showed that for all 11 cases, there were varying degrees of diminishing density and there was no enhancement in the contrast scans of the tumor mass. These effects were mainly due to the tumor coagulation and necrosis. In some cases, the lesion presented with an even lower density value because of the vacuum phenomenon resulting from long-term and multi-session therapy.

Six masses had diminished in size by approximately 30%, two masses had been reduced by approximately 20% and no significant change in size was noted in three masses.

Size reduction of the tumor mass was significantly noted in six out of 11 cases, two masses had been reduced by approximately 20%, and the other three lesions remained unchanged in other five patients in one month CT follow-up. However, 6 mo after synthetic sequential IR therapy, all 11 cases presented with varying degrees of size reduction. This was probably due to the slow progressive development of the coagulated necrosis, liquefaction and fibrosis of the lesion.

To date, all 11 patients are alive. A recent follow-up shows that the survival of a group of 29 cases of Klatskin tumor treated by surgical intervention. The mortality rate in the hospital (during and after surgery) was 17%, the average hospital stay was 71 d, and a survival rate of 1 year was observed in 50% of cases. Tsukada *et al* reported the survival after RFA therapy to be 18 mo on average, ranging between 10 mo and 30 mo so far. No complications among these 11 cases were observed during or after synthetic sequential interventional therapy. Parc *et al*<sup>[12]</sup> reported a group of 39 cases of Klatskin's tumor treated by surgical intervention. Radical resection was performed in 18 cases, and the remaining 21 cases underwent palliative operation. Among the 18 cases treated with radical resection, one had type I, two had type II, eight had type III a, two had type III b and five had type IV. Four of the 18 cases developed post-operative complications and the survival rate ranged between 1 (67%) and 5 (47%) years. Of the 21 cases treated with palliative operation, the post-surgery mortality was 14% and the mean survival range was only 7 mo. Nimura<sup>[30,31]</sup> performed a liver and bile duct resection combined with Whipple's operation in five patients with hilar tumors. Two of the five patients died after surgery and the three survivors died 8, 10 and 27 mo later.

Compared with surgical intervention, the RFA treatment that we used for type III and IV Klatskin's tumor is less invasive and involves less complications. Furthermore, a higher mean survival rate (up to 18 mo) has been shown after RFA than surgical intervention. Thus, we believe that RFA is a less invasive, safe, effective and promising therapy for type III and IV Klatskin tumors. The long-term curative effect requires further study.

## COMMENTS

### Background

Hilar cholangiocarcinoma (also known as Klatskin tumor) was first reported by Gerald Klatskin in 1965. Since then, many therapeutic methods have been established to treat this type of tumor. For those patients presenting with type I and type II tumors, surgical resection is good and has a high 5-year survival rate. However, for those tumors classified as type III and IV tumors, the surgical prognosis is poor even when combined with local tumor resection and left or right hemi-lobectomy of the liver, which can itself lead to further complications. Thus, finding a surgical approach for the treatment of type III and IV Klatskin tumors is problematic.

### Research frontiers

Percutaneous image-guided radiofrequency ablation (RFA) has received increasing attention as a promising technique for the treatment of liver tumors. This technique permits the destruction of tumors without necessitating their removal, and in many cases, can be used in place of more invasive and expensive surgical treatment. Initial attempts at tissue ablation with radiofrequency have been limited to the 1.6-cm diameter coagulation necrosis obtained from a single conventional electrode. In order to achieve larger thermal necrosis, internally cooled, single or clustered electrode technique, as well as expandable needle techniques have been introduced.

### Innovations and breakthroughs

To date, all 11 patients are alive. A recent follow-up shows that the survival range after RFA therapy is 18 mo on average, ranging between 10 mo and 30 mo so far. No complications among these 11 cases were observed during or after synthetic sequential interventional therapy. Compared with surgical intervention, the RFA treatment that we used for type III and IV Klatskin's tumor

is less invasive and involves less complications.

### Applications

RFA is a less invasive, safe, effective and promising therapy for type III and IV Klatskin tumors. The long-term curative effect requires further study.

### Peer review

According to the study, we know that a new therapy for type III and IV Klatskin tumor, and RFA is less invasive, soft and have fewer complications than common surgical treatment. It is worth paying attention and we are looking forward to the better curative effect from RFA.

## INTRODUCTION

Excessive activation of the inflammatory mediator cascade during severe acute pancreatitis (SAP) is a major cause of multiple organ dysfunction syndrome (MODS), which leads to a high mortality rate<sup>[1]</sup>. Therapeutic strategies targeting these inflammatory mediators are thought to be an ideal way to reduce the severity of SAP. This is difficult, however, because the cytokines, such as TNF- $\alpha$  and IL-1 $\beta$ , are released early in the development of a systemic inflammatory response<sup>[2]</sup>. This leaves a narrow therapeutic window for the administration of

therapeutics, and delayed delivery of anti-inflammatory therapeutics are not effective after the inflammatory mediator cascade has developed<sup>[2]</sup>.

High mobility group box 1 (HMGB1) protein, which has been known as a ubiquitously expressed, intracellular DNA-binding protein for about 30 years, was recently identified as a late-acting mediator of endotoxin lethality<sup>[3]</sup>. It was reported that serum HMGB1 levels increased in patients with sepsis/endotoxemia<sup>[3-5]</sup>, hemorrhagic shock<sup>[6]</sup>, acute lung injury<sup>[7,8]</sup>, rheumatoid arthritis<sup>[9]</sup> and disseminated intravascular coagulation<sup>[10]</sup>. HMGB1 is identified as a late mediator of endotoxin lethality because its systemic release during endotoxemia is delayed as compared with the rapid increase of the early proinflammatory cytokines, such as TNF- $\alpha$  and IL-1 $\beta$ . HMGB1 is released by endotoxin-stimulated macrophages only after a delay of 12-18 h. A similar delayed appearance of HMGB1 (8-32 h) was also observed in the serum of mice with endotoxemia after TNF- $\alpha$  had reached its peak and subsided<sup>[3]</sup>. Delayed anti-HMGB1 antibody dosing still confers significant protection against endotoxin lethality<sup>[3]</sup>. Strategies that target HMGB1 with specific antibodies or antagonists seem to have potential value for treating lethal systemic inflammatory diseases characterized by excessive HMGB1 release, and the delayed kinetics indicate that HMGB1 may provide a broader therapeutic window for treating those inflammatory disorders<sup>[11]</sup>.

It has been recently demonstrated that the serum levels of HMGB1 were significantly elevated in patients with SAP on admission, and were correlated with the severity of the disease<sup>[12]</sup>. Early blockade of HMGB1 attenuates the development and associated organ dysfunction in experimental SAP<sup>[13]</sup>. These indicate that HMGB1 may be an effective therapeutic target of SAP. In a previous experimental study, we demonstrated that the serum levels of HMGB1 began to rise significantly at 12 h, and were maintained in high levels up to 48 h after induction of experimental SAP in rats<sup>[14]</sup>. Thus, we conceive that delayed therapeutic delivery targeting HMGB1 might attenuate SAP in rats.

Ethyl pyruvate (EP), a stable lipophilic pyruvate derivative, is an agent that can effectively protect animals from ischemia-reperfusion-induced tissue injury<sup>[15]</sup>. EP administration significantly improves the survival of lethal hemorrhagic shock in standard models<sup>[16,17]</sup>, and significantly inhibits the systemic release of both early (TNF- $\alpha$ ) and late (HMGB1) cytokines that mediate the lethality of sepsis and systemic inflammation, even when administered 24 h after cecal puncture<sup>[18]</sup>. We hypothesize that delayed EP administration could reduce the severity of SAP in rats through inhibiting the systemic release of HMGB1.

## MATERIALS AND METHODS

### Animals

Male Wistar rats weighing 200-250 g were obtained from the Experimental Animal Center of Tongji

Medical College, Huazhong University of Science and Technology (Wuhan, China). Before the experiment, the animals were kept in rooms at 20 °C ± 2 °C in 12-h light-dark cycles for at least 1 wk to acclimate to the surroundings with free access to water and standard rat chow.

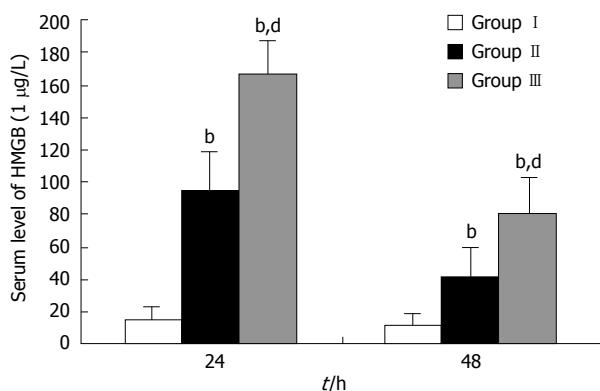

### Induction of pancreatitis

The animals were fasted with free access to water 12 h before surgery. The rats were then intra-abdominally anesthetized by 1% pentobarbital sodium (35 mg/kg body weight), and incised through a median incision of the abdomen. After the common bile duct was clamped in the hepatoduodenal ligament by a small bulldog clamp, the biliopancreatic duct was cannulated through mammary papilla from the anterior wall of the duodenum. 1 mL/kg body weight of 5% sodium taurocholate (Sigma, St. Louis, MO, USA) was injected by the cannula with an even speed of 0.1 mL/min, and the atraumatic vascular clamp was removed 10 min later. Finally, the abdominal incisions were closed in two layers. All procedures were performed using a sterile technique.

### Study protocol

After the stabilization period, 96 male rats were randomly divided into three groups (each group  $n = 32$ ), and each group was divided into two subgroups (each subgroup  $n = 16$ ). Animals in a subgroup were sacrificed at either 24 h or 48 h after surgery. Rats in group I (sham group) underwent laparotomy with manipulation of the pancreas (sham procedure) and received 40 mL/kg normal saline subcutaneously (single dose). Groups II and III underwent laparotomy with induction of SAP, and subsequently received saline every 6 h after induction of SAP. Rats in group II (delayed EP treatment group) additionally received 30 mg/kg body weight EP intravenously at 12, 18 and 30 h after induction of SAP. EP (Sigma, St. Louis, MO, USA) was prepared in solution with sodium (130 mmol/L), potassium (4 mmol/L), calcium (2.7 mmol/L), chloride (139 mmol/L), and EP (28 mmol/L) (pH 7.0). Rats in group III (SAP group) intravenously received the same volume of vehicle at the same time as in group II. Twenty four hours after induction of SAP, the surviving rats were anesthetized with ether, and blood samples were taken from the inferior vena cava to measure serum HMGB1 levels and blood biochemical parameters. The animals were sacrificed, and the right lung was obtained to evaluate lung injury. 48 h after induction of SAP, only blood samples were taken in order to measure serum HMGB1 levels.

To investigate the effect of EP on the survival time of SAP rats, 48 male rats underwent laparotomy with induction of SAP, and were randomly divided into two groups (each group  $n = 24$ ): SAP group and delayed EP treatment group. Rats in the EP treatment group received delayed EP delivery (30 mg/kg body weight) intravenously at 12, 18, 30 and 48 h after induction of SAP, and received

**Figure 1** Serum HMGB1 levels of rats. Group I: Sham group; Group II: Delayed EP treatment group; Group III: SAP group. <sup>b</sup>*P* < 0.01 vs Group I; <sup>d</sup>*P* < 0.01 vs Group II.

the above-mentioned fluid resuscitation. Rats in the SAP group received fluid resuscitation and the same volume of vehicle intravenously as in the EP treatment group. The number of surviving rats was recorded every 4 h after induction of SAP.

#### HMGB1 measurement

HMGB1 was analyzed by Western blot as described by Wang *et al*<sup>[3]</sup>. Briefly, serum was first filtered with Centricon YM-100 (Millipore) to clear the samples from cell debris and macromolecular complexes formed during clotting. Samples were then concentrated 15-fold with Centricon YM-30 and separated on 12% SDS-polyacrylamide gels. Protein was transferred to nitrocellulose membranes (Pall) and HMGB1 was analyzed by using polyclonal anti-HMGB1 antibodies (Santa Cruz) and secondary anti-goat alkaline phosphatase (Beijing Zhongshan Biotechnology). The intensity of the 30-kDa band was analyzed by densitometry. Standard curves were constructed using r-HMGB1 (Sigma, St. Louis, MO, USA).

#### Blood biochemical parameters measurements

Serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), blood urea nitrogen (BUN), and creatinine (Cr) levels were measured using a standard clinical automated analyzer.

#### Lung wet-to-dry-weight (W/D) ratios and histological scores

The right lung was wiped dry with filter paper and weighed. Then, it was dried to a constant weight at 60 °C for 72 h in an oven. W/D ratios could then be calculated. Routine paraffin sectioning was performed on the lung tissue. Pulmonary histological scores were graded using a Gloor score system (normal, 0; mild, 1; moderate, 2; severe, 3; overwhelming, 4) for intra-alveolar oedema, intra-alveolar haemorrhage, and neutrophil infiltration and these scores were then added to give a total score<sup>[19]</sup>.

#### Statistical analysis

mean ± SD values for blood biochemical parameters,

**Table 1** Blood biochemical parameters

Groups	Group I	Group II	Group III
AST (IU/L)	154 ± 20	446 ± 91 <sup>b</sup>	653 ± 98 <sup>b,d</sup>
ALT (IU/L)	51 ± 9	667 ± 103 <sup>b</sup>	1368 ± 271 <sup>b,d</sup>
BUN (mg/dL)	26 ± 3	38 ± 4 <sup>b</sup>	41 ± 4 <sup>b</sup>
Cr (mg/dL)	0.4 ± 0.1	1.2 ± 0.3 <sup>b</sup>	1.8 ± 0.3 <sup>b,d</sup>

Blood samples were obtained 24 h after induction of SAP. Group I: Sham group; Group II: Delayed EP treatment group; Group III: SAP group. <sup>b</sup>*P* < 0.01 vs Group I; <sup>d</sup>*P* < 0.01 vs Group II.

HMGB1 serum levels, lung W/D ratios and histological scores were determined. The differences between the two groups were further evaluated with the Mann-Whitney *U* test. Overall survival was calculated by the Kaplan-Meier Estimate. The log-rank test and the Breslow test were used to compare survival curves in the two groups. A *P* value < 0.05 was considered statistically significant.

## RESULTS

#### Serum HMGB1 levels

At 24 h and 48 h after induction of SAP, serum HMGB1 levels of SAP rats were higher than those of the sham group. Delayed EP administration significantly reduced the serum HMGB1 levels of SAP rats (Figure 1).

#### Lung injury

Lung W/D ratios were observed to evaluate the severity of pulmonary edema. At 24 h after induction of SAP, W/D ratios were elevated in the SAP group in comparison with the sham group ( $9.76 \pm 0.45$  vs  $5.43 \pm 0.21$ , *P* < 0.01). The lung W/D ratio of rats that received delayed EP administration was significantly lower than that of the SAP group (*P* < 0.01), although it was significantly higher than that of the sham group ( $8.22 \pm 0.42$  vs  $5.43 \pm 0.21$ , *P* < 0.01).

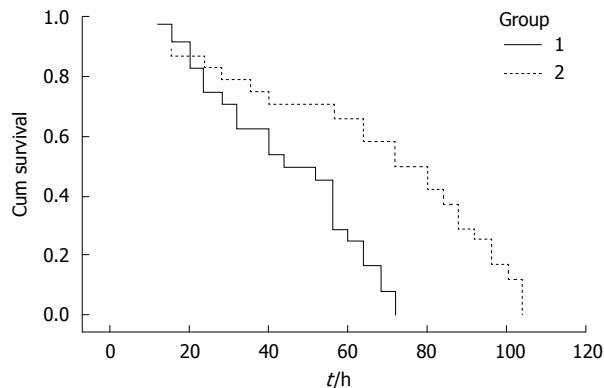

The pulmonary histological scores, an all round evaluation for lung injury, were lower in the EP treatment group than that in the SAP group ( $7.1 \pm 0.7$  vs  $8.4 \pm 1.1$ , *P* < 0.01), although they were significantly elevated in comparison with the sham group (vs  $0.5 \pm 0.1$ , *P* < 0.01).

#### Hepatic and renal dysfunction

EP treatment protected against liver and renal injury. 24 hours after induction of SAP, serum AST, ALT, BUN and Cr levels were significantly elevated in groups II and III. Delayed EP administration significantly attenuated the elevated AST, ALT and Cr levels (Table 1).

#### Survival analysis

SAP rats all died within 3 d without the delayed EP administration, and their median survival time was 44 h (95% confidence interval 29.6 h to 58.4 h). Delayed EP administration significantly prolonged the median survival time to 72 h (95% confidence interval 52.8 h to 91.2 h; Figure 2).

**Figure 2** Kaplan-Meier survival curves of SAP rats. 1: SAP group; 2: Delayed EP treatment group. Log-rank test,  $P = 0.0006$ ; Breslow test,  $P = 0.0050$ .

## DISCUSSION

Extracellular HMGB1 was recently implicated as a late mediator of delayed endotoxin lethality. High serum HMGB1 levels in patients with sepsis are associated with increased mortality, and administration of HMGB1 produces acute inflammation in animal models of lung injury and endotoxemia. During lethal endotoxemia in mice, serum HMGB1 levels accumulate 8–32 h after LPS administration<sup>[3]</sup>. Passive immunization of mice with anti-HMGB1 antibodies attenuates LPS-induced lethality, even when antibody administration is delayed until after the onset of the early proinflammatory cytokine response (2 h after endotoxin administration)<sup>[3]</sup>. The delayed kinetics of HMGB1 appearance indicates that the therapeutic window may be significantly wider than for any previously described cytokine target.

In a previous experimental study, we demonstrated that the serum levels of HMGB1 began to increase significantly at 12 h after induction of SAP, after the TNF- $\alpha$  and IL-1 $\beta$  peak had already occurred. The delayed kinetics of HMGB1 release may provide a wider therapeutic window for SAP. It was shown that EP could inhibit HMGB1 release from macrophages and prevent the accumulation of serum HMGB1 levels in mice with lethal sepsis by inhibiting NF- $\kappa$ B and p38 MAPK signaling<sup>[18]</sup>. In this study, we administered SAP rats with EP intravenously. As a result, EP significantly reduced serum HMGB1 levels in rats with SAP, even though EP delivery began 12 h after induction of SAP.

In SAP, MODS, a consequence of the systemic inflammatory response syndrome, is a contributor to high mortality in the early phase<sup>[11]</sup>. It is conceivable that the release of mediators from the excess of activated macrophages/monocytes and neutrophils may lead to remote organ injury<sup>[11]</sup>. Serum HMGB1 levels are significantly elevated in patients with SAP on admission<sup>[12]</sup>. Purified rHMG-1 is lethal to both LPS-responsive (C3H/HeN, Balb/c) and LPS-resistant (C3H/HeJ) mice, indicating that HMG-1 mediates lethal toxicity in the absence of LPS signal transduction<sup>[3]</sup>. The cytokine activity of HMGB1 has been well-documented in many cell types. In cultured human primary macrophages/monocytes, HMGB1 stimulates

the release of multiple proinflammatory cytokines, including TNF- $\alpha$ , IL-1 $\alpha$ , IL-1 $\beta$ , IL-1RA, IL-6, IL-8, MIP-1 $\alpha$ , and MIP-1 $\beta$ , but not IL-10 and IL-12<sup>[20]</sup>. In cultured human microvascular endothelial cells, addition of HMGB1 induces the expression of adhesion molecules, such as ICAM-1, VCAM-1, and RAGE, as well as the release of TNF- $\alpha$  and IL-8, MCP-1, PAI-1, and tPA<sup>[21]</sup>. HMGB1 also activates human neutrophils to produce proinflammatory mediators, such as TNF- $\alpha$ , IL-1 $\beta$ , and IL-8, suggesting an important role for HMGB1 in activation of neutrophils during inflammation<sup>[22]</sup>. HMGB1 also increases the permeability in cultured enterocytes via a nitric oxide (NO)-dependent pathway<sup>[23,24]</sup>. These indicate that HMGB1 is potent in augmenting the inflammatory response. A previous study showed the early blockade of HMGB1 attenuated organ dysfunction in experimental SAP<sup>[13]</sup>. This study indicated that HMGB1 might be a good target to prevent organ injury in SAP. In this study, to evaluate the degree of injury in distant organs, such as lung, liver and kidney, serum AST, ALT, BUN and Cr levels were measured, and lung W/D ratios were calculated. Serum AST, ALT and Cr levels, and lung W/D ratios were lower in the EP treatment group compared to those in the SAP group. This indicates that delayed EP treatment protected against distant organ injury. An additional study was performed to evaluate the effect of EP on survival times of SAP rats. As a result, delayed EP administration significantly prolonged the survival times of SAP rats.

These results give direct evidence that the beneficial effects of EP are due to downregulation of HMGB1, and reveal that EP may be a useful new therapeutic option against the inflammatory response and MODS in SAP rats, and may also be effective in SAP patients, even when anti-inflammatory therapy is delayed in the early phase. In this study, EP and reduction in serum HMGB1 levels actually reduces the severity of acute pancreatitis, and prolongs survival time of SAP rats. All rats finally die, however. Further studies should be performed to elucidate the role of HMGB1 in SAP and to determine whether a higher dose or earlier delivery of EP could improve the survival rates of SAP rats. Subsequently, clinical investigations could be carried out to study whether EP can be used for SAP patients.

## COMMENTS

### Background

Excessive activation of inflammatory mediator cascade during severe acute pancreatitis (SAP) is a major cause of the high mortality. Cytokines such as TNF- $\alpha$  and IL-1 $\beta$  are released early in the development of systemic inflammatory response. This leaves a narrow therapeutic window for administration of therapeutics and delayed delivery of that anti-inflammatory therapeutics is not effective after the inflammatory mediator cascade has developed.

### Research frontiers

Extracellular high mobility group box 1 (HMGB1) was implicated as a late mediator of endotoxin lethality. The cytokine activity of HMGB1 has been well-documented in many cell types. It was reported that serum HMGB1 levels increased in patients with sepsis/endotoxemia, hemorrhagic shock, acute lung injury, rheumatoid arthritis and disseminated intravascular coagulation. It has been recently demonstrated that the serum levels of HMGB1 correlated with

the severity of SAP.

### Innovations and breakthroughs

In a previous experimental study, the authors demonstrated that the serum levels of HMGB1 began to rise significantly at 12 h, and maintained at high levels up to 48 h after induction of experimental SAP in rats. The delayed kinetics indicates that HMGB1 may provide a broader therapeutic window for treating this lethal systemic inflammatory disease.

### Applications

Ethyl pyruvate (EP), a stable lipophilic pyruvate derivatives, is a nontoxic food additive. According to this study, it is potential to be used as an effective and low-cost therapeutic remedy for SAP patients.

### Peer review

This report is of interest and considerable potential importance, because it indicates that delayed treatment of rats with experimental SAP with EP is associated with a reduction of HMGB1 levels in blood; a decrease in lung, kidney, and liver injury; and prolonged survival. The "therapeutic window" for inhibiting this inflammatory mediator appears to be more favorable than for some other mediators which more rapidly reach a peak in the blood.

± 2.19%,  $P < 0.01$ ) and healthy individuals (4.63% ± 1.23%,  $P < 0.01$ ). Compared to AEHB patients (0.81% ± 0.73%), lower frequency of HBV-specific CD8+ T cells was detected in chronic hepatitis B patients (0.37% ± 0.43%,  $P < 0.05$ ). There was an inverse correlation between the strength of HBV-specific CD8+ T-cell response and the level of PD-1 expression. Besides, there was a significant positive correlation between HBV viral load and the percentage of PD-1 expression on CD8+ T cells in CHB and AEHB subjects ( $R = 0.541$ ,  $P < 0.01$ ). However, PD-1 expression was not associated with disease flare-ups as indicated by alanine aminotransferase (ALT) levels ( $R = 0.066$ ,  $P > 0.05$ ).

**CONCLUSION:** Our results confirm previous reports that HBV specific CD8+ T-cell response in the peripheral blood is more intense in patients with AEHB than in chronic hepatitis B with persistent viral infection. Moreover, there is a negative correlation between the level of PD-1 and the intensity of virus specific CD8+ T cell response.

## Abstract

**AIM:** To define the potential role of programmed death-1/programmed death-ligand (PD-1/PD-L) pathway in different hepatitis B virus (HBV) infection disease status; we examined the expression of PD-1 on antigen specific CD8+ T cells in peripheral blood of patients with chronic hepatitis B (CHB) and acute exacerbation of hepatitis B (AEHB) infection.

**METHODS:** The PD-1 level on CD8+ T lymphocytes and the number of HBV specific CD8+ T lymphocytes in patients and healthy controls (HCs) were analyzed by staining with pentameric peptide-human leukocyte antigen2 (HLA2) complexes combined with flow cytometry. Real-time quantitative polymerase chain reaction (PCR) was used to measure the serum HBV-DNA levels.

**RESULTS:** The level of PD-1 expression on total CD8+ T cells in CHB patients (13.86% ± 3.38%) was significantly higher than that in AEHB patients (6.80%

## INTRODUCTION

Many individuals infected with hepatitis B virus (HBV) become chronic carriers and their liver disease may progress to chronic active hepatitis, cirrhosis, and hepatocellular carcinoma<sup>[1]</sup>. There is substantial evidence

to suggest that adaptive immunity has a central role in determining whether HBV infection is followed by recovery or viral persistence<sup>[2]</sup>. In particular, the cellular immune response plays a critical role in the ability of HBV-infected individuals to control viral replication<sup>[3]</sup>. Patients who develop chronic HBV infection have progressive low frequency and functional impairment of T helper cells (Th cells), both in the peripheral blood and the liver<sup>[4]</sup>. The cytotoxic T lymphocyte (CTL) response is also impaired in chronic HBV infection with high viral load<sup>[5]</sup>. However, the molecular mechanisms underlying the exhaustion of memory T-cell subsets have not yet been elucidated. Understanding the immunopathogenesis of HBV infection is crucial for the development of effective strategies to control HBV.

Our present knowledge suggests that the interaction between positive and negative costimulatory molecules expressed on T cells and antigen presenting cells is essential for the development of T cell responses<sup>[6,7]</sup>. Among the many costimulatory molecules, programmed death-1 (PD-1) and its ligands programmed death 1-ligand 1 (PD-L1) and PD-L2 constitute important pathways that regulate and fine-tune immune responses<sup>[8-10]</sup>. Recent evidence indicates that the exhausted virus-specific CD8+ and CD4+ T cells in chronic viral infection hyperexpress PD-1 molecule<sup>[11-14]</sup>. However, the infected cells that remain productive resist early apoptosis by down regulation of PD-1<sup>[15]</sup>. PD-L1 expression on monocytes and dendritic cells is also increased in HIV infected individuals<sup>[16]</sup>. These findings indicate that the PD-1/PD-L1 pathway plays a crucial role in inhibiting the function of virus-specific CD8+ T cells in chronic viral infections, in mice and humans<sup>[17]</sup> [Human immunodeficiency virus (HIV)<sup>[18-20]</sup>, hepatitis C virus (HCV)<sup>[21,22]</sup> and HBV<sup>[23]</sup>]. These studies illustrated that the level of PD-1 expression correlates with the degree of HBV-specific T-cell impairment. Thus, induction of apoptosis may be a major mechanism employed by the PD-1/PD-L costimulatory pathway to affect the outcome of virus-specific T cell response. Such negative regulation of CD8+ T cell function by PD-1/PD-L system has also been observed in HBV infection<sup>[16]</sup>.

It should be noted that the extent of HBV-specific T-cell exhaustion which influences the disease status of patients with HBV infection has thus far been analyzed only in small groups of patients, both those who were able to control an acute infection and those with established chronic infection<sup>[16]</sup>. However, little is known as to whether PD-1 expression on CD8+ T cells differs between patients with acute exacerbation of hepatitis B (AEHB) and chronic HBV infection.

To define the potential role of PD-1/PD-L pathway in acute exacerbation of HBV infection, we examined the expression of PD-1 on antigen specific CD8+ T cells in the peripheral blood in 32 patients with chronic untreated HBV infection and 11 patients with AEHB. The present study was performed by using pentamer technology combined with flow cytometry, allowing the direct visualization of HBV specific CD8+ T cells.

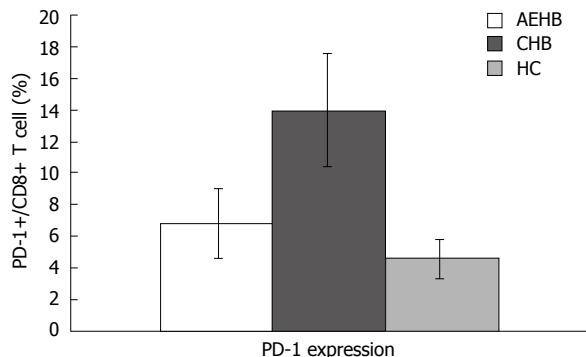

## MATERIALS AND METHODS

### Subjects

A total of 89 patients were enrolled in the study from either the outpatient clinic or the inpatient service of the Department of Infectious Diseases and Hepatology of the Union Hospital, Wuhan, China. The study group comprised of 66 chronic hepatitis B (CHB) patients [32 were human leukocyte antigen (HLA)-A2+], 23 AEHB (11 HLA-A2+) patients and 28 healthy donors. All subjects were anti-HBV treatment naive at the time of enrollment. Since APC-labeled HLA-A2 pentamer complexes specific for the HBV Core 18-27 (FLPSDFFPSU) can only identify HBV specific T cells in HLA-A2+ patients, all HBV-infected individuals subjected to fluorescent monoclonal antibodies and pentamer staining were first serologically identified as having the HLA-A2+ genotype. HLA typing was performed using flow cytometry by staining peripheral blood mononuclear cells (PBMCs) with a fluorescent anti-HLA-A2.01 antibody (Serotec). The criteria for the diagnosis of AEHB and CHB have been described previously in detail<sup>[24]</sup>. Based on the infection status, the subjects were divided into two groups: 11 patients had clinical, biochemical, and virologic evidence of AEHB infection [history of CHB, total bilirubin (TB) levels at least 10 times the upper limit of the normal, and plasma prothrombin activity (PTA) < 40%]. All patients were hepatitis B surface antigen (HBsAg) positive, and negative for antibodies against hepatitis C virus, hepatitis D virus (HDV), hepatitis E virus (HEV), HIV type-1 and HIV-2. Moreover, other causes of chronic liver disease were excluded. Patients with CHB patients had ALT levels ranging from 6 to 1485 U/liters and HBV DNA values from < 10<sup>3</sup> to 4.61 × 10<sup>8</sup> copies/mL. Patients with AEHB had TB levels ranging from 228 to 715.8 μmol/L, ALT from 36 to 174 U/liters, and HBV DNA from 4.3 × 10<sup>4</sup> to 8.9 × 10<sup>7</sup> copies/mL. A total of 28 HLA-A2+ uninfected age and sex matched healthy blood donors with normal liver functions were selected as healthy control (HC). Our study was approved by the local ethics committee, and all subjects gave a written informed consent.

### Serum viral load and ALT determination

The presence or absence of HBsAg, hepatitis B “e” antigen (HBeAg), antibody to hepatitis B surface antigen (anti-HBs), antibody to hepatitis B core antigen (anti-HBc), antibody to hepatitis B “e” antigen (anti-HBe), and antibodies to HCV, HDV, HIV-1, and HIV-2 were determined by using commercial enzyme immunoassay kits. Serum HBV viral load quantification was performed at the laboratory of Hepatology and Infectious Disease, Union Hospital by real-time polymerase chain reaction (PCR) (ABI PRISM 7300 Sequence Detector, PE Biosystems) based on the TaqMan technology using a commercial PCR diagnostic kit (Da An Gene Co. Ltd. of Zhong Shan University, Guangzhou, China). The viral DNA was extracted according to the manufacturer's protocol. Sequences of forward primer (5'-ATCCT

**Figure 1** PD-1 expression on CD8+ T cells in patients with acute exacerbation of hepatitis B (AEHB), chronic hepatitis B (CHB) and healthy controls (HC).

GCTGCTATGCCTCATCTT-3'), reverse primer (5'-ACAGTGGGGAAAGCCCTACGAA-3') and fluorogenic Taqman probes (5'-TGGCTAGTTACTAG TGCCATT-G3') were designed against a highly conserved region of the HBV genome overlapping the genes encoding the X-protein and DNA polymerase. The cycling program was: 50°C for 2 min, 93°C for 5 min, 40 cycles of 93°C for 30 s, 53°C for 30 s, 72°C for 30 s, and 72°C for 7 min. A serum sample quantified by b-DNA method was used as the standard to estimate the number of virus and as the quality control for HBV quantitative PCR. The internal control was estimated by commercialized  $\beta$ -actin kit (PE Biosystems) with reaction condition at 50°C for 2 min first and 5 min at 93°C, followed by 40 cycles of denaturation at 93°C for 30 s and annealing-extension at 65°C for 1 min. The analysis was accomplished within 2 min automatically at the end of the run. The HBV DNA cut-off value was 1000 copies/mL.

The serum ALT levels were assayed by CL-7200 Fully-auto Chemistry Analyzer provided by Shimadzu Co. Ltd, at the Department of Clinical Laboratory, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, China.

#### Isolation of PBMC

Using centrifugation on Ficoll-Hypaque density gradient (HaoYang Biological Manufacture, Tianjin, China) and RBC lysis Solution (Roche), PBMC were isolated from fresh heparinized blood (5 mL) collected from each patient, washed twice in phosphate-buffered saline and analyzed immediately.

#### Peptide-HLA class I pentamer antibodies and cell surface staining

To measure the number of virus-specific CD8+ T cells and PD-1 expression on CD8+ T-cell subsets, cells were stained with fluorescein isothiocyanate (FITC)-, phycoerythrin (PE)-, and allophycocyanin (APC)-labeled monoclonal antibodies or pentamer, according to the manufacturers' instructions. Briefly, a total of  $1 \times 10^6$  to  $5 \times 10^6$  freshly isolated PBMC were incubated for 30 min at room temperature with APC-labeled HLA-A2 pentamer complexes specific for the HBV Core 18-27

(FLPSDFFPSU) (Proimmune Oxford, United Kingdom) in RPMI 1640 and 10% fetal calf serum. After a wash with phosphate-buffered saline-0.1% fetal calf serum, cell surface staining was performed for 15 min in the dark by simultaneously using anti-CD8 (PE-conjugated), anti-PD-1 (FITC-conjugated) and the corresponding IgG2a isotype controls (eBioscience San Diego, CA).

#### Flow cytometry

Cells were washed twice with PBS and gated on CD8+ T cells;  $1 \times 10^6$  events in the lymphogate were collected by a BD Biosciences multi-color flow cytometer (LSR2, Becton Dickinson Biosciences). The data were analyzed by using the FACS Diva software. Pentamer-positive responses were reported as a percentage of pentamer-positive T cells among the total CD8+ T cell population. The frequency of pentamer-positive cells exceeding 0.02% of CD8+ T cells indicated a positive response.

#### Statistical analysis

We used SPSS 12.0 software to perform statistical analyses. Frequency of pentamer positive CD8+ T cells and levels of PD-1 expression in HCs and patients with different viremia levels were compared using the Mann-Whitney test. Spearman correlation analysis was used to evaluate the correlation between viral load, frequency of HBV-specific T cells and PD-1 expression. All tests were two-tailed and *P*-values less than 0.05 were considered significant.

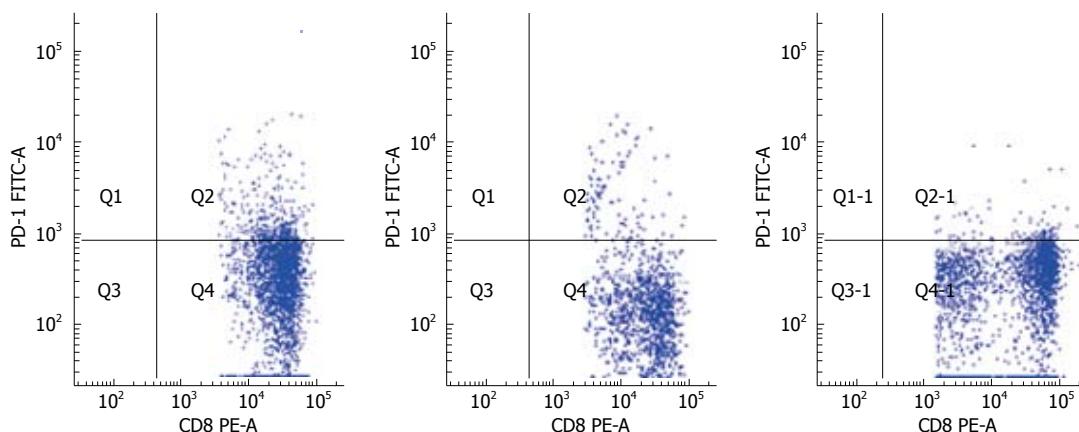

## RESULTS

#### PD-1 expression on PBMC in patients of different disease states

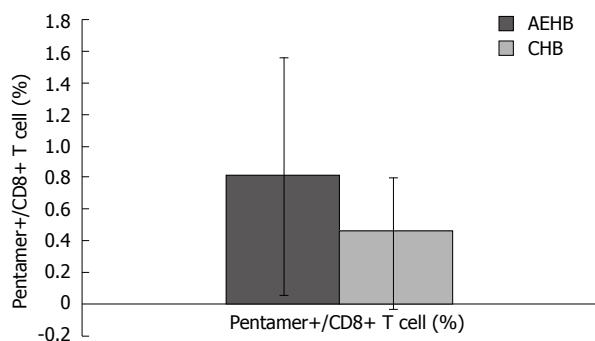

To determine PD-1 expression on CD8+ T cell population, we examined the frequency of PD-1-expression on CD8+ T-cell subsets using polychromatic flow cytometry in the three study groups: AEHB, CHB and HC. The PD-1 levels on the total CD8+ T cells in CHB patients ( $13.86\% \pm 3.38\%$ ) were significantly higher compared to AEHB patients ( $6.80\% \pm 2.19\%$ ,  $P < 0.01$ ) and healthy individuals ( $4.63\% \pm 1.23\%$ ,  $P < 0.01$ ) (Figure 1). Representative flow cytometry plots of PD-1 expression on CD8+ T cells from the peripheral blood of one health individual (5.8%) and two patients with CHB (12.71%) and AEHB (7.1%) are shown in Figure 2.

#### Comparison of HBV-specific CD8+ T cells upregulated in AEHB and CHB patients

The frequency of HBV-specific CD8+ T cells in the three study groups was assessed. The detection limit was 0.02% for CD8+ T cells specific for the core peptide spanning amino acids 18 to 27. None of the 28 healthy individuals showed a positive response with pentamer. Compared to AEHB patients ( $0.81\% \pm 0.73\%$ ), there was a lower frequency of HBV-specific CD8+ T cells ( $0.37\% \pm 0.43\%$ ) in CHB patients ( $P < 0.05$ ) (Figure 3). Representative plots from two patients with CHB (0.07%) and AEHB (0.3%) infection indicating the number of HBV-specific CD8+ T cells are shown in Figure 4.

**Figure 2** Comparison of PD-1 expression on CD8+ T cells in healthy controls (HC; 5.8%), chronic hepatitis B (CHB; 12.7%), and acute exacerbation of hepatitis B (AEHB; 7.1%).

**Figure 3** The number of HBV-specific CD8 T cells in CHB and AEHB patients.

#### **PD-1 expression in relation to different HBV-specific CD8+ T cell responses**

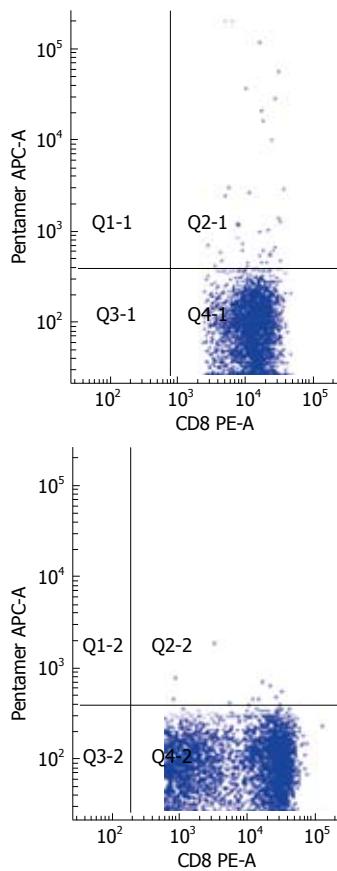

Using linear regression and Spearman's correlation analyses, we found an inverse correlation between HBV-specific CD8+ T-cell response and level of PD-1 expression in AEHB and CHB patients. In other words, the higher the PD-1 expression level, the weaker (or totally absent) HBV-specific CD8+ T-cell response was observed (Figure 5).

#### **Correlation of PD-1 expression with serum HBV DNA load**

In the present study, there was a significant positive correlation between HBV viral load and PD-1 expression on CD8+ T cells in CHB and AEHB subjects. These findings indicate that high plasma viral load correlates with PD-1 upregulation on the total CD8+ T cells in viremic individuals (Figure 6).

#### **Correlation between PD-1 expression and serum ALT levels**

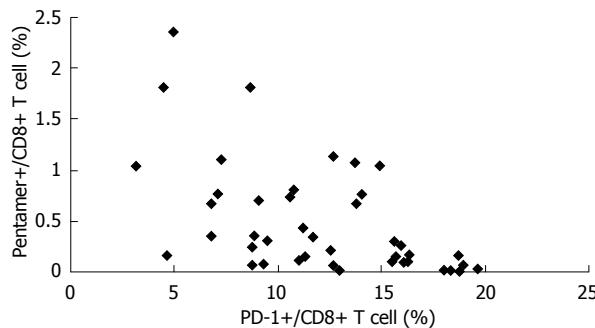

We also assessed the relationship between PD-1 expression and serum ALT levels, another predictor of HBV disease progression. There was no correlation between PD-1 expression and serum ALT levels in the study patients (Figure 7).

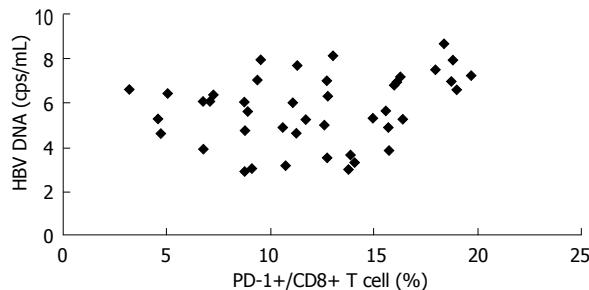

**Figure 4** The number of HBV-specific CD8 T cells in two patients with CHB (0.07%) and AEHB (0.31%) respectively.

## **DISCUSSION**

The development of chronic persistent HBV infection is usually associated with quantitative and qualitative exhaustion of functional T cells. Recent studies have shown that the negative costimulatory receptor PD-1 along with its ligand PD-L1 are upregulated on PBMC and virus specific T cells, to attenuate T cell responses which accounts for the impairment of their function<sup>[15,16]</sup>. However, under acute hepatitis B (AHB) conditions, the

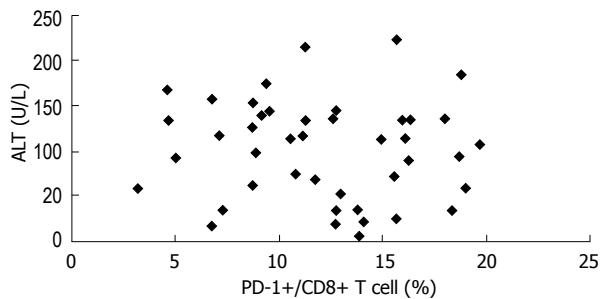

**Figure 5** Significant inverse correlation between the number of HBV-specific CD8+ T-cells and the level of PD-1 expression in patients with AEHB and CHB ( $R = 0.541, P < 0.01$ ).

**Figure 6** Positive correlation between serum viral load and level of PD-1 expression on CD8+ T cells in patients with CHB and AEHB ( $R = 0.272, P < 0.05$ ).

levels of PD-1 are significantly down regulated on PBMC or on HBV specific CD8+ T cells compared to CHB patients. Several previous studies<sup>[10,25,26]</sup> have suggested that operating co-stimulatory pathways may provide a new method to restore the impaired function of virus specific T cells and control chronic virus infection. Blocking the PD-1/PD-L1 pathway by anti-PD-L1 mAb or applying soluble PD-1 results in improvement of T cell functions such as survival, proliferation and cytokine production<sup>[27-29]</sup>. This would result in better control of the virus infection. Thus, an accurate balance between positive and negative co-stimulatory regulation such as PD-1/ PD-L pathway may contribute to the outcome of disease progression in HBV infection.

However, the mechanism by which PD-1 affects the function of CD8+ T cells in AEHB is unclear. To clarify the correlation between PD-1 expression and different presentations of HBV infection, we investigated the role of PD-1 in AEHB and chronic HBV infection, using a MHC class I pentamer specific for 18-27 epitopes, using the flow cytometry technology. Consistent with previous studies, we found that peripheral blood CD8+ T cells showed a higher PD-1 expression in CHB patients compared to AEHB patients and HCs. There was a negative correlation with impaired HBV-specific CD8+ T cell function and a positive correlation with the plasma viral load. However, we did not find an association between PD-1 expression and hepatic inflammatory indicator: serum ALT levels. Our data indicates that similar to AHB patients, CD8+ T cells in AEHB patients expressed a low level of PD-1 and

**Figure 7** Lack of significant correlation between PD-1 expression and serum ALT levels in the study patients ( $R = 0.066, P > 0.05$ ).

an enhanced level of HBV specific CD8+ T cells compared to CHB patients. These results are in line with previous reports which indicate that virus specific T cell function is upregulated during acute exacerbation of hepatitis B infection compared to during persistent CHB. Furthermore, the proportion of CD8+ T cells expressing PD-1 correlated negatively with the intensity of virus specific CD8+ T cell response.

The low levels of PD-1 expression were associated with low levels of HBV viremia. However, we did not find any correlation between PD-1 expression and disease flare-up indicator, ALT. Recent studies have shown that persistent antigenic stimulation has a suppressive effect on functional T cells. Briefly, T cells up-regulate their surface receptors such as PD-1 to restrict positive TCR signaling and, therefore, avoid the development of a strong immune response, including autoimmune diseases. However, some microorganisms may utilize this *in vivo* protection system to escape the host immune system and result in persistent viremia. However, why this phenomenon is broken in patients with AEHB remains to be investigated.

Although PD-1/PD-L pathway plays a prominent role in the regulation of T cell dysfunction, other costimulatory molecules cannot be excluded. In a recent study, it was observed that apart from PD-1, several other gene expressions were involved in promoting exhausted CD8+ T cells during chronic viral infection<sup>[13]</sup>. However, recent data indicates that PD-1 is a major factor of apoptosis sensitivity over and above other factors<sup>[9]</sup>. Future studies should be addressed to clarify the intracellular mechanisms used by the PD-1/PD-L1 pathway to influence disease status during viral infection. Importantly, the use of highly active anti-retroviral therapy (HAART), accompanied by the recovery of the host immune response, has been found to down-regulate PD-1 expression in 'typical progressor' (TP) patients infected with HIV<sup>[11,30]</sup>. Therefore, it is important to determine whether direct suppression of PD-1/PD-L pathway could provide a potentially effective treatment for persistent viral infections.

## COMMENTS

### Background

Nearly, 2 billion people are infected with hepatitis B virus (HBV) worldwide. Persistent HBV infection of the liver is associated with end-stage liver diseases

including cirrhosis and hepatocellular carcinoma. During chronic HBV infection, the effector functions of virus specific T cells often show an impaired activity indicated by low levels of cytokine production and cytotoxic activity. As a result, viruses can persist and establish long-term residency *in vivo*. However, the underlying mechanisms responsible for the induction of T-cell tolerance are not completely understood.

### Research frontiers

The aim of this study was to explore the potential role of programmed death-1/programmed death-ligand (PD-1/PD-L) pathway in antiviral immunity during HBV infection.

### Innovations and breakthroughs

This is the first report on the differences in PD-1 expression on CD8+ T cells in acute exacerbation of hepatitis B (AEHB) and chronic HBV infection.

### Applications

Blockade of PD-1/PD-L1 pathway may open a novel therapeutic strategy for restoring the function of the exhausted CD8+ T cells, and enhancing viral control during chronic viral infections. The perspective of future application: further studies to assess the intracellular mechanisms used by the PD-1/PD-L1 pathway to influence the disease status in viral infection.

### Peer review

This is a requisite investigation. The levels of PD-1 on CD8+ T cells has until now been analyzed only in small groups of patients with acute infection and established chronic infection. The manuscript provides new information about PD-1 expression on CD8+ T cells in different disease states of HBV infection including AEHB and chronic hepatitis B (CHB).

### Abstract

**AIM:** To investigate the effect of admission hypertriglyceridemia (HTG) on the episodes of severe acute pancreatitis (SAP).

**METHODS:** One hundred and seventy-six patients with SAP were divided into HTG group ( $n = 45$ ) and control group ( $n = 131$ ) according to admission triglyceride (TG)  $\geq 5.65$  mmol/L and  $< 5.65$  mmol/L, respectively. Demographics, etiology, underlying diseases, biochemical parameters, Ranson's score, acute physiology and chronic health evaluation II (APACHE II) score, Balthazar's computed tomography (CT) score, complications and mortality were compared. Correlation between admission TG and 24-h APACHE II score was analyzed.

**RESULTS:** SAP patients with HTG were younger ( $40.8 \pm 9.3$  years vs  $52.6 \pm 13.4$  years,  $P < 0.05$ ) with higher etiology rate of overeating, high-fat diet (40.0% vs 14.5%,  $P < 0.05$ ) and alcohol abuse (46.7% vs 23.7%,  $P < 0.01$ ), incidence rate of hypocalcemia (86.7% vs 63.4%,  $P < 0.01$ ) and hypoalbuminemia (84.4% vs 60.3%,  $P < 0.01$ ), 24-h APACHE II score ( $13.6 \pm 5.7$  vs  $10.7 \pm 4.6$ ,  $P < 0.01$ ) and admission serum glucose ( $17.7 \pm 7.7$  vs  $13.4 \pm 6.1$ ,  $P < 0.01$ ), complication rate of renal failure (51.1% vs 16.8%,  $P < 0.01$ ), shock (37.9% vs 14.5%,  $P < 0.01$ ) and infection (37.4% vs 18.3%,  $P < 0.01$ ) and mortality (13.1% vs 9.1%,  $P < 0.01$ ). Logistic regression analysis showed a positive correlation between admission TG and 24-h APACHE II score ( $r = 0.509$ ,  $P = 0.004$ ).

### INTRODUCTION

Hypertriglyceridemia (HTG) is a rare but well-recognized cause for severe acute pancreatitis (SAP), which has been intensively studied since Speck noted the association between hyperlipidemia and acute pancreatitis (AP) in 1865<sup>[1-4]</sup>. HTG can be a primary cause for AP which occurs in 1.3%-3.8% of AP patients, or secondary to other factors prior to the increase of lipid levels, or both<sup>[5]</sup>. Clinically, mild to moderate hyperlipidemia in AP patients, particularly in alcoholic pancreatitis patients, is often observed. However, it is difficult for clinicians to distinguish mild to moderate hyperlipidemia secondary to AP from marked HTG that primarily causes AP.

It is generally believed that a serum triglyceride (TG) level of more than 1000 mg/dL (about 11.3 mmol/L) is needed to precipitate AP, the reduction of which to well below 1000 mg/dL may effectively prevent further episodes<sup>[6]</sup>. Animal studies showed that HTG intensifies the course of AP including both edematous and necrotizing pancreatitis<sup>[7,8]</sup>. It was reported that TG would worsen pancreatic injury induced by AP when it reaches 5.65 mmol/L, thus playing a worth-noting role in predisposing mild pancreatitis to the vicious episode<sup>[9]</sup>. Extreme elevation of TG in AP patients with familial HTG can cause the so-called "hyperlipidemic abdominal crisis"<sup>[10]</sup>. However, it was also reported that

SAP patients with HTG can have pancreatic necrosis, pseudocysts, abscesses and other complications that can be seen in other types of pancreatitis with a different clinical course from other forms of AP<sup>[11]</sup>. Thus, the correlation between HTG and the severity of AP episodes is still uncertain.

In this study, the clinical features and the effect of HTG on the episodes of SAP were investigated with HTG as a coexisting medical condition of SAP.

## MATERIALS AND METHODS

### Patients

The diagnostic criteria for SAP formulated at the Bangkok World Congress of Gastroenterology 2002 in Thailand<sup>[12]</sup> were employed and organ failure was defined according to the Criteria of Clinical Diagnosis and Classification System for AP formulated by the Pancreatic Surgical Society of Chinese Medical Association in 1997<sup>[13]</sup> in this study. From March 2003 to December 2004, all patients diagnosed with SAP and admitted to West China Hospital of Sichuan University within 72 h after onset of symptoms were included. Patients were excluded if they had hepatic dysfunction or renal failure prior to the development of SAP.

### Methods

One hundred and seventy-six SAP patients admitted to our hospital were enrolled and divided into HTG group ( $n = 45$ ) and control group ( $n = 131$ ) according to admission TG  $\geq 5.65$  mmol/L and TG  $< 5.65$  mmol/L, respectively. Blood samples were collected at admission for biochemical examinations in Department of Laboratory Medicine of our hospital.

All patients received standardized comprehensive treatments<sup>[12]</sup>. The main protocols of treatment throughout the study were intensive care, oxygen inhalation, fasting, intermittent gastrointestinal decompression and fluid infusion. The balance of internal environment was maintained, prophylactic antibiotics were used for 7–14 d, H<sub>2</sub> receptor antagonists or proton pump inhibitors were given for 7 d. When the patients developed respiratory failure, a respirator was employed to assist respiration. When the patients developed hypoalbuminaemia, 20% of human serum albumin in 50 mL was used daily until the serum albumin value became normal. When serum lipid value was decreased to normal, fat emulsion was added in parenteral nutrition. During hospitalization, microbiological tests of sputum, urine, feces, or blood were performed, when the following susceptible clinical symptoms or signs appeared: body temperature  $\geq 38.5^{\circ}\text{C}$  and white blood cell (WBC) count  $\geq 20 \times 10^9 / \text{L}$ , signs of peritoneal irritation (area) in more than 2 quadrants, and intractable malnutrition. Contrast-enhanced computed tomography (CECT) was performed to determine necrotic infection of (peri) pancreas. For those who were unsuitable for CECT evaluated by the investigator, magnetic resonance imaging was alternatively eligible. Ultrasound-guided

**Table 1 Clinical features of patients in HTG and control groups**

	HTG group (n = 45)	Control group (n = 131)
Sex (Male/Female)	27/18	72/59
Age (mean $\pm$ SD, yr)	40.8 $\pm$ 9.3 (24–61) <sup>a</sup>	52.6 $\pm$ 13.4 (22–82)
Etiology, n (%)		
Overeating and high fat diet	18 (40.0) <sup>a</sup>	19 (14.5)
Alcohol abuse	21 (46.7) <sup>b</sup>	31 (23.7)
Gallstones	5 (11.1) <sup>b</sup>	37 (28.2)

24-h APACHE II score (mean $\pm$ SD)	13.6 $\pm$ 5.7 <sup>b</sup>	10.7 $\pm$ 4.6
Balthazar's CT score (mean $\pm$ SD)	5.4 $\pm$ 2.3	6.3 $\pm$ 5.4

<sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01 vs control group.

fine needle aspiration (FNA) was performed for microbiological testing when air bubbles appeared in necrotic tissue of the (peri) pancreas. Bacterial infection was confirmed by positive culture or smear examination. Fungal infection was confirmed by positive fungi in no less than 2 different specimens by culture or smear examination.

The sex, age, etiology, underlying diseases, biochemical parameters and incidence of complications including acute respiratory distress syndrome (ARDS), renal failure, acute hepatitis, shock, encephalopathy, infection rate, and mortality, were confirmed by one of the investigators using a standard data collection instrument. The Ranson's score, 24-h APACHE II score and admission Balthazar's CT score were calculated by a single investigator.

### Statistical analysis

Data were expressed as mean  $\pm$  SD or percentage. Data in normal distribution were analyzed using *t*-test. Data in abnormal distribution were analyzed using Wilcoxon rank sum test. Categorical data were analyzed using chi-square test. The correlation between serum TG and 24-h APACHE II score was analyzed using Logistic regression. P < 0.05 was considered statistically significant.

## RESULTS

### Clinical features

The clinical features of the patients in the HTG and control groups are summarized in Table 1. There were no statistical differences in sex distribution and incidence

**Table 2** Incidence of complications and mortality in HTG and control groups *n* (%)

	HTG group ( <i>n</i> = 45)	Control group ( <i>n</i> = 131)
Complications		
ARDS	29 (64.4)	61 (46.6)
Renal failure	23 (51.1) <sup>b</sup>	22 (16.8)
Acute hepatitis	20 (44.4)	38 (29.0)
Shock	17 (37.9) <sup>b</sup>	19 (14.5)
Encephalopathy	10 (22.2)	24 (18.3)
Infection	17 (37.4) <sup>b</sup>	24 (18.3)
Death	14 (31.1) <sup>b</sup>	12 (9.1)

<sup>b</sup>*P* < 0.01 vs control group.

rate of underlying diseases between the two groups. Patients in the HTG group were younger (*P* < 0.05) with a higher rate of overeating and a high fat diet (*P* < 0.05) and alcohol abuse (*P* < 0.01) and less gallstones (*P* < 0.01). The Ranson's score and initial Balthazar's CT score were not statistically different between the two groups, but the 24-h APACHE II score was higher in the HTG group than in the control group (*P* < 0.01). The incidence rate of hypokalemia and hyponatremia had no difference and was higher in the HTG group than in the control group (*P* < 0.01), and admission serum glucose was higher in the HTG group than in the control group (*P* < 0.01).

### Complications and mortality

There were no statistical differences in complications such as ARDS, acute hepatitis and encephalopathy between the two groups. However, more complications, such as renal failure, shock and infection occurred in the HTG group than in the control group (*P* < 0.01). The mortality was higher in the HTG group than in the control group (*P* < 0.01) (Table 2).

## DISCUSSION

HTG-associated SAP is an uncommon, but potentially life-threatening disease<sup>[14]</sup>. HTG may be primary in origin (hereditary or sporadic genetic disorder of metabolism) or secondary (associated with an identifiable disease or condition and is reversible with control or eradication of that disease or condition) to other factors or both<sup>[15-17]</sup>. Although the exact pathogenesis of HTG-associated AP is not clear, it is thought to result from toxic injury to acinar cells and capillary endothelia by excessive free fatty acids from hydrolysis of TG<sup>[18,19]</sup>. Competitive oxidation of ethanol is also responsible for SAP by aggravating the level of serum lipids<sup>[20]</sup>. L-asparaginase-induced HTG is suggested as a possible mechanism of SAP<sup>[21,22]</sup>. HTG is the cause for gestational pancreatitis in 56% cases<sup>[23]</sup>. Elevated estrogen increases the synthesis of TG and depresses plasma postheparin lipolytic activities by inhibiting the removal efficiency of TG, and high-fat intake may be a cause for AP during pregnancy<sup>[24-27]</sup>, which are largely consistent with the results of our study, showing that the patients with

HTG were younger with more diet-associated etiologies including overeating, high-fat diet and alcohol abuse. SAP patients with HTG had a higher incidence of hypoalbuminaemia and hypocalcemia and a higher level of admission serum glucose, which may be associated with the aggravation of HTG, resulting from severe stress response and metabolic disorders<sup>[28]</sup>.

The role of HTG in modulating disease course of AP is still controversial. Although studies demonstrated that HTG has no significant correlation to complications of disease or overall end-of-episode severity in AP patients<sup>[3,12]</sup>. It was reported that HTG is independently associated with the severity of AP and plays a role in the aggravation of acute necrotizing pancreatitis<sup>[29-31]</sup>. The results of our study show that the incidence of admission hypocalcaemia, a predictable index of SAP<sup>[32]</sup>, and the 24-h APACHE II score were higher in the HTG group than in the control group. The complications, such as renal failure, shock and infection, and the mortality were higher in the HTG group than in the control group, indicating that HTG aggravates SAP, leading to systemic complications and a high mortality rate of SAP.

In conclusion, the clinical features of HTG-associated SAP are largely consistent with previous studies. HTG aggravates SAP.

## COMMENTS

### Background

Hypertriglyceridemia (HTG) is associated with severe acute pancreatitis (SAP), which has long been recognized. HTG may be a primary etiology of SAP, and it is difficult for clinicians to identify it. Some previous studies suggest that HTG is independently associated with the severity of acute pancreatitis (AP) and plays a role in the aggravation of acute necrotizing pancreatitis. However, its mechanism underlying such a role is still controversial.

### Research frontiers

HTG is a rare cause for pancreatitis. An elevated TG level is needed to precipitate the episode of AP, which is called "hyperlipidemic abdominal crisis". Moreover, recurrent pancreatitis may occur in patients with familial hyperlipoproteinemia. Which patients progress to the extremely dangerous state during SAP and specific strategy against its deterioration and recurrence are the major research field.

### Innovations and breakthroughs

It is generally believed that the serum triglyceride (TG) level of more than 1000 mg/dL (about 11.3 mmol/L) is needed to precipitate AP, but the clinicians cannot identify mild to moderate HTG secondary to SAP with marked HTG that causes AP in the acute phase. This research used admission HTG as a coexisting factor for SAP patients at admission.

### Applications

At present, the exact role of HTG in the development of SAP remains unclear. Our study, conducted in one of the largest institutions in China, showed that HTG could aggravate SAP and leads to a worse outcome of SAP patients, thus providing applicable and valuable evidence for prognostic evaluation of pancreatitis.

### Terminology

AP is an acute inflammatory process in the pancreas involving local or other organ systems. Severe AP is defined as the occurrence of organ failure. HTG is defined as an abnormal concentration of TG in the blood.

### Peer review

This research investigated the effect of admission HTG on the severity of SAP, by regarding admission HTG as a coexisting factor for SAP. The study was well designed and its results are valuable.

## Abstract

**AIM:** To investigate the expression frequency of endocan in colorectal cancer and analyze the relationship between endocan expression and clinical parameters and to study the role of endocan in colorectal carcinogenesis.

**METHODS:** Expression of endocan in 72 tumor tissue samples of colorectal cancer as well as in 27 normal mucous membrane tissue samples was analyzed using *in situ* hybridization, immunohistochemistry on tissue microarray, Western blot and reverse-transcript polymerase chain reaction (RT-PCR).

**RESULTS:** The expression of endocan was higher in normal colon and rectum tissue samples than in cancerous tissue samples (mRNA = 92.6%, protein = 36%), and was lower in colorectal cancer tissue samples (mRNA = 70.4%, protein = 36.1%). No correlation was found between staining intensity and clinical parameters such as sex, age, tumor size and

## INTRODUCTION

Colon and rectum cancers accounted for about 1 million new cases in 2002 (9.4% of the world total)<sup>[1]</sup>, There is at least a 25-fold variation in the occurrence of colorectal cancer around the world. The incidence of colorectal cancer increases rather rapidly in countries where the overall risk was formerly low (especially in Japan, but also elsewhere in Asia)<sup>[2]</sup>. Although it has been found that many factors are correlated with genesis and development of colon and rectum cancers, it cannot explain all the clinical and pathological manifestations. It is critical to investigate new factors which are intimately correlated with initiation and development of colorectal cancer.

Endocan, previously called endothelial cell-specific molecule-1 (ESM-1)<sup>[3]</sup>, is over expressed in human tumors, and its serum levels are elevated in late-stage lung cancer and experimental tumor, as measured by enzyme-linked immunoassay or by

immunohistochemistry. mRNA level of endocan is also recognized as one of the most significant molecular signatures with a poor prognosis of several types of cancer including lung cancer. Over expression of this dermatan sulphate proteoglycan is also directly involved in tumor progression as observed in mouse models of human tumor xenografts. These results suggest that endocan is a biomarker of inflammatory disorders and tumor progression as well as a validated therapeutic target in cancer.

We studied the expression of endocan in colon and rectum tissue samples. The results of this study indicate that endocan expression is down-regulated in colorectal cancer and positively correlated with the differentiation of colorectal cancer. Changes in endocan expression represent an important step in development and differentiation of colorectal cancer.

## MATERIALS AND METHODS

### **Patients and samples**

Seventy-two colorectal cancer patients, who consecutively underwent radical surgical resection at Anhui Medical University Hospital from the year 2001 to 2003, were recruited into this study. Tumor and mucosa samples were embedded in paraffin after 16 h formalin fixation. None of the patients (23 males, 49 females, mean age 54 years, range 17-87 years) received any anticancer therapy. According to the TNM classification<sup>[4]</sup>, 43 cases were at stages I and II, 29 cases at stages III and IV. Well- and moderately-differentiated adenocarcinoma was found in 57 patients and poorly-differentiated adenocarcinoma was observed 15 patients<sup>[5]</sup>, and strong lymphoid infiltrate including lymphoid follicles with germinal centers was demonstrated in 39 patients.

### **In situ hybridization**

**cRNA probe labeling:** The sequences of specific primers for endocan are as follows: sense, 5'-AGCTGGAATTCCATGAAGAG (20 bp) and antisense, 5'-TCTCTCAGAAAGCTTAGCCG (20 bp)<sup>[3]</sup>. PCR was performed to amplify endocan DNA, and the PCR product was ligated into the pGEM-T-Vector to get the recombinant plasmid pGEM-T-endocan. The recombinant plasmid was transformed into *E.coli*, amplified and digested with the restriction endonuclease (*Eco*RI and *Hind*III). The objective gene (V-gene) was purified using a DNA gel extraction kit to obtain the probes for the following digoxigenin-labeling and detected according to the manufacturer's instructions.

**Hybridization:** All specimens were fixed in 10% neutral buffered formalin and embedded in paraffin. A series of 5-μm thick sections were cut for analysis. In situ hybridization was performed as previously described<sup>[6]</sup> with certain modifications, using digoxigenin-labeled antisense cDNA probes. Briefly, the sections were dried at 60°C for 4 h, dewaxed, rehydrated and pretreated with DEPC-treated PBS containing 100 mmol/L glycine and 0.3% Triton X-100, respectively. The sections were then

permeabilized with 20 μg/mL RNase-free proteinase K (boster, Wuhuan, China) for 20 min, incubated at 37°C for at least 20 min with prehybridization buffer. Each section was overlaid with 30 μL hybridization buffer containing a 10 ng digoxigenin-labeled cDNA probe and incubated at 42°C overnight. After hybridization, the section was incubated with digoxigenin antibody (75 mU/mL) for 2 h. The positive signal for endocan mRNA was detected using DAB as a substrate. The presence of brown staining in the cytoplasm was considered positive.

### **Protein extraction from paraffin-fixed tissue**

Paraffin-fixed tissue was cut into 50 5-μm thick sections for protein extraction and mounted onto plain glass slides. Three 5-μm thick sections for protein extraction were deparaffinized in xylene, rehydrated in graded ethanol, immersed in distilled water, and air-dried. To exclusively collect 5 mm × 5 mm cancer tissues, the targeted areas were cut microscopically with a fine needle for observation of the morphology of HE-stained sections under a microscope. After the tissue sections on the glass slide were immersed in distilled water, only the targeted areas of cancer tissue were separated from the glass slide and recovered. Adenoma tissue was also cut into sections and collected in the same manner. Normal mucosa was recovered from 5 cm-long sections of full-depth colorectal wall with a fine needle as previously described<sup>[7,8]</sup>.

### **Immunohistochemistry**

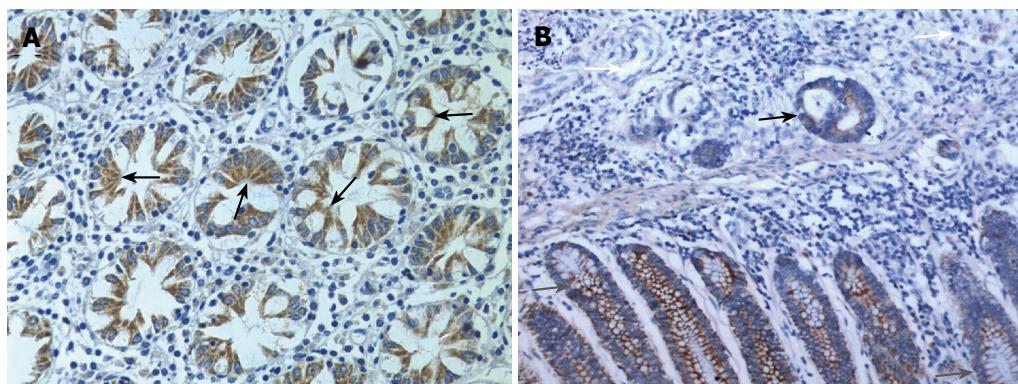

The pathology of colorectal carcinoma was performed on 5-μm thick sections of 10% formalin-embedded samples with a S-P kit. Slides were boiled in 10 mmol/L citrate buffer (pH 6.0) for 10 min to allow antigen retrieval before a 12-h incubation at 4°C with primary antibody against endocan (Santa Cruz). The mean percentage of positive tumor cells was determined in ten areas at a high magnification (× 400) and graded from 0 to 4 (0 ≤ 5% positive cells, 1 = 6%-25%, 2 = 26%-50%, 3 = 51%-75%, and 4 = 76%-100%, 0 = negative, 1-4 = positive). Negative controls were obtained by omitting the primary antibody. Each normal mucosa sample, as an internal positive control, was simultaneously analyzed. Slides were read by two observers blinded to the clinical data.

### **Reverse-transcript polymerase chain reaction (RT-PCR)**

Two micrograms of total RNA was prepared from colon and rectal tissues, randomly primed, and reverse transcribed with Superscript II (Gibco). The sequences of specific primers used for endocan are as follows: sense, 5'-CTCAGGCATGGATGGCATGAAGTG-3'; antisense, 5'-GAGACCCGGCAGCATTCTCTT TCA-3'; and β-actin: sense: 5'-ACTCTCCAGCCTTC CTTC-3' and antisense: 5'-ATCTCCTTCTGCATC CTGTC-3'. After a hot start at 94°C, 35 PCR cycles were performed, each cycle consisting of annealing at 57°C for 45 s and extension at 72°C for 45 s.

### **Western blot analysis**

Twenty micrograms of protein was incubated in a

**Figure 1** Expression of endocan in normal mucous membrane and cancer tissues of colon and rectum tissues. **A:** Endocan was expressed in the cytoplasm of the epithelial cell and it had a high polarity under the nucleus; **B:** The expression of endocan in colon and rectum tissues. This section show that it had a high expression in mucous membrane by the side of carcinoma tissue (gray arrow), also in well and moderately-differentiated colon carcinoma tissues (black arrow), but a weak expression in poorly differentiated carcinoma tissues (white arrow).

loading buffer (125 mmol/L Tris-HCl, pH 6.8, 10%  $\beta$ -mercapto-ethanol, 4.6% SDS, 20% glycerol and 0.003% bromophenol blue) for 5 min at 100°C, separated by sodium dodecyl sulfate polyacrylamide gel (SDS-PAGE) and electroblotted to PVDF membrane (BioRad). After non-specific binding sites were blocked for 1 h with 5% nonfat milk in TPBS (PBS contained 0.05% Tween 20), the membrane was incubated overnight at 4°C with primary antibody. After washing 3 times in TPBS, the membrane was incubated with horseradish peroxidase-conjugated goat anti-rabbit IgG for 2 h at room temperature, and washed twice with TPBS. Immunoblot was detected by autoradiography using an enhanced chemoluminescence detection kit.

#### Statistical analysis

Chi-square test and *F*-test were used to compare the categorical data. SPSS 11.0 was used to analyze the data.

## RESULTS

### Expression of endocan in colon mucous membrane and colorectal cancer specimens

*In situ* hybridization analysis showed that endocan mRNA was expressed in the cytoplasm of epithelial cells in mucous membrane of colon and rectum and in well- and moderately-differentiated colorectal cancer. However, endocan mRNA expression was down-regulated in poorly-differentiated colorectal cancer (Figures 1 and 2).

Meanwhile, we performed immunohistochemical staining for endocan protein with a monoclonal antibody against human endocan. The endocan protein expression

**Table 2 Differential expression of endocan protein in normal and colorectal cancer tissues**

Type	<i>n</i>	Expression of endocan protein		Positive (%)	<i>P</i>
		+	-		
Normal mucous membrane	27	19	8	70.4	0.005
Colon carcinoma tissue	72	26	46	36.1 ( $\chi^2 = 7.965$ )	

was concordantly regulated by mRNA.

The statistical results demonstrated that endocan was differentially expressed in normal colon mucosa and carcinoma tissue samples. The expression rate of endocan was 92.6% (25/27) in normal colon mucosa tissue samples and 36.1% (24/72) in colorectal cancer tissue samples, and was significantly lower in cancerous tissue samples than in normal tissue samples (*P* = 0.001, Table 1). Endocan protein was identically expressed as mRNA; The expression rate was 70.4% (19/27) in normal colon and rectum mucosa tissue samples and 36.1% (26/72) in colorectal cancer tissue samples. Endocan was also differently expressed in normal and colorectal cancer tissue samples (*P* = 0.005, Table 2).

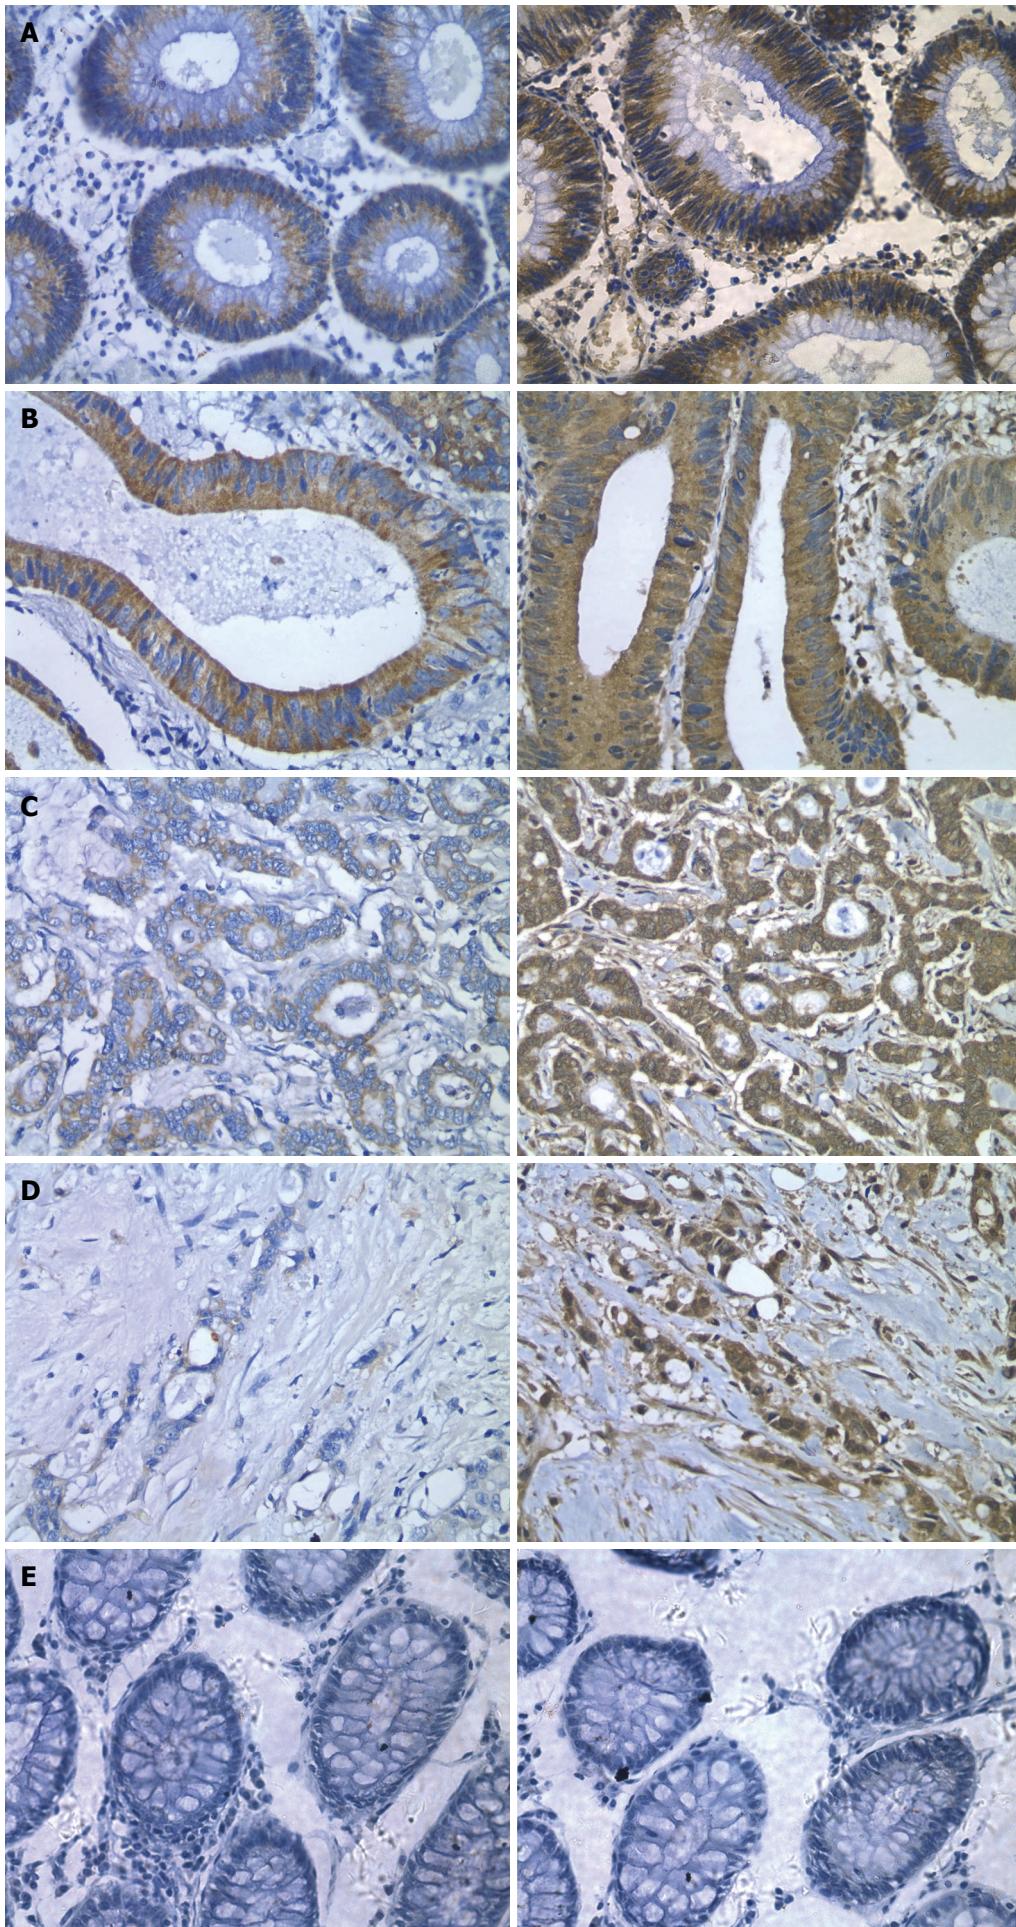

### Correlation between expression of endocan and differentiation of colorectal cancer

The expression of mRNA and protein in colorectal cancer tissue samples was not correlated with age, gender, clinical stage, tumor size or lymph node metastasis, but positively correlated with the differentiation of tumors (Table 3).

RT-PCR and Western blot were performed to further observe the relationship between the expression levels of endocan and differentiation of colorectal cancer (Figure 3). Both endocan transcript and translation were detected in colon mucous membrane and in well- and moderately-differentiated colon carcinoma, but scarcely detected in poorly-differentiated carcinoma.

## DISCUSSION

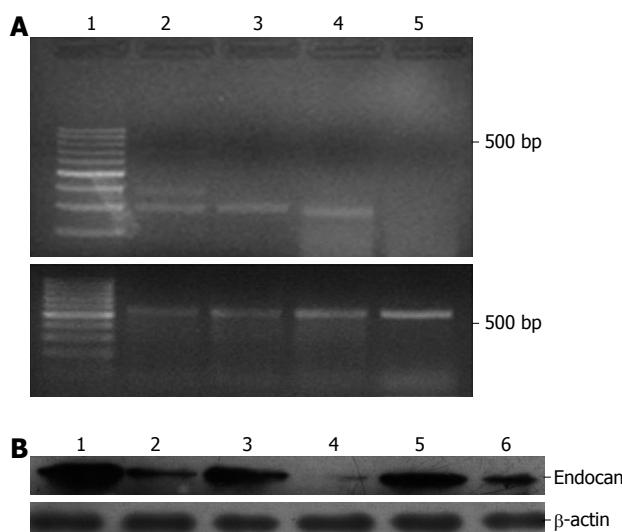

Endocan was originally cloned from a human endothelial

cell cDNA library by Lassalle and collaborators in 1996<sup>[3]</sup>. This molecule is the product of a single gene, localized on human chromosome 5 at the position 5q11.2, that is organized into 3 exons separated by 2 introns. It encodes for a soluble proteoglycan of 50 kDa containing a mature polypeptide of 165 amino acids and a single dermatan sulphate chain, covalently linked to the serine residue at position 137<sup>[9]</sup>.

Endocan, as a proteoglycan, plays an important role in several pathophysiological processes including

inflammatory disorders<sup>[10-15]</sup> and tumor progression, and in the control of fundamental cellular processes, such as adhesion<sup>[16]</sup>, migration and angiogenesis. Inflammatory cytokines, such as TNF- $\alpha$  and LPS<sup>[17]</sup>, and pro-angiogenic growth factors, such as VEGF<sup>[18]</sup>, HGF/SF<sup>[19-22]</sup> and FGF-2<sup>[23,24]</sup>, strongly stimulate the expression and secretion of endocan in human endothelial cells.

Endocan has been identified as a potential novel endothelial cell marker and a new target for cancer therapy. It was reported that high endocan mRNA levels correlate with a poor prognosis and metastasis of several types of cancer, including breast, renal and lung cancer<sup>[1,25,26]</sup>. A study of 78 breast cancer patients, with the aim to define the optimal prognosis classifier, was performed on 70 genes according to standard prognostic criteria, showing that endocan over expression in breast cancer is associated with a higher risk of metastasis and death within 5 years<sup>[27]</sup>. Furthermore, 1234 genes that have been identified are differentially expressed in renal cell carcinoma, and endocan mRNA level is 3-fold higher in renal cell carcinoma samples than in normal tissue samples<sup>[28]</sup>. This up-regulation of endocan expression also correlates with increased tumor vasculature and inflammation in renal cancer, which is actually the ninth most common malignancy in Western countries, and no effective treatment is available for it. Similarly, a recent extensive hybridization study showed that the endocan gene is one of the most highlighted genes, with at least a 2-fold increase in all the 8 renal cell carcinoma samples analyzed, compared to normal tissue samples<sup>[29]</sup>. Interestingly, a parallel up-regulation was also revealed for VEGF and c-Met proto-oncogene receptor for HGF/SF, both of which are heavily implicated in angiogenesis. A comparable study, by dot blotting and hybridization showed that endocan is dramatically up-regulated in several (5/14) renal cell carcinoma biopsies, and is correlated with both VEGF and VEGF receptor gene expressions<sup>[30]</sup>. A gene profiling study of tissues from 23 lung cancer patients demonstrated that endocan is one of the significant poor prognosis classifiers among the 42

genes associated with a high risk of cancer-related death.

Endocan was less reported in colon and rectum tissues. Moreover, little is known about its molecular mechanism. We mapped the regulation of endocan expression in normal membrane mucosa and colorectal cancer tissue samples. Our results reveal that endocan was significantly expressed at transcriptional and translational level in normal colorectal mucous membrane and in well- and moderately-differentiated colorectal cancer, but weakly expressed in poorly-differentiated colorectal cancer. Meanwhile, RT-PCR and Western blot also showed that the expression of endocan was upregulated in normal colon and rectum tissue samples, and down-regulated in poorly-differentiated colorectal cancer tissue samples.

All these data show that endocan is differently expressed in colon and rectum tissue and other tissues. According to the previous results, endocan is almost not expressed in normal human tissue except in lung tissue. Our study showed that endocan was also expressed in normal colon and rectum tissue, but its expression was down-regulated in colorectal cancer, suggesting that regulation may be complex in colon and rectum. As we know, there are a lot of germs in human colon. Most of the outer germs are killed by gastric acid when they get into the stomach through the mouth. In the upper part of the small intestine, the number of germs is also small. However, this number increases gradually at the end of the ileum and reaches its maximum in the colon, where the contents is neutral or alkaline and movement is slower, thus making the germs propagate at a fast pace. There are  $10^9$ - $10^{11}$  germs per gram of colon contents. However, these germs can decompose protein, which is called degradation. In this process, the germs also produce some virulent substances, amino acids, peptide, amine, and hydrogen sulphide and proper indole, all of which can activate macrophages and monocytes to secrete a large number of cell factors, such as IL-1 and TNF- $\alpha$ , which can stimulate expression of endocan. That is why we can detect a high expression of endocan in normal colon and rectum tissue. However, the expression of endocan was down-regulated in poorly-differentiated colorectal cancer, suggesting that endocan may be closely related with differentiation and development of colorectal cancer.

## COMMENTS

### Background

Endocan plays a key role in the regulation of certain processes, such as cell adhesion, inflammatory disorders and tumor progression and correlates with poor prognosis and metastasis in several types of cancer, including breast, renal and lung cancer, indicating that endocan may also play a role in the pathology of cancer cells and/or may be a tumor marker. However, few studies are available on endocan expression in colorectal tissue. This study was to map endocan expression in colorectal tissue and analyze the relationship between endocan expression and tumor differentiation.

### Research frontiers

Colorectal cancer accounted for about 1 million new cases in 2002 and its incidence increases. The results of this study indicate that endocan may be used as a special molecule in the early diagnosis and treatment of colorectal

cancer.

### Innovations and breakthroughs

The results of this study show that endocan expression plays a role in the pathogenesis of colorectal cancer.

### Applications

The expression level of endocan plays an important role in the pathogenesis of colorectal cancer. Endocan may be used in the treatment of colorectal cancer in clinical practice.

### Peer review

The authors showed that the expression level of endocan was lower in colon cancer tissue than in normal colon tissue. The study was well-designed and the data are original and informative.

## Abstract

**AIM:** To investigate the etiology, diagnosis and treatment of spontaneous perforation of the colon.

**METHODS:** The clinical data of 10 cases of spontaneous perforation of the colon, observed at Fuding hospital from January 2004 to December 2007, were analyzed retrospectively.

**RESULTS:** The mean age at onset was 65 years (range from 45 to 73). Seven patients had a history of chronic constipation. All patients complained of sudden lower abdominal pain. The perforation occurred after colostomy and administration of senna leaves in two patients. Nine patients had signs of peritoneal irritation. Seven cases underwent abdominal paracentesis, which was diagnostic in six. Only one case was definitely diagnosed prior to surgery. One patient underwent neoplasty of the colon, another a partial resection of colon, six a neoplasty of the colon plus sigmoid colostomy, and two underwent Hartmann surgery. All perforation sites were opposite to the mesenteric edge. The perforation sites were located on descending colon in one case, sigmoid colon in three cases, and rectosigmoid colon in six cases. In five patients, surgical pathological examination was consistent with the microscopical changes of colonic perforation caused by feces. Three patients died after surgery.

**CONCLUSION:** Spontaneous perforation of the colon most commonly occurs among the elderly with chronic constipation. Abdominal paracentesis is helpful for the diagnosis. The perforation site is located opposite to the mesenteric edge. Sigmoid colon and rectosigmoid colon are the most frequent locations. Neoplasty of the colon and sigmoid colostomy are the most frequent

## INTRODUCTION

Spontaneous perforation of the colon is defined as a sudden perforation of the normal colon in the absence of diseases such as tumors, diverticulosis or external injury<sup>[1]</sup>. It is rare, often misdiagnosed and has a high mortality rate. It is seldom reported in the literature. In this study, we collected 10 cases of such patients during 2004 to 2007, and analyzed their clinical features in order to improve the understanding of this disease. The present study may be helpful for the diagnosis and treatment of spontaneous colonic perforation.

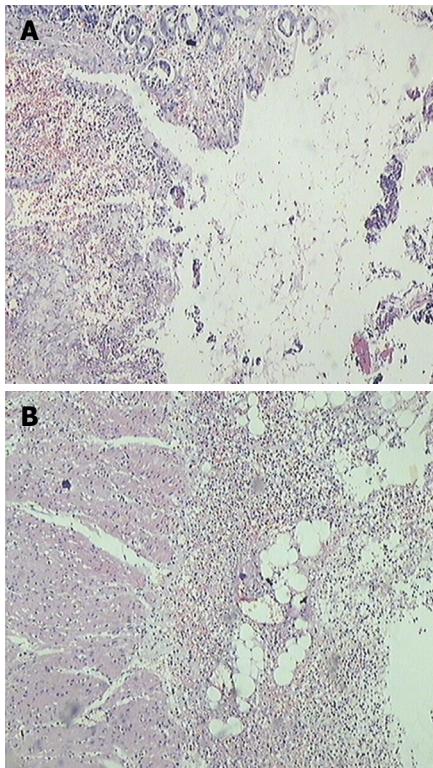

## METHODS AND MATERIALS

Ten cases of spontaneous perforation of the colon were collected at Fuding hospital from January 2004 to December 2007. The clinicopathological data, including gender, age, past history, symptoms, physical examination, diagnostic assays, pathological examination and surgical information as well as outcome were analyzed retrospectively to assess the diagnosis and treatment.

## RESULTS

### Clinical data

There were 8 males and 2 females. The mean age at onset of the disease was 65 years (range, 45 to 73).

**Figure 1** A: Inflammatory sphacelus and abundant neutrophil infiltration at the edge of the ulcer (HE, x 40); B: Numerous neutrophils infiltrate the muscular layer of the colon and the disrupted smooth muscle (HE, x 40).

Seven patients had a history of chronic constipation. All patients reported a sudden lower abdominal pain. Three patients had a history of oral administration of nonsteroid anti-inflammatory drugs (NSAIDs) to relieve abdominal pain. Five patients had possible correlated factors: in three, onset occurred after defecation and in the other two it did after coloclysis and administration of senna leaves. Three patients had symptoms compatible with shock prior to surgery. Physical examination showed signs of peritoneal irritation in 9 cases, with tension of all abdominal muscles, tenderness and rebound tenderness. The abdominal X-ray did not reveal any abnormal findings in 4 patients. Seven patients underwent diagnostic abdominal paracentesis. Feculent material was aspirated in six patients. Only one patient was definitely diagnosed before surgery. Five patients were misdiagnosed as having gastric or duodenal perforation, colorectal tumor in two other cases, acute gangrenous perforating appendicitis in one case and acute pancreatitis in one case.

### Surgery

All patients underwent emergency surgical intervention. The time interval between onset and surgery ranged from 15 to 96 h. Seven patients underwent surgery 6 h after hospital admission. One patient underwent neoplasty of the colon, one a partial resection of the colon, six a neoplasty of the colon plus a sigmoid colostomy, and two had Hartmann surgery. All perforation sites were opposite to the mesenteric edge and were located on the descending colon in one case,

the sigmoid colon in three, and the rectosigmoid colon in the remaining six.

### Pathological examination

Five patients had surgical pathological examination. Macroscopic examination showed that the perforation sites were all located opposite to the mesenteric edge, had circular shape, and ranged from 2 to 3 cm in diameter. Microscopic examination showed necrosis of the whole wall of the colon. The perforation site was characterized at its surface by inflammatory sphacelus. Granulation tissue grew from the bottom. Submucosal edema, diffuse hemorrhage and abundant neutrophil infiltration were found in the surrounding colonic mucosa, consistent with the microscopical changes typical of colonic perforation caused by feces (Figure 1).

### Prognosis

Three patients died after surgery because of multiple organ failure caused by septic shock. The other seven patients survived and six patients who received neoplasty and sigmoid colostomy underwent another surgical intervention to close the stoma 3 months thereafter.

## DISCUSSION

### Cause of spontaneous colonic perforation

The cause of spontaneous colonic perforation is usually unclear. In general, colonic perforation caused by feces is the most frequent occurrence. The disease has often been seen in patients with chronic constipation. In these cases, the solid feculent mass compresses the colonic wall, diminishes the blood supply and leads to ischemia and necrosis of colonic mucosa, which forms marked feculent ulcer changes. The ulcer might lead to colonic rupture in some cases<sup>[2-5]</sup>. Maurer *et al*<sup>[3]</sup> have proposed the diagnostic criteria of feculent colonic perforation: (1) Rounded shape, more than 1 cm in diameter; (2) The colon is full of stool, which diffuses to the abdominal cavity through the perforation; (3) Ischemia and necrosis of colonic mucosa leading to feculent ulcer and acute inflammatory reaction surrounding the perforation site can be seen at microscopical examination; (4) External injury or other diseases such as obstruction, tumors and diverticulosis must be excluded. All five cases with pathological examination were consistent with the above criteria. Maurer *et al*<sup>[3]</sup> also proposed that the feculent ulcer may present at multiple sites. The proportion of cases with multiple ulcers in the same colonic segment is about 28%.

Another cause is idiopathic colonic perforation. The pressure within the colonic lumen increases and distributes asymmetrically, leading to an excess pressure increase at the level of the angle<sup>[6]</sup>. The colonic wall is hyperdilated, becomes excessively thin and the perforation occurs. Compared to feculent perforation, idiopathic colonic perforation has the following features: (1) The perforation is linear; (2) Feculent ulcer cannot be seen at microscopic examination. The mucosal edge is clear and does not extend to the serosa. The broken

ends of the muscular layer are regular<sup>[7]</sup>. Although these two conditions are different both macroscopically and microscopically, they are occasionally difficult to distinguish at surgery. Surgical pathological examination is necessary to make a definite diagnosis<sup>[7]</sup>.

### **The most frequent sites of spontaneous colonic perforation**

The most frequent location is opposite to the mesenteric edge of the sigmoid colon and recto-sigmoid colon. Maurer *et al*<sup>[3]</sup> reported that 52 out of 81 cases (64%) of feculent perforation occurred at the above sites. In the study of Kasahara *et al*, 68% (44/65) of idiopathic colonic perforation were located at those sites<sup>[7]</sup>. In the present study, 9 patients had the same characteristics. This phenomenon may be due to the special physiological and anatomical features of sigmoid colon. There is no ramus anastomoticus between the lowest branch of sigmoid arteries and the superior rectal artery, which causes a physiological ischemia. When some stiff stool goes through sigmoid colon, the colonic wall is compressed and leads to the hindrance of blood supply. The blood supply to the opposite side of the mesentery is poor. The stool is more likely to stay in the rectosigmoid colon because of the confined colonic cavity. The smooth muscle contracts, which leads to the increase of the pressure of colonic cavity<sup>[8-12]</sup>.

This disease is more frequent in the elderly and the mean age at onset is more than 60. About 61% to 81% of patients had constipation history<sup>[2,4]</sup>. It is often misdiagnosed because doctors are unaware about this disease. Only 10% of patients are definitely diagnosed prior to surgery<sup>[6]</sup>. In the present study, only one patient (1/10) was definitely diagnosed before surgery. It is very important to increase the awareness about this disease in order to improve the accuracy of diagnosis. We think that the possibility of this disease should be taken into consideration in elderly patients who have chronic constipation, when they have a history of induction of increased intra-abdominal pressure, present with sudden abdominal pain spreading to the whole abdomen and have peritoneal irritation signs<sup>[13,14]</sup>. In this study, the abdominal paracentesis was diagnostic in 6 out of 7 patients. Therefore, abdominal paracentesis is a valuable tool for the diagnosis of patients with this complication<sup>[15]</sup>.

### **Surgical treatment of spontaneous colonic perforation**

The mortality rate of this disease is as high as 35% to 47%<sup>[2,7]</sup>. In case of perforation, innumerable bacteria spread from the colon into the abdominal cavity and cause acute diffuse peritonitis. Bacterial toxins are absorbed and lead to infectious shock and then multiple organ failure. So, patients should undergo surgery as soon as the disease is definitely diagnosed<sup>[16-20]</sup>. The types of surgery are different depending on the time of onset, degree of peritonitis, general physical condition and lesion of the colon. The following types of surgery are common: neoplasty, colostomy, neoplasty plus proximal colostomy, Hartmann surgery<sup>[21-23]</sup>. Neoplasty

plus proximal colostomy is the most popular since it is safe and time-saving. Six patients underwent neoplasty plus proximal colostomy in the present study. Serpell *et al*<sup>[2]</sup> found that the mortality and complication rates after Hartmann surgery were lower than in case of other operations because Hartmann surgery dissects the affected colon. Maurer *et al*<sup>[3]</sup> proposed that feculent ulcer had multiple origins and, therefore, other segments of the colon should be explored during the operation. If the colonic wall is dilated or thinner, it should be resected. Subtotal colectomy may be essential for some cases, which can spare time-consuming cololysis during the operation and avoid possible later re-perforation of the affected colon<sup>[24,25]</sup>.

Spontaneous colonic perforation is noteworthy due to its high mortality rate. The possibility of this disease should be taken into consideration in elderly patients having chronic constipation and bed-ridden for long periods of time. Doctors should be careful when administering enema and cathartics.

## **COMMENTS**

### **Background**

Spontaneous perforation of the colon most commonly occurs in the elderly, is usually misdiagnosed before surgery and leads to a high mortality rate after surgery. Early correct diagnosis, early surgery and appropriate surgical treatment options are the key to improve the prognosis. Effective measures should be carried out to prevent this disease in high-risk patients. This study may help the surgeon to recognize this rare entity.

### **Research frontiers**

This article focuses on a rare disease, i.e. acute abdomen due to spontaneous perforation of the colon. It is helpful to increase awareness about spontaneous perforation of the colon.

### **Innovations and breakthroughs**

It is very important to increase the knowledge about this disease in order to improve the diagnostic accuracy. The authors think that the diagnosis of this disease should be considered in elderly patients with chronic constipation, who induce an increase of the intra-abdominal pressure, present with sudden abdominal pain spreading to the whole abdomen and have signs of peritoneal irritation. In this study, the results of abdominal paracentesis were positive for 6 out of 7 patients. Therefore, abdominal paracentesis is valuable for the diagnosis of patients with this complication.

### **Applications**

The spontaneous colonic perforation should be correctly diagnosed, due to its high mortality rate. Doctors should be careful when administering enema and cathartics.

### **Peer review**

This is an interesting series of patients with a rare condition. The authors performed a single study center report of 10 patients. They analyzed the clinicopathological data retrospectively and assessed the diagnostic procedures and the treatment. In addition, they point out to surgeons the importance of recognizing this rare cause of acute abdomen with a high mortality rate.

## INTRODUCTION

Anabolic steroid abuse is common among athletes and is associated with a number of medical complications<sup>[1-3]</sup>. Reported hepatic complications include cholestasis, elevation of aminotransferases, jaundice, benign hepatic adenomas, and rare cases of hepatocellular carcinoma<sup>[4-6]</sup>. Histologic findings include peliosis hepatitis, a lesion characterized by hepatic sinusoidal dilatation that is often cystic<sup>[7,8]</sup>. Rupture of these cysts can cause fatal internal hemorrhage<sup>[9]</sup>. We report the first case of adenoma regrowth and hemorrhage after relapse of androgen abuse.

## CASE REPORT

A 27-year-old man with a 5-year history of anabolic steroid abuse presented to the emergency room with 2 d of midepigastric pain and nausea. His only medications were oral androstenedione and intramuscular nandrolone. He was a police officer and competitive bodybuilder. He denied use of alcohol, tobacco, and intravenous drugs. Physical examination disclosed midepigastric tenderness and tender hepatomegaly. Laboratories were notable for 2.2 mg/dL total bilirubin, 1.3 mg/dL direct bilirubin, 2457 U/L ALT, 431 U/L AST, and 275 U/L alkaline phosphatase. Hematocrit was 50.5%. Abdominal computed tomography (CT) on admission showed a round, heterogeneous-appearing 9.9 cm × 9.6 cm mass in the left lobe of the liver. Magnetic resonance imaging (MRI) with gadolinium contrast demonstrated multiple hepatic masses, the largest of which measured 10.6 cm × 10.6 cm. The largest mass had an enhancing capsule and demonstrated signal heterogeneity, characteristic of an adenoma with intralesional hemorrhage (Figure 1A). The patient underwent left lateral hepatic segmentectomy with open cholecystectomy. Pathologic examination revealed an adenoma with peliosis hepatitis, 25 cm in diameter. The patient was instructed to discontinue steroid use. On MRI 3 mo later, the adenomas appeared 40% smaller (Figure 1B). The patient subsequently

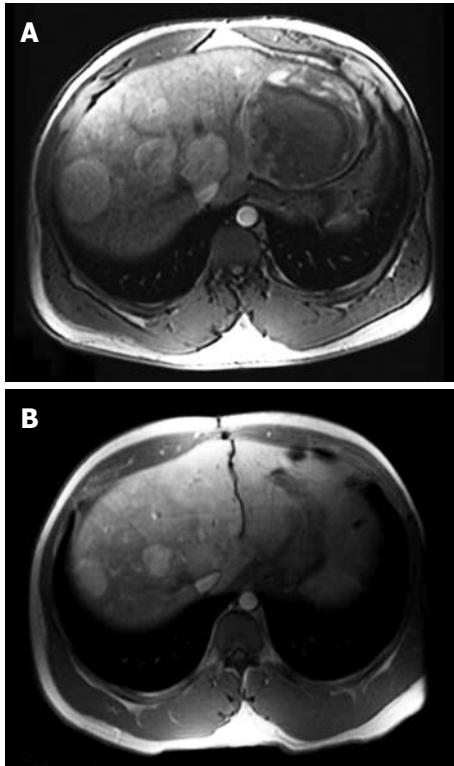

## Abstract

Anabolic steroid abuse is common among athletes and is associated with a number of medical complications. We describe a case of a 27-year-old male bodybuilder with multiple hepatic adenomas induced by anabolic steroids. He initially presented with tumor hemorrhage and was treated with left lateral hepatic segmentectomy. Regression of the remaining tumors was observed with cessation of steroid use. However, 3 years and a half after his initial hepatic segmentectomy, he presented with recurrent tumor enlargement and intraperitoneal hemorrhage in the setting of steroid abuse relapse. Given his limited hepatic reserve, he was conservatively managed with embolization of the right accessory hepatic artery. This is the first reported case of hepatic adenoma regrowth with recidivistic steroid abuse, complicated by life-threatening hemorrhage. While athletes and bodybuilders are often aware of the legal and social ramifications of steroid abuse, they should continue to be counseled about its serious medical risks.

**Figure 1** T1-weighted magnetic resonance imaging (MRI) of multiple hepatic adenomas. **A:** MRI at initial presentation demonstrates a heterogeneous-appearing, well-circumscribed mass measuring 10.6 cm x 10.6 cm in segments 2 and 3 of the liver and several smaller masses in the right liver. The largest mass has an enhancing capsule and demonstrates areas of internal T1 hyperintensity and hypointensity, as well as T2 hyperintensity, characteristic of an adenoma with intralesional hemorrhage; **B:** Three months after left lateral segmentectomy and steroid cessation, the lesions in the right liver appear approximately 40% smaller and enhance more homogeneously on T1-weighted MRI, indicating regression. Images have been electronically adjusted to illustrate lesions.

resumed oral androstenedione only.

Approximately 3 years and a half after his first presentation, the patient returned to the emergency room with sudden-onset, right-upper quadrant pain in the setting of recurrent injection nandrolone use 6 wk earlier. Vital signs were within normal limits, and there was tender hepatomegaly. Laboratories were notable for ALT 625 U/L, AST 398 U/L, and normal alkaline phosphatase and total bilirubin. Prothrombin time (PT) was 13.1 s; international normalized ratio (INR) was 1.1. The hematocrit was 38.7%. Abdominal CT revealed several lesions in the right lobe of the liver, the largest of which had increased in size to 7.7 cm x 7.2 cm and demonstrated intralesional hemorrhage, accompanied by a subcapsular hematoma and intraperitoneal hemorrhage. CT angiogram on hospital day 2 showed no contrast extravasation, but the hematocrit dropped to 24.9%. On hospital day 3, the right upper quadrant pain worsened, and he became tachycardic. Repeat abdominal CT showed expansion of the hematoma, with new anterior subcapsular and subphrenic components (Figure 2). The hematocrit was 24.4%. Because of his limited hepatic reserve and ongoing steroid abuse, he was felt to be a poor candidate for either hepatic

**Figure 2** Abdominal CT at second presentation with abdominal pain after resumption of steroid abuse. A heterogeneous-appearing, right hepatic mass measuring 7.2 cm x 7.7 cm and a large subcapsular hematoma are seen, indicating that one of the hepatic adenomas has enlarged since the previous presentation and has hemorrhaged spontaneously. Image has been electronically altered.

resection or liver transplantation. He, therefore, underwent angiographic embolization of the accessory right hepatic artery. Four units of packed red blood cells were transfused. The serum ALT exceeded 10000 U/L after the procedure but declined over several days. After transient oliguric renal failure, he was discharged to home on post-procedural day 5.

## DISCUSSION

We report a rare case of hepatic adenoma regrowth with recidivistic steroid abuse, complicated by life-threatening hemorrhage. This case underscores the potentially life-threatening complications of anabolic steroid abuse, and calls for a high index of suspicion among health care providers for hepatic complications if a history of steroid use is elicited.

The risk of androgen-associated liver tumors appears to correlate with the cumulative androgen dose and the potency of the steroid used<sup>[10]</sup>. Our patient self-administered both oral androstenedione, which has relatively weak androgenic potential, and parenteral nandrolone, which is particularly potent due to C10 hydroxylation. Since androstenedione has not been associated with liver tumors, it is likely that the nandrolone promoted development of his hepatic adenomas. This is consistent with the recurrence of his symptoms soon after resumption of nandrolone.

Both nandrolone and androstenedione have been classified as Schedule III controlled substances in recognition of their abuse potential<sup>[11,12]</sup>. Despite these legal restrictions, anyone can still obtain these drugs with little difficulty over the Internet.

By resuming anabolic steroid consumption after his first hospitalization, our patient clearly demonstrated a pattern of substance abuse. Risk factors for anabolic steroid abuse in male bodybuilders include body-image disturbances, history of childhood conduct disorder, and poor father-son relationships<sup>[13]</sup>. Had our patient's condition deteriorated and necessitated consideration

of liver transplantation, he would have been required to demonstrate a commitment to abstinence from steroids, in a manner analogous to the alcoholic patient<sup>[14]</sup>.

Patients and physicians must be reminded that the sequelae of anabolic steroid abuse are life threatening. While athletes and bodybuilders are often aware of the legal and social ramifications of steroid abuse, they should also be counseled about its serious medical risks. In the context of an addictive behavior pattern, assiduous surveillance for neoplasms should also be undertaken.

## ACKNOWLEDGMENTS

The authors would like to thank Andrew Loiacono, MD, for his interpretations of the radiologic images.

## INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease (IBD) with unknown aetiology, which is localized in the colon. It affects both adults and children, and approximately 10% of the patients are diagnosed during childhood<sup>[1]</sup>. Drugs used to induce its remission consist mainly of 5-aminosalicylic acid (5-ASA) and steroids, and 5-ASA as its maintenance therapy<sup>[2]</sup> is often used. In more severe or steroid refractory cases, immune modulating therapy with azathioprine or 6-mercaptopurine, may be used, although the evidence for this is less convincing as compared to the treatment of Crohn's disease (CD)<sup>[3]</sup>. Despite intensive pharmacological treatment, relapse is not uncommon. Extra intestinal manifestations are reported to occur in about 40% of adult patients with UC<sup>[4]</sup>. Figures for children are lower.

There are several risk factors for cerebral venous thrombosis (CVT), such as hormones (e.g. contraceptives and pregnancy), different kinds of hereditary thrombophilia and local factors including tumors<sup>[5]</sup>. In childhood, other risk factors such as local head/neck infections, sepsis and dehydration due to systemic illness have been described<sup>[6]</sup>. CVT is associated with a significant morbidity and mortality in children, and antithrombotic therapy with heparin in the acute phase followed by warfarin is recommended both in

## Abstract

The risk of thromboembolism is increased in inflammatory bowel disease and its symptoms may be overlooked. Furthermore, its treatment can be complex and is not without complications. We describe a case of an adolescent boy who developed a cerebral sinus venous thrombosis during a relapse of his ulcerative colitis and who, while on treatment with heparin, developed heparin-induced thrombocytopenia (HIT). The treatment was then switched to fondaparinux, a synthetic and selective inhibitor of activated factor X.

© 2008 The WJG Press. All rights reserved.

**Key words:** Inflammatory bowel disease; Ulcerative

children and in adults<sup>[5,7]</sup>. However, CVT in children and adolescents with IBD is, only sparsely described. Hence, we describe a case of an adolescent boy who developed a cerebral sinus venous thrombosis during a relapse of his UC, and who, while on treatment with heparin, developed heparin-induced thrombocytopenia (HIT).

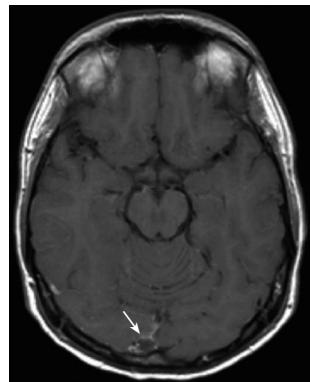

Written consent was received from the patient.

## CASE REPORT

The patient was an 18-year old male who presented with extensive ulcerative colitis at the age of 12.5 years. He was initially treated with steroids and olsalazine. He went into remission within 3 mo. During the following years, it was complicated with several relapses, which were treated with repeated courses of prednisolone. Thus, two years after diagnosis, azathioprine (AZA) was started at a dosage of 1 mg/kg. His clinical condition was quite stable until the age of 17 years when an upper respiratory infection induced another relapse with worsening of the patient's general condition and a pronounced weight loss. A high dose of prednisolone (i.e., 40 mg daily) was restarted and the AZA dose was further increased (approximate 2 mg/kg). One month after the introduction of steroids, the patient developed unilateral peritonsillitis and was admitted to hospital for incision and intravenous penicillin G treatment. The dose of prednisolone was then tapered to 10 mg daily. The pharyngeal symptoms resolved and the patient was discharged on the third day. However, 5 d after discharge, he was readmitted due to a three-day history of severe headache, accompanied with nausea and vomiting. His colitis was clinically improved, apart from continuing daily episodes of loose stools.

The vital signs were normal. Neurological examination did not show any abnormalities or clinical signs of meningitis. During the first days after admission, the patient's headache deteriorated. A CT-scan of the head was performed and interpreted as normal. Hence, a lumbar puncture performed surprisingly revealed an intralumbar pressure of 49 cmH<sub>2</sub>O (< 20). The spinal fluid analyses were otherwise normal. An eye fundoscopy revealed bilateral papilloedema and a diagnosis of pseudotumor cerebri induced by the steroid treatment was suspected. In order to reduce the cerebrospinal pressure, 10 mL of cerebrospinal liquid was withdrawn. After an asymptomatic period of about 14 h, the patient's general appearance deteriorated with recurring severe headache.

Repeated neurological examinations did not reveal any focal symptoms. A magnetic resonance imaging of the brain (MRI) showed a CVT in the right sinus transversum and confluence area (Figure 1). D-dimer was clearly elevated. Treatment with intravenous heparin infusion was initiated with a loading dose of 5000 IU, followed by a continuous heparin infusion adjusted according to aPTT (approximately 27 IU/kg per hour was required to maintain aPTT 2-3 times the baseline value). Despite an ongoing active colitis, anticoagulant therapy was considered safe.

**Figure 1** T1 contrast enhanced transverse image showing a focal dark area (arrow) in the right transverse sinus and confluence, which are consistent with a cerebral sinus thrombosis.

In the following 7 d, the patient's general condition improved, although his appetite was poor and the blood-stained diarrhoea continued. Mild iron deficiency anaemia was noted, but vitamin B12 and homocysteine levels were normal. Parenteral nutrition was given as a nutritional support.

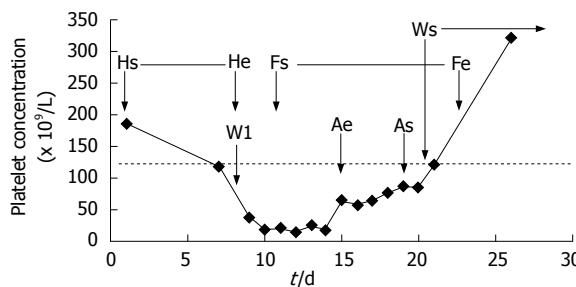

On day 7, warfarin was introduced under concomitant continuous heparin infusion. A rapid platelet count fall of 80% in 48 h was noted. Hence, azathioprine was temporarily stopped due to its known risk of thrombocytopenia. Heparin-induced thrombocytopenia (HIT) was suspected, warfarin was stopped and heparin infusion was switched to fondaparinux (Arixtra®, GlaxoSmithKline). The starting dose of fondaparinux was 7.5 mg, which was tapered to 5 mg after 3 d. The diagnosis was later confirmed by the detection of IgG-antibodies against heparin with consistent criteria for HIT<sup>[8]</sup>. The patient received a total of 6 units of platelet transfusion over a period of 4 d when the platelet count was < 18 × 10<sup>9</sup>/L, due to the high expected risk of bleeding in this patient with colitis. Despite this, he had blood in his stools on several occasions during this period. The platelet count started to rise 7 d after heparin was stopped. When the platelet count reached > 80 × 10<sup>9</sup>/L, azathioprine and warfarin were reintroduced and after 2 d of therapeutic INR between 2 and 3, fondaparinux was stopped after 9 d of treatment. The course of thrombocytopenia and medical intervention are presented in Figure 2.

During the course of CVT and HIT, a low dose of prednisolone and olsalazine was continued.

A follow-up CT scan 6 mo after the CVT diagnosis showed normal blood flow in all cerebral venous sini with no clinical neurological sequels.

A thorough work-up 7 mo after discharge showed that antithrombin, fibrinogen, lipoprotein (a), factor V gene mutation, prothrombin gene mutation, PAI-I, antiphospholipid antibodies, homocysteine, were all normal. Warfarin treatment was stopped after 8 mo of treatment. Thereafter, protein S, protein C, lupus anticoagulants, and FVIII were tested normal.

The colitis eventually went into clinical and biochemical remission. The patient was hesitant to undergo another colonoscopy until 14 mo later, when the biopsies showed a mild diffuse inflammatory activity and some architectural mucosal changes.

**Figure 2** Platelet count expressed in  $10^9/L$  blood (normal range, 125-340) from readmission until discharge showing the progress of thrombocytopenia. The letters denote start or end of heparin (Hs and He), fondaparinux (Fs and Fe), warfarin (Ws), and azatioprine (Ae and As). W1 denotes only one dose. Dotted line denotes a level of thrombocytes lower than their normal range.

## DISCUSSION

The increased risk of thromboembolism (TE) in patients with active IBD is well established<sup>[9-13]</sup> with a 6.5% incidence of thrombosis or a 3-4 fold higher risk than in the general population<sup>[14]</sup>. TE can also occur in the pediatric age group<sup>[15]</sup>. The potential mechanisms underlying the prothrombotic state in IBD are hypercoagulation (elevated FVIII, fibrinogen, decrease in antithrombin, protein S and protein C), hypofibrinolysis [elevated PAI-1 and lipoprotein (a)], platelet abnormalities, endothelial dysfunction (increased von Willebrand factor) and immunological abnormalities (antiphospholipid antibodies)<sup>[14,16]</sup>. The common genetic risk factors for TE factor V mutation (Factor V Leiden) and prothrombin mutation (G20210A) are not overrepresented in patients with TE and IBD compared to other patients with TE<sup>[16]</sup>.

It has been suggested that hyperhomocysteinemia is a risk factor for vascular disease and a mediator of TE in adults and occurs more commonly in both pediatric and adult IBD patients than in healthy controls<sup>[17,18]</sup>, which probably reflects the nutritional status with depleted levels of folate, cobalamin (B12) and pyridoxine (B6)<sup>[19]</sup>. The increased risk of TE in IBD associated with hyperhomocysteinemia is, however, questioned<sup>[19]</sup>. Other acquired risk factors for TE that can affect patients with IBD are steroid treatment, surgery, immobilisation, dehydration, central venous catheters<sup>[16]</sup>, iron deficiency and infections<sup>[6]</sup>.

In our patient, the risk factors for the development of CVT were relapse of the disease, treatment with high doses of steroids and development of peritonitis, surgical incision, dehydration, and iron deficiency anemia. Despite the risk factors, the diagnosis of CVT was delayed mainly due to this complication which is rather rare. It is important to raise the question about sinus thrombosis in the request form to the radiology department since not only unenhanced CT, but also contrast CT needs to be performed for most cases.

Cerebral venous thrombosis is a rare, but serious complication of IBD and seems to be more common in UC than in CD patients<sup>[13]</sup>. Its prognosis is variable with a high risk of residual symptoms in affected children and adolescents. Even death has been reported<sup>[13]</sup>. The most frequent symptom is headache, which occurs in

75%-96% of patients. The headache is often severe and diffuse, usually preceding the appearance of neurological deficits. A combination of focal deficits, headache, seizures and altered consciousness is very suggestive of CVT<sup>[5]</sup>. Apart from supportive care, anticoagulation therapy with heparin is the first line therapy for mild to moderate cases. Thrombolysis using recombinant tissue-type plasminogen activator (rt-PA) or urokinase has also been tried with various successes<sup>[20]</sup>. Due to the potential risks, expert guidelines recommend that local thrombolysis using urokinase<sup>[20]</sup> or (rt-PA)<sup>[5]</sup> should be restricted to comatose patients or patients who deteriorate despite anticoagulant therapy.

HIT is defined as an immune-mediated side effect of heparin therapy, which causes a drop in platelet count of  $\geq 50\%$ <sup>[21]</sup>. HIT usually occurs after 5-10 d of heparin treatment, but a faster drop may be seen if heparin has been given earlier. Apart from thrombocytopenia, venous or arterial thrombosis can occur, even before thrombocytopenia. Other symptoms observed in children with HIT are acute thoracic pain, respiratory distress, anaphylactic shock and prolonged fever<sup>[8]</sup>. An auto-immune response to platelet surface factor 4 (PF4) in complex with heparin is the major pathophysiological factor<sup>[22]</sup>. These complexes lead to cellular activation and development of thrombocytopenia or thrombosis<sup>[22]</sup>. In children, this is probably as common as in adults. In a recent review by Risch and co-workers, the incidence of HIT in children is estimated to be 0%-2.3%<sup>[21]</sup>. Approximately 90 pediatric HIT cases have been reported in the literature until now<sup>[21]</sup>. Children or neonates treated in intensive care units after cardiac surgery and adolescents treated with unfractionated heparin after thromboembolism constitute the highest risk of developing HIT in the pediatric population<sup>[21]</sup>. Although a rapid increase in platelet levels after cessation of heparin is observed, stopping heparin, as a sole treatment, is not recommended since unfavourable outcome has been reported in over 40% of patients due to the risk of thrombosis. Hence, alternative anticoagulant therapy is recommended. Danaparoid (heparinoid) inhibits mainly factor Xa, and to a lesser extent prothrombin, lepirudin (thrombin inhibitor), and argatroban (thrombin inhibitor) are the recommended drugs for the treatment of HIT. Treatment of HIT with danaparoid has a risk of cross reactivity. Lepirudin and argatroban are expensive, administered as continuous intravenous infusion, and require frequent aPTT testing. However, for our patient, fondaparinux was used as anti-coagulant therapy. Fondaparinux is a synthetic and selective inhibitor of activated factor X (Xa), administered as subcutaneous injection once daily. The antithrombotic effect is achieved by a selective binding of fondaparinux to antithrombin, which increases 300-fold the endogenous neutralisation by antithrombin on factor Xa. Hence, it inhibits the production of thrombin and the development of thrombosis<sup>[23]</sup>. Fondaparinux does not appear to interact with HIT-related antibodies to induce platelet activity and aggregation according to *in vitro* tests and small clinical trials<sup>[24]</sup>.

For our patient, all potential future surgical

procedures and longer periods of immobilization should be accompanied with anti-embolic prophylactic treatment. However, due to his episode of HIT, heparin and low molecular weight heparin (LMWH) is contraindicated and alternative anticoagulant treatment must be used.

Patients with severe IBD are frequently treated with AZA, which may cause a problem during anticoagulant therapy for TE. Scarce reports are available on the AZA treatment which may interact with warfarin by diminishing its effect. Hence, the dose of warfarin may have to be increased 3-4 fold in order to achieve an optimal PK INR level<sup>[25]</sup>.

Thromboembolic complications of IBD are not uncommon. If headache occurs during severe relapse of thromboembolism, CVT must be excluded. A CT scan with and without contrast is recommended as the first initial investigation. Platelet levels should be closely monitored during heparin treatment. When heparin is used, LMWH should be considered due to its lower risk of HIT than unfractionated heparin<sup>[26]</sup>. However, heparin has advantages in patients with a high risk of bleeding due to shorter T<sub>1/2</sub>. More studies concerning fondaparinux in treatment of patients with HIT are needed. It is necessary to evaluate the screening methods for identification of IBD patients with a high risk of thromboembolic complications. Furthermore, the efficacy and safety of prophylactic antithrombotic treatment of children with severe IBD must be evaluated in controlled clinical trials.

### Abstract

Pylephlebitis, a rare complication of acute appendicitis, is defined as thrombophlebitis of the portal venous system. Pylephlebitis usually occurs due to secondary infection in the region drained into the portal system. We report a case of pylephlebitis caused by acute appendicitis. The patient was transferred from a private clinic 1 wk after appendectomy with the chief complaints of high fever and abdominal pain. He was diagnosed with pylephlebitis of the portal vein and superior mesenteric vein by CT-scan. The patient was treated with antibiotics and anticoagulation therapy, and discharged on the 25th day and follow-up CT scan showed a cavernous transformation of portal thrombosis.

Chang YS, Min SY, Joo SH, Lee SH. Septic thrombophlebitis of the porto-mesenteric veins as a complication of acute appendicitis. *World J Gastroenterol* 2008; 14(28): 4580-4582 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4580.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4580>

### INTRODUCTION

Pylephlebitis is defined as thrombophlebitis of the portal venous system associated with intraperitoneal septic conditions, such as colonic diverticulitis, acute appendicitis, and cholangitis. Pylephlebitis is considered a seriously lethal condition.

Recent advances in antibiotic therapy have made the occurrence of pylephlebitis very rare. However, the mortality rate remains high because non-specific symptoms and low index of suspicion usually delay the diagnosis of pylephlebitis. The early use of optimal diagnostic modalities and surgical interventions are essential to ensure the survival of patients.

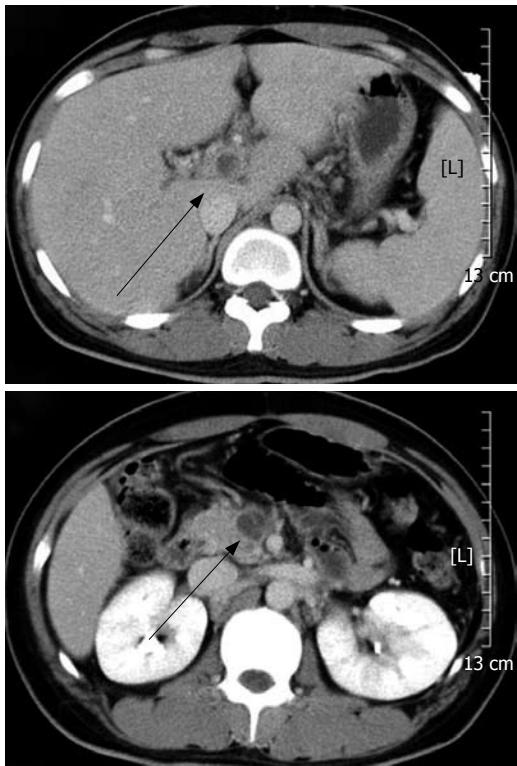

We describe a case of thrombophlebitis of the portal vein and superior mesenteric vein as a complication of acute appendicitis, which was successfully treated with antibiotics and anticoagulation therapy.

### CASE REPORT

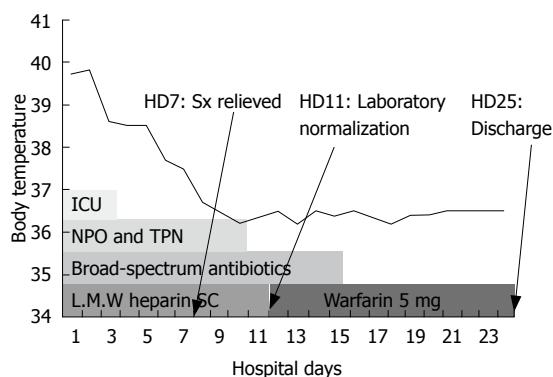

A 26-year-old man was transferred to the emergency department with the complaints of high fever and severe abdominal pain for 4 d. He underwent appendectomy for acute appendicitis 1 wk earlier. During the hospital stay, he had persistent fever up to 40°C and diarrhea, and was treated with antibiotics, fluids and anti-pyretics.

On arrival, he had an elevated temperature of 39.7°C and complained of severe epigastric pain. His blood pressure was 140/80 mmHg, his pulse rate was 114/min, and the respiration rate was 24/min. Physical examination noted epigastric pain and tenderness, but could not find rebound tenderness and muscle guarding. Laboratory results showed mild leukocytosis (11500/mm<sup>3</sup>), anemia (9.9 g/dL hemoglobin), and elevated bilirubin (1.6/0.9 mg/dL total/direct bilirubin), alkaline phosphatase (213 U/L), and γ-GT (73 U/L).

Abdominal CT scan demonstrated thrombus formation in the portal vein extending from the superior mesenteric vein (SMV; Figure 1). He was admitted to the intensive care unit and treated with systemic IV antibiotics (the 3rd generation cephalosporin and metronidazole, chosen by empirical therapy) and anticoagulation therapy (a subcutaneous injection of low molecular heparin, 1 mg/kg every 12 h). He was given nothing by mouth and parenteral nutrition was initiated to decrease the portal blood flow from the mesenteric vein.

**Figure 1** CT scan showing total occlusion of the portal vein with a thrombus (arrow) extending to the superior mesenteric vein.

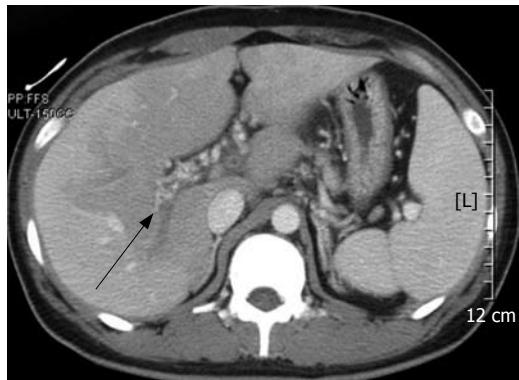

**Figure 2** Clinical progress and treatment course of the patient. ICU: Intensive care unit; NPO: Non per os; TPN: Total parenteral nutrition; HD: Hospital day; L.M.W. heparin SC: Low molecular weight heparin subcutaneous injection.

By the 3rd hospital day, his symptoms were gradually improved and the liver dysfunction and leukocytosis were normalized on the 11th day. Thereafter, oral feeding was started. No microorganisms were identified in his blood culture specimen. On the 12th hospital day, low molecular weight heparin was replaced with warfarin (5 mg/d) and continued until one month after discharge (Figure 2).

The follow-up CT scan taken 2 wk after admission showed a cavernous transformation of portal vein thrombus and improved SMV thrombosis (Figure 3).

The patient was discharged on the 25th day without complications. A follow-up CT scan after 6 mo showed a slightly increased cavernous transformation of the portal vein and marked improvement of the SMV thrombosis.

**Figure 3** Arrow indicates the cavernous transformation of the portal vein on follow-up CT scan.

He appeared healthy and had no clinical and laboratory abnormalities on follow-up.

## DISCUSSION

Although pylephlebitis is a rare complication derived from septic conditions of the portal drainage area most commonly caused by colonic diverticulitis, it occurs in association with acute appendicitis, inflammatory bowel disease, suppurative pancreatitis, acute cholangitis, bowel perforation, and pelvic infection<sup>[1-3]</sup>.

This disease entity occurred in 0.4% of patients with acute appendicitis before 1950, but it has become very rare due to major advances in antibiotic therapy and surgical treatment<sup>[4]</sup>. However, the reported mortality rate of pylephlebitis is 30%-50%, partly due to a delay in diagnosis from its atypical clinical findings and a low index of suspicion<sup>[1,5]</sup>.

Reported cases of pylephlebitis are mainly young children, with a mortality rate of up to 50%<sup>[4,6-8]</sup>. Children are particularly at a great risk of appendiceal perforation because the diagnosis is delayed. As a result, young children are prone to develop pylephlebitis.

The clinical features of pylephlebitis are non-specific. High fever, chills, malaise, right upper quadrant pain, and tenderness are the initial clinical manifestations. Balthazar and Gollapudi<sup>[9]</sup> reported that only 30% of patients with pylephlebitis present with localizing clinical signs of a primary source of sepsis. Laboratory findings, such as leucocytosis and mild abnormalities of liver function tests, are usually non-specific, but jaundice is rare except in case of multiple liver abscesses<sup>[4,5,7,10]</sup>. Our patient was treated conservatively for epigastric pain, high fever, and diarrhea after appendectomy in a private clinic, as there was no suspicion of pylephlebitis.

Blood cultures revealed no microorganisms in our case. Baril *et al*<sup>[5]</sup> reported that bacteremia is present in less than one-half of patients, whereas Balthazar and Gollapudi<sup>[9]</sup> reported that up to 80% of patients have positive blood cultures, and *Escherichia coli*, *Bacteroides fragilis*, *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterobacter* spp. are the most common microorganisms isolated<sup>[4,7,9,10]</sup>.

Modern diagnostic imaging techniques help the early

diagnosis of acute phase pylephlebitis. The sensitivity and specificity of CT scans for pylephlebitis are not known. However, CT scans could simultaneously detect the primary source of infection, extent of pylephlebitis, and intrahepatic abnormalities, such as liver abscesses. Thus, CT scan is the most reliable initial diagnostic choice<sup>[9-11]</sup>. Air bubbles or thrombi of the portal venous system are the critical CT findings of pylephlebitis<sup>[9]</sup>. Ultrasound scan with color flow Doppler is also a sensitive test for confirming partial patency of the portal vein and portal vein thrombosis<sup>[7]</sup>.

Once a diagnosis of pylephlebitis is established, appropriate treatment should be initiated as soon as possible.

The principal of treatment for pylephlebitis is to remove the source of infection and eradicate the toxic microorganisms using appropriate antibiotics. Immediate surgical intervention is necessary in most cases, but Stitzenberg *et al*<sup>[8]</sup> reported that interval laparoscopic appendectomy can be performed 3 mo after treatment with antibiotics and anticoagulants. Regarding the treatment of portal thrombosis, Nishimori *et al*<sup>[11]</sup> reported that surgical thrombectomy can be performed through the ileocolic vein using a Fogarty catheter, but most reported cases are treated with systemic antibiotics and anticoagulants. A minimum of 4 wk of antibiotic therapy is usually recommended and patients presenting with a hepatic abscess should receive at least 6 wk of antibiotic therapy<sup>[7,10]</sup>.

The effectiveness of anticoagulants in the treatment of pylephlebitis is still controversial. We administered low molecular heparin for 11 d initially and warfarin for 1.5 mo. Condat *et al*<sup>[12]</sup> recommended early anticoagulants therapy because the recanalization of the portal system was significantly higher in the anticoagulation group compared to the control group. Baril *et al*<sup>[5]</sup> insisted that anticoagulants should be considered carefully because complications could present in 20% of patients, and it is not necessary in patients with thrombus isolated to the portal vein, but could be used for prevention of intestinal ischemia in patients with involvement of the superior or inferior mesenteric vein. Lim *et al*<sup>[10]</sup> recommended anticoagulation for the prevention

of septic pulmonary embolism from infected portal thrombi.

In summary, pylephlebitis is a rare, but fatal complication of acute appendicitis. Therefore, when pylephlebitis is suspected, immediate CT scan and antibiotic therapy, with or without surgical intervention, should be started to ensure the survival of patients.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common tumors worldwide<sup>[1]</sup>. Direct invasion to the gastrointestinal (GI) tract by HCC is uncommon, with a reported incidence of 0.5%-2% among clinical HCC cases<sup>[2,3]</sup>. GI bleeding or stenosis due to HCC invasion is very uncommon. In such cases, the best treatment remains controversial<sup>[4]</sup>.

Due to improved instruments, techniques, and perioperative management, surgical resection is now safely performed in patients with advanced HCC. Therefore, it is also possible to resect HCC with direct invasion to the GI tract. Here, we present two cases of HCC with direct invasion to the colon that were treated by surgical resection.

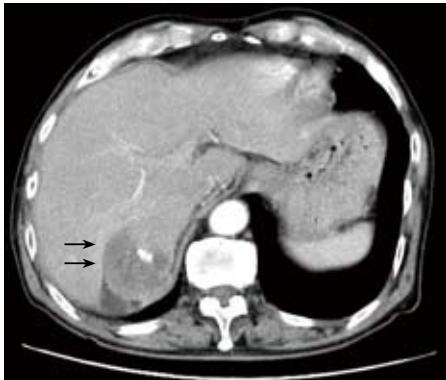

### CASE REPORT

#### Case 1

A 79-year-old man with chronic hepatitis C has been followed up since 1983. In August 1998, computed tomography (CT) revealed a 4-cm tumor in the caudate lobe of the liver, which was diagnosed as HCC. The lesion was treated by transarterial chemo-embolization (TACE). In February 2000, the patient suffered from epigastralgia, and was admitted to our hospital. CT revealed that the liver tumor increased to 7.5 cm in diameter and directly invaded the transverse colon (Figure 1). Liver function tests revealed no abnormalities. The serum  $\alpha$ -fetoprotein (AFP) level was 331 ng/mL, and the protein induced by vitamin K absence or antagonist 2 (PIVKA-2) level was within normal range.

### Abstract

Although hepatocellular carcinoma (HCC) is a common tumor, direct invasion of the gastrointestinal tract by HCC is uncommon. Recently, we encountered two cases of HCC with direct invasion to the colon. The first patient was a 79-year-old man who underwent transarterial chemo-embolization (TACE) for HCC 1.5 years prior to admission to our hospital. Computed tomography (CT) showed a 7.5-cm liver tumor directly invading the transverse colon. Partial resection of the liver and transverse colon was performed. The patient survived 6 mo after surgery, but died of recurrent HCC. The second patient was a 69-year-old man who underwent TACE and ablation for HCC 2 years and 7 months prior to being admitted to our hospital for melena and abdominal distension. CT revealed a 6-cm liver tumor with direct invasion to the colon. The patient underwent partial resection of the liver and right hemicolectomy. The patient recovered from the surgery. But, unfortunately, he died of liver failure due to liver cirrhosis one month later. Although the prognosis of HCC that has invaded the colon is generally poor due to the advanced stage of the disease, surgical resection may be a favorable treatment option in patients with a good general condition.

**Figure 1** Computed tomography images showing a 7.5-cm liver tumor (arrows) arising from the caudate lobe in case 1(A), which appears to invade the transverse colon directly (arrows) (B).

**Figure 2** Macroscopic appearance of the surgical specimen in case 1. The liver tumor invades the colon (arrows).

HCC invading the transverse colon was diagnosed and partial resection of the liver and transverse colon was performed. In the resected specimen, a 96 mm × 58 mm liver tumor invading the transverse colon was found (Figure 2). Histopathologic examination of the specimen also showed poorly-differentiated HCC with direct invasion to the colon. The postoperative course was uneventful, and the patient was discharged on postoperative day 21. He survived symptom free for 6 mo and died of recurrent HCC.

## Case 2

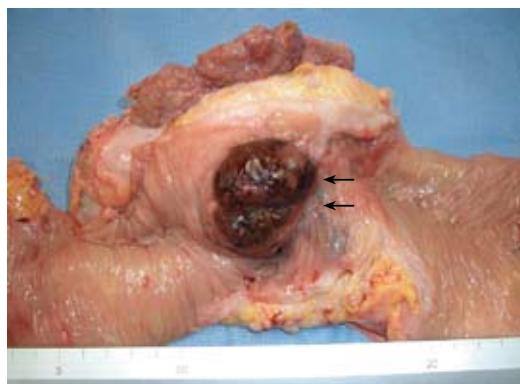

A 69-year-old man has been treated since 2000 for liver cirrhosis due to hepatitis C. In July 2004, CT revealed a 4-cm tumor in segment 6 of the liver, which was diagnosed as HCC. The lesion was treated by radiofrequency ablation (RFA) and TACE. In February 2007, the patient suffered from melena and abdominal distension and was admitted to our hospital. CT revealed that the tumor increased to 6 cm in diameter and directly invaded the diaphragm and the hepatic flexure of the colon (Figure 3). The ascending colon was dilated due to stenosis of the colon. Colonoscopic examination revealed a hemorrhagic and lobulated tumor in the hepatic flexure of the colon (Figure 4). Laboratory tests revealed 2.9 g/dL serum albumin, 1.9 mg/dL serum total bilirubin, 52.1% prothrombin activity, and 17.3% indocyanine green retention rate at 15 minutes,

**Figure 3** Computed tomography images showing a 6-cm liver tumor invades the colon and diaphragm (arrows) in case 2.

**Figure 4** Colonoscopic view showing a hemorrhagic and lobulated tumor with a smooth surface is seen in the ascending colon in case 2.

**Figure 5** Macroscopic appearance of the surgical specimen in case 2. The liver tumor invades the colon (arrows).

15 ng/mL serum AFP, and 370 AU/mL PIVKA-2. HCC invading the hepatic flexure of the colon was diagnosed, and partial resection of the liver, right hemicolectomy and partial excision of the diaphragm were performed. In the resected specimen, a 65 mm × 47 mm liver tumor, which invaded the hepatic flexure of the colon, was found (Figure 5). Histopathologic examination of the specimen also showed moderately differentiated HCC with direct invasion to the colon and diaphragm. The patient recovered from the operation, and had no evidence of HCC recurrence, but unfortunately, he died of liver failure due to liver cirrhosis 1 mo later.

## DISCUSSION

HCC, one of the most common malignant tumors worldwide, is responsible for more than 250 000 deaths annually<sup>[1]</sup>. In some autopsy series, extrahepatic metastasis to the lung, lymphnodes, bone, heart, or adrenal glands has been found in 30%-75% of advanced HCC cases<sup>[5]</sup>. HCC with direct invasion to other organs can occur, with the most frequent sites being the diaphragm and gallbladder<sup>[6]</sup>. HCC only rarely invades the GI tract, the reported incidence is 0.5%-2% of clinical HCC cases and 4% of autopsy cases<sup>[2,3,7]</sup>. GI bleeding or stenosis due to HCC invasion is very uncommon<sup>[8]</sup>. The most frequently invaded GI tract sites are the duodenum and stomach<sup>[2]</sup> and invasion into the colon is very rare. To date, only eight cases of invasion to the colon by HCC have been reported in the English literature (Table 1)<sup>[2,3,9-11]</sup>. Among the 10 patients (including our two cases), the most frequent symptom was bloody stool (8 of 10 patients, 80%). Seven patients (70%) underwent transarterial embolization (TAE) or TACE for HCC prior to development of invasion. Surgical resection or supportive care was almost selected in almost all cases. However, the outcomes were very poor, and the median survival was only 2.5 mo.

GI tract invasion by HCC sometimes occurs after TAE or TACE<sup>[8]</sup>. TAE and TACE can induce exophytic growth of the HCC due to an inflammatory reaction and change in the extrahepatic blood supply. As a result, HCC may invade adjacent organs such as the diaphragm, stomach, duodenum, and colon.

TAE or TACE is not an effective treatment for GI invasion by HCC. RFA is difficult to perform in patients with GI tract invasion because of the risk of GI tract perforation. Fujii *et al*<sup>[12]</sup> reported that the median survival time of patients with GI tract invasion treated by surgical resection, nonsurgically, or by supportive therapies is 9.7 mo, 3.0 mo and 1.2 mo, respectively. Therefore, surgical resection may be the most effective treatment for GI tract invasion by HCC. In addition, surgical techniques including liver resection and perioperative management have recently improved. Surgical resection is probably the best treatment option for HCC invading the GI tract if the patient's general condition including liver function is good.

In conclusion, although the prognosis of colonic invasion of HCC is generally poor due to the advanced stage of the disease, surgical resection may be a favorable treatment option in patients with a good general condition.

### Abstract

Ten mg dexrabeprazole daily has been shown to be more effective than 20 mg rabeprazole daily against gastroesophageal reflux disease (GERD). This report shows that the efficacy of 10 mg dexrabeprazole daily is equivalent to that of 20 mg dexrabeprazole daily against GERD. This implies that a dose of 10 mg dexrabeprazole is sufficient to block the maximum amount of proton pumps without any need to double the dose as suggested with rabeprazole.

### TO THE EDITOR

We read with interest the article by Pai *et al* on the efficacy of 10 mg dexrabeprazole<sup>[1]</sup>. However, the effects of rabeprazole on acid secretion are dose-dependent,

and an increase in gastric pH, coupled with a reduction in oesophageal acid exposure, has been seen in gastroesophageal reflux disease (GERD) patients receiving 20 mg or 40 mg rabeprazole once daily<sup>[2]</sup>. Shimatani *et al*<sup>[3]</sup> showed that 20 mg rabeprazole, twice daily, may result in better acid suppression than 10 mg rabeprazole, twice daily, in GERD patients<sup>[3]</sup>. Hence, we wanted to find out whether 20 mg dexrabeprazole daily would provide a greater efficacy than 10 mg dexrabeprazole daily against GERD.

This was a randomized, double-blinded, comparative study in clinical setting, approved by the institutional review board and conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines. Males and non-pregnant and non-lactating females between the age of 18-65 years, clinically diagnosed with GERD, were included after a written informed consent was obtained from each of them. Excluded from the study were those with abnormal laboratory tests at baseline (including liver enzymes greater than twice the upper limit of normal), those who were refractory to a 2-mo course of H<sub>2</sub>-blocker or PPI therapy for GERD treatment, those who took PPI within 14 d of screening or a H<sub>2</sub>-blocker or a prokinetic agent within 7 d of screening, those who required daily use of NSAIDs, oral steroids, aspirin or were unable to discontinue the use of anticholinergics, cholinergics, spasmolytics, opiates or sucralfate, and those with poorly controlled associated disease, such as heart disease, coagulation disorders, thyroid disorders. Patients having a history of infectious or inflammatory conditions of the intestine (including inflammatory bowel disease), malabsorption syndrome, obstruction, gastrointestinal malignancy, gastric or intestinal surgery including vagotomy, Barrett's esophagus, esophageal stricture, pyloric stenosis, scleroderma or a history of hypersensitivity to any of the PPIs, were also excluded from the study. Enrolled patients were randomized to receive 10 mg dexrabeprazole once daily (D10-OD), 10 mg dexrabeprazole twice daily (D10-BD) or 20 mg dexrabeprazole daily (D20-OD) for 28 d. Visual analog scale (VAS, 0-100) was used to assess the severity of GERD symptoms. A total of 136 patients were enrolled and all completed the study. No difference was found in the baseline demographics of the patients.

A significant reduction ( $P < 0.001$ , Tukey-Kramer multiple comparison test) from baseline (day 0, before therapy) VAS scores of heartburn and regurgitation was

**Table 1** Improvement in Visual Analog Scale (VAS) scores of symptoms (values expressed as mean  $\pm$  SD)

	Day 0			Day 14			Day 28		
	D10-OD (A, n = 74)	D10-BD (B, n = 34)	D20-OD (C, n = 28)	D10-OD (A, n = 74)	D10-BD (B, n = 34)	D20-OD (C, n = 28)	D10-OD (A, n = 74)	D10-BD (B, n = 34)	D20-OD (C, n = 28)
Heartburn	48.5 $\pm$ 22.2	59.7 $\pm$ 12.4	58.2 $\pm$ 13.6	25.1 $\pm$ 16.2 <sup>b</sup>	38.2 $\pm$ 13.1 <sup>b</sup>	32.1 $\pm$ 15.5 <sup>b</sup>	7.6 $\pm$ 15.2 <sup>b</sup>	13.8 $\pm$ 10.7 <sup>b</sup>	12.9 $\pm$ 14.4 <sup>b</sup>
Between group	0.007 <sup>1</sup>	0.007	0.033	0.0001 <sup>1</sup>	0.0001	0.052	0.034 <sup>1</sup>	0.034	0.114
P values	0.033 <sup>2</sup>	0.652 <sup>3</sup>	0.652	0.052 <sup>2</sup>	0.078 <sup>3</sup>	0.078	0.114 <sup>2</sup>	0.779 <sup>3</sup>	0.779
Regurgitation	45.9 $\pm$ 20.4	57.6 $\pm$ 12.6	56.4 $\pm$ 14.5	21.9 $\pm$ 16.2 <sup>b</sup>	35.9 $\pm$ 12.1 <sup>b</sup>	30.7 $\pm$ 16.8 <sup>b</sup>	6.2 $\pm$ 14.2 <sup>b</sup>	11.8 $\pm$ 10.3 <sup>b</sup>	10 $\pm$ 13.6 <sup>b</sup>
Between group	0.003 <sup>1</sup>	0.003	0.014	< 0.0001 <sup>1</sup>	< 0.0001	0.017	< 0.0001 <sup>1</sup>	< 0.0001	0.225
P values	0.014 <sup>2</sup>	0.729 <sup>3</sup>	0.729	0.017 <sup>2</sup>	0.162 <sup>3</sup>	0.162	0.225 <sup>2</sup>	0.556 <sup>3</sup>	0.556

<sup>b</sup>P < 0.001 vs baseline values (Tukey-Krammer Multiple comparison test). Between-group difference (T-test): <sup>1</sup>A vs B; <sup>2</sup>A vs C; <sup>3</sup>B vs C.

seen in all the treatment groups on day 14 with a further reduction on continuing the therapy until 28 d. Improvement in the VAS scores in the D10-OD group was significantly better than in the D10-BD and D20-OD groups on day 14 with no significant difference between the D10-BD and D20-OD groups. On day 28, the D10-OD group showed significantly higher improvement than the D10-BD group with no significant differences between the D10-OD & D20-OD and the D10-BD & D20-OD groups (Table 1). Percentage of patients with  $\geq 50\%$  relief in symptoms of heartburn and regurgitation on day 28 was 86.5% and 91.9% in the D10-OD group, 91.2% and 97.1% in the D10-BD group, 89.3% and 92.9% in the D20-OD group, respectively. No between-group difference in proportion of patients with  $\geq 50\%$  relief was observed ( $P > 0.05$ , chi-square test). None of the patients reported any adverse drug reaction and no differences were seen in baseline laboratory parameters after therapy, indicating that dexrabeprazole at different doses was well-tolerated.

The results of this study demonstrates that the efficacy of 10 mg dexrabeprazole daily is equivalent to that of 20 mg dexrabeprazole daily in relieving symptoms of GERD. This implies that 10 mg dexrabeprazole daily is potent and sufficient enough to block the maximum amount of proton pumps, thus precluding the need to use higher doses as has been suggested with rabeprazole.

## ACKNOWLEDGMENTS

# Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

## Meetings

### Events Calendar 2008-2009

FALK SYMPOSIA 2008  
January 24-25, Frankfurt, Germany  
Falk Workshop: Perspectives in Liver Transplantation

International Gastroenterological Congresses 2008  
February 14-16, Paris, France  
EASL-AASLD-APASL-ALEH-IASL Conference Hepatitis B and C virus resistance to antiviral therapies  
[www.easl.ch/hepatitis-conference](http://www.easl.ch/hepatitis-conference)

February 14-17, Berlin, Germany  
8<sup>th</sup> International Conference on New Trends in Immunosuppression and Immunotherapy  
[www.kenes.com/immuno](http://www.kenes.com/immuno)

February 28, Lyon, France  
3<sup>rd</sup> Congress of ECCO - the European Crohn's and Colitis Organisation Inflammatory Bowel Diseases 2008  
[www.ecco-ibd.eu](http://www.ecco-ibd.eu)

February 29, Québec, Canada  
Canadian Association of Gastroenterology  
E-mail: general@cag-acg.org

March 10-13, Birmingham, UK  
British Society of Gastroenterology Annual Meeting  
E-mail: BSG@mailbox.ulcc.ac.uk

March 14-15, HangZhou, China  
Falk Symposium 163: Chronic Inflammation of Liver and Gut

March 23-26, Seoul, Korea  
Asian Pacific Association for the Study of the Liver  
18<sup>th</sup> Conference of APASL: New Horizons in Hepatology  
[www.apaslseoul2008.org](http://www.apaslseoul2008.org)

March 29-April 1, Shanghai, China  
Shanghai-Hong Kong International Liver Congress  
[www.livercongress.org](http://www.livercongress.org)

April 05-09, Monte-Carlo (Grimaldi Forum), Monaco  
OESO 9<sup>th</sup> World Congress, The Gastro-esophageal Reflux Disease: from Reflux to Mucosal Inflammation-Management of Adeno-carcinomas  
E-mail: robert.giuli@oeso.org

April 9-12, Los Angeles, USA  
SAGES 2008 Annual Meeting - part of Surgical Spring Week  
[www.sages.org/08program/html/](http://www.sages.org/08program/html/)

April 18-22, Buenos Aires, Argentina  
9<sup>th</sup> World Congress of the International Hepato-Pancreato Biliary Association  
Association for the Study of the Liver  
[www.ca-ihpba.com.ar](http://www.ca-ihpba.com.ar)

April 23-27, Milan, Italy

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London, The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

#### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjnet.com](mailto:submission@wjnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

**Patent** (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express  $t$  test as  $t$  (in italics),  $F$  test as  $F$  (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as  $r$  (in italics), degree of freedom as  $v$  (in Greek), sample number as  $n$  (in italics), and probability as  $P$  (in italics).

## Units

Use SI units. For example: body mass,  $m$  (B) = 78 kg; blood pressure,  $p$  (B) = 16.2/12.3 kPa; incubation time,  $t$  (incubation) = 96 h, blood glucose concentration,  $c$  (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration,  $p$  (CEA) = 8.6 24.5  $\mu$ g/L;  $CO_2$  volume fraction, 50 mL/L  $CO_2$ , not 5%  $CO_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities:  $t$  time or temperature,  $c$  concentration,  $A$  area,  $l$  length,  $m$  mass,  $V$  volume.

Genotypes:  $gyrA$ ,  $arg\ 1$ ,  $c\ myc$ ,  $c\ fos$ , etc.

Restriction enzymes:  $EcoRI$ ,  $HindII$ ,  $BamHI$ ,  $KhoI$ ,  $KpnI$ , etc.

Biology:  $H\ pylori$ ,  $E\ coli$ , etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903

Ocean International Center, Building D

No. 62 Dongsihuan Zhonglu

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-59080039

Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

## Abstract

End stage liver disease (ESLD) is a health problem worldwide. Liver transplantation is currently the only effective therapy, but its many drawbacks include a shortage of donors, operative damage, risk of rejection and in some cases recidivism of the pre-transplant disease. These factors account for the recent growing interest in regenerative medicine. Experiments have sought to identify an optimal source of stem cells, sufficient to generate large amounts of hepatocytes to be used in bioartificial livers or injected *in vivo* to repair the diseased organ. This update aims to give non-stem cell specialists an overview of the results obtained to date in this fascinating field of biomedical research.

**Key words:** End stage liver disease; Liver failure treatment; Stem cells; Regenerative medicine

**Peer reviewer:** Dr. Paul J Rowan, Professor, Management, Policy, and Community Health, University of Texas School of Public Health, 1200 Pressler St., RAS E331, Houston 77379, United States

Lorenzini S, Gitto S, Grandini E, Andreone P, Bernardi M. Stem cells for end stage liver disease: How far have we got? *World J Gastroenterol* 2008; 14(29): 4593-4599 Available from: URL: <http://www.wjnet.com/1007-9327/14/4593.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4593>

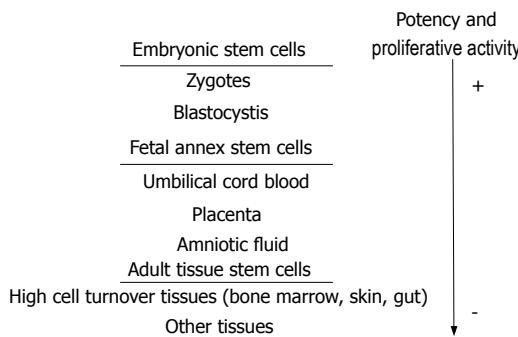

## INTRODUCTION

A stem cell is an undifferentiated cell capable of renewing itself throughout its life and of generating one or more types of differentiated cells. While embryonic stem cells (ESCs) are the only ones to be totipotential, adult tissues with high cellular turnover (e.g. skin, gut mucosa and bone marrow) retain a population of stem cells with restricted differentiation potential that constantly supply the tissue with new cells (Figure 1).

End stage liver disease (ESLD) is the final stage of acute or chronic liver damage and is irreversibly associated with liver failure. ESLD can develop rapidly, over days or weeks (acute and sub-acute liver failure, respectively), or gradually, over months or years (chronic liver failure)<sup>[1]</sup>. Currently, liver transplantation is the most effective therapy for patients with ESLD<sup>[2]</sup>. However, its potential benefits are hampered by many drawbacks, such as the relative shortage of donors, operative risk, post-transplant rejection, recidivism of the pre-existing liver disease, and high costs.

In this scenario, stem cell therapy sounds particularly attractive for its potential to support tissue regeneration requiring minimally invasive procedures with few complications. This field of research, which represents the ground from which the new discipline of “regenerative medicine” has germinated, has rapidly developed in recent years, arising great interest among scientists and physicians, and frequently appearing in newspapers headlines touting miracle cures, but arising ethical crises as well<sup>[3]</sup>. The most debated issue pertains to the use of human ESCs, as it implies, with current technologies, the destruction of human embryos. Opponents of ESC research argue that ESC research represents a slippery slope to reproductive cloning, and can fundamentally devalue human life. Contrarily, supporters argue that such research should be pursued because the resultant treatments could have significant medical potential. It is also noted that excess embryos created for *in vitro* fertilization could be donated with consent and used for the research<sup>[4]</sup>.

The ensuing debate has prompted authorities around the world to seek regulatory frameworks and highlighted the fact that stem cell research represents a social and ethical challenge. Thus, current legislation on ESC use widely varies, with some countries being more permissive (such as UK, Netherlands, Spain and France)

**Figure 1** Stem cell hierarchy in humans. While embryonic stem cells are the only ones to be totipotent, adult tissues with high cellular turnover (e.g. skin, gut mucosa and bone marrow) retain a population of stem cells with restricted differentiation potential that constantly supply the tissue of new cells.

than others (such as North America and most of the North European countries)<sup>[4]</sup>.

## GENERAL ISSUES

### How might stem cells help?

An ongoing debate involves the mechanisms by which stem cells might restore the function of a diseased organ. While some research groups support the hypothesis of stem cell integration into the tissue through "transdifferentiation" or "fusion" with resident parenchymal cells, others favour stem cells helping local cells through soluble factors production.

### How might stem cells be implanted?

The way of stem cell administration to a diseased organ widely varies in different studies, from local (direct vascular delivery) to peripheral (injection in a peripheral vein) route. Moreover, attempts to increase the number of circulating stem cells by administering growth factors have been made. Which way is best it is still unclear, and further studies are needed to clear doubts.

### What is the transferability of the data obtained from animal models to human disease?

Most data come from experiments performed in rodents, in which an organ is injured, either chemically or surgically, to study the effect of subsequent stem cell administration. Whilst animal studies are quite numerous, human usage of stem cells is still far from being everyday practice, particularly in the setting of ESLD. The translation of animal data to human disease has to be taken with great caution, and the validation of basic investigations still requires further extensive research.

### How far are we with stem cell purity and function and stability of their products?

The techniques for both ESC line isolation and adult stem cell separation from tissues need to be refined, since separation from stromal contaminating components is still not optimal. Moreover, although mature cells have been obtained by stem cell transdifferentiation *in vitro*,

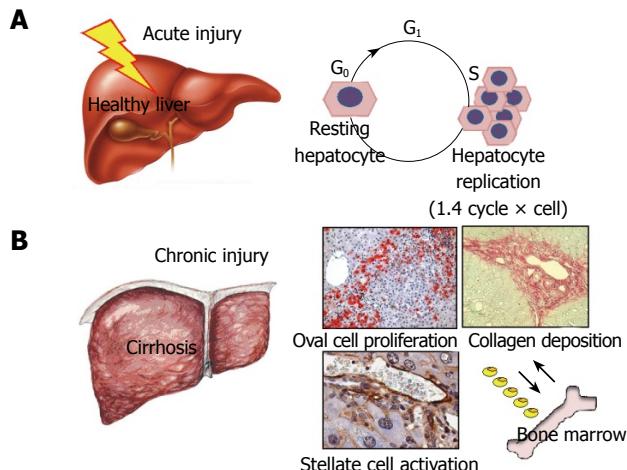

their ability to express the entire repertoire of specific biological functions and maintain them over time has not been clearly demonstrated as yet.

## LIVER REGENERATION

Under physiological conditions, the liver does not need any external source of cells to repair injury, as resting hepatocytes have the ability to re-enter the cell cycle rapidly and efficiently after an injury has occurred. Nevertheless, in persistent liver injury, as is the case with chronic liver diseases in humans, the sustained proliferative stress prematurely ages the hepatocytes and exhausts their ability to replicate. In this context, hepatic progenitor cells (or "oval cells", as they are called in rodents where they were first described) appear as a rich population of small round cells spreading from the periportal area into the parenchyma<sup>[5]</sup>. Oval cells have been demonstrated to be bipotential progenitors able to generate both hepatocytes and biliary cells<sup>[6-8]</sup>. They are thought to reside in the terminal branches of the intrahepatic biliary tree (e.g. the canals of Hering)<sup>[8]</sup> and support liver regeneration when hepatocyte proliferation is ineffective in absolute or relative terms. Rodent oval cells have proved effective in repopulating the diseased liver, but a clearly positive effect on liver function has yet to be fully demonstrated. By contrast, there is evidence that, as bipotential progenitors, oval cells can give rise to both hepatocellular- and cholangiocarcinoma<sup>[9]</sup>. The lack of an exclusive oval cell marker makes this cell population elusive and this has aroused much speculation. Some years ago, the finding of CD34 and Sca-1 hematopoietic markers on oval cells gave rise to the theory of an active trafficking of stem cells between the bone marrow (BM) and the liver and a potential involvement of the BM in liver regeneration during injury<sup>[10]</sup>. Although extremely attractive, this hypothesis is the topic of ongoing debate (Figure 2).

## BONE MARROW-DERIVED STEM CELLS

All the experimental strategies and conceptual paradigms applicable to stem cells in general were initially defined in haematopoietic stem cells (HSCs) residing in the BM. Not being at the top of the stem cell hierarchy, HSCs were initially thought to possess a restricted differentiation potential and therefore to be able to generate only cells of the haematopoietic system. This theory was questioned after studies in BM transplanted patients demonstrated the presence of donor-derived epithelial cells in some extra-haematological tissues, including the liver<sup>[11]</sup>. The hypothesis of a "germ layer-unrestricted plasticity" of HSCs rapidly captured the attention of investigators interested in regenerative medicine. There are several potential advantages of using adult rather than embryonic stem cells to regenerate tissues including fewer ethical concerns, better known biological behaviour, easier accessibility and, therefore, lower costs.

**Figure 2** Under physiological conditions, the liver does not need any external source of cells to repair injury, as resting hepatocytes have the ability to re-enter the cell cycle rapidly and efficiently after an injury has occurred (A). In persistent liver injury, as is the case with liver cirrhosis, the sustained proliferative stress prematurely ages the hepatocytes and exhausts their ability to replicate. In this context hepatic progenitor cells, or oval cells as they are called in rodents where they were first described, appear as a rich population of small round cells spreading from the periportal area into the parenchyma. The contribution of bone marrow derived stem cells to tissue regeneration in chronic liver diseases is still debated (B).

Both rodent and human HSCs have been induced to differentiate into hepatocytes *in vitro*. Most of the protocols to induce CD34+ HSCs differentiation into hepatocytes employed growing media conditioned with growth factors and mitogens [e.g. hepatocyte growth factors (HGF), fibroblast growth factor (FGF) and oncostatin M] and culture layers specific for hepatocyte growth, like matrigel. To reproduce the pathophysiological conditions of liver injury, some studies also employed cholestatic serum or co-culture with chemically damaged liver tissue<sup>[12-14]</sup>. Although these studies showed some HSC “transdifferentiation” into hepatocytes, the reported percentage of hepatocytes derived from HSCs did not exceed 5%. Thus, HSCs exhibit a limited differentiation potential that make them non-optimal candidates for tissue regeneration purposes. The cost of repeated cultures needed to obtain sufficient amounts of hepatocytes from HSC would presumably be too high for cell therapy-based applications.

Another population of stem cells in adults resides in the bone marrow stroma. Bone marrow mesenchymal stem cells (BMMSCs), as they are termed, represent the non-haematopoietic fraction of the bone marrow. *In vitro*, they are adherent, clonogenic, non-phagocytic and fibroblastic in habit. Under proper experimental conditions, they are able to differentiate into bone, cartilage, adipose and fibrous tissue, and hematopoietic supporting tissue<sup>[14]</sup>. There is also evidence that BMMSCs can undergo unorthodox differentiation, giving rise to cells with visceral mesoderm, neuroectoderm and endoderm characteristics. When transplanted, these cells can engraft in bone, muscle, brain, lung, heart, liver, gastrointestinal tract and haematopoietic tissue, and could even contribute to most somatic

cell types when injected into an early blastocyst<sup>[15]</sup>. *In vitro* experiments have shown that human and rodent BMMSCs grown on matrigel and supplemented with HGF and FGF-4 differentiate into mature hepatocytes, with a differentiation rate ranging from 30% to 80%<sup>[16,17]</sup>. BMMSCs that acquire the hepatocyte phenotype *in vitro*<sup>[18]</sup> also exhibit typical hepatocyte functions, including albumin production, glycogen storage, urea secretion, low density-lipoprotein uptake and phenobarbital-inducible cytochrome-P450 activity. BMMSCs likely represent pluripotent stem cells that remain in adult life and experimental evidence suggests that they might be a reliable cellular source to generate hepatocytes for use in cell therapy.

Flanking *in vitro* experiments, *in vivo* tests with BM-derived stem cells have also been performed to treat the diseased liver. Most data have been obtained in rodent models where liver damage was induced by either a hepatospecific necrotic insult (e.g. carbon tetrachloride (CCl<sub>4</sub>), allyl-alcohol or fumarylacetacetate hydrolase (FAH) genetically induced deficiency) or a proliferative stimulus like partial hepatectomy and bile duct ligation. Retrorsine or 2-acetyl-aminofluorene, two liver toxins enhancing oval/progenitor cell proliferation, have frequently been used to simulate chronic liver damage<sup>[19-22]</sup>. Another model of chronic hepatocellular injury used to study the role of BM in liver regeneration is the hepatitis B surface antigen (HBsAg) transgenic mouse model<sup>[23]</sup>.

The results obtained in rodents have frequently been puzzling. What generally emerges is that BMSC engraftment into the damaged liver widely varies, ranging from 0.16% to about 50% in different experiments<sup>[24-27]</sup>. Even though the cellular mechanisms responsible for these variable results are not known, transdifferentiation into hepatocytes occurs at a very low level when CD34+ HSCs are administered to rodents treated with liver toxins<sup>[28]</sup>. On the other hand, cell fusion between hepatocytes and stem cells from the myelomonocytic lineage of the BM (e.g. the precursors of circulating macrophages) has been shown to underlie liver regeneration after BM administration in the FAH-deficient mouse<sup>[20,21]</sup>. A genetic advantage of the transplanted BM stem cells with respect to resident enzyme-deficient hepatocytes likely accounts for the higher level of engraftment and tissue repopulation observed in this model.

Whereas hepatocyte formation from BM cells *in vivo* has proved to be poorly effective, some studies have postulated a much more important role for BM derived stem cells in liver tissue remodelling and fibrosis resolution. In mice injured with CCl<sub>4</sub> and thioacetamide, Russo *et al*<sup>[29]</sup> demonstrated that the BM-derived stem cell contribution to parenchymal regeneration was marginal (0.6%), but they substantially contributed to hepatic stellate cell (68%) and myofibroblast (70%) populations, which were able to influence the liver fibrotic response to toxin injury. In a sex-mismatched bone marrow transplantation model, both stellate cells and myofibroblasts of donor origin found in the

recipient liver did not originate through cell fusion with the indigenous hepatocytes, but largely derived from the circulating BMMSCs<sup>[29]</sup>. Lastly, Duffield *et al*<sup>[30]</sup> showed in rodents that BM-derived macrophages are likely to be crucial in regulating the liver fibrotic response to injury in a time-dependent manner, since depletion of these cells before injury reduces the fibrotic response, whereas their depletion during the recovery phase is associated with a greater fibrosis.

In contrast to the many studies performed in animals, those on BM-derived stem cell administration to patients with liver diseases can be counted on one hand. They can be divided into studies performed in patients with and without an underlying chronic liver disease. In patients with liver malignancies arisen on a "healthy" liver, the intraportal injection of CD133+ BM stem cells (a subpopulation of stem cells with both haematopoietic and endothelial progenitor characteristics) improved liver regeneration after extensive resection and segmental portal vein embolization<sup>[31]</sup>. This procedure was safe and highly effective in terms of liver mass recovery. Looking at future applications, this technique may offer the chance to treat the so-called "small-for-size" liver failure, a dramatic event occurring in transplanted patients who received either a small or a split liver. Few studies dealing with stem cell therapy in patients with liver cirrhosis<sup>[32-34]</sup> have been published to date. Gordon *et al*<sup>[32]</sup> injected CD34+ HSCs directly into the liver vascular system of patients with cirrhosis, whereas Terai *et al*<sup>[32]</sup> injected autologous BM through a peripheral vein. Albeit the small number of patients and lack of a control group<sup>[34]</sup>, both studies demonstrated a slight improvement in liver function and clinical conditions. These results seem to confirm, at least in part, the results obtained in the many experiments performed in rodents showing some role of BM-derived stem cells in liver repair. In our experience<sup>[35]</sup>, the administration of granulocyte colony stimulating factor (G-CSF) to mobilize BM-stem cells to the peripheral blood did not modify the residual liver function in patients with compensated liver cirrhosis. However, the procedure was safe, and may represent a good way to obtain autologous stem cells for cell therapy applications.

## EMBRYONIC STEM CELLS

Due to the difficulty in controlling their huge proliferative and differentiative potential, and major ethical concerns, the use of human ESCs is currently limited to *in vitro* and animal studies. Biotechnology industries and research laboratories are committed to devise effective protocols to optimize the ability of ESCs to differentiate into functional hepatocytes. The final goal is relevant on both scientific and clinical grounds. A suitable source of hepatocytes is what is lacking for the implementation of bio-artificial liver (BAL) technology. Effective protocols are needed not only to promote ESC differentiation into hepatocytes, but also to determine the expression of hepatic functions such as albumin secretion, indocyanine green uptake and release,

glycogen storage and p450 metabolism<sup>[36]</sup>.

Cytokines and growth factors such as HGF and FGF have been shown to promote ESC differentiation and growth<sup>[37]</sup>. In addition, it has been demonstrated that sodium butyrate, a non-proteinaceous compound, supports the action of these factors<sup>[38]</sup>. Hay *et al*<sup>[39]</sup> developed a multistage system in which HGF was used without the requirement of sodium butyrate, and human ESCs differentiated into hepatocyte-like cells without embryoid body formation. Use of an extracellular synthetic or natural matrix can be relevant, as shown by Ishizaka *et al*<sup>[40]</sup> in a three-dimensional system in which hepatocytes developed from mouse ESCs transfected with the hepatocyte nuclear factor-3 beta on a 3-D matrix scaffold. 3-D matrix scaffolds have been reported to be superior to the more commonly used 2-D monolayer culture in inducing differentiation into hepatocytes<sup>[41]</sup>. This is not surprising, as 3-D matrix scaffolds better reproduce the architecture of the liver parenchyma, which is essential for normal tissue function.

Another effective way to obtain hepatic differentiation is genetic modulation. This can be achieved by transfecting stem cells with recombinant DNA encoding for hepatospecific proteins. Adding collagen, appropriate cytokines and growth factors has an important effect on hepatocyte differentiation<sup>[42]</sup>. Recently Agarwal *et al*<sup>[43]</sup> proposed a new differentiation protocol for the generation of high-purity (70%) hepatocyte cultures: the differentiation process was largely uniform, with cell cultures progressively expressing increasing numbers of hepatic lineage markers and functional hepatic characteristics. When transplanted in mice with acute liver injury, the human ESC derived endoderm differentiated into hepatocytes and repopulated the damaged liver.

## FETAL ANNEX STEM CELLS

Cord blood contains multiple populations of embryonic-like and other pluripotential stem cells capable of originating hematopoietic, epithelial, endothelial, and neural tissues both *in vitro* and *in vivo*. The isolation of HSCs and MSCs from cord blood is a relatively new procedure and only few studies have been published<sup>[44,45]</sup>.

Saez-Lara *et al*<sup>[46]</sup> transplanted CD34+ HSCs derived from human cord blood into rats with liver cirrhosis without achieving a significant rate of engraftment, as GFP-positive cells were clearly eliminated. By contrast<sup>[47]</sup>, low-density mononuclear cells obtained from human cord blood transplanted *in utero* in fetal rats generated functional hepatocytes that persisted in the fetal recipient liver at least 6 months after birth. This humanized animal model provides a very interesting approach to *in vivo* investigation of human cord blood stem cell differentiation into hepatocytes. Hong *et al*<sup>[48]</sup> described the ability of human umbilical cord blood MSCs (CD34-) to differentiate into hepatocytes when cultured in pro-hepatogenic conditions. The differentiation rate in their protocol was about 50%, and the hepatocytes obtained

were capable of incorporating low-density lipoprotein, considered one of the most typical hepatocyte functions. More recently, Campard *et al*<sup>[49]</sup> demonstrated that human cord matrix stem cells cultured with growth factors show hepatocyte characteristics like cytochrome P450-3A expression, glycogen storage and urea production. In addition, when transplanted into hepatectomized immune-deficient mice, small clusters of human cells expressing albumin and alpha-fetoprotein appear, thereby demonstrating the good engraftment and differentiation capacity of the transplanted cells<sup>[50,51]</sup>.

Placenta is another potential source of stem cells. Placenta-derived stem cells (PDSCs) are fibroblast-like cells that attach to a plastic surface. Like BMMSCs, they can be expanded for more than 20 population doublings and induced to differentiate into cells of various mesenchymal tissues. Chien *et al*<sup>[52]</sup> recently cultivated PDSCs derived from human placentae in hepatic differentiation media, and obtained cells with hepatocyte morphology expressing specific hepatocyte functions. In comparison with stem cells isolated from other tissues there are no ethical problems associated with the study of PDSCs as the collection of placenta samples does not harm mother or infant. The ability of PDSCs to differentiate and their straightforward handling could make them an appropriate source for cell-based applications.

## CONCLUSION

Under proper experimental conditions, adult, embryonic and fetal annex stem cells have been shown to be able to differentiate into hepatocytes. At present, most biotechnology industries and research laboratories are working to optimize the differentiation protocols. In the future, stem cell-derived hepatocytes will likely be used in BAL employed as “bridge therapy” for patients with liver failure awaiting transplantation or to recover liver function. Intrahepatic injection of stem cell-derived hepatocytes might also be useful in patients with acute liver failure.

In chronic liver diseases, which account for the majority of cases of liver failure worldwide, the future of stem cell therapy is still uncertain. Liver failure occurring in patients with chronic liver disease, namely cirrhosis, is not only due to the lack of healthy cells, but also to the disruption of tissue architecture and progressive accumulation of inflammatory cells and fibrosis. While “brand new” hepatocytes derived from stem cells may temporarily support the impaired liver function, they would hardly be able to restore the original liver structure and eliminate collagen deposition. Thus, further strategies are needed. A better understanding of the mechanisms leading to collagen deposition and re-adsorption, and the development of new antifibrotic agents, combined with effective antiviral agents for patients with viral hepatitis, will be critical for the success of cell-based therapy in chronic liver failure.

### Abstract

Therapeutic endoscopy plays a major role in the management of gastrointestinal (GI) neoplasia. Its indications can be generalized into four broad categories; to remove or obliterate neoplastic lesion, to palliate malignant obstruction, or to treat bleeding. Only endoscopic resection allows complete histological staging of the cancer, which is critical as it allows stratification and refinement for further treatment. Although other endoscopic techniques, such as ablation therapy, may also cure early GI cancer, they can not provide a definitive pathological specimen. Early stage lesions reveal low frequency of lymph node metastasis which allows for less invasive treatments and thereby improving the quality of life when compared to surgery. Endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) are now accepted worldwide as treatment modalities for early cancers of the GI tract.

### INTRODUCTION

Early gastrointestinal (GI) cancers are defined as lesions limited to the mucosa or submucosa without invading the muscularis propria, regardless of the presence of lymph node metastases. Since 10 years, endoscopic resection is now an alternative to surgery. Surgical resection of early GI cancers offers an excellent (90%-100%) chance of cure based on several series<sup>[1,2]</sup>. Any major surgical intervention, however, carries risks of complications including wound infection, prolonged hospital stay, anesthetic complications and death. This is especially problematic in elderly patients or those patients with concomitant severe organ dysfunction including heart failure, kidney failure, and lung disease. For this reason, endoscopic therapy may provide an attractive and less invasive treatment option that may ultimately prove to be safer in this select subgroup of patients, and may be able to translate to the general population. These techniques include endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) which are now accepted as treatments for early GI cancers in selected cases.

Therapeutic endoscopy plays a major role in the management of GI neoplasia. Its indications can be generalized into four broad categories; (1) to remove neoplastic lesion; (2) to obliterate neoplastic lesion; (3) to palliate malignant obstruction; (4) to treat bleeding. Only endoscopic resection allows complete histological staging of the cancer, which is critical as it allows stratification and refinement for further treatment. Although other endoscopic techniques, such as ablation therapy, may also cure early GI cancer, they can not provide a definitive pathological specimen.

Early stage lesions reveal low frequency of lymph node metastasis which allows for less invasive treatments and thereby improving the quality of life when compared to surgery<sup>[3]</sup>. EMR and ESD are now accepted worldwide as treatment modalities for early cancers of the GI tract<sup>[3-5]</sup>.

Early GI cancers (except the esophagus) are defined as being limited to the mucosa or submucosa, but not invading the muscularis propria, regardless of the presence of lymph node metastases. A macroscopic classification of these lesions was first established by Japanese endoscopists in 2002 (Table 1) and has now been accepted worldwide<sup>[5]</sup>.

Detection and diagnosis of early GI cancer can be

**Table 1** Japanese classification of GI cancers

Classification of GI cancers	
Type 0	Superficial, flat with minimal elevation/depression
Type 0-I	Protruding type
Type 0-IIa	Superficial elevated type
Type 0-IIb	Flat type
Type 0-IIc	Superficial depressed type
Type 0-III	Excavated type
Type 1	Polypoid tumors on wide base, distinct demarcation from surrounding mucosa
Type 2	Ulcerated with sharply demarcated and raised borders
Type 3	Ulcerated without definite margins, infiltrating into adjacent wall
Type 4	Diffusely infiltrating lesion without marked ulceration
Type 5	Non classifiable into any of above types

difficult because of the less well defined subtle findings. Chromoendoscopy is an important adjunct technique to enhance visualization of superficial early cancers and to define their borders. Indigo carmine solution (0.2%), a contrast dye, is commonly used in the stomach to highlight the contours and topography of the lesion by entering mucosal depressions and crevices, thus enabling the biopsy of the minute lesions. Recently, narrow band image (NBI) and autofluorescence images (AFIs) are introduced as a virtual chromoendoscopy.

The depth of invasion is measured microscopically and the risk of lymph node metastasis is known to be related with a defined micrometric cutoff. In squamous cell carcinoma (SCC) of the esophagus, when infiltration is less than 200 µm, the risk of nodal metastases is low<sup>[6]</sup>. For early adenocarcinoma in Barrett's esophagus (BE) and early gastric cancer (EGC), a submucosal infiltration micrometric cutoff of 500 µm has been proposed, as the risk of nodal metastases appears low<sup>[7]</sup>. In contrast, a 20%-25% risk of node involvement with submucosal infiltration in Barrett's cancer has been reported in the West. In the colorectum, the risk of lymph node metastasis is negligible when the tumor invasion is less than 1000 µm<sup>[8]</sup>.

## EMR TECHNIQUES

Several different EMR techniques have been described, the most common of which are detailed below.

### Strip biopsy

Strip biopsy requires the use of a two-channel endoscope. The lesion is lifted with submucosal injection in the standard fashion. A snare and forceps are introduced through each channel of the endoscope. The forceps are used to guide the lesion in to the snare, which is then closed around the base of the lesion and resected using standard electrocautery<sup>[1]</sup>.

### Endoscopic double snare polypectomy

A double-channeled endoscope is required for this procedure. Snares are introduced through both channels of the endoscope, one passing through the open loop of the other. The lesion is lifted and

strangulated with the first snare, and resected below with the second snare<sup>[9]</sup>.

### EMR using cap fitted endoscope

A transparent cap with a prelooped snare on its distal tip is placed on the end of an endoscope. The lesion is lifted with a submucosal injection in standard fashion. Suction is then used to draw the lesion into the cap, and the snare is closed on the base. It is then released from the cap by breaking suction, and then removed similarly to any polypoid lesion<sup>[10]</sup>.

### EMR: Ligation device

A standard variceal ligation device is placed on the tip of the endoscope. The lesion may be injected submucosally for lifting. The lesion is then suctioned into the ligation device and a rubber band is deployed. A snare is then used to resect the lesion, usually below the level of the rubber band<sup>[11]</sup>.

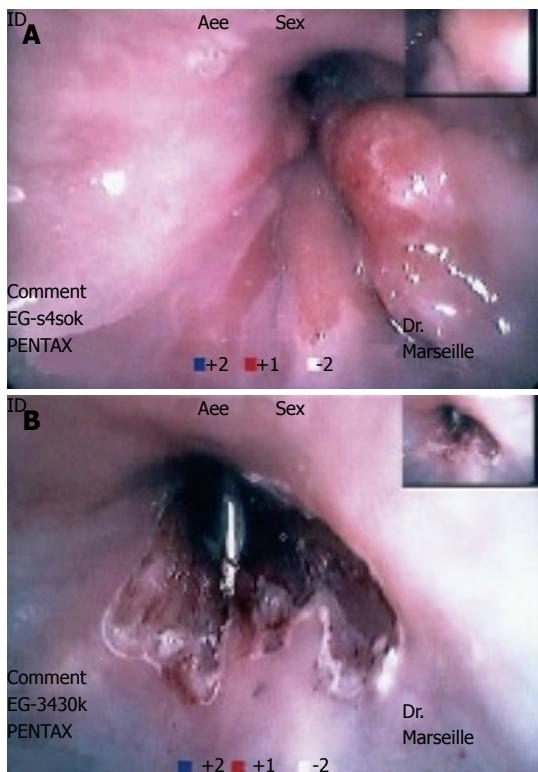

## ESD

ESD is a relatively new technique that has been used to resect larger (greater than 20 mm) size mucosal lesions in the stomach. The target lesion is first marked after careful examination with coagulation current from the tip of a knife approximately 5 mm around the margins of the tumor. The entire marked area is then elevated with a sub-mucosal injection. A needle knife is then used to cut along the outside of the margins, while the lesion is still elevated. Dissection along the submucosal plane is then performed using tools such as a hook knife or flex knife<sup>[12-14]</sup>. This technique takes significantly longer to perform than traditional EMR techniques, and requires the endoscopist to be experienced with these various tools. Larger studies are needed to assess the viability and complete resection rates with submucosal dissection.

## RESULTS OF ENDOSCOPIC RESECTION

### SCC of the esophagus

Multiple synchronous lesions as well as metachronous lesions have been reported up to 31% of patients with esophageal SCC<sup>[15]</sup>. Five-year survival rate is up to 95% after EMR in patients with superficial SCC without lymph node metastasis in m1 and m2 SCC of the esophagus<sup>[16]</sup>. Recently, an expanded indication for EMR in patients with superficial esophageal carcinoma m3 or sm1 has been proposed<sup>[17]</sup>. A study from Germany consisting of 12 HGD and 53 mucosal SCC of the esophagus, reported on the treatment using a ligation EMR technique<sup>[17]</sup>. This was the first Western study which showed similar results to those of the Japan in early esophageal SCC. They reported that complete resection was achieved in 11/12 patients of HGD and 51/53 patients of mucosal SCC. Although recurrence was observed in 16 patients after EMR, the lesions were completely resected after further endoscopic treatment. Complications occurred in 15/65 patients all being

**Figure 1** Circumferential endoscopic resection of BE with high grade dysplasia. **A:** Polypoid tumor on BE; **B:** Post-resection endoscopic aspects.

esophageal strictures which were successfully managed by endoscopy. Seven year survival rate was 77%.

#### **High grade dysplasia and early carcinoma developed in BE**

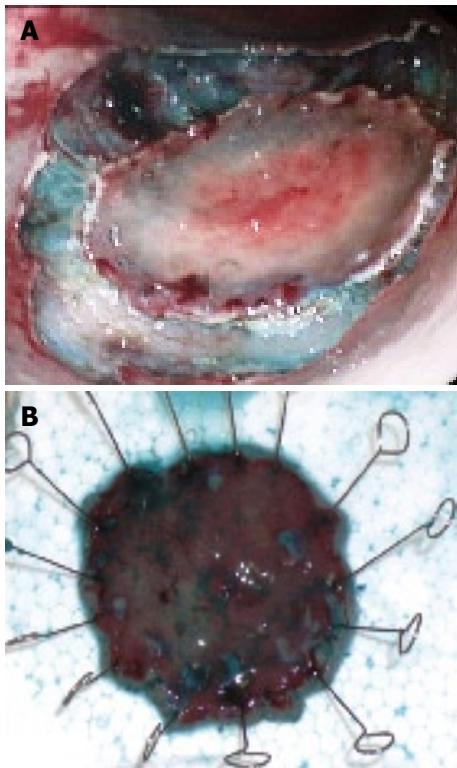

Endoscopic therapy aims to remove the dysplastic Barrett's epithelium allowing restoration of squamous epithelium. EMR could be a therapeutic alternative to surgical esophagectomy which carries substantial morbidity and mortality<sup>[18]</sup>. When HGD is diagnosed in short segment BE (BE shorter than 30 mm in length), EMR would be considered to remove all the metaplastic epithelium. A study reported that visible areas of HGD in long segment BE (BE longer than 30 mm in length) may be removed by EMR, followed by photodynamic therapy to destroy invisible foci<sup>[19]</sup>. Although strictures occurred in 30% of patients, 17 superficial esophageal cancers were removed by combining EMR and photodynamic therapy. A study from Germany reported that circumferential EMR was carried out by using a simple snare technique without a cap in 12 patients with BE containing multifocal high-grade intraepithelial neoplasia or intramucosal cancer<sup>[20]</sup>. Five had multifocal lesions while two developed strictures that required bougienage. There was no recurrence during the median follow-up of 9 mo. Our study reported on circumferential EMR (Figure 1) performed in 21 patients with HGD or mucosal cancer<sup>[21]</sup>. Three patients needed additional therapy such as surgery or chemotherapy due to residual disease after the endoscopic resection. In addition, two local recurrences were retreated by

EMR. A study from Netherlands, consisting of 77 esophagectomy specimens containing HGD or T1 adenocarcinoma, reported that lymph node metastasis occurred in 23% sm2 and 69% sm3 tumors, but not in m1, m2, m3, and sm1 lesions<sup>[22]</sup>. They concluded that m1, m2, m3, and sm1 lesions could be treated endoscopically if the lesions are less than 30 mm, well differentiate type adenocarcinoma, and without lymphangitic invasion. However, care must be taken with the initial diagnosis of endoscopic biopsy since significant changes in diagnosis occur after EMR such as downgrading from HGD to BE without dysplasia or being reclassified from benign to malignant diagnosis<sup>[23]</sup>. Ell *et al* reported that suck-and-cut EMR technique was performed in 100 consecutive patients with low-risk adenocarcinoma of the esophagus arising from BE, and complete local remission was achieved in 99/100 patients<sup>[24]</sup>. During the mean follow-up period of 36.7 mo, recurrent or metachronous carcinomas were found in 11% of the patients, but were successfully treated by repeated EMR. Five-year survival rate was 98%.

Recently, a study tried to define prognostic factors of recurrence after Endoscopic Resection of early carcinoma in BE. The aim of this study was to evaluate the value of p53 and Ki-67 immunohistochemistry in predicting the cancer recurrence in patients with Barrett's esophagus-related cancer referred to EMR. Mucosectomy specimens from 41 patients were analyzed. All endoscopic biopsies prior to EMR presented high-grade dysplasia and cancer was detected in 23 of them. Ki-67 and p53 immunoreactivity were classified as superficial, deep or mixed. EMR samples confirmed cancer in 21/23 (91.3%) cases. In these cases, p53 immunohistochemistry revealed a mixed positivity for the great majority of these cancers (90.5% vs 20%;  $P < 0.001$ ), and Ki-67 showed a mixed pattern for all cases (100% vs 30%;  $P < 0.001$ ); on the contrary, patients without cancer revealed a superficial or negative pattern for p53 (80% vs 9.5%;  $P < 0.001$ ) and Ki-67 (70% vs 0%;  $P < 0.001$ ). During a mean follow-up of 31.6 mo, 5 (12.2%) patients developed six episodes of recurrent or metachronous cancer. Previous EMR samples did not show any significant difference in the p53 and Ki-67 expression for patients developing cancer after endoscopic treatment<sup>[25]</sup>.

#### **Endoscopic resection of early gastric cancer**

Complete resection rates (defined as tumor free horizontal and vertical margins, submucosal invasion  $< 500 \mu\text{m}$ , and no lymphatic invasion) have been reported to be between 74% and 97% with the use of EMR, with lower rates of complete resection reported when expanded indications for EMR were used and when lesions were resected piecemeal instead of *en bloc* (Figure 2)<sup>[25-27]</sup>. Although no head to head prospective trials have been performed looking at long-term survival for EMR *versus* surgery, 2 and 5-year survival rates for EMR are 95% and 100%, respectively, whereas they are 100% and 100% for patients who underwent surgery<sup>[27]</sup>.

**Figure 2** ESD of early gastric cancer. **A:** Peripheral dissection of superficial gastric cancer; **B:** Resected specimen.

Similarly, other investigators have shown no differences in survival rates after 5 and 10-year periods for EMR compared with surgery<sup>[28]</sup>.

No cases of mortality due to EMR have been reported in various case series. The most serious complications of EMR include bleeding and perforation. Reported rates of bleeding vary from 1% to 20% and appear to be more frequent when resecting large lesions and when resecting lesions piecemeal<sup>[29,30]</sup>. One study reported surgical postoperative complications of 14.7% and a 0.7% mortality rate<sup>[31]</sup>. Recurrence rates in a recent study published by Ono *et al*<sup>[32]</sup> were noted to be 2% in those who had complete resection (5 of 278 cases) while there was a 13% recurrence rate in the group of patients whose resection could not be deemed complete histologically (9 of 67 cases). Local recurrences for incomplete resections in the same study are reported to be approximately 37%<sup>[32]</sup>. It should be noted that a global advantage of surgical resection is a near complete cure for early gastric cancers.

Only one study has addressed the issue of quality of life, and EMR appears to have a better post procedure quality of life compared with surgical gastrectomy<sup>[33]</sup>. No cost benefit analyses have been performed. Surgical intervention may have a high initial cost burden, however repeat surveillance endoscopies may add up to a significant cost as well.

#### **Endoscopic resection of duodenal tumors**

EMR has been used for ampullary and peri-ampullary neoplasias and sub-epithelial lesions including stromal cell tumors, cysts, and neuroendocrine tumors.

Although endoscopic resection can provide a wide tumor resection with a negative resection margin, it is not yet recommended as a curative therapy for early stage ampulla of Vater cancer because of the high lymphovascular invasion rate<sup>[34]</sup>. A study reported a higher risk of bleeding (33%) among 27 duodenal EMR after complete resection<sup>[35]</sup>.

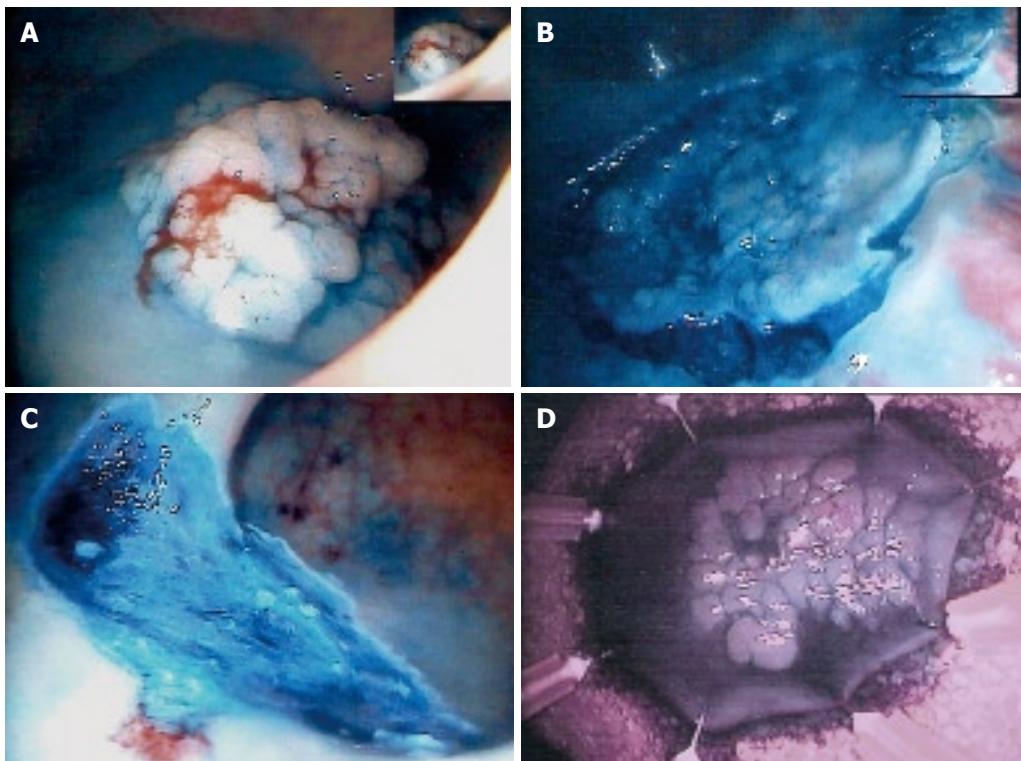

#### **Endoscopic resection of submucosal tumors**

EMR technique may also be applied to submucosal tumors in order to achieve histologic diagnosis and to achieve complete removal. In a German study, complete resection was achieved in 19/20 patients with submucosal esophageal tumors using a rubber band or a simple snare<sup>[36,37]</sup>. Bleeding occurred in 40% of the cases and was successfully managed by endoscopic hemostasis. Rosch *et al* attempted endoscopic *en bloc* resection of mucosal and submucosal tumors of the UGI tract, using the IT knife<sup>[38]</sup>. In this pilot series, complete removal was achieved in 25% of the mucosal and 36% of the submucosal lesions of 37 lesions; 13 in esophagus, 24 in stomach and 1 in duodenum. Perforation occurred in one case, and was managed conservatively with endoscopic clipping.

#### **Endoscopic resection of colorectal tumors**

EMR and ESD are being successfully used for early stage colon cancers, flat adenomas, large superficial colorectal tumors, and rectal carcinoids<sup>[39]</sup>. Lymph node metastasis in T1 colorectal carcinoma occurs only after infiltrating submucosa and is correlated to the depth of submucosal penetration by the tumor<sup>[40]</sup>. This supports the therapeutic effectiveness of endoscopic removal of polyps and flat lesions that are confined to the mucosa, regardless of their size. On the other hand, colorectal laterally spreading tumor (LST) classified as granular (LST-G) and non granular type (LST-NG), are defined as lesions larger than 10 mm in diameter, with a low vertical axis, extending along the luminal wall<sup>[41]</sup>. For *en bloc* resection of flat lesions larger than 20 mm, conventional EMR is inadequate because of incomplete removal and frequent local recurrence. When analyzing the endoscopic features of 257 LSTs in order to assess which features correlated with the depth of invasion, unevenness of nodules, presence of large nodules, size, histological type, and presence of depression in the tumor were significantly associated with the depth of invasion<sup>[41]</sup>. In addition, LST-NG showed a higher frequency of sm invasion than LST-G (14% vs 7%)<sup>[42]</sup>. Presence of a large nodule in LST-G type was associated with higher sm invasion while pit pattern, sclerous wall change, and larger size were significantly associated with higher sm invasion in LST-NG type. Therefore, it is advisable to perform endoscopic piecemeal resection for LST-G type with the area including the large nodule resected first. Besides, LST-NG type should be removed by *en bloc* resection (Figure 3) because of the higher potential of sm invasion when compared to that of the LST-G type<sup>[42]</sup>.

A study from Germany reported that complications

**Figure 3** ESD of a flat villous rectal polyp with sm1 carcinoma. **A:** Flat villous adenoma of the sigmoid colon; **B:** Peripheral dissection; **C:** Resected area; **D:** Resected specimen.

occurred in two patients of 57 patients after EMR in large colorectal neoplasia between 10 mm and 50 mm<sup>[43]</sup>. Recurrence rate following EMR ranges from 0% to 40% which could be reduced when combined by argon plasma coagulation. However, a recent study from Poland revealed that argon plasma coagulation did not reduce the recurrence rate compared to polypectomy alone<sup>[44]</sup>. Besides, another study reported that EMR was performed for 139 SP in 136 patients by snare polypectomy, and invasive carcinoma was found in 17 cases<sup>[45]</sup>. After 12 mo of follow up after EMR, no local recurrence was detected in 7 patients with invasive carcinoma without surgery. Another study from UK reported on 30 large colorectal polyps which were treated by *en bloc* resection in 22 cases and by piecemeal resection in 8 cases<sup>[45]</sup>. Histologically, the lesions were predominantly adenomatous polyps, but 7 cases revealed incidental focus of adenocarcinoma. Although bleeding occurred in 2 cases, there was no bowel perforation. There was no evidence of recurrence during the median follow-up of 21 mo.

In a prospective cohort study in Italy, IT knife was used for EMR of large colorectal polyps larger than 3 cm which are unsuitable for standard polypectomy<sup>[46]</sup>. The results showed the likelihood of complete *en bloc* resection of mucosal lesions improved by new approach with IT knife when compared with previous studies on colonic EMR, even for lesions located in difficult positions or larger than 30 mm. *En bloc* resection was achieved only in 55.1% of the lesions and piecemeal resection was performed in the rest of the cases. Although complete tumor removal was achieved in 19 patients, 13 had LGD, 15 had HGD, and one had a tumor invading the submucosa. Complications occurred

in four patients which were all managed conservatively. Local recurrences were detected in five patients and were treated by argon plasma coagulation and snare polypectomy. There was no recurrence during the median follow-up period of 15.7 mo<sup>[47]</sup>.

## CONCLUSION

EMR and ESD techniques should be considered as elective treatment modality for early GI cancers as long as it is performed under the right indications by an expertise.

### INTRODUCTION

Aboriginal North Americans, which include American Indians and Alaska Natives (AI/ANs), Canadian First Nations, and native Greenlanders, are disproportionately affected by chronic liver disease (CLD). CLD for the purpose of this review includes the diagnoses of cirrhosis, end-stage liver disease (ESLD) and its complications, and chronic elevation of transaminase enzymes. In the United States, CLD was the twelfth leading cause of death in the general population in 2003, but was the fifth leading cause of death in AI/AN populations<sup>[1]</sup>. Likewise, cirrhosis is a disproportionate cause of death in Canadian First Nations<sup>[2]</sup>. Very little is known about the prevalence and incidence of CLD in native Greenlanders, although chronic hepatitis B incidence is known to be high in this population<sup>[3]</sup>. Of great concern, between 1990 and 1998, the overall annual CLD mortality rate in the United States declined by 4.5% but increased 11% among AI/AN populations<sup>[4]</sup>. Despite these striking disparities, studies examining the incidence, prevalence and etiology of CLD in Aboriginal North Americans are scarce. The goal of this paper is to summarize the etiology, natural history, and mortality rates of CLD in Aboriginal North Americans.

### Abstract

A structured literature review was performed to detail the frequency and etiology of chronic liver disease (CLD) in Aboriginal North Americans. CLD affects Aboriginal North Americans disproportionately and is now one of the most common causes of death. Alcoholic liver disease is the leading etiology of CLD, but viral hepatitis, particularly hepatitis C, is an important and growing cause of CLD. High rates of autoimmune hepatitis and primary biliary cirrhosis (PBC) are reported in regions of coastal British Columbia and southeastern Alaska. Non-alcoholic liver disease is a common, but understudied, cause of CLD. Future research should monitor the incidence and etiology of CLD and should be geographically inclusive. In addition, more research is needed on the treatment of hepatitis C virus (HCV) infection and non-alcoholic fatty liver disease (NAFLD) in this population.

### LITERATURE RETRIEVAL

English language articles were identified by a search of the PubMed database from 1966 to August 2007. Because articles on Aboriginals from Mexico and Central America were frequently in non-English, we restricted our study to Aboriginals in the United States, Canada, and Greenland. Search terms included the following 7 individual medical conditions: chronic hepatitis, alcoholic liver disease, liver cirrhosis, fatty liver, hemochromatosis, hepatolenticular degeneration, and hepatitis A. Variants of these terms were also used; for example, in addition to fatty liver, other key words included non-alcoholic steatohepatitis (NASH). To identify publications focused on Aboriginal peoples, our search terms were American Indian(s), Alaska Native, native Alaskan, Native American, North American Indian(s), Greenland, and Inuit(s). Next, the bibliographies of the retrieved

**Table 1** Chronic liver disease mortality rates by etiology, Aboriginal group, and nation (number of deaths per 100 000)

Etiology	AI/AN	General US population	General Canadian population
Alcohol	19	4.6	3
Hepatitis C	2.3	1.7	1.3
Hepatitis B	0.6	0.4	1.3 <sup>1</sup>
Primary biliary cirrhosis	0.1	0.2	N/A
No identified cause	7.7	5.1	N/A
Overall	25.5-28.7	10.4-11.6	6.2-15.4

<sup>1</sup>Canadian data did not include separate categories for hepatitis B and C. Data not available on Canadian First Nations peoples and native Greenlanders specifically. Data adapted from Statistics Canada<sup>[7]</sup> and Vong<sup>[4]</sup>.

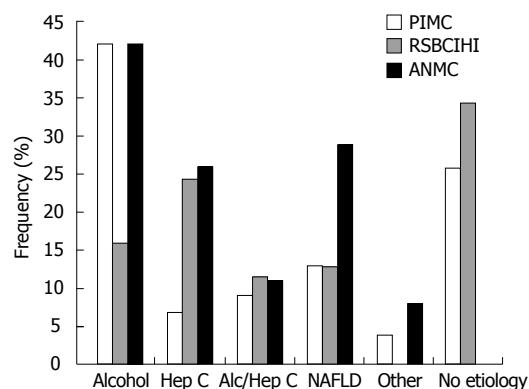

publications and those already in the authors' possession were examined for relevant articles. Finally, we used the above terms to search other databases such as usa.gov and the Native Health Database (U of New Mexico, <http://hsc.unm.edu/library/nhd/>).

In this review, we refer to the 7 disorders above as CLD. A meta-analysis, or other forms of systematic analyses, was not possible to conduct owing to the number of CLDs, variations in study designs, methods (particularly participant selection and case definitions), heterogeneous nature of the population, pockets of certain liver diseases, and the quality of the investigations.

Studies assessing patients with at least 1 CLD that included information on at least one North American Aboriginal population were included. In addition, we excluded studies which had no confirmed diagnosis, such as self-reported symptoms. We focused on publications that reported three kinds of data: prevalence, etiology, and patient characteristics. Prevalence data are summarized in Table 1. Next, we outlined information on discrete diagnoses. These studies, which are more clinically useful than population studies, are shown in Table 2. For each study, information was abstracted on the patient groups and the diagnostic criteria applied, the methods, and the major findings. The sources of the authors' funding had no role in the collection or interpretation of the data. Based on these tables, we summarized information for the sections below.

## EPIDEMIOLOGY OF CLD

Two studies from the past decade reported the overall, age-adjusted death rates due to CLD in AI/AN populations was 25.5-28.7 per 100 000 compared to 10.4-11.6 per 100 000 in the general population<sup>[4,5]</sup>. Moreover, CLD disproportionately strikes young adults; it was the second-leading cause of death among AI/ANs 25-44 years old<sup>[1]</sup>. In another study, researchers classified underlying conditions contributing to death by ICD-9 (International Statistical Classification of Diseases, version 9) codes as listed on death certificates<sup>[4]</sup>. In 1998, the top contributors to CLD mortality in AI/AN were: alcohol (65%), hepatitis C virus (HCV) (8%), hepatitis B virus (HBV) (2%), and primary biliary cirrhosis (PBC)

**Figure 1** Frequency of specific etiologies for chronic liver disease among AI/AN. Phoenix Indian Medical Center (PIMC), Phoenix, Arizona, 2000-2002, n = 1496. Riverside San Bernardino County Indian Health, Inc (RSBCIHI), Riverside, California, 2002-2003, n = 344. Alaska Native Medical Center (ANMC), Anchorage, AK, 2003-2004, n = 1903. Data adapted from<sup>[6,7]</sup> with permission. Not all categories are mutually exclusive in ANMC.

(1%). Notably, 24% of the deaths had no attributable cause.

Among AI/AN patients living with CLD, researchers observed a similar theme of high disease burden from viral hepatitis and alcohol, in conjunction with a large proportion of unexplained liver disease. In a study of AI/ANs obtaining outpatient and inpatient services in Phoenix, AZ, San Bernardino, CA, and Anchorage, AK, 5%-7% of AI/ANs had evidence of CLD<sup>[6,7]</sup>. These studies defined CLD as two elevated AST, ALT, or total bilirubin levels separated by 6 mo. Alcohol and HCV were the most common causes of CLD; however, non-alcoholic fatty liver disease (NAFLD) was also a major etiology and a significant proportion had no identified etiology (Figure 1).

In the general population of Canada, CLD is the 13th most common cause of death<sup>[8]</sup>, accounting for 6.0-15.4 deaths per 100 000. Specific mortality data from CLD in Canadian First Nations was not available in published form or directly from Statistics Canada.

No mortality statistics are available for Greenland. However, in a study of hospitalized patients, the prevalence of cirrhosis, as determined by ICD-10 (International Statistical Classification of Diseases, version 10) discharge diagnoses, was lower in Greenlanders (0.19%) than in a similar cohort in Denmark (0.54%)<sup>[9]</sup>. This finding was unexpected because Inuit Greenlanders are known to have high rates of viral hepatitis and thought to consume more alcohol on average than their Danish counterparts living in Greenland.

CLD in Aboriginal North American populations is heterogeneous, with certain causes of CLD found in unique geographic regions, such as HBV in the circumpolar regions and PBC in coastal British Columbia (Figure 2).

## HEPATITIS A

Before the implementation of hepatitis A virus (HAV) vaccination, this disease caused large outbreaks,

**Table 2 Major causes of viral hepatitis in Aboriginal North Americans**

Aboriginal group	Study populations	Hepatitis A	Hepatitis B	Hepatitis C	Comments
Native Americans	South Dakota NA Navajo NA Urban and Veterans populations	Pre-vaccine incidence was 96/100000  Seroprevalence: 76%	N/A	Seroprevalence range: 3%-32%	Hepatitis A incidence now is comparable to general population: 1.0-2.0/100000
Alaska Natives	Random distribution of AN tribes	49% seroprevalance pre-vaccination	6% sAg+, 24% core IgG+	0.8% seroprevalance	Heavy burden of hepatitis a prior to vaccination. Hepatitis B endemic to AN with high rates of HCC in certain regions, vaccination has lead to decreased incidence
First Nations (Canada)	Manitoba FN British Columbia FN Inuit	Seroprevalence of 90% in those < 40 yr; 31/100000 incidence pre-vaccine	5% sAg+, 27% core IgG+ in circumpolar regions, much lower outside circumpolar areas	1.1% seroprevalence in Inuit, 2%-20% in non-Inuit	Similar patterns of hepatitis as seen in US.
Native Greenlanders (Inuit)	Inuit	54% seroprevalence	7%-12% sAg+, 42% core IgG+	< 1% seroprevalence	Hepatitis B may be spread sexually more frequently than other Aboriginal populations. HCC also less common

**Figure 2** Common causes of chronic liver disease in Aboriginal North Americans.

cycling every 5-7 years in many AI/AN communities. Although US national prevalence statistics have not

been published, incidence rates of hepatitis A in AI communities in South Dakota have been reported as 33

times higher than the non-Indian rates (92.6 compared to 2.8/100 000 persons per year)<sup>[10]</sup>. A study of Navajo schoolchildren found that 70% had antibodies to HAV, with higher rates in older children; this is one of the highest rates reported among US children<sup>[11]</sup>. Among ANs, almost 50% tested positive for antibody to HAV<sup>[12]</sup>. Past infection was strongly age-related, increasing from 7% in persons born since 1975 to 85% among persons born before 1945. The seroprevalence patterns indicated that village-wide outbreaks have been the norm and appear to be dependent on the presence of a young susceptible population. Finally, urban AI/ANs have a higher incidence of hepatitis A than their rural counterparts (151 vs 106/100 000)<sup>[13]</sup>.

Following the introduction of HAV vaccine in 1995, AI/AN communities witnessed remarkable reductions in incidence of this disease, declining to levels near the general US population<sup>[10,14,15]</sup>. In South Dakota, community wide immunization programs that provided hepatitis A immunizations to children aged 2-12 years halted outbreaks when 70% or more of these children were vaccinated<sup>[10]</sup>.

Because of frequent outbreaks and high levels of endemic transmission, the US Public Health Service Advisory Committee on Immunization Practices recommends routine HAV vaccination of all 2-year-old AI/AN children<sup>[10]</sup> and the US Public Health Service Preventive Services Task Force also recommends the vaccine for AI/AN adults. Widespread use of hepatitis A vaccine to maintain a high rate of seropositivity among young persons appears to be critical in preventing future epidemics in AI/AN communities.

Similar to the situation in the US, Canadian First Nations peoples had a much higher incidence and prevalence of hepatitis A than did the general population. In studies of Manitoba First Nations peoples, more than 90% of patients over age 40 had evidence of exposure to HAV<sup>[16]</sup>. British Columbian First Nations tribes studied from 1990 to 2001 had a crude incidence rate (31 per 100 000) twice the rate of the general population of British Columbia<sup>[17]</sup>.

Data from Greenland is sparse, but a cross-sectional study of Inuit Greenlanders found similarly high seroprevalence of 54%<sup>[18]</sup>. It is not known how the hepatitis A vaccine has changed the incidence in native Greenlanders.

## HEPATITIS B

A recent national study of hepatitis B in AI/ANs indicated that HBV accounted for just 11 deaths, a rate of 0.60/100 000 persons<sup>[4]</sup>. In contrast, hepatitis B is an important cause of CLD in AN living in the circumpolar region. Among AN, high rates of acute, icteric hepatitis B were first reported in the 1970's<sup>[19]</sup>. Subsequent studies found that 6.4% of ANs were surface antigen-positive and 24.2% were positive for hepatitis B core antibody<sup>[20]</sup>.

The vast majority of HBV infection in AN is acquired horizontally, usually before the age of five. A small pocket of AN with genotype C (Asian variant)

transmit HBV vertically (personal communication, Brian McMahon). As a result, most AN have an intermediate risk of becoming chronic carriers. Of those AN children exposed before the age of five, 28.8% will be chronic carriers<sup>[21]</sup>. Once chronically infected, AN carriers of HBV rarely clear the infection. A large study of HBsAg positive AI/AN patients showed an average annual seroconversion rate to anti-HBs of 0.3%; however, patients over 40 years had a much higher seroconversion rate (4.4%) than those under 40 years (1.7%)<sup>[22]</sup>.

Another survey of 1536 HBsAg positive AN people demonstrated that 42% were HBeAg positive at baseline<sup>[23]</sup>. Of those who were HBeAg positive, 73% cleared HBe-antigen within 10 years. After a median of 20.5 years of follow-up, 8% remained HBe antigen positive and 22% became anti-HBe positive but then reactivated to HBe antigen-positivity. Among those who were anti-HBe positive and HBe antigen negative at the beginning of the study, 86% remained anti-HBe positive throughout the period of observation<sup>[24]</sup>. The time to clearance was shorter for those who were HBeAg negative than for those who were HBeAg positive.

Several sequelae are common amongst hepatitis B carriers, most notably ESLD and hepatocellular carcinoma (HCC). These combined outcomes occur at a rate of 2.3 per 1000 carrier-years; the majority of events (82%) are HCC<sup>[23]</sup>. The link between chronic hepatitis B and HCC was first observed in the 1970s, when the incidence of HCC was reported to be five times greater in an Alaska Native population than the US white population<sup>[25]</sup>. Most of that excess risk was attributable to chronic hepatitis B carriage rather than alcohol consumption. In a study of 1400 HBsAg positive AI/ANs, 13 of the 60 deaths (22%) and 57% of all fatal neoplasms during the study were due to HCC<sup>[22]</sup>. The incidence of HCC is higher in AN men, 2.3 per 1000 carrier years, *versus* 1.2 per 1000 carrier years in AN women. The relative risk of developing HCC for an HBsAg carrier is 148 times greater compared to a non-carrier, as documented in a more recent study<sup>[22]</sup>.

Within HBsAg positive AI/AN populations, HCC is observed more frequently in older patients, those with reversion to HBeAg positivity, those of Yupik ethnicity, and carriers with genotype F<sup>[23,26]</sup>. AN living in the Yukon delta region of western Alaska develop HCC at very young ages, in the context of no cirrhosis<sup>[27]</sup>; however, more recent studies found that half (15/30) of the cases of HCC elsewhere in AN were found in cirrhotics<sup>[26]</sup>. It is possible that the genotype F variant seen in this part of Alaska confers a very high risk of developing HCC.

Among Canadian Inuit living in the Arctic region, 5% were surface antigen-positive and 27% had been exposed<sup>[28]</sup>. However, Canadian First Nations members living outside of the circumpolar region have similar chronic infection (0.3%-3%) and exposure rates (10%-22%) as compared to non-Aborigines engaging in similar activities<sup>[29]</sup>.

Among native Greenlanders, 7%-12% were surface antigen-positive carriers and 42% had evidence of past infection<sup>[18,30]</sup>. The peak incidence occurs in young adults,

suggesting that sexual acquisition is the predominant route of exposure<sup>[30]</sup>. This route of transmission differs from the perinatal or early horizontal transmission seen in AN<sup>[21]</sup>. Among native Greenlanders, the incidence of HCC is not higher than in the general Danish population (1.9 *vs* 2.2 cases per 100 000), despite the high prevalence of chronic hepatitis B<sup>[31]</sup>. There are several possible explanations for this discrepancy in HCC rates seen in the circumpolar regions. First, native Greenlanders acquire HBV later in life and more frequently clear the virus. Second, chronic carriers tend to have low viral loads (median: 40 000 copies/mL)<sup>[32]</sup>. Finally, the majority of native Greenlanders with chronic HBV appear to have a new genotype (Bj variant), which may be less carcinogenic than other genotypes.

Despite the heavy disease burden from chronic HBV in Aboriginal North Americans, there are still many unanswered questions. For example, it is unclear why the natural history, routes of transmission, and risk for HCC differ so dramatically within the circumpolar region. In addition, the route of transmission and natural history has not been thoroughly studied in AI/AN living in the lower 48 states of the US.

## HEPATITIS C

Hepatitis C is one of the most common and important causes of CLD in AI/AN (Table 1, Figure 1). However, seroprevalence studies have come to disparate conclusions regarding the prevalence of hepatitis C in AI/AN. For example, in the largest study of AI/AN, the overall seroprevalence was just 0.82%<sup>[33]</sup>, which is lower than the overall seroprevalence in the US (1.8%)<sup>[34]</sup>. In contrast, studies of pregnant AI women in the US Southwest, urban AI/AN in the US Midwest, and AI/AN in the Veterans Affairs system showed seroprevalence rates of 11.5%, 3%, and 32%, respectively<sup>[35–37]</sup>. Part of the discrepancy in findings may be attributable to selection bias; the study from Alaska was a true population-based study<sup>[33]</sup>, whereas the others were convenience samples.

The route of transmission appears to be similar to the general US population; namely, injection drug use and blood transfusions. In a study of HCV-positive Alaska Natives, 60.1% had a history of intravenous drug use and 14.0% had a history of blood transfusion<sup>[33]</sup>. Similarly, in a study from an urban US Midwest city, intravenous drug and cocaine use accounted for the majority of those who were HCV positive<sup>[36]</sup>. Other identified risk factors were tattoos > 5 years old and having a sexual partner with HCV.

In the US general population, genotype 1 accounts for the majority of chronic HCV (72%), followed by genotypes 2 (15%) and 3 (6%)<sup>[38]</sup>. In AI/AN, the more easily-treated genotypes are more common: 60% have genotype 1, 23% have genotype 2, and 14% have genotype 3<sup>[33]</sup>. In this Alaska cohort, 73% tested positive for HCV RNA; men were more likely to have higher levels of HCV RNA.

Studies of antiviral efficacy in AI/AN are limited

to one small study from Alaska. However, the results indicate that antiviral therapy may be markedly less efficacious than in American whites (35% *vs* 52%)<sup>[39,40]</sup>. The rate of sustained virologic response (SVR) was 7% (1/15) in patients with genotype 1, 54% (7/13) in genotype 2, and 50% (6/12) in genotype 3.

Studies of First Nations members in Canada show a similar pattern as those done in the US. In a study of Canadian Inuit, the seroprevalence of HCV was 1.1%<sup>[29]</sup>, but in areas outside of the circumpolar region, the seroprevalence ranged from 2.2% to 20%<sup>[16,41]</sup>. Among First Nations Canadians who used injection drugs, the seroprevalence was 33%<sup>[41]</sup>. Interestingly, Aboriginal North Americans may have an increased ability to clear the virus, a finding reported in both Canada and the US<sup>[16,42]</sup>. In native Greenlanders, the seroprevalence is similarly low, < 1%<sup>[31]</sup>.

## HEPATITIS D AND E

Hepatitis D (or delta) virus (HDV) is a very small RNA virus which is dependent on HBV for its life cycle; therefore, in humans it is only seen in the context of concurrent HBV infection. HBV-infected patients who become super-infected with HDV are more likely to develop acute fulminant liver failure than if they just had HBV<sup>[43]</sup>. Similarly, HBV/HDV co-infected patients progress more rapidly (1–2 years in some cases) and more frequently (70%) to cirrhosis<sup>[43]</sup>. HDV is believed to be uncommon in most Aboriginal North American populations, with the exception of Greenland, where 40% of those with HBV also have HDV<sup>[44]</sup>.

Hepatitis E virus (HEV) is also an RNA virus but is spread by the fecal-oral route, similar to HAV. It is predominantly seen in developing countries. However, a recent study showed that 3% of a population of Canadian Inuit had IgG antibodies to HEV (none were viremic). HEV infection has been linked to consumption of deer and caribou, although local caribou were all HEV-negative in this study<sup>[45]</sup>.

## ALCOHOLIC LIVER DISEASE

Alcohol has long been recognized as the most important cause of cirrhosis and liver-related death in AI/AN<sup>[46]</sup> and continues to be the most common cause of CLD (Figure 1). In one study, 65% of all deaths from CLD were attributable to alcoholic cirrhosis<sup>[4]</sup>. Moreover, the excess cirrhosis mortality observed in AI/AN men is independent of socioeconomic status<sup>[47]</sup>.

While binge alcohol use is common (up to 16% in a phone survey of AI/AN)<sup>[48]</sup>, there is also evidence that alcohol consumption in Native American populations is not significantly greater than consumption in other ethnic groups but rather that alcohol has more serious effects on AI/AN populations<sup>[49]</sup>. A study of alcohol consumption and subsequent health effects showed that Native Americans did not drink more alcohol per day or drink for longer periods of time than their Caucasian, Hispanic, and Afro-American counterparts, but

suffered significantly higher rates of alcoholic hepatitis and cirrhosis. In addition, AI/AN in this study had a much lower survival rate, although small sample sizes prevented statistical significance. Such results suggest that AI/AN populations have a genetic predisposition to alcohol liver injury, a finding that has been suggested by other studies<sup>[50]</sup>.

Data from Canada presents a more mixed picture regarding the influence of alcohol on CLD. One study found that the death rate from alcoholism and cirrhosis was three times greater in Canadian First Nations as compared to the general population<sup>[51]</sup>. However, a study reviewing indications for liver transplants in Aboriginal populations in British Columbia found that while alcoholic cirrhosis was the third leading indicator for transplant recipients in the general population, it was not an indicator for any of the fifteen Aboriginal patients who received a transplant. Instead, PBC and autoimmune hepatitis were the two most common reasons (13/15) for liver transplantation in Canadian First Nations<sup>[52]</sup>.

Native Greenlanders have a high per capita alcohol intake. However, when comparing patients in alcohol treatment programs in Greenland *vs* Denmark, the Greenlanders less frequently had abnormal liver function tests (42% *vs* 91%) and cases of cirrhosis or advanced fibrosis (0 *vs* 13)<sup>[53]</sup>. This study suggests that Greenland Inuit may be more resistant to the hepatotoxic effects of alcohol.

Prevention and treatment of alcohol abuse in Aboriginal populations has been an area of active research<sup>[54]</sup>.

## AUTOIMMUNE HEPATITIS

AI/AN have one of the highest rates of autoimmune hepatitis (AIH) in the world. A review of AI/AN in Alaska with AIH between 1984 and 2000 found a point prevalence of definite or probable AIH (using International Autoimmune Hepatitis Group criteria<sup>[55]</sup>) of 42.9/100 000<sup>[56]</sup>. Revised data from this cohort through 2005 showed a point prevalence of 61.7/100 000<sup>[57]</sup>. The only other population-based study of AIH was from Norway and reported a prevalence of 16.9/100 000<sup>[58]</sup>. Fortunately, AI/AN with AIH responded to treatment with systemic steroids with normalization of ALT more rapidly than in previously reported studies<sup>[59]</sup>.

AIH is similarly more common in First Nations peoples in British Columbia<sup>[52]</sup>. A study of indications for liver transplants in British Columbia showed that 7% of recipients the overall population received transplants with AIH as their primary diagnosis, whereas 27% of aboriginal recipients had AIH as their primary diagnosis. Autoimmune hepatitis was fourth leading indication for liver transplant overall, but was the second leading indication within the Aboriginal population. Among those referred for transplant evaluation with AIH, a statistically significant proportion, 12/68 (18%), were First Nations, when compared to their overall proportion in the general population (4.4%)<sup>[60]</sup>. Most cases appear to be type 1 AIH<sup>[61]</sup>.

There are no studies on AIH in native Greenlanders.

## PBC

PBC, like autoimmune hepatitis, is an autoimmune disease that has a strikingly high prevalence in Alaska Natives and British Columbia's First Nations population. A genetic predisposition and female gender are the primary risk factors for developing PBC.

In a study of AN persons with autoimmune liver disease, a combined prevalence rate of antimitochondrial antibody (AMA)-positive and AMA-negative persons with PBC was 21/100 000, including a prevalence of 71.5/100 000 in Southeast Alaska Indian persons<sup>[56]</sup>. Five of 23 persons (22%) had AMA-negative PBC and only 1/23 persons was male.

Outside of Alaska, PBC affects AI/AN populations less frequently than the general population. PBC accounted for 0.18 deaths per 100 000 in the general population in 1998, but a slightly lower rate of 0.11 deaths per 100 000 in the AI/AN population. The death rate from PBC in AI/AN women was 0.28 per 100 000. Furthermore, this rate remained static in the AI/AN population during the 1990's<sup>[4]</sup>.

Native populations in British Columbia, like AN, have a high PBC prevalence. For example, in British Columbia, First Nations people comprise 4% of the population, yet account for 25% of those needing liver transplants due to PBC<sup>[52]</sup>. From 1989 to 1998, PBC was the leading indication for a liver transplant in British Columbia First Nations patients<sup>[52]</sup>. First Nations patients were also referred for liver transplants at a much younger age than non-First Nations patients<sup>[62]</sup>. Of those First Nations patients referred for liver transplantation, most (33/34) are female.

Several factors indicate a strong genetic component to the occurrence of PBC. Within a population of British Columbia First Nations patients with PBC, 19/24 reported at least one other autoimmune condition and 33% had a family history of PBC<sup>[62]</sup>. First Nations patients were unusual in that 18% tested negative for AMA, which are normally present in 95% of PBC patients.

There are no studies of PBC in native Greenlanders.

## NAFLD

NAFLD is the deposition of fat in the liver, commonly as a consequence of obesity and diabetes mellitus type 2. This condition may progress to NASH, in which there is inflammation, sometimes with resulting fibrosis and cirrhosis. NAFLD was the fourth most common cause of CLD in a study from the Southwestern US, accounting for one-eighth of the total cases (Figure 1). Preliminary results from a retrospective study of abnormal ALT values in AI/AN indicate that NAFLD is the second most common etiology<sup>[7]</sup>.

It is not surprising that NAFLD accounts for a significant proportion of CLD, given the high prevalence of risk factors for NAFLD in AI/AN (obesity, hypertriglyceridemia and diabetes mellitus type 2). For example, the prevalence of obesity among AI/AN is 24%-40%, the highest rate in any American ethnic group<sup>[63]</sup>. Similarly, the prevalence of diabetes is higher

in AN/AI than any other ethnic group, ranging from 9.7%-19.7%<sup>[48,63]</sup>. Rates of these conditions are expected to rise in the general population, so NAFLD can likewise be expected to increase in the future.

There are no available studies of NAFLD in Canadian FN and native Greenlanders.

## GENETIC

Inherited causes of liver disease are an uncommon cause of cirrhosis in North American Aboriginal populations. One exception is in the Ojibway-Cree population in Northwestern Quebec where North American Indian childhood cirrhosis (NAIC) has been described<sup>[64]</sup>. This autosomal recessive trait is carried by 10% of the local population and 1/250 to 1/750 are believed to have the condition. A missense mutation on chromosome 16q22 causes a change in the secondary structure of cirrin, a protein crucial in embryonic liver development<sup>[65]</sup>. Intrahepatic cholestasis develops and manifests clinically as a sustained elevation in the alkaline phosphatase level. Children born with this condition have transient neonatal jaundice, with rapid progression to biliary cirrhosis and portal hypertension. In a case series of 30 children with NAIC, 14 (47%) died, mostly from complications of ESLD<sup>[64]</sup>. Liver transplantation is the only cure. A syndrome termed fatal familial cholestatic syndrome has been reported in Greenland Eskimo children<sup>[66]</sup>. This autosomal recessive disease is associated with dwarfism, osteodystrophy, jaundice, and malnutrition. Death in infancy is common and there is no specific treatment available.

Hemochromatosis, an autosomal recessive trait leading to iron overload and cirrhosis, is common in persons of northern European descent, affecting about 5 of every 1000 persons<sup>[67]</sup>. Initial studies screening patients from primary care clinics in Alabama suggested that patients with AI ancestry may have greater ferritin and lower mean transferrin levels, findings which are suggestive of hemochromatosis<sup>[68]</sup>. However, genetic testing of 80 patients with hemochromatosis did not show a difference in phenotype among those with and without AI ancestry<sup>[69]</sup>.

Familial clusters of HCC have been observed in AN, sometimes in childhood. Because p53 mutations have been observed in 29% of patients with HCC, researchers hypothesized that p53 mutations might account for the early onset and clustering<sup>[70]</sup>. However, they found no antibody, immunohistochemical or DNA evidence of p53 mutations in 14 AN patients with HCC. It is still possible, however, that a germline mutation in a tumor suppression gene exists.

There are no studies examining Wilson's disease in Aboriginal North Americans.

## CONCLUSION

CLD is an important cause of morbidity and mortality in Aboriginal North Americans. Alcohol abuse is the most common etiology of CLD in this population and incidence rates remain stable. However, the incidence of

CLD due to viral hepatitis, especially HCV, is rising. In addition, NAFLD is an understudied, but an increasingly more common, cause of CLD. Taken together, CLD in this population can be expected to increase in the coming decade. Accordingly, future studies should continue to monitor the incidence and etiology of CLD and should be geographically inclusive. In addition, future research should focus on the treatment of HCV and NAFLD.

### INTRODUCTION

Despite a decrease in the occurrence of infective diseases, autoimmune and chronic inflammatory disorders are on the increase in developed countries. Many of these illnesses remain poorly understood due to the intricate network of interactions among genetic, cellular and environmental factors underlying pathogenesis.

Various theories have been developed as to the etiopathogenesis of inflammatory bowel disease (IBD), but so far none of them has led to a therapy with long-term efficacy and free of side effects. The advancement of our knowledge of the biological basis of pathogenesis, combined with recent findings on the regenerative, trophic and immunoregulatory potential of stem cells, have triggered research that could lead to a significant evolution, or revolution, in the treatment of IBD.

Mesenchymal and hematopoietic stem cells (MSCs and HSCs) are catalyzing the attention of IBD investigators, physicians and clinicians. After a number of case reports, and following initial steps within *in vitro* and *in vivo* models, cell-based approaches are now moving from the laboratory bench to the patient's bed. Stem cell transplantation may soon become a therapeutic option for IBD.

Crohn's disease (CD) and ulcerative colitis (UC), the two main forms of inflammatory bowel diseases, are chronic, relapsing and remitting diseases profoundly affecting the quality of life in an enlarging portion of the population: their incidence and prevalence are growing in Western countries<sup>[1]</sup>. CD may affect every tract of the digestive system-most commonly the ileal and colonic

### Abstract

The incidence and prevalence of Crohn's disease (CD) and ulcerative colitis (UC), the two major forms of inflammatory bowel diseases (IBD), are rising in western countries. The modern hygienic lifestyle is probably at the root of a disease where, in genetically susceptible hosts, the intestinal commensal flora triggers dysregulated immune and inflammatory responses. Current therapies ranging from anti-inflammatory drugs to immunosuppressive regimens, remain inadequate. Advances in our understanding of the cell populations involved in the pathogenetic processes and recent findings on the regenerative, trophic and immunoregulatory potential of stem cells open new paths in IBD therapy. Hematopoietic and mesenchymal stem cells are catalyzing the attention of IBD investigators. This review highlights the pivotal findings for stem cell-based approaches to IBD therapy and collects the encouraging results coming in from clinical trials.

**Key words:** Inflammatory bowel disease; Stem cells;

tracts, and exhibits a histological pattern of transmural inflammation. UC only affects the colon starting from the rectum and moving backward, the inflammation being localized in the mucosal layer. In both CD and UC an alteration of the mucosa leads to the symptoms of the disease. CD can be complicated by the occurrence of fistulas, abscesses and stenosis.

Genetic, environmental and immunological factors contribute to the development of inflammatory bowel disease. The “hygiene hypothesis” proposes a scenario in which a radical change of lifestyle may have led to the shift from infective to chronic inflammatory diseases in Western countries. An immune system exposed to a low number of antigens and struggling against only a few challengers, may be lapsing into an uneducated state. Thus its efforts at eliminating offending agents could then be ineffective or misdirected. The vary environmental modifications that brought humans to this hygienic lifestyle may have contributed to the rise of immune-based disorders.

IBD is thought to be the result of an aberrant immune response to commensal bacteria and luminal antigens in a susceptible host. The “no bacteria, no colitis” paradigm summarizes the evidence obtained from animal models: experimental colitis can only be induced in a conventional, non-germ-free environment. The evidence supporting the existence of a classic infectious agent causing IBD is weak. The enteric flora may trigger an inappropriate, “loss of tolerance”-based immune response, further evolving to chronic inflammation and IBD.

The mucosal tolerogenic state is maintained by dynamic, strictly regulated, physical and immunochemical interactions in a complex crosstalk among the gut microbiome, gut luminal antigens, the intestinal epithelial barrier, lymphocytes, dendritic and mesenchymal cell populations<sup>[2]</sup>. The circuitry is coordinated so as to obtain a minimal persistent inflammatory state (physiological inflammation) able to control the enteric flora and to cope with non-self antigens. In normal conditions the innate and adaptive immune systems cooperate in order to create this controlled status of inflammation: in CD and UC the balance is lost.

## IMMUNE-BASED DISORDERS

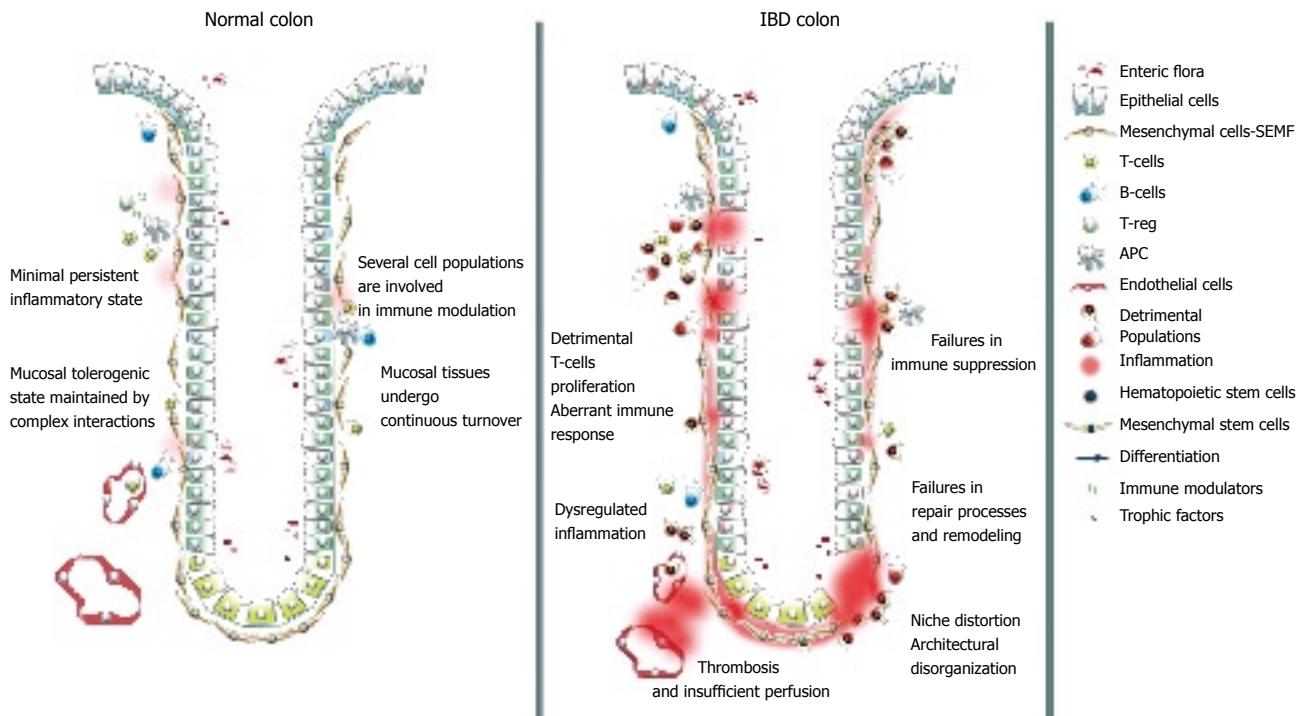

Analysis of genetics and immune responses in IBD patients and animal models sheds light on the biological function of the metabolic pathways and cell populations with a central role in the immune tolerance network. Most of the genetic factors that are so far known to contribute to susceptibility towards IBD act as key links in immune recognition and modulation. The existence of a genetic predisposition for IBD has been demonstrated. Genome-wide screening in familial clusters has identified 7 loci with a linkage to IBD (IBD 1-7)<sup>[3]</sup>. Most linkage regions are associated with both CD and UC: this suggests the existence of common genetic features and mechanisms. The genes residing in the IBD loci (e.g. NOD2/CARD15, TNF-

alpha) are implicated in immune function and intestinal permeability<sup>[4-7]</sup>. Initially, connections between innate immune impairments and IBD emerged. The association between CD and NOD2/CARD15 mutations showed that innate pattern recognition impairments and bacterial sensing may undermine the host/microbe interplay at a critical point. The NOD2/CARD15 protein recognizes peptidoglycans (bacterial muramyl dipeptide, MDP) and is expressed by macrophages and dendritic cells. The mutated gene product fails to bind MDP. The production of alfa-defensins by epithelial Paneth cells, expressing NOD2, is decreased in CD patients when NOD2 is mutated<sup>[8]</sup>. Innate and adaptive immunity are intimately interconnected, impaired mechanisms may simultaneously affect the two vast pathways of immune response.

Cell populations and mediators of adaptive immunity have been extensively investigated in IBD patients and murine models<sup>[9]</sup>. A dramatic increase in antibody production has been described both at the mucosal and at the systemic level in IBD patients. An alteration in the relative proportions of the immunoglobulin classes has been found<sup>[10]</sup>. Autoantibody production has been investigated, but confirmation of their existence is still needed<sup>[11]</sup>.

T lymphocytes are recognized as central effector cells. Their activation in IBD is accompanied multiple alterations in the production of cytokines and soluble mediators with proinflammatory and immunoregulatory significance. Consensus exists on the differing CD4 helper polarization tendency between the two major forms of IBD. In CD the IFN-gamma and IL-2 producing Th1 CD4+ phenotype is predominant, while UC seems to be dominated by atypical Th2 CD4+ T-cells, producing TGF beta and IL-5, and by IL-13 producing CD1d-restricted nonclassical Natural Killer T cells<sup>[12]</sup>. CD resembles experimental Th1-mediated colitis, whereas the features of UC are recapitulated in models of Th2-mediated colitis<sup>[13,14]</sup>. Observations in patients and murine models suggest that the suppressor activity of CD4+ CD25<sup>high</sup> T regulatory cells may be abrogated or insufficient to balance the chronic inflammation at the mucosal level<sup>[15]</sup>. Murine models confirm the ability of CD4+ CD25<sup>high</sup> T regulatory cells to prevent or ameliorate experimental colitis<sup>[16]</sup>, indicating the positive effect of anergy induction in the inflammatory environment. The suppressor activity of immunoregulatory populations, mediated by cytokines like IL-10 and TGF-beta, may fail because of a disruption of the signaling pathway in activated T cells: Smad7 overexpression antagonizes the TGF-beta dependent inhibition of T proliferation<sup>[17]</sup>.

The involvement of cell populations other than the classical immunological ones in immune modulation and IBD pathogenesis is becoming clear. Epithelial, endothelial, mesenchymal cells and platelets cooperate in modulating the immune response, and play a role in the establishment and protraction of inflammatory processes, in recovery and in tissue remodeling (Figure 1). Intestinal epithelial cells (IECs) have been claimed to

**Figure 1** Schematic representation of normal and IBD mucosal tissues. In normal conditions the innate and the adaptive immune systems cooperate in order to create a controlled status of inflammation; In IBD the balance is lost.

act as non professional antigen-presenting cells. In the inflamed mucosa, IECs inappropriately express HLA-DR class II and costimulators of the B7 family<sup>[18]</sup>. In healthy subjects antigen presentation by IECs results in activation of a CD8+ regulatory T cell subset through a non classical MHC class I pathway. IECs interact with the T compartment through members of the CEA family and CD1d, and in normal conditions expand a CD8+ VB5.1+ subset of T cells with regulatory functions. In IBD IECs a defective expression of CEA family members and CD1d occurs, leading to a failure in expansion of the regulatory subset and to a proliferation of CD4+ T cells with the production of inflammatory cytokines<sup>[19,20]</sup>. Moreover, UC IECs fail to express MHC I molecules and CD IECs express HLA-E, MICA and MICB, but not CD1d, failing to expand the regulatory T cell subset<sup>[21]</sup>.

Endothelial cells control the egression of migrating leukocytes in a complex process mediated by cytokines, chemokines and adhesion molecules. A deficit in nitric oxide synthase (NOS) production has been found in IBD intestinal microvascular endothelial cells. Impairment of NO-dependent vasodilation may result in decreased perfusion and poor wound healing<sup>[22]</sup>. Thrombosis is a frequent complication in IBD patients and platelets are implicated, but interest in these entities has risen following the definition of their immunological properties<sup>[23]</sup>. Platelets become activated in IBD patients and contribute to exacerbating inflammation through the release of CD40, which triggers a broad spectrum response in the intestinal microvasculature, stroma, and immune cells<sup>[24]</sup>.

The role of mesenchymal cells in mucosal homeostasis and microenvironmental modeling is far more critical than previously thought. Traditionally considered as

extracellular matrix (ECM) producers, fibroblasts were thought to be a passive cell population responsive to the chronic inflammatory environment and causing fibrotic complication<sup>[25]</sup>. Fibroblasts are the main source of matrix metalloproteinases (MMPs); proteolytic enzymes responsible for ECM degradation and ultimately for tissue destruction during inflammation. Interactions with activated T-cells potently stimulate fibroblast production of MMPs and result in tissue injury<sup>[26,27]</sup>.

## MESENCHYMAL CELLS AND RESTITUTIO AD INTEGRUM

Epithelial ulcerations caused by inflammatory process recover *via* tissue remodeling in the normal intestine. Resolution of inflammatory activity is associated with repair processes, and mesenchymal cells have a central role in coordinating these events to help remodeling. The repair processes in UC patients are usually able to restore a normal intestinal architecture, but in CD patients an excessive fibrosis frequently leads to the formation of strictures and obstructions. Fibrosis is one of the main complications and a recurrent finding in IBD patients: it is associated with mesenchymal cell persistence and hyperplasia, tissue disorganization and fibrillar collagen deposition.

Isolation and characterization of intestinal fibroblasts has allowed the determination of some peculiar biological features of IBD fibroblasts, for example they display significantly higher proliferation and collagen secretion rates than normal intestinal fibroblasts. Such evidence suggests that a fibroblast subset may be functionally activated in the IBD intestine<sup>[28,29]</sup>.

Recent findings suggest that mesenchymal cells derived from bone marrow stem cells may have an important role in repair processes and fibrosis<sup>[30]</sup>. Intestinal subepithelial myofibroblasts (ISEMFs) are located under the basement membrane, juxtaposed with the base of epithelial cells. These mesenchymal cells regulate a number of epithelial cell functions such as proliferation, differentiation and ECM metabolism, affecting the growth of the basement membrane<sup>[31]</sup>. They cooperate in pathogen sensing and actively participate in immune responses<sup>[32]</sup>. Moreover, they exert important functions in tolerance induction<sup>[33]</sup>. ISEMFs control mucosal repair processes by ECM manipulation, cytokine and growth factor release. Two separate mechanisms mediate the repair operations. Restitution is the first, a response to minor to moderate injury, when the basement membrane remains intact. Here, ISEMFs promote the proliferation and migration of residual epithelial cells over the denuded area by the release of TGF-beta, EGF, aFGF, bFGF and inflammatory cytokines. When the wound is deep and a reconstruction of the subepithelial tissues is needed, mesenchymal cells proliferate and form a new basement membrane, over which epithelial cells will then proliferate and migrate. ISEMFs are therefore responsible for a crucial process in mucosal repair: the maintenance and reconstitution of the basement membrane.

Alpha-SMA positive ISEMFs are increased in IBD mucosa as compared with normal mucosa, and the increase is very marked at the edges of UC ulcerations<sup>[34]</sup>. A higher ISEMF proliferation rate and growth factor secretion could account for CD fibrogenesis<sup>[28]</sup>. This cell population, actively participating in ECM metabolism and basement membrane turnover, is a major effector in the tissue remodeling process. Inflammatory cytokines and growth factors like TGF-beta, PDGF-BB, KGF, IGF-1 and EGF control MMP and their tissue inhibitor (TIMP) expression in ISEMFs, and it has been shown that the expression of MMPs and TIMPs is elevated in the inflamed mucosa of IBD patients<sup>[35]</sup>. ECM metabolism and inflammatory responses are regulated in close association: in colonic SEMFs TNF-alpha, IL-1 beta and IL-17 induce the expression of chemokines like monocyte chemoattractant protein-1 (MCP-1) and interleukin-8 (IL-8) together with MMPs<sup>[36]</sup>. IL-11, a chemokine with antiinflammatory properties, is able to inhibit the production of IL-1 beta, TNF-alpha and other proinflammatory cytokines from LPS-stimulated macrophages. Data from animal models show that in the gastrointestinal tract IL-11 can prevent or improve acute and chronic inflammation<sup>[37]</sup>. ISEMFs secrete IL-11 in response to inflammatory cytokines like IL-1 beta, TGF-beta and IL-22. Activated T cells are the main source of IL-22, and this cytokine induces secretion of IL-11 by ISEMF. Mesenchymal cells thus display suppressive immunomodulatory properties<sup>[38]</sup>. ISEMFs provide support for epithelial cell proliferation and regeneration, having a role in the *restitutio ad integrum* in IBD. Evidence is mounting as to their role in forming the niche that accommodates epithelial stem cells and

in determining epithelial cell fate: pericryptal ISEMFs are the main source of morphogenic signaling<sup>[39]</sup>. Wnt signaling for example, has specific functions in the intestinal crypt stem cell region. Through its receptor, Fzd, expressed in both ISEMFs and crypt epithelium, Wnt triggers paracrine and autocrine responses. Nuclear localization of beta-catenin/T cell factor (TCF) is confined to epithelial cells at the bottom of the crypts, and upregulated by Wnt signaling. FoxF proteins are key mesenchymal factors that control Wnt expression and ECM deposition, affecting epithelial cell proliferation, polarization and differentiation<sup>[40]</sup>.

## MSCS AND HSCS: CONTRIBUTION TO INTESTINAL LINEAGES

Adult bone marrow HSCs possess well-known multipotent capacities and are able to restore the entire haemopoietic compartment after myeloablation. The hypothesis that certain adult stem cells might possess a different, greater potential first came from the observation that in human bone marrow transplants donor cells were subsequently found in several recipient tissues<sup>[41]</sup>. The attention of cell biologists moved to the bone marrow mesenchymal compartment and evidence regarding the stem potential of stromal cells soon appeared: the plastic-adhering fibroblast-like population displayed a self renewal capacity, high *in vitro* expansion potential and the ability to differentiate into multiple mesodermal lineages, e.g. osteoblasts, chondrocytes and adipocytes<sup>[42,43]</sup>. These cells, named MSCs and initially isolated from the bone marrow<sup>[44]</sup>, were found to reside in several other tissues. MSCs possess migratory capacity, may be diversely distributed *in vivo* and may occupy a ubiquitous stem cell niche<sup>[45,46]</sup>.

A remarkable amount of evidence exists regarding the multilineage differentiation potential of bone marrow stem cells. Marrow-derived cells have been shown to differentiate towards endodermal<sup>[47,48]</sup>, mesodermal<sup>[49,50]</sup> and ectodermal commitments<sup>[51]</sup>. A unitarian theory on the derivation of the intestinal epithelium from resident stem cells has been developed and widely accepted<sup>[52]</sup>, but a number of recent studies report a bone marrow contribution to gut epithelial and mesenchymal lineages<sup>[53-55]</sup>, even at the single cell level<sup>[56]</sup>. A repopulation of the gastrointestinal tissues occurs in bone marrow-transplanted patients and donor-derived cells engraft with a high efficiency in the areas of mucosal ulceration undergoing regeneration<sup>[57]</sup>. Bone marrow sex-mismatched transplants were performed in mice and a stable engraftment of alpha-SMA+, desmin-, F4/80-, CD34- pericryptal myofibroblasts of donor origin was documented through *in situ* hybridization for the Y chromosome. The analysis of intestinal biopsies from sex-mismatched BM-transplanted patients with GVHD gave similar results<sup>[50]</sup>. Inflammatory cytokines and signals may be strong stimuli for the recruitment of marrow stems in the areas of mucosal damage. The engraftment of BM-derived ISEMFs was investigated by using mouse models of chemo-induced acute colitis and IL-10-/ chronic

colitis. A significant increase in the number of donor-derived ISEMFs was found in the inflamed areas when compared with the normal adjacent mucosa<sup>[58]</sup>.

## MSCS: REGENERATION AND IMMUNE MODULATION

MSCs have been shown to differentiate into a wide range of cell types and to produce a number of growth factors and cytokines that are important for tissue repair and remodeling. Intense studies on the paracrine activity of these cells suggest they are able to participate in tissue healing and long-term repair as trophic mediators<sup>[59]</sup>. Of fundamental interest for the treatment of chronic inflammatory diseases is the fact that MSCs possess the ability to modulate the immune response and to persist at length in the tissues of allogeneic transplanted recipients<sup>[60]</sup>. Cells with mesenchymal stem potential can be isolated from several tissues, with differences in yield and in differentiation capacity<sup>[46,61,62]</sup>. The best characterized MSC population is the one found in the bone marrow where the *in vitro* expansion protocol is almost standardized<sup>[63]</sup> but due to the absence of characteristic markers it is still impossible to prospectively isolate MSCs from fresh samples. Differences among laboratories in expansion potential, differentiation capacity, gene expression and phenotype have been ascribed to slightly different *in vitro* culture and expansion conditions.

Several studies have demonstrated that MSCs possess valuable characteristics for tissue repair or regeneration: these cells have been shown to functionally integrate and remodel bone<sup>[64,65]</sup>, cartilage<sup>[66]</sup> and myocardial tissues<sup>[67-69]</sup>. MSCs display a further remarkable feature, the ability to migrate and home to the sites of injury<sup>[70-73]</sup>. Early clinical trials have shown the benefits of allogeneic MSC transplantation for the treatment of graft-versus-host disease (GVHD)<sup>[74]</sup>. A phase III clinical trial is currently enrolling patients to evaluate the efficacy of Prochymal™, an allogeneic bone marrow derived MSC preparation, for the treatment of steroid refractory acute GVHD<sup>[75]</sup>. Human MSCs express intermediate-low levels of HLA class I, low levels of HLA class II and do not activate allogeneic T cells. This ability to escape alloreactive recognition is probably due to a lack in the expression of costimulatory molecules like B7-1, B7-2, CD 40 and CD 40 ligand<sup>[76,77]</sup>. Moreover, MSCs suppress allogeneic T-cell proliferation and do not elicit an immune response after transplantation in immunocompetent recipients<sup>[69,76,78]</sup>. Several authors have reported the suppression of lymphocyte proliferation in primary mixed leukocyte reactions (MLR) and mitogen responses to phytohemagglutinin (PHA), concanavalin and tuberculin<sup>[79,80]</sup>. Again, MSCs inhibit the T-lymphocyte activation mediated by anti CD3 and CD28 antibodies at primary and *in vitro* expanded cultures<sup>[76,81]</sup>. The molecular mechanisms that enable MSC to abrogate lymphoproliferation are still unknown but several reports claim the importance of soluble factors: modifications in the cytokine balance, such as an increase in IL-2 and IL-10 levels, are

suggested to have lymphosuppressive ability<sup>[82-84]</sup>.

IL-10 is a pleiotropic anti-inflammatory cytokine which potently suppresses antigen presentation by the down-regulation of classical HLA-class I and II, and which inhibits the synthesis of pro-inflammatory cytokines like IFN-gamma, IL-2, IL-3, TNFalpha and GM-CSF<sup>[85]</sup>. Furthermore, IL-10 induces differentiation of regulatory T cells<sup>[86]</sup> and the secretion of soluble HLA-G molecules by activated CD14+ peripheral blood monocytes<sup>[87]</sup>. MSCs have been shown to improve the clinical outcome of autoimmune disease, as a result of suppressive modulation of the pathogenic T-cell autoimmune response<sup>[88]</sup>.

## ADVANCES IN CELL THERAPY: HSC AND MSC TRANSPLANTATION

The long-term management of inflammatory bowel disease depends on the intensity, location, endoscopic severity, clinical manifestations and complications of the disease. Many cellular and molecular pathological pathways have been identified as therapy targets<sup>[89]</sup>.

The common progression into an exacerbated form of IBD requires an escalation from antiinflammatory (e.g. 5-aminosalicylates, corticosteroids), to immunosuppressant (e.g. azathioprine, mercaptopurine, cyclosporin) regimens or to biological drugs (e.g. infliximab anti-TNFalpha, vizilizumab anti-CD3), usually with limited success. Non-responding IBD patients will frequently face the decision to undergo necessary invasive surgical procedures, although surgical intervention will not resolve the disease<sup>[89]</sup>. Since no curative options exist to date, a stem cell-based approach could drive a major change in disease management and treatment.

Impairment in the control of intestinal immune cell function and turnover appears to be of central importance for the dysregulated and protracted inflammatory response in IBD. A high-dose immune ablation regimen could allow detrimental T-lymphocyte repertoires to be eliminated and after HSC transplantation (HSCT) *de-novo* hematopoiesis would generate naive cells. Patients receiving an autologous HSCT are thought to be subject to an immune system reboot: the genetic defects would not be eliminated but remission could persist in the absence of deleterious environmental triggers. HSC allotransplanted patients probably experience a graft-versus-autoreactive (GVA) response and the immune system gets almost completely replaced. These concepts form the basis of a new therapeutic approach to IBD, and a number of case reports show long-lasting remission of IBD patients undergoing HSC or bone marrow transplantation.

In 1993 the first case of CD regression after autologous HSC transplantation for hematopoietic malignancy was reported<sup>[90]</sup>. More cases then started to be recorded: in 1996 one UC and two CD patients treated for coincidental malignancies experienced a remission from IBD after high dose chemotherapy and autologous HSCT<sup>[91]</sup>. In 1998 the case of a 9-year-old patient with CD was reported: after autologous BM transplantation for non-Hodgkin's

lymphoma, a clinical and laboratory CD remission occurred and lasted for at least 7 years<sup>[92]</sup>. In the same year the clinical outcome of six CD patients undergoing allogeneic transplantation for hematological malignancies was reported. In one patient the inactive CD remained inactive for at least 15 years without immunosuppression and in three patients with active CD the pathology became inactive<sup>[93]</sup>. In 2000 the case of a 30-year-old patient with a 10-year history of severe CD was reported: after developing Hodgkin's disease he received an autologous peripheral blood HSCT and remained in remission for both diseases for at least 3 years after transplant<sup>[94]</sup>. In 2001 a case report described the remission of a 57-year-old UC patient after an autologous peripheral blood HSCT performed for breast cancer chemotherapy<sup>[95]</sup>. In 2002 a report showed the case of a CD patient, treated with autologous HSCT for acute myeloid leukemia, who remained in clinical remission from both diseases for 5 years<sup>[96]</sup>. More recently a complete normalization of the Crohn's Disease Activity Index (CDAI) was reported after HSC transplantation in two patients with severe, non responsive, infliximab-resistant CD<sup>[97]</sup>. Two further cases were reported by the same group<sup>[98]</sup>. A phase I HSCT trial involving 12 patients with refractory CD showed evidence of beneficial effects from autologous HSCT<sup>[99]</sup>. Peripheral blood stem cells were mobilized with cyclophosphamide plus G-CSF and CD34+ enriched. Eleven of the 12 patients underwent remission with a significant reduction in the CDAI index. A recent phase I - II study investigated the safety and efficacy of autologous HSCT without CD34+ enrichment in patients with refractory CD: 3 out of 4 patients obtained and maintained clinical and endoscopic remission, despite withdrawal of all drugs<sup>[100]</sup>. All of these reports encourage further studies on HSC transplantation in IBD. A radical ablation of an aberrant immune system followed by autologous reconstitution may regenerate a naïve, non aberrant immune compartment. The European phase III "ASTIC" trial has been designed to investigate the potential clinical benefit of autologous HSCT after high-dose immune ablation in non-responding patients with severe CD.

Transplant conditioning calls for an aggressive immunosuppression regimen that may play a role in inducing remission, but patients with severely impaired mucosal barrier function undergoing such a regimen may worsen their plight and face even more severe consequences. Nevertheless, the management of CD and UC complications is a major goal of therapy. IBD patients develop non-healing, long-lasting ulcerations which are very resistant to common treatments and to advanced surgical cure. MSCs may allow a therapeutic approach targeting the site of injury, aimed at tissue regeneration and at local immune modulation.

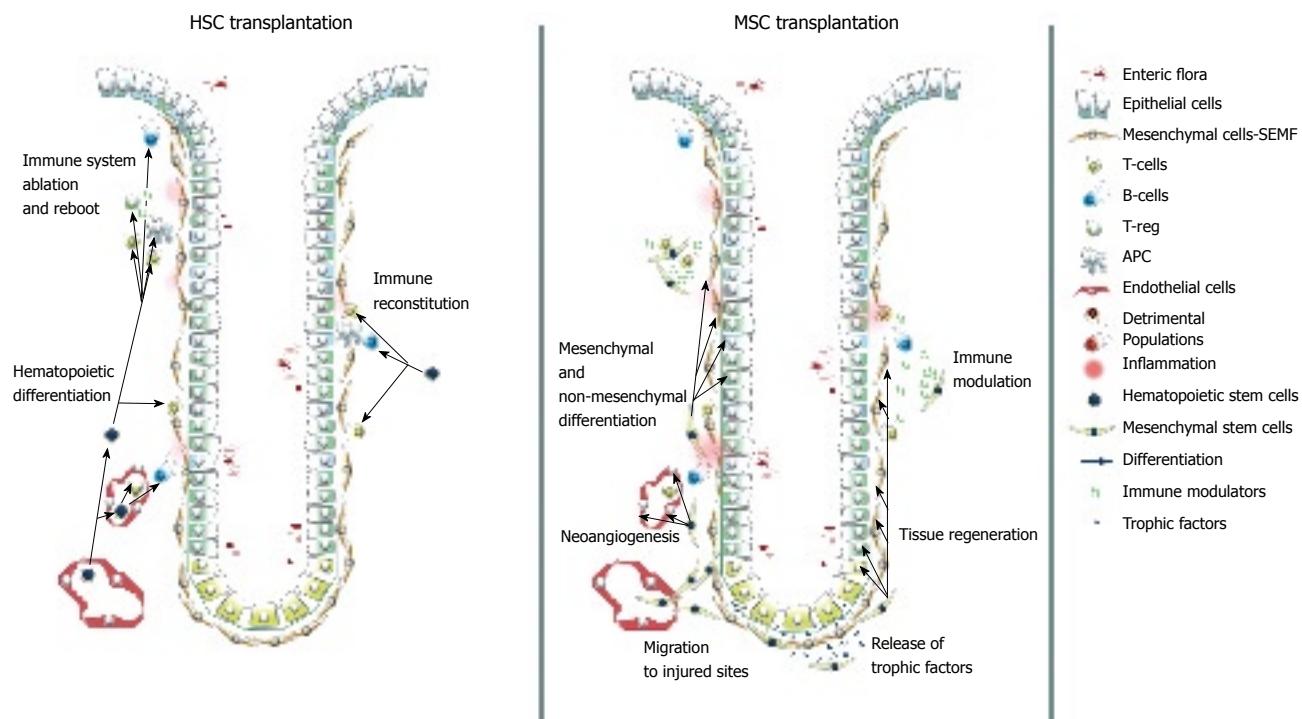

Adipose tissue-derived MSCs<sup>[101]</sup> have been shown to possess promising potential for ulceration healing in perianal manifestations. A young patient with CD and recurrent rectovaginal fistula was treated with autologous stem cell transplantation using lipoaspirate-derived MSCs. At the time of the stem cell therapy the patient had been treated with different surgical and medical procedures, including infliximab infusion, without effective manage-

ment of the manifestations. Autologous adipose tissue derived MSCs were isolated, expanded for three or fewer passages and injected into the rectal mucosa; the rectal opening approaching from the posterior vaginal wall was closed with absorbable stitches prior to cell injection. A complete closure of the wound was demonstrated one week after the injection without any adverse events<sup>[102]</sup>.

The group designed a prospective Phase I clinical trial involving 5 CD patients to study the safety and the efficacy of stem cell transplantation in perianal manifestations and complications using autologous adipose tissue-derived stem cells. Three  $\times 10^6$  to  $30 \times 10^6$  cells were injected directly under each lesion. Healing of the fistula was considered achieved when a total epithelialization of the external opening was evident. They observed complete healing in six of the eight procedures<sup>[103]</sup>. These reports describe an innovative approach to the local treatment of CD manifestations, based on *in situ* delivery of autologous MSCs. Whether MSCs contribute to tissue regeneration by direct differentiation, by trophic effect or by immunomodulatory functions has not been investigated yet and could become a matter of concern. Prochymal™, developed by Osiris Therapeutics Inc.<sup>[75]</sup>, is a preparation for intravenous infusion of bone marrow-derived MSCs obtained from healthy adult donors. The Prochymal™ phase II clinical trial was a prospective, randomized and open label trial. Patients with moderate to severe CD (CDAI > 220), who had previously failed treatment with steroids, infliximab and other immunosuppressive agents, were enrolled and received two infusions of the preparation. Every patient evaluated reported a reduction in CDAI, and a statistically significant decrease in mean CDAI scores, from 341 to 236, occurred by day 28 after the infusions. Improvement was rapidly obtained, with an average CDAI reduction of 62 points by day 7. One-third of the patients reported Inflammatory Bowel Disease Questionnaire (IBDQ) scores of at least 170, indicating they had achieved clinical remission of their disease. The Food and Drugs Administration recently allowed Prochymal™ to advance to a phase III double-blind placebo-controlled trial via Fast Track for the treatment of CD. After GvHD, CD is the second indication for which Osiris received Fast Track status to advance to Phase III. Osiris received orphan drug designation from the FDA and the European Medicine Agency (EMEA) for Prochymal™. This intravenous preparation of MSCs may have peripheral immunomodulatory functions, leading to abrogation of the pathological inflammation typical of CD. MSCs may contribute to tissue regeneration by direct differentiation toward intestinal lineages<sup>[104]</sup>, but they may also have trophic functions in the healing environment and their immunomodulatory ability may arrest disease protraction (Figure 2).

## CONCLUSION AND FUTURE PROSPECTS

IBD are thought to be the result of an abnormal immune response to commensal bacteria and luminal antigens in a susceptible host. The intermittent and

**Figure 2** Contribution of transplanted HSCs and MSCs to the immune compartment and to intestinal lineages. HSCs are able to restore the immune system to a naive state. MSCs contribute via direct differentiation to mesenchymal and non-mesenchymal lineages, exert trophic functions and modulate in a suppressive fashion the immune response.

aggressive presentation of the pathology profoundly affects the quality of life of the patients. The inadequacy of conventional therapies and the current understanding of IBD biology are motivating investigators to develop novel approaches to IBD treatment: the advancement in stem cell-based therapies could drive a major change.

Having to cope with exuberant commensal flora and abundant non-self antigens, a number of cell populations cooperate to control intestinal mucosa integrity and to maintain a status of persistent physiological inflammation. Impairments in immunological and regenerative functions at this level lead to IBD. The behavior of classical immune cells appears dysregulated in IBD patients. T-lymphocytes are considered central effector cells, responsible for the release of cytokines implicated in the onset and in the protraction of the inflammation. A lack of suppression is probably the cause of the abnormal and persistent activation of the T-cell compartment. Immunomodulatory activity, impaired in IBD, is carried out by populations of T regulators and by cell populations traditionally considered not involved in immunity. Aberrant epithelial and endothelial cell functions concur in the pathogenesis. Epithelial cells act as non-professional antigen presenting cells: defective expression of molecules implicated in the expansion of immunoregulatory T-cells may cause a failure in the immune inhibition. Deficits in cells of the microvasculature causing inadequate perfusion could account for ineffective ulceration healing. A set of intestinal subepithelial myofibroblasts (ISEMFs), a mesenchymal population juxtaposed to the mucosal epithelial layer exerting trophic and immunomodulatory effects, become activated

in IBD and impair correct tissue remodeling processes, so that the *restitutio ad integrum* ultimately fails (Figure 1). Stem cells residing in the bone marrow have been shown to contribute with their progeny to all of these intestinal lineages and may be of value and interest in clinical settings. Clinical improvements in IBD patients have been reported after allogeneic and autologous transplantation of hematopoietic and MSCs. After immune ablation and reconstitution via HSC transplantation, a reboot to a naive immune system could bring about long-lasting remission. In autologous transplantation genetic defects would persist, but the indulgence may last in the absence of environmental triggers. In allogeneic transplantation the immune replacement would be more radical and potentially more reliable, but the risks associated with graft rejection and complications are probably too high for application in IBD. MSC only received the attention of IBD investigators in recent times. Experimental and clinical data indicate that MSCs have great potential for those clinical applications that require tissue regeneration or repair promotion, owing to their plasticity and their immunomodulatory properties. The biology of this stem population is still largely obscure, but their impressive differentiation potential, combined with exceptional trophic and immunomodulatory capacities, could make MSC an outstanding tool in IBD treatment (Figure 2). Pioneering works have reported impressive results: in mouse models and in IBD patients treated for coincidental malignancies, bone marrow-derived cells of donor origin contribute to tissue repair by differentiating towards the epithelial, myofibroblastic, endothelial and pericytic lineages in the areas of inflammation. Bone

marrow transplantation from an unaffected donor is able to ameliorate pathology in a mouse model of chronic genetic-based colitis. Moreover, CD34- bone marrow- and peripheral blood-derived stem cells contributed to mucosal repair *via* neoangiogenesis in moderate-severe murine colitis and were effective in reducing the pathologic features associated with IBD<sup>[104]</sup>. Pivotal trials have demonstrated the efficacy of MSC transplantation in patients with CD, though the mechanisms of action underlying the clinical effects of MSCs still need clarifying and the follow-up periods need to be extended. Both HSC and MSC transplantation in IBD are currently being evaluated in Phase III clinical trials.

Ways of recognizing easily accessible and non-controversial new sources of pluripotent stem cells, such as term extraembryonal tissues<sup>[62,105]</sup> as well as improving methods for *ex vivo* isolation, expansion and delivery may become of central interest. Moreover, MSCs displaying pluripotent, immunomodulatory and trophic potential, and suitable for implanting without manipulation in an allogeneic setting, would have obvious implications and may be promising “off the shelf” therapeutic approaches to IBD. In the future, the possibility of banking cord-blood derived HSC and placenta-derived MSCs<sup>[106]</sup>, could enable these stem cells to be used both in autologous and in allogeneic transplantation settings.

PET/CT, the final diagnosis was recurrence of mucinous adenocarcinoma in the anastomosis in one patient and abdominal wall metastasis in the other. Importantly, PET/CT revealed true-positive findings in 11 (47.8%) patients who had negative or no definite findings by CT. PET/CT revealed extra-abdominal metastases in 7 patients and additional esophageal carcinoma in one patient. Clinical treatment decisions were changed in 7 (30.4%) patients after introducing PET/CT into their conventional post-operative follow-up program.

**CONCLUSION:** Whole body <sup>18</sup>F-FDG PET/CT was highly effective in discriminating true recurrence in post-operative patients with gastric cancer and had important impacts on clinical decisions in a considerable portion of patients.

## Abstract

**AIM:** To evaluate the clinical role of <sup>18</sup>F-fluorodeoxyglucose positron emission and computed tomography (<sup>18</sup>F-FDG PET/CT) in detection of gastric cancer recurrence after initial surgical resection.

**METHODS:** In the period from January 2007 to May 2008, 23 patients who had previous surgical resection of histopathologically diagnosed gastric cancer underwent a total of 25 <sup>18</sup>F-FDG PET/CT scans as follow-up visits in our center. The standard of reference for tumor recurrence consisted of histopathologic confirmation or clinical follow-up information for at least 5 mo after PET/CT examinations.

**RESULTS:** PET/CT was positive in 14 patients (61%) and negative in 9 (39%). When correlated with final diagnosis, which was confirmed by histopathologic evidence of tumor recurrence in 8 of the 23 patients (35%) and by clinical follow-up in 15 (65%), PET/CT was true positive in 12 patients, false positive in 2, true negative in 8 and false negative in 2. Overall, the accuracy of PET/CT was 82.6%, the negative predictive value (NPV) was 77.7%, and the positive predictive value (PPV) was 85.7%. The 2 false positive PET/CT findings were actually chronic inflammatory tissue lesions. For the two patients with false negative

## INTRODUCTION

Gastric cancer is the second most common cause of cancer death worldwide<sup>[1]</sup>. Within the Asian region, high incidence areas include Japan, China and Korea. It is a major health burden in the Asia-Pacific region<sup>[2]</sup>. Complete surgical resection of gastric cancer is considered potentially curative, but its long-term survival is frequently reported as poor. In fact, despite successful surgery, the five-year survival rate is approximately 35%; and even with adjuvant chemoradiotherapy in selected patients, the survival rate is 40%<sup>[3]</sup>. After curative surgery,

about 80% of the patients die within a short period of time from locoregional recurrence (87%) and/or distant metastasis (30%)<sup>[4]</sup>.

Positron emission tomography (PET) and, particularly, positron emission tomography/computed tomography (PET/CT) are widely accepted imaging methods in the management of a variety of cancers<sup>[5]</sup>. Variable uptake of <sup>18</sup>F-fluorodeoxyglucose (<sup>18</sup>F-FDG) has been noticed in PET studies of gastric carcinoma patients, with low uptake occurring especially in some particular histological subtypes and early carcinomas. Larger or more advanced tumors with nodal involvement have a higher detection rate by PET. In the initial staging of gastric cancer, preoperative PET was useful for the detection of nodal involvement and distant metastasis<sup>[6,7]</sup>. The role of PET/CT in patients with gastric cancer after operation however, is not clear. In this study, we aimed to analyze the value of <sup>18</sup>F-FDG PET/CT scans in the follow up of post-operative patients with gastric cancer.

## MATERIALS AND METHODS

### **Patients**

A retrospective review of our electronic database of 23 post-operative patients with gastric cancer (15 males and 8 female; age range: 27-84 years; mean age: 55.4 years) imaged by <sup>18</sup>F-FDG PET/CT between January 2007 and May 2008 was performed to select and analyze PET/CT scan findings for patients with or without clinically and/or radiologically suspicious findings for tumor recurrence. Only the patients with correlative histopathological data were included. The standard of reference for tumor recurrence consisted of histopathologic confirmation ( $n = 8$ ) or clinical follow-up information ( $n = 15$ ) for at least 5 mo after PET/CT.

### **<sup>18</sup>FDG PET/CT technique**

The patients were asked to fast for at least 4 h before undergoing <sup>18</sup>F-FDG PET/CT. Their blood glucose level should be within the normal range (70-120 mg/dL) prior to intravenous injection of <sup>18</sup>F-FDG. The patients received an intravenous injection of 370-666 MBq (10-18 mCi) of <sup>18</sup>F-FDG. Data acquisition by an integrated PET/CT system (Discovery STE; GE Medical Systems, Milwaukee, WI, USA) was performed within 60 min after injection. The data acquisition procedure was as follows: CT scanning was first performed, from the head to the pelvic floor, with 110 kV, 110 mA, a tube rotation time of 0.5 s, and a 3.3-mm section thickness which was matched to the PET section thickness. Immediately after CT scanning, a PET emission scan that covered the identical transverse field of view was obtained. Acquisition time was 3 min per table position. PET image data sets were reconstructed iteratively by applying the CT data for attenuation correction, and coregistered images were displayed on a workstation.

### **Definitive diagnoses of positive and negative findings**

Reviewer 1 and Reviewer 2, who were aware of other clinical or imaging information, read the <sup>18</sup>F-FDG PET/

**Table 1 Patient characteristics**

Clinical characteristics	Data
Mean age (yr)	55.4
Gender	
Male	15
Female	8
Mean time after operation to PET/CT exam	2 mo-10 yr; mean 25 mo
Mean follow up time after PET/CT exam	5-18 mo; mean 9 mo

CT images on a high-resolution computer screen. The reviewers reached a consensus in cases of discrepancy. Reviewer 1 had 20 years of experience in both nuclear medicine and radiology, and Reviewer 2 had 5 years of experience in both nuclear medicine and radiology. <sup>18</sup>F-FDG PET/CT scan was considered positive or suspicious when abnormal non-physiologic metabolic activity was identified. Focal hypermetabolic activity within the liver which was greater than adjacent normal liver tissue was considered abnormal. Diffuse mild activity in the intestinal tract was considered normal physiologic uptake. Quantification of tumor metabolic activity was obtained using the Standardized Uptake Value (SUV) normalized to body weight. Mean  $\pm$  SD of maximum-pixel SUV (SUVmax) of the lesions were calculated.

## RESULTS

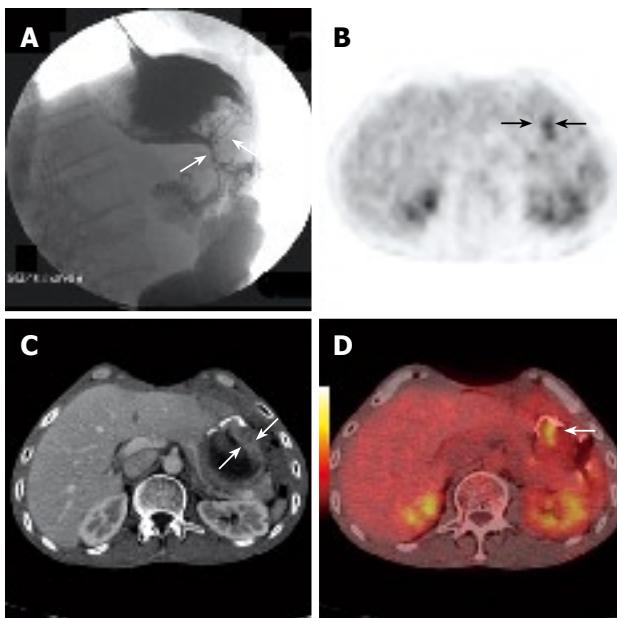

A total of 25 <sup>18</sup>F-FDG PET/CT studies in 23 patients after gastric cancer were reviewed. <sup>18</sup>F-FDG PET/CT was ordered in 12 patients due to suspected disease recurrence on conventional image examinations, on history and physical exam. The remaining 11 patients underwent <sup>18</sup>F-FDG PET/CT as part of routine post-operative follow-up. The characteristics of the patients are summarized in Table 1. At the time of recurrent gastric cancer being suspected, the mean patient age was 57 years with a tendency to male gender distribution (65%). All the patients had undergone surgical resection, with chemotherapy prior to or following the resection. Surgical exploration was undertaken within 1 mo after <sup>18</sup>F-FDG PET/CT scan in 5 patients.

<sup>18</sup>F-FDG PET/CT scan was considered negative in 9 patients (39%) and positive in 14 (61%, Table 2). Final diagnoses were confirmed by histopathologic evidence of tumor recurrence in 8 of the 23 patients (Figure 1) and by clinical follow-up in 15 patients (Figure 2). Overall, the accuracy of <sup>18</sup>F-FDG PET/CT diagnosis was 82.6%, negative predictive value (NPV) was 77.7%, and positive predictive value (PPV) was 85.7%. Of the 14 positive <sup>18</sup>F-FDG PET/CT scans, 12 were true positive and two were false positive. For the two patients with false positive <sup>18</sup>F-FDG PET/CT scans, the final diagnosis was anastomosis inflammation with high metabolism. Seven patients were found to have true negative <sup>18</sup>F-FDG PET/CT scans while two were false negative. For the patients with false negative <sup>18</sup>F-FDG PET/CT scans, the final diagnosis was recurrence of mucinous adenocarcinoma in the anastomosis in one patient and metastasis in the abdominal wall of another patient (Figure 3).

**Table 2** PET/CT findings in 14 patients with positive PET/CT scans

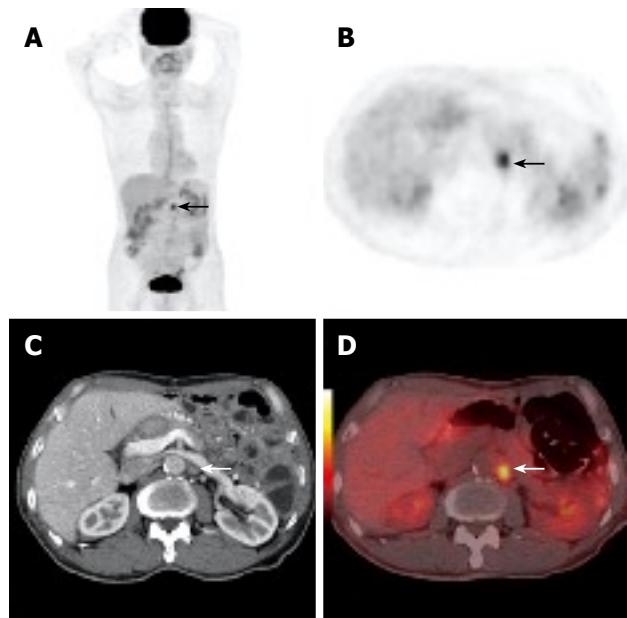

No.	PET/CT findings	SUV max	Pathology of resected GC	Interval time
1	Retroperitoneal lymph nodes	6.0	MPD tubular adeno ca and mucinous adeno Ca	12 mo
2	Retroperitoneal lymph nodes	5.2	PD adeno ca and signet-ring cell Ca	3 mo
	Supraclavicular lymph nodes	6.6		
	Osseous metastasis	3.8		
3	Esophageal carcinoma	14.2	MPD adeno Ca	10 yr
4	Anastomosis recurrence with pancreas involvement	5.6	PD adeno Ca	5 mo
5	Osseous metastasis	2.5	MPD adeno Ca	25 mo
6	Liver metastasis	7.2	MPD signet-ring cell Ca	15 mo
7	Greater omentum lymph nodes	1.3	PD signet-ring cell Ca	8 mo
8	Abdominal wall metastasis	2.5	PD signet-ring cell Ca	24 mo
	Ovarian metastasis			
9	Liver metastasis	5.3	PD adenosquamous Ca	3 mo
	Intraperitoneal lymph nodes	17.6		
10	Abdominal wall metastasis	3.2	MPD adeno Ca	24 mo
11	Intraperitoneal lymph nodes	7.7	MPD adeno Ca	36 mo
12	Brain metastasis	8.1	PD adeno Ca	6 mo
13	Osseous metastasis	12.6	MPD adeno Ca	20 mo
	Retroperitoneal lymph nodes	7.0		
14	Anastomosis recurrence	4.3	MPD adeno Ca	5 mo

MPD: Moderately to poorly differentiated; PD: Poorly differentiated; GC: Gastric cancer; Interval time: Time period from operation to PET/CT scan; Ca: Carcinoma.

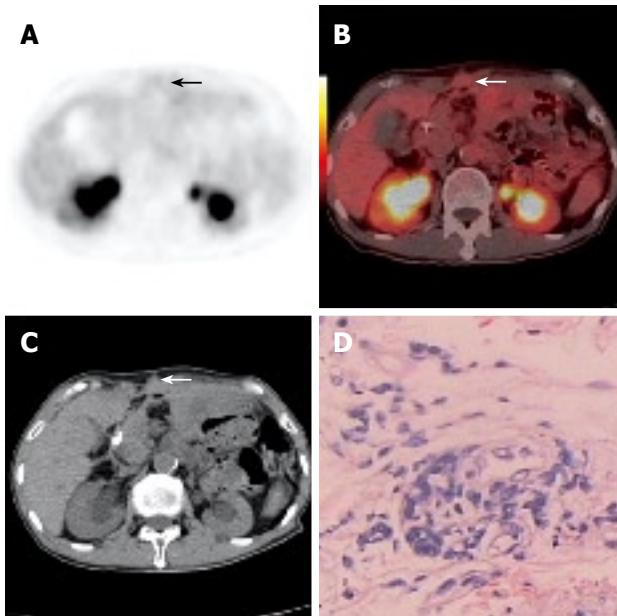

**Figure 1** A 56-year-men who had had gastric cancer resection 3 years previously underwent PET/CT because of suspected disease recurrence upon barium swallow examination (white arrows, A), Axial contrast CT demonstrated local thickened stomach wall at anastomosis (white arrows, C). Axial PET (black arrows, B) and PET/CT fusion images (white arrow, D) showed focal hypermetabolic activity in the remnant stomach, which was later verified as malignant by histopathology.

Importantly, tumor recurrence was revealed in 27.2% (3/11) of the patients who underwent PET/CT as part of routine post-operative surveillance; these patients were asymptomatic, with no evidence of disease. <sup>18</sup>F-FDG PET/CT revealed true-positive findings in 11 patients who had either negative or no definite CT findings. <sup>18</sup>F-FDG PET/CT demonstrated extra-abdominal

**Figure 2** A 75-year-old asymptomatic man who had gastric cancer resection 1 year previously underwent PET/CT as part of routine post-operative surveillance. Whole body PET projection image and axial PET image showed focal hypermetabolic activity in the abdomen (black arrow, A and B). Axial contrast CT detected a small lymph node at the same position (white arrow, C). PET/CT fusion images showed a focus of highly metabolic metastasis in retroperitoneal lymph node (white arrow, D). This was later verified by follow up. The case illustrated the value of early discovery by PET/CT in asymptomatic patients after surgery.

metastases in 7 patients (Figure 4) and new esophageal carcinoma in one patient. Clinical treatment decisions were changed in 7 (30.4%) patients after introducing <sup>18</sup>F-FDG PET/CT into their conventional post-operative follow up program.

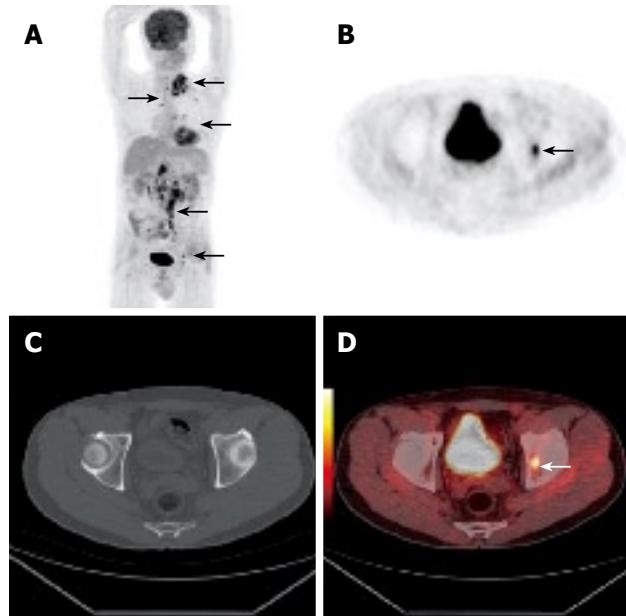

**Figure 3** A 71-year-old asymptomatic man underwent PET/CT as part of routine post-operative surveillance after gastric cancer resection was performed 2.5 years previously. Axial PET and PET/CT fusion images (arrows, **A** and **B**) showed no focal hypermetabolic activity in the abdominal wall. Axial contrast CT (white arrow, **C**) demonstrated local thickness in the abdominal wall. This was later verified as malignant by histopathological assessment of a CT guided core tissue biopsy (**D**).

In our study, 11 (84.5%) cases of recurrence after curative resection occurred within 25 mo and 2 (15.5%) occurred 3 years after the resection. A high percentage of first failures presented as regional nodal metastases and distant metastases. Only 4 (17.3%) patients with recurrence had increased serum tumor markers.

## DISCUSSION

At the time of diagnosis, gastric cancer is found to be localized and surgically resectable in approximately 50% of patients; however, regional nodal metastases or direct invasion into surrounding organs or structures are frequently encountered and preclude cure by surgery alone in many patients<sup>[8,9]</sup>. Analyses of patterns of relapse after complete surgical resection demonstrate that subsequent relapse of cancer is common in the tumor bed and nodal regions as well as all over the body<sup>[10,11]</sup>. The optimal method for assessing early recurrence in patients with gastric cancer is unknown<sup>[12]</sup>. Conventional imaging (ultrasonography, CT and magnetic resonance imaging) has represented the standard for staging and restaging of gastric cancer<sup>[13,14]</sup>. Conventional imaging is noninvasive and is the least costly of the available methods, although it has limited value in differentiating post-surgical changes from local tumor recurrence. Therefore, these techniques have limitations in terms of accurate assessment of re-staging results<sup>[15,16]</sup>.

Modern cancer care is critically dependent on imaging technologies, which are used to detect early tumors and guide their therapy or surgery<sup>[17,18]</sup>. Molecular imaging technologies provide information about the

**Figure 4** A 67-year-old man underwent PET/CT due to clinically suspected disease recurrence in supraclavicular lymph nodes after his gastric cancer resection which was performed 2 mo previously. Whole body PET projection image showed retroperitoneal and supraclavicular metastatic lymph nodes and bone metastasis. (arrows, **A**, **B** and **D**). Axial CT failed to reveal early bone metastasis (**C**).

functional or metabolic characteristics of malignancies, tumor stage and therapeutical response, and tumor recurrence; whereas conventional imaging technologies predominantly assess anatomical or morphologic features of the tumor including its size, density, shape, etc<sup>[19,20]</sup>. There are now various indications for <sup>18</sup>F-FDG PET and PET/CT imaging in gastrointestinal malignancies<sup>[21]</sup>. Detection and staging of recurrent colorectal cancer with <sup>18</sup>F-FDG PET has largely been documented<sup>[22,23]</sup>. However, there is a paucity of data concerning its role in patients with suspected gastric cancer recurrence. In our study, <sup>18</sup>F-FDG PET/CT could be applied reliably in such patients to allow for earlier detection of nodal involvement and distant metastasis in 3 asymptomatic patients. Because most metastatic gastric cancers are inoperable, they are usually treated with combination chemotherapy. Early detection and treatment of tumor recurrence may be the only hope to improve long-term survival and made the early management of recurrent gastric cancer possible in three patients in our study.

<sup>18</sup>F-FDG PET/CT is highly effective in discriminating true recurrence in patients with suspected recurrence, highly sensitive for detecting recurrence in asymptomatic patients, and has important impacts on clinical decisions in a considerable portion of patients<sup>[24]</sup>.

<sup>18</sup>F-FDG-PET is also of benefit in assessing response to neoadjuvant treatment<sup>[25]</sup>. <sup>18</sup>F-FDG PET/CT has been demonstrated as a useful molecular imaging modality to evaluate the biological response of advanced hepatic metastasis and peritoneal carcinomatosis to Cetuximab plus Endostar in patients after remnant gastric cancer resection<sup>[26]</sup>. In our study, there was a 55-year-old male who developed advanced hepatic metastasis and

peritoneal carcinomatosis after resection of remnant gastric cancer resection 3 mo previously. The patient received a treatment only by epidermal growth factor (EGF) receptor antibody (Cetuximab) plus recombinant human endostatin (Endostar). Anti-tumor activity was assessed by <sup>18</sup>F-FDG PET/CT at baseline and every 4 wk thereafter.

<sup>18</sup>F-FDG PET can reveal recurrent sites in the intraperitoneum, liver, lungs, bones and retroperitoneal lymph nodes<sup>[27,28]</sup>. However, the minimum tumor size detectable by PET depended on the sites of recurrence. In the two false-negative cases of intraperitoneal tumors suggested by CT images, <sup>18</sup>F-FDG PET/CT was able to detect a solitary small intraperitoneal mass, which was very difficult to reveal with CT alone<sup>[29]</sup>. <sup>18</sup>F-FDG PET/CT imaging was also able to detect normally sized metastatic lymph nodes in 4 patients with retroperitoneal metastasis. Our results demonstrated that the application of PET/CT imaging was useful for early detection of recurrent sites, especially for decision making in determining treatment strategy for patients with recurrent gastric cancer. Positive PET/CT findings did not affect the prognosis in 7 of the 14 recurrent patients; however, the remaining 7 patients consequently underwent combination therapy consisting of surgery and chemotherapy and survived for more than 10 mo after the positive <sup>18</sup>F-FDG PET/CT results.

Diagnostic contrast-enhanced multiphase CT as part of the combined <sup>18</sup>F-FDG PET/CT protocol has the potential to provide considerable augmented value in specific clinical conditions with resultant change of management in a substantial proportion of patients<sup>[30]</sup>. The greatest benefit of its diagnostic CT is in category localization of pathological FDG uptake and precise tumor delineation, making changes in <sup>18</sup>F-FDG PET/CT interpretation for some patients<sup>[31]</sup>. The reported increase in sensitivity of PET/CT over CT has been attributed to the ability of <sup>18</sup>F-FDG PET to detect metabolic abnormalities that precede the morphologic changes seen by CT. The global (from skull base to proximal thighs) nature of the <sup>18</sup>F-FDG PET/CT study also contributes to the increased sensitivity through detection of distant metastatic lesions. In our study, <sup>18</sup>F-FDG PET/CT demonstrated extra-abdominal metastases (metastases in lymph nodes, the abdominal wall, bones, and the brain) in 7 patients and in one gastric cancer patient who had the comorbidity of a new esophageal carcinoma, which was confirmed by post-operative pathology.

Our study had several limitations. The first was our small sample size which may have limited the robustness of our study in terms of statistics. The second was the retrospective nature of our study. Because of this nature, we were unable to obtain baseline clinical and laboratory data in some of the patients, except for one patient who accepted three PET/CT scans during his treatment. Additionally, there are some disadvantages associated with PET/CT imaging. For example, small, early-stage tumors may go undetected because partial-volume effects result in a falsely low measurement of true <sup>18</sup>F-FDG activity, as was indicated in our

previous report<sup>[32]</sup>. Another drawback of PET/CT is that <sup>18</sup>F-FDG frequently accumulates in areas of inflammation<sup>[33,34]</sup>. In our study, two patients had false positive PET/CT scan results, and the final diagnosis was anastomosis inflammation with high metabolism. Low <sup>18</sup>F-FDG uptake occurred especially in some particular histological subtypes or at special locations. For the two patients with false negative PET/CT findings, the final diagnosis was recurrence of mucinous adenocarcinoma in the anastomosis in one patient and abdominal wall metastasis in the other.

In conclusion, whole body <sup>18</sup>F-FDG PET/CT was highly effective in discriminating true recurrence in gastric cancer patients with suspected recurrence and highly sensitive in detecting recurrence in asymptomatic patients. This had important impacts on clinical decisions in a considerable portion of these patients. Any positive finding in post-operative patients with gastric cancer that could lead to a clinically significant change in patient management should be confirmed by subsequent histopathologic examination because of the risk of false-positive results.

## COMMENTS

### Background

After curative surgery, about 80% of patients die within a short period of time from locoregional recurrence and/or distant metastasis. The optimal method for assessing early recurrence in patients with gastric cancer is not clear. This study aimed to analyze the value of <sup>18</sup>F-fluorodeoxyglucose positron emission tomography/computed tomography (<sup>18</sup>F-FDG PET/CT) in the follow up of post-operative patients with gastric cancer.

### Research frontiers

<sup>18</sup>F-FDG PET and, particularly, <sup>18</sup>F-FDG PET/CT are widely accepted imaging methods in the management of a wide variety of cancers. However, the role of PET/CT in patients with gastric cancer after surgery is not clear.

### Innovations and breakthroughs

Whole body <sup>18</sup>F-FDG PET/CT was highly effective in discriminating true recurrence in gastric cancer patients with suspected recurrence and highly sensitive in detecting recurrence in asymptomatic patients. This had important impacts on clinical decisions in a considerable portion of these patients.

### Applications

The findings could be helpful for early discrimination of true recurrence in gastric cancer patients with suspected recurrence and highly sensitive at detecting recurrence in asymptomatic patients, especially when recurrence can not be accurately diagnosed by conventional imaging.

### Peer review

In this study, the authors reported the clinical significance of <sup>18</sup>F-FDG PET/CT for early discrimination of true recurrence in gastric cancer patients. This manuscript arouses interest for readers and provides an important clue to assess whole body, early recurrence in gastric cancer patients. The paper is scientific and innovative and is for rapid communication part of journal.

## Abstract

**AIM:** To investigate the effects of lentivirus vector mediated short hairpin RNA interference targeting methionine adenosyltransferase 2 $\beta$  gene (LV-shMAT2B) on hepatocellular carcinoma (HCC) cells.

**METHODS:** We constructed four plasmids of RNA interference targeting the MAT2B gene. After LV-shMAT2B was transfected with L-02 cells and two kinds of HCC cells, cell viability and proliferation were measured with MTT and [<sup>3</sup>H]thymidine assays respectively. Flow cytometry was used to assess cell apoptosis. The level of S-adenosyl methionine (SAMe) in HepG2 cells was evaluated. The expressions of cyclin D1, cyclin D2, bcl-x<sub>L</sub> and bcl-x<sub>S</sub> were detected with western blot.

**RESULTS:** We constructed LV-shMAT2B successfully. LV-shMAT2B was safe for human normal liver cells. LV-shMAT2B caused dramatic reduction in proliferation compared with controls in HCC cells Bel-7402 ( $P = 0.054$ ) and HepG2 ( $P = 0.031$ ). Flow cytometry analysis showed that cell apoptosis caused by LV-shMAT2B was greater in HCC cells Bel-7402 and HepG2 than in control induced by scrambled siRNA ( $P = 0.047$ ), but apoptosis rates in L-02 induced by LV-shMAT2B and scrambled siRNA respectively had no significant difference. Moreover, LV-shMAT2B significantly suppressed expression of MAT2B leading to growth-inhibition effect on HCC cells by down-regulating cyclin D1. Apoptosis induced by LV-shMAT2B was involved in

down-regulating bcl-x<sub>L</sub> and up-regulating bcl-x<sub>S</sub>.

**CONCLUSION:** LV-shMAT2B can induce cell apoptosis and growth-inhibition in HCC cells. MAT2B may be a therapy target in HCC in the future.

Wang Q, Liu QY, Liu ZS, Qian Q, Sun Q, Pan DY. Lentivirus mediated shRNA interference targeting MAT2B induces growth-inhibition and apoptosis in hepatocellular carcinoma. *World J Gastroenterol* 2008; 14(29): 4633-4642 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4633.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4633>

## INTRODUCTION

In mammals, methionine adenosyltransferase 1A (MAT1A) and MAT2A encode two homologous MAT catalytic subunits, MAT $\alpha_1$  and MAT $\alpha_2$  respectively. MAT1A is expressed mostly in liver and encodes MAT $\alpha_1$  found in two native MAT isozymes, which are either a dimer (MATIII) or tetramer (MAT I) of this single subunit. MAT2A encodes MAT $\alpha_2$  found in a native MAT isozyme (MAT II) which is associated with a catalytically inactive regulatory subunit ( $\beta$ ) in lymphocytes encoded by the MAT2B gene. MAT2A predominates in the fetal liver and is progressively replaced by MAT1A during liver development<sup>[1,2]</sup>. It has been demonstrated that a switch in MAT expression in liver cancer (from MAT1A to MAT2A) played an important pathogenetic role in facilitating the tumorigenesis of liver cancer<sup>[3]</sup>. The switch in MAT expression of liver cancer is important, because it offers cancerous cells a growth advantage as well as a decrease in intracellular S-adenosyl methionine (SAMe) content. The function of the  $\beta$  subunit is to regulate MATII activity by lowering its  $K_m$  for L-methionine and by increasing the sensitivity of the enzyme to feedback inhibition by SAMe<sup>[4]</sup>. Therefore, regulation

of the expression of the  $\beta$  subunit may be a mechanism to regulate the intracellular content of SAMe. The importance of MAT expression on SAMe level and liver phenotype has been confirmed in the MAT1A knockout mouse model. In this research, the replacement of MAT1A with MAT2A has resulted in chronic hepatic SAMe depletion and eventual development of hepatocellular carcinoma (HCC)<sup>[5,6]</sup>. SAMe has also been found to be antiapoptotic in cultured rat hepatocytes but proapoptotic in human hepatoma cells<sup>[7]</sup>.  $\beta$  subunit has been proved to be associated with cirrhosis and cancer by providing a proliferative advantage in hepatoma cells through its interaction with MAT II  $\alpha_2$  and down-regulation of SAMe levels<sup>[8]</sup>. Since the decreased content of intracellular SAMe has been proved to be related with the increased expression of the MAT2B gene, we wanted to know whether cancerous cell growth advantage or SAMe depletion could be prevented by knockout of MAT2B. So we constructed lentivirus vector mediating RNA interference targeting MAT2B (LV-shMAT2B). The efficacy of siMAT2B plasmids in interference with MAT2B was confirmed by two different ways. We found that LV-shMAT2B promoted growth-inhibition and apoptosis in human hepatocellular cancer cells by markedly increasing the intracellular content of SAMe and the expression of bcl-x<sub>S</sub> and decreasing the expressions of cyclin D1 and bcl-x<sub>L</sub>. But it had no effect on normal liver cells.

## MATERIALS AND METHODS

### **Construction and production of Lentivirus vectors**

The construction and production of Lentivirus vectors were previously described<sup>[9]</sup>. We designed and cloned a short hairpin siRNA template into a lentivirus vector. A third generation of self-inactivating lentivirus vector containing a CMV driven GFP reporter and a U6 promoter upstream of cloning restriction sites (Age I and EcoR II) to allow the introduction of oligonucleotides encoding shRNAs (Figure 1A) was as described previously<sup>[10]</sup>. We constructed the scrambled siRNA (as a control) and four siMAT2B lentivirus vectors, namely LV-shiMAT2B-1, LV-shMAT2B-2, LV-shMAT2B-3 and LV-shMAT2B-4, targeting human MAT2B from corresponding siMAT2B plasmids (pGCL-GFP-siMAT2B). Each hairpin consisted of a 20-21 nt sense sequence, a short spacer (CTCGAG), the antisense sequence, 5Ts (a stop signal for RNA polymerase III), and an Age I site<sup>[10,11]</sup>. The oligos were annealed and inserted between the Age I and EcoR II sites of the plasmid. Some mutations were introduced in the sense sequence of the hairpin structure to facilitate sequence and avoid destruction by bacteria during amplification in bacterial host<sup>[12]</sup>. Correct insertions of shRNA cassettes were confirmed by restriction mapping and direct DNA sequencing. Recombinant lentivirus vectors were produced by co-transfected 293T cells with the lentivirus expression plasmid and packaging plasmids (pHelper 1.0 including gag/pol and pHelper 2.0 including VSVG) using the calcium phosphate

method<sup>[13-15]</sup>. Infectious lentivirus vectors were harvested at 48 and 72 h post-transfection, centrifuged to get rid of cell debris, and then filtered through 0.22 cellulose acetate filters<sup>[16]</sup>. The infectious titer was determined by fluorescence-activated cell sorting analysis of GFP positive in 293 cells. The virus titers were at the range of  $10^9$  transducing units/mL medium.

### **Cell culture and transfection**

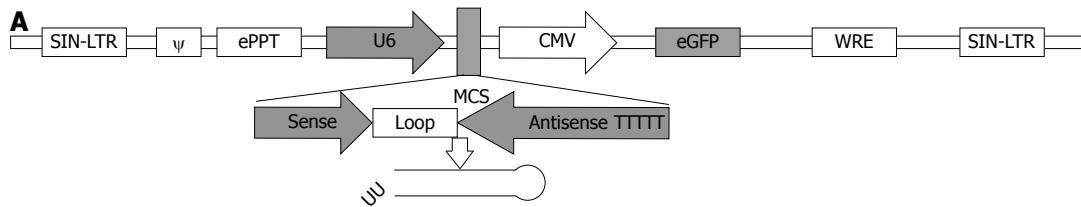

Human hepatocellular cancer HepG2 and Bel-7402 cell lines and normal liver cell L-02 were purchased from Classic Specimen Culture and Storage Centre at Wuhan University. Cells were grown in 5% CO<sub>2</sub> saturated humidity, at 37°C and cultured as monolayers in RPMI 1640 supplemented with penicillin/streptomycin, 2 mmol/L glutamine and 10% FBS. Cells were subcultured at  $1 \times 10^5$  cells per well into six-well tissue culture plates. After 72 h of culture, the cells were transfected with LV-shMAT2Bs (0.5  $\mu$ L per well) formulated into liposomes according to the manufacturer's instructions (TransMessenger™, Qiagen, Valencia, CA; Figure 1B). The final volume of culture medium was 2 mL per well.

### **Knockdown of MAT2B in HepG2 cells by real time-PCR analysis**

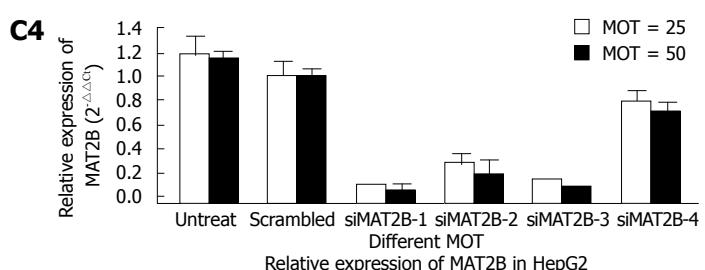

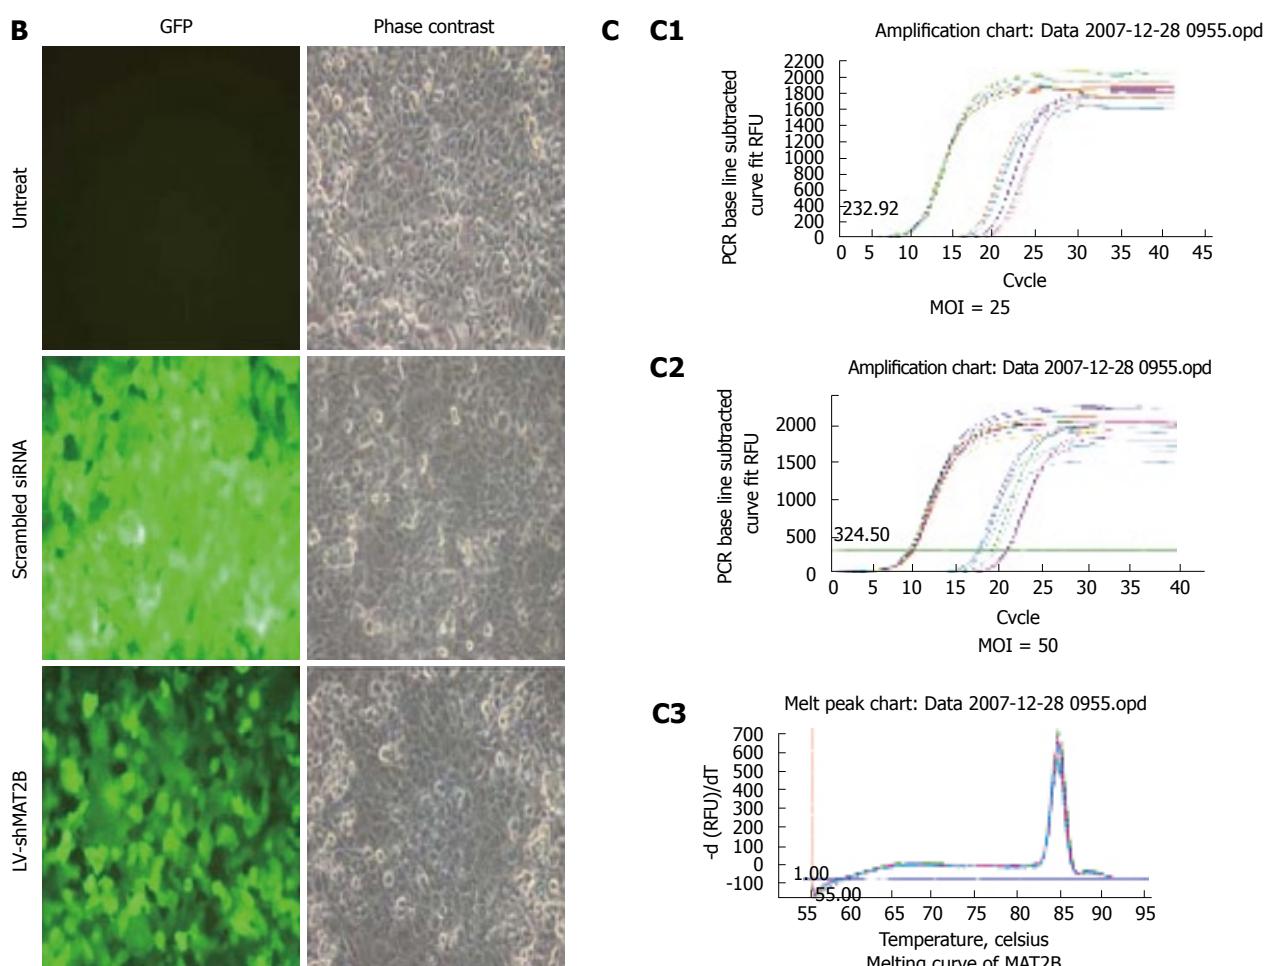

Total RNA was subjected to reverse transcription (RT) with Moloney murine leukemia virus reverse transcriptase (Invitrogen, Carlsbad, CA). Cells were then respectively prepared with scrambled siRNA, and lentivirus vectors such as LV-shMAT2B-1, LV-shMAT2B-2, LV-shMAT2B-3 and LV-shMAT2B-4. Three days after virus infection at the multiplicity of infection (MOI) 25 and 50, the RT products were subjected to quantitative real-time PCR analysis. The primers and TaqMan probes for human MAT2B and universal PCR master mix were purchased from Promega Company. GAPDH was used as a control housekeeping gene. The thermal profile consisted of 1 cycle at 95°C for 15 min followed by 45 cycles at 95°C for 15 s and at 60°C for 30 s. The expression of MAT2B was checked by normalization of the cycle threshold (C<sub>t</sub>) of these genes to that of the control housekeeping gene (GAPDH). The delta C<sub>t</sub> ( $\Delta C_t$ ) = (C<sub>t</sub> of MAT2B) - (C<sub>t</sub> of GAPDH in each group).  $\Delta\Delta C_t$  obtained was used to find the relative expression of MAT2B gene according to the following formula: Relative expression =  $2^{-\Delta\Delta C_t}$ ;  $\Delta\Delta C_t$  = (mean  $\Delta C_t$  of MAT2B genes in siRNAs groups) - ( $\Delta C_t$  of MAT2B genes in different treatment groups). Melting curve of MAT2B was drafted.

### **Western-blot analysis**

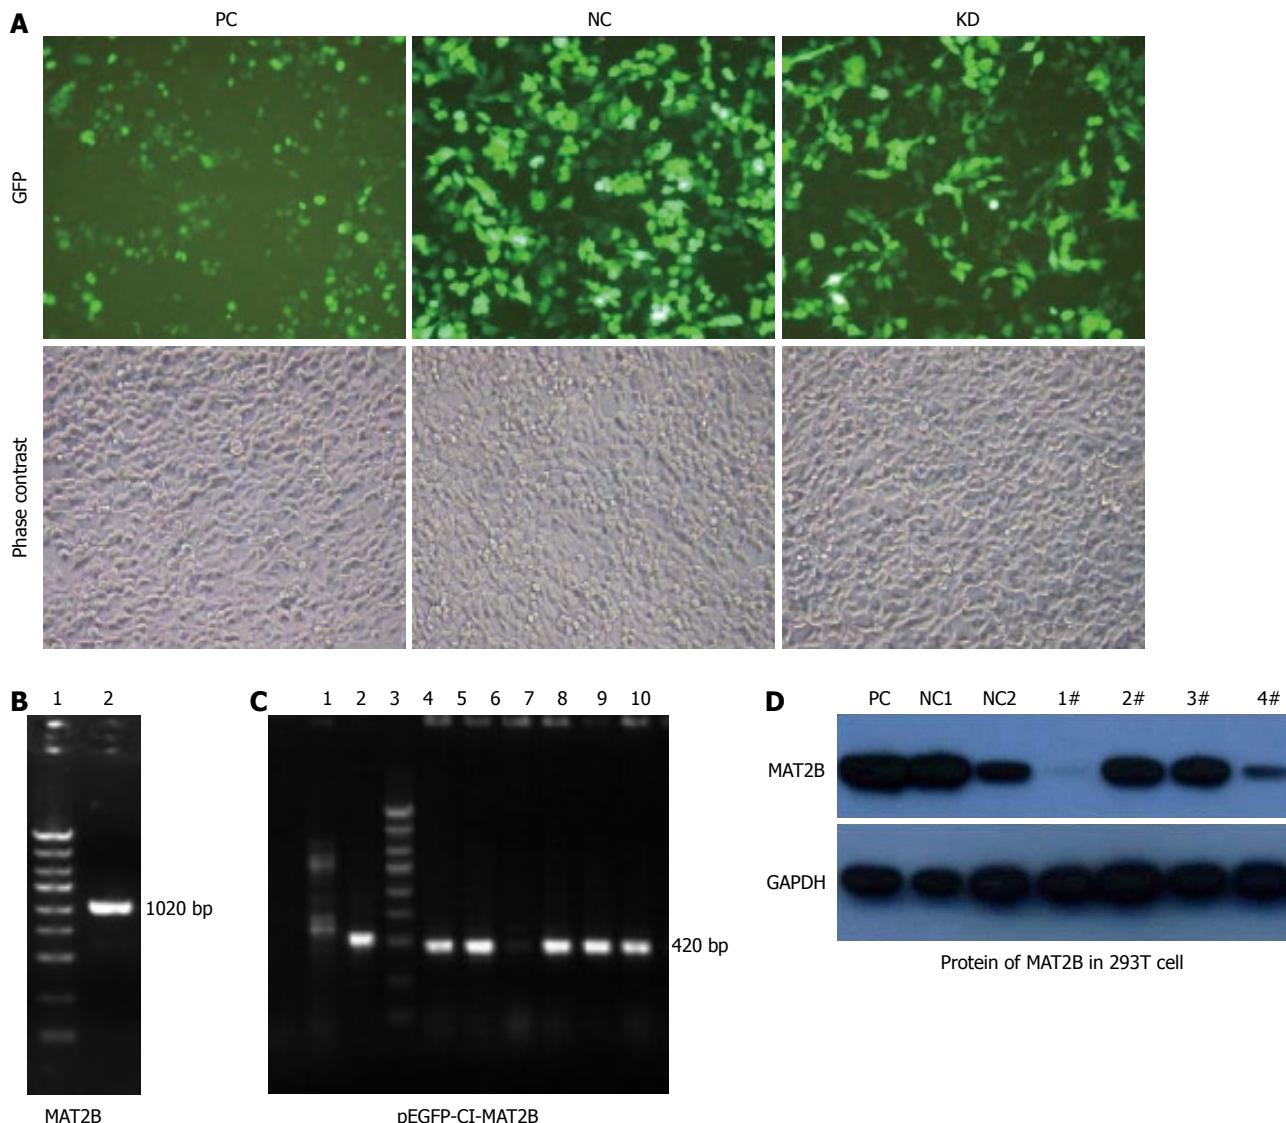

pEGFP-C1-MAT2B was eukaryotic expression plasmid of the MAT2B gene (Figure 2C). Four siMAT2B plasmids (pGCL-GFP-siMAT2B) were co-transfected with pEGFP-C1-MAT2B in 293T cells, respectively. Forty-eight hours after transfection, cells were collected, rinsed in ice-cold PBS 15 min, and lysed in lysis buffer containing 50 mmol/L HEPES (pH 7.9), 0.4 mol/L

**Figure 1** A: Each consist of a hairpin as was demonstrated; B: HepG2 cells were without treatment (untreated), and infected with control lentivirus (scrambled siRNA) or LV-shMAT2B. The cells were infected (MOI = 25), GFP expression and the phase contrast images of the same areas were taken after 72 h. C: mRNA level of MAT2B after HepG2 cell was treated with LV-shMAT2B in different MOI (C1 and C2) detected by real-time PCR (C4), melting curve of MAT2B (C3).

**Figure 2** MAT2B gene was cloned from the cDNA library with production of 1020 bp by PCR (**B**), pEGFP-C1-MAT2B was constructed after restricted enzyme cutting and connection with production of 420 bp by PCR as showed in Figure 2C. Plasmids containing siMAT2B (pGCL-GFP-siMAT2B) were co-transfected with pEGFP-C1-MAT2B in 293T cell, phase contrast and GFP expression under a fluorescent microscope was taken after 72 h (**A**). Protein level of MAT2B in 293T cells was detected by western blot (**D**). pGCL-GFP-siMAT2B-1 and -4 can significantly knock down expression of MAT2B at the protein level (**D**). PC, pcDNA3.1; NC, non-silence control vector. Lanes 1-4: pGCL-GFP-siMAT2B-1, -2, -3 and -4, respectively.

NaCl, 1 mmol/L EDTA, 2 µg/mL leupeptin, 2 µg/mL aprotinin, 5 µg/mL benzamidine, 0.5 mmol/L phenylmethylsulfonyl fluoride and 1% NP40. The lysates were centrifuged at 14 000 r/min to remove any cellular debris. Protein concentrations of the lysates were determined by the Bio-Rad Dc protein assay system which was 2 µg/µL. An equal amount of protein was separated by 12% SDS-PAGE, transferred to PVDF membrane, and blocked with 5% nonfat dry milk in TBS/Tween 20 (0.05% v/v) for 1 h at room temperature. The membrane was incubated with primary antibody overnight. Anti-cyclin D1, anti-cyclin D2 and anti-GAPDH antibodies were obtained from Santa Cruz Biotech Anti-bcl-x<sub>L</sub> and Anti-bcl-x<sub>S</sub> antibodies were obtained from Dako Biotech. Anti-MAT2B was purchased from Abnova Company (Taiwan). After washing, the membrane was incubated with secondary antibody (1:4000, Amersham Pharmacia Biotech

Arlington Heights, IL) for 1 h. After several washes, the blots were developed by enhanced chemiluminescence (Amersham Arlington Heights, IL). Each experiment was repeated at least twice with similar results.

#### Viability assay

Equal numbers of cells per well were seeded into 24-well plates and incubated until 60% confluent and treated with LV-shMAT2B (0.5 µL) or DMSO for 72 h. 3-(4, 5-dimethylthiazole-2-yl)-2, 5-diphenyltetrazolium bromide (MTT, Sigma, St. Louis, MO), 10% weight/volume in phosphate buffered saline was added to each well. After appropriate incubation, cells were washed, lysed with isopropanol and the solubilized product spectrophotometrically quantified at 490 nm.

#### Proliferation assay

Proliferation assay with [<sup>3</sup>H]thymidine. Equal numbers

of cells per well were plated onto 24-well plates and cultured until 60% confluent. Cells were treated with LV-shMAT2B (0.5  $\mu$ L) or DMSO as described above. [ $^3$ H]thymidine was added to the medium for 72 h at 2.5 Ci/mL. Cells were fixed with 0.5 $\mu$ g LV-shMAT2B, rinsed, dried and 1 mL of 0.33 mol/L sodium hydroxide added. [ $^3$ H]thymidine incorporation was measured in a liquid scintillation counting system (Beckman Coulter, Fullerton, CA).

### Flow cytometry

The inducing apoptosis effects of LV-shMAT2B on human hepatocellular cancer cells and normal liver cell (L-02) were analyzed by Flow cytometry. Briefly,  $1 \times 10^5$  cells were trypsinized, then washed with PBS, centrifuged at 800 r/min, fixed with 70% precooling alcohol to the second day, alcohol was extracted by trypsinization at 1000 r/min, the cells were incubated in the solution mixture with PI (100  $\mu$ g), Triton-X100 (0.5%) and RNase (2000  $\mu$ g/mL) 15 min then analyzed by FCM.

### Assay of MATII enzyme activity

Enzyme activity was measured as described previously<sup>[17]</sup>. Protein extracts were obtained from transfected cells by sonicating and then centrifuged at 13000 g for 15 min. Two hundred and fifty  $\mu$ g of protein as determined by the method of Bradford<sup>[18]</sup> was added to the reaction mixture containing 80 mmol/L Tris-HCl (pH 7.4), 50 mmol/L KCl, 40 mmol/L MgCl<sub>2</sub>, 5 mmol/L ATP, 10 mmol/L dithiothreitol, 0.5 mmol/L EDTA, 50  $\mu$ mol/L methionine and 0.3  $\mu$ Ci L-[Methyl-3H] methionine. The mixture was applied to a phosphocellulose paper disc (HA 0.45  $\mu$ m, Millipore) and placed on a filtering system for washing. The disc was added to 10 mL of ScintiVerse E for scintillation counting using a Beckman model LS6000TA Liquid Scintillation Counter (Beckman Instruments, Fullerton, CA, USA). MAT II activity was reported as nmol SAMe formed per mg protein per 40 min.

### Assay of hepatic SAMe levels

Hepatic SAMe levels were measured using a method described previously<sup>[19]</sup> with slight modifications. Liver specimens were homogenized in phosphate-buffered saline, and an aliquot was saved for protein assay. The rest was treated with 100  $\mu$ L of 1 mol/L perchloric acid (PCA) on ice for 5 min and centrifuged at 1000 g for 15 min at 4°C. The aqueous layer was quantitatively removed, neutralized with 3 mol/L KOH and centrifuged at 3000 g for 10 min at 4°C. SAMe levels were determined in the neutralized PCA extracts by HPLC (LC-10ATVP pump, SCL-10AVP system control) with a SPD-10AVP UV detector and a SIL-10ADVP autosampler (Shimadzu) using a Partisil SCX 10  $\mu$ m column (25 cm  $\times$  0.44 cm i.d.; Whatman Chem-Sep, Maidstone, Cleveland). SAMe was eluted isocratically at 1 mL/min with 0.19 mol/L NH<sub>4</sub>H<sub>2</sub>PO<sub>4</sub> adjusted to pH 2.6 with 2 mol/L H<sub>3</sub>PO<sub>4</sub>. SAMe levels were calculated

using a standard curve of SAMe prepared at the same time as the samples and are reported as nmol/mg protein.

### Statistical analysis

Data are expressed as mean  $\pm$  SD, and statistical analyses of the data were performed using ANOVA Post Hoc Dunnett *t* test. Values of *P* < 0.05 were considered to be statistically significant.

## RESULTS

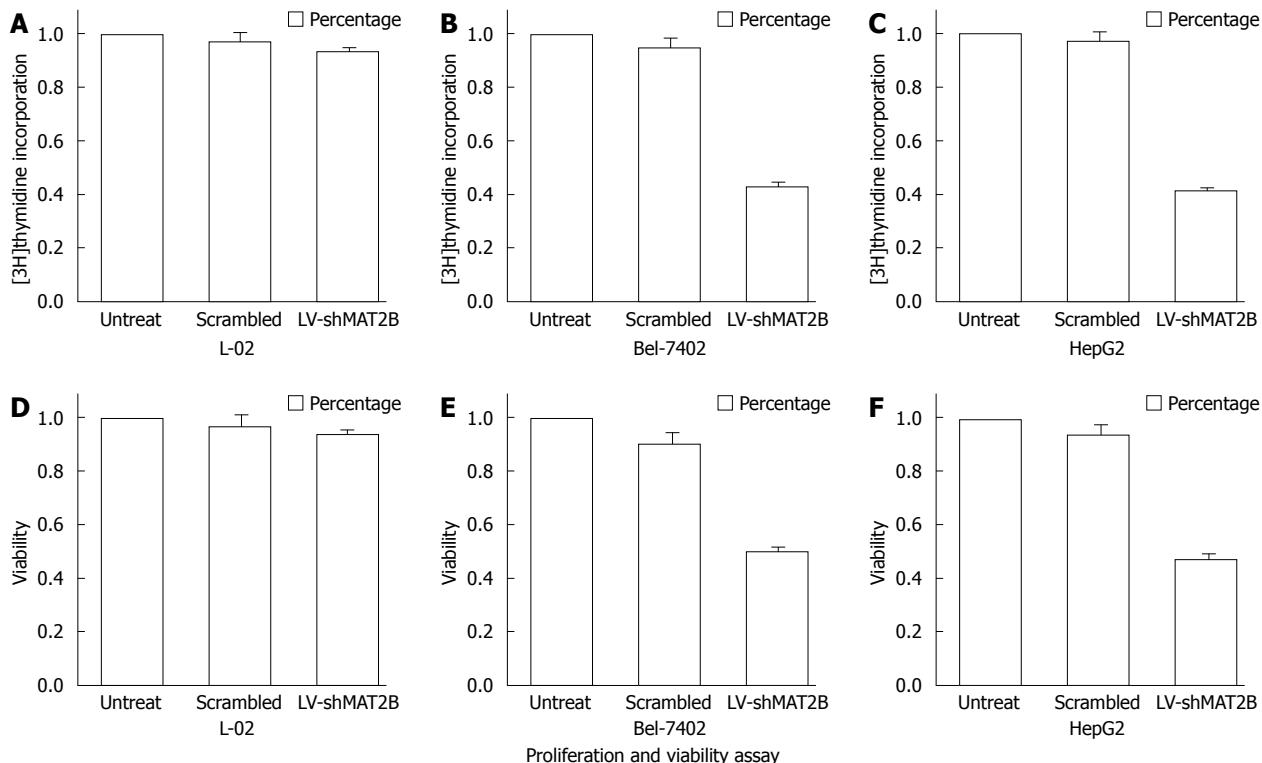

### Expression of MAT2B suppressed by LV-shMAT2B in HCC HepG2 cells *in vitro*

In this research, GFP expression was observed under a fluorescent microscope in HepG2 cells 72 h after infection with LV-shMAT2B at MOI 25 (Figure 1B). Then we performed real time-PCR<sup>[8]</sup> to determine the mRNA level of MAT2B in HCC HepG2 cells *in vitro*. We observed significant suppression of MAT2B by LV-shMAT2B-1 and LV-shMAT2B-3 at two different MOI 25 and 50 (Figure 1C).

Phase contrast and GFP expression was observed (Figure 1B), 72 h after 4 plasmids containing siMAT2B (pGCL-GFP-siMAT2B) co-transfected with pEGFP-C1-MAT2B in 293T cell respectively. Results of a quantitative RT-PCR assay showed that the expression of MAT2B mRNA was reduced by 90% (Figure 2C) when siMAT2B-1 or siMAT2B-3 cotransfected with pEGFP-C1-MAT2B in 293T cells. Results of western-blot assay showed that pGCL-GFP-siMAT2B-1 and pGCL-GFP-siMAT2B-4 could significantly suppress the expression of MAT2B at the protein level in 293T cells (Figure 2D). According to the results of the quantitative RT-PCR and western-blot assays, siMAT2B-1 was the most ideal siMAT2B of the four siMAT2B. Thus LV-shMAT2B-1 corresponding to siMAT2B-1 was used as LV-shMAT2B in the following research.

### Cell viability and proliferation significantly inhibited by LV-shMAT2B in HCC cells

To assess the potential effects of Lentivirus RNAi-mediated MAT2B silencing, we investigated cell proliferation and viability 72 h after L-02 and HCC cells were transfected with LV-shMAT2B. We then examined thymidine incorporation as a measure of DNA synthesis and cell proliferation. MTT assay was used to evaluate cell viability. Value of absorption at 490 nm was obtained. Percentage of cell viability treated with LV-shMAT2B compared with controls was counted. As a result we found that scrambled siRNA had no effect on cell proliferation and viability in all cells (Figure 3), LV-shMAT2B caused dramatic reduction in proliferation (Figure 3B, C) compared with controls in HCC cells Bel-7402 (*P* = 0.054) and HepG2 (*P* = 0.031), but it had no effect on normal liver cells L-02 (Figure 3D). In all HCC cells, significant decrease in viability was observed by MTT assay (Figure 3E, F). We discovered that the growth-inhibition caused by LV-shMAT2B was involved in down-regulation of cyclin D1 by western-blot assay.

**Figure 3** Proliferation of L-02 cell and HCC cells Bel-7402, HepG2 were shown in Figure 3A-C. The relative value of [ $^3\text{H}$ ]thymidine incorporation was measured after cells were treated with LV-shMAT2B. Percentage cell viability of L-02 cells and HCC cells Bel-7402, HepG2 were counted with MTT after cells were treated with LV-shMAT2B Figure 2D-F. It was seen that LV-shMAT2B can inhibit cell viability and proliferation of HCC cells but had no effect on normal liver cells.

#### Apoptosis induced by LV-shMAT2B in HCC cells

To investigate the effects of LV-shMAT2B on cell death, apoptosis rate was evaluated with flow cytometry analysis. Seventy-two hours after hepatoma cells were transfected with LV-shMAT2B, the sub-G1 population of apoptotic cells was determined. Results from analysis of L-02, Bel-7402 and HepG2 cells showed that apoptosis rates were  $10.1\% \pm 1.9\%$ ,  $26.3\% \pm 2.1\%$  and  $32.6\% \pm 3.7\%$ , in the presence of LV-shMAT2B, respectively. Flow cytometry analysis also showed cell apoptosis caused by LV-shMAT2B was greater in HCC cells Bel-7402 and HepG2 than in control cells induced by scrambled siRNA ( $P = 0.047$ ), but apoptosis rates in L-02 induced by LV-shMAT2B and scrambled siRNA, respectively, had no significant difference (Figure 4). Results of western-blot indicated that LV-shMAT2B caused the apoptosis in HCC cells by decreasing the expression of  $\text{bcl-x}_L$  and increasing the expression of  $\text{bcl-x}_S$ .

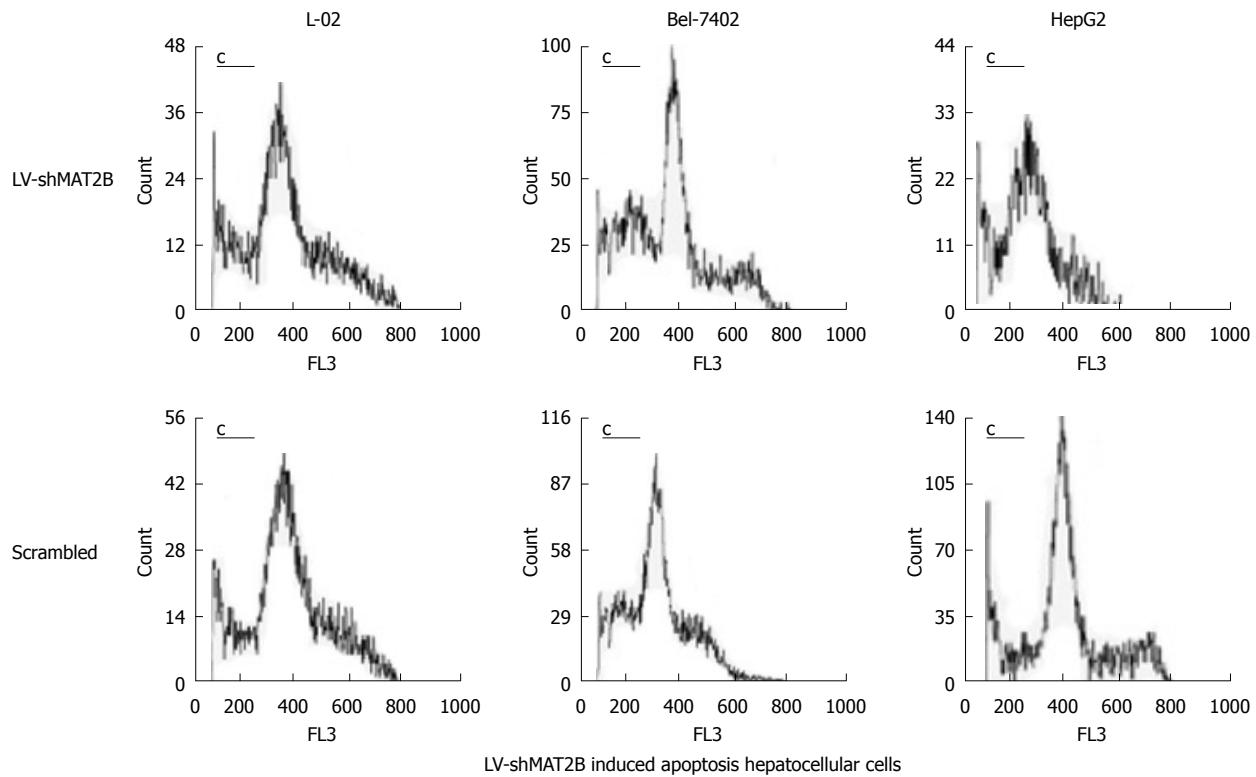

#### Decreased MAT II enzyme activity and increased intracellular SAMe content caused by LV-shMAT2B in HCC cells

To determine the effect of LV-shMAT2B on enzymatic activity of MAT II, HepG2 and Bel-7402 cells were transfected with LV-shMAT2B. At different time points after transfection, protein extracts were prepared, enzyme activity assays were performed. Results from Liquid Scintillation Counter analysis indicated that MAT II enzyme activity was gradually decreased from

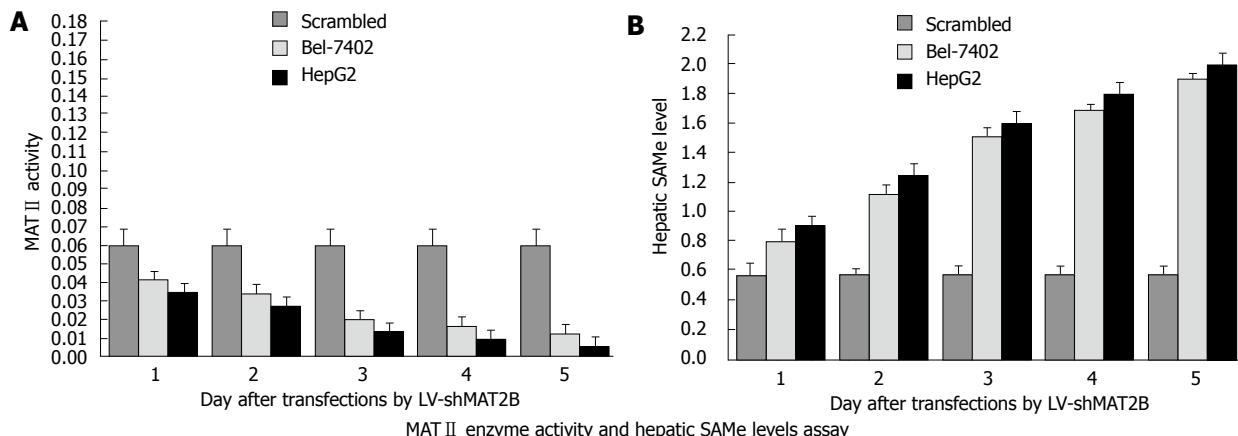

1 d to 5 d in a time-dependent manner, but remained relatively unchanged in cells treated with scrambled siRNA (Figure 5A). These data demonstrated that LV-shMAT2B significantly inhibited MAT II enzyme activity in Bel-7402 and HepG2 cells. The changes in MAT gene's expression were likely to cause changes in the production of SAMe. To analyze the effect of LV-shMAT2B on SAMe production, we measured the contents of SAMe in HCC cells. Results from reverse-phase high performance liquid chromatography analysis showed that the intracellular content of SAMe in cells transfected with scrambled siRNAs was low at  $0.58 \pm 0.05$  (nmol/mg protein), and increased to  $1.89 \pm 0.13$  in HepG2 and  $1.81 \pm 0.17$  in Bel-7402 after they were treated with LV-shMAT2B in a time-dependent manner ( $P = 0.0071$ , Figure 5B).

#### Down-regulation of cyclin D1 and $\text{bcl-x}_L$ by LV-shMAT2B in HCC cells

It has been indicated that the  $\beta$  subunit provided a proliferative advantage in HCC cells and this effect could be mediated through its interaction with MAT II  $\alpha_2$  and down-regulating SAMe levels. SAMe inhibited HGF-dependent induction of cyclin D1 and cyclin D2 expression without affecting the activation of extracellular signal-regulated protein kinase (ERK)<sup>[20]</sup> and SAMe is proapoptotic in HCC cells *in vitro* by promoting the expressions of  $\text{bcl-x}_L$  and  $\text{bcl-x}_S$ <sup>[21]</sup>. Our results showed that LV-shMAT2B could down-regulate the protein levels of cyclin D1 (Figure 6B) and  $\text{bcl-x}_L$

**Figure 4** Cell apoptosis caused by LV-shMAT2B was increased in human hepatocellular cancer cells Bel-7402 and HepG2 compared to controls induced by siRNAs, but they all had no impact on the normal hepatic cell (L-02) which does not express MAT2B.

**Figure 5** MAT II enzyme activity was gradually decreased from 1 d to 5 d in a time-dependent manner after transfected with LV-shMAT2B, but remained relatively unchanged in cells treated with siRNAs. In human cancer cells Bel-7402 and HepG2 (A), Hepatic SAMe level in the two HCC cells were increased by LV-shMAT2B in a time-dependent manner, but remained relatively unchanged in cells treated with siRNAs (B).

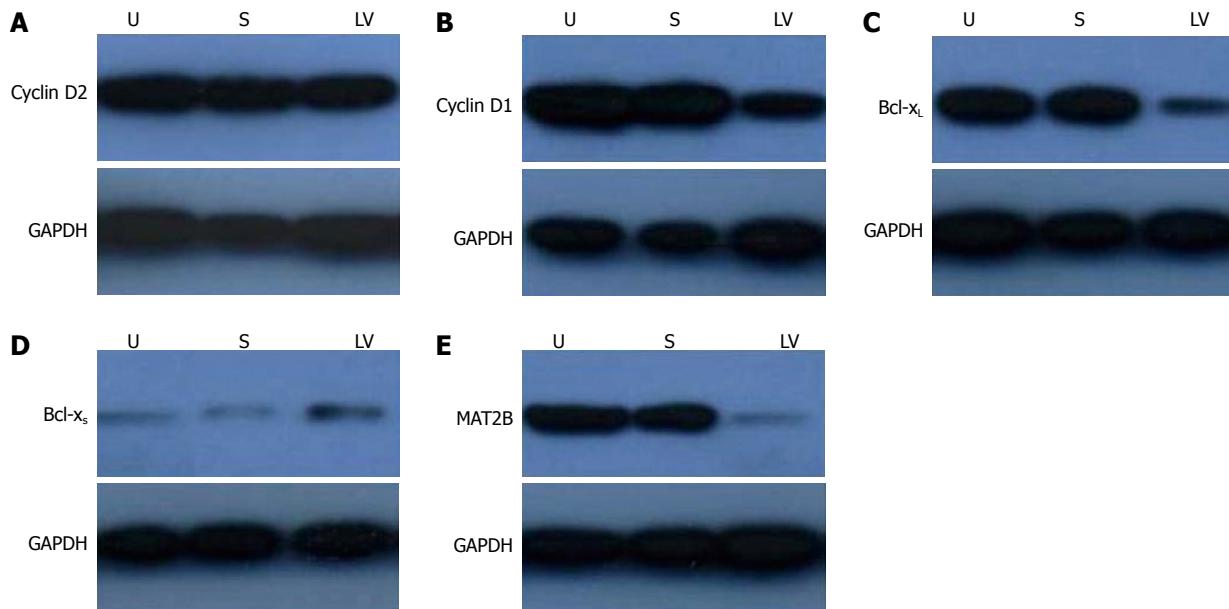

(Figure 6C) in human liver cancer cells. LV-shMAT2B increased the expression of bcl-x<sub>S</sub> (Figure 6D) but had no effect on cyclin D2 (Figure 6A).

#### Expression of MAT2B suppressed by LV-shMAT2B in protein level in HepG2 cells

To investigate the effect of LV-shMAT2B on HCC cells, we also detected the protein level of MAT2B in HepG2 cells. There was no expression of MAT2B after it was treated with LV-shMAT2B (Figure 6). This demonstrated that expression of MAT2B was suppressed by LV-shMAT2B.

## DISCUSSION

It was demonstrated that a switch in MAT expression in liver cancer was accompanied with increasing expression of MAT2B which encoded the  $\beta$  subunit. The  $\beta$  subunit is associated with MAT II and MAT2B is not expressed in normal liver. The expression of MAT2B is increased in liver cirrhosis and hepatocellular carcinoma, and chronic hepatic SAMe deficiency leads to malignant degeneration<sup>[22]</sup>. Recently there was also a report that hepatocyte growth factor (HGF) could promote proliferation of hepatoma cells by up-regulating the expression of MAT2B<sup>[23]</sup>. Leptin used to be taken as an

**Figure 6** After HepG2 cells were transfected with LV-shMAT2B for 72 h, western blot was used to detect the protein levels of cyclin D1 and cyclin D2, bcl-x<sub>L</sub> and bcl-x<sub>S</sub>, results show the expressions of cyclin D1 (B) and Bcl-x<sub>L</sub> (C) were decreased compared to controls and untreated cells. The expression of bcl-x<sub>S</sub> (D) was increased but that of cyclin D2 did not change (A). The expression of MAT2B was suppressed by LV-shMAT2B significantly (E). U, untreated HepG2 cell; S, HepG2 cell treated with scrambled siRNA; LV, HepG2 cells treated with LV-shMAT2B. The protein level of MAT2B was measured by western blot.

adipokine shown to be mitogenic in human liver cancer cell lines HepG2 and Huh7, and its mitogenic effect was also related with the expression of MAT2B.

In order to find the role played by MAT2B in HCC, we suppressed MAT2B in HCC cells using the RNAi method. The inhibitory potency and the method of transferring siRNA into HCC cells were two critical factors for successful application of RNAi method. shRNAs were proved to provide long-lasting silencing and maximal inhibition of gene expression at lower concentration<sup>[24,25]</sup>. Inhibitory potency of shRNA was related to specificity of the targeting sequence, so we used two different methods to confirm the efficacy of siMAT2B in HepG2 cells and in 293T cells. Then we selected siMAT2B-1 which could knock out the expression of MAT2B in both methods. Thus we decided to use LV-siMAT2B-1 as LV-shMAT2B in following research. In this research we found that LV-shMAT2B could suppress the expression of MAT2B at the level of both mRNA and protein in HCC. LV-shMAT2B could dramatically decrease cell proliferation and viability as well as increase cell apoptosis in Bel-7402 and HepG2 cells, but it had no effect on normal liver cell L-02 which had no expression of MAT2B. We concluded that LV-shMAT2B had a high specificity for MAT2B.

In this research we chose lentivirus vector as our shRNAs delivery vehicle because lentivirus could transfect both dividing and nondividing cells at a high efficiency and sustain long-term gene expression by integrating into the host genome. It was shown that the suppression of MAT2B caused by LV-siMAT2B was in a MOI-dependent manner. Significant inhibitory effects were found at MOI of 25 and 50, where

the expression of MAT2B was all reduced by 90%. Lentivirus vector is also safe for humans. Lentivirus vector encoding antisense targeting HIV envelope sequence has been used for HIV treatment in clinical trials with no obvious side effects<sup>[26,27]</sup>. Most recently, lentivirus vector containing beta-globin gene has been approved in phase I / II clinical trials for human beta-thalassemia and sickle cell anemia gene therapy<sup>[28]</sup>. The MAT2B's expression is very important because it not only can provide a proliferative advantage in hepatoma cells but can also decrease intracellular SAMe content. It was discovered that transfection with  $\beta$  subunit reduced the cellular content of SAMe in HuH7 cells, on the contrary we suppressed the expression of MAT2B by LV-shMAT2B, which resulted in decreased activity of MATII and increased content of SAMe. We found that their changes were all time-dependent. SAMe was antiapoptotic in cultured rat hepatocytes but proapoptotic in human hepatoma cells<sup>[7]</sup>. LV-shMAT2B could induce apoptosis of HCC cells but had no impact on normal liver cells, the reason might be that there was no expression of the MAT2B gene in normal liver cells. It was demonstrated that induction mRNA of bcl-x<sub>S</sub> by SAMe in HepG2 cells resulted in apoptosis, but SAMe had no effect on expression of bcl-x<sub>L</sub><sup>[29]</sup>. We discovered that the protein level of bcl-x<sub>S</sub> was increased and the expression of bcl-x<sub>L</sub> was down-regulated by LV-shMAT2B. We supposed that it might be related to cellular stress brought on by LV-shMAT2B, bcl-x<sub>L</sub> was able to induce apoptosis in response to cellular stress<sup>[30]</sup>. We found that LV-shMAT2B prevented proliferation in HepG2 cells, Leptin could induce proliferation in human hepatocarcinoma cells by up-regulating cyclin D1<sup>[31]</sup> but Komal<sup>[30]</sup> found that Leptin could increase SAMe levels

in HepG2 cells. On the contrary, SAMe was believed to inhibit the expressions of cyclin D1 and cyclin D2<sup>[20]</sup>. It was indicated in our research that the expression of cyclin D1 was decreased, so we considered that the down-regulation of cyclin D1 may be caused by knocking down of MAT2B, but not by increasing SAMe. We also found that the decreased activity of MAT II was caused by LV-shMAT2B. The  $\beta$  subunit associated with cirrhosis and cancer could provide a proliferative advantage in hepatoma cells through its interaction with MAT II  $\alpha_2$  and down-regulate SAMe level<sup>[8]</sup>. When the MAT2B gene was knocked out, the interaction between  $\beta$  and  $\alpha_2$  subunit was interrupted. As a result, the activity of MAT II decreased and SAMe level increased time-dependently, the proliferative advantage induced by MAT2B was prevented by LV-shMAT2B.

On the whole, we found that the suppression of MAT2B with LV-shMAT2B could lead to growth-inhibition and apoptosis in HCC cells. We concluded that the MAT2B gene could be used as a therapy target for hepatoma in the future.

## COMMENTS

### Background

It was demonstrated that a switch in methionine adenosyltransferase (MAT) expression in liver cancer played an important pathogenetic role by facilitating liver cancer growth. MAT2A encodes a catalytic subunit ( $\alpha_2$ ) found in a native MAT isozyme (MAT II) which is associated with a catalytically inactive regulatory subunit ( $\beta$ ) encoded by MAT2B. It has been proved that  $\beta$  subunit is associated with cirrhosis and cancer providing a proliferative advantage in hepatoma cells through its interaction with MAT II  $\alpha_2$  and down-regulation of S-adenosyl methionine (SAMe) levels. We supposed that suppression of MAT2B may result in growth-inhibition and increasing of SAMe which could induce hepatoma cells into apoptosis and we wanted to find the mechanism.

### Research frontiers

We found that expression of MAT2B in hepatic cancer HepG2 cells were decreased by 90%. Suppression of MAT2B in hepatocellular carcinoma (HCC) cells significantly induced their growth-inhibition by down-regulation of cyclin D1. Apoptosis was induced by LV-shMAT2B involving down regulation of bcl-x<sub>S</sub> and up-regulation of bcl-x<sub>L</sub>.

### Innovations and breakthroughs

LV-shMAT2B could induce HCC cells into apoptosis but had no impact on normal liver cells, which may occur because there is no expression of the MAT2B gene in the normal liver cell. It has been demonstrated that induction mRNA of bcl-x<sub>S</sub> by SAMe in HepG2 cells resulted in apoptosis but SAMe had no effects on expression of bcl-x<sub>L</sub>. We discovered that protein level of bcl-x<sub>S</sub> was increased and the expression of bcl-x<sub>L</sub> was down-regulated by LV-shMAT2B. We considered that the down-regulation of cyclin D1 may be caused by knocking down MAT2B but not because of increasing of SAMe.

### Applications

Lentivirus vector is also safe for humans. Lentivirus vector encoding the antisense targeting HIV envelope sequence has been used for HIV treatment in clinical trials with no obvious side effects. Most recently, lentivirus vector containing beta-globin gene has been approved in phase I / II clinical trials for human beta-thalassemia and sickle cell anemia gene therapy. What is, more LV-shMAT2B could induce HCC cells into apoptosis but had no impact on normal liver cells.

### Peer review

The manuscript written by Wang et al reports that knockdown of MAT2B by transfection of lentivirus vector carrying siRNAs inhibits the growth of human hepatocellular cell lines but not that of human normal liver cells. The data are interesting and provide potentially important new clues for the future treatment of HCC. However, there are some points which need to be addressed.

19 years), 749 healthy controls, and 546 healthy parents (273 trios) were included in the study. The rs2241880 [*autophagy-related 16-like 1 (ATG16L1)*], rs11209026 and rs7517847 [*interleukin 23 receptor (IL23R)*], rs2066844, rs2066845, rs2066847 (*CARD15*), rs1050152 (*OCTN1*), and rs2631367 (*OCTN2*) gene variants were genotyped.

**RESULTS:** The frequency of G allele of *ATG16L1* SNP (Ala197Thr) was increased in patients with CD compared with controls (59% vs 54% respectively) (OR = 1.25, CI = 1.08-1.45, P = 0.003), but not in UC (55%). The frequency of A and G (minor) alleles of Arg381Gln, rs11209026 and rs7517847 variants of *IL23R* were reduced significantly in CD (4%, OR = 0.62, CI = 0.45-0.87, P = 0.005; 28%, OR = 0.64, CI = 0.55-0.75, P < 0.01), compared with controls (6% and 38%, respectively). The A allele (but not G) was also reduced significantly in UC (4%, OR = 0.69, CI = 0.5-0.94, P = 0.019). No association was demonstrated with sub-phenotypes and interaction with *CARD15*, and *OCTN1/2* genes, although both gene variants were associated with pediatric-onset disease.

**CONCLUSION:** The present study confirms the association of *IL23R* polymorphisms with IBD, and *ATG16L1* with CD, in both adult- and pediatric-onset subsets in our study population.

## INTRODUCTION

Inflammatory bowel disease (IBD) is a polygenic trait that includes two similar, yet distinct conditions, namely Crohn's disease (CD) and ulcerative colitis (UC)<sup>[1]</sup>. It is widely accepted that both diseases result from an inappropriate response of a defective mucosal immune system to indigenous flora and other luminal agents in a genetically susceptible host<sup>[2]</sup>.

Eleven IBD genome-wide linkage analyses in families with multiple IBD affected members, as well as two different meta-analyses<sup>[3,4]</sup> have identified several linkage regions<sup>[5]</sup>. Following the identification of *NOD2* (or *CARD15*), the first gene contributing to CD susceptibility (IBD1 locus), further fine mapping studies have identified a risk haplotype (IBD5 locus) on chromosome 5q<sup>[6]</sup>, along with two polymorphisms in the solute carrier family 22A4/22A5 (*SLC22A4/A5*) coding for *OCTN1* and *OCTN2*, suggested as candidate genes<sup>[7]</sup>, and another polymorphism on the *disk large homolog 5 (DLG5)* gene<sup>[8]</sup>. However, these risk-associated variants and several others reported<sup>[9-13]</sup> with conflicting results, explain only a minor component of the genetic risk in IBD.

Whole genome association (GWA) studies in IBD have rapidly led to the identification of novel susceptibility loci associated with CD<sup>[14]</sup>, such as *interleukin-23 receptor (IL23R)* and *autophagy-related 16-like 1 gene (ATG16L1)*. An uncommon coding mutation (rs11209026) in the *IL23R* gene<sup>[15]</sup> on chromosome 1 (1p32.1-p31.2), a G-to-A transition at nucleotide 1142 (Arg381Gln), has been identified to confer strong protection against CD in case-control ( $P = 5.05 \times 10^{-9}$ ) and family-based studies of Caucasian and Jewish cohorts with ileal CD. Further, GWA<sup>[16-19]</sup> and replication studies<sup>[1,2]</sup> have consistently confirmed strong association between variations at *IL23R* and CD. The intronic rs7517847 SNP (single nucleotide polymorphism) gave the most significant signal ( $P = 3.36 \times 10^{-13}$ )<sup>[15]</sup>. The association of this variant appeared statistically independent from Arg381Gln and not in linkage disequilibrium ( $r^2 = 0.03$ )<sup>[15]</sup>. A large number of replications in adult<sup>[20-24]</sup> and pediatric-onset<sup>[25-29]</sup> cohorts have been reported, but no significant association with specific CD sub-phenotype has been identified. Moreover, an association with UC has also been observed<sup>[23,24,28,30,31]</sup>.

In a recent German GWA scan<sup>[32]</sup>, the non-synonymous rs2241880 (Ala197Thr) variant of *ATG16L1* on chromosome 2p37.1 was found to be associated with CD, and appeared to account for all of the disease risk conferred by this locus. This association has been consistently demonstrated in a number of independent studies in adult<sup>[24,33-36]</sup> but with conflicting data in pediatric<sup>[34,37,38]</sup> IBD cohorts.

The aims of the present study were to investigate the association between variants of two candidate genes

*IL23R* and *ATG16L1* and IBD in an Italian cohort. In addition, we examined the genotype-phenotype correlation with specific disease subtypes, including the early onset of disease, and the possible genetic interactions with *OCTN1/2*, and *CARD15* genes.

## MATERIALS AND METHODS

### Materials

The study population included 763 CD and 843 UC unrelated patients recruited from four referral centers for adult IBD: the "Casa Sollievo della Sofferenza" Hospital of San Giovanni Rotondo, and the University Hospitals of Padua, Naples and Milan. In addition, 368 patients with pediatric onset of disease (age at diagnosis < 19 years) were included in the study because of a multi-center effort of the Italian Society of Pediatric Gastroenterology, Hepatology and Nutrition (SIGENP). This study cohort has been reported elsewhere<sup>[39]</sup>. Two hundred and seventy-three IBD patients also had both parents available for the purpose of a family-based analysis. The 749 healthy controls (415 male, mean age  $43 \pm 11$  years, range 22-75) were randomly recruited from three sites: San Giovanni Rotondo (Southern Italy,  $n = 451$ ), Rome (Central Italy,  $n = 114$ ) and Milano (Northern Italy,  $n = 184$ ), in order to minimize potential geographic heterogeneity. These subjects comprised of unrelated, asymptomatic individuals (blood donors, students, and staff members), all Caucasians with no Jewish descent. The study protocol was approved by the local Ethics Committees, and a written informed consent was obtained from each subject (or parents).

Demographic and sub-phenotype data of IBD patients are presented on Table 1. The diagnosis of CD and UC was established according to accepted clinical, endoscopic, radiological, and histological criteria<sup>[1]</sup>. The Montreal<sup>[40]</sup> classification was used for CD, based on the age at diagnosis (A), location (L), and disease behavior (B). In patients with UC, the disease location was categorized according to the Montreal classification, by distinguishing ulcerative proctitis (E1), left-side colitis (E2), and extensive colitis (E3). Patients with indeterminate colitis were excluded from the study. In all patients, the following clinical features were recorded: family history, age at diagnosis, duration of follow-up, presence of perianal fistulae, extraintestinal manifestations (presence or absence of any extraintestinal manifestation), previous abdominal surgery (either colectomy in UC or bowel resection in CD), and smoking habit (at least 1 cigarette/d). To account for the known modification of clinical characteristics during the disease course, only patients with at least two years of follow-up from the time of a confirmed diagnosis were included in the genotype/phenotype analysis.

### Methods

Genotyping of rs11209026 (*IL23R*), rs7517847 (*IL23R*), rs2241880 (*ATG16L1*), rs10150152 (*OCTN1*) and rs2631367 (*OCTN2*)<sup>[41]</sup> SNPs was performed using Applied Biosystems 7700 TaqMan assay

(Applied Biosystems, Foster City, CA). The *CARD15* variants were detected by means of Denaturing High Performance Liquid Chromatography (DHPLC) (Wave System, Transgenomic Ltd, UK) (R702W, L1007fsinsC) and RFLP (G908R), respectively, as described previously<sup>[39]</sup>. PCR reactions were carried out in 96-well plates on ABI 9700 Thermocyclers (Applied Biosystems, Foster City, CA). All samples were genotyped at the Molecular Laboratory of Gastroenterology Unit in San Giovanni Rotondo Hospital, Italy.

For the purpose of statistical analysis, after genotyping the markers, the Hardy-Weinberg equilibrium was tested by comparing the expected and observed genotypes in  $2 \times 3 \chi^2$  tables. All markers showed no deviation from the Hardy-Weinberg equilibrium in controls ( $P > 0.05$ ). Allele-genotype frequencies and genotype/phenotype association were analysed by  $\chi^2$  and Fisher exact tests, when appropriate, by the SPSS software ver 1.5. The Hardy-Weinberg equilibrium and marker linkage disequilibrium analysis were also performed by the Arlequin software ver 2.0. Pairwise SNP linkage disequilibrium (LD) coefficients, haplotype frequencies, and Transmission Disequilibrium Test (TDT) were estimated using Haplovview<sup>[42]</sup>. Logistic regression analysis was used to assess the conditional independence between genotypes and IBD phenotypes and to test for gene-gene interactions. The frequencies and odds ratios of individual *CARD15* genotypes were stratified by *ATG16L1* (rs2241880) and *IL23R* (rs1209026); and *IL23R* genotypes were stratified by *ATG16L1* genotypes. An interaction was considered significant at  $P < 0.05$ .

## RESULTS

### Patients and controls

A total of 2901 subjects were investigated. These comprised of 763 patients with CD (435 males and 328 females), with a mean age at diagnosis of 29 years (range 1-79), and 843 patients with UC (492 males, 351 female), with a mean age at diagnosis of 32 years (range 1-76 years). In addition, 749 healthy controls and 546 healthy parents were also evaluated. Of note, 368 patients (180 male) were diagnosed at the age of 18 years or less.

### Genotyping of *ATG16L1* variant in IBD patients

The evaluation of the T300A polymorphism (rs2241880) was available in 667 CD and 668 UC patients: the frequency of the G allele was increased in CD patients compared with controls (59% vs 54%) ( $P = 0.003$ , OR = 1.25, CI = 1.08-1.45) (Table 2). Accordingly, by comparing genotype frequencies (Table 2), a significant increase in carriers of G risk allele was found in CD patients compared to controls (84% vs 79%) ( $P = 0.008$ , OR = 1.44, CI = 1.10-1.89). After stratifying the CD cohorts on the basis of age at diagnosis (adult  $\geq 19$  years; pediatric  $< 19$  years), the allele/genotype difference remained significant only in the adult subgroup ( $P = 0.004$ ), perhaps due to the small sample size of the pediatric subgroup, although the frequencies were similar.

There was no significant difference in the allele and genotype frequencies between UC patients and controls for the groups as a whole and after stratifying on the basis of pediatric and adult age at diagnosis.

### Genotyping of *IL23R* variants in IBD patients

A total of 723 CD, 804 UC, and 716 controls were genotyped for the rs7517847 polymorphism. The minor allele (G) frequency was significantly reduced (28%) in CD cases compared with controls (38%) ( $P < 0.01$ , OR = 0.64, CI = 0.55-0.75), with a significant reduction in carriers (49% vs 61% in controls) ( $P < 0.01$ , OR = 0.63, CI = 0.51-0.77) (Table 2). These differences remained significant after stratification of the patients on the basis of age at diagnosis. In contrast, no significant difference in allele and genotype frequencies was found in UC patients (Table 2).

A total of 735 CD and 823 UC patients, and 726 healthy controls were genotyped for rs1209026 polymorphism. The minor allele frequency (A) in CD patients was 4%, compared with 6% in controls, yielding a protective OR of 0.62 (CI = 0.45-0.87;  $P = 0.005$ ) (Table 2). Compared with controls (87%), the frequency of the risk genotype was significantly increased in CD patients (92%) ( $P = 0.005$ , OR = 0.61, CI = 0.43-0.86). These differences resulted in similar statistical significance after stratifying CD patients on the basis of age at diagnosis.

In addition, a high significant association was also found in UC patients, with a similar MAF frequency (4%) leading to a protective OR of 0.69 (CI = 0.50-0.94;  $P = 0.019$ ). Accordingly, the frequency of GG genotype was also significantly increased in UC patients (91%,  $P = 0.015$ )

**Table 2** Genotypes and alleles distribution for *ATG16L1* and *IL23R* SNPs in CD, UC and controls

"A" refers to wild type and "a" to mutated allele. Adult and pediatric subgroups are divided on the basis of the age at diagnosis ( $\geq 19$  years and  $< 19$  years, respectively).

**Table 3** Haplotypes frequency of the two *IL23R* variants in IBD patients and controls

Haplotype		IBD		CD		UC	
rs7517847	rs11209026	Cases/Controls (%) Haplotype	P	Cases/Controls (%) Haplotype	P	Cases/Controls (%) Haplotype	P
T	G	68/62	0.0032	71/62	< 0.01	65/62	0.2166
G	G	28/32	0.0548	25/32	< 0.01	31/32	0.7398
G	A	4/6	0.0121	4/6	0.0088	4/6	0.0578

(Table 2). These statistical differences remained after stratifying the cohort on the basis of age at diagnosis.

Haplotype association analysis of two *IL23R* variants, rs7517847 and rs11209026, was also estimated (Table 3). An increase in TG haplotype frequency was observed in IBD (68%,  $P = 0.0032$ ) and CD patients (71%,  $P \leq 0.01$ ), compared with controls (62%).

### Family-based analysis

Given the lack of a significant association of allele/genotype frequencies of the *ATG16L1* gene in the pediatric subset, and the availability of 273 pediatric IBD Trios (138 CD, and 135 UC), the T300A polymorphism was tested by transmission disequilibrium test; a significant over-transmission of the G allele was found in CD patients ( $T:U = 90:62$ ;  $P = 0.023$ ), but not in UC (Table 4). With respect to *IL23R*, a significant over-transmission of the T allele of rs7517847 ( $T:U = 137:101$ ), and the G allele of rs11209026 ( $T:U = 34:19$ ) SNPs was observed in the whole IBD cohort ( $P = 0.0196$ ,  $P = 0.0394$ ; respectively), and more specifically in CD patients ( $P = 0.0015$ ,  $P = 0.0833$ , respectively). However,

the results in the UC subset did not reach statistical significance. An association between the rs7517847-rs11209026 (TG) haplotype and IBD, CD, and UC was also tested using the TDT. Consistent evidence of over-transmission of this haplotype in the whole IBD cohorts ( $T:U = 141:100$ ,  $P = 0.0084$ ) was maintained (Table 4).

### Genotype/phenotype correlation

Analysis of the allele and genotype frequencies of the rs2241880 SNP of the *ATG16L1* gene, showed no association with disease location, behaviour, and age at diagnosis based on the Montreal classification of CD cases (Table 5). More specifically, we observed the lowest frequency of the G allele in isolated colonic disease (55%), increasing to 60% in ileal and ileo-colonic disease, without a clear difference in adult and pediatric subsets (colonic disease: adult 55%, pediatric 54%). Similarly, there was no association with gender, smoking history, perianal fistulae, and presence of extra-intestinal manifestations. Moreover, no association was found with any specific sub-phenotypes of UC (Table 6).

Similarly, there was no correlation between risk

**Table 4** Transmission disequilibrium test (TDT) for rs7517847 and rs11209026 *IL23R* SNPs for IBD, CD, and UC

Only patients with at least 2 years of follow-up from diagnosis were included.

alleles and genotypes of the *IL23R* genes with specific sub-phenotypes of CD (Table 5) and UC (Table 6). Of note, the frequency of A allele of rs11209026 was the lowest in patients diagnosed at < 16 years of age (2.8%), increasing to 3.6% in the age group of 17-40 years, and 6.7% in those over 40 years, but the differences did not reach statistical significance (Table 5). More specifically, despite the large number of pediatric onset IBD patients investigated, genotype/phenotype frequencies were similar after further stratifying IBD population into adult and pediatric age of onset of the disease (data not shown).

#### Interaction between *ATG16L1*, *IL23R*, *CARD15*, and *OCTN1/2* genes

Logistic regression analysis was used to evaluate the individual contributions of *CARD15* (at least 1 variant against wild type), *ATG16L1* (GG/AG vs AA), *IL23R*

rs11209026 (AG/AA vs GG) and *OCTN* (diplotype TTCC against the rest) and CD risk, and to test for statistical interaction. The analysis included 763 CD cases and 749 controls. Table 7 shows the results of the logistic regression model with the individual contributions of *CARD15*, *ATG16L1*, *IL23R*, and *OCTN* to disease risk, their contribution after adjustment for *CARD15* genotype, and the contribution of interactions with *CARD15*. The individual contribution of all the predisposing genes was confirmed. By contrast, there was no evidence of a statistical interaction between all loci ( $P = 0.428$ ), and *ATG16L1*, *IL23R*, and *OCTN* by pairs and triplets (data not showed).

## DISCUSSION

With the recent introduction of the GWA technology,

**Table 6** Genotype and allele frequencies of *ATG16L1* and *IL23R* SNPs in UC cases stratified by phenotypic subgroups, (n)

several novel genes and loci involved in the pathogenesis of IBD have been uncovered, as well as the successful identification and replication of multiple susceptibility genes for CD<sup>[11,15,18,20,21,32]</sup>, such as *IL23R* and *ATG16L1*. However, these genetic variations account for only a small portion of the overall genetic susceptibility to CD, and their contribution to the pathogenesis of UC is even lower.

The present study confirms the reported association between *IL23R* and *ATG16L1* variants and susceptibility to CD, both in the case-control and family-based analysis, and in both adult- and pediatric-onset disease. Moreover, we also replicated the significant association between the rs11209026 variant of *IL23R* and UC ( $P = 0.018$ ), suggesting that this gene may also have a role in the genetic susceptibility to UC. Although the size of the cohort was sufficiently large, consisting

of more than 1600 IBD patients, we were unable to detect an association between *IL23R* and *ATG16L1* variants and any sub-phenotypes for both diseases, as described in the majority of published studies, thus suggesting that the overall effect of these variants on certain CD subtypes<sup>[22,23,31,34-36,38]</sup> is much weaker than that observed in *CARD15*. Moreover, we found no statistical evidence for epistatic interaction between *IL23R*, *ATG16L1*, *OCTN1/2*, and *CARD15* genes. Since our cohort also included a large number of pediatric cases (368 diagnosed at age < 19 years), this study confirmed that the rs2241880 polymorphism in the *ATG16L1*<sup>[34,37]</sup> gene and the rs7517847, rs11209026 polymorphisms in the *IL23R* gene<sup>[22,25,27-30]</sup> also influence susceptibility to CD in pediatric-onset patients, at allele and genotype frequencies comparable to that seen in adults.

Recent studies have reported genotype-phenotype associations in adult-pediatric onset CD and *ATG16L1* Ala197Thr variant. Specifically, Prescott *et al*<sup>[34]</sup> demonstrated an association with ileal form of CD with or without colonic involvement (61.7%) but not with isolated colonic disease (52.2%), as well as with diagnosis at an earlier age (≤ 16 years at diagnosis: 63.8%). Subsequently, van Limbergen *et al*<sup>[38]</sup> confirmed the association of isolated ileal disease with rs2241880G-allele ( $P = 0.02$ ) in a combined genotype-phenotype analysis of early and adult onset CD, although after stratifying CD cases in early- and adult-onset the association did not reach statistical significance ( $P = 0.28$  and  $P = 0.08$ , respectively), probably due to the reduced power of the sample sizes.

We observed rs2144880G variant allele frequency of 55% in colonic disease (L2 ± L4), which increased to 60% in pure ileal disease (L1 ± L4), without significant

association with any sub-phenotypes. To definitively answer this question, studies with a larger cohort of CD are needed to increase the statistical power, particularly when considering SNPs that only show a modest increase in the odds ratios for susceptibility. Moreover, different ethnic populations and true heterogeneity may also explain these differences.

IL-23 is a heterodimeric cytokine, composed of the IL-12p40 and p19 subunits. Human and mouse IL-23 share structural homologies with IL-12, and exhibit similar activities, but differ in their capacity to stimulate populations of specific memory T cells, activated to produce the proinflammatory mediators IL17 and IL16<sup>[43]</sup>. This so-called TH17 T-cell subset expresses the master transcription factor POp $\gamma$ t and mediates chronic inflammatory and autoimmune diseases in animal models<sup>[44]</sup>. IL-23 binds with a complex consisting of IL-23R and IL-12R $\beta$ . IL-23R associates constitutively with Jak2 and in a ligand-dependent manner with stat3. The human IL-23R gene is on human chromosome 1 within 150 kb of IL-12R $\beta$ 2<sup>[45]</sup>. It appears that IL-23 plays a unique role in the initiation and perpetuation of innate and T cell-mediated forms of IBD, and variations in the early IL-12 and IL-23 dependent regulatory mechanisms may impact the subsequent inflammatory response. The strong effect of the protective allele, first identified by Duerr *et al*<sup>[15]</sup>, could potentially be exploited to define functional outcomes and targeted therapy that to date remain as possibilities.

*ATG16L1* is a member of a large family of genes involved in autophagy, a mechanism by which cells recycle redundant organelles, an essential process in the resistance to pathogens, targeted for immune evasion by viruses and bacteria<sup>[46]</sup>. The exact functional impact of the rs2241880 variant is currently unknown, although the *ATG16L1* protein is a key component of autophagy and the T300A substitution occurs in an evolutionarily conserved domain<sup>[32]</sup>. The gene is expressed in intestinal epithelial cell lines and functional knockdown of this gene abrogates autophagy of *Salmonella typhimurium*<sup>[16]</sup>. The important role of autophagy as predisposing factor to CD has recently been highlighted with the identification of variants in immunity-related guanosine triphosphatase (IRGM) gene, involved in elimination of intracellular bacteria, and susceptibility to CD<sup>[47]</sup>. How this process is implicated in the pathogenesis of CD remains unclear, although it further supports the concept of inflammatory barrier disorder<sup>[48]</sup>.

Our results provide an independent confirmation of the association between the candidate genetic variations in *IL23R* and *ATG16L1* genes and CD, and reinforce the role of these new polymorphisms as genetic determinants in IBD. Further research is needed to understand how *IL23R* and *ATG16L1* variants contribute to disease susceptibility in IBD, and whether they have therapeutic implications.

## ACKNOWLEDGMENTS

The authors wish to thank Dr. Angelo Andriulli for

thoughtful review of the manuscript and Dr. Elisabetta Colombo, Mrs. Latiano Tiziana and Mrs. Ermelinda De Santo for their assistance with data collection and technical support. We wish to thank all the patients and families that participated in this study. The following physicians of the SIGENP\* and adult Gastrointestinal Units contributed to the study by providing DNA samples and clinical information of their patients (number of probands is shown in brackets): \*Ancona: Catassi , Nobile S (7); \*Bari: Rutigliano V, De Venuto D (14); \*Foggia: Campanozzi A (6); \*Messina: Vieni G, Sferlazzas C (35); Milano: Bianchi Porro G, Vecchi M, Saibeni S, Ardizzone S (286); Napoli: Riegler G, de Leone A, Giaquinto S (98); \*Napoli: Berni Canani E, Staiano AM (43); Padova: D'incà R, Sturniolo GC (295); \*Padova: Guariso G, Lodde V (30); \*Palermo: Accomando S (11); \*Parma: de'Angelis GL (17); \*Pescara:Lombardi G (8); \*Reggio Calabria: Romano C (9); \*Roma: Cucchiara S, Borrelli O, Bascietto C (69); S. Giovanni Rotondo: Colombo E, Andriulli A (664); \*S. Giovanni Rotondo: Pastore M, D'Altilia M, Marseglia A (14).

## COMMENTS

### Background

It is widely accepted that ulcerative colitis (UC) and Crohn's disease (CD) result from an inappropriate response of a defective mucosal immune system to indigenous flora and other luminal agents in a genetically susceptible host. Eleven inflammatory bowel disease (IBD) genome-wide linkage analyses in families with multiple IBD affected members, and two meta-analyses have identified several linkage regions. Following the identification of *NOD2* (or *CARD15*), the first gene contributing to CD susceptibility (IBD1 locus), further fine mapping studies have identified a risk haplotype (IBD5 locus) on chromosome 5q, and another polymorphism on the *disk large homolog 5* (*DLG5*) gene. However, these risk-associated variants and many others reported with conflicting results, explain only a minority of the genetic risk in IBD. Whole genome association (GWA) studies have rapidly led to the identification of novel susceptibility loci such as *interleukin-23 receptor* (*IL23R*) and *autophagy-related 16-like 1 gene* (*ATG16L1*).

### Research frontiers

An uncommon coding mutation (Arg381Gln) in the *IL23R* gene has been identified as conferring strong protection against CD with ileal involvement. Further GWA and replication studies have consistently confirmed strong association between variations at *IL23R* and CD, with a large number of replications in adult- and pediatric-onset cohorts, without significant association with specific CD sub-phenotype. Moreover, an association with UC has also been observed. The non-synonymous (Ala197Thr) variant of *ATG16L1* was found to be associated with CD, but not UC, and has been consistently demonstrated in a number of independent studies in adult subjects, but with conflicting data in pediatric IBD cohorts.

### Innovations and breakthroughs

The present study included a large population of Italian IBD patients (763 CD and 843 UC), including 368 patients with pediatric onset of disease (age at diagnosis < 19 years), 546 healthy parents and 749 healthy controls. All patients were accurately phenotyped. Two SNPs of *IL23R*, one of the *ATG16L1*, and three of the *CARD15* genes were genotyped, and were also evaluated for interaction with specific clinical features among genes.

### Applications

The present study confirms the reported association between *IL23R* and *ATG16L1* variants and susceptibility to CD, both in the case-control and family-based analysis, and both in adult- and pediatric-onset disease. Moreover, we also replicated the significant association of the rs11209026 variant of *IL23R* with UC, suggesting that this gene may also have a role in genetic susceptibility to UC. Although the size of the cohort was large, consisting of more than 1600 IBD patients, we were unable to detect an association between *IL23R* and *ATG16L1* variants and any sub-phenotypes for both diseases.

## Terminology

GWA is the Genome Wide Association which is examined through a chip platform evaluating several thousand SNPs. SNP is Polymorphism of Single Nucleotide evaluated to investigate variants of gene probably modifying the gene function.

## Peer review

This is a nice follow-up study which confirms the association between the candidate genetic variations in *IL23R/ATG16L1* and IBD, in both pediatric- and adult-onset population.

### Abstract

**AIM:** To investigate the role that single nucleotide polymorphisms (SNPs) in the promoter of the tumour necrosis factor-alpha (TNF- $\alpha$ ) gene play in the risk of inflammatory bowel diseases (IBDs) in a New Zealand population, in the context of international studies.

**METHODS:** DNA samples from 388 patients with Crohn's disease (CD), 405 ulcerative colitis (UC), 27 indeterminate colitis (IC) and 201 randomly selected controls, from Canterbury, New Zealand were screened for 3 common polymorphisms in the TNF- $\alpha$  receptor: -238 G→A, -308 G→A and -857C→T, using a Taqman<sup>®</sup> assay. A meta-analysis was performed on the data obtained on these polymorphisms combined with that from other published studies.

**RESULTS:** Individuals carrying the -308 G/A allele had a significantly (OR = 1.91,  $\chi^2 = 17.36$ ,  $P < 0.0001$ ) increased risk of pancolitis, and a 1.57-fold increased risk (OR = 1.57,  $\chi^2 = 4.34$ ,  $P = 0.037$ ) of requiring a bowel resection in UC. Carrying the -857 C/T variant decreased the risk of ileocolonic CD (OR = 0.56,  $\chi^2 =$

4.32,  $P = 0.037$ ), and the need for a bowel resection (OR = 0.59,  $\chi^2 = 4.85$ ,  $P = 0.028$ ). The risk of UC was reduced in individuals who were smokers at diagnosis, (OR = 0.48,  $\chi^2 = 4.86$ ,  $P = 0.028$ ).

**CONCLUSION:** TNF- $\alpha$  is a key cytokine known to play a role in inflammatory response, and the locus for the gene is found in the IBD3 region on chromosome 6p21, known to be associated with an increased risk for IBD. The -308 G/A SNP in the TNF- $\alpha$  promoter is functional, and may account in part for the increased UC risk associated with the IBD3 genomic region. The -857 C/T SNP may decrease IBD risk in certain groups. Pharmacogenomic approaches may be desirable for individuals with such affected genotypes.

### INTRODUCTION

Inflammatory bowel diseases (IBDs) are chronic multifactorial disorders, commonly classified as autoimmune diseases, and comprise of Crohn's disease (CD) and ulcerative colitis (UC). Up to 10%-15% of reported cases are described as "indeterminate colitis" (IC), where an unequivocal classification is not possible using established diagnostic criteria. Twin studies and segregation analysis strongly support IBD, especially CD, as complex genetic traits<sup>[1]</sup>, whose etiology also involves immunological and environmental factors, including diet. Several IBD-susceptibility chromosomal regions have been replicated

in a number of studies, and in some cases causative genes have been found. For example, the key gene in the IBD1 region on chromosome 16q12, has been identified as Nucleotide Oligomerization Domain 2 (*NOD2*)<sup>[2]</sup>. Three polymorphisms of this gene (*R702W*, *G908R*, and *1007fs*) increase the susceptibility to IBD, especially CD.

The IBD3 region on chromosome 6p was initially described in a large European cohort<sup>[3]</sup> by Hampe and coworkers, who suggested that this observation was consistent with single nucleotide polymorphism (SNPs) in either the Human Leukocyte Antigen (HLA) and/or tumor necrosis factor (TNF) genes as being risk factors for IBD. Rioux *et al*<sup>[4]</sup> confirmed this association in a genome-wide search of 158 Canadian sib-pair families, a finding also replicated by Dechairo *et al*<sup>[5]</sup> in 284 IBD-affected sib pairs from 234 Caucasian families in the UK, showing an almost equal contribution to the linkage with CD and UC. Fisher *et al*<sup>[6]</sup> investigated 353 northern European sib pairs, and suggested that the strongest evidence for linkage in both CD and UC occurred at the IBD3 region on chromosome 6p21.3 (OMIM 604519). This effect appeared to be male-specific. It should be noted that the human TNF-alpha (TNF- $\alpha$ ) gene is located on chromosome 6p21.3, spanning approximately 3 kb<sup>[7]</sup>.

TNF- $\alpha$  is an important pro-inflammatory cytokine that is involved in systemic inflammation, and stimulates acute phase reactions<sup>[8,9]</sup>. TNF- $\alpha$ /TNF receptor interactions not only play a pivotal role in the pathogenesis of the inflammatory response, but also cause programmed cell death (apoptosis), cell proliferation and differentiation<sup>[10]</sup>. Ligand binding to TNF receptors causes a conformational change in the receptor, leading to several downstream effects including activation of the heterodimeric transcription factor and nuclear factor (NF)- $\kappa$ B. Through translocation to the nucleus, this mediates the transcription of a variety of proteins involved in cell survival and proliferation, as well as inflammatory response. Alterations in the regulation of TNF- $\alpha$ , especially TNF- $\alpha$  overproduction, have been implicated in a variety of symptoms associated with autoimmune disorders, including IBD, and especially CD. Inflammation, anorexia, and weight loss are all associated with increased levels of circulating TNF- $\alpha$  that is seen in CD. Indeed, a common treatment of CD is the use of TNF- $\alpha$  inhibitors such as the monoclonal antibody, infliximab (IFX).

Several SNPs in the TNF- $\alpha$  promoter region are known to affect the level of gene expression. For example, two SNPs located at nucleotides -238 and -308 represent substitutions of adenine for guanine in the TNF transcriptional start site<sup>[11]</sup>. Such variations in the TNF- $\alpha$  promoter region have previously been associated with susceptibility to a range of autoimmune disorders, including asthma<sup>[12,13]</sup>, psoriasis<sup>[14]</sup> and rheumatoid arthritis<sup>[15]</sup>. The G $\rightarrow$ A polymorphism at position -238 in the TNF gene is associated with lower production of TNF- $\alpha$  in patients with UC<sup>[16]</sup>. Conversely, the -308A polymorphism is associated with enhanced TNF- $\alpha$  production in cells *in vitro* and in CD patients *in vivo*<sup>[16-18]</sup>. The -857 C $\rightarrow$ T SNP is functional through binding to the transcription factor octamer transcription factor-1 (OCT-1). Carriers of the -857C allele show higher levels

of circulating TNF- $\alpha$ , and van Heel *et al*<sup>[19]</sup> suggested that the TNF -857C/T SNP increased the susceptibility to IBD in a UK population through its effects on the interaction between the OCT-1 gene and the NF- $\kappa$ B transcription factor.

The present study was designed to determine whether SNPs in the TNF- $\alpha$  promoter region confer susceptibility to CD or UC, and whether they are associated with the clinical phenotype, in a New Zealand Caucasian population.

## MATERIALS AND METHODS

### Study participants

The Canterbury IBD Project is a population-based study of genetic and environmental determinants of the aetiology IBD, which has been described in detail elsewhere<sup>[20]</sup>. The participants consented to the collection of peripheral blood for DNA extraction and genotyping. The subjects included in the present study were a random subset of the Caucasian participants of the Canterbury IBD Project. Both CD and UC were defined using standard diagnostic criteria<sup>[21]</sup>. The subjects were phenotyped according to the Montreal Classification systems, allowing genotype-phenotype analysis to be performed<sup>[22]</sup>.

A total of 388 CD participants, 405 UC participants, and 27 IC participants were genotyped for this study. All participants self-reported European ancestry, and patients who self-reported having any Maori or other non-Caucasian ancestry are not included in the data set. Clinical and demographic characteristics of the Caucasian IBD cohort for this study are shown in Table 1.

The New Zealand Caucasian controls used in this study were selected at random from the electoral roll, comprising 93% of the population over eighteen years of age in Canterbury, New Zealand<sup>[23]</sup>.

### Criteria for SNP selection

The TNF- $\alpha$  region is complex, and a considerable number of SNPs are necessary to haplotype tag this region<sup>[24]</sup>. Therefore, we elected to study 3 SNPs in the promoter region for which functionality has been shown previously<sup>[10,25]</sup>. The SNPs studied were: -238 G $\rightarrow$ A (rs361525), -308 G $\rightarrow$ A (rs1800629) and -857C $\rightarrow$ T (rs1799724).

### Applied biosystems TaqMan® SNP genotyping assay for TNF- $\alpha$ variants

The three alleles were genotyped using the ABI TaqMan MGB dallellic discrimination system. A custom made, quality controlled and functionally tested genotyping assay (Assay-by-Design online service) for all three variants was obtained from Applied Biosystems (Melbourne, Australia) (Table 2). The reactions were prepared by using 2  $\times$  TaqMan Universal Master Mix, 20  $\times$  SNP Genotyping Assay Mix, DNase-free water, 10 ng genomic DNA in a final volume of 5 l per reaction. The PCR amplification was performed using the ABI Prism 7900 HT sequence-detector machine under the following conditions: 10 min 95°C enzyme activation followed by 40 cycles at 92°C for 15 s and 60°C for 1 min.

**Table 1 Summary of clinical and demographic data on Caucasian IBD patients genotyped for at least one TNF- $\alpha$  polymorphism n (%)**

### Statistical analysis

The allelic trend test<sup>[26]</sup> and Fisher's exact genotypic test were used to compare patients and control allele frequencies. An exact test was used to test for departures from Hardy-Weinberg equilibrium (HWE) in the patient and the control samples<sup>[27]</sup>. Allelic odds ratios were calculated and confidence intervals for the allelic odds ratio were calculated under the assumption of HWE in the patient and the control groups. Within the region of TNF- $\alpha$ , HAPLO. SCORE in R was used to estimate haplotypes and to test for association of these haplotypes within the patient-control population. Meta-analysis was carried out to obtain an overall index of the effect magnitude of the studied relationship. These analyses were carried out using R and SAS (V9.1 SAS Institute., Cary, NC, USA). We also performed an exploratory analysis of allele frequency differences between controls and patient subgroups, using the clinical characteristics shown in Table 1.

## RESULTS

For each of the polymorphisms studied, the risks of carrying the variant was compared between CD, UC

**Table 2 Primer and probe sequences for custom made TaqMan SNP genotyping assay for TNF- $\alpha$  -857C/T, TNF- $\alpha$  -308G/A and TNF- $\alpha$  -238G/A**

<b>TaqMan SNP genotyping assay</b>	<b>DNA sequence</b>
TNF- $\alpha$ -857C/T forward primer	5'-GGGCTATGGAAGTCGAGTATGG-3'
TNF- $\alpha$ -857C/T reverse primer	5'-GTCCTGGAGGCTCTTCACT-3'
TNF- $\alpha$ -857C/T VIC probe	5'-CCCTGTCTCGTTAAGG-3'
TNF- $\alpha$ -857C/T FAM probe	5'-CCTGCTCTCATTAAGG-3'
TNF- $\alpha$ -308G/A forward primer	5'-CCAAAAGAAATGGAGGCAATAGGTT-3'
TNF- $\alpha$ -308G/A reverse primer	5'-GGACCCCTGGAGGCTGAAC-3'
TNF- $\alpha$ -308G/A VIC probe	5'-CCCGTCCCCATGCC-3'
TNF- $\alpha$ -308G/A FAM probe	5'-CCCGTCCCTCATGCC-3'
TNF- $\alpha$ -238G/A forward primer	5'-CAGTCAGTGGCCCAGAAC-3'
TNF- $\alpha$ -238G/A reverse primer	5'-CCCTCACACTCCCCATCCT-3'

TNF- $\alpha$ -238G/A FAM probe	5'-CTCGGAATCAGAGCAG-3'

and control groups, as shown in Tables 3 and 4. Those individuals carrying the variant TNF- $\alpha$  -238A allele showed no statistically significant effect on the patterns of disease risk. There were no significant differences between males and females in the risk for CD or UC (Table 5).

Carrying the TNF- $\alpha$  -308 G/A allele again showed no statistically significant effect on patterns of disease risk, and there was no significant difference between males and females in the risk for CD or UC (Table 5). Having the A allele increased the probability of the risk for pancolitis in UC, from 0.17 (for controls) to 0.28, giving an odds ratio of 1.91 (OR = 1.91, CI = 1.41-2.60, P < 0.0001). Carrying this polymorphism, significantly increased the necessity for bowel resection in UC (OR = 1.57, CI = 1.02-2.41, P = 0.037).

Carrying the TNF- $\alpha$  -857 C/T variant did not result in any statistically significant changes in the overall disease risk, or a significant male-female imbalance. However, in individuals carrying the variant allele, the risk of having CD in an ileocolonic location was reduced compared to control subjects (OR = 0.56, CI = 0.32-0.97, P = 0.037), and the risk of requiring a bowel resection was also significantly reduced to 0.59 (CI = 0.37-0.95, P = 0.028) (Table 4). Only in individuals who were smokers at the time of diagnosis, did this allele have a significant impact on UC (OR = 0.48, CI = 0.25-0.94, P = 0.028).

### Haplotype analysis

Haplotype analysis of two-SNPs was performed using HAPLO.SCORE. The results are summarized in Table 6. Haplotype frequencies were estimated, and association analyses were performed with respect to CD and

UC and Caucasian controls. A score for each haplotype (Hap-score) was calculated and *P*-value was obtained for the significance of each Hap-score. A positive hap-score implied that the haplotype occurred more frequently in the CD or UC patient group. A global *P*-value indicated the overall association between haplotypes and the response. The results showed that there was no significant association between these haplotypes for either CD or UC patients as compared with control subjects, *P* = 0.82 and *P* = 0.18 respectively (Table 6).

In the analysis of the two SNPs (rs1800629, rs361525) in CD, the haplotypes in patient and control subjects occurred at equal frequencies (*P* > 0.05, Table 6). Frequency haplotype AA was uncommon in both CD and UC subjects, 0.3% and 0% respectively and 0% for control subjects.

### Meta-analysis

Forest plots in Figure 1 show the results of the meta-analysis of three common polymorphisms in the TNF- $\alpha$  receptor: -238, -308, and -857. Four to sixteen studies satisfied, depending on the TNF- $\alpha$  receptor, the inclusion criteria. All studies provided description of the participants, CD and UC status, and compared the control group with CD or UC subjects. We included our own data along with the other studies. Cochran's *Q* test and *I*<sup>2</sup> index were performed in order to examine the heterogeneity of the outcomes of the studies.

**TNF- $\alpha$  -238:** The forest plot in Figure 1A shows the risk

of CD in each study. These seven studies appeared to be homogeneous in results (*Q* statistic = 4.10, df = 6, *P* = 0.66) and *I*<sup>2</sup> index was negative (*I*<sup>2</sup> < 0). The pooled odds ratio for these studies was 1.15 (95% CI = 0.88-1.49), indicating that carrying the variant TNF- $\alpha$  -238G/A allele did not significantly affect the overall risk of CD. The forest plot of six studies on UC subjects with controls is shown in Figure 1B. These studies were reasonably homogeneous (*Q* statistic = 2.24, df = 5, *P* = 0.82, *I*<sup>2</sup> < 0) and the pooled odds ratio was 1.04 (95% CI = 0.77-1.42), indicating that carrying the variant TNF- $\alpha$  -238G/A allele was not significantly associated with the overall risk of UC.

**TNF- $\alpha$  -308:** The forest plot of sixteen studies assessing the effect of carrying the variant allele on risk of CD is shown in Figure 1C. The combined estimate of odds ratio for these studies was 0.99 (95% CI = 0.84-1.15) by the random effect model with no homogeneity (*Q* statistic = 17.4, df = 15, *P* = 0.30, *I*<sup>2</sup> = 0.14). This finding indicates that carrying the variant TNF- $\alpha$  -308G/A allele was not significantly associated with the risk of CD. In addition, Figure 1D provides a graphical summary of the risk of carrying the variant TNF- $\alpha$  -308G/A allele in UC. The results indicate that this variant was not significantly associated with the overall risk of UC. The pooled odds ratio for the thirteen studies was 1.14 (95% CI = 0.84-1.54) by the random effect model (*Q* statistic = 9.5, df = 12, *P* = 0.08, *I*<sup>2</sup> = 0.39).

**TNF- $\alpha$  -857:** The forest plot Figure 1E shows the risk

of CD in each study of carrying the variant TNF- $\alpha$  -857C/T allele. The overall estimate of odds ratio for the eight studies was 1.11 (95% CI = 0.89-1.38) by the random effect model with no homogeneity (*Q* statistic

= 6.73, *df* = 7, *P* = 0.46,  $I^2 < 0$ ). Carrying the variant TNF- $\alpha$  -857C/T allele was not significantly associated with the risk of CD. In addition, the random effect model gave a pooled odds ratio of 0.84 (95% CI = 0.63-1.13)

**Figure 1** Tree plots for meta-analysis. **A:** TNF- $\alpha$  -238 on CD; **B:** TNF- $\alpha$  -238 on UC; **C:** TNF- $\alpha$  -308 on CD; **D:** TNF- $\alpha$  -308 on UC; **E:** TNF- $\alpha$  -857 on CD; **F:** TNF- $\alpha$  -857 on UC.

with no homogeneity ( $Q$  statistic = 3.1,  $df = 3$ ,  $P = 0.38$ ,  $I^2 = 0.03$ ) for carrying the variant TNF- $\alpha$  -857C/T allele in UC (Figure 1F).

The present meta-analysis shows that carrying the TNF- $\alpha$  receptor SNPs -238, -308, or -857 was not significantly associated with the risk of IBD, both in the New Zealand population as well as in the international studies. However, the present analysis does not provide any information on male-female differences or site specificity.

## DISCUSSION

The present study adds to the international database available for all 3 alleles. In both males and females, carrying the variant TNF- $\alpha$  -238 G→A allele had no

significant effect in our study population. Previous reports suggesting that this allele was a risk factor for IBD, especially CD, have generally used small sample sizes, and the data were not consistent. The initial publications reported positive data in Japanese, Hungarian and Korean groups, albeit with small numbers of patients. Kim *et al*<sup>[30]</sup> in a study on Korean patients observed a significantly higher frequency of -238A allele of TNF- $\alpha$  in CD patients with perianal lesions compared with patients without perianal disease. Vatay *et al*<sup>[29]</sup> also showed an increased risk in their study on Hungarian subjects. However, several negative studies have been published, including Levine *et al*<sup>[48]</sup> who examined a pediatric Jewish population, and Sashio *et al*<sup>[28]</sup> in a study on Japanese patients. In particular, the latter authors found a difference in the carrier frequency for haplotype AG (-308 A, -238

G) between UC patients and controls, and suggested that one of the genes responsible for UC may be the TNF gene. Our own haplotype analysis failed to confirm these findings. However, we observed that this SNP led to lower production of TNF- $\alpha$  in IBD patients<sup>[16]</sup>.

The overall risk of either UC or CD was not significantly affected by carrying the TNF- $\alpha$  -308 G→A allele in our study. The meta-analysis shows 8 positive and 8 negative studies, leading to an overall allelic odds ratio of almost exactly zero. The published data are somewhat skewed by the strong negative association with CD found by Kim *et al* in the Korean population<sup>[30]</sup>. The data for UC are also somewhat dominated by the strong positive association reported by Sashio (Japanese)<sup>[28]</sup>, Song (Han Chinese)<sup>[38]</sup> and Sykora (Czech)<sup>[42]</sup>. Our own data is close to the overall figure based on the meta-analysis on UC patients.

Subgroup analysis may provide greater information on this allele. The present study shows that individuals carrying the variant TNF- $\alpha$  -308 G→A allele have a significantly greater risk of pancolitis in UC, and are also more likely to require bowel resection. The probable need for bowel resection in these individuals is consistent with other reports. Cucchiara *et al*<sup>[49]</sup> reported that Italian CD patients carrying this allele were more frequently resistant to steroids compared with non-carriers, and were more likely to require surgical resection. They suggested a causal relationship between these two events. This is in contrast to the findings of Louis *et al*<sup>[50]</sup> who found that the presence of this variant favoured steroid-dependent disease and to a lesser extent fistulizing and colonic disease. Both authors suggested that this genotype indicated a more intense TNF- $\alpha$ -driven inflammatory reaction at the mucosal level.

The increased need for surgery in our subjects carrying the variant TNF- $\alpha$  -308 G→A allele is consistent with the observations of other authors, including Cucchiara *et al*<sup>[49]</sup> in an Italian pediatric cohort and Sykora *et al*<sup>[42]</sup>, in their studies on Czech subjects. The latter group not only genotyped the TNF- $\alpha$  308 G→A polymorphism, but also measured the serum levels of inflammatory C-reactive protein (CRP), in relation to disease activity. Both UC and CD patients carrying the TNF- $\alpha$  -308 A variant showed a significant increase in CRP. The authors concluded that the TNF- $\alpha$  308 A polymorphism may play a role in modifying the IBD phenotype, influencing disease activity and leading to a more intense inflammatory activity. Other authors have also associated this genotype with inflammation, as measured by CRP or other measures<sup>[29,35,51]</sup>.

Carrying the TNF- $\alpha$  -857C→T variant failed to modify the overall risk in our study. The tree diagram shows that the international database provides a good number of Japanese and Australian individuals with an increased risk for CD, whereas a small study on Canadian subjects suggests a strong protective effect. Although the overall risk of CD is somewhat increased, there appears to be a comparable decreased risk for UC associated with carrying the variant allele. However, the TNF- $\alpha$  -857C→T variant significantly decreased the

risk of specific types and locations of CD. The risk of disease in an ileocolonic location decreased to 0.56 (limits 0.32-0.97), and the risk of requiring a bowel resection reduced to 0.59 (0.37-0.95). Only in individuals who were smokers at diagnosis, did this allele have an impact on UC [OR 0.48 (0.25-0.94)].

Fowler *et al*<sup>[39]</sup> identified a possible association of TNF- $\alpha$  -857 variant with an increased CD risk, especially in patients with structuring disease, in their case-control study on Australian subjects. Additionally, the TNF- $\alpha$  -857 CC genotype was independently associated with familial CD. The CD risk in their study was the strongest when individuals carried polymorphisms in both 308G/A and -857C/T. However, in a study in the UK, van Heel *et al*<sup>[25]</sup> showed an association of TNF-857C with IBD overall and with sub-phenotypes in either UC or CD, only in patients not carrying other common mutations. The transcription factor OCT1 binds TNF-857T but not TNF-857C, and interacts *in vitro* and *in vivo* with the pro-inflammatory NF- $\kappa$ B p65 subunit RELA at an adjacent binding site. van Heel *et al*<sup>[25]</sup> hypothesized that interaction of these transcription factors with specific alleles of TNF- $\alpha$  in gut tissue may be relevant in the pathogenesis of IBD.

Infliximab (IFX) is a monoclonal antibody against TNF- $\alpha$  that is commonly used as an IBD treatment. Ozeki *et al*<sup>[52]</sup> found that the -857T allele was in linkage with a lymphotoxin alpha (LTA) haplotype. They suggested that differences in therapeutic effects of IFX among patients with CD may be explained in part by the induction ability of TNF- $\alpha$  via the -857C/T polymorphism.

Each of the alleles in the present study appeared to enhance the risk in males as compared to females. Unfortunately, such gender stratification was not carried out in many of the other published studies. Therefore, it is not possible to determine whether this is true in other populations. However, it should be noted that such a sex imbalance is characteristic of the risks that have previously been associated with the IBD3 locus<sup>[6]</sup>. The TNF- $\alpha$  gene is closely linked to HLA-B<sup>[53]</sup>, and both Satsangi *et al*<sup>[54]</sup> and Ruuls and Sedgewick<sup>[55]</sup> pointed to the difficulties of distinguishing the effect of TNF genes from that of other genes of the Major Histocompatibility Complex, including HLA, to susceptibility and disease phenotype in IBD. It is possible that genes in this region interact with one another to influence IBD risk, as has been suggested in cardiovascular disease<sup>[56]</sup>. We propose that our data is consistent with TNF- $\alpha$  itself being the key factor in the increased IBD risk that has so consistently been associated with the IBD3 region.

The analysis of SNPs in the TNF- $\alpha$  promoter may suggest both pharmacogenomic and nutrigenomic approaches to overcoming the pathway defect. Stio *et al*<sup>[57]</sup> observed that TX 527 [19-nor-14,20-bisepi-23-yne-1,25(OH)(2)D(3)], a Vitamin D analogue, could exert an immunosuppressive effect on TNF- $\alpha$  production in CD patients, and that this effect was mediated by NF- $\kappa$ B down-regulation. The activation of NF- $\kappa$ B leads to its migration into the nucleus where it binds to the DNA

response elements in gene promoter regions. TX 527 inhibited the activation of NF- $\kappa$ B through the activation of the Vitamin D receptor (VDR). Thus, natural or synthetic vitamin D analogues may provide a basis for nutrigenomic or pharmacogenomic interventions that could be especially beneficial in individuals carrying variant alleles in the TNF- $\alpha$  promoter.

## ACKNOWLEDGMENTS

We thank the Canterbury participants of our study. Nutrigenomics New Zealand is in collaboration between AgResearch Ltd., Crop & Food Research, HortResearch and The University of Auckland.

## COMMENTS

### Background

There is international recognition that the IBD3 region, on chromosome 6p21, *IBD3* (MIM604519), confers susceptibility to inflammatory bowel disease (IBD). However, the nature of the relevant gene has been debated. Tumor necrosis factor-alpha (TNF- $\alpha$ ) is a strong possibility, and variant single nucleotide polymorphisms (SNPs) in the TNF- $\alpha$  promoter have previously been associated in some studies with increased risk of IBD, while other studies have produced conflicting results. The present study provides data based on a substantial New Zealand cohort, and a meta-analysis, that suggests increased IBD risk in individuals carrying any of three functional SNPs in the TNF- $\alpha$  promoter.

### Research frontiers

While an overall association with risk was not found, the carriers of either the -308 or -857 variants showed modified risk of specific IBD phenotypes. In particular, the study provides strong evidence that those individuals carrying the -308 G/A variant allele had an increased risk of pancolitis, and bowel resection in ulcerative colitis (UC). In contrast, carrying the -857 C/T variant decreased the risk of Crohn's disease (CD) in an ileocolonic location, and for the need for a bowel resection.

### Innovations and breakthroughs

The present study reveals that specific variant polymorphisms either increase the risk of certain forms of IBD, while others actually decrease the risk. Until now, there has been an assumption that all variants may be detrimental, but the present data suggests that this is not the case.

### Applications

There may be some justification for genotyping IBD patients for the presence of these polymorphisms, since this may indicate the need for surgery (or not) at an early stage. Further studies may usefully stratify patients according to gender and disease characteristics.

### Terminology

An "allele" is one of several alternative forms of a gene occupying a given locus on a chromosome. "SNP" describes a polymorphism (variation in sequence between individuals) caused by a change in a single nucleotide. This is responsible for most of the genetic variation between individuals.

### Peer review

This is a well written paper. The analysis is especially welcome considering the different conclusions from different researchers. This is an interesting paper which indicated that SNPs in the promoter of TNF- $\alpha$  gene may play a role in the risk of IBD in a New Zealand population.
