National Journal Award  
2005

# World Journal of Gastroenterology®

Baishideng™

Weekly Established in October 1995

Volume 14 Number 25  
July 7, 2008

## Contents

- EDITORIAL** 3937 Risk for colorectal cancer in ulcerative colitis: Changes, causes and management strategies

*Lakatos PL, Lakatos L*

- 3948 IgG4-related sclerosing disease

*Kamisawa T, Okamoto A*

- REVIEW** 3956 Evolving management of colorectal cancer

*Van der Voort van Zijp J, Hoekstra HJ, Basson MD*

- TOPIC HIGHLIGHT** 3968 Gaucher disease: New developments in treatment and etiology

*Harmanci O, Bayraktar Y*

- 3974 Primary sclerosing cholangitis - What is the difference between east and west?

*Shorbagi A, Bayraktar Y*

- ESOPHAGEAL CANCER** 3982 Lithium inhibits proliferation of human esophageal cancer cell line

Eca-109 by inducing a G<sub>2</sub>/M cell cycle arrest

*Wang JS, Wang CL, Wen JF, Wang YJ, Hu YB, Ren HZ*

- 3990 Antitumor effect and mechanism of *Gecko* on human esophageal carcinoma cell lines *in vitro* and xenografted sarcoma 180 in Kunming mice

*Liu F, Wang JG, Wang SY, Li Y, Wu YP, Xi SM*

- LIVER CANCER** 3997 Characteristics of liver on magnetic resonance diffusion-weighted

## INTRODUCTION AND EPIDEMIOLOGY

Since the first report of an inflammatory bowel disease (IBD) case associated with colorectal cancer (CRC) by Crohn and Rosenberg<sup>[1]</sup>, significant efforts have been made to elucidate this presumed association. Nowadays, the association between IBD and the increased risk for CRC is widely accepted. Although CRC, complicating ulcerative colitis and Crohn's disease, accounts only for 1%-2% of all cases of CRC in the general population, it is considered a serious complication of the disease and accounts for approximately 10%-15% of all deaths in IBD patients<sup>[2]</sup>. The age at diagnosis of CRC associated with IBD is 15-20 years earlier compared to sporadic cancers. In the meta-analysis by Eaden *et al*<sup>[3]</sup>, the average age at diagnosis was 43.2 years. Similarly, in a recent publication from Eastern Europe<sup>[4]</sup>, it was found to be 50.9 years, 10-15 years younger compared to sporadic CRC cases from the same area (62.2 years)<sup>[5]</sup>. According to US<sup>[6]</sup> and Canadian<sup>[7]</sup> publications, almost two-thirds of the affected patients were males, yet results are conflicting<sup>[4,8]</sup>. In addition, the frequency of multiple CRCs is higher than in patients with sporadic CRC<sup>[9]</sup>.

The increased risk of CRC in UC is almost a universal finding<sup>[3,10-13]</sup>, yet the extent of this risk varies considerably with differences in study design and geographic area. The initial reports were published by tertiary gastroenterology centers, thus the high risk detected might have been a consequence of referral bias and overinterpretation due to the high percentage of extensive and chronically active cases in these cohorts. Results of population-based studies are more reliable; however, several geographical and ethnic differences have been noted.

The report of the meta-analysis by Eaden *et al*<sup>[3]</sup> in 2001 was one of several milestones in this subject. The incidence of UC-associated CRC was estimated based on 116 articles involving 54 478 patients in whom 1698 CRC cases were detected. This was a mixture of referral center-based, hospital-based, and population-based studies of variable methodological qualities and levels of detail. The reported incidence was higher in the US

## Abstract

The risk of colorectal cancer for any patient with ulcerative colitis is known to be elevated, and is estimated to be 2% after 10 years, 8% after 20 years and 18% after 30 years of disease. Risk factors for cancer include extent and duration of ulcerative colitis, primary sclerosing cholangitis, a family history of sporadic colorectal cancer, severity of histologic bowel inflammation, and in some studies, young age at onset of colitis. In this review, the authors discuss recent epidemiological trends and causes for the observed changes. Population-based studies published within the past 5 years suggest that this risk has decreased over time, despite the low frequency of colectomies. The crude annual incidence rate of colorectal cancer in ulcerative colitis ranges from approximately 0.06% to 0.16% with a relative risk of 1.0-2.75. The exact mechanism for this change is unknown; it may partly be explained by the more widespread use of maintenance therapy and surveillance colonoscopy.

and UK than in Scandinavia. Only limited data were available from other European countries, for example Eastern Europe<sup>[14]</sup>. Based on the 41 studies, the duration of UC was 3 (2-4) cases per 1000 person-years, equaling an annual risk of 0.3% or 1 in 333 patients. However, this calculation did not take into account varying degrees of annual risk based on the duration of UC. The well known risk figures at 10 years' (1.6%), 20 years' (8.3%), and 30 years' disease (18.4%) duration were derived from 19 studies that reported CRC incidence according to UC duration at a 10-year interval. In other words, one would expect to diagnose CRC in almost one in five individuals with UC after 30 years' disease duration.

The new, independent population-based studies suggest, however, a lower incidence rate (Table 1)<sup>[4,7,8,15-17]</sup>. During the follow-up of 689 UC patients in Florence between 1978 and 1992, ten new CRC cases were reported<sup>[15]</sup>, equaling a yearly incidence of 0.13%. Bernstein *et al*<sup>[7]</sup> reported 36 colon and 13 rectal cancers in 2672 patients, the annual risks of colon and rectal cancer being 0.16% and 0.06%, respectively, in a follow-up of 19 665 person-years. In an inception cohort from Denmark between 1962 and 1987, only 13 cases of CRC were reported among 1160 patients with UC, and followed up for 22 290 person-years, yielding an annual risk of 0.06%<sup>[16]</sup>. The 30-year cumulative CRC risk was 2.1%. The rate of surgery in Denmark is among the highest reported worldwide. A much smaller cohort of 378 patients with UC diagnosed between 1940 and 2001 in Olmsted County were followed up for 5567 person-years, leading to detection of six CRCs<sup>[8]</sup>. The crude annual incidence was 0.1%, while the cumulative risk after 30-years' disease duration was as low as 2.0%. The authors of the study concluded that, in general, the risk of CRC is not increased in UC, only in patients with extensive disease. Finally, despite one of highest incidence rates for sporadic CRC, and a much lower non-CRC related colectomy rate (3.4%), the incidence of UC-related CRC was only moderately increased in a Hungarian population-based study. The cohort consisted of 723 individuals diagnosed with UC over a 30-year period and followed up for 8564 person-years. The cumulative risk for CRC during the follow-up of these 723 UC patients was 0.6% after a disease duration of 10 years, 5.4% after 20 years, and 7.5% after 30 years, with an overall incidence

rate of 1.52/1000 person-years. Somewhat contradictory, Terdiman *et al*<sup>[18]</sup> still report a significantly increased risk for both UC and CD ( $OR_{CRC}$ , 6.72-6.60) based on insurance database reports in 364 IBD-CRC and 1172 IBD patients. Similarly intriguing data were presented at the 2008 European Crohn's and Colitis Organization Congress. Based on the Dutch National Registry, almost 50% of all IBD-associated CRC cases developed in patients with Crohn's disease<sup>[19]</sup>. How these reports might influence current surveillance strategies is unclear.

Therefore, these population-based studies would indicate a much lower UC-related CRC incidence rate, ranging from 1/500 to 1/1600 patients annually. The causes for this change remain unclear, but possibilities include more widespread institution of surveillance colonoscopy and a higher prevalence of patients on maintenance therapy. An additional option may be that the population-based acquisition of the data, in other words, the study design per se, is at least partially responsible for the apparent decline in the incidence rates. In these studies, the proportion of severe or extensive cases was much lower compared to that reported by tertiary centers<sup>[3,17]</sup>.

The risk of CRC can also be expressed in relative terms, as standardized morbidity ratio (SMR; observed cancers in a UC cohort divided by expected cancers, with expected rates derived from the general population) or an incidence rate ratio (IRR; observed incidence of cancers in a UC cohort divided by observed incidence of cancers in a control cohort of the general population). The SMR or IRR values in the new population-based studies were only moderately increased in Denmark, Canada, and Italy. Compared to the general population, the risk varied between 1.05 and 2.75. Although these studies suggest that the relative risk of CRC is considerably lower than previously described, some would argue that the low rates of CRC observed in these studies are the successful result of timely and appropriate access to good health care, including maintenance therapies, surveillance colonoscopy, and surgery<sup>[20]</sup>. This is further corroborated by the data arising from a large colonoscopic surveillance program at St. Mark's Hospital between 1970 and 2001<sup>[17]</sup>. Six hundred patients with extensive UC were followed up for 5932 person-years. The cumulative probability of CRC in UC patients undergoing surveillance was only 7.6% after

30 years. Linear regression suggested that CRC incidence declined over the course of the study, supporting a role for surveillance in decreasing the risk for CRC. In addition, although the prognosis of UC-related CRC cases has generally been considered to be worse compared to sporadic cases, the experience from the study at St. Mark's Hospital<sup>[17]</sup> is much better. In 600 patients during 5932 patient-years of follow-up, 30 patients (5%) developed CRC, with a 5-year survival rate of 73.3%. Similarly high 5-year survival rates were reported from the Mayo Clinic<sup>[21]</sup> (55%) and from Eastern Europe<sup>[4]</sup> (68.4% at 5 years and 10 years).

The incidence of colorectal dysplasia in UC is even more difficult to determine than the incidence of CRC. There is considerable interobserver variability as well as a lack of uniform definitions. In addition, underlying inflammation might influence the diagnosis of dysplasia. Two population-based studies have examined the incidence of colorectal dysplasia in UC. In Sweden<sup>[22]</sup>, 52/204 patients (24%), including 66% with pancolitis developed dysplasia at some points in their disease course, during follow-up with a median of 16.5 years. Lower incidence rates were reported from the US<sup>[23]</sup>, where adherence to surveillance was lower. A total of 22 dysplastic lesions were diagnosed. In concordance, relatively low incidence rates were reported from the St. Mark's Hospital<sup>[17]</sup>. During a follow-up of 5080 person-years, the cumulative probability of dysplasia at 20 years was 7.7% and 15.8% at 30 years. Low grade dysplasia developed in 7.8%, while high grade developed in 3.2% of the patients. In addition, polypoid dysplasia was revealed in 3.3% and sporadic adenoma in 5.3% of the patients.

## RISK FACTORS FOR COLORECTAL CANCER IN ULCERATIVE COLITIS

The most important risk factors for UC-associated CRC are disease duration and extent. The possible mechanisms include chronic inflammation and as the duration of chronic bowel inflammation increases, so does the risk for colorectal dysplasia and CRC. In some studies, this annual risk rises exponentially with a duration beyond 30 years. This has led some guidelines to recommend surveillance colonoscopy every 1 year to 3 years between years 8 and 20 and every 1 year to 2 years thereafter<sup>[24]</sup>. In contrast, some of the recently published population-based studies could not demonstrate a clear-cut relation in UC duration<sup>[8]</sup>, and cancer risk or the gradual increase of the risk was much lower<sup>[4,7]</sup>.

In the landmark trial by Ekbom *et al*<sup>[12]</sup>, more than 3000 UC patients were followed up and the risk for CRC increased gradually from 1.7-fold in proctitis and 2.8-fold in left-sided colitis to 14.8-fold in pancolitis, compared to the general population. Most studies including the meta-analysis by Eaden *et al*<sup>[11]</sup>, have come to similar conclusions. The overall prevalence of CRC among patients with UC in all 116 studies was 3.7%, but when restricted to the 35 studies that stratified their analyses by extent of UC, the prevalence of CRC among patients with ex-

tensive involvement rose to 5.4%.

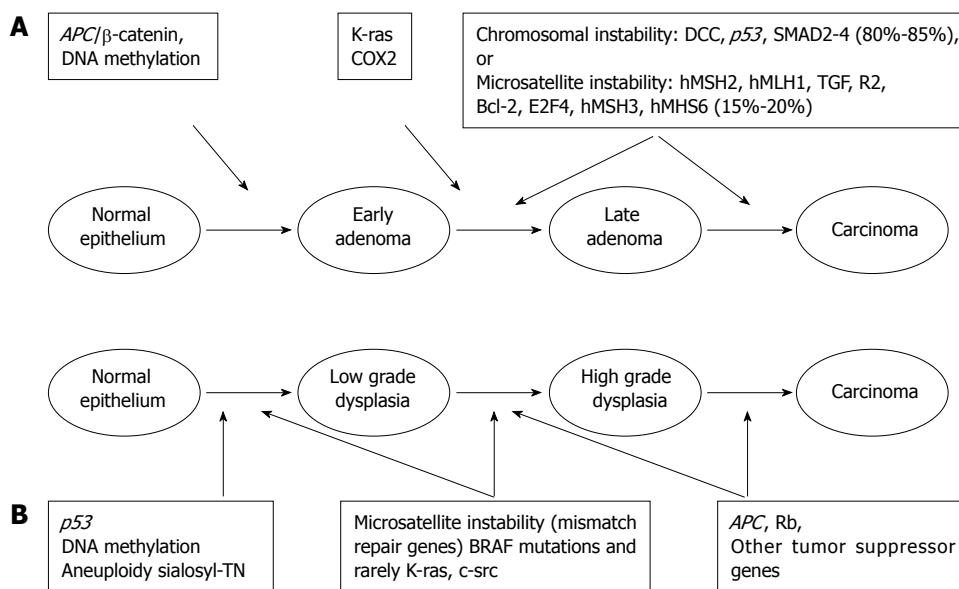

Important risk factors include primary sclerosing cholangitis (PSC)<sup>[25-27]</sup>, family history of CRC<sup>[28]</sup>, whereas the role of other factors, such as age at onset of UC, frequency of flare-ups, severity of inflammation<sup>[29]</sup>, "backwash ileitis"<sup>[30]</sup>, smoking, medical therapy used (5-amino-salicylates, azathioprine)<sup>[31]</sup>, is more controversial.

There is some debate as to whether patients with an early onset of colitis have a higher risk than patients with a later onset. Ekbom *et al*<sup>[12]</sup> identified the age below 15 years at onset as an independent risk factor for CRC. The cumulative risk for CRC after a disease duration of 35 years was 40% in extensive colitis if the disease started before the age of 15 years, while it was 25% if the disease onset was between 15 years and 39 years of age. Furthermore, disease onset during childhood was also established as an independent risk factor in the meta-analysis<sup>[3]</sup>. In contrast, other studies could not confirm this finding<sup>[4,32]</sup>; for example the age at onset above 30-40 years was associated with a higher risk in an American study, compared with a group of patients with onset below 20 years of age<sup>[33]</sup>. Since disease duration may be longer, theoretically, the risk of CRC should be greater in patients whose disease begins during early childhood.

Several studies have recognized PSC as a risk factor for CRC in UC patients<sup>[4,27,34,35]</sup>; however, this was not proven in all studies<sup>[36]</sup>. In one of the first reports, Broome *et al*<sup>[37]</sup> noted in a case-control study that the prevalence of PSC was 28% in the 17 patients with UC investigated with colorectal dysplasia or DNA aneuploidy *vs* 0 in the 55 patients without precancerous abnormalities. In the study by Kornfeld *et al*<sup>[35]</sup>, the cumulative CRC risk was 33% at 20 years and 40% at 30 years after UC diagnosis. In addition, the percentage of right-sided CRCs was higher in the subgroup of colitis patients with PSC<sup>[34]</sup>. In the study by Shetty *et al*, right-sided CRCs were observed in 76% of patients. The mechanism by which PSC induces CRC remains unclear. It has been hypothesized that alterations in the bile salt pool and a high concentration of bile acids in the colon may, at least partially, be responsible for the increased risk, but evidence also supports a strong association between PSC and quiescent to mild pancolitis. Colonic disease activity was milder in the 29 patients with PSC-IBD compared to the 58 patients with extensive UC without PSC in the study by Lundqvist *et al*<sup>[38]</sup>. Furthermore, patients with PSC were twice as likely to have never required corticosteroid treatment (52% *vs* 24%). In another study, patients with PSC-IBD were significantly less likely to require a proctocolectomy, in comparison to patients with extensive UC without PSC<sup>[27]</sup>.

The role of smoking in the development of UC-associated CRC has been a focus of controversy. Nonetheless, it has been identified as a risk factor for sporadic CRC<sup>[39]</sup>. In UC, an additive protective role might be hypothesized, as it might attenuate the inflammation and prevent relapses.

Finally, until recently, no direct evidence was available to support a link between the severity of inflammation

**Figure 1** Summary of genetic alterations in sporadic colorectal cancer (A) and colitis-associated colorectal cancer (B). The timing of p53 and APC mutations is different; unlike in sporadic neoplasia, mutations and LOH in p53 are early events in UC-associated CRCs. The opposite was reported for APC mutations<sup>[42]</sup>.

and the risk for CRC. A number of case-control studies with negative result relied on indirect outcome measures such as hospitalization, frequency of diagnostic testing, and frequency of symptomatic exacerbations<sup>[40]</sup>. Rutter *et al*<sup>[29]</sup> retrospectively reviewed endoscopic and pathologic reports of 68 UC patients with CRC or dysplasia and 136 UC patients without CRC, and assigned a severity score to each segment of the colon for each colonoscopy. The endoscopic (OR, 2.5; 95% CI, 1.4-4.4) or histologic (OR, 5.1; 95% CI, 2.4-11.1) scores were associated with the risk of CRC in univariate analysis. In addition, the histologic score was identified as an independent risk factor for CRC even after adjustment for confounding variables. This association was recently confirmed in a report from the Texas University<sup>[41]</sup>. During follow-up, 15 UC patients progressed to advanced neoplasia (high-grade dysplasia or colorectal cancer), and 65 progressed to neoplasia (low-grade dysplasia, high-grade dysplasia, or colorectal cancer). Univariate and multivariate analysis demonstrated significant relationships between histologic inflammation over time and progression to advanced neoplasia (HR, 2.2-3.4).

## GENETICS OF ULCERATIVE COLITIS ASSOCIATED COLORECTAL CANCERS

Both genetic and environmental factors contribute to the pathogenesis of CRC in IBD. Most sporadic CRC cases arise from a preceding adenoma (adenoma-carcinoma cascade) associated with unique genetic mutations. IBD-related cancers, however, are associated with a partially different genetic background<sup>[42]</sup>. The increased risk is thought to be an acquired event in IBD, although common inherited factors (e.g. glycosylation of mucin) have been proposed as a link between both forms of IBD and CRC<sup>[43]</sup>.

Complete elucidation of the mechanism of UC-CRC carcinogenesis will require further investigations; however, chronic inflammation is thought to be the most

important driving mechanism. Although the same three molecular pathways that have been described for sporadic colon carcinogenesis [loss of heterozygosity (LOH), microsatellite instability (MSI) and CpG methylator phenotype (CIMP)] are also found in colitis-associated neoplasms, yet the timing and frequency of some of the key genetic changes are different (Figure 1), possibly due to the different main driving mechanisms.

Changes in DNA methylation and microsatellite instability are also frequently found at an early stage in UC-associated CRCs. The prevalence in dysplasia-cancer cases ranges from < 1% to 70%<sup>[44-46]</sup>, for example hypermethylation of p14ARF occurs in approximately 30% of cases with dysplasia<sup>[47]</sup>. Unlike sporadic MSI-H (MSI-high) CRCs, MSI-H IBD CRCs present with heterogeneous mismatch repair defects involving MLH1, MSH2, MSH6, or PMS2, and a low frequency of MLH1 promoter methylation. They exhibit frequent BRAF but no KRAS mutations and frameshift mutations in genes containing coding repeat sequences. IBD patients exhibiting MSI-H present at younger age at diagnosis, and there is neither female predominance nor right-sided predominance<sup>[48]</sup>. In UC patients with MSI-H CRCs, MSI could already be demonstrated 2-12 years prior to the diagnosis of CRC in about 25% of the cases<sup>[49]</sup>. In contrast, hypermethylation of different target genes is a relatively rare event (MINT1, 2, 31, hMLH1, p16, p14, MGMT, HPP1, SFRP1, ERa and LINE-1)<sup>[50]</sup>. Thus MSI seems to be an important mechanism in UC-related carcinogenesis, at least in a subset of UC-CRC cases.

Loss of heterozygosity is a frequent but late event, primarily affecting SMAD4 and DCC loci (PACAP at 18p or DCC, SMAD2, SMAD4, GALNR at 18q-n)<sup>[51]</sup>. Unlike in sporadic CRCs, IBD-associated cancer mutations and LOH in p53 are early events that can already be found in macroscopically normal looking mucosa<sup>[52-54]</sup>. In contrast, mutations in k-ras are relatively infrequent. Since mutations in k-ras are believed to occur in sporadic adenoma cases<sup>[55]</sup>, this may partially explain the flat growth pattern of CRCs in IBD. Mutations in k-ras are

associated with polyp formation, which might explain why neoplasias in IBD are usually flat. Mutations of APC are infrequent (0%-3%), late events in UC, often occurring only in HGD or cancers<sup>[56]</sup>. Genetic events in DALM (dysplasia-associated lesion or mass) are similar to those observed in other UC-CRC cases including changes in MSI and LOH<sup>[57]</sup>.

Recently, an association was reported by the Mayo Clinic<sup>[58]</sup> between the G308A TNF $\alpha$  polymorphism and the risk of UC-associated CRC in 114 UC-CRC cases and matched controls, further corroborating the importance of chronic inflammation in CRC pathogenesis.

## HOW CAN WE DECREASE THE RISK OF CRC IN IBD?

The positive association between UC and CRC raises several practical questions. The causes behind the changing trends in UC-related CRC epidemiology are complex. One key element may be the early diagnosis and treatment of precancerous lesions by colonoscopic surveillance or sometimes prophylactic colectomy, while the third option is primary chemoprevention. Nowadays, prophylactic colectomy is obsolete. Nonetheless, the high colectomy rate, especially in Scandinavian countries has been associated with lower CRC risks<sup>[16]</sup>. There are however, obvious changes in the patient management, also in Scandinavia. In the new population-based cohorts, a decrease in the colectomy rate can be observed<sup>[59]</sup>.

## ENDOSCOPIC SURVEILLANCE IN IBD

Endoscopic surveillance remains an important but often disputed cornerstone of IBD management<sup>[60]</sup>. Colonoscopic surveillance to detect dysplasia and/or cancer is routinely indicated in compliant UC patients in clinical practice. Surveillance colonoscopy may permit earlier detection of CRC, with a correspondingly improved prognosis; however, unequivocal evidence is lacking that surveillance colonoscopy prolongs survival in patients with UC. Based on previous epidemiological data, international guidelines of the Crohn's and Colitis Foundation of America (CCFA)<sup>[24]</sup> and very recently the European Crohn's and Colitis Organisation (ECCO)<sup>[61]</sup> suggest a relatively strict surveillance policy. Whether these recommendations require adjustments in light of new epidemiological data that suggest a much lower CRC incidence remains questionable. Many factors (e.g. cost effectiveness, geographical differences, access to endoscopy and pathology) need to be considered. Nonetheless, it is possible that the lower incidence rates reported in recent population-based studies are at least partly a consequence of the vigorous surveillance programs.

As of today, the guidelines regarding the surveillance of CRC in UC patients can be summarized as follows: (1) Surveillance endoscopy should be performed in remission; (2) Initial screening colonoscopy should be performed in each patient after a 8-10 year disease duration, partly to reassess disease extent; (3) Regular surveil-

lance should begin after 8-10 years for pancolitis and after 15-20 years for left-sided disease. There should be a decrease in the screening interval with increasing disease duration (from 2 to 1 year). No surveillance is indicated in proctitis; (4) Two to four random biopsy specimens, every 10 cm, should be taken from the entire colon, with additional samples of suspicious areas. Alternatively methylene blue or indigo carmine chromoendoscopy can be offered for appropriately trained endoscopists and is superior to random biopsies in the detection rate of neoplastic lesions; and (5) Patients with primary sclerosis cholangitis represent a subgroup at higher risk, thus surveillance should be performed annually from the time of PSC diagnosis.

The use of random biopsies is being increasingly criticized. Since the reports by Rutter *et al*<sup>[62]</sup> and Rubin *et al*<sup>[63]</sup>, we know that dysplasia (71.7%-77.3%) and cancer (89.3%-100%) were macroscopically visible during colonoscopies in UC patients without PSC. Thus, the cost of additional random biopsies is difficult to justify. On the other hand, random biopsies visualize only 1% of total colonic mucosa surface area, promoting a high sampling error. In a retrospective analysis, it was demonstrated that the probability of detecting dysplasia was 90% if 33 and 95% if 56 random biopsies were taken<sup>[64]</sup>, with current guidelines for dysplasia surveillance recommending a minimum of 33 biopsies. In addition, almost half of patients with dysplasia initially detected in flat mucosa were later diagnosed to have colorectal cancer in the colectomy specimen<sup>[65]</sup>. Furthermore, almost one-third of patients with low grade dysplasia progressed to high grade dysplasia or cancer during follow-up. In the most recent meta-analysis, low-grade dysplasia was found to be associated with a 9-fold increased risk of developing CRC and a 12-fold risk of developing advanced neoplasia<sup>[66]</sup>. However, because some follow-up studies of patients with low-grade dysplasia have shown a low rate of CRC development (2%-10% during a 10-year follow-up)<sup>[67]</sup>, it seems there is a reasonable compromise to continue surveillance with extensive biopsy sampling at shorter intervals (e.g. 3-6 mo) in those who will adhere strictly to the surveillance program. In summary, a patient with low-grade dysplasia in flat mucosa should be offered proctocolectomy or repeat surveillance biopsies within 3-6 mo, while high-grade dysplasia in flat mucosa and adenocarcinoma are indications for proctocolectomy.

Raised lesions on a background of UC have been traditionally referred to as dysplasia-associated lesion or mass (DALM). Until recently, this finding had been considered an absolute indication for colectomy. It is increasingly recognized, however, that some of these raised lesions may resemble sporadic adenomas and that they may be treated by endoscopic resection<sup>[68]</sup>, if polypectomy can be performed safely and completely, without any dysplasia present in the adjacent mucosa in patients who will adhere to strict surveillance program afterwards.

The detection of CRC by surveillance is still not very

**Table 2** Summary of studies investigating the chemopreventive effect of sulfasalazine and 5-ASA therapies in ulcerative colitis

Study	Study design	n	Drug studies	Principal outcome
Pinczowski <i>et al</i> <sup>[31]</sup>	Case-control	298	Sulfasalazine > 3 mo	OR <sub>CRC</sub> : 0.38 (95% CI, 0.2-0.69) patients administered sulfasalazine
Moody <i>et al</i> <sup>[101]</sup>	Case-control	175	Sulfasalazine < 6 mo	10-fold elevated risk in non-exposed patients (30% vs 3%)
Eaden <i>et al</i> <sup>[40]</sup>	Case-control	102	Sulfasalazine, mesalamine regular use	OR <sub>CRC</sub> : 0.25 (95% CI, 0.13-0.48) in regular users
Lindberg <i>et al</i> <sup>[102]</sup>	Cohort study	143	Sulfasalazine > 6 mo	Non-significant decrease of risk (34% vs 44%)
Bernstein <i>et al</i> <sup>[87]</sup>	Case-control	373	5-ASA	Non-significant elevation of risk in patients exposed
Rutter <i>et al</i> <sup>[29]</sup>	Case-control	204	5-ASA	Non-significant elevation of risk of dysplasia in patients exposed
Rubin <i>et al</i> <sup>[90]</sup>	Case-control	124	5-ASA > 1.2 g regular use	OR <sub>CRC</sub> : 0.28 (95% CI, 0.09-0.85) in regular users

encouraging. Almost half of 92 CRC cases identified in surveillance programs in 1916 UC patients were in advanced stages (Dukes' C or D)<sup>[69]</sup> and only 12% of CRC cases were identified during surveillance colonoscopies in earlier studies. In concordance, a meta-analysis by the Cochrane group in 2006<sup>[70]</sup> failed to demonstrate a benefit for surveillance programs in preventing CRC-related death in UC (OR, 0.81, 95% CI, 0.17-3.83), but authors included only two studies in their final analysis. Furthermore, in the largest and most meticulous screening programs<sup>[17]</sup> reported to date, involving 600 patients, 2627 colonoscopies, 5932 patient-year of follow-up and a caecal intubation rate of 98.7% without significant complications, 16 of 30 cancers were interval cancers.

The diagnosis of dysplasia is demanding. During a period of active disease, it is almost impossible to differentiate between inflammation and true dysplasia. Furthermore, a significant interobserver variation was reported for the detection of dysplasia, and an agreement concerning low-grade dysplasia may be as low as 43%. Therefore, because of important prognostic implications, any case of dysplasia should be confirmed by an experienced pathologist<sup>[71,72]</sup>.

Targeted biopsies represent an alternative to random biopsies. All studies have confirmed an improved yield of surveillance colonoscopy by dye spraying (e.g. methylene blue or indigo carmine). When applied, random biopsies of apparently normal mucosa had no additional value compared to targeted biopsies obtained after dye staining of the mucosa. In the study by Rutter *et al*<sup>[73]</sup>, the clinical accuracy of consecutive, random (*n* = 2904) and targeted (indigocarmine: 157) biopsies was compared. Nine dysplastic lesions were diagnosed at chromoendoscopy, while no dysplasia was detected in random biopsies and no additional lesions were detected. Separate prospective studies have arrived at similar conclusions<sup>[74,75]</sup>, including the study by Hurlstone *et al*, who compared magnified chromoendoscopic surveillance in 350 UC patients and 350 disease-extent matched controls on traditional surveillance using random biopsies. Sixty-nine dysplastic lesions were identified by chromoendoscopy, compared with only 24 dysplastic lesions in the traditional surveillance group (*P* < 0.001). The diagnostic yield for detecting a dysplastic lesion increased in these studies by 3-4.5 folds and comparable diagnostic yields from chromoendoscopy have been obtained with both methylene blue and indigo carmine. In fact, Marion *et al*<sup>[76]</sup> was the first to identify a significant increase in the total number of patients (not

just lesions) with dysplasia following chromoendoscopy (1.5-fold).

Currently there are only limited data available regarding the role of advanced endoscopic techniques [e.g. narrow band imaging (NBI), fluorescence endoscopy, optical coherence tomography or confocal laser endomicroscopy]<sup>[77,78]</sup>. In a study by Kiesslich *et al*<sup>[79]</sup> endomicroscopy or colonoscopy were performed in 153 UC patients. Despite a significantly lower number of biopsies taken in the targeted group, the number of identified dysplastic lesions increased by 4.7 folds. In a very recent report by the same group<sup>[80]</sup>, confocal chromoscopic endomicroscopy was superior to chromoscopy alone for the detection and characterization of intraepithelial neoplasia in chronic ulcerative colitis.

In contrast, the use of NBI<sup>[81]</sup> did not improve the diagnostic accuracy compared to conventional colonoscopy. Although more lesions were identified using NBI, an almost equal number of dysplastic foci were identified and missed by both methods. Despite the promising results, further studies are needed before the use of these advanced techniques can be suggested in clinical practice.

## CHEMOPREVENTION IN IBD-IS IT POSSIBLE?

Given the theory that chronic inflammation is the driving force behind malignant transformation, the possibility exists for the use of maintenance anti-inflammatory therapy as primary chemoprevention<sup>[82]</sup>. The ideal chemopreventive agent would be safe, effective at preventing neoplastic progression, inexpensive, and able to prevent flares and control disease activity and symptoms. 5-aminosalicylic acid (5-ASA), including mesalamine and sulfasalazine, are attractive candidates; they are safe, relatively inexpensive, and effective maintenance therapy. Mesalamine is a potent anti-inflammatory drug exhibiting strong scavenger capacity, affecting *in vitro* NF-κB activity and apoptosis at least partly by increasing peroxisome proliferator-activated receptor-γ (PPAR-γ) expression<sup>[83-85]</sup>.

However, data supporting this possible chemopreventive effect are somewhat conflicting (Table 2). Promising results were produced by a case-control study by Eaden *et al*<sup>[40]</sup>, who identified 102 cases of CRC from a population of UC patients treated at a combination of academic and community-based gastroenterology practices. Overall

the use of any 5-ASA compound was associated with a 75% decreased risk of CRC (95% CI, 0.13-0.48). Among all 5-ASA compounds, mesalamine use was associated with the greatest degree of protection, providing the most benefit at doses greater than 1.2 g/d (OR, 0.09; 95% CI, 0.03-0.28). Sulfasalazine use was associated with a smaller protective effect, which was statistically significant only at doses of 2 g/d or more (OR, 0.41; 95% CI, 0.18-0.92). Of note, however, > 2 outpatient visits/year, use of systemic steroids, and regular colonoscopic surveillance were also associated with the decreased risk. If sulfasalazine is used, folate supplementation is mandatory, since folate deficiency alone might increase the risk of CRC in IBD<sup>[86]</sup>. In contrast, other studies, including the one by Bernstein *et al*<sup>[87]</sup>, failed to demonstrate a protective effect even after stratifying for dose and duration of therapy. Since controlled trials would necessitate withholding a drug used for remission maintenance by randomizing some patients into the placebo arm, these studies will never be performed due to ethical reasons. In addition, based on available data and statistical power analysis, theoretically, the follow-up of a total of 5260 patients for at least 10 years would be necessary to demonstrate a positive effect for 5-ASA vs placebo, if the estimated risk of cancer is approximately 0.51<sup>[88]</sup>. A much larger sample size would be required if a comparison with placebo would not be an option and the primary objective would be to assess a dose response.

A more recent meta-analysis has provided a systematic overview of the studies available with respect to 5-aminosalicylates<sup>[89]</sup>. A total of nine studies, three cohort and six case-control studies, were included. Half of the studies found significantly diminished incidence of colon cancer in aminosalicylate users, with an adjusted summary OR covering all trials of 0.51 (95% CI, 0.37-0.69). Only two studies focused on dysplasia incidence and 5-ASA use was not associated with lower risk of dysplasia (OR, 1.18). Nonetheless, the combination of both endpoints, dysplasia and cancer, again resulted in an OR of 0.51 (95% CI, 0.38-0.69). Surprisingly, the results were similar in short-term users (2-6 mo) or long-term users (2-20 years) with an OR of 0.56 and 0.50, respectively. An even lower OR was obtained in patients on a dose of 1.2 g/d or more (OR, 0.19-0.28). These conclusions were confirmed by a very large British study in regular mesalamine users with an OR of 0.31. In contrast, in the subgroup of CD patients, although numbers were small, the OR was 1.66, indicating no preventive effect for 5-ASA. Therefore, evidence in UC may not be simply extrapolated to CD. In the editorial<sup>[65]</sup> of this meta-analysis, the authors concluded that 5-ASA is a probable chemopreventive agent based on safety and current maintenance use. Reports following the meta-analysis were also contradictory. Investigating 96 cases and matched controls, Rubin *et al*<sup>[90]</sup> found that aminosalicylate use of 1.2 g/d or more was associated with a 72% reduction in the odds of dysplasia/CRC (OR, 0.28; 95% CI, 0.09-0.85). A trend for dose response was also reported ( $P = 0.056$ ). Of note, the OR for doses between 1.2-2.4 g/d was 0.19, while for doses  $\geq 2.4$  g/d

it was 0.48. In contrast, no benefit for 5-ASA use was found in a study based on two large claim databases<sup>[18]</sup>. Among patients with IBD (364 CRC cases, 1172 controls), exposure to 5-ASA therapy of any dose or duration during the 12 mo preceding CRC diagnosis was not associated with a reduced risk of CRC (OR, 0.97; 95% CI, 0.77-1.23). However, there was a trend toward a decreased risk of CRC with increasing number of mesalamine prescriptions ( $\geq 5$  prescriptions) in the previous year, though statistical significance was not achieved (trend,  $P = 0.08$ ). No long-term prescription data were analyzed.

The chemopreventive role for ursodeoxycholic acid (UDCA) therapy in PSC is well-supported by both experimental data and clinical studies<sup>[91,92]</sup>. In a post hoc analysis of a randomized clinical trial, three patients (10%) initially assigned to UDCA developed colorectal dysplasia or CRC compared to eight patients initially assigned to placebo (35%)<sup>[92]</sup>. The relative risk of dysplasia or CRC was 0.26 in the UDCA group.

There is only limited evidence for the role of other anti-inflammatory agents. In the study by Eaden *et al*<sup>[40]</sup>, 5% of cases and 19% of controls used systemic steroids (durations unknown), which was associated with a statistically significant reduction in CRC risk among UC patients (OR, 0.26; 95% CI, 0.01-0.70). No dose response effect was demonstrated. Results are, however, conflicting as in the later study by Lashner *et al*<sup>[93]</sup>, a positive effect by at least 6 mo of azathioprine or 6-mercaptopurine therapy could not be demonstrated. Similarly, no preventive effect (HR, 1.06-1.3) of azathioprine/6-mercaptopurine use could be demonstrated during an 8-year follow-up in a more recent study<sup>[94]</sup>. Of note, azathioprine was reported to be associated with a 4-fold elevated risk of lymphomas in some previous studies<sup>[95]</sup> and a recent meta-analysis<sup>[96]</sup>. Although IBD itself was not associated with an increased risk for lymphoma<sup>[97]</sup>, disease severity cannot be excluded as a confounding variable. Finally, no data are available on anti-TNF agents in this context. Risk for malignancy (RR, 1.1; 95% CI, 0.71-1.63) and lymphoma (RR, 1.3; 95% CI, 0.36-5.03) was not increased in CD according to the TREAT (TREAT-Crohn's therapy, resource, evaluation, assessment and tool) registry<sup>[98]</sup> and some other studies<sup>[99]</sup>. Somewhat in contrast, a recent meta-analysis<sup>[100]</sup> on the safety of TNF inhibitors in rheumatoid arthritis patients has shown a significantly increased risk of malignancies (OR, 3.29; 95% CI, 1.09-9.08). Many of the patients however, received a combination of anti-TNF and methotrexate, and only a single patient with colorectal cancer (rectal) was reported.

## CONCLUSION

The risk of colorectal cancer for any patient with ulcerative colitis is known to be elevated, and was estimated to be 2% after 10 years, 8% after 20 years and 18% after 30 years of disease. Recent population-based studies published within the past 5 years suggest that this risk has decreased over time, despite the relatively low

frequency of colectomies. The crude annual incidence rate of colorectal cancer in ulcerative colitis ranges from approximately 0.06% to 0.16% with a relative risk of 1.0-2.75. Risk factors for cancer include extent and duration of ulcerative colitis, primary sclerosing cholangitis, a family history of sporadic colorectal cancer, severity of histologic bowel inflammation, and in some studies, young age at onset of colitis. Complete elucidation of the mechanism of UC-CRC carcinogenesis will require further investigations; however, chronic inflammation is thought to be the most important driving mechanism. Although the same three molecular pathways that have been described for sporadic colon carcinogenesis [loss of heterozygosity (LOH), microsatellite instability (MSI) and CpG methylator phenotype (CIMP)] are also found in colitis-associated neoplasms, yet the timing and frequency of some of the key genetic changes are different. The exact mechanism for this change in epidemiology trends of UC-associated CRC is unknown. One key element may be the early diagnosis and treatment of precancerous lesions by colonoscopic surveillance or sometimes prophylactic colectomy, while a third option is primary chemoprevention. Nowadays, prophylactic colectomy is obsolete. Increasing amount of evidence is now available supporting an improved yield of surveillance colonoscopy by targeted biopsies. The method of choice or data regarding the role of advanced endoscopic techniques is under investigation. Another important factor contributing to the changing trends in epidemiology may be the more widespread use of maintenance therapy by aminosalicylates and UDCA in patients with PSC, making 5-ASAs a probable chemopreventive agent based on safety profile and current maintenance use. As of today, based on available literature and international guidelines, the use of surveillance endoscopy and maintenance chemopreventive therapy should be advised and discussed in patients with ulcerative colitis.

## Abstract

Based on histological and immunohistochemical examination of various organs of patients with autoimmune pancreatitis (AIP), a novel clinicopathological entity of IgG4-related sclerosing disease has been proposed. This is a systemic disease that is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs. Clinical manifestations are apparent in the pancreas, bile duct, gallbladder, salivary gland, retroperitoneum, kidney, lung, and prostate, in which tissue fibrosis with obliterative phlebitis is pathologically induced. AIP is not simply pancreatitis but, in fact, is a pancreatic disease indicative of IgG4-related sclerosing diseases. This disease includes AIP, sclerosing cholangitis, cholecystitis, sialadenitis, retroperitoneal fibrosis, tubulointerstitial nephritis, interstitial pneumonia, prostatitis, inflammatory pseudotumor and lymphadenopathy, all IgG4-related. Most IgG4-related sclerosing diseases have been found to be associated with AIP, but also those without pancreatic involvement have been reported. In some cases, only one or two organs are clinically involved, while in others, three or four organs are affected. The disease occurs predominantly in older men and responds well to steroid therapy. Serum IgG4 levels and immunostaining with anti-IgG4 antibody are useful in making the diagnosis. Since malignant tumors are frequently suspected on initial presentation, IgG4-related sclerosing disease should be considered in the differential diagnosis to avoid unnecessary surgery.

## INTRODUCTION

Since Yoshida *et al*<sup>[1]</sup> proposed the concept of autoimmune pancreatitis (AIP) in 1995, many cases have been reported in Western countries, as well as in Japan, and AIP has become a distinct entity recognized worldwide. Although the precise pathogenesis or pathophysiology of AIP remains unclear, many clinical, radiological, serological and histopathological characteristics are obvious. In patients with AIP, serum IgG4 levels are frequently and significantly elevated, and various extrapancreatic lesions are present<sup>[2]</sup>. Based on histological and immunohistochemical examination of various organs of AIP patients, we have found dense infiltration of IgG4-positive plasma cells and CD4- or CD8-positive T lymphocytes, as well as fibrosis in the peripancreatic retroperitoneal tissue, bile duct wall, gallbladder wall, periportal area of the liver, salivary glands, and the pancreas. Furthermore, all of the extrapancreatic lesions associated with AIP, such as sclerosing cholangitis, sclerosing sialadenitis, and retroperitoneal fibrosis, show infiltration of abundant IgG4-positive plasma cells<sup>[2-5]</sup>. Both the pancreatic and extrapancreatic lesions of AIP respond well to steroid therapy<sup>[6-8]</sup>.

Therefore, we proposed the existence of a novel clinicopathological entity, IgG4-related sclerosing disease, and suggested that AIP is a pancreatic lesion of this systemic disease. Many recent reports of multorgan, inflammatory, mass-forming lesions with increased numbers of IgG4-positive plasma cells affirm that AIP may have a systemic component<sup>[2,3,8]</sup>. On <sup>18</sup>F-fluorodeoxyglucose positron emission tomography (FDG-PET) performed in AIP patients, abnormal FDG uptake

**Table 1** Clinicopathological findings of IgG4-related sclerosing disease

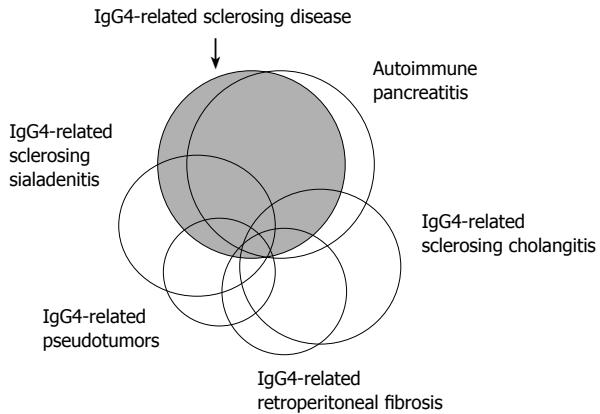

Clinicopathological findings	
Systemic disease characterized histopathologically by extensive IgG4-positive plasma cell infiltration of various organs together with T lymphocytes	
Major clinical manifestations are apparent in the organs in which tissues fibrosis with obstructive phlebitis is pathologically induced	
Pancreas	Autoimmune pancreatitis
Bile duct	IgG4-related sclerosing cholangitis
Gallbladder	IgG4-related sclerosing cholangitis
Salivary gland	IgG4-related sclerosing cholangitis
Retroperitoneum	IgG4-related retroperitoneal fibrosis
Kidney	IgG4-related tubulointerstitial nephritis
Lung	IgG4-related interstitial pneumonia
Prostate	IgG4-related prostatitis
Some inflammatory pseudotumors (liver, lung and hypophysis) may be involved in this disease	
Occasional association with lymphadenopathy	
Elderly male preponderance	
Frequent elevation of serum IgG4 levels	
Favorite response to steroid therapy	
Differentiation from malignant tumor is important	
Precise pathogenesis and pathophysiology remain unclear	

has been observed in various extrapancreatic lesions<sup>[9]</sup>. Furthermore, many IgG4-related sclerosing diseases of organs other than the pancreas have been recently reported. Although the nomenclature differs, IgG4-related sclerosing disease has been noted in hepatology, cholangiology, rheumatology, urology, nephrology, respirology, endocrinology, pathology, and radiology, as well as pancreatology. Based on our experience with 50 AIP patients, this review focuses on the clinical, laboratory, imaging, and histopathological features of IgG4-related sclerosing disease, including AIP.

## IgG4-RELATED SCLEROSING DISEASE

IgG4-related sclerosing disease is a systemic disease characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs. Clinical manifestations are apparent in the pancreas, bile duct, gallbladder, salivary gland, retroperitoneum, kidney, lung and prostate, in which tissue fibrosis with obliterative phlebitis is pathologically induced (Table 1). AIP is not simply pancreatitis, but it is a pancreatic disease that is indicative of IgG4-related sclerosing disease. Most IgG4-related sclerosing diseases have been found to be associated with AIP, but IgG4-related sclerosing diseases without pancreatic involvement have been reported. Some inflammatory pseudotumors may be involved in this disease. In some cases, only one or two organs are clinically involved, while in others, three or four organs are affected (Figure 1). The disease occurs predominantly in older men, is frequently associated with lymphadenopathy, and responds well to steroid therapy. Serum IgG4 levels and immunostaining with anti-IgG4 antibody are useful in making the diagnosis. The precise pathogenesis and pathophysiology of IgG4-related sclerosing disease remain unclear. Since malignant tumors are frequently suspected on initial presentation, IgG4-related sclerosing disease should be considered in the differential diagnosis to avoid unnecessary surgery<sup>[2,3,8]</sup>.

Multifocal fibrosclerosis is an uncommon fibroproliferative systemic disorder with multiple manifestations,

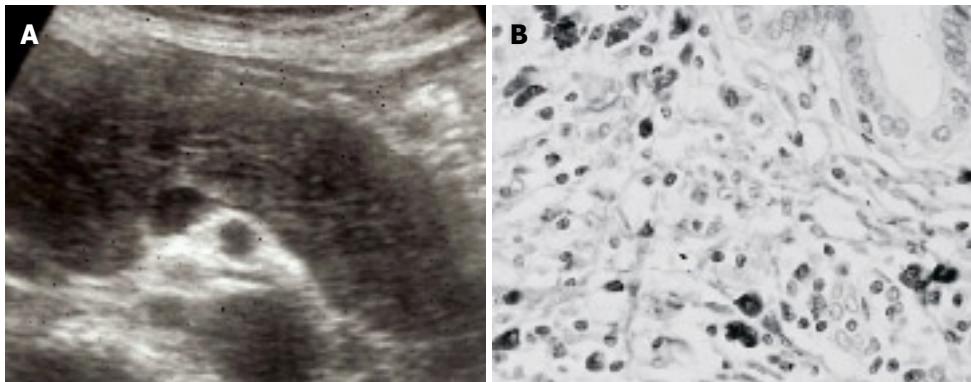

**Figure 1** Schematic illustration showing the relationship between IgG4-related sclerosing disease, AIP, IgG4-related sclerosing cholangitis, IgG4-related sclerosing sialadenitis, IgG4-related retroperitoneal fibrosis, and IgG4-related pseudotumors.

including sclerosing cholangitis, salivary gland fibrosis, retroperitoneal fibrosis, Riedel's thyroiditis, and fibrotic orbital pseudotumor<sup>[10]</sup>. As the histopathological findings of these disorders are similar, fibrotic changes with lymphoplasmacytic infiltration and occasional phlebitis, it is suggested that they are all interrelated and probably different manifestations of a common disorder of fibroblastic proliferation. Several cases of pancreatic pseudotumor or chronic pancreatitis associated with multifocal fibrosclerosis have been reported. The histopathology of the extrapancreatic lesions associated with AIP strongly suggests that multifocal fibrosclerosis is an IgG4-related sclerosing disease<sup>[5]</sup>.

## AIP

### Concept and clinical features

AIP is a unique form of pancreatitis in which autoimmune mechanisms are suspected to be involved in the pathogenesis. The histopathological findings of AIP include marked lymphoplasmacytic infiltration with fibrosis in the pancreas, known as lymphoplasmacytic

**Figure 2** AIP. (A) Diffuse hypoechoic enlargement of the pancreas on ultrasonography; (B) Dense infiltration of IgG4-positive plasma cells in the pancreas.

sclerosing pancreatitis. AIP occurs more commonly in older men. In our series, the mean age of the patients was 66.5 years (range, 25–83 years), and the male-to-female ratio was 4:1. The major clinical symptom is obstructive jaundice, due to associated sclerosing cholangitis (74% in our series). Failure of pancreatic exocrine or endocrine function is frequently seen. Up to 50% of AIP patients present with glucose intolerance. Diabetes mellitus and AIP are simultaneously diagnosed in many cases, but some cases show exacerbation of pre-existing diabetes mellitus with the onset of AIP<sup>[11]</sup>.

Recently, AIP with neutrophilic infiltration of the pancreatic duct epithelium has been reported by American<sup>[12]</sup> and European<sup>[13]</sup> pathologists. Their patients showed different clinicopathological features from AIP to those defined in Japan, as follows: no predilection for older men, a frequent association with inflammatory bowel disease, and a weaker association with other sclerosing diseases. In Japan, young AIP patients are more likely to have abdominal pain and serum amylase elevation than middle-aged or elderly patients<sup>[14]</sup>. Further, international surveys of a larger series of clinically relevant AIP subtypes are needed.

### Pathogenesis

Levels of serum IgG4 are frequently elevated, and they are particularly high in AIP. Dense infiltration of IgG4-positive plasma cells is seen in various organs of AIP patients. These findings suggest that IgG4 plays a major role in the pathogenesis of AIP, although the trigger for the IgG4 elevation or its pathogenetic role in AIP has not been clearly established.

Although the actual effector cells of AIP have not been clearly delineated, there are an increased numbers of activated CD4- and CD8-positive T cells bearing HLA-DR among the peripheral blood lymphocytes and in the pancreas of AIP patients. In 2001, Okazaki *et al*<sup>[15]</sup> reported that the number of CD4+ T cells producing interferon- $\gamma$  in peripheral blood and its secreted level were significantly higher in AIP patients than in controls, whereas the number of interleukin (IL)-4-producing CD4+ cells was not increased in AIP patients. They concluded that AIP may be mediated by a Th1-predominant immune reaction, similar to that in Sjogren's syndrome or primary sclerosing cholangitis (PSC).

There are many findings that support the involvement of immunological mechanisms in AIP, but target

antigens for AIP have not been detected. Given the preponderance of the disease amongst elderly males and the marked, dramatic response to oral steroid therapy, the pathogenesis of AIP may not involve an autoimmune mechanism, but other mechanisms, such as an allergic reaction. Zen *et al*<sup>[16]</sup> have reported that the expression of Th2 cytokines (IL-4, IL-5, and IL-13) and regulatory cytokines (IL-10 and transforming growth factor- $\beta$ ) was up-regulated in the affected tissues of patients with IgG4-related sclerosing pancreatitis and cholangitis. They have suggested that the predominant Th2 and regulatory immune reactions in this disease might reflect an allergic mechanism in its pathogenesis.

### Diagnosis

It is of utmost importance that AIP be differentiated from pancreatic cancer, as some patients with AIP in whom pancreatic cancer is suspected undergo unnecessary laparotomy or pancreatic resection. Since there is currently no diagnostic serological marker for AIP, diagnosis should be on the basis of the presence of a combination of abnormalities unique to AIP. In 2002, the Japan Pancreas Society established the Diagnostic Criteria for AIP<sup>[17,18]</sup>, which were revised in 2006<sup>[19]</sup>. In 2006, two new sets of diagnostic criteria for AIP were proposed, one in Korea and one in the USA.

Japanese criteria are based on the minimum consensus features of AIP, to minimize the risk of misdiagnosing pancreatic cancer. Revised criteria consist of three items: (1) radiological imaging showing diffuse or segmental narrowing of the main pancreatic duct with irregular walls and diffuse or localized enlargement of the pancreas; (2) laboratory data demonstrating abnormally elevated levels of serum gammaglobulin, IgG, or IgG4, or the presence of autoantibodies; and (3) histological examination of the pancreas showing lymphoplasmacytic infiltration and fibrosis. The diagnosis of AIP is made when either all three criteria are present, or criterion 1 together with either 2 or 3 is present. In addition to the Japanese criteria, the Korean criteria include the patient's response to steroid therapy and the presence of extra-pancreatic lesions.

Radiologically, pancreatic enlargement is usually hypoechoic, sometimes with scattered hyperechoic spots on ultrasonography (Figure 2A). On dynamic computed tomography (CT), there is delayed enhancement of the enlarged pancreatic parenchyma. Typical AIP cases

show diffuse enlargement of the pancreas, the so-called sausage-like appearance. Since inflammatory and fibrous changes involve the peripancreatic adipose tissue, a capsule-like rim surrounding the pancreas, which appears as a low density on CT, is detected in some cases. Pancreatic calcification or a pseudocyst is rarely seen. Cases of focal enlargement of the pancreas are sometimes difficult to differentiate from pancreatic cancer. Endoscopic retrograde cholangiopancreatography discloses an irregular, narrow (< 3 mm in diameter) main pancreatic duct. In patients with segmental narrowing, absence of upstream dilatation of the main pancreatic duct is characteristic<sup>[20]</sup>.

In our series of AIP patients, hypergammaglobulinemia (> 2.0 g/dL) and elevated serum IgG levels (> 1800 mg/dL) were detected in 34% and 56%, respectively, while autoantibodies, including antinuclear antibody and rheumatoid factor, were present in 44% and 16%.

Serum IgG4 levels are significantly and specifically high (> 135 mg/dL) in AIP patients. The sensitivity of elevated serum IgG4 levels is reported to be 67%-95%<sup>[21,22]</sup>. Although the measurement of serum IgG4 levels is useful for differentiating between AIP and pancreatic cancer, it should be noted that some patients with pancreatic cancer also have elevated serum IgG4 levels. Ghazale *et al*<sup>[23]</sup> have reported that serum IgG4 levels were elevated above 140 mg/dL in 13/135 (10%) patients with pancreatic cancer.

Histologically, dense lymphoplasmacytic infiltration with fibrosis is detected in the pancreas of AIP patients. Immunohistochemically, infiltrating inflammatory cells in the pancreas consist of CD4- or CD8-positive T lymphocytes and IgG4-positive plasma cells (Figure 2B). Lymphoid follicles are occasionally formed. The pancreatic duct is narrowed by periductal fibrosis and lymphoplasmacytic infiltration. Another characteristic histological finding is obliterative phlebitis that involves minor and major veins, including the portal vein. Such an inflammatory process extensively and markedly involves the contiguous soft tissue and peripancreatic retroperitoneal tissues.

#### Treatment and prognosis

The dramatic response to corticosteroids is well-known in AIP, but a standard steroid therapy regimen has not been established. Before steroid therapy is started, endoscopic or percutaneous transhepatic biliary drainage must be carried out in cases with obstructive jaundice, and glucose levels must be controlled in cases with diabetes mellitus. Oral prednisolone is usually started at 30-40 mg/d, and then it is tapered by 5 mg every 1-2 wk. Serological and imaging tests are followed periodically after commencement of steroid therapy. Usually, pancreatic size is normalized within a few weeks, and biliary drainage becomes unnecessary after 1-2 mo. Patients in whom complete radiological improvement is documented can stop their medication. To prevent relapse without complete discontinuation of steroids, continued maintenance therapy with prednisolone 5 mg/d is sometimes required. In half of steroid-treated patients,

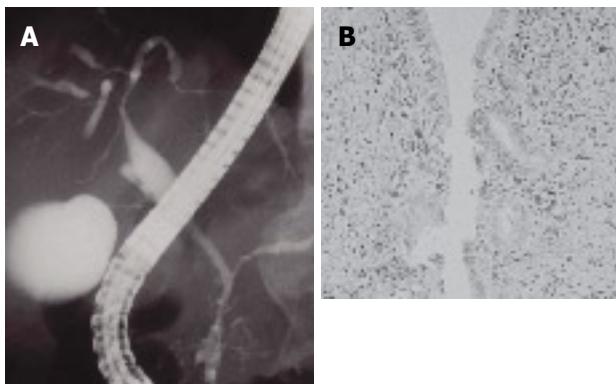

impaired exocrine or endocrine function improves. Some AIP patients relapse during maintenance therapy or after steroid medication is stopped; they should be retreated with high-dose steroid therapy. The indications for steroid therapy in AIP include obstructive jaundice due to stenosis of the bile duct, or the presence of other associated systemic diseases, such as retroperitoneal fibrosis<sup>[24-26]</sup>.

The long-term prognosis of AIP is not well known. Recurrent attacks of AIP resulting in pancreatic stone formation have been reported<sup>[27,28]</sup>.

## IgG4-RELATED SCLEROSING CHOLANGITIS

Sclerosing cholangitis is a heterogeneous disease that may be associated with choledocholithiasis, biliary tumor, or infection. Sclerosing cholangitis of unknown origin is called PSC. PSC is progressive despite conservative therapy, and it involves the intra- and extrahepatic bile ducts, and results in liver cirrhosis. The effect of steroid therapy is questionable, and liver transplantation currently provides the greatest hope for a possible cure. PSC occurs from 30 to 40 years of age and is frequently associated with inflammatory bowel disease<sup>[29,30]</sup>. Pancreatography is not abnormal in most PSC cases<sup>[31]</sup>.

IgG4-related sclerosing cholangitis is included within the sclerosing cholangitis group. This form is frequently associated with AIP and occasionally with other diseases such as sclerosing sialadenitis, all of which fall within the category of IgG4-related sclerosing disease. However, IgG4-related sclerosing cholangitis is not associated with inflammatory bowel disease. In many AIP cases, stenosis is located in the lower part of the common bile duct, but thickening of the common bile duct wall is sometimes detected even in the segment in which abnormalities are not clearly observed upon cholangiography. When stenosis is found in the intrahepatic or the hilar hepatic bile duct, the cholangiographic appearance is very similar to that of PSC (Figure 3A)<sup>[31,32]</sup>. Many cases of IgG4-related sclerosing cholangitis have been described with isolated biliary tract involvement in the absence of pancreatic disease<sup>[33,34]</sup>. Elevation of serum IgG4 is frequently observed in patients with IgG4-related sclerosing cholangitis, and it responds dramatically to steroid therapy, unlike PSC. Clinically, patients with IgG4-related sclerosing cholangitis are older at diagnosis than those with PSC. Patients with IgG4-related sclerosing cholangitis present more abruptly with obstructive jaundice, whereas obstructive jaundice is rarely present in PSC patients. The histological appearance is similar to that in the pancreas of AIP patients: transmural fibrosis, dense lymphoplasmacytic infiltration of the bile duct wall, along with lymphoplasmacytic infiltration and fibrosis in the periportal area of the liver, and obliterative phlebitis. Despite the dense periluminal inflammation, the biliary epithelium is usually intact, in contrast to PSC, in which mucosal erosion is often present. Furthermore, unlike in PSC, the inflammatory process is often more dense at the periphery of the duct. Neutrophils, commonly

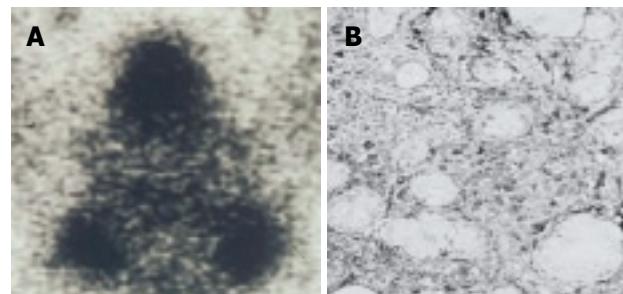

**Figure 3** IgG4-related sclerosing cholangitis. (A) Stenosis of the intrahepatic bile duct, similar to that in PSC; (B) Dense infiltration of IgG4-positive plasma cells in the bile duct wall.

seen in PSC, are not a feature of this disease. Immunohistochemically, infiltration of abundant IgG4-positive plasma cells is detected in the bile duct wall (Figure 3B), in contrast to PSC. Given the age at onset, associated diseases, pancreatic findings, response to steroid therapy, prognosis, and IgG4-related serological and immunohistochemical data, it can be said that IgG4-related sclerosing cholangitis is a different disease, and distinct from PSC<sup>[35,36]</sup>.

### IgG4-RELATED SCLEROSING SIALADENITIS

Sclerosing sialadenitis has been referred to as Kuttner's tumor, due to its presentation as a firm swelling of the salivary gland that is difficult to differentiate from a neoplasm<sup>[37]</sup>. Mikulicz's disease is a unique condition that refers to bilateral, painless and symmetrical swelling of the lacrimal, parotid and submandibular glands<sup>[38]</sup>. Although Mikulicz's disease has been considered a subtype of Sjögren's syndrome, there are several differences between the two diseases. Patients with Mikulicz's disease lack anti-SS-A and anti-SS-B antibodies, but frequently have elevated serum IgG4 levels. Infiltration of many IgG4-positive plasma cells into the lacrimal and salivary glands has been detected in Mikulicz's disease.

Swelling of the salivary glands was present in 24% of our AIP patients (Figure 4A), and it was associated with cervical or mediastinal lymphadenopathy. Swelling of the salivary glands and the lymph nodes improves after steroid therapy. In the salivary glands of these patients, dense infiltration of IgG4-positive plasma cells and fibrosis were detected (Figure 4B). Kitagawa *et al*<sup>[39]</sup> have reported that dense infiltration of IgG4-positive plasma cells was detected in the salivary glands of 12 patients with sclerosing sialadenitis (Kuttner's tumor). Five of these patients had associated sclerosing lesions in extrasalivary glandular tissue, such as in AIP, while the remaining seven patients had only salivary gland involvement. Thus, many cases of sclerosing sialadenitis, including Kuttner's tumor and Mikulicz's disease, may be salivary gland lesions of IgG4-related systemic disease<sup>[40,41]</sup>.

**Figure 4** IgG4-related sclerosing sialadenitis. (A) Bilateral swelling of submandibular glands (Gallium scintigraphy); (B) Dense infiltration of IgG4-positive plasma cells in the salivary gland.

### IgG4-RELATED RETROPERITONEAL FIBROSIS

Retroperitoneal fibrosis generally presents in a non-specific manner with malaise, fatigue, fever and weight loss. The pathognomonic feature of retroperitoneal fibrosis is a thick retroperitoneal fibrotic mass that covers the abdominal aorta and compresses the ureters<sup>[42]</sup>. The process of fibrosis can result in obstruction of the ureters and renal failure, or signs and symptoms may be related to the encasement or entrapment of other structures by the inflammatory mass, such as hydronephrosis. Retroperitoneal fibrosis has many causes, although in about 70% of cases, the cause is unknown<sup>[43]</sup>.

Retroperitoneal fibrosis was present simultaneously or metachronously in 8% of our AIP patients. Dense infiltration of IgG4-positive plasma cells and obliterative phlebitis were found in the pancreas and the retroperitoneal fibrous mass. Both the retroperitoneal fibrosis and AIP resolved after steroid therapy<sup>[44]</sup>. Neild *et al*<sup>[43]</sup> have reported the histological findings of 12 patients with idiopathic retroperitoneal fibrosis, which showed, to varying degrees, fibrosis and intense inflammatory cell infiltration with T lymphocytes and IgG4-positive plasma cells, as well as venulitis and obliterative arteritis. Biopsy of the mass after steroid therapy revealed decreased infiltration of IgG4-positive plasma cells. Some cases of retroperitoneal fibrosis are the retroperitoneal lesions of IgG4-related systemic disease. Recently, a 52-year-old man with retroperitoneal and mediastinal fibrosis without AIP was reported to have elevated serum IgG4 levels<sup>[45]</sup>.

### IgG4-RELATED TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis may be related to various causative factors, including infection, and allergic, toxic and autoimmune conditions. Tubulointerstitial nephritis is sometimes associated with AIP, but there have been a few cases of tubulointerstitial nephritis showing high serum IgG4 levels without notable pancreatic lesions<sup>[46-50]</sup>. Some AIP cases show several nodular lesions in the kidney that mimic metastatic tumors<sup>[46,47]</sup>. Takahashi *et al*<sup>[48]</sup>

have reported that, in 40 AIP patients, 14 (35%) had renal involvement (12 with parenchymal involvement and five with extraparenchymal involvement). The renal lesions regressed after steroid therapy, but they progressed without steroid therapy. Immunohistochemically, dense infiltration of IgG4-positive plasma cells was detected in the renal interstitium. Furthermore, in some AIP cases, membranous nephropathy that showed IgG4-positive deposits in the glomeruli or tubular basement membrane have been reported<sup>[49]</sup>. These IgG4-positive lesions decreased with improvement of renal function after steroid therapy.

### IgG4-RELATED INTERSTITIAL PNEUMONIA

Interstitial pneumonia, with X-ray findings such as an interstitial pattern, ground-glass appearance, and honeycombing, is sometimes associated with AIP<sup>[51-53]</sup>. On high-resolution CT of the lung, dense alveolar consolidation and air bronchograms in bilateral perihilar regions have been reported<sup>[51]</sup>. Some cases have respiratory failure, and steroid therapy is effective in improving respiratory function and radiological findings. In biopsy specimens, dense infiltration of IgG4-positive plasma cells is detected in the thickened alveolar septum<sup>[51-53]</sup>. Hirano *et al*<sup>[53]</sup> have reported that 4/30 AIP patients had pulmonary involvement during follow-up.

### IgG4-RELATED SCLEROSING CHOLECYSTITIS

In our series, thickening of the gallbladder was detected on US and/or CT in 32% of AIP patients. Dense infiltration of IgG4-positive plasma cells and lymphocytes, as well as transmural fibrosis, was detected in the gallbladder wall of 6/8 patients examined<sup>[54]</sup>.

### IgG4-RELATED PROSTATITIS

IgG4-related prostatitis has recently been reported in patients with and without AIP. Patients show lower urinary tract symptoms, and prostate enlargement is evident on digital rectal examination. Significant FDG uptake by the prostate has been demonstrated. The symptoms and radiological findings improve after steroid therapy. Histologically, the prostate shows dense infiltration of IgG4-positive plasma cells and lymphocytes, obliterative phlebitis, and gland atrophy with dense fibrosis<sup>[55-57]</sup>.

### IgG4-RELATED INFLAMMATORY PSEUDOTUMOR OF THE LIVER, LUNG AND HYPOPHYSIS

Inflammatory pseudotumors occur in almost all major organs. An inflammatory pseudotumor is characterized histologically as an irregular proliferation of myofibroblasts intermixed with an infiltrate of inflammatory cells,

mainly lymphocytes and plasma cells. One inflammatory pseudotumor is categorized as a plasma cell-rich type, plasma cell granuloma<sup>[58]</sup>. Although its pathogenesis is not known, a close relationship between plasma cell granuloma and IgG4-positive plasma cells has recently become obvious<sup>[5]</sup>.

Some IgG4-related inflammatory pseudotumors of the liver<sup>[54,59,60]</sup> and lung<sup>[61]</sup>, which are characterized by dense infiltration of IgG4-positive plasma cells and lymphocytes intermixed with fibrosis and obliterative phlebitis, have been recently reported in patients with or without AIP. Four cases of hypophysitis in association with AIP have been reported; they all presented with hypopituitarism and swelling of the pituitary lesion<sup>[62-65]</sup>. In one case<sup>[62]</sup>, abundant infiltration of IgG4-positive plasma cell was demonstrated in the pituitary tumor. Steroid therapy is effective for these IgG4-related inflammatory pseudotumors.

### IgG4-RELATED LYMPHADENOPATHY

In a study using gallium-67 scintigraphy, pulmonary hilar gallium-67 uptake was found in 41/51 (80.4%) patients with AIP<sup>[66]</sup>. In our series, abdominal lymphadenopathy of up to 2 cm in diameter was observed in 5/8 patients at laparotomy, and cervical or mediastinal lymphadenopathy of up to 1.5 cm in diameter was observed on CT in 33% of our AIP patients. In all these cases, the lymphadenopathy disappeared after steroid therapy. Dense infiltration of IgG4-positive plasma cells was detected in all abdominal and cervical lymph nodes. When bilateral hilar lymphadenopathy is marked, sarcoidosis is suspected clinically<sup>[4]</sup>.

Other reported lesions associated with AIP are immune thrombocytopenic purpura<sup>[67,68]</sup>, autoimmune sensorineural hearing loss<sup>[68]</sup>, hypothyroidism<sup>[69]</sup>, anosmia<sup>[70]</sup>, and loss of taste<sup>[70]</sup>.

### CONCLUSION

IgG4-related sclerosing disease is a new clinicopathological systemic entity. It is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs, and major clinical manifestations are apparent in the organs, in which tissues fibrosis with obliterative phlebitis is pathologically induced. As steroid therapy is effective, accurate diagnosis is necessary.

## INTRODUCTION

Colorectal cancer is a common cause of morbidity and mortality. Although the basic principles of screening, surgical resection when possible, and adjuvant therapy when indicated remain valid, considerable new information offers the possibility of substantially improving outcomes for such patients in the future. This review will briefly summarize current epidemiologic and prognostic information about this disease for context, and then will focus on new approaches to surgery, adjuvant therapy, the management of established metastasis, and the prevention of metastasis. Although screening for colorectal neoplasm is critical for prevention, early diagnosis, downstaging, and improved survival, this subject has been extensively reviewed elsewhere<sup>[1-4]</sup> and is beyond the scope of the current review.

## INCIDENCE AND PREVALENCE

Colorectal cancer is the third most common cancer and the third leading cause of cancer related mortality in the United States<sup>[5]</sup>. Colorectal cancer is also very common in Western Europe, Australia and New Zealand, whereas the age standardized incidence rate of colorectal carcinoma is very low in India and Africa<sup>[6,7]</sup>. There seems to be an association of higher incidence rates in colorectal cancer with increasing affluence<sup>[8]</sup>. Over the past decade, colorectal cancer rates have modestly decreased or remained level. Until age 50, men and women have similar incidence and mortality rates; after age 50, men are more vulnerable<sup>[5]</sup>. Colorectal cancer is generally a malignancy associated with the elderly, with a mean age at diagnosis of 73 years<sup>[9]</sup>. In the Netherlands, statistics showed that a peak incidence of colorectal cancer for both men and women occur between the age of 70-79 years<sup>[10]</sup>. Before the age of 75 years, men and

## Abstract

This article reviews recent advances in surgical techniques and adjuvant therapies for colorectal cancer, including total mesorectal excision, the resection of liver and lung metastasis and advances in chemoradiation and foreshadows some interventions that may lie just beyond the frontier. In particular, little is known about the intracellular and extracellular cascades that may influence colorectal cancer cell adhesion and metastasis. Although the phosphorylation of focal adhesion kinases and focal adhesion associated proteins in response to integrin-mediated cell matrix binding ("outside in integrin signaling") is well described, the stimulation of cell adhesion by intracellular signals activated by pressure prior to adhesion represents a different signal paradigm. However, several studies have suggested that increased pressure and shear stress activate cancer cell adhesion. Further studies of the pathways that regulate integrin-driven cancer cell adhesion may identify ways to disrupt these signals or block integrin-mediated adhesion so that adhesion and eventual metastasis can be prevented in the future.

women in the Netherlands have a 4.67% and 3.34% cumulative incidence to develop colorectal cancer<sup>[11]</sup>. By the age of 70 years, at least 50% of the western population will develop some form of colorectal tumor, spanning the spectrum from an early benign polyp to an invasive adenocarcinoma.

## STAGE OF COLORECTAL DISEASE

The stage of disease is one of the most important prognostic factors for survival in patients with colorectal cancer. It is therefore clinically significant to know the relative incidence for each stage of the disease. The incidence of Stage I disease in the United States has increased over the past years due to better screening and is currently around 30%. This is an important development since the detection of early stage disease increases the chance for R0 resection and potential cure for colorectal cancer. The incidence of Stage II and III disease are respectively 27% and 24%, while Stage IV disease is present in 19% of patients in the United States. A remarkable observation is that older patients are diagnosed more frequently at an early stage (Stage 0 and 1) and diagnosed three times less frequently with stage IV disease than younger patients. A possibility is that younger patients feel less at risk and ignore symptoms for a longer period of time and are therefore diagnosed at a later stage<sup>[12]</sup>.

The relative 5-year survival rates in the United States show that when the disease is detected early, at a localized stage, survival rates for Stage I colon and rectal cancer are 93% and 92%, respectively. At Stage II disease the 5-year survival rates are between 72%-85% for colon cancer and between 56%-73% for rectal cancer. The fluctuations in Stage II survival rates are due to the fact that Stage II disease includes both T3 (Stage II A) and T4 (Stage II B) tumors. For more advanced disease at diagnosis, the survival rates drop significantly. At Stage III, the 5-year survival rates for colon and rectal cancer vary from 44%-83% and 30%-67% respectively. Again the wide range of survival rates reflects the fact that Stage III disease is further categorized into the following sub-categories, Stage III A (T1-2, N1, M0), Stage III B (T3-T4, N1, M0) and Stage III C (any T, N2, M0) disease. For Stage IV colorectal disease the 5-year survival rate may be as low as 8%<sup>[13,14]</sup>.

## SURGICAL TREATMENT

Surgical management is the primary treatment of potentially curable colorectal cancer. In most cases, this involves resection of the primary tumor and regional lymph nodes. However, treatment of curable colorectal cancer patients may vary from endoscopic polypectomy for malignant polyps or local excision in carefully selected patients with limited rectal carcinomas to multimodality management for locally advanced rectal cancers or cancers invading adjacent organs. The objective in all cases is to maximize both oncologic and functional results. Due to the improvements in

surgical techniques, as well as better screening and new developments in adjuvant therapy, the ratio of people with potentially curable disease has increased over the past decades. This evolution has included the development of total mesorectal excision, the introduction of laparoscopic surgery, the sentinel lymph node technique, curative resections of liver and lung metastasis and improvements in adjuvant therapies such as chemotherapy and radiotherapy.

En bloc resection and the no-touch technique were first described in 1967 by Trumbell *et al* and remain valid and important<sup>[15]</sup>. The best prevention strategy of potential tumor cell distribution is maintained by the surgeon strictly using the principles of en-bloc resection. As the likelihood of lymph node involvement increases with depth of tumor invasion (5.6% for pT<sub>1</sub>, 10% for pT<sub>2</sub>, 36.7% for pT<sub>3</sub>, and 77.7% for pT<sub>4</sub> colon carcinoma)<sup>[16]</sup>, invasive adenocarcinomas require ligation and resection of the lymphovascular pedicle directly draining the intestinal segment containing the tumor. When the lesion is equidistant between two pedicles, then both should be encompassed in the resection. Another surgical option is the no-touch isolation technique with primary ligation of the corresponding vessels, and dissection of the lymph nodes<sup>[17-20]</sup>. The concept of this technique is to avoid tumor manipulation during surgery so that shedding of tumor cells into the lymphatic or vascular circulation is kept to a minimum. The presence of free cancer cells within the lymphatic, vascular circulation or in the peritoneal cavity can be detected by mRNA coding using qPCR and is associated with a poorer prognosis for patients undergoing curative colorectal cancer surgery<sup>[21,22]</sup>. However, there seems to be limited benefit in the no-touch isolation group; the morbidity and mortality rates after a 5-year follow-up of patients were equal<sup>[20]</sup>. More recently, a study by Hayashi *et al* has suggested that the no-touch isolation technique may be useful to prevent cancer cells from being shed into the portal vein during surgical manipulation<sup>[23]</sup>. Today, en-bloc resection without the primary ligation of corresponding vessels is still the more common technique.

Other advances in surgical techniques have resulted in less tumor recurrence and given patients with advanced colorectal disease the opportunity to undergo surgery with curative intent. In 1982 Heald developed an important surgical technique for the treatment of rectal cancer. The concept of total mesorectal excision (TME) was introduced in conjunction with low anterior resection (LAR) as a means of procuring all perirectal fat while facilitating sphincter preservation<sup>[24]</sup>. Recent studies have reported local recurrence rates of around 10% in various TME series<sup>[25-30]</sup>. In the study by Moore *et al*, local recurrence rates of less than 5% have been reported with a distal margin of 1 cm, provided that the mesorectum can be excised as a complete lymphovascular package<sup>[31]</sup>. Today TME has been successfully taught as a standardized procedure and translated to other colorectal surgical environments with reproducible cancer-specific outcomes<sup>[32]</sup>.

Advances in laparoscopic equipment and technique have revolutionized the surgical approach to many diseases. Laparoscopic surgery for colorectal cancer is currently considered an acceptable alternative to open resection for colorectal cancer. There are small but measurable short term benefits such as decreased post-operative narcotic use, earlier return of bowel function, shorter length of stay and better cosmetic results. Today there is no question that laparoscopic surgery can be performed safely and effectively by experienced surgeons. There is enough evidence that survival rates are not compromised by the laparoscopic approach<sup>[33,34]</sup>.

Although the first laparoscopic colon resection was reported in 1991<sup>[35]</sup>, the adoption of minimally invasive colon resection has been impeded by several factors. First, laparoscopic colon surgery is technically demanding. Second, and more importantly, there has been historical concern about whether minimally invasive surgery for colonic malignancies would achieve adequate oncologic resection. The most recent studies, including retrospective and prospective registries, as well as comparative studies clearly demonstrate that oncologic principles are not compromised by laparoscopic techniques, and the yield of lymph nodes, surgical margins (proximal, distal and radial), and length of bowel resected were comparable to open cancer surgery<sup>[17,36,37]</sup>. Another problem that has been discussed controversially is the issue of whether laparoscopic surgery is associated with an increased hematogenous and intraperitoneal tumor cell distribution. Some studies have shown that there is a higher incidence of intraperitoneal tumor cell dissemination during laparoscopic resection for colorectal cancer when compared to open surgery for colorectal cancer<sup>[38,39]</sup>. On the other hand, other studies have contradicted this observation<sup>[40,41]</sup>. Finally, another concern has been the incidence of port-site metastasis after laparoscopic resection<sup>[16,42-45]</sup>. Although port-site metastases have not been restricted to laparoscopic surgery for colorectal cancer, the major impact of this phenomenon has been in this field. A closer look at the literature reveals most reports with a high incidence rate were small series published in the early 1990s<sup>[44,45]</sup>. Within the last ten years, three large trials of laparoscopic surgery for colorectal cancer have been published that clearly demonstrated a low incidence of wound recurrence not statistically significantly increased compared to wound recurrence after open laparotomy sites<sup>[33,34,46]</sup>. However, it should be cautioned that these trials were not adequately powered to fully address the question. Moreover, in the COST-trial<sup>[33]</sup>, wound recurrence rates demonstrated an incidence of port site recurrence that, although both low and not statistically significantly different from that after open surgery, was nevertheless more than twice the rate of wound implantation seen after open surgery (0.5% incidence in the laparoscopic arm vs 0.2% in the open surgical arm of the trial). Although the question therefore still has not been completely addressed, it appears that the incidence is quite low and within acceptable clinical range, and it seems dubious that a randomized trial of sufficient

size ever will be conducted to settle conclusively this issue. It seems likely that insufficient technical skills and experience at the beginning of the laparoscopic era contributed to the early reports that described considerably higher rates of port site recurrence.

Many cancers, including colorectal cancer, spread first to the lymph nodes before reaching other parts of the body. Lymph node status remains one of the most important prognostic factors in the management of colorectal cancer. In patients without nodal disease, recurrent tumors still develop in about 15% to 20% of cases within 5 years of diagnosis<sup>[47]</sup>. The reasons for this are unclear, but may depend upon the quality of surgical resection and conventional pathologic review. Node-negative patients are usually not treated with adjuvant chemotherapy outside a clinical trial because of the lack of definitive evidence of survival benefit. Patients with nodal disease, on the other hand, should be treated with adjuvant chemotherapy because of potential reduction of mortality up to 33%<sup>[48]</sup>. Therefore, it is critical to avoid pathological understaging of the specimen. Standard pathologic evaluation may overlook low volume nodal metastasis, thereby failing to identify nodes imperative to accurate staging. Inconsistencies in number of nodes harvested at time of pathologic processing impact significantly colon cancer staging accuracy. This nodal sampling error serves as the basis for guidelines establishing a 12 node minimum for adequate staging utilizing conventional techniques<sup>[49]</sup>. Up to 78% of metastases are identified in subcentimeter nodes that may be overlooked during standard gross pathologic dissection of resected specimens<sup>[49-51]</sup>. Microscopic examination of 1 or 2 hematoxylin and eosin-stained sections of a 5-mm node limits pathologic assessment to < 1% of the entire node, making identification of small tumor cell aggregates challenging. In a study by Saha *et al*, sentinel lymph node mapping appears superior to conventional pathologic review and may therefore be a useful method to avoid understaging<sup>[47]</sup>. Nodal positivity was 48% for the group assigned sentinel-lymph-node mapping, compared with 35% for the group assigned conventional staging ( $P < 0.001$ ). In this study, sentinel lymphatic mapping accounts for the upstaging of 13% of colon cancer. In other studies, sentinel lymph node mapping accounts for the upstaging of 19%-24% of patients<sup>[52-57]</sup>. The consequence of upstaging is that these patients now become candidates for adjuvant chemotherapy. After a minimum of 2 years follow-up, patients assigned nodal mapping ( $n = 153$ ) had an overall recurrence of 7%, compared with 25% ( $n = 162$ ) for the patients assigned conventional staging ( $P = 0.001$ )<sup>[47,58]</sup>. As the sentinel lymph node technique has developed, some investigators describe over 90% success in identifying the sentinel node and accuracy rates of approximately 90%<sup>[47,53-56]</sup>.

In patients with colorectal metastases, advances in surgical techniques have made it possible that the goal of surgery is no longer palliative but of curative intent. Therefore, a complication such as wound recurrence may have grave clinical consequences for patients that

are operated on with curative intent. It thus becomes increasingly important that surgeons minimize tumor spill into the peritoneal cavity or into the lymphatic/vascular systems during surgical procedures for colorectal cancer. If not, tumors may recur and compromise a potentially curative resection.

The liver is the most common site for colorectal metastasis, since the venous outflow of the gut first reaches the liver through the portal system before flowing back into the systemic circulation. Approximately one-third of patients diagnosed with colorectal cancer will develop synchronous or metachronous metastases to the liver. The incidence of synchronous metastasis has ranged from 23.0% to 46.8%<sup>[59-62]</sup> and the 5-year survival rate after hepatic resection has been reported to be 14% to 40% in studies with more than 100 or more patients<sup>[60,61]</sup>. Several studies have suggested that careful selection of patients for hepatic resection of colorectal metastases can result in favourable survival<sup>[63-65]</sup>. A recent study by Rees *et al* found 7 risk factors (Basingstoke Prediction Index) that were found to be independent predictors of poor survival in a multivariate analysis<sup>[66]</sup>. The 7 risk factors were number of hepatic metastases > 3, node positive primary, poorly differentiated primary, extrahepatic disease, tumor diameter ≥ 5 cm, carcinoembryonic antigen level > 60 ng/mL, and positive resection margin. The first 6 of these criteria were used in a preoperative scoring system and the last 6 in the postoperative setting. Patients with the worst postoperative prognostic criteria had an expected median cancer-specific survival of 0.7 years and a 5-year cancer-specific survival of 2%. Conversely, patients with the best prognostic postoperative criteria had an expected median cancer-specific survival of 7.4 years and a 5-year cancer-specific survival of 64%<sup>[66]</sup>. It is therefore very important to preoperatively assess if resection is achievable, most preferably with a 1 cm margin<sup>[67,68]</sup>. It is often difficult to measure a 1 cm distance to the tumor edge on the specimen because of dissection or cautery artifact. Other times a surgical margin of 1 cm cannot be obtained because of the relation of the tumor to the hepatic veins, portal veins, or vena cava. When tumor is left behind after surgery, meaning that RO resection is not achieved, the survival is not different than that in the nonresected group.

While surgical resection remains the gold standard of therapy, only a few patients are suitable candidates for curative surgical resection because of the presence of liver malignancy in unresectable locations, the number of and anatomic distribution of tumor lesions, or the presence of extrahepatic disease or poor liver function. An alternative treatment to control and potentially cure liver disease has been developed for use in patients with malignant liver tumors. Radiofrequency ablation (RFA), also known as “radiofrequency thermal ablation”, is a recently developed thermoablative technique. It induces temperature changes by using high-frequency alternating current applied *via* electrodes placed within the tissue to generate areas of coagulative necrosis and tissue desiccation<sup>[69,70]</sup>. Overall recurrence for colorectal cancer

was most common after RFA (84% *vs* 64% RFA and resection *vs* 52% resection only,  $P = 0.001$ )<sup>[71]</sup>. Thus, RFA has been reserved as an adjunctive tool to resection, when complete resection is not possible, either alone or in combination with resection<sup>[72-74]</sup>. The study by Abdalla *et al* demonstrates that RFA alone or in combination with resection for unresectable patients does not provide survival comparable to resection, and provides survival only slightly superior to nonsurgical treatment<sup>[71]</sup>.

After colorectal metastases to the liver, the lungs are the second most common site of metastasis. The number of possibly resectable cases of lung metastasis after primary surgery for colorectal cancer has increased considerably over the past 20 years. The typical pattern of lung metastasis is single or multiple nodules rather than miliary tumors or lymphangitis carcinomatosa. No effective chemotherapy regimen has been found for metastatic disease. Hence, a surgical procedure to eliminate pulmonary metastases is generally accepted as the only potentially curative treatment. In favor of surgery is the recent trend toward earlier detection of pulmonary metastases as small peripheral densities with increasingly common use of screening with spiral or high-resolution computed tomography. The reported 5-year survival rates for lung metastectomy surgery were 24% to 63%, and most were around 40%<sup>[75-90]</sup>. The criteria for resection of pulmonary metastases from colorectal carcinoma included unilateral or bilateral excisable lung lesions per preoperative chest radiography, no local recurrence of primary lesions, and no extrapulmonary lesions with the exception of associated prior or simultaneous resectable hepatic metastases. Elevated CEA level and the number of metastasis are the most significant prognostic factors for overall survival after resection of lung metastases from colorectal cancer<sup>[91]</sup>.

## ADJUVANT THERAPY

For the treatment of rectal cancer, adjuvant radiotherapy has become a standard procedure. The following two schedules of treatment have been explored over the last decades: short term treatment that delivers 25 Gy in 5 fractions during 1 wk, followed immediately by surgery, and conventional schedules that deliver 40 Gy to 50 Gy in 20-25 fractions during 4 to 5 wk, followed by surgery 3-6 wk later. Regardless of the schedule, preoperative radiotherapy decreases local recurrence rates by 50%-60% when compared to surgery alone<sup>[92,93]</sup>. The conventional schedules are delivered in combination with chemotherapy to patients with locally advanced rectum cancer (T3-T4 tumors and N+ disease). The radiobiological dose delivered in a short term treatment schedule is too low for adequate response in locally advanced rectal tumors. In 2001, a study by Marijnen *et al* demonstrated that short term treatment with 25 Gy during 1 wk did not achieve tumor down staging for T1-T3 tumors within a period of 10 d<sup>[94]</sup>. However, a schedule of 50.4 Gy given over a period of 6 wk in combination with 5-FU and leucovorin did cause

down staging of locally advanced rectum tumors<sup>[95]</sup>. Today the standard treatment for locally advanced rectum carcinoma is pre-operative radiotherapy in combination with 5-FU and leucovorin<sup>[96]</sup>. In addition, it has been demonstrated that timing of chemoradiation for locally advanced tumors is important, since less toxicity and better local control may be achieved when chemoradiation is given pre-operatively instead of post-operatively<sup>[97]</sup>. Thus far, there has been no conclusive demonstration of a gain in overall survival for patients with locally advanced rectal tumors treated with adjuvant chemoradiation<sup>[98]</sup>.

During the past years, various phase I and II trials have been performed with capecitabine<sup>[98,99]</sup>. It is a form of chemotherapy that is administered orally and is a tumor activated fluoropyrimidine carbonate. During the last of three enzymatic processes, thymidine phosphorylase converts capecitabine to 5-FU. The enzyme thymidine phosphorylase is found in high concentrations in rectal tumors and it is therefore less likely that healthy tissue within the radiation field is subjected to 5-FU. The advantages of this form of therapy are less toxicity, oral administration, and less chance of infections since a venous port access catheter is no longer necessary. Although the phase II trials with capecitabine in combination with radiotherapy for locally advanced rectum tumors show promising results, there are currently no phase III trials that give information about local recurrence during a long term follow-up period. However, the National Surgical Breast and Bowel Project trial in the United States is planning on performing such a study in the near future. If the results from this study show acceptable local recurrence rates, then capecitabine may replace the 5-FU/leucovorin schedule. A study by Kim *et al* suggests that the addition of leucovorin to capecitabine does not work synergistically but actually seems more toxic<sup>[100]</sup>. For this reason a combined capecitabine and leucovorin schedule does not seem desirable. Other phase I and II studies have tried to combine capecitabine with oxaliplatin<sup>[101-103]</sup>. The results seem promising as well, and grade III/IV toxicity does not seem greater than the capecitabine and 5-FU/leucovorin schedules. Although there are many new developments, 5-FU and leucovorin in combination with radiotherapy remains the standard of neo-adjuvant treatment in most countries for patients with locally advanced rectum carcinoma.

Although research efforts continue to be directed at deriving new cytotoxic and antiproliferative agents directed specifically at cancer cells, the concept of targeting the angiogenic support of tumors has recently become of interest, and angiogenesis inhibitors have also been introduced for treatment of cancer. Bevacizumab is an anti-VEGF antibody. When combined with conventional chemotherapy, this agent has been reported to prolong survival in patients with advanced colorectal cancer treated in a palliative setting<sup>[104,105]</sup>. Additionally, recent trials with neo-adjuvant chemotherapy suggest that irresectable liver metastases can be downstaged with this agent. Thus, an increasing number of patients

with colorectal metastases to the liver may now become candidates for liver resection. Indeed, in such patients preoperative treatment with bevacizumab and chemotherapy may be associated with less blood loss compared to chemotherapy alone<sup>[106]</sup>. If bevacizumab and chemotherapy are discontinued at least 8 wk before hepatic resection, the addition of bevacizumab to preoperative irinotecan and oxaliplatin does not increase morbidity after hepatic resection<sup>[106,107]</sup>. Unfortunately, there are no studies yet that compare whether the combination of bevacizumab and chemotherapy allows for better downstaging of liver metastases than conventional chemotherapy alone. This will be an important subject for future study, as will the long term outcomes of patients downstaged with these agents and then subjected to liver resection of the remaining obvious metastases.

Despite all of these advances in surgical techniques and adjuvant therapies, colorectal tumor recurrence remains a problem. Manfredi *et al* described a 5-year cumulative rate of local recurrence of 12.8% and a 25.6% per cent rate of distant metastases<sup>[108]</sup>. During surgery it is important that tumor free margins of the resected specimen are achieved and that tumor spill is avoided. Unfortunately, some tumor spill occurs in approximately half of patients that are operated for colorectal cancer<sup>[109]</sup>. Many research studies have provided evidence for direct implantation of the port site or surgical wound by exfoliated cancer cells, hematogenous seeding, tissue manipulation, sterilization by pneumoperitoneum, patient's positioning and immune dysfunction as potentially etiologic factors. Approximately 0.2%-1% of patients will eventually develop wound recurrence<sup>[33,110]</sup>. Many of these patients also exhibit more diffuse peritoneal recurrence, although approximately half exhibit isolated wound recurrence. Either phenomenon has a negative impact on survival for those patients that are operated with curative intent. Since more than 80% of patients with colorectal disease are initially operated with curative intent, a complication such as wound or peritoneal recurrence may drastically influence their 5-year survival rate in a negative manner.

## TUMOR CELL ADHESION

The contrast between the high rates of tumor cell spillage and circulating tumor cells and the much lower rates of clinical tumor metastasis or implantation after surgery suggests that tumor implantation may be regulated in some way. The mechanisms that determine which tumor cells adhere to target organs and tissues are poorly understood. Normally, if a cell is unable to attach to the extracellular matrix, it dies through induction of the cell suicide program known as apoptosis. Cancer cells, however, develop a means to avoid death in this situation. Cells that have suffered irreparable DNA damage activate specific proteases and nucleases that destroy the proteins and DNA of the cell, thereby effectively limiting the spread of potentially deleterious mutations. Cancer cells often exhibit mutations in genes

involved in regulating this pathway.

Since not all cancer cells that are shed into the peritoneal cavity undergo apoptosis, there is always a possibility that these cells will eventually cause wound metastasis. Tumor implantation begins with the adhesion of tumor cells to the matrix proteins in the wound. The extracellular matrix consists chiefly of type I and IV collagens, laminins, heparin sulfate proteoglycan, fibronectin, and other noncollagenous glycoproteins<sup>[111]</sup>. Cell adhesion to extracellular matrix proteins is mediated by diverse receptors, most notably by members of the integrin family. Integrins, heterodimeric transmembrane proteins, are composed of noncovalently associated alpha and beta subunits that define the integrin-ligand specificity<sup>[112]</sup>, and their pattern of expression is likely to promote specific cellular adhesions. Both the physiologic status of the cell<sup>[113]</sup> and divalent extracellular divalent cation concentrations<sup>[114]</sup> can influence the affinity between integrins and their ligands. After adhesion of the cell, proliferation and angiogenesis are then required to support tumor growth, invasion and subsequent metastasis.

#### **Treatments to prevent wound or peritoneal metastasis**

During the past years not much progress has been booked in reducing wound recurrence in patients with curable colorectal cancer. The application of topical ointments<sup>[115,116]</sup>, abdominal irrigation<sup>[117]</sup> and port-site resection of wounds<sup>[118]</sup> have had limited success. The most promising results to date are probably the studies that investigate the anticancer effect of COX-2 inhibitors. Various studies have shown that COX-2 inhibitors have both antiangiogenic<sup>[119,120]</sup> and apoptotic effects<sup>[121,122]</sup> on human colon cancer cells. A more recent study demonstrated that COX-2 inhibitors down-regulated  $\beta 1$ -integrin expression, with consequent impairment of the ability of colon cancer cells to adhere to and migrate on extracellular matrix in an *in vitro* study<sup>[115]</sup>. It is therefore possible that these drugs may reduce wound recurrence since they may interfere with the adhesion of the cell to extracellular matrix. However, to date, the mechanisms of drug action and interaction are still far from clear, and their roles within the clinical setting are yet to be observed. It is therefore important to further investigate factors that may be of significance during wound implantation and eventual tumor formation.

#### **Extracellular influences on colon cancer cell adhesion**

Interaction between cells and the extracellular matrix are in large part mediated by integrins in divalent cation-dependent processes. This means that extracellular processes that alter divalent cation concentrations may also influence colon cancer cell adhesion to the extracellular matrix. Local shifts in the concentrations of extracellular Mg<sup>2+</sup> and Ca<sup>2+</sup> occur during wound healing, impacting the function of divalent cation-dependent cell surface molecules responsible for cell-cell and cell-extracellular matrix interactions<sup>[123]</sup>. Early in the process, when cell migration into the wound is

initiated, Mg<sup>2+</sup> is elevated and Ca<sup>2+</sup> is reduced. As wound healing progresses, wound concentrations of Mg<sup>2+</sup> and Ca<sup>2+</sup> return to normal plasma levels. Ebert *et al* reported that Mn<sup>2+</sup> and Mg<sup>2+</sup> stimulate binding of HT-29 colon cancer cells to extracellular matrix proteins<sup>[124]</sup>, and similar effects have been described in SW 620 and Caco-2 human colon cancer cells<sup>[125]</sup>. However, calcium inhibits adhesion of SW 620 and Caco-2 human colon cancer cells to collagen I, which is the dominant collagen of the interstitial matrix<sup>[125]</sup>. Furthermore, Mg<sup>2+</sup> and Mg<sup>2+</sup> potentiate cancer cell adhesion to murine surgical wounds and subsequent tumor development. In contrast, Ca<sup>2+</sup> inhibits cancer cell adhesion to murine surgical wounds and subsequent tumor development<sup>[126]</sup>. The biological and chemotherapeutic response characterization of transplantable mouse colon tumors suggests that they are reasonable models for colon cancer in humans<sup>[127]</sup>. Although more studies are required, these results raise the possibility that in the future, manipulation of divalent cation concentrations in irrigation of the surgical site may diminish perioperative tumor implantation.

#### **Effects of physical forces on colon cancer cell adhesion**

Cancer cells are subjected to pressure during surgical manipulation and passage through the venous and lymphatic system. Cells that are shed into the peritoneal cavity postoperatively are also subjected to increased pressure from postoperative edema. Surgical manipulation during either laparoscopic or open procedures is likely to result in the direct application of much higher pressures to tumors or lymphatic channels containing malignant cells. For instance, during laparoscopic colectomy for cancer, intra-abdominal pressure is often increased by 15 mmHg as the abdominal cavity is expanded to provide room to operate. The pressure engendered by a surgical forceps grasping tissue may be as high as 1500 mmHg<sup>[128]</sup>. Although pressure by the surgeon's hand during tumor dissection has not been quantified to our knowledge, parallel studies suggest that intraocular pressures may exceed 50 mmHg during ocular manipulation during enucleation<sup>[129]</sup>. Normal portal venous pressures may be as high as 10 mmHg, and this may increase substantially in portal hypertension. Mesenteric venous pressures may exceed this under normal circumstances to generate portal flow and might be accentuated by intra-abdominal pressure generated by ascites, Valsalva maneuvers, or bowel edema after surgery. Mesenteric lymphatic pressures in the setting of tumor infiltration into the lymphatics are unclear but might also be expected to be of similar orders of magnitude. Tumor cells in the systemic arterial circulation, of course, are exposed to substantially higher pressures.

Physical forces such as shear stress, and pressure have been reported to affect colon cancer cells<sup>[130]</sup>. Increasing ambient pressure and the application of shear stress increased cell adhesion of several colon cancer cell lines and primary human colon cancer cells isolated directly from surgical specimens<sup>[130,131]</sup>. Indeed, an increase of

15 mmHg above ambient pressure had a maximum effect on colon cancer cell line adhesion *in vitro*<sup>[130]</sup>. An interesting observation is that during colorectal cancer surgery cells are shed into the abdominal cavity and subjected to increases in shear during irrigation and increased pressure during and after surgical procedures. Such increases in pressure may enhance the adhesion of shed cells to surgical sites. Although these original studies were performed *in vitro*, 30 min exposure to 15 mmHg increased pressure has more recently been demonstrated to increase cancer cell adhesion to murine surgical wounds<sup>[132]</sup> and to adversely affect survival in a murine transplantable tumor model<sup>[133]</sup>. There are obviously manifest differences between transplantable tumors in mice and the pathophysiology of human colon cancers, but as these same signal events have also been described in primary human colon cancer cells<sup>[130,131]</sup>, the animal data are suggestive that the same pathway might affect the development of metastatic tumors in humans.

#### **The effect of pressure on focal adhesion-associated proteins**

If pressure and shear stimulate the adhesion of cancer cells<sup>[125,130]</sup>, it may then be important to unravel the intracellular mechanisms that mediate this effect so that interventions can ultimately be targeted to prevent cancer cell adhesion. In many cells, the focal adhesion kinase FAK transduces signals after adhesion through association with the cytoplasmic domains of integrin subunits<sup>[134]</sup>. However, “inside-out signaling” by which intracellular events modulate integrin function is less well understood. A study by Cooke *et al* suggests that mechanical stimulation of enterochromaffin-derived BON cells directly or indirectly stimulates a G protein-coupled receptor that activates Gαq, mobilizes intracellular calcium, and causes 5-HT release<sup>[135]</sup>. Although this study did not portray increased adhesion due to mechanotransduction, it did show that shear stress on carcinoid cells activate an intracellular cascade that releases 5-HT. Consistent with such force-activated intracellular signaling, Thamilselvan *et al* demonstrated that extracellular pressure may increase integrin affinity and promote colon cancer adhesion *in vitro* via actin-dependent inside-out FAK and Src signals<sup>[136]</sup>. Indeed, it is likely that the intracellular cascade involved in colon cancer cell adhesion to extracellular matrix is very complex. Recently, the activation of PI 3-kinase/Akt signaling pathway has been correlated with prostatic metastasis<sup>[137]</sup>, colon cancer cell invasion<sup>[138]</sup> and post-operative growth<sup>[139]</sup>. The overexpression of the PI 3-kinase/Akt pathway has also been described in human cancers including ovarian and colonic carcinomas<sup>[140,141]</sup>. Recent studies suggest that the PI 3-kinase/Akt pathway may also be required for pressure-stimulated cancer cell adhesion<sup>[142]</sup>, acting specifically via Akt-1<sup>[143]</sup>.

Several key structural proteins also seem to be involved in the mechanotransduction pathway, including cytoskeletal elements<sup>[144]</sup>, the adapter proteins paxillin<sup>[145,146]</sup> and alpha actinin-1<sup>[147]</sup>. Both paxillin and alpha actinin-1 facilitate focal adhesion formation

and physically link integrin-associated focal adhesion complexes with the cytoskeleton. These focal adhesion associated proteins are often abnormally expressed or mutated in cancer cells<sup>[148-150]</sup>. Therefore, they may be important in tumor biology in general. Although these focal adhesion associated proteins are not kinases themselves, these proteins facilitate the interaction of various kinases and other proteins required for this pathway to function. This makes them a promising target to uncouple the pathway required for force-activated adhesion without actually inhibiting cellular kinases, possibly leading to fewer side effects. Indeed, in a preliminary proof of principle, knockout of alpha actinin-1 has been shown to abolish the effect of pressure on tumor-free survival in a murine transplantable tumor model<sup>[133]</sup>.

#### **CONCLUSION**

Over the past decades, screening for colorectal neoplasm has shown to be critical for prevention, early diagnosis, downstaging, and improved survival. Beyond intensified screening programs, surgical techniques have evolved over the past years. Total mesorectal excision has improved survival rates for rectal cancer<sup>[92]</sup>. Other major advances have included liver and lung resections for patients with colorectal metastasis, so that at least some of these patients are no longer candidates for palliative treatment but instead can be treated with curative intent. Besides improvements in surgical techniques, adjuvant therapies such as radiotherapy and chemotherapy also have undergone improvement. At this moment, sentinel lymph node mapping is a technique that lies on the frontier, as does the proper role of anti-angiogenesis agents. Some studies suggest that the sentinel lymph node technique may upstage a significant number of patients who then become candidates for chemotherapy, while anti-angiogenic therapy may downstage patients who then become candidates for surgical resection of known metastases. However, before conclusions are made on these points, further follow-up of patient cohorts will be necessary. The cellular biochemistry involved in metastasis currently lies beyond the frontier. Unfortunately, little is known about the intracellular and extracellular cascades that may influence colorectal cancer cell adhesion and metastasis. Several studies have suggested that increased pressure and shear stress activate cancer cell adhesion. Further studies of the pathways that regulate integrin-driven cancer cell adhesion may identify ways to disrupt these signals or block integrin-mediated adhesion so that perioperative adhesion and eventual metastasis can be prevented in the future, adding yet another strategy to combat colorectal malignancy.

## INTRODUCTION

Gaucher disease (GD) is a storage disease in which macrophage sphingolipidosis accumulation occurs. This progressive disease results from deficiency of glucocerebrosidase (acid- $\beta$ -glucosidase) in lysosomes. This enzyme is responsible for cleaving  $\beta$ -glycoside into  $\beta$ -glucose and ceramide subunits<sup>[1]</sup>. GD is inherited in an autosomal recessive fashion. The OMIM (Online Mendelian Inheritance in Man: <http://www.ncbi.nlm.nih.gov/Omim>) code for adult type GD is 230800.

It has 2 major forms: non-neuropathic (type 1, most commonly observed type in adulthood) and neuropathic (type 2 and 3). The disease is characterized by massive splenomegaly due to excessive accumulation of glucosylceramide in splenic macrophages. Other than spleen, so called "Gaucher cells" are the lipid-laden macrophages and can be observed in liver and bone marrow. Therefore GD causes organ damage where macrophages are densely present. Clinical alterations in bone, liver and spleen resulting in splenomegaly, hepatomegaly, hematological changes and orthopedic complications are the most predominant ones. Rarely kidney, skin, heart and central nervous system may be involved.

Recent advances in genetic technology have made it possible to manage the GD patients with enzyme replacement treatment (ERT). Substrate reduction treatment (SRT) is also currently available. In this review, we will discuss new developments in adult type GD disease in terms of its etiology and treatment from a gastroenterologists' point of view.

## ETIOLOGY AND PATHOGENESIS

The gene coding for the enzyme responsible for GD is located on chromosome 21. In this single gene, about 200 mutations are defined up to date<sup>[1]</sup>. Most commonly observed mutations are N370S, L444P, RecNciI, 84GG, R463C, recTL and 84 GG is a null mutation in which there is no capacity to synthesize enzyme. However, N370S mutation is almost always related with type 1

## Abstract

Gaucher disease (GD) is an autosomal recessive disease which if undiagnosed or diagnosed late results in devastating complications. Because of the heterozygous nature of GD, there is a wide spectrum of clinical presentation. Clinicians should be aware of this rare but potentially treatable disease in patients who present with unexplained organomegaly, anemia, massive splenomegaly, ascites and even cirrhosis of unknown origin. The treatment options for adult type GD include enzyme replacement treatment (ERT) and substrate reduction treatment (SRT) depending on the status of the patient. Future treatment options are gene therapy and "smart molecules" which provide specific cure and additional treatment options. In this review, we present the key issues about GD and new developments that gastroenterologists should be aware of.

disease and milder forms of disease. Very rarely, deficiency of sphingolipid activator protein (Gaucher factor, SAP-2, saposin C) may result in GD. This rare condition is due to congenital absence of carrier protein involved in sphingolipid catabolism<sup>[2]</sup>.

Worldwide differences in genetic mutations are shown in Table 1. Therefore, genetic heterogeneity results in phenotypic heterogeneity. The phenotypic presentation of the same mutation may vary in a wide spectrum. This difference is most possibly related with ethnicity, genetic background, environmental and nutritional factors. But most important of all, the exact pathophysiological mechanisms of GD are not clear yet. Since the total accumulation of glycosphingolipid in a massively enlarged spleen constitutes only about 2%, there must be other unknown pathways that result in splenic proliferation, activation and enlargement<sup>[10]</sup>. One of the most important changes occurs in macrophages. The accumulation of glycosphingolipid in the lysosomes of macrophages results in some expected consequences by unknown mechanisms. One important pathway is the activation of macrophages. The great majority of evidence of macrophage activation stems from the fact that patients with GD have increased levels of macrophage-derived inflammation related molecules such as interleukin-1 $\beta$ , interleukin-6, interleukin-10 and TNF- $\alpha$ <sup>[11,12]</sup>. With regard to macrophage activation, these cytokines might be responsible for some consequences like increased osteoclastic activity in bones resulting in osteopenia, osteoporosis and fractures.

Activated macrophages also secrete some other molecules that can be used as a marker of disease activity and surveillance. The enzyme chitotriosidase (CT) and CC chemokine ligand 18 (CCL8) are examples of these markers. CT is originally a chitinase which is responsible for degradation of chitin. In humans, CT plays a role during the remodeling phase of the tissue healing process and in immune-chemotaxis<sup>[13,14]</sup>. Previous studies reported that screening of increased CT activity can be used as a GD marker<sup>[15,16]</sup>. But the null allele in

the general population, which is expressed at a mean frequency of 4%, causes deficiency of the enzyme<sup>[17]</sup>. The levels of the enzyme may also increase in elderly people<sup>[18]</sup> and in other granulomatous diseases such as sarcoidosis<sup>[19]</sup>. In addition, other macrophage markers such as macrophage inflammatory protein (MIP)-1 $\alpha$ , MIP-1 $\beta$ <sup>[20]</sup> and soluble CD163<sup>[21]</sup> can also be used for surveillance of the disease.

## CLINICAL MANIFESTATIONS

In general, GD patients present initially with hematological abnormalities due to hypersplenism. Gastroenterologists can be consulted because of anemia, massive splenomegaly or hepatomegaly of unknown cause. Although rare, patients presenting with hepatosplenomegaly and ascites are reported<sup>[22]</sup>. As mentioned previously, GD involvement changes in severity according to the density of macrophages in the particular organ and partially depends on the phenotypically heterozygous nature of the disease itself.

The most common mutation, N370S, could result in subtle symptoms and silent disease due to presence of some degree of enzymatic activity resulting in delays in diagnosis. The delays in diagnosis eventually results in irreversible complications. A recent study by Mistry *et al* showed that in adult patients with type 1 disease the average time from first appearance of symptoms of GD to final diagnosis was 48 mo. In addition, hematology-oncology specialists who were managing two-thirds of the patients considered diagnosis of GD only in 20% for the classical symptoms (bone pain, organomegaly and low blood counts)<sup>[23]</sup>.

The diagnosis of GD is straightforward. The demonstration of genetically miscoded or absent enzyme levels is diagnostic. For this purpose, direct analysis of glucocerebrosidase in peripheral blood leukocytes is utilized. The activity of glucocerebrosidase is variable in white cell type<sup>[24]</sup>, enzyme activity usually increases from granulocytes to lymphocytes to monocytes. Type 1 GD patients have 10 to 15 percent of the normal enzyme activity whereas type 2 and 3 patients usually have lower activity. Due to considerable overlap of enzymatic activity between heterozygote carriers and normal individuals, enzyme analysis cannot distinguish GD carriers from non-GD-carriers. In order to differentiate the carrier state, the genetic analysis which was mentioned previously should be applied for definitive diagnosis.

After diagnosis, GD patients should be classified according to clinical severity scores. The modified scoring system developed by Zimran (Zimran severity score index, ZSSI)<sup>[25]</sup> should be used during initial evaluation and during follow up of patients taking treatment (Table 2).

### Gastrointestinal system involvement in GD

In the type 1 GD, gastrointestinal complications such as hepatomegaly, splenomegaly, cirrhosis, ascites, and esophageal variceal hemorrhage predominate and

are well known. However, other associations such as increased risk of hepatic carcinogenesis and cholelithiasis are not taken into consideration.

In the literature, there are reports of increased risk GD associated hepatocellular carcinoma (HCC)<sup>[26-28]</sup>. In a recent survey, the risk of development of HCC in GD patients is found to be 141 times more than normal controls<sup>[29]</sup>. The overall risk of malignancy (especially hematological malignancies such as multiple myeloma) development is known to be increased. However, some studies suggest that this risk is not different from the normal population in early and middle age<sup>[30]</sup>.

Patients with GD, especially females over age of forty are found to be increased in risk of cholelithiasis. This increased risk is usually attributed to factors like anemia, prior splenectomy, hepatic involvement and an increased biliary excretion of glucosylceramide<sup>[31,32]</sup>. The management of cholelithiasis is not different from non-GD patients.

The portal hypertension observed in GD has 2 causes. The first is the overflow in the portal system secondary to splenomegaly which usually resolves after splenectomy. The second is observed in patients who already had a splenectomy. In these patients, massive infiltration of Gaucher cells in the liver parenchyma results in intrahepatic portal hypertension. The accumulation of excessive sphingolipid in liver macrophages (Kupffer cells) might result in activation of some unknown mechanisms or cell-to-cell interactions might ensue which eventually results in hepatic fibrosis. Hepatic fibrosis and eventual cirrhosis is the most feared complication of GD for liver involvement<sup>[33,34]</sup>. Although ERT results in reversal of hepatomegaly to normal, hepatic fibrosis still remains a challenge. The exact pathophysiological pathways of progressive hepatic fibrosis are unknown, but progressive fibrosis is observed mostly in pediatric patients. In initial presentation, hepatic transaminase levels are found to be elevated in nearly 50% of patients<sup>[25]</sup>.

Other non-specific findings of GD involvement of the liver are hepatomegaly (detected in 100% of patients with splenomegaly but detectable only in 87% of patients with splenectomy), non-specific mass like lesions in liver, peri-portal and retroperitoneal lymph nodes<sup>[35]</sup>.

Liver transplantation is rarely necessary compared to a few decades ago because of the introduction of ERT. However, development of features of progressive liver fibrosis such as elevated liver transaminase levels and no normalization in hepatomegaly despite adequate enzyme treatment should alert for rapidly developing fibrosis in a given patient. Liver transplantation should always be an option in patients with GD. Theoretically, there is a risk of recurrence of liver disease due to excessive burden of glycosphingolipid influx more than transplanted liver can handle. This risk is higher in patients with a spleen; therefore a splenectomy (if not performed until time of transplantation) should also be performed when transplantation is decided.

Despite its rarity, GD may involve other sites of the

**Table 2 Zimran severity score index, 1992 (SSI scores of 0-10: Mild disease; 11-25: Moderate disease; > 25: Severe disease)**

gastrointestinal system other than the liver and spleen. GD may result in "Gaucher cell pseudotumors" in the abdomen resulting in mass like lesions<sup>[36,37]</sup>. This phenomenon is very important because GD is related with increased incidence of cancer but currently, GD pseudotumors are rare due to ERT. Association of GD with colonic infiltration of "Gaucher cells"<sup>[38]</sup>, massive gastrointestinal bleeding due to ileal involvement<sup>[39]</sup> and Menetrier disease of the stomach<sup>[40]</sup> are also reported.

## TREATMENT STRATEGIES IN GD

### Pre-treatment evaluation in GD

Since adult GD patients come to attention after development of symptomatic anemia, organomegaly or complications such as fractures, indications for specific treatment of GD are beyond the presence of these symptoms. The available ERT and SRT options are expensive (annual cost of ERT is around 1 billion US dollars<sup>[41]</sup>) and individual responses for these treatments are highly variable so that some patients may report no improvement. Therefore, with parallel to variability in phenotypic presentation, decision for treatment

must be individualized. In our personal practice, severe organomegaly, high degree of cytopenia, event of minor bleeding due to thrombocytopenia, bone disease, liver enzyme elevations with severe organomegaly and presence of any organ involvement other than liver-spleen-bone triad are indications of treatment. The aims of treatment are reversal of organomegaly, prevention of complications and increase in quality of life.

### **ERT**

Alglucerase (extracted from human placenta) is the first enzyme treatment modality for GD patients to provide specific treatment. Major limitations of this product were its low degree of reproducibility (because of low number of available placenta), risk of blood borne infections, very short half-life (about 4.7 min in blood and 2 h in visceral organs including liver and spleen)<sup>[42,43]</sup>. These limitations had resulted in new research and development of a recombinant enzyme; imiglucerase. Imiglucerase is obtained from genetically manipulated ovary cells of Chinese hamsters. This enzyme has a longer half life and lack of blood borne infection risk. Despite the clinical results, imiglucerase looks excellent; there is only one randomized controlled trial with imiglucerase up to date. In this study by Schiffmann *et al*<sup>[44]</sup>, the primary end-point was the improvement in bone mineral density of the lumbar spine. ERT (combination of alglucerase and imiglucerase) was compared with vitamin D and calcitriol in three patient arms. The total number of randomized patients was 29. The authors concluded that "ERT alone, or in combination with calcitriol, cannot repair the bone composition in splenectomized adult Gaucher patients. They also stated that the ERT significantly improved hemoglobin, platelet counts, and liver volume. There are two other randomized trials. The first one was designed to compare the effectiveness of imiglucerase vs. alglucerase (15 patients per treatment arm) which found no significant difference in the two molecules<sup>[45]</sup>. The second randomized controlled trial is a recent study by deFost *et al*<sup>[46]</sup> who showed that "low frequency administration of ERT in adult Gaucher type I patients maintains stable disease in most patients".

Although the number of randomized controlled trials in ERT does not satisfy clinicians as compared with other conditions, this currently available treatment option remains unique. The other option of treatment is substrate reduction therapy (SRT) and has a limited field of clinical use.

### **SRT**

The idea underlying SRT is the inhibition of formation of sphingolipids that accumulate during GD. N-alkylated imino sugars are the prototype of this treatment. N-butyl-deoxynojirimycin (NB-DNJ) or miglustat is used on GD to reduce the formation of glucosylceramide by inhibiting the glucosylceramide synthase enzyme<sup>[47]</sup>. There are various studies related to efficacy of SRT, which showed improved blood counts, decrease in volumes of liver and spleen and increased quality of life<sup>[48,49]</sup>. One recent study showed

comparable results with ERT<sup>[50]</sup>. The most important advantages of SRT are its oral administration (ERT is given as intravenous administration over several hours and must be repeated in 2-3 wk intervals), low costs and availability. Major drawbacks of SRT are safety issues. Theoretically, long term inhibition of glycosphingolipid inhibition may result in detrimental results but no major adverse reaction is reported up-to-date. Minor adverse reactions are weight loss, mild tremor, diarrhea, and gastrointestinal upset. In patients who received previous ERT, switch to SRT is well tolerated<sup>[51]</sup>. SRT is currently limited only to adult type 1 patients who can not tolerate ERT.

---

## **"THE FUTURE" OF GD THERAPY**

### **Gene therapy**

The administration and incorporation of a healthy genome replacing a deficient genome appears to be the cure for GD. There are a few studies in the literature investigating this possibility. In early animal models of gene therapy the vectors responsible for "infecting" a healthy genome were viruses (adeno-associated virus, lentivirus and retrovirus). These studies showed promising results for the future<sup>[52-54]</sup>. Neither ERT nor SRT have achieved excellent results in terms of neurological and pulmonary involvement due to problems such as inability to pass through the blood-brain barrier. The advantage of gene therapy is its widespread infection of specific targeted cells in the body substantially increasing the enzyme levels to a considerable level.

### **Chaperone treatment**

The ability of imino sugars to increase the strength of the target enzyme (glucocerebrosidase) is shown previously by Sawkar *et al* in a study<sup>[55]</sup>. These chemicals increase the half life of the enzyme by inhibiting its degradation and by providing stabilization. Although this option currently does not seem to offer a monotherapy option, chaperones might be an option for combination treatment strategies.

---

## **CONCLUSION**

Adult type GD is a heterozygous disease. Because of vulnerability to delayed diagnosis, timely diagnosis and early initiation of appropriate therapy are crucial and prevent detrimental complications and stops the progression of disease to some extent. In the future, it might be possible to "cure" this genetic disease by gene-vaccines. Therefore, we require more investment on investigations for gene therapy. ERT and SRT have undeniable therapeutic effects, but there seems to be need for more evidence before putting them into "gold-standard" therapy for all patients.

## INTRODUCTION

Primary sclerosing cholangitis (PSC) is a rare cholestatic liver disease characterized by chronic inflammation and fibrotic obliteration of the hepatic biliary tree, resulting in bile stasis and hepatic fibrosis. Ultimately cirrhosis, end-stage liver disease and death ensue. It is commonly associated with inflammatory bowel disease (IBD).

PSC is more commonly a disease of adults, with patients typically presenting during the 4th and 5th decades<sup>[1-3]</sup>, although it has been reported to occur in the pediatric age group<sup>[1]</sup>. Patients typically present with pruritus and fatigue at the early stages of the disease, although patients with incidental elevated liver enzymes may be diagnosed earlier. As the cholestatic picture progresses with further obliteration of the bile ducts and increased fibrosis, patients develop jaundice and signs of advanced liver disease. Rare presentations include variceal bleeding and cholangiocellular carcinoma (CCC)<sup>[4,5]</sup>. Due to the diverse clinical picture, PSC patients are generally categorized based on the presence of symptoms, involvement of small *versus* large bile ducts, and its association with IBD or other autoimmune diseases (Table 1).

The cause of PSC is unknown; however, it is not a typical autoimmune disease especially since sex predominance varies with geography. In this review we attempted to establish any differences regarding epidemiology, natural history and management of PSC between different geographical locations, as well as providing insight into recent developments regarding the pathogenesis and treatment of the disease.

## Abstract

Primary sclerosing cholangitis (PSC) is a chronic, progressive, cholestatic liver disease characterized by inflammation and fibrotic obliteration of the hepatic biliary tree. It is commonly associated with inflammatory bowel disease (IBD). A number of complications can occur which require special consideration, the most important of which is the development of cholangiocellular carcinoma (CCC). Unfortunately, no medical therapy is currently available for the underlying liver disease. Liver transplantation is an effective, life-extending option for patients with advanced PSC. Geographical variations between East and West include a second peak for age with a lower association with IBD in a Japanese population and female predominance in a lone study from Turkey. The clinical and biochemical Mayo criteria may not be universally applicable, as different patients show variations regarding the initial presentation and natural course of the disease. Directing research towards explaining these geographical differences and understanding the pathogenesis of PSC is required in order to develop better therapies for this devastating disease.

## EPIDEMIOLOGY AND SYMPTOMATOLOGY

Takikawa *et al*<sup>[2]</sup> have been pioneers in establishing the

**Table 1 Mayo criteria for the diagnosis of PSC<sup>[27]</sup>**

<b>Mayo criteria</b>	
Typical cholangiographic abnormalities involving any part of the biliary tree	Multifocal stricturing and beading, usually involving both the intrahepatic and extrahepatic biliary system
Compatible clinical and biochemical findings (for longer than 6 mo)	Cholestatic symptoms, history of inflammatory bowel disease Twofold to threefold increase in serum alkaline phosphatase levels
Exclusion of identifiable causes of secondary sclerosing cholangitis	AIDS cholangiopathy Bile duct neoplasm (unless diagnosis of PSC previously established) Biliary tract surgery, trauma Choledocholithiasis Congenital abnormalities of biliary tract Caustic sclerosing cholangitis Ischemic stricturing of bile ducts Toxicity or stricturing of bile ducts related to intra-arterial infusion of floxuridine

characteristics of PSC in Japanese patients. In an early analysis of 192 patients<sup>[2]</sup>, they discovered two peaks for age distribution, a characteristic which they reported as “unique”, with the disease being associated more often with IBD in the younger age group. In a more recent study<sup>[3]</sup>, the same group performed a nationwide survey, comparing the results with their previous study. They reported on male predominance (59%) with a mean age of 47 years at diagnosis. Although most patients were asymptomatic at the time of diagnosis, jaundice (28%) and pruritus (16%) were the most commonly encountered presenting symptoms.

Ponsioen *et al*<sup>[4]</sup> evaluated the natural history of PSC in a Dutch population. Of the 174 patients included in this study, 60% were male, with a mean age of 40.4 years<sup>[4]</sup>. In a similar study by Broome *et al* on 305 Swedish PSC patients, 64% were male and the median age at the time of diagnosis was 39 years (range 5-80)<sup>[5]</sup>. Of the symptomatic 171 (56%) patients, abdominal pain (37%), jaundice (30%), pruritus (30%), and fever (17%) were most commonly reported complaints. In a more recent multicenter study on 273 German patients, again male predominance was established at 71.4%, with a mean age at time of diagnosis of 32.4 years (range 9-72 years)<sup>[6]</sup>. Slightly more than half of these patients were symptomatic initially, with right upper quadrant abdominal pain once being again the most prevalent symptom (34.4%).

On the other side of the Atlantic, in an early study, Weisner *et al*<sup>[7]</sup> evaluated the natural history of PSC in 174 patients; 37 were asymptomatic and 137/174 (79%) had symptoms related to underlying liver disease. At the time of diagnosis, the mean age was 39.9 years, and 66% of the patients were male. Long-term follow-up (mean: 6.0 years; range: 2.7-15.5 years) was available in all patients. In a more recent population based study in Minnesota by the Mayo clinic, it was projected that approximately 29 000 cases of PSC exist in the white USA population. In this study, the median age at diagnosis was 40 years, and 68% of the patients were men. Although asymptomatic patients with incidental

abnormal liver tests was not an infrequent clinical scenario, most patients presented with symptoms of advanced stages of the disease, including jaundice, pruritus, fever, or manifestations of portal hypertension.

In an earlier study from Turkey, the “crossroad between east and west”, by Bayraktar *et al*<sup>[8]</sup> evaluating the association between PSC and IBD, the median age of presentation for patients with PSC was 35 years (range 19-48 years). The most intriguing feature was that 15 of the 16 patients with PSC were females, a predominance that had never been previously reported. Although results of two subsequent studies originating from Turkey<sup>[9,10]</sup> were found to be consistent with those from the West, the reasons behind the findings in the Bayraktar study remain elusive.

It would seem that PSC patients worldwide share the same characteristics regarding sex, age and symptoms on presentation (Table 2). The only differences of note would be the second peak for age of presentation observed in the Japanese population, as well as of course the overwhelming female predominance reported in the Turkish study.

## ASSOCIATION WITH IBDS

The intimate relationship between PSC and ulcerative colitis (UC), and to a lesser extent Crohn’s disease (CD), is no secret. One of the most attractive hypotheses linking the two entities is that disruption of intestinal mucosa due inflammation results in increased permeability and eventual translocation of bacteria into

the portal system, whose cell products may trigger an immune response in genetically susceptible individuals resulting in peribiliary fibrosis. Indeed, Grant *et al*<sup>[11,12]</sup> managed to demonstrate the enterohepatic circulation of lymphocytes where memory cells originating from the intestines may actually stimulate hepatic inflammation due to the liver and the intestines sharing the same homing receptors. This may help explain why the course of PSC is usually dependent on the severity and extent of bowel involvement.

In the Dutch study<sup>[4]</sup>, a total of 114/174 (66%) patients were known to have concurrent IBD, of which 73% had UC while 25% had CD. Tichendorf *et al* reported similar results in a German population, with 172/273 (63%) having concomitant IBD (82% UC, 17% CD, and 1.2% indeterminate colitis). A study in a Swedish population<sup>[5]</sup> reported a slightly higher association of IBD with PSC of 81% (249/305), of which 88% had UC, and 8% had CD. The situation in the US was no different, with an association of 71% between IBD and PSC, mainly UC<sup>[7]</sup>.

In Japan, however, a much lower prevalence of IBD has been reported by Takikawa *et al*<sup>[3]</sup>, with only 125 of the 388 patients (32%) having an established diagnosis of IBD, 79% of which had UC, while 6.4% were diagnosed with CD. They also discovered that most patients who were afflicted with IBD were mainly adolescents or young adults. The author's went so far as to suggest that this low prevalence deemed some of the Mayo diagnostic criteria to be inapplicable for Japanese patients.

The association with IBD seems to show variability depending on geographical location, with higher rates in the European and American population, and a significantly lower association in Japanese patients (Table 2).

## PATHOGENESIS OF PSC

The etiology and pathogenesis of PSC are not yet well understood. However, it is widely believed that immune dysregulation plays a key role in the development of the disease.

### Immunogenetics

Most studies on the immunogenetics of PSC were concentrated in the late eighties to the early nineties. Earlier reports by Schrumpf *et al*<sup>[13]</sup> and Chapman *et al*<sup>[14]</sup> demonstrated associations of HLA-B8 and -DR3 of up to 60% in patients with PSC associated with ulcerative colitis. In DR3 negative patients, a second association of up to 55% was reported for DR2<sup>[15]</sup>. The most striking result was reported by Prochazka *et al*<sup>[16]</sup>, where they found HLA-DRw52, encoded by the gene locus DRB3, in 100% PSC patients evaluated for liver transplantation, with a relative risk of 109 when compared to a control group. Subsequent studies failed to demonstrate a similar correlation<sup>[17]</sup>, which raised the suspicion that HLA-DRw52 may perhaps be associated with more severe disease, thus suggesting the need for liver transplantation in such patients. Clinical significance lies in the fact that

DR3 positive patients seem to have an earlier age of onset when compared to DR3 negative, DR2 positive patients. Similarly, DRB380101 positivity, coding for DR52, was associated with reduced survival rate<sup>[15]</sup>.

*MICA* and *MICB* genes, found in the class I region between HLA-B and DRB, express MICA, which is responsible for the activation of T-cells in the gastrointestinal tract. Although initially identified in association with IBD, their contribution to genetic susceptibility to develop PSC has been investigated. PSC was found to be associated to the extended B8-MICA5.1-MICB24-DR3 haplotype<sup>[18]</sup>. In another study, a previously unreported protective association with the DRB1\*0701-DQB1\*0303 haplotype was also demonstrated<sup>[19]</sup>. Other reported associations include significantly increased TNFA2 allele frequency PSC patients, particularly the homozygous genotype in a southern European population<sup>[20]</sup>.

Intercellular adhesion molecule-1 (ICAM-1, CD54) gene polymorphisms have been implicated in the susceptibility to IBD. ICAM-1 is expressed on proliferating and interlobular bile ducts and elevated serum levels of soluble ICAMs have also been detected. Surprisingly, the E469E homozygote status for ICAM-1 was found to be associated with protection against PSC<sup>[21]</sup>.

Studies regarding the immunogenetics of PSC were inconclusive in establishing a difference between East and West, due to a lack of extensive population based research.

### Autoantibodies

There is no specific autoantibody for PSC, although ANCA positivity has been known to occur in up to 88% of patients, while ANA positivity has been observed in a substantial portion (53%) of PSC patients<sup>[22]</sup>. More notably, anticardiolipin positivity, reported in up to two-thirds of patients, was found to be associated with more prominent histological changes and disease severity<sup>[23]</sup>. In the report by Moritoki *et al*<sup>[23]</sup>, it was concluded that autoimmunity plays a more important role in autoimmune hepatitis and primary biliary cirrhosis rather than PSC, a notion that is supported by the fact that PSC does not respond to immunosuppressive treatment. Some degree of association has also been reported with *H pylori* IgG<sup>[24]</sup>.

Data in the pertinent literature was insufficient to help establish any geographical differences in immunogenetics.

## DIAGNOSIS OF PSC-LABORATORY, ENDOSCOPY, HISTOLOGY AND RADIOGRAPHY

In the Japanese study<sup>[3]</sup>, ALP levels were elevated in 65% of patients, while 39% had eosinophilia. ANA were positive in 36% of patients. The majority of the patients (80%) were diagnosed with endoscopic retrograde cholangiography (ERC), while for 32% magnetic

**Figure 1** Classical ERCP findings for PSC: Multifocal stricturing (thin arrows) and beading (thick arrow) of the intrahepatic and extrahepatic biliary ducts.

resonance cholangiography (MRC) was utilized, by which more than two-thirds of the patients were observed to have involvement of both intrahepatic bile ducts (IHBD) and extrahepatic bile ducts (EHBD). Isolated involvement of the IHBD and EHBD was encountered in 27% and 4.8% of patients, respectively, while small duct (SD) PSC was observed only in 1.6% of cases. Sixty-nine percent of the patients had histologically proven bile duct damage, with cholestasis apparent in 46% of the 284 patients who underwent a liver biopsy.

Tischendorf *et al*<sup>[6]</sup> also reported a similar rate of simultaneous involvement of IHBD and EHBD (68%). While 24.9% and 3.7% of patients had either IHBD or EHBD involvement, respectively, SD involvement was encountered in 3.3% of patients. In this study, all patients had undergone ERC evaluation, with no mention of MRC. The Swedish population<sup>[5]</sup> wasn't far different with 67% dual involvement, 27% IHBD involvement only, and 6% had only extrahepatic PSC. Interestingly, none of the patients in this study had SD PSC.

ERC and liver biopsy are still the most widely used modalities for the diagnosis of PSC, although use of MRC is on the rise.

#### ERC vs MRC for PSC

PSC was first described by Delbet in 1924<sup>[25]</sup>. The advent of the widespread use of endoscopic retrograde cholangiopancreatography (ERCP) in the mid-1970s led to further recognition of what was previously thought to be a very rare disease. In an excellent report, MacCarty *et al* described what are now known as the classical ERCP findings (Figure 1) in PSC<sup>[26]</sup>, which later formed the backbone for the updated Mayo Clinic diagnostic criteria of 1984<sup>[27]</sup>.

ERC remains the current standard for imaging of the biliary tract in patients with suspected PSC. However, being less invasive, MRC has gained popularity in recent years. Although promising, many authors have had reservations regarding the sensitivity and specificity of MRC for diagnosing and defining the extent and the severity of PSC. Two recent reports compared these two modalities head-to-head. Berstad *et al*<sup>[28]</sup> thought that the diagnostic accuracy of ERC and MRC were comparable,

despite MRC providing a slightly poorer depiction than ERC of extrahepatic and intrahepatic ducts. They reported independent reader sensitivity and specificity rates of 80% and 87%, with an accuracy of 83% for MRC, compared to 89%, 80% and 85 % for ERC. They concluded that MRC and ERC performed equally well in the diagnosis of PSC when used blinded to clinical information. In a separate study by Moff *et al*<sup>[29]</sup>, EHBD and IHBD visualization was excellent in 64% and 66% of MRCs, and 86% and 74% of ERCS. MRC had sensitivity ranging from 81%-91%, and specificity 85%-96% for diagnosis of PSC. Interobserver agreement for the diagnosis of PSC and for identifying the presence of IHD strictures was good for both modalities, but once again only ERC was good for the presence and the severity of EHD strictures. Similarly, for the assessment of disease severity patients with PSC, interobserver agreement was very poor for both MRC and ERC. They concluded that ERC and MRC were comparable for diagnosing PSC, with very good interobserver agreement for the diagnosis of PSC and IHD strictures. Only ERC had good agreement for EHD strictures. Interobserver agreement was very poor for both MRC and ERC when disease severity of PSC was assessed.

## COMPLICATIONS OF PSC

### ***Cholelithiasis, choledocholithiasis, and biliary strictures***

Chronic cholestasis predisposes to the formation of cholesterol gallstones and bile stasis with bacterial cholangitis leads to the formation of pigment stones of the bile ducts, which are known to occur in a third of PSC patients. Continuing inflammation eventually results in the development of benign biliary strictures, usually of the EHBD, and they have been reported in up to 7% of patients within 10 years<sup>[30-32]</sup>. Patients usually present increased jaundice, pruritus or relapsing bacterial cholangitis. Progression of these symptoms warrants cholangiographic examination. Endoscopic intervention, with balloon dilatation for biliary strictures, remains the preferred treatment modality. Some authors have advocated the use of short-term biliary stenting to help improve prognosis<sup>[33]</sup>. Surgical intervention should be avoided where possible, as it may predispose to recurrent bacterial cholangitis, while at the same time making future attempts at liver transplantation more challenging.

### **CCC**

CCC is the most feared complication among patients with PSC, occurring in 7% to 15% of patients with PSC<sup>[34,35]</sup>. Chronic inflammation of the bile ducts and cholestasis predispose the development of CCC in PSC patients, although a correlation between severity of disease and incidence of CCC has yet to be established. The difficulty in establishing a diagnosis of CCC lies in the fact that they may not be easily distinguished from benign biliary strictures. The usual serum marker CA 19-9 is not useful in this setting, as PSC itself may result in marked elevations, and secondary bacterial cholangitis

has also been reported to result in increases in CA 19-9 levels<sup>[36,37]</sup>. Nevertheless, in a patient with PSC, sudden and unexpected clinical deterioration, which is associated with progressive elevation of alkaline phosphatase and serum CA 19-9 (> 100 U/mL), in the absence of bacterial cholangitis indicates probable development of CCC.

Novel diagnostic methods include digital image analysis (DIA) and fluorescence *in situ* hybridization (FISH) performed on bile duct brushings collected at the time of ERC. DIA allows deoxyribonucleic acid (DNA) content quantification, assessment of chromatin distribution and nuclear morphology, while FISH offers promise to evaluate bile duct lesions for cellular aneuploidy and chromosomal aberrations<sup>[37]</sup>. A number of studies have demonstrated higher sensitivity of both modalities when compared to standard cytological examination, with comparable specificities<sup>[36,38,39]</sup>.

The diagnosis of CCC requires a meticulous and careful combination of a clinical exam, biochemical results, and imaging procedures (ERC, MRC), especially in patients who present with sudden clinical deterioration. Early diagnosis of CCC in PSC can be treated by liver transplantation in selected medical centers.

## SPECIAL CONSIDERATIONS

### **Pruritus**

Pruritus in PSC is a rather disabling symptom, resulting in a diminished quality of life. The mechanism behind pruritus associated with cholestasis is unknown. Ursodeoxycholic acid (UDCA), cholestyramine, and antihistaminics opiate receptor antagonists have been used to treat patients with cholestatic pruritus<sup>[40]</sup>.

### **Fat-soluble vitamin deficiency**

Fat-soluble, A, D and E, vitamin deficiencies have been recorded to occur in 2%-40% of patients with PSC, especially in those with advanced disease<sup>[41]</sup>. Recommended treatment doses for established or suspected deficiencies are 25-50 000 units two to three times per week orally for Vitamins A and D and 100 U/d for Vitamin E. Vitamin E deficiency is the most difficult to correct, with poor responses to replacement therapy. Vitamin K deficiency, although rare, is treatable with intravenous replacement.

### **Metabolic bone disease**

Metabolic bone disease, usually caused by osteoporosis, rather than osteomalacia, is relatively common and an important complication among patients with PSC<sup>[42]</sup>. It is a rather unfortunate complication, with no proven therapy. Calcitonin and bisphosphonates have been tested on patients with primary biliary cirrhosis with mixed results<sup>[43,44]</sup>, but data on their benefit on PSC is still lacking.

For patients who are on steroid therapy for PSC associated with IBD or AIH, recommendations include close monitoring of bone mineral density with initiation

of vitamin D and calcium supplementation at the first signs of osteopenia.

## MEDICAL TREATMENT OF PSC

### **UDCA**

A hydrophilic dihydroxy bile acid, UDCA has its roots in ancient Chinese medicine. Its ability to dissolve gallstones contributed to its newly found worldwide fame in the eighties. It was then that its benefit for the cholestatic syndromes was established. Described mechanisms of action include stimulation of hepatobiliary secretion, inhibition of apoptosis and the protection of bile epithelial cells from the toxic effects of hydrophobic bile acids<sup>[45]</sup>.

The use of UDCA was first explored after the earlier success with primary biliary cirrhosis. Although the three major studies all showed decreases in liver enzyme levels with UDCA, they failed to demonstrate any improvement in symptoms or liver histology<sup>[46-48]</sup>. In a meta-analysis by Chen<sup>[49]</sup>, no difference was observed between UDCA and placebo regarding overall survival and disease progression with the development of complications, requiring transplantation. UDCA also did not prevent deterioration of histological or cholangiographic findings. However, patients included in these studies had advanced disease, making them less responsive.

The general belief is that although UDCA is widely recommended in the treatment of PSC, there is a desperate need for new therapies which may hopefully prevent disease progression.

### **Immuno modulators/suppressants**

Steroid therapy has been the mainstay for the treatment of autoimmune liver diseases; however, its role in the treatment remains controversial. Good response rates have been observed on patients showing histologic signs of both PSC and AIH, otherwise known as autoimmune cholangitis, an overlap syndrome<sup>[50]</sup>. This group of patients show more characteristic signs of autoimmune disease, such as female predominance, which may account for this response.

In classical PSC, however, the situation is rather bleak. No study has conclusively demonstrated the benefit of systemic steroids in preventing disease progression<sup>[51,52]</sup>. Endoscopic application of topical corticosteroid failed to impress, but in fact resulted in more frequent episodes of bacterial cholangitis<sup>[53]</sup>. The results of these studies have left many clinicians baffled, but an interesting study by Tjandra *et al*<sup>[54]</sup> offered an explanation. They demonstrated a reduction in steroid receptors on hepatic T lymphocytes in a rat model of cholangitis, making them less responsive to steroid treatment. Many authors firmly believe that corticosteroids only help to augment the risks commonly associated with classical PSC, such as metabolic bone disease (osteoporosis) and increased susceptibility to infections.

Several studies on other agents like methotrexate, colchicine, D-penicillamine, pentoxifylline and

tacrolimus<sup>[55,56]</sup>, failed to show any added benefit in the treatment of PSC.

## LIVER TRANSPLANTATION FOR PSC

Liver transplantation is the only option that can reverse or correct end-stage liver disease seen in advanced PSC. Controversy lies in the most appropriate timing for surgery, since transplantation after the development of CCC is associated with a poorer outcome<sup>[57]</sup>. The classical indications still apply, including complicated cirrhosis, intractable itch and fatigue, jaundice refractory to endoscopic or medical treatment or the development of hepatocellular or CCC<sup>[58]</sup>. The MELD system is used in the United States for all patients with end stage liver diseases, regardless of etiology.

Survival rates after transplantation for PSC have improved throughout the years, rates as high as 84%<sup>[59]</sup>. Post-transplantation survival has been found to be dependent on a number of pretransplantation factors, such as compromised renal function and the presence of hepatobiliary malignancy at the time of surgery, with recurrence of the original disease being a particular problem<sup>[60-62]</sup>.

## CONCLUSION

PSC is a chronic slowly progressive cholestatic liver disease of unknown etiology. A number of complications can occur, which require special consideration, the most important of which is the development of CCC. Unfortunately, no medical therapy is currently available for the underlying liver disease. Liver transplantation is an effective, life-extending option for patients with advanced PSC.

Geographical variations include a second peak for age with a lower association with IBD in a Japanese population, female predominance in a lone study from Turkey. The clinical and biochemical Mayo criteria may not be universally applicable, as different patients have shown variations regarding the initial presentation and natural course of the disease.

Directing research towards explaining these geographical differences and understanding the pathogenesis of PSC is required in order to develop better therapies for this devastating disease.

## ACKNOWLEDGMENTS

A special thank you goes out to Tuna Gul and Nihal Kurtcimen for all their effort and support.

## Abstract

**AIM:** To investigate the effect of lithium on proliferation of esophageal cancer (EC) cells and its preliminary mechanisms.

**METHODS:** Eca-109 cells were treated with lithium chloride, a highly selective inhibitor of glycogen synthase kinase 3β (GSK-3β), at different concentrations (2–30 mmol/L) and time points (0, 2, 4, 6 and 24 h). Cell proliferative ability was evaluated by 3-(4,5-dimethylthiazole-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay, and cell cycle distribution was examined by flow cytometry. Expressions of p-GSK-3β, β-catenin, cyclin B1, cdc2 and cyclin D1 protein were detected by Western blotting, and the subcellular localization of β-catenin was determined by immunofluorescence. The mRNA level of cyclin B1 was detected by reverse transcription polymerase chain reaction (RT-PCR).

**RESULTS:** Lithium could inhibit the proliferation of Eca-109 cells. Lithium at a concentration of 20 mmol/L lithium for 24 h produced obvious changes in the distribution of cell cycle, and increased the number of cells in G<sub>2</sub>/M phase ( $P < 0.05$  vs control group). Western blotting showed that lithium inhibited GSK-3β

by Ser-9 phosphorylation and stabilized free β-catenin in the cytoplasm. Immunofluorescence further confirmed that free β-catenin actively translocated to the nucleus. Moreover, lithium slightly elevated cyclin D1 protein expression, whereas lowered the cyclin B1 expression after 24 h lithium exposure and no obvious change was observed for cdc2 protein.

**CONCLUSION:** Lithium can inhibit the proliferation of human esophageal cancer cell line Eca-109 by inducing a G<sub>2</sub>/M cell cycle arrest, which is mainly mediated through the inhibition of lithium-sensitive molecule, GSK-3β, and reduction of cyclin B1 expression.

## INTRODUCTION

Esophageal cancer (EC) is prevalent in some regions of the world, and occurs at a very high frequency in certain parts of China and the mortality rate ranked the fourth among cancer-related death<sup>[1,2]</sup>. However, the molecular basis of esophageal carcinogenesis remains poorly understood.

Glycogen synthase kinase-3β (GSK-3β) is a serine/threonine kinase that controls cell survival and cell fate through its involvement in multiple signaling pathways<sup>[3]</sup>. Recent studies in colorectal cancer, pancreatic cancer, hepatocellular carcinoma and ovarian cancer<sup>[4-7]</sup> demonstrate that GSK-3β is involved in the process of tumorigenesis. Inhibition of the expression and activity of GSK-3β attenuates cell proliferation and causes apoptosis in colorectal, pancreatic and ovarian cancer cells<sup>[4,5,7]</sup>.

Lithium has been shown to be a specific and noncompetitive inhibitor of GSK-3 $\beta$  activity *in vitro*<sup>[8,9]</sup> and *in vivo*<sup>[10]</sup>. It has been proved that lithium could promote<sup>[11-14]</sup> or inhibit<sup>[7,15-17]</sup> cell cycle transition and proliferation of some primary cultures or cell lines by inhibiting GSK-3 $\beta$ , depending on the cell type. However, whether lithium influences the growth and proliferation of EC cells remains unknown to date.

In this report, we chose Eca-109 cells as a model, and observed the potential role of lithium in cell cycle progression and growth of EC cells and investigated its preliminary mechanisms.

## MATERIALS AND METHODS

### Cell culture and treatment

Human esophageal squamous cell carcinoma cell line Eca-109 was obtained from Institute of Biochemistry and Cell Biology, Shanghai, China and maintained in RPMI 1640 medium (Gibco Biocult, Paisley, UK) supplemented with 10% calf bovine serum (Sijiqing Biotechnology, China), 100 U/mL penicillin and 100  $\mu$ g/mL streptomycin at 37°C in a water-saturated atmosphere of 5% CO<sub>2</sub> in air. For G<sub>0</sub>/G<sub>1</sub> synchronization, when Eca-109 cells grew to 70% confluence, the routine medium was removed and replaced by free-serum medium for 24 h. Then these cells were cultured in the free-serum medium supplemented with 2-30 mmol/L lithium (Alexis, USA) for indicated times.

### 3-(4,5-dimethylthiazole-2-yl) 2,5-diphenyl-tetrazolium bromide (MTT) assay

The IC<sub>50</sub> of lithium on Eca-109 cells was measured by MTT assay, which was conducted as described before<sup>[18]</sup>, and was calculated by Logit method. Briefly, one thousand Eca-109 cells ( $5 \times 10^3$ /mL) were seeded in 96-well plates and cultured for 12 h. When they were adhesive, these Eca-109 cells were exposed to a range of concentrations of lithium from 2 to 30 mmol/L for 72 h, respectively. The Eca-109 cells treated with routine medium served as negative control. All exposures were performed in six wells. At the end of exposure, 20  $\mu$ L of MTT (Sigma, USA) stock solution (5 mg/mL) was added to 200  $\mu$ L of medium in each well and plates were incubated for 4 h at 37°C, and subsequently 150  $\mu$ L of dimethyl sulfoxide (DMSO) was added to each well. The plates were incubated about 10 min at room temperature and read with enzyme-linked immunosorbent assay (490 nm) to determine absorbance values ( $A$ ). The rate of inhibition was calculated by the following equation:

$$\text{Rate of growth inhibition (\%)} = (1 - A_{\text{treated}}/A_{\text{control}}) \times 100\%.$$

### Flow cytometry

Before the analysis was conducted by FCM, Eca-109 cells were exposed to lithium at a concentration of 20 mmol/L for 0, 2, 4, 6 and 24 h, respectively. According to the routine method,  $1.0 \times 10^6$  Eca-109 cells from the control and treated groups were harvested by

trypsinization and centrifugation, washed twice with ice-cold PBS and resuspended in PBS containing 10 mg/L propidium iodide (Sigma, USA) and 100 mg/L RNase A (Huamei Biotechnology, China) and then incubated at 25°C in the dark for at least 30 min. The percentage of cell population in each phase of the cell cycle was measured using FACStar and the results were analyzed with the software CELLQUEST. All measurements were carried out with the same instrument under the same experimental conditions.

### Reverse transcription polymerase chain reaction (RT-PCR)

Total RNA was extracted from specimens using Trizol reagent (Invitrogen, USA) and treated with DNase I (Tiangen Biotechnology, China). cDNA was synthesized from 2  $\mu$ g of total RNA according to the manufacturer's instruction (Fermentas, USA), and negative control reactions were run without reverse transcriptase. An equal volume of product was subjected to PCR. The levels of gene transcripts were quantified as the ratio of the intensity of the target gene to the intensity of  $\beta$ -actin. The PCR primers used in this study were as follows: forward primer 5'-CCATTATTGATCGGTTCATGCAGA-3' and reverse primer 5'-CTAGTGCAGAATTCAAGCTGTG GTA-3' for cyclin B1 (585 bp)<sup>[19]</sup>.  $\beta$ -actin was amplified as internal control using the following primers: forward primer 5'-AGTTGCGTTACACCCTTTCTTG-3' and reverse primer 5'-TCACCTTCACCGTTCCAGTT-3', with a 150 bp fragment product. The amplification conditions were 30 cycles of 94°C for 50 s, 55°C for 40 s, 72°C for 40 s for cyclin D1, and 30 cycles of 94°C for 50 s, 59°C for 40 s, 72°C for 40 s for cyclin B1 and  $\beta$ -actin. PCR products were run on 1.6% agarose gel and results were analyzed using Image Tool 3.0.

### Extraction of nuclear protein

Cells were lysed in 400  $\mu$ L of ice-cold buffer A [10 mmol/L HEPES (pH 7.9), 10 mmol/L KCl, 0.1 mmol/L ethylene diamine tetraacetic acid (EDTA), 0.1 mmol/L EGTA, 1 mmol/L DTT, 0.5 mmol/L PMSF] by gentle pipetting. The cells were allowed to swell on ice for 15 min, then 40  $\mu$ L of a 10% solution of Nonidet P-40 was added and the tube was vigorously vortexed for 10 s. The homogenate was centrifuged for 30 s in a microcentrifuge. The supernatant was transferred and the nuclear pellet was lysed with 50  $\mu$ L of buffer B [20 mmol/L HEPES (pH 7.9), 0.42 mol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 1 mmol/L DTT, 1 mmol/L PMSF] and the tube was vigorously rocked at 4°C for 15 min on a shaking platform. The nuclear extract was centrifuged for 5 min in a microcentrifuge at 4°C. The supernatant containing nuclear protein was stored at -70°C.

### Western blotting

Cells were washed twice with ice-cold PBS, collected by adding 0.25% trypsin and lysed in buffer [50 mmol/L Tris-HCl (pH 7.5), 150 mmol/L NaCl, 1 mmol/L ethylene diamine tetraacetic acid (EDTA), 0.25%

sodium deoxycholate, 1% TritonX-100, 0.1% sodium dodecyl sulfate (SDS), 1 mmol/L NaF, 1 mmol/L Na<sub>3</sub>VO<sub>4</sub>], protease inhibitors (10 mg/L aprotinin and 1 mmol/L phenylmethylsulfonyl fluoride) were added to obtain whole cell protein. Equal amounts of cell protein, quantified by BCA protein assay kit (Pierce Biotechnology, Rockford, IL), were subjected to 10% SDS-polyacrylamide gel electrophoresis, and then transferred to polyvinylidene difluoride membrane. The membranes were blocked with 5% non-fat milk in TBST [50 mmol/L Tris-HCl (pH 7.6), 150 mmol/L NaCl, 0.1% Tween 20] for 2 h at room temperature, and subsequently incubated with primary antibody (anti-p-GSK3β, 1:400, anti-cyclin D1, 1:200, anti-cyclin B1, 1:400, anti-cdc2, 1:500, β-actin, 1:2000, were all purchased from Sant Cruz Biotechnology, USA, and anti-β-catenin, 1:400, was purchased from Chemicon Biotech, USA) in blocking buffer at 4°C overnight. Following a wash with TBST, the membranes were incubated with horseradish peroxidase conjugated rabbit anti-mouse secondary antibody (1:1000, Dako, Denmark) for 2 h at room temperature. The membranes were washed with TBST and protein bands were visualized by enhanced chemiluminescence according to the manufacturer's instructions (KPL, USA). The β-actin bands were taken as loading control. The protein quantity was analyzed by UTHSCSA Image Tool 3.0. The target protein expression was evaluated by the relative intensity ratio of target protein/loading control.

### Immunofluorescence

Cells were plated on the coverslips which had been put into the six-well plates in advance. After being treated with 20 mmol/L lithium for the indicated time as described above, cells were washed with ice-cold phosphate-buffered saline (PBS) prior to fixing with 4% paraformaldehyde for 15 min at room temperature. Next, cells were treated with 1 g/L TritonX-100 for 30 min and subsequently incubated with a blocking solution (10% normal goat serum in PBS) for 20 min, anti-β-catenin monoclonal antibody in PBS (1:100, Chemicon, USA) overnight at 4°C and followed by fluorescein isothiocyanate-labeled goat anti-mouse IgG (Dako Biotechnology, Denmark) for 1 h at room temperature. Finally, the cells were visualized and photographed with an Olympus fluorescence microscope.

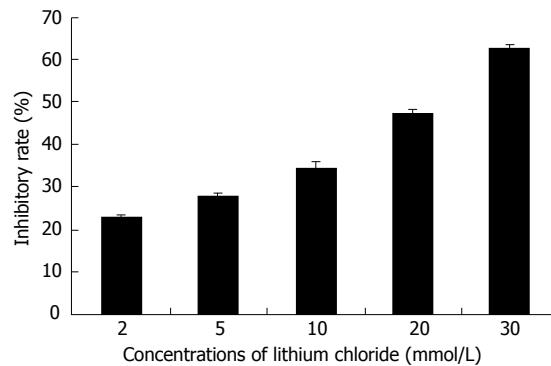

### Statistical analysis

The data were obtained from at least three repeated experiments and expressed as mean ± SD. In order to compare the data between the treated groups and the control group, statistical significance was analyzed through analysis of variance (ANOVA) and values of  $P < 0.05$  were considered significant.

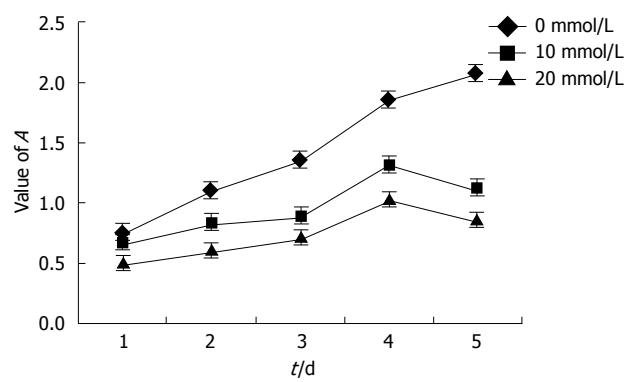

## RESULTS

### Lithium inhibits proliferation of Eca-109 cells

The mean IC<sub>50</sub> of lithium was  $21.7 \pm 0.5$  mmol/L. The effect of inhibition of lithium on Eca-109 cells could be

**Figure 1** Lithium could impose inhibition on Eca-109 cells in day 3. With the increased concentration of lithium, the inhibitory effect was enhanced. Each bar came from six wells of 96-well plate and represented mean ± SD.

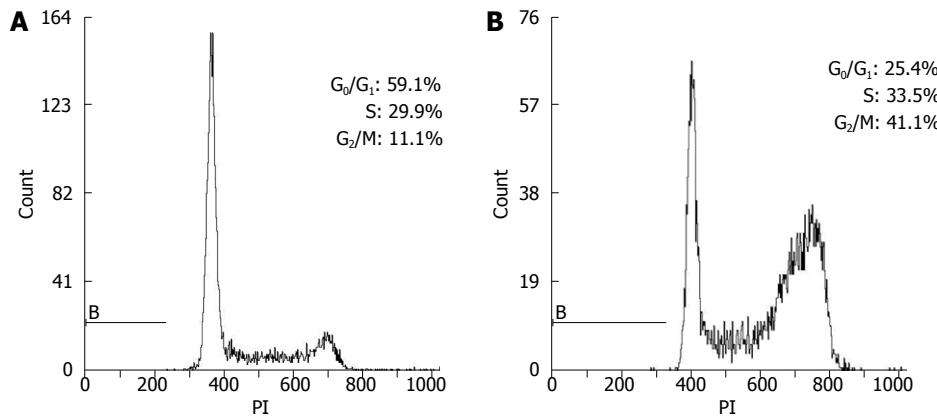

**Figure 2** Growth curves of Eca-109 cells plotted by MTT assay. Each point was the mean ± SD from six independent experiments.

observed at a concentration of 2 mmol/L. From 2 to 30 mmol/L, the inhibitory effect was enhanced along with the increased concentration of lithium. The exhibition of dose-response relationship could be observed (Figure 1).

The growth curves of Eca-109 cells within 5 d after treatment with lithium were also plotted according to the data obtained from the MTT assay (Figure 2). The Eca-109 cells treated with different concentrations of lithium showed much slower growth than the untreated cells. The results indicated that the proliferation of Eca-109 cells *in vitro* was inhibited compared to that of the untreated cells.

### Lithium induces a G<sub>2</sub>/M cell cycle arrest in Eca-109 cells

To determine whether the lithium-induced inhibition of proliferation of Eca-109 cells was due to altered cell cycle regulation, Eca-109 cells were treated with lithium for various times, and cell cycle profiles were monitored by flow cytometric analysis of DNA content (Figure 3 and Table 1). The percentage of cells in G<sub>0</sub>/G<sub>1</sub> phase decreased with the length of treatment from 59.6% at 0 h to 22.1% at 24 h, and the percentage of cells in S phase increased accordingly from 28.5% at 0 h to 42.5% at 6 h. At 24 h, while the cells were entering from S phase to G<sub>2</sub>/M phase, the percentage of cells in S phase decreased from 42.5% at 6 h to 31.5% at 24 h, but the percentage of cells in G<sub>2</sub>/M phase was increased markedly. The distribution in the phases of

**Figure 3** Lithium inhibited the proliferation of Eca-109 cells by an arrest in G<sub>2</sub>/M phase. Eca-109 cells were treated with lithium (20 mmol/L) for 0 h (A) and 24 h (B). Eca-109 cells were harvested and cell cycle profiles were obtained by staining with propidium iodide (PI).

**Table 1** Lithium affects cell cycle progression in Eca-109 cells

Groups	Distribution in cell cycle (%) <sup>1</sup>		
	G <sub>0</sub> /G <sub>1</sub>	S	G <sub>2</sub> /M
0 h	59.6	28.5	11.9
2 h	53.6	33.6	12.8
4 h	47.4 <sup>a</sup>	39.4 <sup>a</sup>	13.2
6 h	43.1 <sup>a</sup>	42.5 <sup>a</sup>	14.5
24 h	22.1 <sup>a</sup>	31.5	46.4 <sup>a</sup>

<sup>1</sup>Lithium reduced the G<sub>0</sub>/G<sub>1</sub> phase population sharply and increased the population in G<sub>2</sub>/M phase accordingly. <sup>a</sup>P < 0.05 vs the control group.

cell cycle indicated that lithium could promote Eca-109 cells entering into S phase and then G<sub>2</sub>/M, in which the population was increased by approximate 4 folds compared with that of the untreated group at 24 h. These results suggested that the growth-inhibitory effect of lithium on Eca-109 cells might be partly due to its ability to induce G<sub>2</sub>/M cell cycle arrest.

#### Lithium induces a G<sub>2</sub>/M arrest by decreased cyclin B1 expression

Having established that lithium induces a G<sub>2</sub>/M cell cycle arrest, we attempted to characterize, at the molecular level, the mechanisms by which this effect is achieved. Since the cyclin B1/cdc2 complex is a master intracellular regulator entry into mitosis<sup>[20]</sup>, we therefore investigated the effects of lithium in Eca-109 cells on key regulators of the G<sub>2</sub> to M phase transition, cdc2 and cyclin B1 using Western blotting. Treatment for 24 h with lithium reduced the protein expression of cyclin B1 (Figure 4A). Moreover, down-regulation of cyclin B1 expression at 24 h was also confirmed at the mRNA levels by RT-PCR (Figure 4B). Similar to the untreated cells, the total levels of cdc2 protein remained stable upon lithium treatment (Figure 4C). These findings suggested that the lithium-induced G<sub>2</sub>/M arrest was probably due to decreased expression of cyclin B1, and had nothing to do with the expression of cdc2 protein.

#### Lithium induces β-catenin stabilization via inhibition of GSK-3β

Inhibition of GSK-3β (GSK-3β Ser-9 phosphorylation)

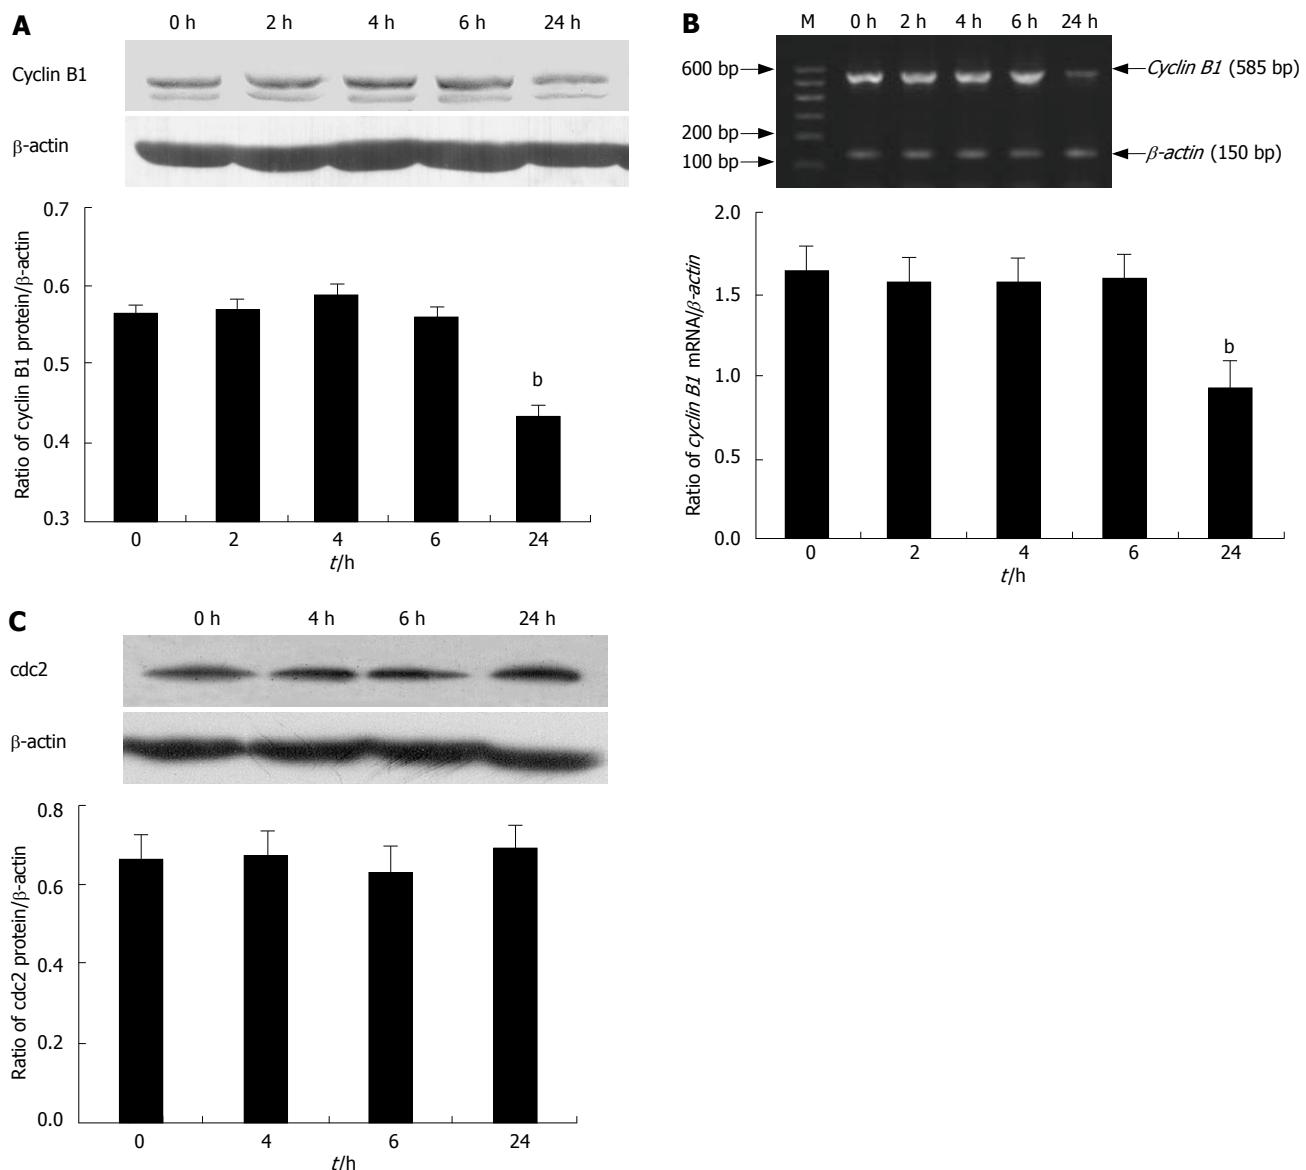

was assessed by Western blotting using a phospho-Ser-9-specific antibody. As shown in Figure 5A, 20 mmol/L lithium increased the phosphorylated inactive form of GSK-3β in Eca-109 cells. Moreover, at a range of 2-30 mmol/L, this effect of lithium was dose-dependent (data not shown). β-catenin, a signaling molecule in the Wnt/β-catenin signaling pathway, is a target of GSK-3β. Inactivation of GSK-3β by Wnt signaling or by lithium leads to stabilization and nuclear translocation of β-catenin<sup>[21]</sup>. Here, we investigated the expression of β-catenin by Western blotting of total and nuclear extracts from Eca-109 cells treated with lithium. Results indicated that the intracellular total protein concentrations of β-catenin were increased following stimulation with 20 mmol/L lithium (Figure 5A). An increase of β-catenin nuclear pool was also observed in Eca-109 cells, exhibiting the similar trend (Figure 5B). In contrast to the untreated cells, in which β-catenin was primarily located in the cytoplasm, β-catenin was predominantly located in the nuclear of the lithium-treated Eca-109 cells (Figure 5C). These results showed that lithium could induce β-catenin nuclear translocation by inhibition of GSK-3β activity.

#### Lithium up-regulates intranuclear cyclin D1 levels

GSK-3β has been shown to regulate cyclin D1 proteolysis by directly phosphorylating cyclin D1 at Thr-286<sup>[22,23]</sup>. We hypothesized that inhibition of GSK-3β by lithium would be associated with an increase in cyclin D1 protein. As shown in Figure 6, lithium treatment induced a slight increase in the cyclin D1 protein levels by 1.3-fold at 4 h and 1.8-fold at 6 h of lithium treatment as compared with control cells, and the cyclin D1 protein levels diminished to the normal level at 24 h, which may be attributed to the decrease of cells in G<sub>0</sub>/G<sub>1</sub> phase.

## DISCUSSION

In this report, we treated EC cell line Eca-109 cells with different concentrations of lithium and in different time points, and observed the effect of lithium on EC cells. Results indicated that lithium inhibited the proliferation of Eca-109 cells (Figures 1 and 2). We performed flow cytometry to assess cell cycle progression of Eca-109 cells treated with

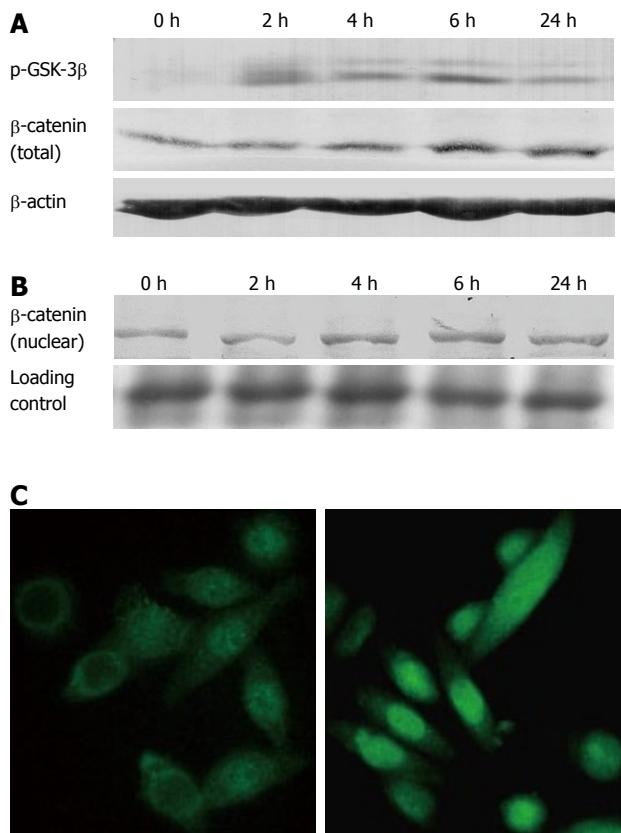

**Figure 4** Effects of lithium on cell cycle regulatory molecules. **A:** Western blotting analysis for cyclin B1 protein levels after treatment with 20 mmol/L lithium; **B:** RT-PCR analysis for quantification of the relative mRNA abundance of *cyclin B1* after treatment with 20 mmol/L lithium; **C:** Western blotting analysis for cdc2 protein levels after treatment with 20 mmol/L lithium. <sup>b</sup>P < 0.01 vs the control group.

lithium. Analysis of cell cycle distribution showing an increase of cells in G<sub>2</sub>/M phase and a decrease in G<sub>0</sub>/G<sub>1</sub> phase indicated that lithium could lead to a G<sub>2</sub>/M cell cycle arrest (Figure 3 and Table 1), which is the common characteristic of cell cycle arrest induced by lithium. However, different cell types have their own doses of sensitivity<sup>[15,17]</sup>. In the report of Mao *et al*<sup>[17]</sup>, 5 mmol/L lithium was enough to induce a G<sub>2</sub>/M phase arrest of bovine aortic endothelial cells. In our study, the mean IC50 of lithium on Eca-109 cells growth was 21.7 ± 0.5 mmol/L by MTT assay (Figure 1). Therefore, 20 mmol/L lithium was used to treat EC cells for indicated times for correlation detections.

Inhibition of cell proliferation can occur through activation of several possible checkpoints during cell cycle progression. Lithium is a highly selective inhibitor of GSK-3β, a multifunctional serine/threonine kinase which has a variety of putative substrates including cyclin

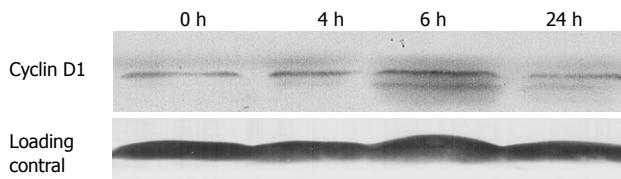

D1, p21<sup>Waf1/Cip1</sup>, and transcription factors like c-myc, c-jun and β-catenin<sup>[24]</sup>, which are implicated in the regulation of cell proliferation. It is well known that intracellular β-catenin levels are regulated through GSK-3β mediated phosphorylations on its serine and threonine residues (at Ser-33, Ser-37 and Thr-41)<sup>[25]</sup>. Inhibition of GSK-3β activity by lithium can result in β-catenin stabilization and its accumulation in the nucleus<sup>[26]</sup>. Our Immunoblot results showed that in Eca-109 cells lithium inhibited GSK-3β by Ser-9 phosphorylation and stabilized free β-catenin in the cytoplasm (Figure 5A). An increase of β-catenin nuclear pool was also observed (Figure 5B). Immunofluorescence studies further confirmed that free β-catenin translocated to the nucleus where β-catenin was transcriptionally active (Figure 5C). Although inhibition of cell proliferation by β-catenin signaling has not been described to date, β-catenin may be the signal for cell cycle arrest. Orford *et al*<sup>[27]</sup> showed that the nuclear

**Figure 5** Lithium induced  $\beta$ -catenin stabilization via inhibition of GSK-3 $\beta$  in vitro. **A:** Eca-109 cells were incubated with 20 mmol/L lithium for 0-24 h. Expressions of p-GSK-3 $\beta$  and total  $\beta$ -catenin protein were analyzed by Western blotting. The untreated Eca-109 cells (0 h) served as negative control; **B:** Western blotting analysis for  $\beta$ -catenin protein level of nuclear lysates; **C:** Immunofluorescence demonstrated a predominant cytoplasm localization of  $\beta$ -catenin in the untreated cells (left) whereas after incubation with lithium (20 mmol/L) for 6 h,  $\beta$ -catenin was predominantly located in the nucleus of Eca-109 cells (right).

localization of  $\beta$ -catenin was cell cycle regulated in the epithelial Madin-Darby canine kidney cells with a peak during the S phase. Interestingly, with the percentage of cells in S phase increased,  $\beta$ -catenin expression increased accordingly in our experiments (Table 1 and Figure 5). Damalas *et al*<sup>[28]</sup> reported that the accumulation of p53 in mouse fibroblasts NIH3T3 overexpressed a stable form of  $\beta$ -catenin (S37A). Stabilization of p21<sup>Waf1/Cip1</sup> and induction of G<sub>2</sub>/M cell cycle arrest by lithium was demonstrated in bovine aortic endothelial cells, where lithium up-regulated p21<sup>Waf1/Cip1</sup> protein level through activation and stabilization of p53<sup>[17]</sup>, an effect of lithium possibly associated with GSK3 $\beta$ , as p53 was recently shown to be a substrate of this kinase<sup>[29]</sup>. Furthermore, lithium was shown to stabilize p21<sup>Waf1/Cip1</sup> by inhibiting GSK-3 $\beta$  activity, and induce G<sub>2</sub>/M cell cycle arrest in human umbilical vein endothelial cells<sup>[30]</sup>. It is thus possible that a sustained retention of  $\beta$ -catenin in the nucleus during G<sub>2</sub> or G<sub>2</sub>/M transition can be a signal for p53 induction and cell cycle arrest.

The cyclin B1/cdc2 complex is a master intracellular regulator entry into mitosis<sup>[20]</sup>, G<sub>2</sub>/M cell cycle arrest may be associated with decreased expression or activity

**Figure 6** Lithium induced cyclin D1 stabilization via inhibition of GSK-3 $\beta$  in vitro. Eca-109 cells were incubated with 20 mmol/L lithium for 0-24 h. Expression of cyclin D1 was analyzed by Western blotting. The untreated Eca-109 cells (0 h) served as negative control.

of this complex. Recently, Smits *et al*<sup>[15]</sup> observed a G<sub>2</sub>/M cell cycle arrest in various transformed (P19 embryonal carcinoma, U2OS osteosarcoma, and SK-N-MC neuroepithelioma) or immortalized (NIH3T3) cell lines after lithium treatment. They found that the activity of the cyclin B1/cdc2 complex was impaired after lithium treatment due to sustained phosphorylation of cdc2 on tyrosine residue 15, and the reduction in cyclin B1/cdc2 kinase activity was not caused by the reduction of cyclin B1 expression, since cyclin B1 protein levels were not influenced by lithium treatment. We detected the expression of cyclin B1 and cdc2 protein, and found that lithium lowered protein levels of cyclin B1 (Figure 3A), which is also a signal for cell cycle arrest in G<sub>2</sub>/M. The mRNA levels of *cyclin B1* exhibited the similar results (Figure 3B). The above results suggested that lithium could influence the expression of cyclin B1 at the levels of both transcription and translation in Eca-109 cells. Chen *et al*<sup>[31]</sup> observed that lithium treatment caused a cell cycle arrest at G<sub>2</sub>/M phase in pig airway epithelial cells, thus inhibiting proliferation of the cells. However, the increased expression of cyclin B1 was observed, which may be attributed to the accumulation of cells in G<sub>2</sub> phase. Our results indicated that G<sub>2</sub>/M cell cycle arrest was partly due to the reduction of cyclin B1 expression. However, further research is needed to clarify the mechanisms of cyclin B1 expression induced by lithium. Moreover, lithium treatment produced no obvious influences on cdc2 protein (Figure 3C). As we did not investigate the activity of the cyclin B1/cdc2 kinase, we could not know the change of cyclin B1/cdc2 kinase activity.

Previously, it was reported that phosphorylation of cyclin D1 at Thr-286 by GSK-3 $\beta$  regulates positively proteasomal degradation of cyclin D1<sup>[22]</sup>. Therefore, inactivation of GSK-3 $\beta$  was expected to lead to an increase of cyclin D1 protein. Our results agreed well with this rationale. Lithium treatment resulted in the inactivation of GSK-3 $\beta$  and induced a slight increase of cyclin D1 protein at 4 and 6 h (Figure 6). These results indicated that cyclin D1 might be involved in the transition of cell cycle from G<sub>1</sub> to S phase in Eca-109 cells induced by lithium. Chen *et al*<sup>[31]</sup> observed that lithium treatment increased cyclin D1 expression and induced a G<sub>2</sub>/M cell cycle arrest in pig airway epithelial cells, which was consistent with our results. However, they failed to find evidence of G<sub>1</sub>/S transition. Mao *et al*<sup>[17]</sup> also observed a slight increase of cyclin

D1 and G<sub>2</sub>/M cell cycle arrest in lithium-treated bovine aortic endothelial cells. On the contrary, a recent investigation on NIH3T3 cells indicated that the change of GSK-3β activity by lithium had no effect on cyclin D1 expression<sup>[32]</sup>. The causes of the discrepancy from these data might lie in the different experimental methods and different cell lines as well.

In conclusion, our present study demonstrated, for the first time, that lithium can arrest the growth of EC cells and induce a G<sub>2</sub>/M cell cycle arrest, which is mainly mediated through the inhibition of lithium-sensitive molecule, GSK-3β, and reduction of cyclin B1 expression. However, further studies are needed to determine the precise mechanisms that contribute to the regulation.

## COMMENTS

### Background

Esophageal squamous cell carcinoma (ESCC) is one of the leading causes of cancer-related death in certain parts of China, and the molecular basis of esophageal carcinogenesis remains poorly understood. It is necessary to develop effective new strategies for the treatment of esophageal cancer (EC).

### Research frontiers

Recent researches have proved that lithium could promote or inhibit cell cycle transition and proliferation of certain primary cultures or cell lines by inhibiting GSK-3β, depending on the cell type. However, whether lithium influences the growth and proliferation of EC cells remains unknown to date.

### Innovations and breakthroughs

This study demonstrated for the first time that lithium can inhibit the proliferation of esophageal squamous cell carcinoma cells (Eca-109), which is mainly mediated by the inhibition of GSK-3β and reduction of cyclin B1 expression.

### Applications

This study indicates the possibility for the treatment of the esophageal squamous cell carcinoma with lithium chloride.

### Terminology

Lithium is an inhibitor of GSK-3β activity. Lithium has been reported to reduce GSK-3β activity in two ways, both directly and by increasing the inhibitory phosphorylation of GSK-3β. These dual effects can act in concert to magnify the influence of lithium on crucial GSK-3β-regulated functions (gene expression, cell structure and survival).

### Peer review

The purpose of this study is reasonable and results are clearly demonstrated, however, further studies are needed to determine the precise mechanisms that contribute to the regulation.

growth factor (VEGF) and basic fibroblast growth factor (bFGF) were detected by immunohistochemistry. The cell apoptotic rate was detected by terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL) assay.

**RESULTS:** The *A* value in each group treated with *Gecko* after 72 h was reduced significantly in EC9706 and in EC1. The tumor weight in each group of *Gecko* was decreased significantly ( $1.087 \pm 0.249$  vs  $2.167 \pm 0.592$ ;  $1.021 \pm 0.288$  vs  $2.167 \pm 0.592$ ;  $1.234 \pm 0.331$  vs  $2.167 \pm 0.592$ ;  $P < 0.01$ , respectively). However, the thymus index and Spleen index of mice in *Gecko* groups had no significant difference compared with the NS group. The immunoreactive score of VEGF and bFGF protein expression of each *Gecko* group by immunohistochemical staining were lowered significantly. The apoptosis index (AI) of each group was increased progressively with increase of dose of *Gecko* by TUNEL.

**CONCLUSION:** *Gecko* has anti-tumor effects *in vitro* and *in vivo*; induction of tumor cell apoptosis and the down-regulation of protein expression of VEGF and bFGF may be contributed to anti-tumor effects of *Gecko*.

## INTRODUCTION

Malignant tumor is always a great menace to human health. The incidence and mortality of tumor keep ascending all over the world. Anti-tumor therapies contain surgery, radiotherapy and chemotherapy, and it depends on synthetic agents to a great extent in chemotherapy. Although chemical anti-neoplastics have definite effect; they cause severe adverse effects. Moreover, many chemotherapy drugs bring about multiple drug resistance. Great efforts have been made to develop new anti-cancer pharmaceuticals from Chinese herbal medicine<sup>[1-4]</sup>.

*Gecko* is a traditional Chinese medicine found to restrain inflammation and allergic response, detumescence and alimentation. *Gecko* is also called *Tian Long*, *Shou Gong*. It contains *Gekko swinhonis* Gunther, *Gekko japonicus*, etc.. It is cold in nature and flavor. The dosage forms are pill, powder and mastic<sup>[5]</sup>. Although the *Gecko* was not recorded in a medical dictionary, there have been reports that *Gecko* and its compound prescriptions could treat malignant tumors, tuberculosis, osteomyelitis and syrinx. In clinical practice, it has definite effect against malignant tumors, especially digestive system tumors, such as esophagus cancer, gastric cancer and liver cancer<sup>[6-8]</sup>. Research on *Gecko* mainly focused on the anti-tumor compound prescriptions, but there have been few pharmacological studies of *Gecko* and its mechanisms of anti-tumor action.

The present study was to observe the anti-tumor activities of *Gecko* *in vivo* and *in vitro* using the transplanted tumor model of the mouse S180 sarcoma on mice and the human esophageal carcinoma cells and investigate the effects of *Gecko* on cell apoptosis and the expression of (vascular endothelin growth factor) VEGF and (basic fibroblast growth factor) bFGF of S180 mice.

## MATERIALS AND METHODS

### Materials

Chinese medicine *Gecko* was purchased from Anhui Bozhou Yonggang Co. Ltd. They were identified *Gekko japonicus*. The whole dry *Gecko* were ground to fine powder and diluted in suspension using 0.2% carboxymethyl cellulose (CMC). Cytoxin (CTX) was purchased from Jiangsu Hengrui Medicine Co. Ltd. (Batch No. H32020857). Fifty Kunming mice and ten SD rats were provided by the Medical Experimental Animal Center, Henan Province. All were female. The code number of the animals was 0001350. The human esophageal carcinoma EC9706 cell line was of esophageal carcinoma of fungating type which is well-differentiated squamous cell carcinoma, EC1 cell line was isolated from esophageal carcinoma cell line EC9706 and one subline, and the S180 mouse sarcoma cell line was kindly provided by the Medical College, Zhengzhou University.

### Cell culture and establishment of S180 model

The cells were grown in a monolayer culture containing

humidified 5% CO<sub>2</sub> in air at 37°C. They were cultured in RPMI-1640 (Sigma, USA) medium supplemented with 10% fetal calf serum, 100 U/mL and penicillin and 100 mg/L streptomycin. The S180 model was established by subcutaneous injection as previously described<sup>[9]</sup>. Briefly, the S180 mouse sarcoma cells with ascites were harvested, diluted with sterilized saline at a ratio of 1:8 (cell concentration was adjusted to 1.0 × 10<sup>6</sup>/mL), and inoculated subcutaneously into the right armpit region of Kunming mice.

### Preparation of the serum with medicine

Ten SD rats (aged 10-12 wk and weighing 280 ± 30 g) were randomly divided into five groups: the negative group (NS group), the positive group (CTX group) and three *Gecko* groups. The CTX group received 50 mg/kg intraperitoneally once a day. Three *Gecko* groups were treated respectively with oral administration of *Gecko* at a dose of 13.5 g/kg, 9 g/kg and 4.5 g/kg, twice a day. The NS group received the equivalent amounts of normal saline in the same way. After 1 wk of treatment, according to the method principle of Li Yikui<sup>[10,11]</sup>, blood was collected aseptically and serum was collected by centrifugation. It was deactivated at 56°C for 30 min and filtrated for sterilization. Medical serum was stored at -20°C for use.

### 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay

Cell growth was measured by a modified MTT assay<sup>[12,13]</sup>. The logarithmic cells (EC9706, EC1) were dispersed with 0.02% (w/v) EDTA to prepare 1 × 10<sup>4</sup>/mL cell suspension, and partitioned into 96-well plates at 180 μL/well for 24 h culture in a 5% CO<sub>2</sub> incubator under 37°C. Five groups were divided, the negative group, the CTX group and the three *Gecko* groups. Each group had 6 wells. Each well was treated respectively with 20 μL medical serum prepared as above. Cells were incubated for 24, 48 and 72 h. Then 20 μL MTT (Sigma, USA) was added to each well and the cells were further incubated at 37°C for 4 h. The supernatant was removed and 200 μL DMSO (Sigma, USA) was added into each well to solubilize the formazan product. The absorbance also known as *A* value at wavelength of 470 nm was measured by a microplate reader (Sigma, USA). Triplicate experiments were performed in a parallel manner for each concentration point and the results were presented as mean ± SD. Cell inhibitory rate was calculated by the following formula: inhibitory rate (%) = (1-*A* treated/*A* control) × 100%.

### Viable cell number counting and growth curve

EC9706, EC1 cells (1 × 10<sup>4</sup>/mL cell suspension) were plated onto 96-well plates at 180 μL/well. Each well was treated respectively with 20 μL medical serum prepared as above and cultured for 7 d. Viable cells were counted under the inverted light microscope by trypan blue dye (Sigma, USA) exclusion method and growth curves were drawn.

**Table 1** Inhibition effect of *Gecko*-contained serum on EC9706 by MTT assay (mean  $\pm$  SD, n = 6)

Groups	24 h		48 h		72 h	
	A	Inhibition rate (%)	A	Inhibition rate (%)	A	Inhibition rate (%)
NS	0.472 $\pm$ 0.05		0.97 $\pm$ 0.118		1.63 $\pm$ 0.224	
CTX	0.286 $\pm$ 0.06 <sup>a</sup>	39.1	0.55 $\pm$ 0.09 <sup>a</sup>	42	0.82 $\pm$ 0.163 <sup>a</sup>	49.6
Gecko 1	0.355 $\pm$ 0.04 <sup>a</sup>	24.8	0.65 $\pm$ 0.136 <sup>a</sup>	32.5	0.99 $\pm$ 0.154 <sup>a</sup>	39.1
Gecko 2	0.372 $\pm$ 0.07 <sup>a</sup>	21	0.721 $\pm$ 0.09 <sup>a</sup>	25.1	1.15 $\pm$ 0.925 <sup>a</sup>	29.8

<sup>a</sup>P < 0.05 vs control.

### Inhibitory effect of *Gecko* on S180 in vivo

Twenty-four hours after establishment of S180 model, the fifty transplanted mice (aged 8-10 wk and weighing 26  $\pm$  2 g) were randomly divided into five groups: the NS group, the CTX group (CTX was proved to have definite effect against mouse S180 sarcoma and frequently used in experiment), and the three *Gecko* groups. They were treated respectively with oral administration of saline once a day, intraperitoneal injection of CTX 100 mg/kg only once, and oral administration of *Gecko* at a dose of 13.5 g/kg, 9 g/kg and 4.5 g/kg once a day. After 2 wk of treatment, the anti-tumor activity was evaluated by tumor tissue weighing. The following formula was used: Tumor inhibitory rate (%) = (1-average tumor weighing of administration team/average tumor weighing of the control)  $\times$  100%<sup>[9]</sup>.

### Immune function

According to the above-mentioned methods, at the 14th day, 5% chicken-red cells were injected intraperitoneally into each group. After 12 h, the mice were killed and 1 mL peritoneal fluid was drawn for glass slide. After incubated for 30 min, peritoneal fluid was fixed with the mixture of acetone/methanol (1:1, v/v) and dyed with 4% Giemsa stain. Peritoneal macrophages were counted under microscope. The effect of *Gecko* on phagocytosis of enterocoelia macrophage was evaluated by the chicken-red cell phagocytic index and phagocytic rate<sup>[14]</sup>. At the same time, thymus and spleen were taken from mice. The impact on immune organ was evaluated based on the thymus index and spleen index<sup>[15]</sup>.

### Immunohistochemistry

The tumor tissues were fixed with 10% neutral formalin at room temperature for 24 h. The paraffin-embedded specimens were cut into sections with a thickness of 5  $\mu$ m. The detection procedure was done as described in Kit protocol (Wuhan Boster Biological Technology Co. Ltd). PBS instead of the first antibodies was used in the negative control. The VEGF and bFGF positive cells were defined when there was an aggregation of brown particles in the cytoplasm of the tumor cells. The immunoreactive score was determined by the sum of extension and intensity as reported previously<sup>[16]</sup>. The intensity of staining was scored on a scale of 0 to 3 (0 = negative staining, 1 = weakly positive staining, 2 = moderately positive staining, and 3 = strongly positive staining). The extent of positivity ("extent of

distribution" of positive cells) was estimated on a scale of 0 to 4 (0 = negative, 1 = positive staining in 1%-25% of cells, 2 = positive staining in 26%-50%; 3 = positive staining in 51%-75%; and 4 = positive staining in 76%-100%). The combined staining score (extension + intensity) was considered as positive staining.

### Detection of apoptosis by terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL)

Apoptotic cells were detected *in situ* using TUNEL method according to the manufacturer's instructions<sup>[17]</sup>. Slices were treated with proteinase K and 0.3% H<sub>2</sub>O<sub>2</sub>, labeled with fluorescein dUTP (Wuhan Boster Biological Technology Co.Ltd) in a humid box for 1 h at 37°C, then combined with POD-horseradish peroxidase, stained with DAB and counterstained with methyl green. Controls received the same management except the labeling fluorescein dUTP. Dark brown nucleus represented the positive apoptotic cells. In each section, 5 high -power fields were chosen and the apoptosis index (AI), the percentage of positive cells in the total cells, was calculated. The AI was calculated as follows: AI = number of apoptotic cells/total number  $\times$  100%.

### Statistical analysis

Data were presented as mean  $\pm$  SD and analyzed with SPSS 11.0 software. The one-way ANOVA or Student's *t* test was used to analyze data. All comparisons were made with untreated controls and significance of difference is indicated as P < 0.05 and P < 0.01.

## RESULTS

### Effects of *Gecko* on cell proliferation

As shown in Tables 1 and 2, compared with control group, the growth of cells treated with serum of different concentrations of mice with medicine *Gecko* was inhibited significantly in a concentration and time-dependent manner. Seventy-two h after treatment, the inhibitory rates were 22.3%-39.1% (EC9706) and 18%-34.1% (EC1). Compared with the NS group, the differences were significant among the groups of *Gecko* (P < 0.05).

### Growth curves of EC9706 and EC1

To investigate anti-tumor activity of the *Gecko* *in vitro*, tumor cells treated with serum medicine were cultured

for 7 d, and then the cell growth curve was drawn. Under the inverted light microscope, obvious difference was observed in the cell morphology among the five groups of cells. Compared with the control group, growth curves of the three *Gecko* groups gradually moved down in a dose-dependent manner (Figure 1). These results indicated that the serum with medicine *Gecko* could inhibit EC9706 and EC1 growth and proliferation *in vitro*.

#### Anti-tumor effects of *Gecko* on S180 mice

As shown in Table 3, compared with the NS group, the tumors of the *Gecko* and CTX groups shrank significantly (P < 0.01), but the tumor weight of three *Gecko* groups had no difference statistically compared with the CTX group (P > 0.05). The tumor inhibitory rates of the CTX group and *Gecko* groups were 74.6%, 49.8%, 52.8% and 43.1%, respectively. After experiment, there no significant

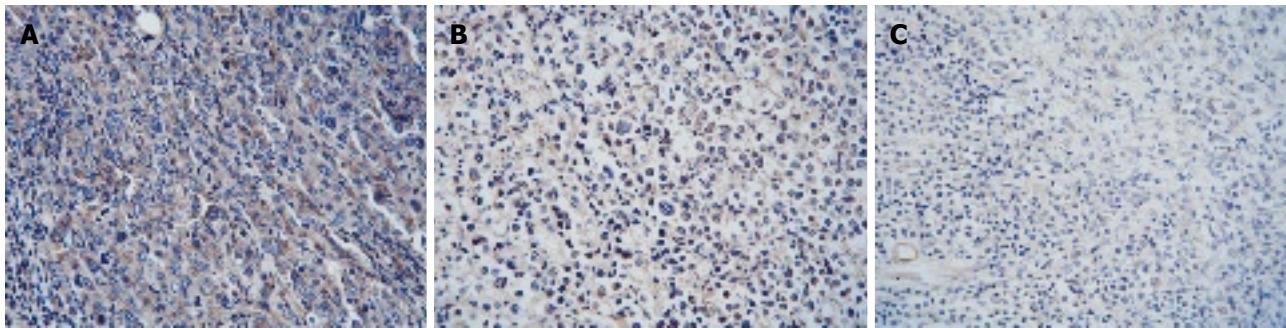

difference was found in mouse weight between the *Gecko* groups and the NS group (P > 0.05). Compared with the NS groups, the weight of mice in the CTX group decreased significantly (P < 0.05).

#### Influence of *Gecko* on immune organs

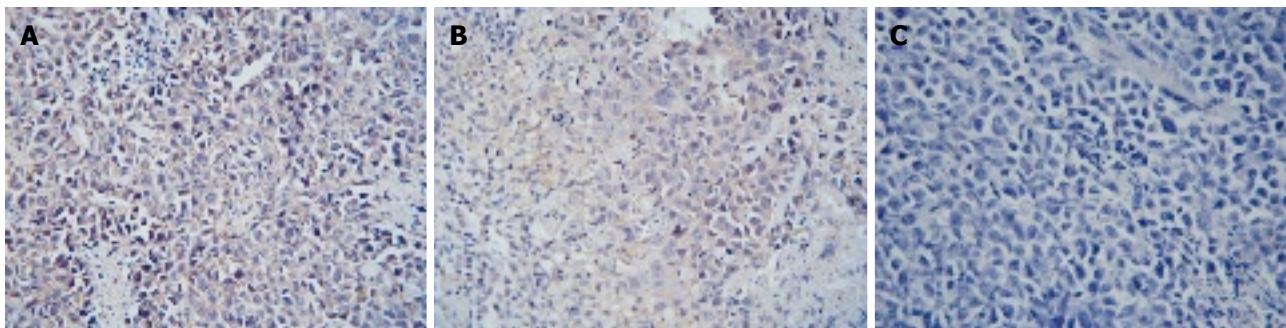

As shown in Table 4, compared with the NS group, the thymus index and Spleen index of mice in the CTX group decreased significantly (P < 0.05). However, there was no significant difference between the *Gecko* groups and the NS group; CTX could decrease the phagocytic index and phagocytic rate very significantly (P < 0.01); *Gecko* could decrease the phagocytic index and phagocytic rate significantly (P < 0.05). These results indicated that *Gecko* could not enhance the immune functions.

#### Effects of *Gecko* on VEGF and bFGF expressions

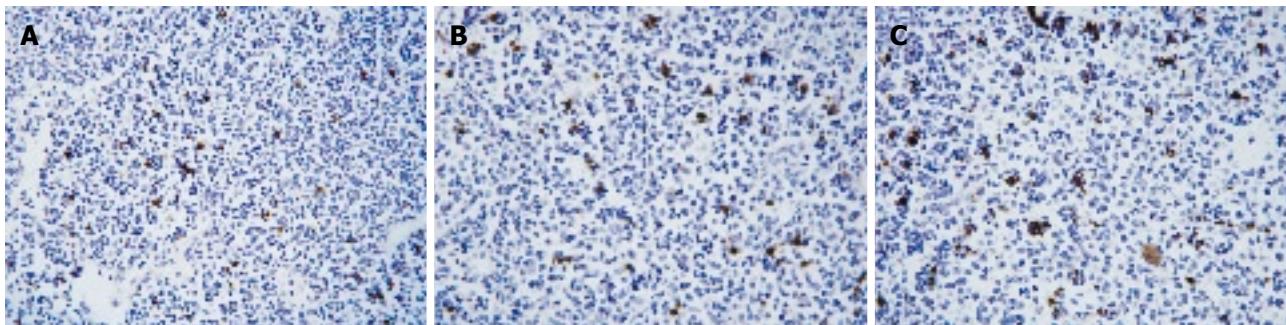

As shown in Figures 2 and 3, the VEGF and bFGF

**Figure 2** Expression of VEGF on S180 tissues in mice (DAB,  $\times 400$ ). NS group (**A**), Gecko group (**B**), CTX group (**C**).

**Figure 3** Expression of bFGF on S180 tissues in mice (DAB,  $\times 400$ ). NS group (**A**), Gecko group (**B**), CTX group (**C**).

**Figure 4** Apoptotic cells on S180 the tissue in mice (DAB,  $\times 400$ ). NS group (**A**), Gecko group (**B**), CTX group (**C**).

positive cells were defined when there was an aggregation of brown particles in the cytoplasm of the tumor cells. The proteins of VEGF and bFGF had high expression in the tissue of transplanted sarcoma 180 in mice. Compared with the NS group, the immunoreactive score of expression VEGF and bFGF expression of CTX group and *Gecko* groups decreased significantly (*P* < 0.05). It indicated *Gecko* could decrease VEGF and bFGF protein expression in the tissue of transplanted sarcoma 180 in mice.

#### Effects of *Gecko* on AI

As shown in Figure 4, dark brown nucleus represented the positive apoptotic cells on the tissue of transplanted sarcoma 180 in mice. As shown in Table 5, compared with the NS group, AI of the CTX group and the *Gecko* groups increased very significantly (*P* < 0.01), indicating that *Gecko* could increase AI in the tissue of transplanted sarcoma 180 in mice.

**Table 5 Expressions of VEGF, bFGF and AI on S180 tissues in mice (mean  $\pm$  SD,  $n = 10$ )**

Groups	Dose (g/kg)	AI (%)	Immunoreactive score

<sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs control.

#### DISCUSSION

The processing of *Gecko* introduced in the “Holy Benevolent Prescription” is to “grind it into powder”, while according to “The Medical Science Outline”, the processing is “drying by baking”<sup>[18]</sup>. Basically two

processing methods, living and drying, are used in clinical practice. For fresh *Gecko*, there are a few studies describing the mechanisms of lyophilized powder of fresh *Gecko* in inhibiting H22 hepatocarcinoma and C6 glioma cells<sup>[19-22]</sup>, but there has been no experimental study on anti-tumor of drying *Gecko*. We therefore, selected drying *Gecko* as a study object.

Serum pharmacological method was first introduced by Japanese authors. It is a good approach to study traditional Chinese medicine(TCM). The serum pharmacology points out that the serum collected from animals treated with traditional Chinese medicine can be used in experiments *in vitro*. This kind of experimental methods can expel various interference of traditional Chinese medicine and they are close to the true process of the pharmacological effect inside the body<sup>[10-11,23]</sup>. So we used the method of serum pharmacology *in vitro* experiments and observed the effect of *Gecko*-contained serum on growth of the tumor cells. In this study, MTT showed the growth of EC9706, EC1 cells treated with different concentrations of the *Gecko*-contained serum was inhibited significantly in a concentration and time-dependent manner. Growth curves of the three *Gecko* groups gradually moved down, being obviously dose dependent. These results indicated that the *Gecko*-contained serum could inhibit the growth and proliferation of human esophageal carcinoma cells. *In vivo*, the transplanted tumor model of the mouse S180 sarcoma was established. In the *Gecko* groups at dosage of 13.5, 9 and 4.5 g/kg, the inhibitory rate was 49.8%, 52.8% and 43.1%, respectively. The differences of the groups of *Gecko* were very significant from the control group ( $P < 0.01$ ). These results indicated that *Gecko* could inhibit growth of solid tumor of S180 mice.

The effect on anti-tumor of TCM is related to pathways and targets. Most studies on anti-tumor mechanisms of TCM showed that TCM could inhibit tumors though supporting the healthy energy and strengthening the body resistance<sup>[1,2]</sup>. In our study, the thymus index, Spleen index, phagocytic index and phagocytic rate showed that *Gecko* could not reinforce immunity of organism. These results indicated the anti-tumor mechanism of TCM might not be related to reinforcement of immune organs.

With the development of modern molecular technology, the anti-angiogenic effect and inducing apoptosis by TCM has become a new area for the research and development of TCM. Apoptosis is a fundamental cellular activity to maintain the physiological balance of the organism and plays a necessary role as a protective mechanism against carcinogenesis by eliminating damaged cells or cells that proliferate excessively<sup>[24]</sup>. Furthermore, the apoptotic cell death plays an important role in the regulation of pathological conditions as well, such as development and progression of malignant tumors<sup>[25,26]</sup>. Among the methods that are used to identify cells undergoing the apoptotic process, the TUNEL technique is one of the most successfully utilized<sup>[26]</sup>. Angiogenesis, the growth of new blood vessels from pre-existing capillaries, is necessary for solid tumor growth and metastasis. Angiogenesis is initiated

by the release of certain angiogenic factors from tumor cells. VEGF and bFGF which have been shown to be the most potent angiogenic factors are associated with tumor-induced angiogenesis<sup>[27,28]</sup>. To investigate the mechanisms of anti-tumor action of *Gecko*, we detected the protein expression of VEGF and bFGF using immunohistochemical method and detected apoptotic index by the TUNEL. The results indicate *Gecko* can decrease VEGF and bFGF protein expression in tumor tissues and induce tumor cell apoptosis.

In conclusion, this study has demonstrated that traditional Chinese medicine *Gecko* has anti-tumor activity *in vitro* and *in vivo*; its mechanism might be related to the induction of tumor cell apoptosis and down-regulation of protein expression of VEGF and bFGF.

## ACKNOWLEDGMENTS

We thank Xiao-Juan Ma for her assistance with the experiments and Rui-Fang Li for her valuable advice and review for this paper.

## COMMENTS

### Background

Malignant tumor is always a great menace to human health. Chemical anti-neoplastics have definite effect, but they cause much severe adverse effects. *Gecko* is a traditional Chinese medicine. It could treat malignant tumors, especially in the tumor of digestive tract. Research on *Gecko* mainly focuses on anti-tumor compound prescriptions, but the pharmacological studies of *Gecko* and its mechanisms of anti-tumor action are rare.

### Research frontiers

Basically, two processing methods of *Gecko*, living and drying, are used in clinical practice. Questions still remain to be answered such as what is the difference of anti-tumor effect between fresh *Gecko* and dry *Gecko*? What kind of tumors can *Gecko* treat? What is the mechanism of *Gecko* in treating tumors?

### Innovations and breakthroughs

This article describes the effect of the *Gecko* on esophageal carcinoma cell lines (EC9706 and EC1) *in vitro* and xenografted sarcoma 180 *in vivo*. Serum pharmacological method *in vitro* was used to study the anti-tumor mechanism of *Gecko* in the aspect of the anti-angiogenic and apoptosis inducing effect and investigate if *Gecko* had impact on immune organs.

### Applications

The incidence and mortality of tumors keep ascending all over the world. The study on anti tumor effect and mechanisms of anti-tumor action of *Gecko* can provide the theoretical evidence in clinical practice. Furthermore, the results may lay a foundation for further research in *Gecko*'s effective constituent.

### Terminology

Serum pharmacological method is a good approach to study traditional Chinese medicine *in vitro*. It can expel various interference of traditional Chinese medicine as it is close to the true process of the pharmacological effect inside the body

### Peer review

This is a well-conducted study. This manuscript describes the effect of the Chinese medicine *Gecko* on esophageal carcinoma cell lines (EC9706 and EC1) and in xenografted sarcoma 180 Kunming mice. The studies have provided data that support the conclusions of the authors. This is an interesting study.

## Abstract

**AIM:** To investigate dynamical and image pathological characteristics of the liver on magnetic resonance (MR) diffusion-weighted imaging (DWI) in the rabbit VX-2 tumor model.

**METHODS:** Forty New Zealand rabbits were included in the study and VX-2 tumor piece was implanted intrahepatically. Fifteen animals received two intrahepatic implantations while 25 had one intrahepatic implantation. DWI, T1- and T2-weighted of magnetic resonance imaging (MRI) were carried out on the 7th and the 14th d after implantation and DWI was conducted, respectively on the 21th d. Ten VX-2 tumor samples were studied pathologically.

**RESULTS:** The rate of lump detected by DWI, T1WI and T2WI was 78.7%, 10.7% and 53.5% ( $\chi^2 = 32.61$ ,

$P < 0.001$ ) on the 7th d after implantation and 95.8%, 54.3% and 82.9% ( $\chi^2 = 21.50$ ,  $P < 0.001$ ) on the 14th d. The signal of most VX-2 tumors on DWI was uniform and it was equal on the map of apparent diffusion coefficient (ADC). The signal of VX tumors did not decrease on the 7th d after implantation, most of them slowly growing during the week following implantation without significant cell dying within the tumor. VX-2 tumors grew increasingly within 14 d after implantation but the signal of most VX-2 tumors on DWI or on the map of ADC was uniform or uneven and ADC of VX tumors decreased obscurely or slightly because tumor necrosis was still not obvious. On the 21th d after implantation, the signal of most VX-2 tumors on DWI or on the map of ADC was uneven because tumor necrosis was evident and ADC of VX-2 tumor necrotic areas decreased. The areas of viable cells in VX-2 tumors manifested a high signal on DWI and a low signal on the map of ADC. The areas of dead cells or necrosis in VX-2 tumors manifested low signals on DWI and low, equal or high signals on the map of ADC but they manifested high signals on DWI and on the map of ADC at the same time when the areas of necrotic tumor became liquefied or cystic. The border of tumors on DWI appeared gradually distinct and internal signals of tumor became progressively uneven.

**CONCLUSION:** The manifestations of viable, necrotic and liquefied or cystic areas in VX-2 tumors on DWI are typical and DWI is of significant and potential values in clinical application in both the early detection and diagnosis of liver tumors.

investigation in rabbit liver VX-2 tumor model. *World J Gastroenterol* 2008; 14(25): 3997-4004 Available from: URL: <http://www.wjgnet.com/1007-9327/14/3997.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.3997>

## INTRODUCTION

Magnetic resonance (MR) diffusion-weighted imaging (DWI) is a new functional imaging technology developed in recent years<sup>[1-5]</sup>, which is able to reflect non-woundingly water molecule diffusion *in vivo*. It is generally accepted that DWI is valuable in the qualitative and quantitative diagnosis of cerebral ischemia during the hyper-inchoate period<sup>[6-9]</sup>. In the past, DWI has not been extensively used in the diagnosis and evaluation of progression and prognosis of hepatic tumors, mainly because of its poor image quality. However, with the recent development of MR software and scanning technology, especially for echo planar imaging (EPI) series, the DWI poor imaging quality and slow scanning speed have been overcome<sup>[10-14]</sup>. This has led to the employment of DWI on the monitoring of focal and diffuse hepatic lesions, such as cysts, hemangiomas, hepatocellular carcinomas, metastases and liver cirrhosis. As reported by Ichikawa *et al*<sup>[15-16]</sup>, Yamashita *et al*<sup>[17]</sup>, Taouli *et al*<sup>[18]</sup>, and Sun *et al*<sup>[19]</sup>, the apparent diffusion coefficient (ADC) of such lesions grew gradually on DWI, the ADC of cysts being the biggest, followed by benign tumors and malignant tumors. Colagrande *et al*<sup>[20]</sup> demonstrated that the coagulation necrosis manifested a low signal when compared to the normal parenchyma. Kamel *et al*<sup>[21]</sup> confirmed in 8 patients with hepatocellular carcinoma that the apparent diffusion coefficient (ADC) becomes higher with the extent of tumor necrosis and that the signals of 6 tumors were higher than normal parenchyma on DWI. The signals of liquor puris in abscesses were moderate or high on DWI but they were lower than the signals of cysts and cystic metastatic tumors because of their high consistency, and the signals of abscess walls were equal to those of normal parenchyma around<sup>[22-26]</sup>.

From what has been discussed above, DWI, especially ADC, has potential values in reflecting characteristics of hepatic pathological changes and differentiating benign tumors from malignant tumors<sup>[27-31]</sup>. However, to date, no dynamic and image pathological investigation on the characteristics of hepatocellular carcinomas on DWI has been reported. Rabbit liver VX-2 tumor is the most valuable animal model of hepatocellular carcinoma in imaging investigation. The purpose of our experiment was to investigate the dynamic characteristics and the pathological mechanisms underlying the signals on DWI in rabbit VX-2 tumor models after implantation and to evaluate the superiority of DWI in detecting, diagnosing and differentiating tumors.

## MATERIALS AND METHODS

### Animals

Animal studies were carried out under the supervision

of a veterinarian according to the Guidelines of Chinese Ministry of Health for the Use of Laboratory Animals. All animals were provided by the Laboratory Animal Center of the Second Xiangya Hospital and all protocols were approved by the Animal Use and Care Committee of the Second Xiangya Hospital.

Forty New Zealand normal white rabbits were employed (22 males and 18 females), weighing 1.7-2.5 kg and aged 5-6 mo.

### Establishment of VX-2 tumor model

The rabbit VX-2 tumor strain was provided by the Fourth Military Medical University of China.

### Procedure of implantation

The VX-2 tumor donors were anesthetized by injecting 3% soluble pentobarbitone into auriborder vein or abdominal cavity at a dose of 1 mL/kg. The site of implantation was disinfected by Iodine, the skin was incised to expose one cauliflower of the subcutaneous tumor which was implanted before experiment and then one cauliflower was excised from it. The tumor parenchyma was exposed and quickly put into saline solution containing 40 000 unit gentamycin per 100 mL. The necrotic tissue and blood clot were discarded and the viable tumor tissue was divided into 1-2 mm<sup>2</sup> microblocks.

The VX-2 tumor strain was subsequently implanted into the liver parenchyma of rabbits as follows. The animals were anesthetized by injecting 3% soluble pentobarbitone and the skin of abdomen was disinfected. The liver lobe chosen for implantation was exposed through incising the skin and vagina musculi recti abdominis. The tube containing the VX-2 tumor strain was implanted into the lobe by rotating and pushing it into the liver parenchyma. Then a gelatin sponge was inserted to prevent bleeding. Afterward, the peritoneum, musculus, and skin were sutured, respectively. Implantation was performed in one lobe in 25 rabbits and in two lobes in 15 rabbits. After implantation, 200 000 unit penicillin was administered by intramuscular injection for 4 d while the animal room was kept dry and ventilated.

### MRI protocol

The animals were anesthetized with 3% soluble pentobarbitone injected into auriborder vein at different doses based on the animal status to make sure that the breathing was slow and stable. T1-weighted imaging (T1WI), T2-weighted imaging (T2WI) and DWI were performed on a 1.5-Tesla Signa Twinspeed MR scanner (General Electron Medical Systems, USA), using a small diameter cylindrical brain radiofrequency coil. DWI (axial) and MRI (T1WI and T2WI, axial) were carried out on the 7th d and the 14th d after implantation and DWI (axial) was performed also on the 21th d after implantation. The scanning parameters of DWI included spin echo echo planar imaging (SE-EPI) series, *b*-value 100 and 300 s/mm<sup>2</sup>, repetition time (TR) 6000 ms, echo time (TE) 45 ms, 20 cm × 15 cm field of view (FOV),

8NEX, 2 mm thick layer, 0.5 mm space,  $128 \times 128$  matrix, etc. The scanning parameters of common MRI included fast reverse, fast spin echo (FRFSE) series, T1WI (TR 400/TE 12.3 ms), T2WI (TR3000/TE80 ms), 20 cm  $\times$  15 cm FOV, 4 NEX, 5 mm thick layer, 0 mm space,  $256 \times 192$  (T1WI) and  $320 \times 256$  (T2WI) matrix.

### Pathological protocol

Twelve samples of VX-2 tumors were processed. Ten samples were taken on the 21th d after implantation, one on the 7th d and the other one on the 14th d. The animals were euthanized with an overdose of 3% soluble pentobarbitone into auriborder vein. The VX-2 lump surrounded by normal liver parenchyma was taken under aseptic conditions. Then the lump was cut open and sliced (Figure 1). After 24 h of fixation in formaldehyde solution, all samples were embedded in mineral wax.

### Statistical analysis

The distinction of tumor detection between DWI, T1WI and T2WI on the 7th d and the 14th d after implantation was respectively assessed. The statistical significance was calculated by  $\chi^2$  analysis using SPSS12.0 software.

## RESULTS

### DWI, T1- and T2-weighted imaging

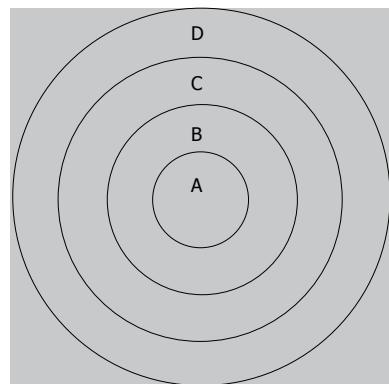

Thirty-eight of 40 rabbits were still alive 21 d after implantation, while 2 rabbits died from overdose of anesthesia. Forty-seven VX-2 tumors were detected in 47 hepatic lobes of 35 rabbits.

On the 7th d after implantation, 37 lumps, 3 lumps and 15 lumps were respectively detected by DWI, T1- and T2-weighted imaging and the detection rates were 78.7% (37/47), 10.7% (3/28) and 53.8% (15/28), respectively. The difference of detection was significant among DWI, T1- and T2 weighted imaging, between DWI and T2 weighted imaging and between T1- and T2 weighted imaging ( $\chi^2 = 32.61$ ,  $P < 0.001$ ;  $\chi^2 = 5.22$ ,  $P = 0.022$ ;  $\chi^2 = 11.79$ ,  $P < 0.001$ ). On the 14th d after implantation, 45 lumps, 19 lumps and 29 lumps were detected by DWI, T1- and T2-weighted imaging and the detection rates were 95.87% (45/47), 54.3% (19/35) and 82.9% (29/35), respectively. The difference of detection was significant among DWI, T1- and T2-weighted imaging, between DWI and T2 weighted imaging and between T1- and T2 weighted imaging ( $\chi^2 = 21.50$ ,  $P < 0.001$ ;  $\chi^2 = 3.78$ ,  $P > 0.05$ ;  $\chi^2 = 6.63$ ,  $P = 0.01$ ). On the 14th d after implantation, all 47 tumors were detected by DWI ( $b = 100$  or  $b = 300$  s/mm $^2$ ).

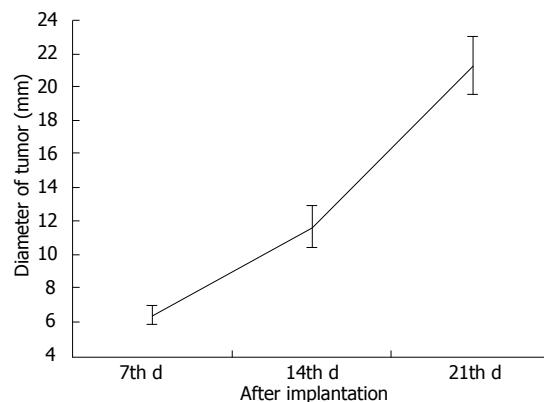

The average diameter of VX-2 tumors detected by DWI, T1- and T2 weighted imaging was 6.49 (3.00-12.90) mm, 11.78 (5.00-25.10) mm and 21.44 (7.50-36.70) mm respectively on the 7th, the 14th d and the 21th d after implantation (Figure 2).

### Image manifestations of hepatic VX-2 tumor

The signals of most VX-2 tumors were low and the

**Figure 1** A: The area of VX-2 tumor center; B: The area of VX-2 tumor periphery; C: The area of VX-2 tumor outer layer; D: The normal liver parenchyma area around tumor when the values of ADC and signals were measured on DWI and samples were investigated pathologically.

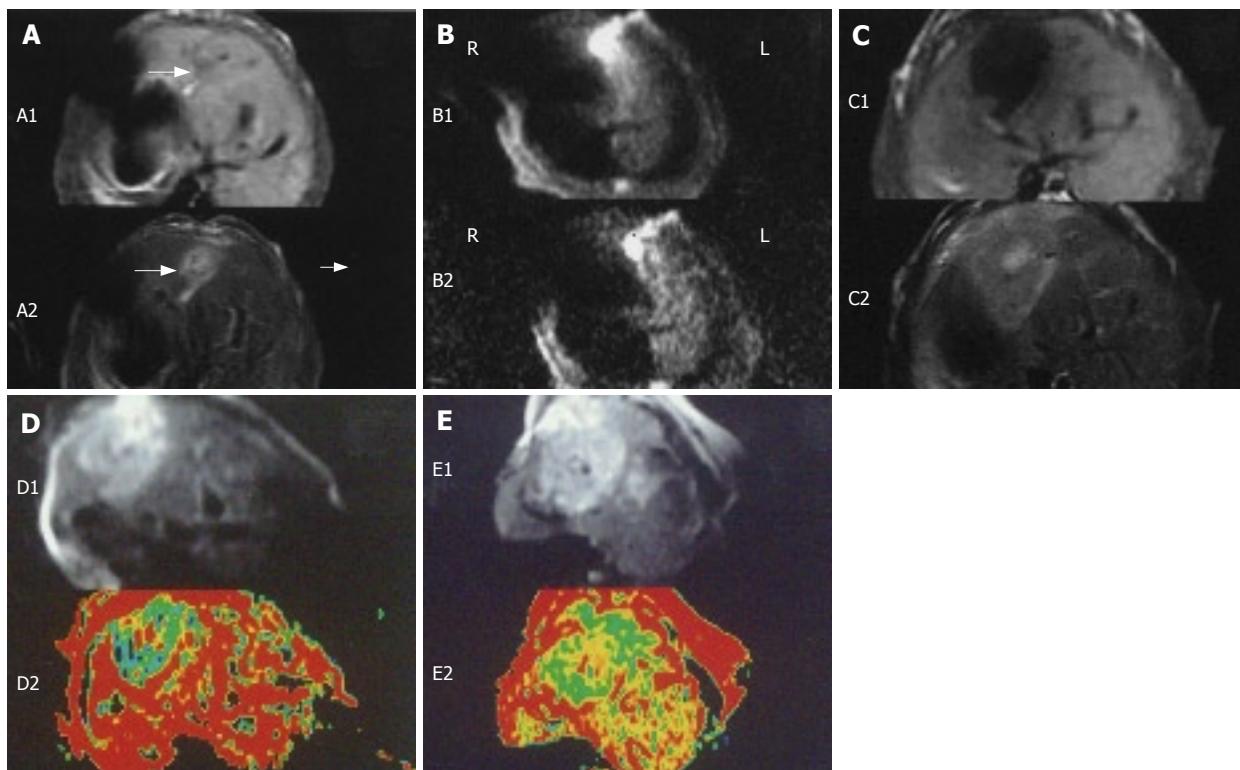

**Figure 2** The average diameter of VX-2 tumors on the 7th, the 14th and the 21th d after implantation detected by DWI, T1- and T2 weighted imaging.

borders were unclear on T1-weighted imaging (5/15), whereas the signals were high and the borders were clear on T2-weighted imaging (14/15) seven days after implantation (Figure 3). The signals of VX-2 tumors were high with unclear borders on T1-weighted imaging (18/19), while they were high with clear borders on T2-weighted imaging (14/29) two weeks following implantation (Figure 3). DWI appearance of hepatic VX-2 tumors is summarized in Tables 1 and 2.

### Manifestations of VX-2 tumor dissection and pathology

On the 7th and 14th d after implantation, intrahepatic VX-2 tumors appeared pale without identifiable margin or envelope. No lumps were detected in the hepatic peritumoral parenchyma, whereas residuum of gelation sponge in or around VX-2 tumors was detected. On the 21th d after implantation, many encroachments and metastatic tumors were found in dissection, including abdominal wall encroachment in 15 cases, abdominal dropsy in 16, mesenterium encroachment in 15, lung metastases in 19, pleural effusion in 12 and diaphragm encroachment in 2. The extrahepatic surface was uneven and VX-2 tumors were pale, with a clear distinction between tumoral tissues and normal surrounding parenchyma. The tumors were hard and there was no clear amiculas. Cavitates of unequal size were found in the lumps of some cases because of kermesinus liquid running off after the tumors were cut open and there was some residuum of gelation sponge in or around the lumps of some tumors (Figure 4).

**Figure 3** Image manifestations of hepatic VX-2 tumor on DWI, ADC map, T1WI or T2WI. **A:** A1, a low signal and obscure margin of VX-2 tumor on T1WI and A2, a slightly high signal on T2WI on the 7th day after implantation; **B:** a high signal and distinct margin of VX-2 tumor on DWI when  $b$  value was 100 (B1) or 300 (B2)  $\text{s/mm}^2$  and low SNR when  $b$  value was 300  $\text{s/mm}^2$  on the 7th day after implantation; **C:** C1, a low signal of VX-2 tumor on T1WI and C2, a slightly high signal of it on T2WI and a lamellar high signal in the tumor center on T2WI on the 14th day after implantation; **D:** A high signal and distinct margin of VX-2 tumor on DWI when  $b$  value was 100  $\text{s/mm}^2$  (D1) and low signal of VX-2 tumor and a lamellar high signal in its center on the map of ADC on the 14th d after implantation (D2); **E:** A high and uneven signal of VX-2 tumor on DWI when  $b$  value was 100  $\text{s/mm}^2$  (E1) and low signal of VX-2 tumor while a high signal in the center tumor on the map of ADC on the 21th d after implantation (E2).

A: 7th d after implantation; B: 14th d after implantation; C: 21th d after implantation.

Macroscopically, the surface of the peritumoral hepatic parenchyma was brown-grey; 11 small lumps, observed on the liver surface, proved to be metastatic by pathology. The texture of normal hepatic parenchyma was soft after being cut open. Microscopically ( $\times 100$ ), the peritumoral architecture and cell morphology were normal and necrotic zones were not observed. However, there were some different thickening blood

vessels and inflammatory cells as well as areas of edema or ballooning degeneration. At higher magnification ( $\times 400$ ), the size of cell was equal on the whole and there was abundant endochylema in cells. Abnormal caryocinesia was not observed in cell nucleuses.

The outer layer areas and the periphery areas in VX-2 tumors appeared grey, fish and hard without distinct borders and amiculas between the area of

**Figure 4** Cavitas was observed in the tumor center of some samples on the 21th d after implantation.

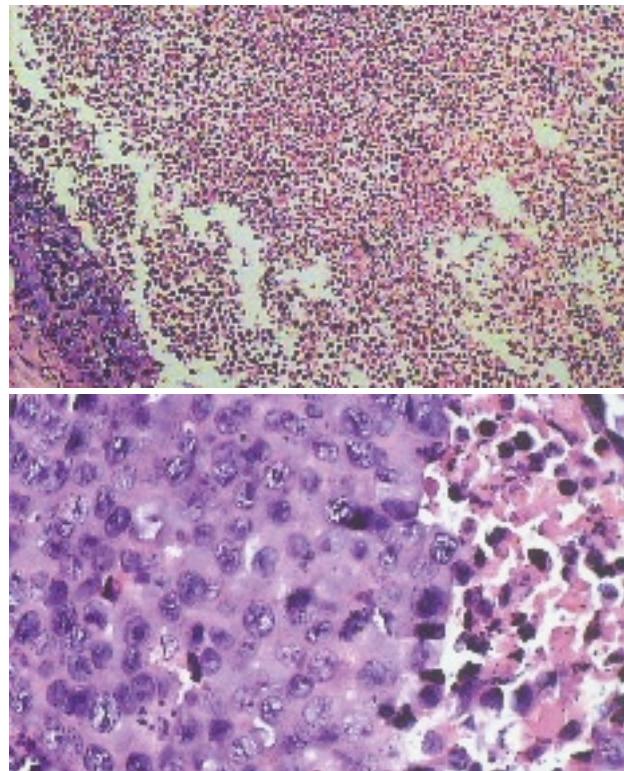

normal hepatic parenchyma and the area of VX-2 tumor outer layer (Figure 4). The distribution of necrotic areas differed between the cancer center and its periphery, being prevalent in the tumor core and significantly less at its periphery or its outer layer. Tumor necrotic tissue looked like tofukasu and tumor viable tissue looked like fish (Figure 4).

At low magnification ( $\times 100$ ), a plenty of tumor nests in lumps were observed and they showed inequality in size, and round or ellipse in shape. There were more blood capillaries and little connective tissue in lumps. Calcification changes and residuum of gelation sponge could be observed in some cases. There were unequal necroses in the area of most VX-2 tumor center but there was little necrosis in the area of tumor periphery (Figure 5).

At higher magnification ( $\times 400$ ), the size of most tumor cells was not equal and tumor nests differed in size, and round or ellipse in shape. There was little intercellular substance in tumors and some cell membranes appeared poorly defined. The size of cell nucleuses was uneven and the number of cell nucleuses was not equal so that the karyoplasmic ratio of cells was altered. Most of cell nucleuses were stained deeply and some of them had obvious caryocinesia. Some apoptotic cells were also observed.

## DISCUSSION

Diffusion is caused by water molecular random motion, so-called “Brownian motion”<sup>[24-27]</sup>. By adding a powerful polar and quick switching gradient radiofrequency (RF) pulse, it is possible to amplify these phase changes in order to detect water molecule diffusion motion, known as diffusion-weighted imaging (DWI)<sup>[16,18,20,25]</sup>. By using such an approach, the signals of hepatocellular carcinoma, metastases and hemangiomas were higher than that of the surrounding hepatic parenchyma, as reported by Ichikawa *et al*<sup>[15,16]</sup>, Taouli *et al*<sup>[18]</sup> and Yang *et al*<sup>[32]</sup>. This phenomenon can be explained by differences in terms of water molecular motions, which are limited in hepatocellular carcinoma, metastases and hemangiomas when compared to normal hepatic tissues. Changes of their phase position in the magnetic

**Figure 5** Cell nest of VX-2 tumor and wide zone of necrosis in the tumor were observed under microscope (up  $\times 100$ , down  $\times 400$ ).

field were therefore smaller and signal deamplification is reduced. Although the limitation of water molecular motion in the hemangioma is smaller than that of hepatocellular carcinoma or metastasis, the signal of the former was higher than that of the latter because there were more water molecules in the hemangioma.

As VX-2 tumor is a solid tumor and its body mainly consists of tumor cells, tumor nests and other cells, its water molecular diffusion motion is restricted. The signals of VX-2 tumor on DWI are higher than that of normal hepatic parenchyma because the signal deamplification of VX-2 tumor is small. On the 7th, the 14th d and the 21th d after implantation in our experiment, the signals of most VX-2 tumors were higher than that of normal parenchyma, and they looked like “lamp bulbs” (Figure 3). Their margins were usually distinct and their ADC values were lower than that of normal parenchyma, confirming the published data.

On the 7th d after implantation, the ability of detecting tumors by DWI was significantly higher than that of T1-weighted imaging (78.7% vs 10.7%) or T2-weighted imaging (78.7% vs 53.5%) and the signal contrast on DWI between VX-2 tumor and normal parenchyma was more evident when compared to T1-weighted or T2-weighted imaging (Figure 3A and B). DWI has important and potential clinical value in detecting tumors earlier because a powerful polar and quick switching gradient RF pulse besides MRI routine RF is added, molecular phase changes are amplified, which has not been reported in literatures before. The signals of most VX-2 tumors on DWI were high and uniform, including the central area of tumor on the

7th d after implantation; the signals on the map of ADC were equal even if most borders were unclear (Figure 3), probably because, at this time, the blood provision of VX-2 tumors is sufficient and there is no coagulative necrosis or colliquation.

On the 14th d after implantation, the signals of DWI in 31% (b-value 100 s/mm<sup>2</sup>) and 38% (b-value 300 s/mm<sup>2</sup>) of all tumor models were uneven and the borders were relatively distinct. The low signals detected in the central areas of 11 cases proved by pathology to be caused by unabsorbed gelatin sponge. At this time, no coagulative necrosis or colliquation were observed. Inflammation and cellular edema tended to decrease at d 14 after implantation in comparison with day 7.

On the 21th d after implantation, the signals of VX-2 tumors were high and 95% of margins were distinct on DWI while the signals on the map of ADC were low, with equally distinct borders. However, the histopathological examination did not show amiculas or distinct borders between VX-2 tumors and normal parenchyma ( $\times 100$  and  $\times 400$ ). A possible explanation of the high signals and distinct borders of tumors on DWI is related to the obvious limitations of water molecular motion in VX-2 tumors. The VX-2 tumor periphery area manifested mostly uniform, producing a high signal on DWI and low signal on the map of ADC. Samples in the area of VX-2 tumor periphery looked like grey fish macroscopically (Figure 4), containing viable tumor cells which showed inequality in size, and round or ellipse tumor nests under microscope (Figure 5). The intra-tumor signals were uneven on DWI with low and unequal areas in 28 lumps (Figure 3), where coagulative necrosis was confirmed by pathology (Figure 5). Because VX-2 tumors grow quickly, blood provision becomes insufficient causing local or lamellar coagulation necroses in the tumor. This result confirms the published data by Colagrande *et al*<sup>[20]</sup>, Kamel *et al*<sup>[21]</sup> and Geschwind *et al*<sup>[22]</sup>. The limitation of water molecule diffusion is inversely proportional to the extent of the tumor necrosis, because intact cell membranes can restrict the diffusion of water molecules when tumor cells are viable. The necrotic areas generated unequal signals (Figure 3D and E), being significantly smaller than the areas of viable tumor. Histologic analysis demonstrated unequal size, endochylema disproportion and pathological caryocinesis of most viable tumor cells. Areas of high signal on DWI were observed intratumorally in 5 cases (b-value 100 s/mm<sup>2</sup>) and 3 cases (b-value 300 s/mm<sup>2</sup>) (Figure 3D). Histopathological analysis showed that these areas were due to colliquation after necrosis. The signals of constitution on DWI were affected not only by diffusion of water molecules, but also by its T2-value contribution. When the T2-value of this constitution is long (value long<sup>2</sup>) and the b-value is small in diffusion-weighted imaging scanning, the signal of constitution will be affected significantly by the long T2-value contribution, the so called "shine-through". As reported by Yamashita *et al*<sup>[17]</sup>, Taouli *et al*<sup>[18]</sup> and Yang *et al*<sup>[32]</sup>, the limitation of water molecular motion in hepatic cysts was lower than that of the normal parenchyma; however,

the signals of the cysts were higher on DWI because the number of water molecules in hepatic cysts is higher than the hepatic parenchyma. The great amount of extracellular water molecules within the necrotic region caused by cell lysis allows free diffusion to take place, justifying the resultant high signals on DWI.

As shown in Figure 2, the growth velocity of VX-2 tumor from day 7 to 14 after implantation was lower than that from d 14 to 21. At the same time, several infiltrating and metastatic tumors were found by dissection on the 21th d after implantation. According to our experience, it is a period of quick growing for VX-2 tumor from the 14th d to the 21th d after implantation and it is suitable for rabbit VX-2 tumor models to be treated interventional or by other therapies.

Overall, the appearance of viable, necrotic and liquefied or cystic areas of VX-2 tumor on DWI is typical. Therefore, DWI could be applied in clinics for the early detection and diagnosis of liver tumors. The areas of viable cells in VX-2 tumors are associated with high signals, distinct borders, so called "lamp bulb" on DWI and low signals on the map of ADC. On the contrary, the necrotic areas in VX-2 tumors show low signals on DWI and equal or low signals on the map of ADC. Finally, high signals on DWI and on the map of ADC are produced when the areas of necrotic tumor are liquefied or have become cystic.

## ACKNOWLEDGMENTS

We thank the staff of the Radiology Department and the Laboratory Animal Center of the Second Xiangya Hospital for their help and support in this study, especially Miss Ying-Si He.

## COMMENTS

### Background

Magnetic resonance (MR) diffusion-weighted imaging (DWI) is a new functional imaging technology developed in recent years, which is able to reflect non-woundingly water molecule diffusion *in vivo* and is valuable in the qualitative and quantitative diagnosis of cerebral ischemia during the hyper-inchoate period. Ichikawa *et al*, Yamashita *et al*, Taouli *et al*, Sun *et al* and Yang *et al* have reported the characteristics of hepatic lesions on DWI, such as cysts, hemangiomas, hepatocellular carcinomas, metastases and liver cirrhosis. However, because of its poor image quality, DWI has not been extensively used in the diagnosis and evaluation of progression and prognosis of hepatic tumors in the past. Moreover, to date, a dynamic and image pathological investigation in the characteristics of hepatocellular carcinomas on DWI has never been reported. We believe that DWI has potential values in reflecting characteristics of hepatic pathological changes and differentiating benign tumors from malignant tumors with the recent development of MR software and scanning technology, especially for echo planar imaging (EPI) series.

### Research frontiers

Many studies of hepatic pathological changes on DWI have been reported. ADC values of benign lesions, such as hepatic cysts and hemangiomas, were higher than those of malignant lesions, such as hepatocellular carcinomas and metastases on DWI and many studies also indicated that the signals of tumor coagulative necrotic areas were lower than that of tumor viable areas. Moreover, Colagrande *et al* demonstrated that the coagulation necrosis manifested a low signal when compared to the normal parenchyma. There has been no dynamical and image pathological investigation on the characteristics of the liver on DWI in the rabbit VX-2 tumor model.

### Innovations and breakthroughs

This study clearly demonstrates that the areas of viable cells in VX-2 tumors manifested a high signal on DWI and a low signal on the map of apparent diffusion coefficient (ADC), the areas of dead cells or necrosis in VX-2 tumors manifested a low signal on DWI and a low, equal or high signal on the map of ADC, but they manifested high signals on DWI and on the map of ADC at the same time when the areas of necrotic tumors had become liquefied or cystic. The manifestations of viable, necrotic and liquefied or cystic areas in VX-2 tumors on DWI were typical. The rate of lump detected by DWI was much higher than that by T1WI or T2WI after implantation. DWI has significant and potential clinical application values in detecting and differentiating viable tumors from necrotic tumors and in the early detection and diagnosis of liver tumors.

### Applications

Physicians can apply this knowledge to evaluate obviously progressive hepatic tumors and differentiate accurately the areas and degrees of necrotic tumors from that of viable tumors.

### Peer review

This is an interesting, well designed and written study on the clinical significance of the liver on diffusion-weighted imaging and the manuscript contained important information on the manifestations of viable, necrotic and liquefied or cystic areas in tumors and clinical application values in the early detection and diagnosis of liver tumors.

removed surgically if they were close to the main lesion or followed by examinations of alpha-fetoprotein (AFP) level and ultrasound and/or CT/MR every 3 mo.

**RESULTS:** IOUS found 41 nodules in total, among which 17 (41.46%) were newly detected compared to preoperative imaging. Thirty-three nodules were diagnosed malignant by CE-IOUS, including one missed by IOUS. The sensitivity and specificity of CE-IOUS on detecting HCC nodules are 100% (33/33) and 100% (9/9), respectively. Nine nodules were considered benign by CE-IOUS, four was confirmed at histology and five by follow-up. CE-IOUS changed the surgical strategy in 35% (7/20) of patients and avoid unnecessary intervention in 30% (6/20) of patients.

**CONCLUSION:** CE-IOUS is a useful means to characterize the nodules detected by IOUS in cirrhotic liver, to find isoechoic HCC nodules which can not be shown on IOUS and to improve the accuracy of conventional IOUS, thus it can be used as an essential tool in the surgical treatment of cirrhotic patients with HCC.

## INTRODUCTION

Intraoperative ultrasound (IOUS) is an important tool for surgical treatment of liver tumors<sup>[1,2]</sup>, and particularly for hepatocellular carcinoma (HCC). It has been shown

that IOUS is the most accurate diagnostic technique for detecting focal liver lesions (FLL) and has a great impact on the surgical approach to liver tumors<sup>[3-7]</sup>. However, in cirrhotic patients with HCC, not all nodules detected by IOUS are neoplastic<sup>[8]</sup>. Compared with CT and magnetic resonance (MR) imaging, IOUS has better spatial resolution with high frequency probe<sup>[9]</sup>, however, it can not provide information about tumor vascularity and tissue microcirculation. How to differentiate small HCC from the nodules detected by IOUS poses a big challenge both for surgeons and ultrasonic doctors. The application of intravenous ultrasound contrast agents during transcutaneous ultrasonography of the liver has shown to improve nodule characterization in comparison with unenhanced ultrasound<sup>[10-14]</sup>. Therefore, we investigated if the application of contrast-enhanced ultrasound examination intraoperatively could solve the aforementioned deficiencies of IOUS during liver exploration.

## MATERIALS AND METHODS

This study was conducted under the approval of the Committee of Ethics of West China Hospital and informed consents of all the patients were obtained. From January 2007 to September 2007, a total of 20 consecutive cirrhotic patients with HCC scheduled to undergo partial liver resection were studied. They included 15 men and 5 women, aged 28-68 (mean 50) years. Preoperative contrast enhanced CT and/or MR scans were performed within 1-2 wk of operation. Contrast enhanced CT scans were obtained with multi-detector CT scanners (Somatom Sensation 64, Siemens Medical Solutions, Erlangen, Germany). The patients received 120-150 mL iopromide (Ultravist 300 or 370; Schering, Berlin, Germany) at a rate of 3 mL/s. CT was performed during the arterial phase using a 25-35 s delay, portal venous phase using a 70-75 s delay, and equilibrium phase using a 3 min delay after i.v. administration with 7-mm section thickness. Contrast-enhanced MRI examinations were performed with a 1.5 T imaging system (Gyroscan Intera, Philips Medical Systems Best, Netherlands), using a breathhold 3D gradient echo sequence with fat saturation sequence, following an iv bolus of 0.1 mmol gadobenate dimeglumine (MultiHance, Bracco SpA, Milan, Italy) per kg of body weight at a rate of 2 mL/s. Data was acquired in the hepatic arterial, portal venous, and equilibrium phases. CT was performed in 15 patients and MRI in two and both in three patients. The number of the lesions was recorded.

### Intraoperative imaging techniques

We used VIVID4 unit (GE, USA) with an I-shaped 10-4 MHz intraoperative probe for IOUS scans. After mobilization of the liver, IOUS was performed to search for nodules and suspected lesions were counted and mapped. CE-IOUS was carried out both for lesion characterization and new nodule detection. Considering no specific intraoperative probe is available for contrast

study, we used IU22 unit (Philips, USA) equipped with a 5-2 MHz convex transducer and a 9-3 MHz linear transducer instead. Both of the probes have the capacity for contrast enhanced ultrasound studies. The contrast agent was SonoVue (Bracco Imaging, Milan, Italy) which consists of sulphur hexafluoride microbubbles stabilized by a phospholipid shell; 4.8 mL of SonoVue per exploration was injected intravenously through a peripheral vein. A low mechanical index (MI < 0.1) mode was used. All phases of contrast enhancement, including arterial (10-20 s to 25-35 s after injection), portal (30-45 s to 120 s) and late parenchymal (> 120 s) phases were recorded and analyzed<sup>[13]</sup>. HCC is characterized by arterial phase hyper-enhancing and wash out of microbubbles during the portal and late phase, while benign solid lesions are characterized by persistence of contrast enhancement during the portal and late phase<sup>[15]</sup>.

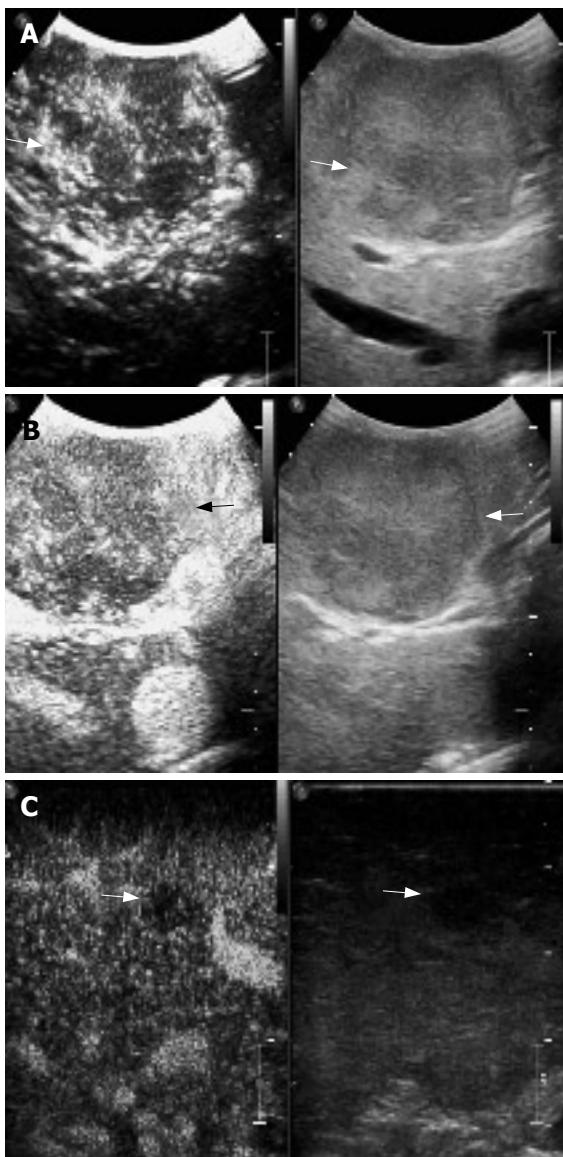

Nodules showing arterial hyper-enhancement and/or hypo-enhancement in late parenchymal phase were removed surgically. Ultrasound-guided biopsy and ethanol ablation would be an alteration if the nodule can not be removed surgically. Nodules depicting isoenhancement both in arterial and late parenchymal phases were considered benign and removed only in cases located close to the main lesion and the others were followed by examinations of alpha-fetoprotein (AFP) level and ultrasound and/or spiral CT every 3 mo.

## RESULTS

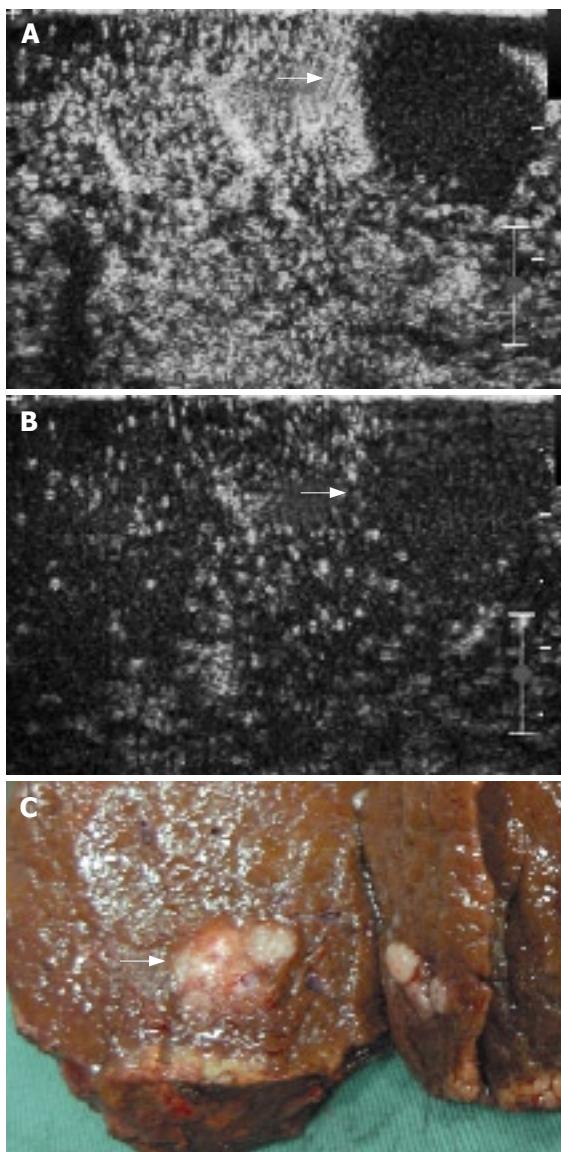

The number of nodules detected by different imaging methods is summarized in Table 1. The sensitivity and specificity of CE-IOUS in detecting HCC nodules is 100% (33/33) and 100% (9/9), respectively. IOUS and CE-IOUS confirmed the existence of all the 24

**Figure 1** It illustrates the enhancing pattern of HCC and normal liver parenchyma. With more arterial supply, HCC appears hyperechoic in the arterial phase and the lesion is slightly and then clearly hypoechoic, and relative to the surrounding parenchyma in the portal and late phases with the washout of contrast agents.

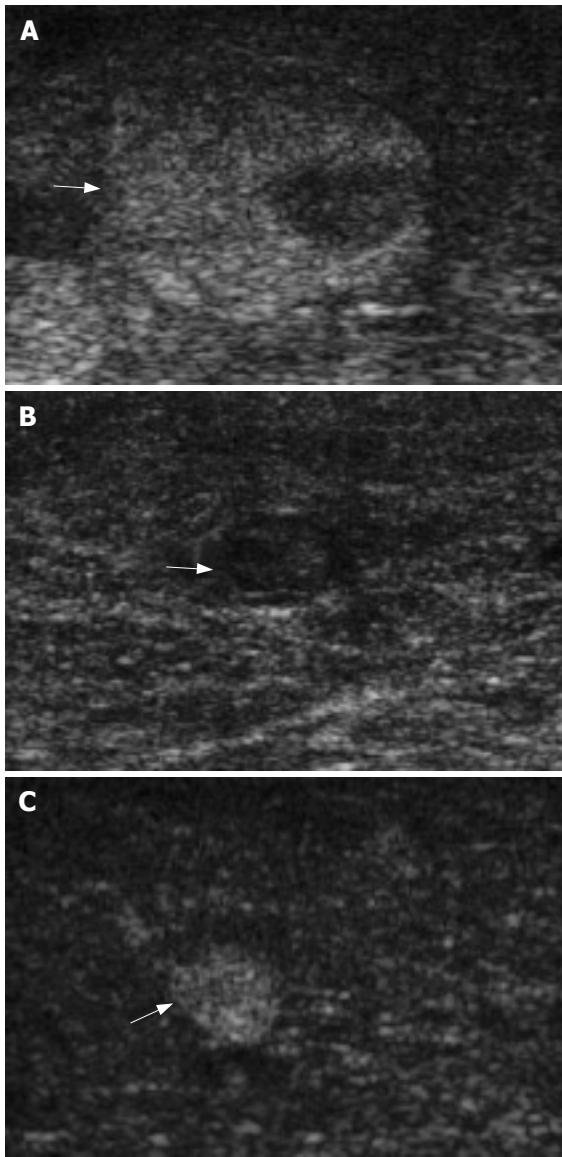

**Figure 2** A mosaic nodule in a cirrhotic liver at IOUS. **A:** At arterial phase, the nodule shows early enhancement (arrows); **B:** The nodule demonstrates contrast agent wash-out in late phase: it was a typical appearance of HCC and proved malignant at histology (arrows); **C:** Another hypoechoic nodule at IOUS was hypoenhanced in late phase: it was considered intrahepatic metastasis and confirmed malignant at histology (arrows).

**Figure 3** A mosaic nodule in a cirrhotic liver at IOUS. **A:** The nodule shows no contrast agent uptake in arterial phase (arrows); **B:** The nodule shows no contrast agent uptake in late parenchymal phase (arrows); **C:** Specimen of the mass after resection proved to be HCC at histology.

nodules found preoperatively. Among the 24 lesions, which were proved to be HCC at histology, 23 nodules demonstrated arterial phase hyper-enhancement and late phase hypo-enhancement (Figures 1 and 2). One nodule had no contrast agent uptake both in arterial and late parenchymal phases (Figure 3). Seventeen nodules were newly detected by IOUS (Figure 4). Among the 17 IOUS newly detected nodules, 8 were hyper-enhanced in arterial phase and hypo-enhanced in late phase on CE-IOS and proved to be malignant at histology. The other 9 nodules illustrated isoenhancement in both arterial and late parenchymal phases (Figure 5). Four of them were removed because they were located close to the main lesions and these lesions were dysplastic nodules in histology. Five nodules were not removed and follow-up ultrasound and/or CT showed no sign of malignancy with normal AFP level after 6–15 mo. One isoechoic HCC nodule

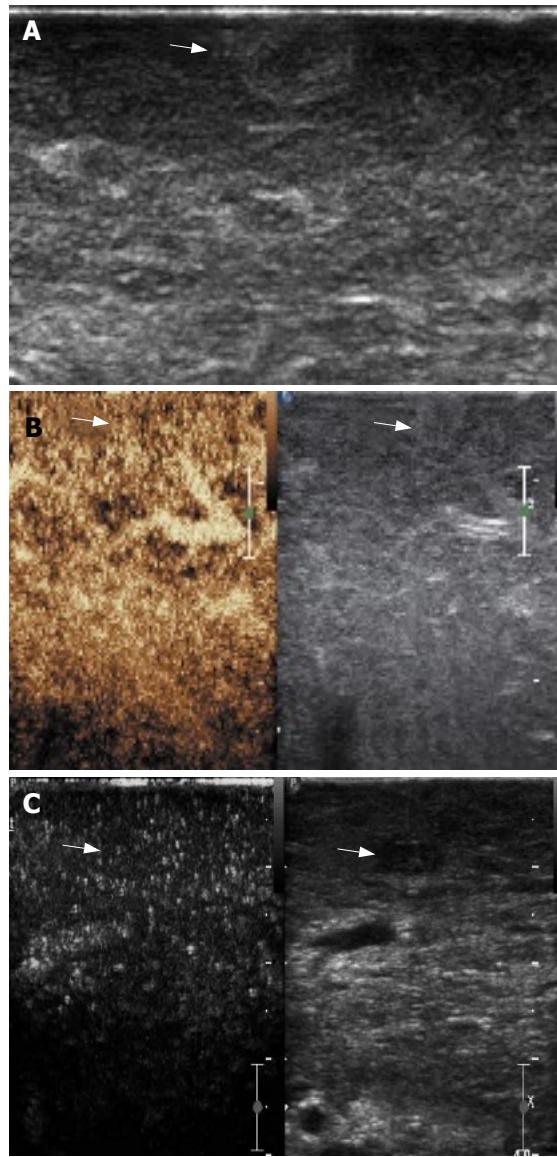

**Figure 4** Appearance of nodules in a cirrhotic liver at IOUS. **A:** Mosaic pattern nodule (arrows); **B:** Hypoechoic nodule (arrows); **C:** Hyperechoic nodule (arrows).

was missed by IOUS, but showed a typical contrast agent washout pattern on CE-Ious late parenchymal phase (Figure 6).

CE-Ious changed the surgical strategy in 35% (7/20) of patients, including additional tumor enucleation in five and ultrasound guided ethanol injection in two patients. CE-Ious also avoided unnecessary intervention in 30% (6/20) of patients who otherwise need additional nodule enucleation or extended hepatectomy according to the IOUS results.

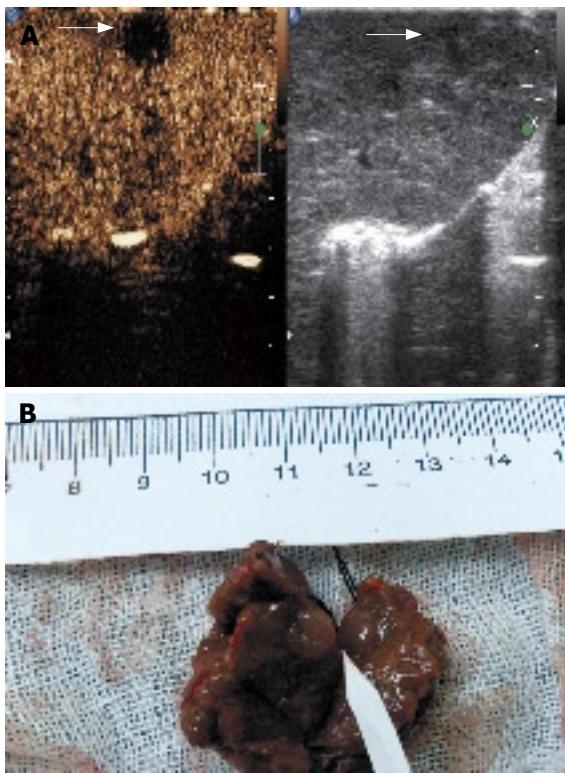

## DISCUSSION

Radicality and preservation as much remnant liver parenchyma as possible are a goal for hepatic resection for cirrhotic patients with HCC. Since it is not uncommon that multiple nodules exist in cirrhotic liver with HCC, differential diagnosis of such nodules is critical, because the operation strategy may have to be changed if

**Figure 5** **A:** A hyperechoic nodule detected at IOUS in cirrhotic liver; **B:** The nodule shows no arterial enhancement and late parenchymal phase wash-out; **C:** A hypoechoic nodule detected at IOUS in cirrhotic liver, and it shows the same enhancing pattern with the surrounding parenchyma. These two nodules were considered dysplastic and the diagnosis was confirmed by pathologic examination.

another HCC lesion is found. Utilizing high frequency probe, compared with CT and MRI, IOUS has better spatial resolution and it is regarded as the most accurate diagnostic method for detecting FLL. In our study, besides the 24 nodules which were already detected preoperatively, IOUS found 17 new nodules in 50% (10/20) of patients. However, new nodules lack specific IOUS findings for HCC. Some studies showed that nodules with a mosaic ultrasound pattern are malignant in 84% of cases; about 24%-30% of hypoechoic nodules, and 0%-18% of hyperechoic nodules are malignant<sup>[16]</sup>. In our study, only 47.06% (8/17) of the IOUS newly detected nodules were confirmed to be HCC at histology. Patients would be at higher risk for postoperative complications if all the nodules detected by IOUS were removed. So it is urgent that new ways are developed to increase the accuracy of IOUS.

**Figure 6** A: An isoechoic nodule measuring 7 mm was missed at IOUS but appeared clearly at late phase of CE-IOUS with contrast agent wash-out; B: Specimen of the nodule after resection proved to be HCC at histology.

Studies suggest that liver ultrasound performed with microbubble contrast agents has led to improved characterization and detection of FLL since it provides information about tumor vascularity and tissue microcirculation comparable to that provided by contrast-enhanced CT and MR imaging, with the added benefit of real-time imaging<sup>[17,18]</sup>. Different enhancing patterns to differentiate FLL have been described<sup>[19,20]</sup>, for example, typical HCC shows arterial phase hyperenhancement and wash-out of contrast agent in portal and late parenchymal phase. The late phase is useful to determine the benign or malignant nature of a lesion while the arterial phase helps predict its histology<sup>[21-25]</sup>. About 86%-93% of benign lesions retain the contrast in the late phase, while 78%-98% of the malignant ones demonstrate wash-out of the contrast<sup>[21,22]</sup>.

In our study, CE-IOUS confirmed the malignancy of the 24 HCC nodules detected preoperatively and showed the vascularity and microcirculation of the IOUS newly detected nodules. In total, 96.97% (32/33) of the HCC nodules depicted arterial phase hyperenhancement and 100% (33/33) showed late phase hypoenhancement, while 100% (9/9) of dysplastic nodules illustrated isoenhancement in both arterial phase and late phase.

CE-IOUS can also help find isoechoic HCC nodules. An isoechoic nodule measuring 7 mm which was missed at IOUS showed a typical contrast agent wash-out in late phase at CE-IOUS. Its malignancy was confirmed at histology. This phenomenon highlights the importance of scanning of the whole cirrhotic liver in late phase of CE-IOUS to detect occult lesions at IOUS.

It is known that IOUS affects surgical strategy in 20%-43.8% of patients with liver tumors<sup>[26-28]</sup>. CE-IOUS findings further demonstrate the benign or malignant nature of the lesions detected by IOUS. Since the duration of late parenchymal phase is much longer than arterial phase, a comprehensive assessment of the whole liver parenchyma which can not be accomplished in arterial phase is required in late phase. Generally, resection of the hypo-enhanced nodules in late phase on CE-IOUS is recommended. In our study, CE-IOUS changed the surgical strategy in 35% (7/20) of patients and avoided unnecessary intervention in 30% (6/20) of patients. That is to say CE-IOUS makes IOUS more accurate, thus enhancing the impact of this technique on operative decision-making for liver tumors.

There is still atypical enhancing mode of HCC. One nodule with a diameter of 2 cm which was enhanced in preoperative CT, mosaic at IOUS and hard on palpation showed no contrast agent uptake in both arterial and late phases. It was proved to be HCC at histology. This atypical pattern of enhancement of HCC nodule at CE-IOUS, when compared with that at spiral CT, supposes that some tumor vascular architecture may permit the spread of CT contrast agent while prevent that of ultrasound contrast agent<sup>[29]</sup>. However, this needs further studies to find any pathological correlations.

In our experience, high frequency probe (L9-3) is more suitable for CE-IOUS study of superficial lesions because of its high resolution in the near field. But for lesions deeper than 3 cm, lower frequency probe (C5-2) is recommended for better penetration and echo-enhancement. The respiratory tract pressure increased during general anesthesia and the scanning is performed directly on the liver surface, bubble destruction thus increased<sup>[30]</sup>. Therefore 4.8 mL SonoVue per exploration is recommended for CE-IOUS.

In conclusion, though only preliminary experience is available, CE-IOUS appears to be an exciting and promising new application. It helps differentiate nodules detected by IOUS in cirrhotic liver and find isoechoic nodules which can not be shown on IOUS, and then improves the accuracy of conventional IOUS. Considering the small number of patients, more studies are needed for further evaluation of this new technique.

## COMMENTS

### Background

Intraoperative ultrasound (IOUS) is an important tool for liver tumors, but it has some drawbacks such as lack of specificity to differentiate cirrhotic nodules from small malignant nodules. Contrast-enhanced ultrasound was shown with improved nodule characterization by recent studies. Therefore, authors investigated if the application of contrast-enhanced ultrasound intraoperatively could solve the aforementioned deficiencies of IOUS.

### Innovations and breakthroughs

The application of CE-IOUS improves nodule characterization. It helps surgeons to eradicate malignant nodules and avoid unnecessary intervention of benign ones.

### Applications

CE-IOUS raised the accuracy of conventional IOUS, thus improving the management of nodules detected in liver surgeries.

### Terminology

To apply ultrasound examination during surgeries, IOUS is considered an

essential tool for detecting focal liver lesions (FLL) and has a great impact on the surgical approach to liver tumors. Besides the merits of IOUS, CE-Ious can display the tumor vascularity and tissue microcirculation using intravenous ultrasound contrast agents, thus helping differentiate malignant nodules from benign ones.

#### Peer review

The research is quite interesting and the results are relevant to improve the quality of hepatic surgery, mainly in cirrhotic patients. The role of contrast-enhanced ultrasound in the study of hepatocellular carcinoma has already been studied in the preoperative setting. However few studies have focused on its intraoperative role, and thus this report is quite innovative.

a pooled sensitivity of 99.2% (95% CI: 97.1-99.9). For nodal staging, the pooled sensitivity for N1 was 58.2% (95% CI: 53.5-62.8) and N2 was 64.9% (95% CI: 60.8-68.8). Pooled sensitivity to diagnose distant metastasis was 73.2% (95% CI: 63.2-81.7). The *P* for chi-squared heterogeneity for all the pooled accuracy estimates was > 0.10.

**CONCLUSION:** EUS results are more accurate with advanced disease than early disease. If EUS diagnoses advanced disease, such as T4 disease, the patient is 500 times more likely to have true anatomic stage of T4 disease.

## Abstract

**AIM:** To evaluate the accuracy of endoscopic ultrasound (EUS) for staging of gastric cancers.

**METHODS:** Only EUS studies confirmed by surgery were selected. Only studies from which a  $2 \times 2$  table could be constructed for true positive, false negative, false positive and true negative values were included. Articles were searched in Medline, Pubmed, Ovid journals, Cumulative index for nursing & allied health literature, International pharmaceutical abstracts, old Medline, Medline nonindexed citations, and Cochrane control trial registry. Two reviewers independently searched and extracted data. The differences were resolved by mutual agreement.  $2 \times 2$  tables were constructed with the data extracted from each study. Meta-analysis for the accuracy of EUS was analyzed by calculating pooled estimates of sensitivity, specificity, likelihood ratios, and diagnostic odds ratio. Pooling was conducted by both the Mantel-Haenszel method (fixed effects model) and DerSimonian Laird method (random effects model). The heterogeneity of studies was tested using Cochran's *Q* test based upon inverse variance weights.

**RESULTS:** Initial search identified 1620 reference articles and of these, 376 relevant articles were selected and reviewed. Twenty-two studies ( $n = 1896$ ) which met the inclusion criteria were included in this analysis. Pooled sensitivity of T1 was 88.1% (95% CI: 84.5-91.1) and T2 was 82.3% (95% CI: 78.2-86.0). For T3, pooled sensitivity was 89.7% (95% CI: 87.1-92.0). T4 had

## INTRODUCTION

Gastric cancer is one of the most common cancers worldwide. Despite the decreasing incidence and mortality, gastric cancer remains the world's second leading cause of cancer-related deaths in the world<sup>[1]</sup>. A treatment option for patients with gastric cancer depends on an accurate evaluation of the stage of the cancer. The prognosis of patients with gastric cancer is determined by the tumor extent and includes both nodal involvement and direct tumor extension beyond the gastric wall<sup>[2,3]</sup>.

Accurate staging of gastric cancers is essential for well-informed decisions on patient management. Accurate gastric cancer staging needs to address two critical questions: which patients qualify for curative therapy and which patients qualify for palliative therapy? This is becoming increasingly important with improvements in non-surgical treatment regimens. Surgery is the

main stay of curative therapy for gastric cancers. While patients with early localized disease clearly benefit from complete surgical resection, increasing evidence exists that multimodal treatment including chemoradiotherapy is superior to surgery alone for patients with resectable gastric cancer<sup>[4]</sup>. Accurate local cancer staging provides the information necessary for such important decisions to be made while not denying patients potentially curative surgical resection, with or without neoadjuvant therapy. The development of other non-surgical techniques at both ends of the disease spectrum has also reinforced the need for accurate cancer staging. Endoscopic ultrasound (EUS) in conjunction with endoscopic mucosal resection has become an appropriate alternative to surgery for superficial non-invasive cancers<sup>[5]</sup>.

The 5-year survival of patients with gastric cancer ranges from 5% to 95% depending on the tumor stage<sup>[6]</sup>. Early gastric cancer or superficial spreading carcinoma is defined as adenocarcinoma limited to the gastric mucosa or submucosa. Patients with early gastric cancer have a favorable prognosis<sup>[7]</sup> and the survival is > 90% after surgical resection<sup>[8-11]</sup>. Therefore, a diagnostic tool that helps diagnose the depth of tumor invasion in the gastric mucosa is essential. In those patients considered unfit for curative surgery, accurate staging is essential to allow an informed decision to be made regarding the most appropriate method of palliation. If comparisons of the outcomes of available and future treatment protocols are to be made, comparable input data-specific to the stage of disease should be available from all patients. This is particularly important if the patient does not undergo primary surgical resection, due to the consequent loss of pathological confirmation, as then the stage of the cancer can only be assessed from the best imaging modality or modalities.

Imaging studies like computerized topographic scan have the advantage of being widely available and noninvasive, but is not very accurate for assessing the depth of invasion or the presence of lymph node involvement<sup>[12,13]</sup>. EUS has emerged as one of the tests for preoperative staging of upper gastrointestinal cancers. The advantage of EUS is the ability to differentiate the layers of gastric mucosa. The accuracy of EUS in staging gastric cancers has been varied, with reports that EUS understages the depth of invasion and overstages the nodal invasion because of inflammation around the tumor or in the lymph nodes<sup>[14]</sup>. The goal of this meta-analysis and systematic review is to evaluate the accuracy of EUS in staging gastric cancers. Due to multiple studies published that looked at EUS in staging gastric cancers and no published meta-analysis in this area, this meta-analysis was performed in an attempt to answer this very important clinical question.

The EUS criteria for depth of tumor invasion and nodal metastasis have changed over the past two decades. Also, the technology of EUS has changed over this period of time. It is not clear if this change in EUS criteria and technology has had an impact on gastric cancer staging. In this meta-analysis and systematic review, we pooled the available studies to evaluate if

changing EUS criteria or technology affects the accuracy of EUS to stage gastric cancers<sup>[15]</sup>.

This meta-analysis and systematic review was written in accordance with the proposal for reporting by the QUOROM (Quality of Reporting of Meta-analyses) statement<sup>[16]</sup>. Since this manuscript looks at diagnostic accuracy of a test, the study design for this meta-analysis and systematic review conformed to the guidelines of Standards for Reporting of Diagnostic Accuracy (STARD) initiative<sup>[17]</sup>.

## MATERIALS AND METHODS

### **Study selection criteria**

Only EUS studies confirmed by surgery were selected. EUS criteria used for T staging were: T1- the tumor invades the lamina propria or submucosa but does not invade the muscularis propria, T2- the tumor invades but does not extend beyond the muscularis propria, T3- tumor penetrates serosa (i.e. visceral peritoneum) without invasion of adjacent structures, and T4- the tumor invades adjacent structures. The criteria used for nodal metastasis were: larger than 1 cm or hypoechoic or round instead of elliptical. Distal metastasis was defined as metastasis to peritoneum or liver. Only studies from which a 2 × 2 table could be constructed for true positive, false negative, false positive and true negative values were included.

### **Data collection and extraction**

Articles were searched in Medline, Pubmed, Ovid journals, Cumulative Index for Nursing & Allied Health Literature, ACP journal club, DARE, International Pharmaceutical Abstracts, old Medline, Medline nonindexed citations, OVID Healthstar, and Cochrane Control Trial Registry. The search terms used were endoscopic ultrasound, EUS, ultrasound, gastric cancer, nodal invasion, staging, surgery, sensitivity, specificity, positive predictive value, and negative predictive value. 2 × 2 tables were constructed with the data extracted from each study. Two authors (SP and JR) independently searched and extracted the data into an abstraction form. Any differences were resolved by mutual agreement.

### **Quality of studies**

Clinical trial with a control arm can be assessed for the quality of the study. A number of criteria have been used to assess this quality of a study (e.g. randomization, selection bias of the arms in the study, concealment of allocation, and blinding of outcome)<sup>[18,19]</sup>. There is no consensus on assessing studies without a control arm and also, these criteria do not apply to studies without control arm<sup>[19]</sup>. Therefore, for this meta-analysis and systematic review, studies were selected based on completeness of data and studies that met the inclusion criteria.

### **Statistical analysis**

Meta-analysis for the accuracy of EUS in staging gastric cancers was performed by calculating pooled estimates

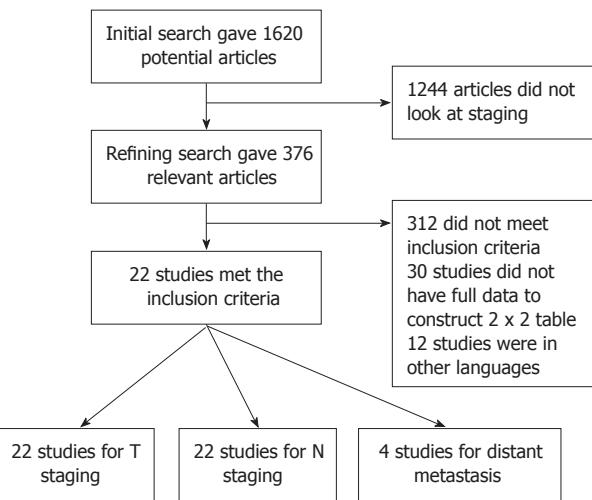

**Table 1 Characteristics of studies included in this meta-analysis for calculating diagnostic accuracy of EUS for gastric cancer staging**

of sensitivity, specificity, likelihood ratios, and diagnostic odds ratio. EUS studies were grouped into periods of time to standardize the change in EUS technology and also to standardize the change in EUS criteria for lymph node involvement. These periods of time were 1986 to 1994, 1995 to 1999, and 2000 to 2006. Pooling was conducted by both Mantel-Haenszel method (fixed effects model) and DerSimonian Laird method (random effects model). The confidence intervals were calculated using the F distribution method<sup>[20]</sup>. For 0 value cells, a 0.5 was added as described by Cox<sup>[21]</sup>. The point estimates in the Forrest plots are proportional to the weight or size of the individual study. The heterogeneity of the sensitivities and specificities were tested by applying the likelihood ratio test<sup>[22]</sup>. The heterogeneity of likelihood ratios and diagnostic odds ratios were tested using Cochran's *Q* test based upon inverse variance weights<sup>[23]</sup>. Heterogeneity among studies was also tested by using summary receiver operating characteristic (SROC) curves. SROC curves were used to calculate area under the curve (AUC). The effect of publication and selection bias on the summary estimates was tested by Egger bias indicator<sup>[24]</sup> and Begg-Mazumdar indicator<sup>[25]</sup>. Also, funnel plots were drawn using the standard error and diagnostic odds ratio to look at bias<sup>[26,27]</sup>.

## RESULTS

Initial search using the search terms identified 1620 reference articles. Among these, 376 relevant articles were selected and reviewed by two authors independently. Twenty-two studies ( $n = 1896$ ) which met the inclusion criteria were included in this analysis and data was extracted from these studies<sup>[28-49]</sup>. All the selected 22

**Figure 1** Flow sheet shows search results.

studies were published as full-text articles in peer review journals. Figure 1 shows the search results and Table 1 shows the details of the included studies. The pooled estimates given here are estimates calculated by the fixed effect model.

### T stage

Pooled sensitivity and specificity of T1 was 88.1% (95% CI: 84.5-91.1) and 100.0% (95% CI: 99.7-100.0) respectively. Figure 2A shows the Forrest plot of sensitivity and specificity of various EUS studies in staging T1 gastric cancers. For T2, the sensitivity was 82.3% (95% CI: 78.2-86.0) and specificity was 95.6% (95% CI: 94.4-96.6). Forest plot in Figure 2B depicts the sensitivity and specificity of EUS in staging T2 cancers. Pooled sensitivity for T3 was 89.7% (95% CI: 87.1-92.0) and specificity was 94.7% (95% CI: 93.3-95.9). Figure 2C depicts sensitivity and specificity of EUS to stage T3 cancers. T4 had a pooled sensitivity of 99.2% (95% CI: 97.1-99.9) and specificity of 96.7% (95% CI: 95.7-97.6). The sensitivity and specificity of EUS to stage T4 in various studies is Figure 2D as a Forrest plot. Pooled likelihood ratios and diagnostic odds ratios for various T stages are shown in Table 2. The pooled estimates of sensitivity, specificity, likelihood ratios, and diagnostic odds ratio computed by random effect model were similar to the fixed effect model. The *P* for chi-squared heterogeneity for all the pooled accuracy estimates was  $> 0.10$ .

### N stage

The pooled sensitivity and specificity for N1 was 58.2% (95% CI: 53.5-62.8) and 87.2% (95% CI: 84.4-89.7) respectively. N2 had a pooled sensitivity of 64.9% (95% CI: 60.8-68.8) and specificity of 92.4% (95% CI: 89.9-94.4). Pooled likelihood ratios and diagnostic odds ratios for various N stages are shown in Table 2. All the pooled estimates calculated by random effect model were similar to fixed effect model. The chi-squared heterogeneity for all the pooled accuracy estimates showed a *P*  $> 0.10$ .

**Table 2 Accuracy of EUS with confidence intervals to diagnose T and N stages in gastric cancer patients**

	<b>Pooled sensitivity</b>	<b>Pooled specificity</b>	<b>Pooled LR +</b>	<b>Pooled LR-</b>	<b>Pooled DOR</b>

	2000 to 2006	4	49.0% (40.7-57.30)	93.0% (87.5-96.6)	6.4 (1.7-24.1)	0.6 (0.4-0.7)	12.7 (2.9-56.2)

### M stage

Data for EUS accuracy to diagnose distant metastasis was available in four studies<sup>[29,35,36,41]</sup>. The pooled sensitivity to diagnose distal metastasis was 73.2% (95% CI: 63.2-81.7). EUS specificity was 88.6% (84.8-91.7). The positive likelihood ratio to diagnose distal metastasis was 17.2 (2.8-106.3) and the negative likelihood ratio was 0.4 (95% CI: 0.2-0.7). The diagnostic odds ratio of EUS to correctly diagnose distal metastasis was 60.9 (95% CI: 8.2-463.7). All the pooled estimates calculated by random effect model were similar. The *P* for chi-squared heterogeneity for all the pooled accuracy estimates was > 0.10. The SROC curve showed an AUC of 0.98 with a standard error (SE) of 0.005. This curve showed a *Q* value of 0.94 with a SE of 0.01, as shown in Figure 3.

### Affect of technology

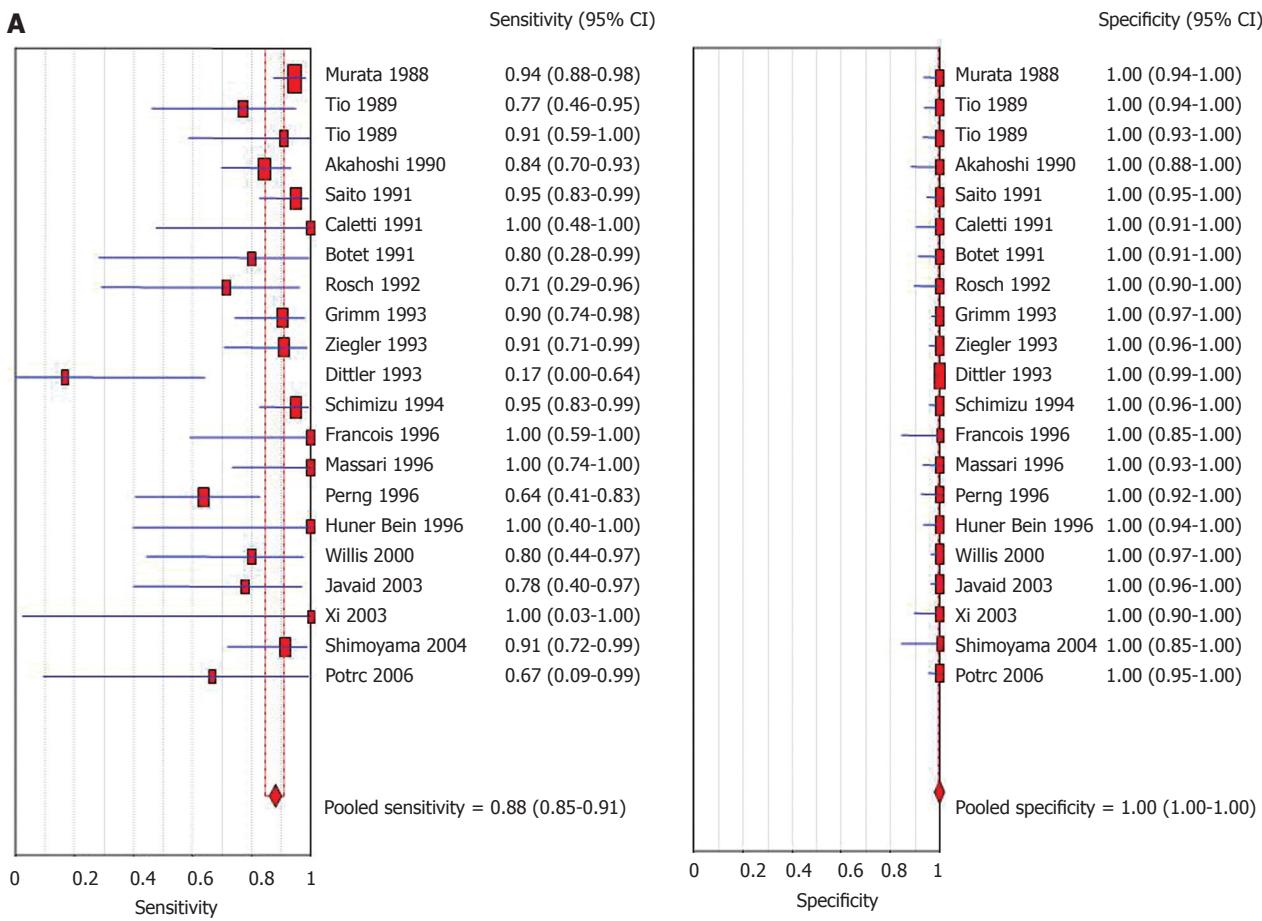

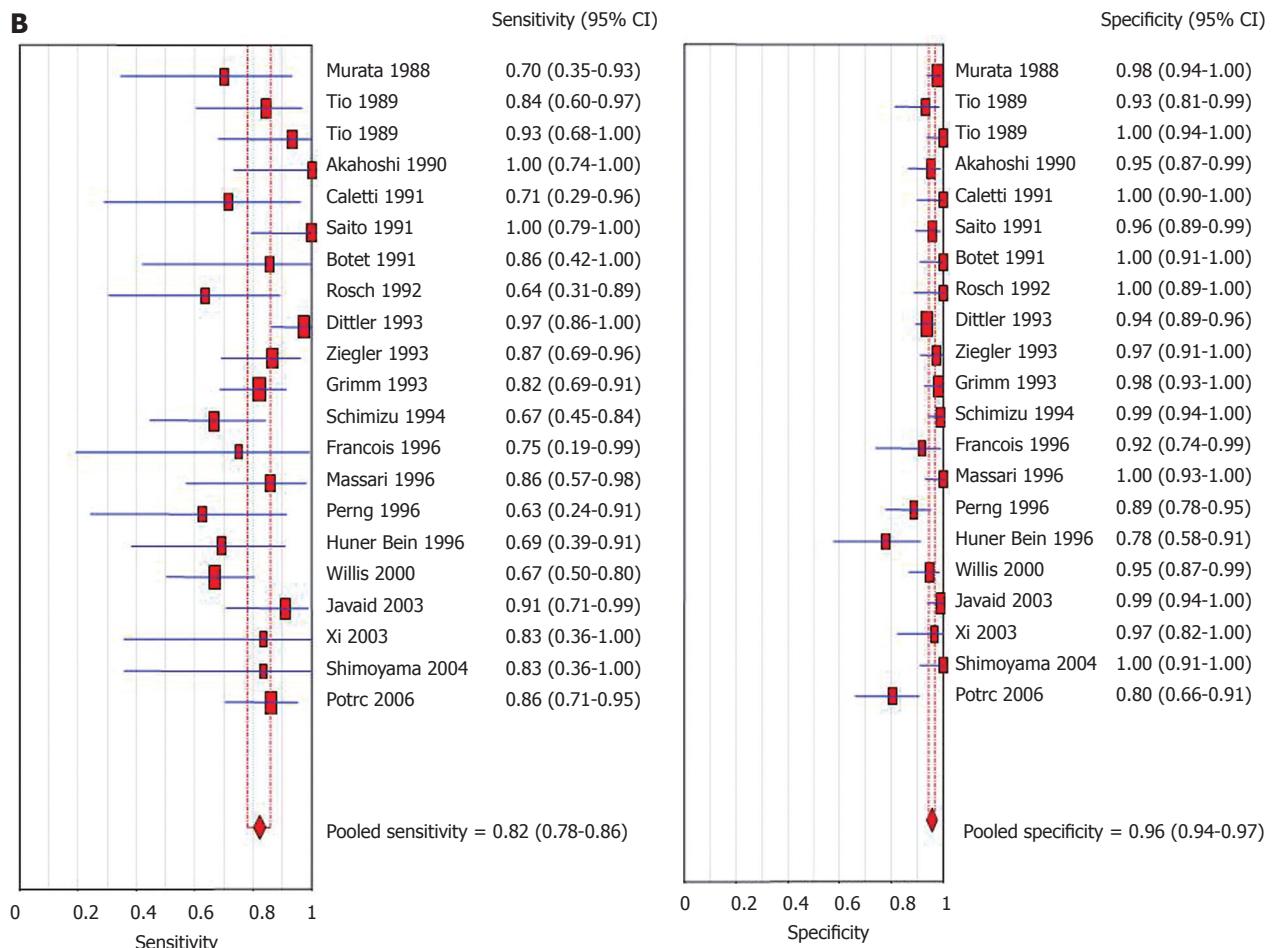

EUS studies were grouped into three periods of time to standardize the change in EUS technology and also to standardize the change in EUS criteria for tumor staging. These periods of time were 1986 to 1994, 1995 to 1999, and 2000 to 2006. The pooled estimates of studies during these periods of time are shown in Table 3. The *P* for chi-squared heterogeneity for all the pooled accuracy estimates was > 0.10. The bias calculations using Egger's bias indicator gave a value of 0.97 (95% CI = -0.77 to 2.71, *P* = 0.26). The bias calculated by Begg-Mazumdar indica-

tor gave a Kendall's tau value of 0.19, *P* = 0.24. The funnel plot for bias is shown in Figure 4.

## DISCUSSION

Correct staging of patients with gastric cancer helps to direct precise therapy and predict prognosis<sup>[7-9]</sup>. Majority of patients in all the included studies had adenocarcinomas. Patient with other types of gastric cancers couldn't be excluded from the analysis. Gastric cancer staging aids in determining non-operative versus operative management, pre-operative adjuvant chemoradiation, and local excision or endoscopic therapy versus wide resection<sup>[50]</sup>. Imaging modalities such as trans-abdominal B-mode ultrasonography, computed tomography, or magnetic resonance imaging lack the ability to differentiate layers of the gastric mucosa<sup>[51,52]</sup>.

The studies included in this analysis used established criteria for gastric cancer staging<sup>[53]</sup>. The definition for T staging given in the methodology was used in the included studies. This meta-analysis and systematic review shows that the pooled sensitivity of EUS for tumor invasion (T stage) is high and it is higher for advanced disease when compared to early disease. The pooled specificity for depth of tumor invasion is very high for all the T stages. Diagnostic odds ratio is defined as the odds of having a positive test in patients with

**A****B**

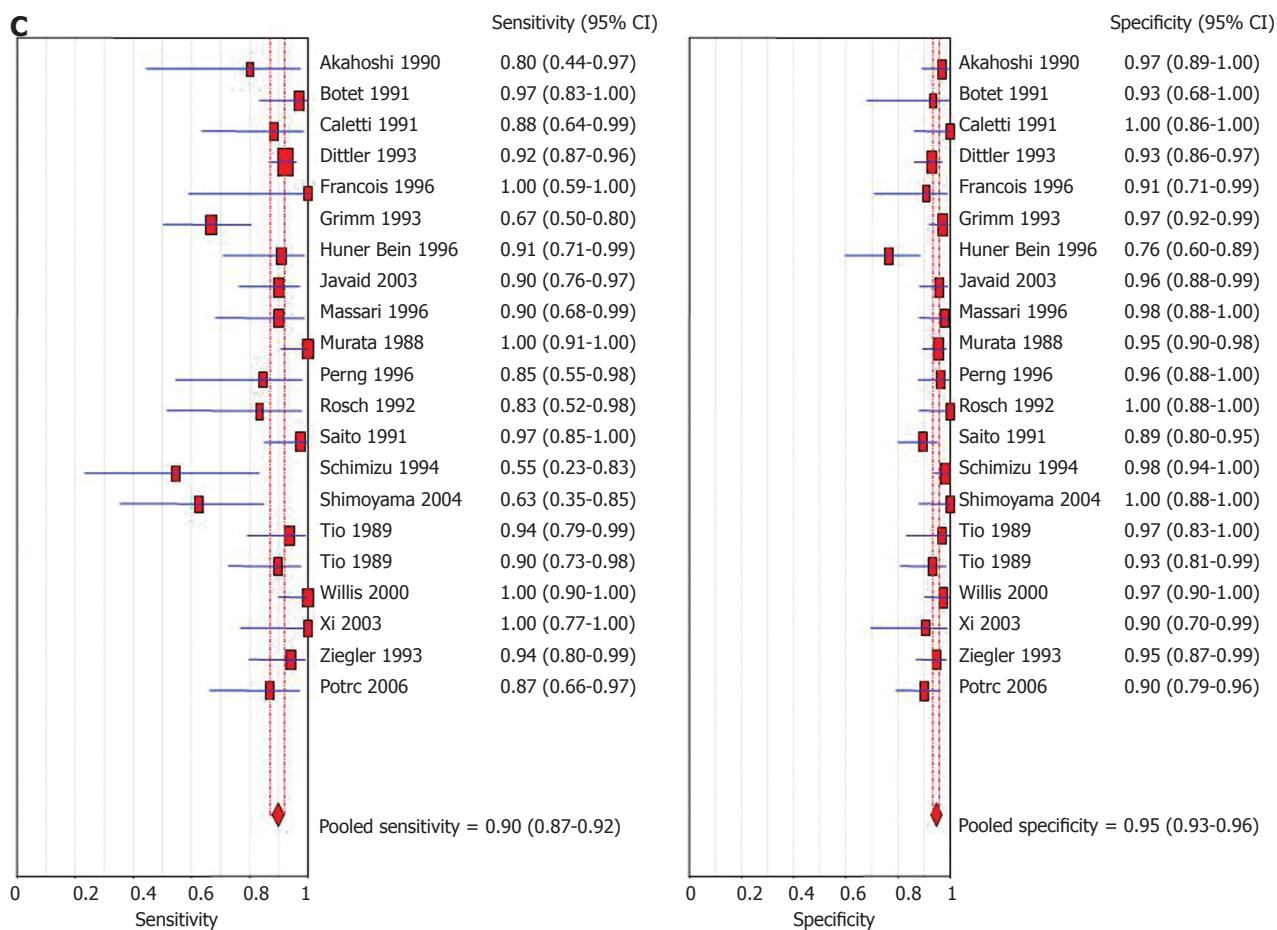

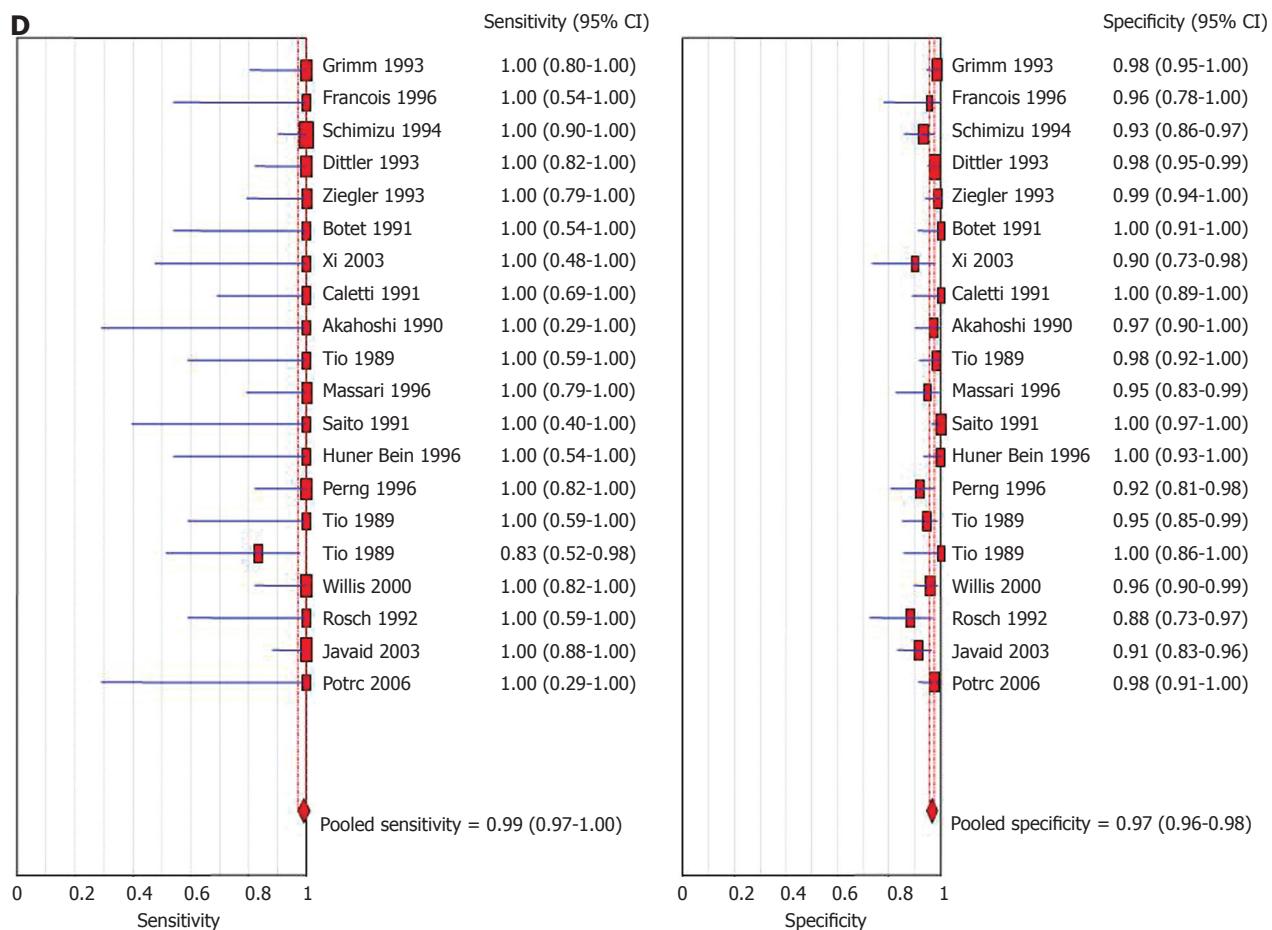

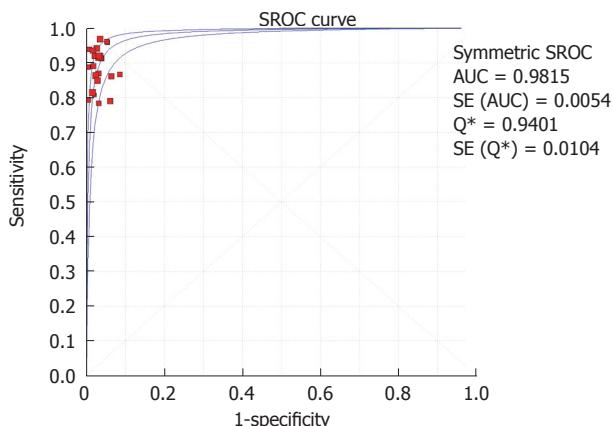

**C****D**

Figure 2 Forrest plot showing sensitivity and specificity of EUS in diagnosing T stage of gastric cancers. A: T1 Stage; B: T2 Stage; C: T3 Stage; D: T4 Stage.

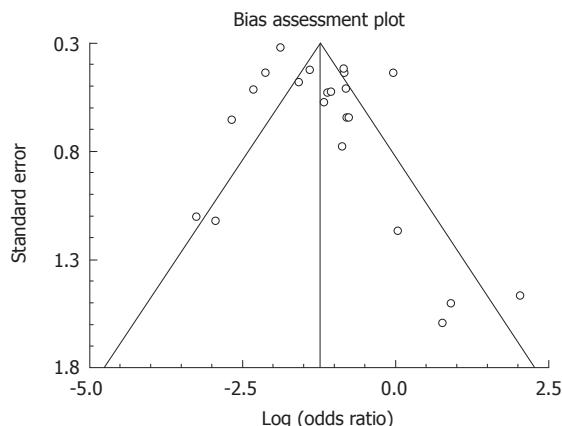

**Figure 3** Summary receiver operator curve showing AUC.

true anatomic stage of the disease when compared to patients who don't have the disease. EUS has a very high diagnostic odds ratio for T staging. For example, if EUS demonstrates a patient has T1 disease, the patient has odds of 605 times to have the correct anatomic stage of T1 disease. This helps physicians offer curative therapy either surgical or endoscopic with confidence to patients with early disease<sup>[10]</sup>. Another perspective is: if a small lesion is found with the tissue diagnosis of gastric cancer, EUS would be an excellent test to examine the depth of tumor invasion due to a very high sensitivity and specificity.

The negative likelihood ratio of a test is a measure of how well the test performs in excluding a disease state. Lower the negative likelihood ratio, the better the test performs in excluding a disease. The positive likelihood ratio is a measure of how well the same test identifies a disease state. For T staging, EUS has a low negative likelihood ratio for T4 disease when compared to T1 disease and a high positive likelihood ratio for all T stages. This indicates that EUS performs better in excluding T4 disease than T1 disease. Another perspective of looking at it is: if EUS diagnoses T2 disease then the patient might still have anatomic T1 disease but if EUS diagnoses T1 disease then the patient probably truly has anatomic T1 disease and can have curative therapy. This helps physicians offer endoscopic treatments such as EMR or ESD with confidence for T1 gastric cancer as alternatives to curative surgery<sup>[54-58]</sup>.

According to our meta-analysis, EUS is more accurate to diagnose advanced than early gastric cancer. If EUS diagnoses advanced disease, such as T4 disease, the patient is 500 times more likely to have true anatomic T4 stage of disease and will benefit from palliative therapy. This helps physicians to offer with confidence surgical and non-surgical palliative therapies such as placement of self-expanding metal stents for obstruction<sup>[59]</sup>. For nodal staging of gastric cancers, all the pooled accuracy estimates of EUS are higher for N2 (advanced disease) when compared to N1. The accuracy of EUS in diagnosing N stage is not high. Also, it is not clear if using all the three criteria together or in combination for nodal involvement improves the diagnostic accuracy. The

**Figure 4** Funnel plot showing bias assessment.

role of FNA in nodal staging of gastric cancers could not be evaluated because of lack of substantial number of studies with the data. Obtaining tissue, however, is expected to improve accuracy of EUS/FNA but more studies are needed before this is concluded.

Over the last two decades, the sensitivity of EUS for T staging improved, especially for early disease (T1). Thus EUS is vital in answering the question which patients qualify for curative therapy. EUS, however, as an imaging modality did not improve for N staging. The specificity for both T and N staging remained high during the past two decades. For distant metastasis, though the number of studies with data was smaller, the pooled specificity is high but the sensitivity is not as high. EUS as a diagnostic tool is not designed to look at distant metastasis.

Heterogeneity among different studies was determined by drawing SROC curves and finding the AUC, since different studies might use slightly different criteria for staging. An AUC of 1 for any test indicates that the test is excellent. SROC curves for EUS showed that the value for AUC was very close to 1, indicating that EUS is an excellent diagnostic test for staging gastric cancers.

Publication bias and selection bias can affect the summary estimates. Studies with statistically significant results tend to be published and cited. Smaller studies can show larger treatment effects due to fewer case-mix differences (e.g. patient with only early or late disease) than larger trials. This bias can be estimated by bias indicators and by drawing funnel plots. Bias among studies can affect the shape of the funnel plot. In this meta-analysis and systematic review, bias calculations using Egger bias indicator<sup>[24]</sup> and Begg-Mazumdar indicator<sup>[25]</sup> showed no statistically significant bias. Funnel plot also showed no significant bias.

In conclusion, EUS is an accurate and minimally invasive diagnostic tool to evaluate T stage of a patient with gastric cancer. EUS results are more accurate with advanced disease than early disease. If EUS diagnoses advanced disease, such as T4 disease, the patient is 500 times more likely to have true anatomic T4 stage of disease. Considering that new curative and palliative endoscopic therapies are emerging as an alternative

to surgery in gastric cancer, EUS should be strongly considered for staging. Our meta-analysis supports the use of EUS in determining if curative or palliative therapies are the most appropriate approach for a particular stage of the disease. Further studies are needed to improve accuracy of EUS in detecting early nodal invasion.

## COMMENTS

### Background

Gastric cancer is one of the most common cancers worldwide. The prognosis of patients with gastric cancer is determined by the tumor extent and includes both nodal involvement and direct tumor extension beyond the gastric wall. Endoscopic ultrasound (EUS) has emerged as one of the tests for preoperative staging of upper gastrointestinal cancers. The goal of this meta-analysis and systematic review by Puli *et al* was to evaluate the accuracy of EUS in staging gastric cancers.

### Research frontiers

The accuracy of EUS in staging gastric cancers has been varied, with reports that EUS understages the depth of invasion and overstages the nodal invasion because of inflammation around the tumor or in the lymph nodes.

### Innovations and breakthroughs

Due to multiple studies published that looked at EUS in staging gastric cancers but no published meta-analysis in this area, this meta-analysis was performed in an attempt to answer this very important clinical question of how good EUS is in TNM staging of gastric cancers.

### Applications

EUS is an accurate and minimally invasive diagnostic tool to evaluate the T stage of a patient with gastric cancer. EUS results are more accurate with advanced disease than early disease. If EUS diagnoses advanced disease, such as T4 disease, the patient is 500 times more likely to have true anatomic T4 stage of disease. Considering that new curative and palliative endoscopic therapies are emerging as an alternative to surgery in gastric cancer, EUS should be strongly considered for staging. Our meta-analysis supports the use of EUS in determining if curative or palliative therapies are the most appropriate approach for a particular stage of the disease. Further studies are needed to improve accuracy of EUS in detecting early nodal invasion.

### Terminology

Meta-analysis for the accuracy of EUS in staging gastric cancers was performed by calculating pooled estimates of sensitivity, specificity, likelihood ratios, and diagnostic odds ratio. Pooled was conducted by both Mantel-Haenszel method (fixed effects model) and DerSimonian Laird method (random effects model).

### Peer review

This is an interesting study; also it is a comprehensive review article, comparing the results of some authors' studies. The effectiveness of endoscopic ultrasound use for TNM staging of gastric cancers was discussed.

## Abstract

**AIM:** To prove the hypothesis that patients with chronic pancreatitis would show increased theta activity during painful visceral stimulation.

**METHODS:** Eight patients and 12 healthy controls underwent an experiment where the esophagus was electrically stimulated at the pain threshold using a nasal endoscope. The electroencephalogram (EEG) was recorded from 64 surface electrodes and "topographic matching pursuit" was used to extract the EEG information in the early brain activation after stimulation.

**RESULTS:** A major difference between controls and patients were seen in delta and theta bands, whereas there were only minor differences in other frequency bands. In the theta band, the patients showed higher activity than controls persisting throughout the 450 ms of analysis with synchronous brain activation between

the channels. The main theta components oscillated with 4.4 Hz in the patients and 5.5 Hz in the controls. The energy in the delta (0.5-3.5 Hz) band was higher in the controls, whereas the patients only showed scattered activity in this band.

**CONCLUSION:** The differences in the theta band indicate that neuropathic pain mechanisms are involved in chronic pancreatitis. This has important implications for the understanding and treatment of pain in these patients, which should be directed against drugs with effects on neuropathic pain disorders.

## INTRODUCTION

Chronic pancreatitis (CP) is defined as a disease causing inflammation of the pancreas resulting in progressive and irreversible morphological and functional derangements with end-stage exocrine/endocrine failure. The most important symptom is abdominal pain that is present in 80%-90% of patients along evolution of the disease<sup>[1]</sup>. Pancreatic pain presents characteristically with severe dull epigastric pain, eventually radiating to the back. The pain is often recurrent, intense and long-lasting, and may be associated with malnutrition, narcotic addiction and major socio-economical problems. The pain mechanisms are

incompletely understood and perhaps multifactorial. So far, the following causes have been suggested: (1) increased intrapancreatic pressure within the pancreatic duct or parenchyma ensuing tissue ischemia; (2) inflammation in the pancreas; (3) extrapancreatic causes of pain such as bile duct and duodenal stenosis due to extensive pancreatic fibrosis and inflammation, and (4) alterations in pancreatic nerves including an increase in nerve fibers and neurogenic inflammation<sup>[2]</sup>. Histological findings in the pancreas in patients with pain due to CP have revealed an increase in the number and diameter of pancreatic nerve fibers and in the amount of neurotransmitters. These findings are also seen after neuronal lesions in other tissues and have supported the theory that neurogenic inflammation plays a key role in the pain pathogenesis<sup>[3-5]</sup>. Supporting the neurogenic pain theory, the pain in CP is often described as shooting and lancinating. Therefore, it may clinically resemble that of neuropathic pain typically presenting as stimulus-independent shooting or burning pain together with stimulus-evoked hyperalgesia<sup>[6]</sup>.

Due to the difficulties to access the pancreas and potential harmful complications during the procedure, it is not possible directly to investigate whether, for example, allodynia or other characteristic features of neuropathic pain are present during manipulation of the organ. However, visceral pain is typically diffuse and difficult to localize, which to a large extend can be explained by the widespread termination of visceral afferents into 2nd order neurons in multiple segments of the spinal cord<sup>[7]</sup>. Due to this overlap in central termination of visceral afferents, disease mechanisms of the pancreas are typically also reflected during pain stimulation of the esophagus<sup>[8]</sup>. Hence, experimental models where the esophagus is involved will typically reflect any abnormal pain mechanisms relating to the pancreas. Previous studies have given evidence for neuroplastic changes and reorganization of the brain in patients with chronic and neuropathic pain<sup>[9]</sup>, and in recent experiments done by our group such changes were also seen during pain stimulation of the esophagus in patients with CP<sup>[10]</sup>. An approach to detect characteristics of neuropathic pain in CP can, therefore, be related to analysis of the electroencephalographic (EEG) during pain stimulation of the esophagus. It has been proposed that power in the theta (3.5-7.5 Hz) EEG band may be a hallmark of patients with different kinds of neuropathic pain<sup>[11-13]</sup>. Recently, Sarnthein and coworkers showed that patients with neuropathic pain disorders exhibited higher spectral power of the resting EEG especially in the theta range<sup>[14]</sup>. After treatment with a therapeutic lesion in the thalamus, the pain resolved together with normalization of the EEG abnormalities. Hence, EEG analysis may be a tool to diagnose neurogenic pain. Among the methods used for brain imaging EEG (and magnetoencephalography) has the highest temporal resolution reflecting the functions of the brain directly. However, the scalp EEG is a composite of oscillatory activity from deep neuronal sources reaching the scalp by volume conduction with major distortion of the signal. Furthermore, the overall signal is composed by infinity of electrical sources resulting in complex dynamic

changes over short time periods. Therefore, mathematical models are needed to analyze the EEG. Power analysis using, for example, Fast Fourier Transform is a commonly used method, but it does not give reliable information about the frequency content in the very short time window of less than 0.5 s representing the exogenous pain component<sup>[15]</sup>. A relatively new approach for the analysis of biomedical signals is represented by adaptive methods<sup>[16,17]</sup>. Recently, a new method called Topographic Matching Pursuit (TMP) was developed to analyze specific components of the EEG<sup>[18]</sup>. The method decomposes the multichannel EEG signal into a relatively small number of components (called atoms) chosen from a very big and redundant set (called dictionary). Such atoms are able to describe specific spatio-temporal evolution of EEG components in adaptive and very short time windows.

In the current study, TMP analysis was used to evaluate the EEG after experimental pain in the esophagus in patients with chronic pancreatitis and in healthy controls. We hypothesized that there would be differences in the theta band due to the neurogenic component involved in CP.

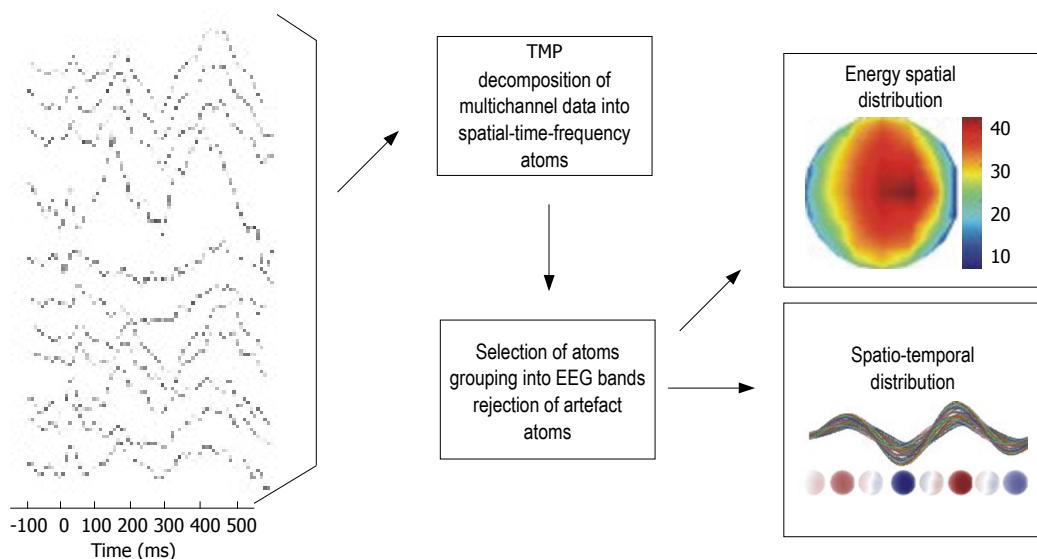

## MATERIALS AND METHODS

### Subjects

Eight patients, six men and two women, mean age 55 years (range, 53-62 years) with CP fulfilling the Marseille-Rome/Cambridge diagnostic criteria<sup>[19]</sup> were enrolled in the study. They all had intermittent pain attacks characteristic for CP and were only included if they had no present alcohol abuse or chronic intake of painkillers. The duration of the pancreatitis was mean 6.1 (range, 1-10) years and the mean frequency of the pain was 5.0 times a week (range, 2-7) with a mean duration of 3.9 h (range, 2-9). None of the patients had any other diseases associated with pain or any history of neurological diseases. Twelve volunteers (ten men and two women, median age 37.5 years (23-49) served as controls. They were all healthy without any gastrointestinal symptoms or disorders associated with pain. The study was conducted according to the Helsinki II Declaration and approved by the Ethical Committee of North Jutland (No. VN 2003/120 mch).

### Experimental protocol and gut stimulation

The subjects were fasting 8 h before the experiment. The same method as previously described was used<sup>[20]</sup>. Briefly, intubation of the esophagus was done through the nose with a 6 mm endoscope [Ultra Slim Gastroscope (Pentax EG-1840)]. The device for bipolar electrical stimulation was inserted through the biopsy channel in the endoscope. The stimulator was positioned 5 cm above the gastro-esophageal junction. A constant current electrical stimulator (Noxitest, Aalborg, Denmark) was used to deliver the visceral stimuli. The intensity of the current was limited to 80 mA and the voltage to 200 V. Before all stimulations the inter-electrode impedance was measured to be < 2 kΩ, securing optimal electrode position throughout the experiment. The intensity of the current was gradually increased in steps of 0.1-0.5 mA until the

**Figure 1** The analysis scheme used for the data investigation. The EEG data were decomposed into a set of TMP atoms, which parameterized the data. Next, the atoms were grouped into bands according to their frequency parameter. This allowed convenient analysis of time and spatial properties of oscillations in all frequency bands.

sensation changed from unpleasantness to pain (pain detection threshold). During the experiment the subject rested quietly and relaxed with the eyes open and was asked to minimize blinking and focus on a fixed point. A single stimulus consisted of 5 fast rectangular constant current pulses at 200 Hz with duration of 1 ms<sup>[21]</sup>. Thirty-five single stimuli were applied with intensity at the pain threshold with an inter-stimulus interval of 5 s. During the stimulations the subjects were observed by a physician, and the electrocardiogram was continuously monitored.

### Recordings

The EEG was recorded from 64 surface electrodes using a standard EEG cap (Quick-Cap International, Neuroscan, USA) following the extended international 10-20 system. The impedance of the electrodes was below 2 kΩ. In addition, two electrodes were placed at the right upper brow and the left external canthus to monitor eye movements. A linked-ears reference was used. EEG signals were recorded and sampled at 1000 Hz, and bandpass filtered between 0.05 Hz and 70 Hz (SynAmps, Neuroscan, USA).

### EEG analysis using TMP

Following the recording, thirty-five single trials were visually examined for artifacts. The contaminated epochs were removed off-line. The data were then baseline corrected and corrected for linear trends (SynAmps, Neuroscan, USA). The artifact free epochs of 450 ms were then collapsed into a single average file. The averaged data from the patients and controls were submitted to TMP analysis. In summary, the TMP is an adaptive and iterative algorithm. It creates spatio-temporal data approximations using a relatively small number of simple components (called atoms) chosen from a very big and redundant set (called dictionary). The TMP method is based on the Matching Pursuit algorithm<sup>[22]</sup>. However, the standard "Gabor atoms" used in the Matching Pursuit describes only the temporal evolution of EEG components in a single channel or channel-averages. The TMP uses atoms, which are distributed in time and space

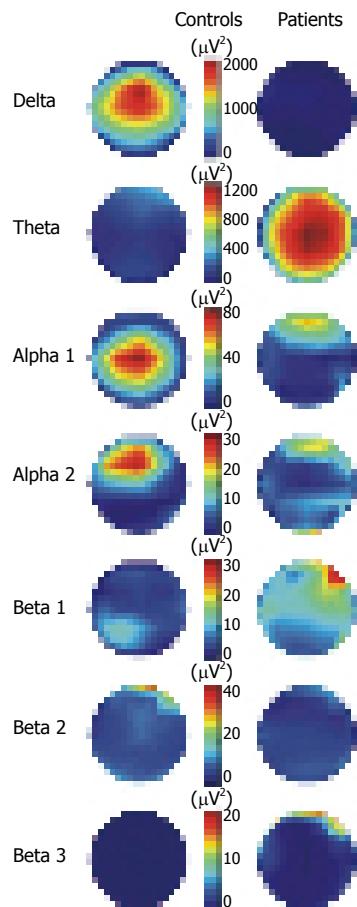

enabling the analysis of multichannel data. The TMP atoms are very well localizable in time, frequency and space domains and are described by only a few parameters. This approach simplifies analysis of multichannel data and enables identification and extraction of spatio-temporal components with biological meaning as well as identification of artifacts.

Figure 1 shows the analysis scheme used for the data in this study. First, the EEG data were decomposed into TMP atoms. Twenty atoms per subject were used. The computed atoms were grouped into frequency bands according to their modulation (frequency) parameter. This is an equivalent of a band-pass filtering into delta (0.5-3.5 Hz), theta (3.5-7.5 Hz), alpha1 (7.5-10 Hz), alpha2 (10-12.5 Hz), beta1 (12.5-18 Hz), beta2 (18-24 Hz) and beta3 (24-30 Hz). Typically, each frequency band was represented by one to three atoms. For each atom or group of atoms from a specific band, a spatial distribution of signal's energy as well as spatio-temporal patterns was examined.

## RESULTS

All subjects reported painful sensations to the electrical stimulation of the esophagus. The mean current intensities (at the pain thresholds) for the controls and patients were  $12.8 \pm 3.9$  mA and  $10.0 \pm 1.4$  mA, respectively ( $P = 0.08$ ).

The grand mean averages of the spatial distributions of signal energy during the 450 ms analysis after the evoked esophageal pain for patients and controls are shown in Figure 2. The spatial distributions are shown separately for the delta, theta, alpha and beta bands. Clearly major differences between controls and patients were seen in the delta and theta bands, whereas there were only minor differences in the other frequency bands. In Figure 3, the temporal evolution together with the spatial distribution maps of energy for the delta and theta activities in the analyzed time period are shown in the two groups. The butterfly plots showing the individual channels show that the mean amplitude (energy) in the delta band was higher in the controls. The patients only showed scattered activity in this band without any

**Figure 2** The spatial distribution of energy divided into frequency bands for patients and controls throughout the 450 ms of analysis. Note that a different color scaling for each frequency band was used.

consistency between the individual channels. In the theta band, the patients showed higher activity than controls and the theta activity persisted throughout the 450 ms of analysis, whereas in controls it was strongly attenuated after 250 ms. Finally, the theta activity had a lower frequency in the patients. The main theta components oscillated with about 4.4 Hz in the patients and with about 5.5 Hz in the controls. When the mean activity in the patients was subtracted from that in controls (difference in the Figure 3), there were major differences in energy. The delta activity in controls and theta activity in patients had similar amplitudes and topographic distributions. However, the delta oscillations in controls were slightly stronger in the frontal lobe, whereas the theta activity in patients was stronger in the parietal lobe (Figure 3B1 and 3B4).

In Figure 4, the topography relating to the time evolution in the delta and theta bands are shown. The time evolution of the spatial distribution showed differences for patients and controls. The oscillations in the delta band for controls were synchronous with a stable monopolar spatial distribution. This means that there were only minor and constant phase differences between channels. In contrast, the patients exhibit slightly larger phase differences between different channels which desynchronized the oscillations (see arrows in Figure 4). The amplitude of the oscillations was also smaller for patients in the delta band. However, in the theta band the patients exhibit synchronous brain activation with almost constant and relatively small phase differences between the channels. The theta activity for controls, however, had inconstant phase differences between channels. The

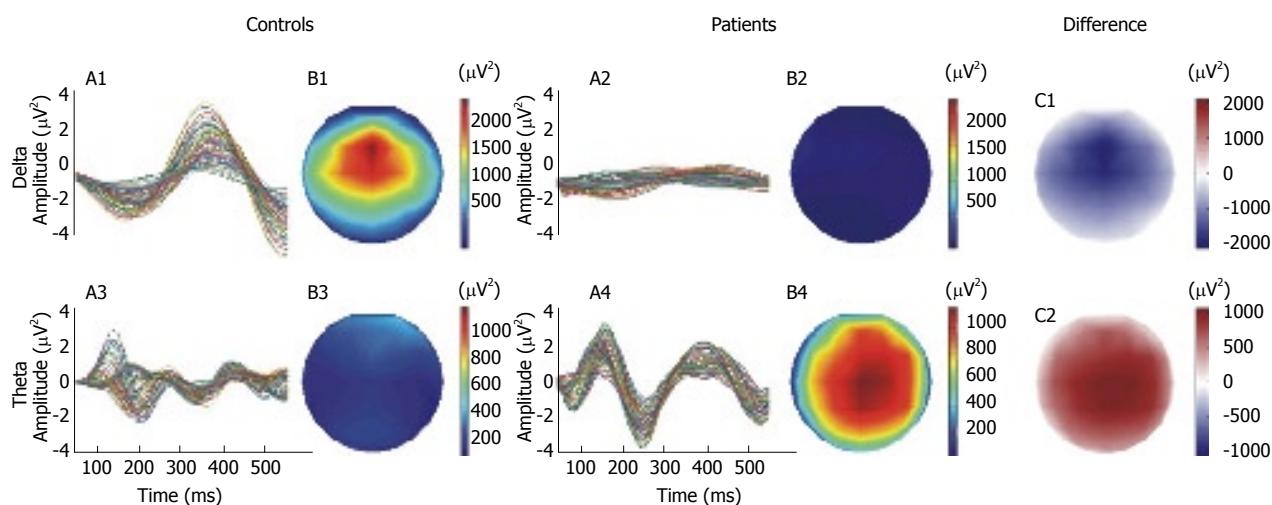

topographical EEG data evolution of the theta activity was rather consistent in all patients as shown in Figure 5.

## DISCUSSION

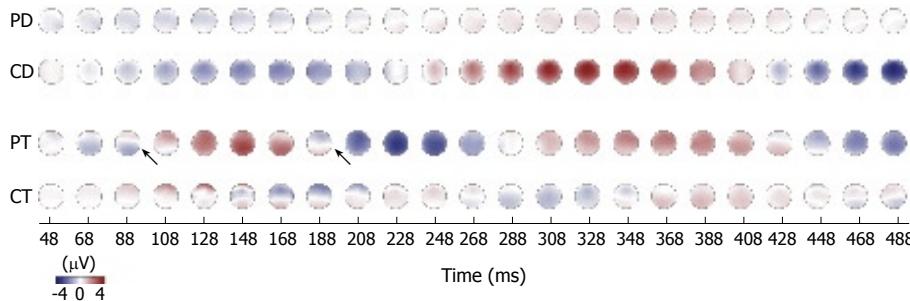

The topographic matching pursuit method allowed multichannel signal decomposition of EEG data and showed that during evoked visceral pain there are major differences in the delta and theta band between patients with chronic pancreatitis and healthy controls. The differences in the theta band were the most consistent and indicate, together with previous observations, that neuropathic pain mechanisms may be involved in chronic pancreatitis.

In the classical description of EEG, time and frequency distribution is computed using frequency analysis, but as the specific brain processing of phasic exogenous pain stimuli is very short lasting (about 100-200 ms)<sup>[15]</sup> ordinary signal analysis cannot be used (see below). To encompass the problems with time-resolution, some researchers have used a tonic pain stimulus<sup>[23]</sup>. However, tonic pain with the same intensity is difficult to evoke consistently in GI tract where, for example, long-lasting stimulation typically creates a waxing or waning response<sup>[24-26]</sup>. Furthermore, nausea and vomiting is often evoked interfering with the cortical response<sup>[27]</sup>. Hence, in experimental pain experiments of the gut phasic stimuli such as electrical stimulation of the mucosa are often used. Another way to overcome the problems with analysis of short time segments is to give a series of stimuli and compute the evoked brain response based on summation of the stimulus sequences<sup>[28]</sup>. However, such averaged evoked brain responses carry the risk for discarding much of the dynamic information contained in the original data<sup>[20]</sup>. To obtain detailed information of the EEG in individual channels, other methods where the signal is analyzed must, therefore, be added.

Common analysis schemes of multichannel bioelectromagnetic data involve analysis of selected single channels in the time or time-frequency domain. Typically, methods such as Wavelet Transform are used to extract the time-frequency information from the data. These represent signals by correlations with all their basis functions. This may result in "blurred" representations of data when some simple signal components are represented in terms of many basis functions and interpretation can be difficult. Further, they are only stable for rather long EEG segments and discrete changes relating to the exact time and duration of individual waveforms cannot be measured<sup>[18]</sup>. The TMP method represents a completely different approach to signal analysis. It is able to decompose the data under analysis into a relatively small number of simple components. Such a concise description of the data simplifies the analysis and interpretation of the results. The parameterization of signal components allows convenient further analysis. It enables identification and separation of signals with biological origin or removal of artifacts<sup>[18]</sup>. Each signal component is represented by a TMP atom that can be inspected individually in the time, frequency and space domains, and a topographic distribution of amplitude and phase differences between

**Figure 3** The temporal evolution and the spatial distribution maps of energy of the delta and theta activities for the 450 ms of analysis. In the right panel, the difference maps of energy were computed by subtracting the energy maps of controls from the patients.

**Figure 4** The time evolution of amplitude distribution for delta and theta bands in patients and controls. Note the stable, monopolar spatial distribution of delta activity in controls (CD). This is due to constant and small phase differences between measurement channels. The theta activity in patients has slight changes in phase and, therefore, the spatial distribution is not always stable (see arrows). PD: Patients delta; PT: Patients theta; CD: Controls delta; CT: Controls theta.

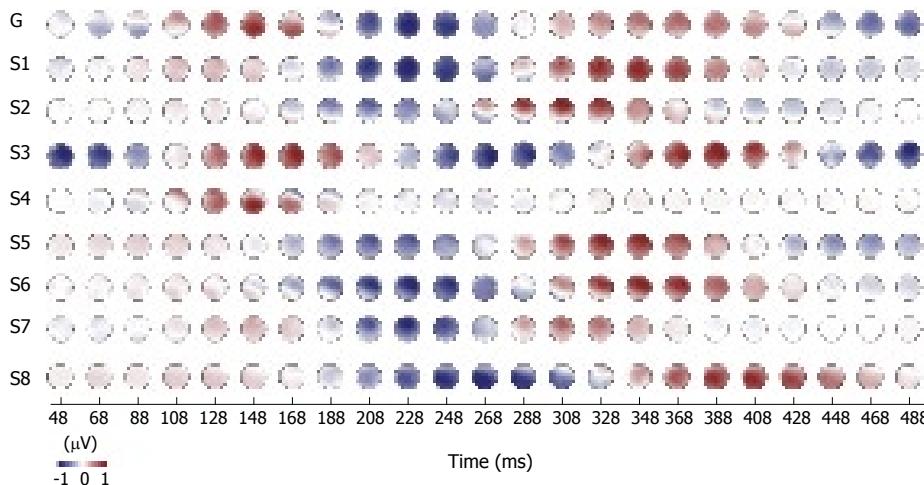

channels can be plotted. Additionally, temporal changes of amplitude topography can be analyzed. This allows identification of patterns and components in the time-frequency-space domain. The main disadvantage of the TMP algorithm is its high computation cost.

We used electrical stimulation of the esophagus to mimic the visceral pain response. Although the pain was not evoked in the pancreas per second, the visceral afferents terminate rather diffuse in the spinal cord affecting many neurons at different segmental levels<sup>[7]</sup>. Hence, the esophagus innervates neurons spreading from C5-L2 explaining the diffuse pain seen in the clinic<sup>[29]</sup>. The visceral afferents from different organs terminate often in the same functional neuron pool, resulting in viscero-visceral convergence (e.g. pain from one visceral can cause a change in the sensory response in another<sup>[30]</sup>). In accordance with the neurophysiologic findings we have previously shown that patients with pancreatitis have hypoalgesia to distension in both the esophagus and duodenum<sup>[8]</sup>. Furthermore, that the latency of the evoked brain potentials to electrical stimulation of both the esophagus and duodenum was decreased in these patients<sup>[10]</sup>. Thus it is most likely that any neuroplastic changes and abnormal mechanisms in the pain processing caused by the intermittent pancreatic pain will also affect visceral pain evoked in the nearby organs.

Neuropathic pain is typically described as stimulus-independent shooting, lancinating or burning pain<sup>[6]</sup> resembling the pain in CP. Recently, evidence for a neuropathic component of the pain in CP was provided

by histological findings demonstrating an increase in the number and diameter of pancreatic nerves. Furthermore intensification of neurotransmitters, such as substance P, calcium gene-related peptide and interleukin 8, being markers of neuronal plasticity were found<sup>[5]</sup>. The growth-associated protein-43 is increased after neuronal lesions and has been found in the majority of pancreatic nerve fibers with a correlation with the pain scores<sup>[31]</sup>. As increased activity in the theta band seems to be a marker of neuropathic pain<sup>[14]</sup>, the current findings strengthen this neuropathic pain hypothesis in CP. The increased theta activity may reflect a thalamocortical dysrhythmia, as shown with coherence between direct single-unit thalamic recordings in patients suffering from ongoing neuropathic pain and other neurological disorders<sup>[12,13]</sup>. In these studies, it was hypothesized that the theta activity reflects a disturbance in the thalamocortical interplay needed for higher cognitive functions such as those engaged in pain. The normalization of the EEG after therapeutic lesions in the thalamus (and a 95% reduction of the pain), further support this hypothesis<sup>[14]</sup>. Our patients all suffered from intermittent pain and hence we studied evoked gut pain and not the resting EEG. Besides a demonstration of increased theta activity we were able to show that the activity persisted throughout the 450 ms of analysis, whereas it faded out in controls. Furthermore, the theta pattern was consistent in all patients.

The low activity in the delta band was consistent in all patients. However, there was a major spread between subjects and the features were more difficult to

**Figure 5** Normalized time evolution of amplitude distributions for theta bands in patients with chronic pancreatitis No. 1-8. G: Grand mean of all patients.

interpret. Increase in delta power, especially in the frontal derivations has been shown in some previous studies using experimental tonic pain<sup>[23]</sup>, but the findings were not consistent<sup>[32-34]</sup>. Recently, we used independent component analysis of the EEG following esophageal stimulation in healthy subjects<sup>[20]</sup>. In this experiment, electrical pain evoked dominant synchronous activity in the delta band in several brain regions, especially in the components with dipoles in the thalamus and cingulate cortex. Whether the difference between controls and patients seen in the current study reflects the expected delta power increase during experimental pain in healthy volunteers, or whether it is a feature of chronic pain remains to be investigated in further detail.

The findings of the current study may have clinical implications. Treatment of chronic pancreatitis is difficult and it often becomes necessary to use strong analgesics such as opioids<sup>[11]</sup>. However, drugs shown to be effective in neuropathic pain also seem to be efficient. Hence, Wilder-Smith *et al* showed that tramadol, a weak opioid drug with several non-opioid effects in the central nervous system, in high doses was superior to traditional opioids in the treatment of pain in CP<sup>[35]</sup>. Tricyclic antidepressants and pregabalin, which are also effective in neuropathic pain, have in our experience been of value as adjuvant therapy in difficult patients. Obviously, it could be interesting to use the current method before and after effective therapy of pain in patients with CP.

The increased theta activity during experimental visceral pain in patients with chronic pancreatitis gives further evidence that the pain mechanisms in this disease share many features with those seen in neuropathic pain. This has important implications for the clinical understanding and treatment of pain in chronic pancreatitis, which may be directed against drugs with effects on neuropathic pain disorders.

## COMMENTS

### Background

The pain mechanisms in chronic pancreatitis are incompletely understood, but it has been suggested that neuropathic mechanisms (like in phantom pain) are important. The energy in the theta (3.5-7.5 Hz) band of the electroencephalogram may be a hallmark of patients with neuropathic pain, and we compared the energy in the theta band during painful stimulation of the esophagus in patients

with chronic pancreatitis and in healthy controls.

### Research frontiers

Histological findings in the pancreas in patients with pain due to chronic pancreatitis have mimicked those seen in patients with neurogenic inflammation. The neurogenic theory is also supported by clinical and experimental findings.

### Innovations and breakthroughs

To assess the neurophysiological mechanisms standardization of the pain stimulus in experimental settings is necessary. During short-lasting experimental pain stimulation of the esophagus, as used in the paper, it is difficult to compute discrete electrophysiological signals using conventional methods. We, therefore, used a new method called "Topographic Matching Pursuit" and found a selective increase of the theta energy in the patients during the evoked esophageal pain.

### Applications

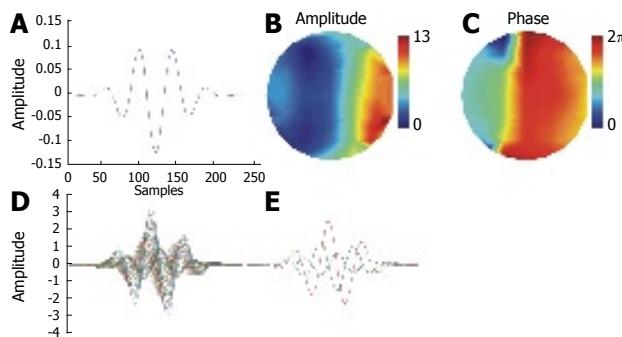

The increased theta activity during experimental pain gives further evidence that the pain mechanisms in chronic pancreatitis share many features with neuropathic pain. This has important implications for the clinical understanding and treatment of pain in chronic pancreatitis.

### Peer review

The differences in the theta band indicate that neuropathic pain mechanisms are involved in chronic pancreatitis. This has important implications for the understanding and treatment of pain in these patients, which should be directed against drugs with effects on neuropathic pain disorders.

## APPENDIX

Topographic Matching Pursuit (TMP) is an adaptive method for sparse decomposition of multichannel signals. It is based on the Matching Pursuit (MP) algorithm<sup>[36-39]</sup>. It iteratively creates approximations of signals using relatively small number of simple components chosen from a very big and redundant set. The components are called atoms. A set of atoms is called dictionary. Typical atoms are scaled and modulated as translated Gaussian functions and are called Gabor atoms. The advantage of Gabor atoms is their optimal time-frequency resolution. MP has very interesting and useful properties. However, it can be directly used only for decomposition of single-channel data, because Gabor atoms are distributed only in time. Biomedical signals are typically measured with multiple sensors. The TMP algorithm is searching the standard MP dictionary to find a Gabor atom, which has the biggest similarity simultaneously to all measurement channels. A multichannel extension of the MP algorithm was discussed by Gribonval and applied to EEG data by Durka *et al*<sup>[40]</sup>. In the TMP version of multichannel MP the amplitude and the phase shift of the Gabor atom is optimized for each channel in order to obtain the

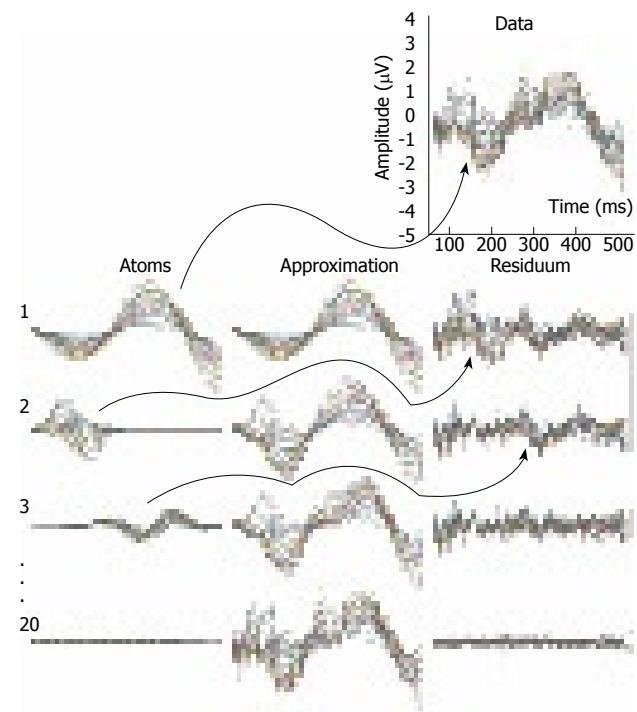

**Figure Appendix1** Example of a TMP atom for a 61 channel EEG system. **A:** Base Gabor atom; **B:** Spatial distribution of amplitude; **C:** Spatial distribution of phase; Overlay plots of the TMP atom: All 61 channels (**D**), channels 1, 10 and 30 (**E**).

highest correlation of the Gabor atom with the respective channel. The Gabor atom with the highest value of the sum of squared correlation coefficients with all measurement channels is chosen for the approximation in the first iteration: with  $\text{Fi-i-th}$  data channel,  $g_{\gamma}$ -atom from the dictionary with index  $\gamma$ .

The correlation coefficients define a topographic distribution of amplitude over measurement channels. One can describe a TMP atom as a Gabor atom with an additional list of amplitudes and phase shifts for all channels (Figure Appendix1). A high amplitude value for a particular channel indicates strong presence of the component in this channel. In contrast, a low amplitude value denotes that the component is weakly present in this channel. Next, the TMP atom which has the biggest similarity with the multichannel data under analysis (as described above) is subtracted from the data. This creates the first order spatio-temporal residuum of the data. The data under analysis can be treated as the 0th order residuum. The further steps of the TMP algorithm can be summarized in the three iterative points: (1) Search the dictionary for the atom, which has the biggest similarity (correlation) with the previously computed spatio-temporal residuum. (2) Create the next order residuum by subtracting the chosen atom from the previously computed residuum. (3) Repeat steps 1 to 2 until the current residuum is sufficiently low.

An example of decomposition of EEG data is presented in Figure Appendix2. The EEG data is presented in the top right corner. Each row in the figure represents one iteration of the TMP algorithm. The chosen atoms and computed approximations with their respective residues for four different iterations are presented. The approximations are computed by summing atoms from all previous and the present iteration. With increasing number of iterations, one can observe the convergence of the approximation to the EEG data. Simultaneously, the residuum, which is the difference between the data and the approximation, is vanishing.

The result of the TMP algorithm is a set of TMP atoms. The sum of the atoms approximates the data under analysis. The TMP atoms are localized very well in the time, frequency and space domains. They have six

**Figure Appendix2** Example of decomposition of multichannel EEG data. The data is presented in the top-right corner (61 channels overlay plot). In the following rows chosen atoms, approximations and residues for the 1st, 2nd, 3rd, and 20th iteration are shown. In each iteration the chosen atom is the most similar one with the previously computed residuum (see arrows). The residuum is created by subtracting the chosen atom from the residuum computed in the previous iteration. The signal itself can be treated as the 0th order residuum. The approximation in each iteration is the sum of all atoms chosen in the present and previous iterations. Hence, in the first iteration the chosen atom is simultaneously the first approximation of the data. Note that with the increasing number of iterations the approximation is approaching the data and the residuum is vanishing. All time plots of atoms, approximations and residues are 61-channel overlay plots shown in the same scale.

parameters: scale (time length), modulation (frequency), translation (time localization), and relating to the different channels-a spatial distribution of phase and amplitude. Thus, the choice of the atoms for the approximation parameterizes the multichannel data under analysis. This allows convenient analysis and processing of such parameterized data. For example it enables identification and separation of signal components with biological origin or removal of artifacts. Each signal component represented by a TMP atom can be inspected individually in the time, frequency and space domains. A topographic distribution of amplitude and phase differences between channels can be plotted. Additionally, temporal changes of amplitude topography can be analyzed. This allows identification of patterns and components in the time-frequency-space domain.

## Abstract

**AIM:** To develop a novel model of colitis in rats, using a combination of iodoacetamide and enteropathogenic *E. coli* (EPEC), and to elucidate the pathophysiological processes implicated in the development of ulcerative colitis (UC).

**METHODS:** Male Sprague-Dawley rats ( $n = 158$ ) were inoculated intrarectally on a weekly basis with 4 different combinations: (a) 1% methylcellulose (MC), (b) 100  $\mu$ L of 6% iodoacetamide (IA) in 1% MC, (c) 200  $\mu$ L containing  $4 \times 10^8$  colony factor units (CFU) of EPEC, and (d) combined treatment of (IA) followed by bacteria (B) after 2 d. Thirty days post treatment, each of the four groups was divided into two subgroups; the inoculation was stopped for one subgroup and the other subgroup continued with biweekly inoculation until the end of the experiment. Colitis was evaluated by the clinical course of the disease, the macroscopic and microscopic alterations, activity of myeloperoxidase (MPO), and by TNF- $\alpha$  gene expression.

**RESULTS:** Findings indicative of UC were seen in the combined treatment (IA + B) as well as the IA conti-

## INTRODUCTION

It is well established that ulcerative colitis (UC) is an inflammatory condition of the gastrointestinal tract (GIT), resulting from interrelated genetic and environmental factors, especially bacteria which cause disruption of the mucosal barrier thus exposing the mucosal immune system to luminal bacteria and bacterial products<sup>[1]</sup>.

For several years, researchers have been addressing the question as to whether a specific pathogen could cause inflammatory bowel disease (IBD)<sup>[2]</sup>. Attempts made, so far, to find a causative bacterial strain for IBD, and particularly for UC, have been unsuccessful. Over the years, evidence has accumulated implicating endogenous luminal bacteria in the pathogenesis of

UC, especially since the highest bacterial concentration and diversity are found in the colon. Much attention has been given to the role of *E. coli* in the onset of UC, since this organism is the predominant facultative anaerobic gram negative species of the normal intestinal flora. *E. coli* play an important role in promoting the stability of the intestinal microbial flora and in maintaining the normal intestinal physiology<sup>[3]</sup>. Besides commensal strains, certain clones of *E. coli*, possess virulent properties that cause disease in humans. More recently, it has been suggested that a particular subtype of *E. coli* may play a pathogenic role in UC<sup>[4,5]</sup>. Studies on mucosal adhesion of pathogenic bacteria in UC revealed an enhanced adhesion of *E. coli* isolates (obtained from stool specimens and rectal biopsies of UC patients) to buccal epithelial cells causing mucosal damage similar to that seen with enteropathogenic *E. coli* (EPEC)<sup>[4-7]</sup>. Adherence of EPEC strains on the intestinal mucosa is a complicated process and produces dramatic effects on the ultrastructure of the cells resulting in reduced tight junction density and leaky epithelial barrier<sup>[7-9]</sup>.

More than 60 different experimental models of IBD have been developed in the past two decades<sup>[10,11]</sup>. These studies confirmed the need for the presence of normal enteric flora for the development of experimental colitis<sup>[12-15]</sup>. However, none of the models mimic precisely the human disease. Therefore, more studies are required to further develop this area of research. The iodoacetamide-induced acute UC model in rat developed by Satoh *et al*<sup>[16]</sup> has been extensively studied<sup>[17,18]</sup>. In this model, an array of morphological and functional alterations have been described, however, the model lacked features of chronicity<sup>[17-20]</sup>.

The present study reports the successful development of a chronic UC model, using the combined effects of iodoacetamide, a sulphydryl group blocker, and enteropathogenic *E. coli* (EPEC), a strain with adhesion properties, instilled repetitively into the descending colon of rats.

## MATERIALS AND METHODS

### Animals

A total of 158 adult male Sprague-Dawley rats, weight range  $200 \pm 25$  g, were used in this experiment in accordance with the criteria of the Institutional Animal Care and Use Committee for the care and use of animals. The study was conducted at the American University of Beirut. Animals were housed in rack mounted cages, with a maximum of 10 rats per cage, and kept on a 12 h light/dark cycle in a controlled temperature and humidity room. Standard laboratory pelleted formula and tap water were provided ad libitum.

### Induction of experimental colitis

The rats were randomized into 4 groups: (1) the methylcellulose treated control group ( $n = 37$ ), the animals were inoculated intrarectally on a weekly basis with 100  $\mu$ L of 1% methylcellulose (MC), the vehicle (Sigma, M-0512, USA); (2) the iodoacetamide-treated group ( $n = 42$ ), in

this group the rats were inoculated with 100  $\mu$ L of 6% iodoacetamide (IA) (Sigma, I-6125, USA) dissolved in methylcellulose according to the previously described study by Satoh *et al*<sup>[16]</sup>; (3) The bacteria-treated (B) group ( $n = 37$ ), this group was inoculated with 200  $\mu$ L suspension containing  $4 \times 10^8$  colony factor units of EPEC; (4) The combined treatment group ( $n = 42$ ), received a combination of iodoacetamide and bacteria (IA + B); this group was inoculated intrarectally on a weekly basis with the same doses of IA followed by bacteria after 48 h. Experimental colitis was induced by regular weekly intracolonic inoculation, 7 cm proximal to the anal verge using a 2 mm diameter polyethylene tube. On day 30, each group was split into 2 subgroups. In one subgroup, the inoculation of different treatments continued bi-weekly while in the second subgroup the treatment was discontinued. Three rats from each group and later subgroup (after 30 d), were anesthetized by intraperitoneal injection of sodium pentobarbital (75 mg/kg body weight) and sacrificed on day 3, 7, 14, 21, 42, 56, and 70. A portion of the colon was fixed in 10% formalin while the remaining part was stored at -80°C.

### Clinical course assessment

The animals were observed on a daily basis and checked for diarrhea, loose stools, gross rectal bloody stools, or any other gross abnormalities. The weight of each animal was obtained on a weekly basis to check for weight loss after induction of colitis. These observations were reported as a numerical score (Table 1).

### Macroscopic assessment

The evaluation of inflammation was performed according to the modified criteria for colonic changes (Table 1)<sup>[17,21]</sup>. Parameters like diarrhea, hyperemia, adhesions, ulceration and megacolon were assessed to describe the inflammatory status. Each colon was assigned, in a double blind way, a score on a scale ranging from 0 (normal) to 15 (maximal activity of colitis) indicating ulcerations and severe inflammation of the colon.

### Microscopic assessment

The descending colon was removed and immersed in cold phosphate buffer (PBS) at pH 7.4. A 1.0 cm piece of the colon was removed proximal to the site of inoculation. It was immediately immersed in 10% buffered formalin and was processed for routine light microscopy according to standard procedures. Serial 5  $\mu$ m sections were cut and stained with hematoxylin and eosin (HE) and Periodic Acid Schiff (PAS) using standard methods. The microscopic alterations were assessed according to the criteria shown in Table 2<sup>[17-22]</sup>, and a numerical score of the colonic abnormalities was obtained. The histologic grades ranged from 0 (normal) to 18 (intense inflammatory reaction). The scoring was based on the findings of 2 independent observers obtained by examining six sections from each colon. Thus, the scores represented the average of 36 readings (2 observers, 6 sections per animal and 3 animals per time point). The histological abnormalities

**Table 1 Criteria for macroscopic grading of the experimental colitis**

Feature	Macroscopic grading			
	0	1	2	3
Stool	Normal	Loose stool	Diarrhea	Diarrhea with blood
Hyperemia	None	Focal	Focal and thickening of bowel wall	Extensive thickening of bowel wall
Adhesions	None	Mild	Moderate	Extensive
Megacolon	None	Mild	Moderate	Toxic megacolon
Ulcerations	None	Mild ulceration on one side < 1 cm	Moderate ulceration > 1 cm	Severe damage extending > 2 cm

**Table 2 Criteria for microscopic grading of experimental chronic colitis**

Feature	Histologic grading			
	0	1	2	3
Abnormalities of mucosal architecture	None (Normal)	Mild or focal, not exceeding lamina propria	Moderate, not exceeding the submucosa	Severe & diffuse, exceeding the submucosa
Crypt abnormalities	None	Mild atrophy	Moderate atrophy, Branched crypts	Severe atrophy, branched crypts, cryptitis, crypt abscess
Inflammatory cell infiltration	Normal	Scattered cells	Moderate or confluent cells	Massive infiltration of cells
Vascular dilatation	Normal blood vessels	Mild dilatation (localized)	Moderate dilatation of several blood vessels	Severe generalized dilatation of blood vessels
Edema	None	Low level limited to villi	In the submucosa	All over the section
Mast cells	Normal scattered cells	Three cells clustered in submucosa	Clusters of > 3 cells in the submucosa	Clusters in submucosa and serosa

were photographed and the findings were reported as numerical scores.

#### **Colonic inflammation assessment by myeloperoxidase activity (MPO)**

The assessment of MPO activity in the mucosal scrapings was carried out as a quantitative marker for granulocytic infiltration in the colonic tissue. Protein concentration and quantification were determined in the mucosal scrapings of the descending colon using the protein assay reagent kit (Bio-Rad). One unit of MPO activity was defined as the quantity of enzyme able to convert 1 μmol/min of hydrogen peroxide at 25°C as described by Krawisz *et al*<sup>[23]</sup>. The results were expressed as MPO units per gram of wet tissue.

#### **Analysis of TNF-α mRNA by reverse-transcriptase PCR (RT-PCR)**

Total RNA was extracted from colonic tissues by TRI Reagent (Invitrogen) reagent. RNA was resuspended in RNase free water, quantified and subjected to RT-PCR reaction using RT-PCR kit; Ready Mix Version (Abgene, Promega). RT-PCR was performed on the final volume of 25 μL containing 12.5 μL ready mix (optimize reaction buffer, dNTP mix, MgCl<sub>2</sub> and DNA polymerase), 0.5 μL of 25 pmol specific primers as described for TNF-α, β-actin, 0.5 μL of reverse transcriptase and 1 μg of RNA. Reverse transcription was performed at 48°C for 30 minutes, followed by heating for 2 min at 94°C. Then 45 cycles of PCR for TNF-α and 25 cycles for β-actin was performed using the following conditions: denaturation at 94°C for 30 s, annealing temp of 55°C for 60 s and extension

temperature of 68°C for 2 min, followed by a final extension step at 68°C for 7 min. The primers were TNF-α sense, 5'-AGAACT CCAGGCGGTGTCC-3'. TNF-α antisense, 3'-GATTCTGTGGGGACTCCC T-5' (484 bp). β-actin sense, 5'- AAC CCT AAG GCC AACCGTGAAAAG-3'; β-actin antisense, 3'-ATA CAACGGGATCTGAAGCTCG-5' (540 bp). The PCR products were separated in 1.5 % agarose gel electrophoresis and visualized by ethidium bromide staining (1 μg/mL). The DNA product sizes were estimated relative to 100 bp DNA ladder. A control reaction were run to rule out contamination of RNA with genomic DNA, in which reverse transcriptase was omitted from the reaction mixtures. Transcripts were normalized to the corresponding β-actin band and expressed as arbitrary density units.

#### **Analysis of TNF-α level by western blot**

Protein isolation was carried out by lysing colonic mucosal scrapings in 1.5 mL homogenization buffer (NaCl 11.7 g/L, MgCl<sub>2</sub>·6H<sub>2</sub>O 1 g/L, EDTA 0.76 g/L KCl 0.37 g/L, Tris 24.2 g/L, pH 7.4) using polytron homogenizer on ice. The homogenates were subjected to 30 s sonication and centrifugation at 12000 r/min for 10 min at 4°C. The protein content of the supernatant was quantified by Bio-Rad Reagents. The protein samples diluted in sample buffer 2X (10% glycerol, 5% betamercaptoethanol, 4% SDS, 125 mmol/L Tris-HCL 1 mol/L pH 6.8 and traces of bromophenol blue) were loaded as 40 μg/lane in 12% SDS-acrylamide gels, separated by electrophoresis, and electrotransferred to nitrocellulose membranes (Bio-Rad). To detect the specific protein, the TNF-α rabbit polyclonal anti-rat (Chemicon) antibody

was used at the concentrations recommended by the manufacturers. Equal loading of the protein samples was confirmed by parallel western blots for GAPDH. The intensities of the protein bands were quantitated by image scanning X-ray films and each band was measured by Image J software (NIH imaging software). Correction was performed by subtracting for level background and normalizing against GAPDH protein level.

### Statistical analysis

Statistical significance of differences between treatment and control groups was determined by the Student's *t* test. Where applicable, *P* values were reported for the 3 independent comparisons. Differences were considered statistically significant for *P* < 0.05. Values are presented as the mean  $\pm$  SD.

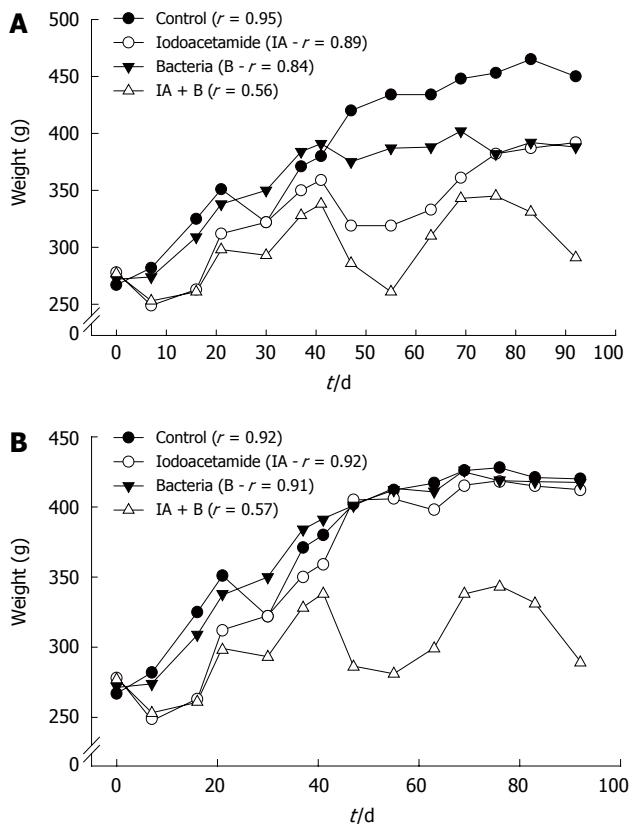

## RESULTS

The present study shows that the synergistic effect of repetitive intracolonic instillation of iodoacetamide and EPEC, resulted in chronic colitis, and the inflammatory process was sustained for the duration of the experiment: 100 d.

### Induction and clinical course

**Changes in animals' weight:** As shown in Figure 1, rats in the control, bacteria or iodoacetamide-treated groups had a trend towards increase in weight, which was significantly higher compared to rats treated with the combined treatment (iodoacetamide and bacteria), in both the continued and discontinued injection subgroups. Rats in the combined treatment group (IA + B) showed the lowest rate of increase in weight gain (*P* < 0.005), 0.15 g/d compared to 1.83 g/d for control, 1.14 g/d for iodoacetamide, and 1.48 g/d for the bacteria treated groups. Similar results were obtained in the discontinued injection subgroups: 0.13 g/d in the combined treatment (IA + B) compared to 1.5 g/d in the normal, 1.37 g/d in the IA and 1.45 g/d in the bacteria treated groups. The decrease in weight gain supports the diagnosis of chronic UC, a phenomenon not seen in the iodoacetamide-treated animals once the inoculations were discontinued after 30 d. Furthermore, two way ANOVA analysis for two experimental parameters (i.e. treatments and duration in days) detected the presence of significant differences among the different experimental groups (*P* < 0.005) as well as among the various treatment intervals (*P* < 0.005), with respect to the effect on body weight.

**Inspection of stools:** Throughout the duration of the study, the control animals passed normal beaded compact stools. Similarly, none of the animals injected with the bacterial suspension of EPEC alone demonstrated abnormal stools except in a few instances of loose stools, 1 to 2 d post inoculation. By contrast, the iodoacetamide-treated group developed diarrhea consistently for 2 to 3 d post instillation that changed later to loose stools. However, after 30 d when the animals were divided into the continued and discontinued subgroups:

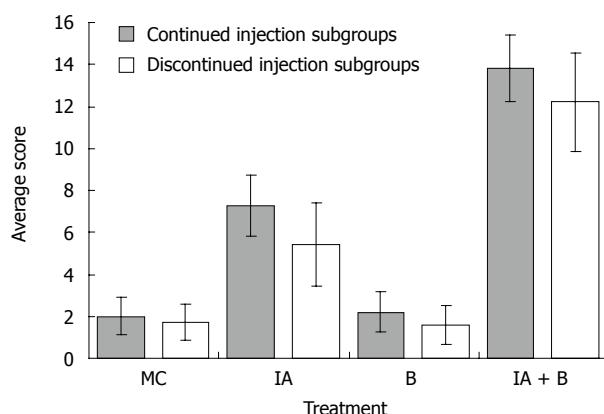

**Figure 1** Changes in the average rats' weight in various experimental groups, and in the continued and discontinued treatment subgroups. **A:** Continued injection subgroups; **B:** Discontinued injection subgroups. *r*: represents the correlation coefficient of weight change vs time. All readings were statistically significant (*P* < 0.005). Note the slow oscillating rate of increase in the two (IA + B) subgroups and in the continued injection IA subgroup.

the iodoacetamide-treated discontinued injection subgroup exhibited a pattern similar to the control group, starting 1 wk after the last IA injection and continuing for the duration of the experiment. The iodoacetamide-treated continued injection subgroup developed diarrhea for the first 2 to 3 d after the injection in nearly all animals, followed by loose stools and occasionally beaded compact stools for the remainder of the week until the next injection.

On the other hand, all animals in the combined treatment group (IA + B) both continued and discontinued subgroups, appeared sick and had severe diarrhea and bloody stools at some stage of the experiment, a feature rarely seen in the iodoacetamide-treated discontinued subgroup. These findings correlated with the lowest rate of weight increase observed in the combined treatment group (IA + B).

### Macroscopic findings

**MC-treated group (Control group):** The findings were considered as normal baseline. An average of three observations were made at each time point. Rats in the control group did not show any inflammation in the descending colon, however, a whitish discolouration at the site of the injection,  $\leq 0.5 \text{ cm}^2$  in diameter, was easily identified. The average score was  $2 \pm 0.9$  out of 15 indicating the absence of ulcer formation (Figure 2). These

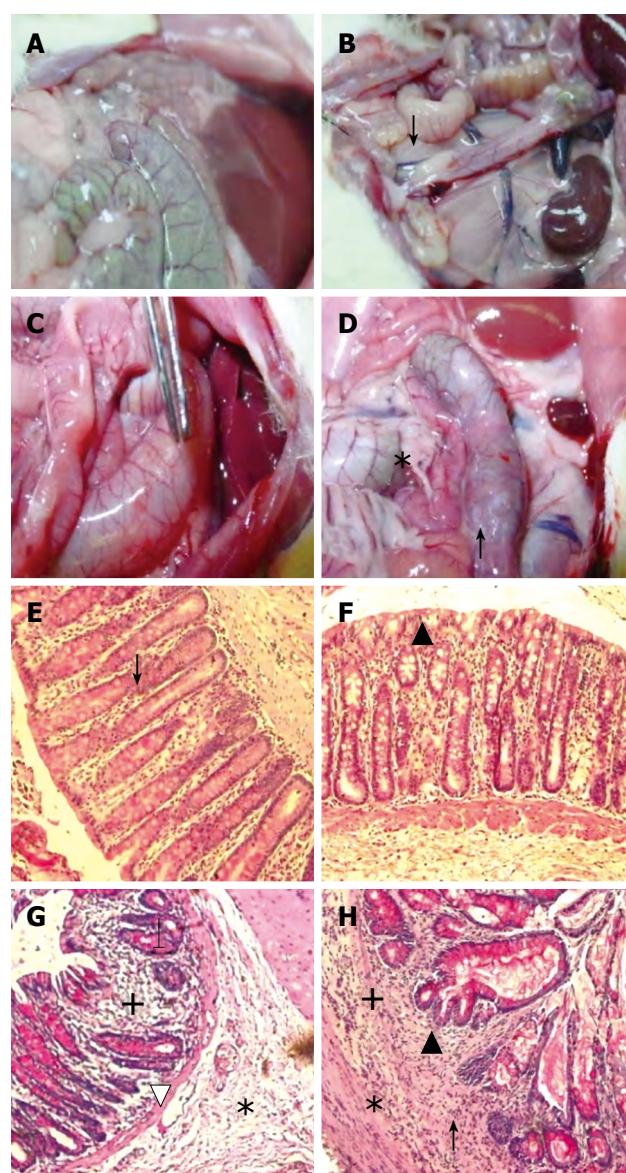

**Figure 2** Macroscopic assessment. The overall average colonic score at different time intervals of the various experimental groups both in the continued and discontinued injection subgroups (Readings represent the average of the scores on days 3, 7, 14, 28, 42, 56, and 70 in each group).

findings were observed although the experimental duration in the continued and discontinued subgroups was different (Figure 3A).

**B-treated group:** The findings in this group were similar to the control group except for the occasional findings of vasodilatation, and the presence of a white granulomatous area at the site of inoculation, with an overall size  $\leq 0.5 \text{ cm}^2$  (Figure 3B). The overall average score for the group was  $2.0 \pm 0.96$  out of 15, as illustrated in Figure 2.

**IA-treated group:** Perianal redness was sometimes noticed prior to sacrifice. The ascending and transverse colon were invariably normal. At most time points, inflammation was restricted to the descending colon including the occasional presence of an area of redness of the jejunum around the site of injection. There was dilatation of blood vessels and hyperemia around the site of the inoculation, along with the presence of adhesions (Figure 3C). The size of the inoculation site was 1 to  $1.5 \text{ cm}^2$ . The overall average score for the mucosal damage at the various time points in the continuous injection subgroup was  $7 \pm 0.9$  out of 15, while the average score in the discontinued injection subgroup was  $5.2 \pm 1.6$  out of 15. These findings correlated with the findings of less severe symptoms in treatment-discontinued subgroup compared to the treatment-continued subgroup (Figure 2).

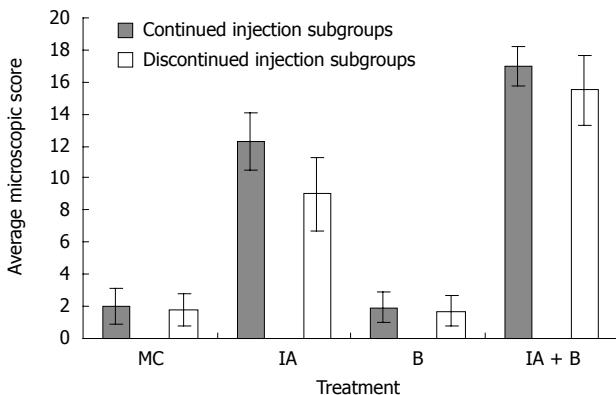

**IA + B-treated group:** Perianal redness was consistently observed, accompanied by staining with stools and blood. Protrusion of structures through the abdominal wall of the rat prior to surgery was clearly noticeable. The dilated descending colon was severely inflamed. The animals exhibited multiple abdominal adhesions over the descending colon with extensive generalized dilatations of the abdominal vessels (Figure 3D). Occasionally, megacolon was observed in this group and at times toxic megacolon was seen particularly in the continuous injection subgroup. It is important to note that the descending colon was hyperemic with vasodilatation starting from day 3 and persisting throughout the duration

**Figure 3** Representative photographs of macroscopic (upper row) and microscopic (lower row, HE stain  $\times 200$ ) findings on day 70 in treatment groups MC, B, IA and IA + B. **A and B:** Normal colon, note the whitish area at the site of multiple inoculation of the EPEC in colons of B-treated animals (↓); **C:** Note the vasodilatation and enlargement of the colon (forceps) in the IA treated rats; **D:** Note adhesions (\*), hyperemia and vasodilatation of an enlarged colon and a darkened site reflecting blackish mucosa (↑) in the IA + B treated animals; **E and F:** Normal microscopic appearance of the colon in the MC and B-treated groups. Well aligned parallel crypts (↓) continuous epithelial lining (▲) normal muscularis mucosa and normal lamina propria infiltration by cells; **G:** Shows cryptitis (↓), infiltration of inflammatory cells (+) and edema (\*) in the submucosal with thinning of the muscularis mucosa and vasodilatation (Δ); **H:** Crypt deformities and bifurcation (▲), cryptitis (↑), extensive inflammatory cells infiltrate (+) and edema (\*).

of the experiment (Figure 3D). The mucosa was always thickened, with a larger ulcer ( $2-3 \text{ cm}^2$ ). The overall average score was  $13.5 \pm 1.4$  for the continued and  $12 \pm 1.8$  for the discontinued injection subgroups (Figure 2).

In brief, the ulcer score in the control group was significantly lower than that in the iodoacetamide-treated group ( $P < 0.005$ ) and the combined treatment group ( $P < 0.005$ ) but not significantly different from the bacteria-treated group. Moreover, there was a significant

**Figure 4** Microscopic assessment. The overall average histological score in the different experimental groups both in the continued and discontinued injection subgroups (Readings represent average of day 3, 7, 14, 28, 42, 56, and 70 in each group).

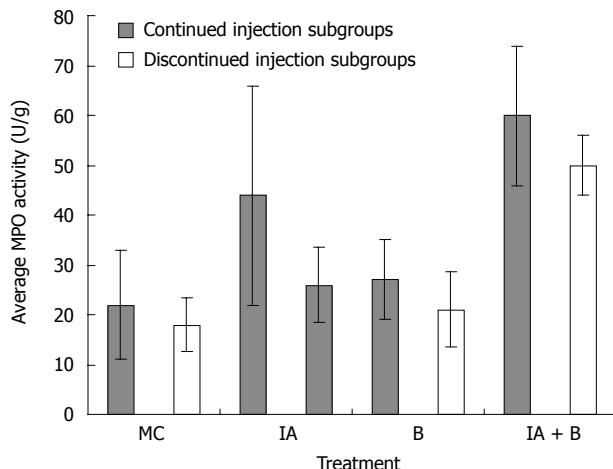

difference in the ulcer score between the iodoacetamide and the bacteria-treated groups ( $P < 0.005$ ) as well as between the combined treatment and the iodoacetamide groups ( $P < 0.05$ ). Furthermore, the score of the combined treatment group was significantly higher than that in the bacteria-treated animals ( $P < 0.005$ ).

#### **Microscopic findings**

The microscopic alterations focused mainly on the descending colon proximal to the site of the inoculation and its surroundings. The findings were compared with commonly reported colonic alterations seen in chronic ulcerative colitis. All layers of the colon were thoroughly studied and reference was made to the normal intestinal mucosa obtained from control animals.

**MC and B-treated groups:** The mucosal architecture of the MC group was considered as normal. There was no ulceration of the epithelial lining. The crypts, and the lamina propria inflammatory infiltrate were normal (Figure 3E). The overall average histologic score was  $2 \pm 1.2$  (Figure 4), with no significant difference between the continued and discontinued injection subgroups. Similar findings were observed in the B-treated group, with an average score of  $1.89 \pm 1.1$  (Figures 3F and 4).

**IA-treated group:** The iodoacetamide-treated continued injection subgroup showed focal mucosal ulceration and depletion of the epithelial lining; the inflammation involved the entire descending colon, sigmoid colon, rectum and anus (Figures 3G and 4). In addition, there was massive infiltration of inflammatory cells and an increase in the gut-associated lymphoid tissues. The crypts were partially destroyed, hypertrophied, and surrounded by inflammatory cells and edema (Figure 3G). The mucosa and submucosa contained several cell types including neutrophils, lymphocytes, macrophages, eosinophils, and clusters of mast cells. The overall average histologic score for IA-treated animals was  $12 \pm 1.35$ . However, when the treatment with IA was stopped, the tissues regained to a great extent their normal appearance, starting 1 wk after discontinuing the injections. The epithelial lin-

**Figure 5** Average MPO activity in the various experimental groups in the continued and discontinued injection subgroups (readings represent average of day 3, 7, 14, 28, 42, 56, and 70 in each group). The increase in the MPO activity in the IA+B subgroup was significantly greater ( $P < 0.005$ ) compared to all the other subgroups. The IA continued injection subgroup also showed a significant increase ( $P < 0.005$ ) compared to the control group.

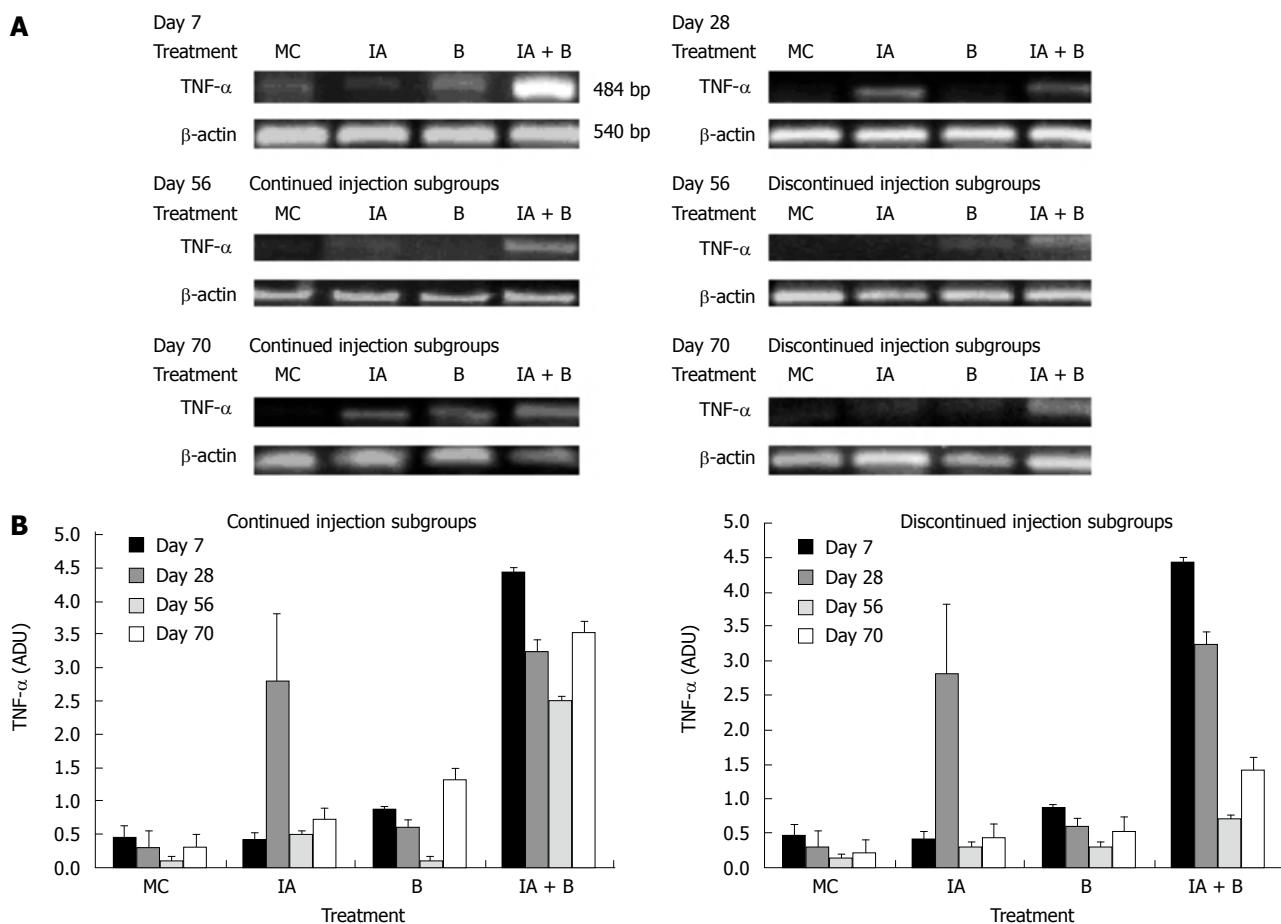

ing was almost normal, with little inflammatory infiltrate, scattered mast cells and no vasodilatation. The overall histologic score for IA-treated discontinued injection subgroup animals was  $9 \pm 1$ .

**Combined (IA + B)-treated group:** Severe inflammation was noted proximal to the site of inoculation with frequent involvement of all four layers of the colon. Histological examination revealed diffuse distortion of the mucosal architecture, with marked crypt atrophy and extensive infiltration by mononuclear cells (Figure 3H). The mucosal surface was irregular, villiform, and heavily infiltrated by various types of inflammatory cells exceeding that in the submucosa. The crypts showed loss of parallelism, with irregularity in crypt size, spacing and shape. In addition, cryptitis and crypt abscesses were present (Figure 3H). Mast cells were clustered in the submucosa. The sites affected by inflammation were edematous, ulcerated, and devoid of any glands. Furthermore, there was thinning or complete absence of the muscularis mucosa. Mucosal ulcers were covered with a large cellular debris (necrotized tissue and products of inflammation). These findings were observed throughout the duration of the experiment in both subgroups. The highest overall histologic score was seen in the continued injection subgroup, with an average score of  $16.2 \pm 0.9$ , compared to  $15.4 \pm 1.7$  for the discontinued injection subgroup (Figure 4).

#### **Myeloperoxidase (MPO) activity**

Assessment of MPO activity is considered a good estimate of the intestinal inflammatory status. MPO activity was consistently the highest in the combined (IA + B) treatment group receiving continuous inoculations, at all time points from day 7 to day 30. This high activity was maintained until the last day of the experiment (Figure 5).

One week following induction of inflammation, the MPO activity in the combined (IA + B) treatment group

**Figure 6** A: Representative photographs from three independent experiments of TNF- $\alpha$  mRNA expression in the descending colon in the various experimental groups at selected time points: day 7, day 28, day 56 continued injection subgroup, day 56 discontinued injection subgroup, day 70 continued injection subgroup, and day 70 discontinued injection subgroup. Band intensity was adjusted for the corresponding  $\beta$ -actin, and values were expressed as arbitrary density units (ADU); B: Expression of TNF- $\alpha$  mRNA in the descending colon in the various experimental groups both in the continued and discontinued injection subgroups, at all time points. Note the presence of significant difference in expression between the IA + B compared to the other groups ( $P < 0.005$ ).

reached an average of  $41 \pm 2.2$  U/g tissue which was significantly higher than the respective control values ( $11.7 \pm 2.1$ ,  $P < 0.005$ ) and almost twice the values of the bacteria-treated group ( $28.5 \pm 2.8$ ,  $P < 0.005$ ) and almost twice those of IA group ( $23.2 \pm 7.7$ ,  $P < 0.005$ ). The MPO activity in the IA ( $23.2 \pm 7.7$ ) and B ( $28.5 \pm 2.8$ ) treated animals were significantly higher than in the MC-treated group (Figure 5). A pattern similar to that observed on day 7 was also noted on day 14, 21, 28, 42, 56 and 70 (Figure 5).

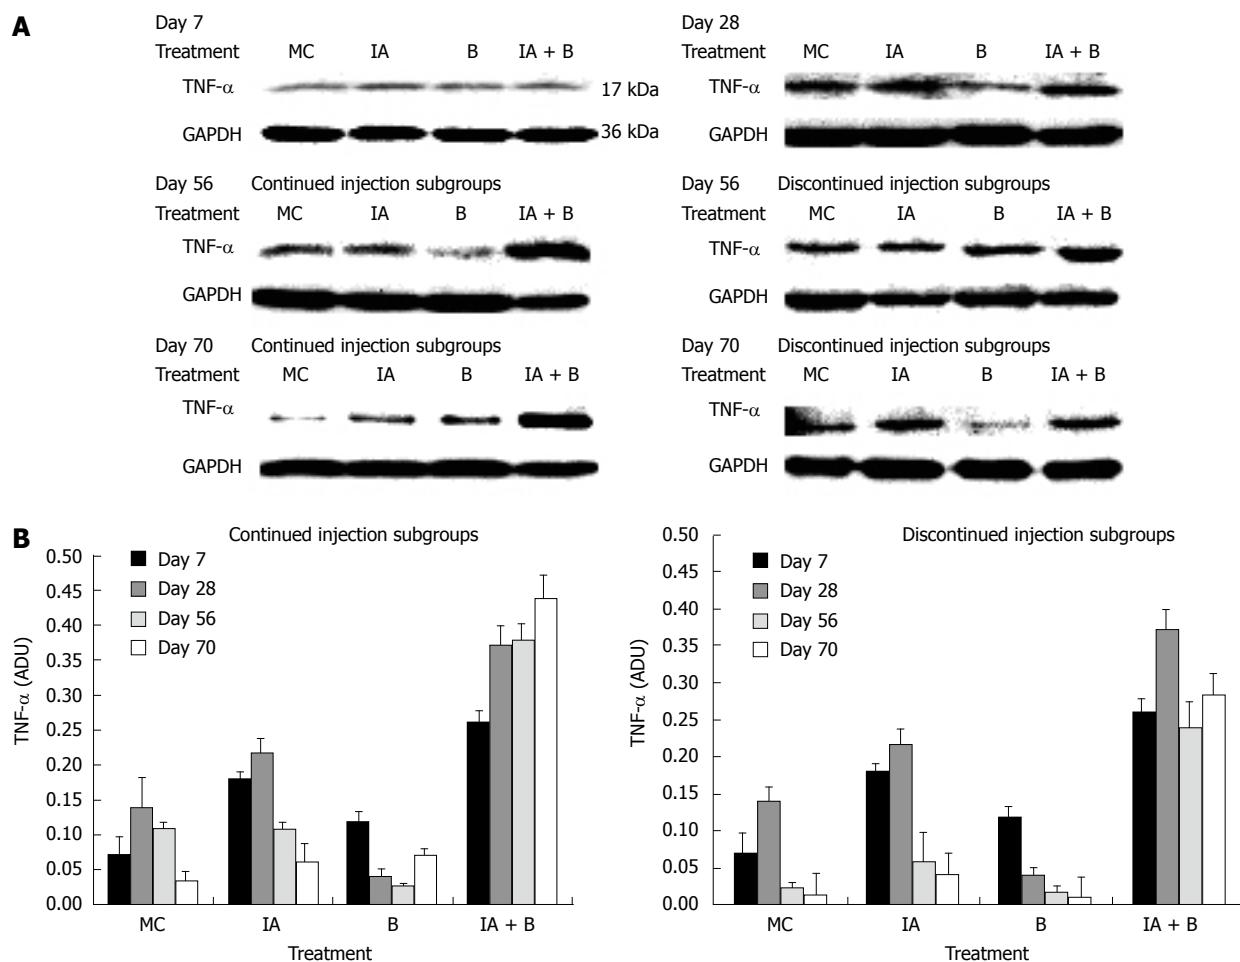

In general, in the continued injection experiment, the MPO score in the control group was significantly lower than that in all the other groups ( $P < 0.005$ ) but not significantly different from the bacteria-treated group. Furthermore, MPO level in the combined treatment group was significantly higher than that in the bacteria-treated animals ( $P < 0.005$ ). Even in the discontinued injection subgroups, there was a significant difference in MPO activity score between the control group and the combined treatment group ( $P < 0.005$ ). In brief, the combined treatment group had a significantly higher MPO activity score than the iodoacetamide-treated group ( $P < 0.05$ ).

#### Inflammatory signaling: TNF- $\alpha$ expression

TNF- $\alpha$  is a prototypical proinflammatory cytokine and a

key regulatory factor in various inflammatory processes involved in the pathogenesis of ulcerative colitis [24-27]. In this study, TNF- $\alpha$  mRNA expression levels were assessed as arbitrary density units (ADU) in relation to the endogenous level of  $\beta$ -actin. Our findings are similar to previous studies that reported an increase in TNF- $\alpha$  expression at both mRNA and protein levels in patients with IBD.

**TNF- $\alpha$  mRNA expression:** On day 7, TNF- $\alpha$  mRNA expression was increased 7-to-8 fold in the combined treatment (IA + B) group compared to the other groups (Figure 6A). On day 28, there was a significant rise in TNF- $\alpha$  expression in the IA-treated group reaching 7-fold higher than that in the B-group, slightly higher than that in the combined (IA + B) group which was slightly down regulated but still significantly higher than the other groups (Figure 6B). On day 56, there was a transient overall decline in the expression of the TNF- $\alpha$  mRNA in the IA-continued injection subgroup followed by an elevation in the levels on day 70. However, in the discontinued injection subgroup, there was a time-dependent decrease in the TNF- $\alpha$  levels following day 28 to day 70 post-treatment. On day 56, the TNF- $\alpha$  mRNA levels were reduced in all groups (Figure 6B).

**Figure 7** A: Representative photographs from three independent experiments of TNF- $\alpha$  protein expression in the descending colon in the various experimental groups at selected time points: day 7, day 28, day 56 continued injection subgroup, day 56 discontinued injection subgroup, day 70 continued injection subgroup and day 70 discontinued injection subgroup. Band intensity was adjusted for the corresponding GAPDH, and values were expressed as arbitrary density units (ADU); B: TNF- $\alpha$  protein expression in the descending colon in the various experimental groups both in the continued and discontinued injection subgroups, in response to treatment at all time points. Note the significant difference in expression between the IA + B and the other groups ( $P < 0.005$ ).

The combined treatment (IA + B) continued injection subgroup maintained a relatively higher level of the TNF- $\alpha$  mRNA compared to IA-treated or the B-treated and MC-treated control groups (Figure 6B). However, the discontinued injection subgroup exhibited mRNA expression below the detection limits (Figure 6B). During the course of the entire study, the increase in TNF- $\alpha$  mRNA reached its peak in the combined treatment (IA + B) group (both in the continued and discontinued injection subgroups) except for a transient rise in the iodoacetamide-treated group at day 28 (Figure 6B). However, it is important to note that after the inoculations were stopped, TNF- $\alpha$  mRNA expression decreased in the discontinued compared to the continued injection subgroup and this difference was observed at all time points, with greater expression in the combined treatment (IA + B) subgroup.

**TNF- $\alpha$  protein expression:** Western blot analysis of TNF- $\alpha$  protein expression showed that at 7 d post treatment, all groups exhibited close levels of TNF- $\alpha$  protein. In both MC and B-treated groups the protein levels were 2-fold lower than the protein levels in the

IA-treated and the combined treatment (IA + B) groups (Figure 7A). During the entire study, TNF- $\alpha$  protein levels were the highest in the combined treatment (IA + B) continued injection subgroup (Figure 7A), whereas in the discontinued injection subgroup all animals showed reduced expression following the cessation of the injections (Figure 7B). It is worth mentioning that the combined treatment (IA + B) discontinued injection subgroup maintained the highest values of TNF- $\alpha$  protein levels. In general, there was a good correlation between TNF- $\alpha$  protein and mRNA expression levels in all the experimental groups and subgroups, indicating the effect of treatment on both post-transcriptional and post-translational processes of TNF- $\alpha$ .

## DISCUSSION

Over the past three decades, several models of UC have been developed, with a variable range of clinical manifestations resembling those observed in human IBD, however, none of these closely mimic the clinical entity of human UC [10,11,16,17]. Using animal models, there is much indirect evidence to suggest an interaction between

luminal flora and the immune system, based mostly on the disruption of the immunoregulatory mechanisms<sup>[28-30]</sup>. The present study showed that a UC model, using an SH blocker and enteropathogenic *E. coli*, closely resembles the human situation and is reproducible with findings indicative of chronicity. The characteristics of the present model were colonic disease induced for nearly hundred days, the presence of clinical features such as weight loss (Figure 1), diarrhea and rectal bleeding, accompanied with macroscopic (Figure 2) and histological alterations (Figures 3 and 4) typical of chronic ulcerative colitis in humans<sup>[16,17,29,31]</sup>. Moreover, an analysis of colonic myeloperoxidase activity<sup>[32]</sup> showed a consistent elevation of activity in the combined IA + B treatment group, indicative of severe mucosal inflammation of the descending colon (Figure 5). Furthermore, upregulation of TNF- $\alpha$  mRNA and protein expression in the IA + B group supported the chronicity of the inflammatory process (Figures 6 and 7).

Analysis of body weight gain across the various experimental groups and subgroups revealed that rats treated with a combination of IA + B exhibited the lowest rate of weight gain in both the continued and the discontinued injected subgroups compared to MC, IA-treated discontinued injection subgroup and B-treated group. In addition, the IA continued injection subgroup behaved similar to the combined treatment continued injection subgroup, but with a higher overall growth rate. Once the injections in the IA-treated subgroup were discontinued (day 30), the growth rate increased again. Moreover, the combined treatment group showed an undulating course of increase and decrease in weight, which may indicate periods of relapse and remission of the disease. Such a decrease was observed consistently in both the continued and discontinued combined treatment subgroups as well as in the iodoacetamide-treated continued injection subgroup. On the other hand, the iodoacetamide-treated subgroup with discontinued treatment behaved like the controls after the injections were stopped (Figure 1B). The low weight gain (in the IA + B group) was due probably due to malabsorption secondary to a defective intestinal barrier. This barrier may not be restored appropriately because of persistent activation of mucosal inflammation<sup>[17]</sup>, with malabsorption in addition to diarrhea, affecting the physiology of other parts of the gut<sup>[33,34]</sup>. The changes in weight gain in the experimental groups (IA + B) were paralleled by the increased rates of diarrhea, loose and bloody stools, and sometimes swollen abdomen and megacolon.

Abdominal examination revealed tenderness over the descending colon as well as various degrees of megacolon in the combined treatment group. These findings provide further support to the validity of our animal model in inducing UC. Besides, the IA-treated animals in the continued injection subgroup showed similar findings but were not as consistent, particularly with regard to the development of megacolon. This feature was not encountered in the B-treated or MC control groups.

The validity of the combined treatment induced-UC was further supported by the high range of scores for macroscopic alterations. These included generalized va-

sodilatation, adhesions, enlargement of the descending colon and ulcer formation (Figure 2). These observations suggest that continuous stimulation by iodoacetamide is necessary for maintaining the inflammatory process. In this case, the score range in the iodoacetamide-treated and combined treatment groups showed moderate to severe inflammation in the descending colon (Figure 3C and D) and is consistent with the clinical findings seen in UC<sup>[14,18]</sup>. In general, the gross abnormalities observed in the combined treatment group were more consistent and more characteristic of chronic UC. There was diffuse hyperemia, with adhesions, megacolon, ulcerations, vasodilatation, and redness in the nearby segment of the jejunum. The overall score in the combined IA + B group with continued treatment ranged between 10-15, while the score ranged from 9-14 in the discontinued injection subgroup. Therefore, despite discontinuing the injections, the inflammatory process maintained its course, a point of special interest for further investigations.

In addition, the microscopic findings in the descending colon revealed histological abnormalities, particularly in the combined IA + B treatment group, followed by the IA-treated group with continuous injection (Figure 3). Such changes were seen mostly in the mucosa. These observations are in line with the findings seen in UC. However, in a few instances, the inflammation in the combined IA + B treatment group was very severe, involving all four layers of the colon, the mucosa, submucosa, muscular layer and serosa. Histological assessment of the colonic damage showed that during the entire duration of the experiment, the combined IA + B treatment group had the highest score, in both continued and discontinued subgroups (between 8 to 16). These changes were less pronounced in the iodoacetamide groups and were minimal or absent in the B-treated and MC-treated control groups (Figure 4). Therefore, changes in the microscopic structure of the combined treatment subgroups mimicked the changes commonly encountered in severe UC in humans<sup>[30,35,36]</sup>. These include extensive hyperemia and loss of epithelial lining, ulceration of the mucosa, severe depletion of goblet cells, loss of crypts, crypt abscesses, cryptitis, with dense inflammatory cell infiltration, severe dilatation of several blood vessels, loss or thinning of muscularis mucosa, and invasion by lymphoid cells<sup>[3,17,19]</sup>.

Assessment of MPO activity provides a reproducible and qualitative estimate of mucosal inflammation<sup>[23]</sup> and may serve as a quantitative index of disease severity. At the site of the mucosal injury, MPO content is a marker of the magnitude of neutrophil infiltration. The combined treatment group exhibited the highest MPO activity in the descending colon (Figure 5). It is therefore, clear that the degree of inflammation was the highest in the combined IA + B treatment group; in particular the subgroup with continued injection. The inflammatory activity was maintained at a much higher rate than in the control, B-treated or the IA-treated groups. However, it is important to note that once the injections were discontinued, the combined IA + B treatment subgroup maintained its highest activity compared to the other

groups. This observation provides further support to the notion that the inflammation persisted in the combined treatment group regardless of continued or discontinued injections. Once again, these findings are in line with the findings of chronic UC in humans<sup>[35,36]</sup>.

Further characterization of our animal model was carried out at the molecular level in order to evaluate the expression of inflammatory signaling. We analyzed the mRNA and protein expressions of TNF- $\alpha$ , a proinflammatory cytokine which can induce COX-2 and COX-2 protein expression. It should be noted that increased local expression of TNF- $\alpha$  is of prime importance in driving the chronic inflammatory reaction and the development of tissue injury<sup>[25,26]</sup>. There is significant correlation between the production of TNF- $\alpha$  and the severity of UC. High levels of proinflammatory cytokines in the mucosa lead to excessive production of matrix degrading enzymes by the gut fibroblasts, loss of mucosal integrity and ulceration. In UC, high levels of TNF- $\alpha$  have been documented in the lamina propria as well as increased TNF- $\alpha$  mRNA and protein expression in the mucosa associated with tissue injury<sup>[34,37]</sup>. TNF- $\alpha$  is the most important mediator of response to Gram-negative bacteria and also plays a critical role in the immune response to other micro-organisms<sup>[36]</sup>. There is much evidence to suggest that either enteric bacteria or immune dysfunction play a pivotal pathogenic role in IBD<sup>[1,2]</sup>. Endotoxins or lipopolysaccharides (LPS), derived from the outer membrane of Gram negative enteropathogenic *E. coli* interact with CD14 on the surface membrane of mononuclear cells, thus triggering a signal cascade that leads to the production and release of TNF- $\alpha$ , which is strongly involved in the pathogenesis of ulcerative colitis<sup>[38]</sup>. In this respect, both TNF- $\alpha$  and LPS may represent putative therapeutic targets for the treatment of UC.

The present study has demonstrated that mucosal scrapings of the colon contained significantly elevated levels of TNF- $\alpha$  mRNA and protein in both the combined treatment (IA + B) subgroups and at all time points compared to control animals (Figures 6 and 7). However, an occasional increase in TNF- $\alpha$  mRNA expression was noted in the IA-treated group on day 28 and 70.

The abnormalities resulting in chronic mucosal inflammation can be divided into two types; defects in immune regulation pathways and defects involved in the barrier function of the epithelium<sup>[5,8,9]</sup>. Models of disrupted barriers function have resulted in mucosal inflammation<sup>[5]</sup>. Chemical agents such as acetic acid, dextran sodium sulfate, and iodoacetamide, can injure the epithelium. In a normal animal, all means of chemical injuries result in a transient inflammatory process. Repair mechanisms step in and a stable mucosal barrier is reestablished. Indeed, a leading concept in the pathogenesis of chronic intestinal inflammation is the break in mucosal tolerance, an active process by which an injurious immune response is prevented, suppressed or shifted to a non-injuring class of immune reaction<sup>[39,40]</sup>. The intestine is in permanent contact with billions of bacteria belonging to the normal gut flora, food protein, and potentially

pathogenic bacteria and has to discriminate and define selective action towards pathogenic and non-pathogenic components. Mucosal tolerance exists in order to prevent an immune response against the body's "own" bacteria that would otherwise give rise to chronic intestinal inflammation. EPEC colonize the intestinal mucosa and, by subverting intestinal epithelial cell cytoskeleton function, produce a characteristic histopathological response. EPEC with invasive properties cause gross destruction of the epithelial architecture and tight junction proteins. Thus the presence of a chemical agent in addition to EPEC can create an optimal environment for the development and maintenance of chronic UC.

Experimental studies indicate that defects in intestinal permeability induced by iodoacetamide may facilitate the passage of LPS, derived from the Gram-negative enteropathogenic *E. coli* or other enteric bacterial flora, into the circulation. It is speculated that enhanced intestinal permeability, probably caused by the inflammation induced by iodoacetamide, could precede and prepare the ground for the development of UC in rats.

In conclusion, the development of animal models is critical in elucidating the molecular pathways by which human ulcerative colitis develops and progresses to an advanced stage. Indeed, identifying the molecular pathways involved in initiating this disorder may allow us to gain an insight into the strategy(ies) that can lead to IBD prevention. Furthermore, the present study may permit the characterization of molecular and morphologic effects of the disease that may enhance our ability to develop therapeutic agents with higher efficacy or with fewer side effects.

Furthermore, such a study may result in the development of agents that target molecular pathways known to play a role in the initiation of IBD, specifically in the subset of asymptomatic individuals at high-risk for the development of UC.

## COMMENTS

### Background

We employed the two-hit hypothesis, both chemical and bacterial, for our chronic ulcerative colitis (UC) model, based on several lines of indirect evidence implicating gut flora in the pathogenesis of inflammatory bowel disease in general, and ulcerative colitis in particular. Bacterial flora appears to be always involved in the development of ulcerative colitis, and a sulphydryl group blocker such as iodoacetamide may further increase the metabolic stress on the epithelial cells especially when it is instilled into the colon followed by enteropathogenic *E. coli*. The resident cells of the lamina propria, under such conditions, constitute an important target for endotoxins. The resulting secretion of cytokines causes the induction of a chronic colitis. This model requires a regular inoculation schedule to maintain the inflammatory process.

### Research frontiers

A chronic ulcerative colitis model which mimics to a great extent the human disease was developed. Our model is characterized by clinical, macroscopic, microscopic and molecular parameters that are similar to human UC.

### Innovations and breakthroughs

The present study confirmed one of the possible mechanisms of ulcerative colitis whereby a chemical reagent introduced into the colon induces colonic inflammation with morphological and clinical features suggestive of ulcerative colitis. The inflammatory condition was further provoked by inoculating *E. coli* bacteria at the same site allowing for an interaction between the bacteria, the mucosal barrier and the intestinal tissues, in particular the mucosal layer. Such

interactions aggravated the inflammatory reaction as evidenced by the upregulation of peroxidase, indicating an increase in the inflammatory cells, and the upregulation of TNF alpha, a prototypical proinflammatory cytokine secreted by the inflammatory cells and a key regulatory factor involved in ulcerative colitis. Such a phenomenon was maintained for the entire duration of the experiment.

### Applications

The present study provides a well characterized experimental model for ulcerative colitis essential for elucidating the mechanisms and molecular pathways involved. It also sheds light on the effect of the colonic microecology and the potential of manipulating the microbial environment in the intestines through the use of probiotics. This model may allow insight into strategies that can lead to the prevention of inflammatory bowel disease (IBD) and for the assessment of agents that can be used in the management of UC.

### Terminology

Inflammatory bowel disease (IBD): IBD is characterized by chronic, recurrent inflammation of the GI tract of unknown etiology. The disease varies in the extent and severity of the symptoms. IBD is known to develop between the ages of 15 to 35 years. Ulcerative colitis (UC): UC is an IBD characterized by passage of bloody diarrhea, which usually constitutes the earliest sign of the disease. Progression of UC may be associated with fever, abdominal pain and weight loss. UC is often termed left-sided colitis for it affects mainly the mucosa of the descending colon. The disease may extend to the proximal part of the large bowel; when the entire colon is affected, the disease is called pancolitis. Crohn's disease (CD): CD is an IBD that can involve any part of the digestive tract, from the oral cavity to the anus. It causes deep chronic ulcerations involving the mucosa and the deeper layers.

### Peer review

This is a solid and valuable piece of work. It is an extension of the authors' previous work on experimental colitis. It is definitely an original work of great scientific value. The experimental design is sound, results are well presented, and conclusions are documented by the findings of the study.

### Abstract

**AIM:** To study the composition of liver inflammatory infiltrate in biopsy material from patients chronically infected with hepatotropic viruses and to evaluate the correlation of inflammatory infiltrate with hepatitis B virus (HBV) and hepatitis C virus (HCV) viral antigen expression in chronic B and C hepatitis.

**METHODS:** The phenotype of inflammatory cells was evaluated by the EnVision system, using a panel of monoclonal antibodies. HBV and HCV antigens were detected with the use of monoclonal anti-HBs, polyclonal anti-HBc and anti-HCV antibodies, respectively.

**RESULTS:** The cellular composition of liver inflammatory infiltrate was similar in the patients with B and C hepatitis: ~50%-60% of cells were T helper lymphocytes. Approximately 25% were T cytotoxic lymphocytes; B lymphocytes comprised 15% of inflammatory infiltrate; other cells, including NK, totalled 10%. Expression of HLA antigens paralleled inflammatory activity. Portal lymphadenoplasia was found more often in hepatitis C (54.5%) than in hepatitis B (30.6%). Expression of HBcAg was found more often in chronic B hepatitis of moderate or severe activity. Overall inflammatory activity in HBV-infected cases did not correlate with the intensity

of HBsAg expression in hepatocytes. Inflammatory infiltrates accompanied the focal expression of HCV antigens. A direct correlation between antigen expression and inflammatory reaction *in situ* was noted more often in hepatitis C than B.

**CONCLUSION:** Irrespective of the etiology and activity of hepatitis, components of the inflammatory infiltrate in liver were similar. Overall inflammatory activity did not correlate with the expression of HBsAg and HCVAg; HBcAg expression, however, accompanied chronic hepatitis B of moderate and severe activity.

### INTRODUCTION

A cytopathic effect is absent in hepatocytes during viral replication, which is a characteristic feature of infection with hepatotropic viruses. Necrosis of hepatocytes is considered to be a result of cellular immunity reactions directed against viral antigens on the surface of these cells<sup>[1,2]</sup>. It is assumed that immunological mechanisms, insufficient for the full eradication of viruses, are responsible for liver damage and extrahepatic manifestations of infection<sup>[3]</sup>. Extrahepatic manifestations of hepatitis B virus (HBV) and hepatitis C virus (HCV)

infection, i.e. glomerulonephritis and vasculitis caused by the deposition of immune complexes, are connected with the humoral immunity directed at viral antigens<sup>[4-6]</sup>.

Analysis of the etiopathogenic phenomena of chronic viral hepatitis takes into account two basic factors that influence the course and resolution of infection. The first, and of paramount importance, is a viral factor. It has been demonstrated that mutations in the HBV genome<sup>[7]</sup>, superinfection or coinfection with hepatitis D virus (HDV)<sup>[8]</sup>, infection with HCV 1b genotype, and appearance of HCV quasispecies worsen the disease prognosis<sup>[9]</sup>. However, the second factor of great importance is the host factor and virus to host interaction<sup>[10,11]</sup>.

Inflammatory infiltrate present in a needle biopsy specimen is evidence of immunological processes *in situ*, as a reaction to viral protein expression. Host attempts to eliminate viruses lead to damage and subsequent necrosis of hepatocytes<sup>[12-14]</sup>. Damage to infected hepatocytes is a result of immune reactions aimed at eliminating infection. Therefore, necrosis of hepatocytes and mononuclear cell reaction are key features of such a reaction<sup>[15]</sup>. The intensity of the immune reaction in liver tissue depends both on the immunological status of the host and immunogenicity of HBV or HCV proteins expressed in the liver.

The aim of this study was to evaluate the type of immune reaction (by immunophenotyping the inflammatory infiltrate components) and the relationship between viral antigen expression and inflammation. The pattern of immunological response may bring the insight into etiopathogenesis of chronic viral hepatitis and mechanisms of immune reactions *in situ*.

## MATERIALS AND METHODS

Liver biopsy taken from 217 patients of Hepatology Clinic, Institute of Infectious and Parasitic Diseases, chronically infected with HBV or HCV were evaluated histopathologically. All patients were diagnosed on the basis of plasma presence of HBsAg, anti-HBc, HBeAg, anti-HBc and anti-HCV by the immunoenzymatic method (Abbott, Chicago, USA) and presence of HBV DNA, HCV RNA by PCR and RT-PCR, respectively. Out of 217, there were 137 patients with chronic hepatitis C (mean age 41; range 9-73 years), 72 patients with chronic hepatitis B (mean age 29.7; range 7-79 years) and 8 patients with mixed etiology of hepatitis: HBV/HCV or HBV/hepatitis D viroid (HDV) (mean age 33.8; 21-44 years). Out of 217 liver biopsies, we chose at random 20 biopsies of chronic type B hepatitis and 20 biopsies of chronic type C hepatitis. The main criterion was the amount of frozen tissue and tissue in paraffin block.

### **Examination of needle liver biopsy specimens**

Specimens taken by a blind biopsy with 1.6 mm needle were received fresh on gauze rinsed with PBS. Tissue material > 15 mm in length was divided into 3 pieces with a sterile surgical blade. One fragment, ca. 5 mm in length, was frozen at -80°C in petroleum ether cooled with acetone and dry ice. The frozen tissue was stored

at -40°C for further use. The second fragment, 2 mm long, was frozen and stored at -65°C until homogenization, extraction of nucleic acids and testing by PCR or RT-PCR. The third fragment, at least 15 mm long, was fixed in 4% buffered formalin and routinely processed in paraffin. Serial slides 4 microns thick were stained with H&E, impregnated with silver by the Gomori method for reticulin fibres and stained by chromotrope 2R and aniline blue for collagen fibres.

Liver disease was diagnosed according to generally accepted criteria<sup>[16,17]</sup>. Examinations of inflammatory activity and the stage of fibrosis of chronic hepatitis were performed according to criteria proposed by international experts<sup>[18]</sup>. All histological features were finally scored using Histological Activity Index (HAI) using eighteen points scale to assess the grade of the disease (inflammatory activity in the lobules and portal tracts, piecemeal necrosis and bridging necrosis) as: minimal: 1-3 points; mild: 4-8 points; moderate: 9-12 points; severe: 13-18 points. The stage of the disease was assessed using five points scale as: 0-no fibrosis, normal connective tissue; 1-portal fibrosis, fibrous portal expansion; 2-periportal fibrosis, periportal or rare portal-portal septa; 3-septal fibrosis, fibrous septa with architectural distortion; 4-cirrhosis.

Analysis of the cellular composition of inflammatory infiltrate in liver tissue was performed on the frozen sections. A total of 40 tissue samples, five specimens each of minimal, mild, moderate and severe hepatitis B and C, were examined. The number of samples studied by immunohistochemistry was determined by the size of frozen material available for extensive evaluation. Five liver specimens diagnosed by histopathology as normal (liver biopsy performed for other reasons than hepatitis, e.g. Gilbert's syndrome), served as controls. The evaluation was performed not by calculating cells, but by approximation of proportion.

The phenotype of inflammatory cells was evaluated by the EnVision system (anti-mouse globulins, DAKO, DakoCytomation, 2600 Glostrup, Denmark) using monoclonal antibodies listed below: (1) Anti CD45RO (UCHL-1 clone)-activated T cells, memory cells of both CD4 and CD8 subpopulations; (2) Anti-CD45RO (OPD-4 clone)-CD4 memory cells; (3) Anti-CD8-cytotoxic CD8 lymphocytes; (4) Anti-CD45 RA (clone 4KB5)-most B lymphocytes and a small subpopulation of T naive lymphocytes; (5) Anti-CD20 (L26 clone)-B lymphocytes; (6) Anti-CD35 (follicular dendritic cells); (7) Anti-CD56 (part of NK cells); (8) Anti-CD68 (macrophages); (9) Anti-HLA (class I); anti-HLA DR (class II α-chain); anti-HLA DP, DQ, DR (class II β-chain).

Serial sections of frozen liver biopsy fragments were dried at 22°C and fixed in acetone, 5 min [for HBV and HDV, cluster of differentiation (CD) antigens, HLA class I & II molecules and adhesion molecules]; or in acetone, 5 min, followed by chloroform, 5 min (for HCV antigens).

The expression patterns of HBV, HCV and HDV antigens were investigated in order to prove the viral etiology of hepatitis. HBV antigens were detected in fro-

zen sections by the indirect immunoperoxidase method with the use of monoclonal anti-HBs antibodies (Dako) and rabbit polyclonal anti-HBc antibodies (immunization with HBcAg coding HBV fragment synthesized in *Escherichia coli*). HCV antigens were detected with the use of human FITC-labeled polyclonal anti-HCV antibodies<sup>[19,20]</sup>, followed by monoclonal anti-fluorescein antibodies and finally by anti-mouse globulin antibodies labeled with peroxidase (EnVision system, Dako). In cases in which HCVAg was not detected in the first attempt of staining, serial sections were examined. The immunomorphological search for viral antigens expression was performed on frozen, and additionally, if technically possible, on paraffin sections.

The specificity of the methods applied in this study was ascertained by negative staining results when a primary antibody was omitted, or replaced by animal or human sera that did not contain antibodies against antigens of the viruses examined.

## RESULTS

### Etiology

Chronic hepatitis C was confirmed histologically in 137 cases and chronic hepatitis B in 72 cases. There were also 8 patients with mixed etiology of HBV/HCV and HBV/HDV hepatitis.

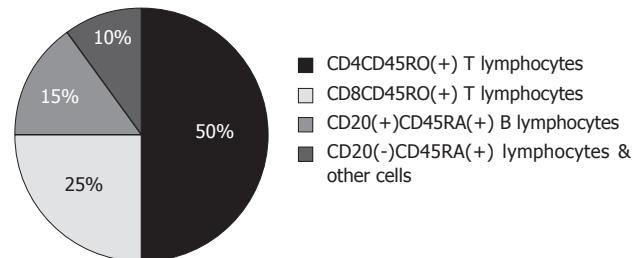

### The phenotype of cells in the inflammatory infiltrate

Cellular composition of the inflammatory infiltrate was the same both in patients with hepatitis B and hepatitis C (Figure 1). The same proportion was also found in the normal liver (a few mononuclear cells were scattered in sinusoids and single mononuclear cells in the portal tracts).

Lymphocytes of helper-inducer phenotype ( $CD4^+CD45RO^+$ ) made up 50%-60% of cells. CD4 lymphocytes were localized within lobules, as well as in portal tracts. They were the main component of the inflammatory infiltrate in areas of spotty necrosis within lobules, and in the foci of piecemeal necrosis. Lymphocytes of the CD8 phenotype constituted 20%-25% of the inflammatory infiltrate. In the normal liver they were present mainly in the sinusoids and as single cells in portal tracts. They made up a significant, but not the only, element of spotty and piecemeal necrosis. In some areas they constituted almost 100% of cells. In the portal tracts they were localized mainly in the peripheral part of this structure.

Altogether,  $CD45RO^+$  cells, i.e. activated T memory cells, constituted 75%-80% of the inflammatory infiltrate. In chronic hepatitis B or C of any activity,  $CD45RO^+$  T lymphocytes were found around foci of spotty necrosis within lobules, in portal tracts, and in sinusoids.

Taking into account the number of activated T lymphocytes ( $CD45RO^+$ ) (almost 80% of all the inflammatory cells) and percentage of T helper and T suppressor lymphocytes (~50% and ~25%, respectively), it may be

**Figure 1** Approximate composition (%) of inflammatory infiltrate in chronic hepatitis B and C.

presumed that about 5%-10% of T lymphocytes express both CD4 and CD8 phenotypes.

About 20% of the infiltrating cells consisted of  $CD45RA^+$  phenotype cells: B lymphocytes and a small subpopulation of virgin T lymphocytes. The number of  $CD45RA^+$  lymphocytes rose together with the increasing activity of hepatitis.  $CD20^+$  B lymphocytes constituted 5%-10% of the inflammatory infiltrate. In normal liver, single B cells were present only in the sinusoids. The number of B lymphocytes increased parallel to inflammatory activity, but the proportion of the cellular composition of inflammatory infiltrate remained constant.

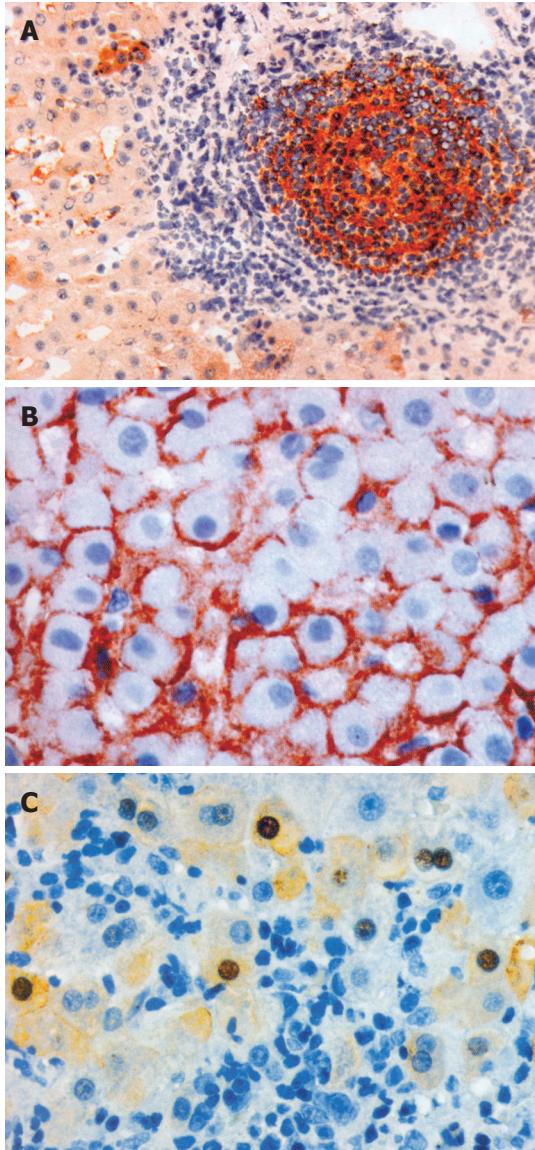

The relative composition of  $CD68^+$  macrophages and  $CD56^+$  NK cells in the infiltrate was also evaluated. In normal liver, macrophages were found mainly as single cells in sinusoids and in the portal tracts. The number of macrophages increased in sinusoids and portal tracts in chronic hepatitis B and C. Single  $CD68^+$  cells were found in lymphoid follicles (mainly secondary) and in germinal centers. Cells of the  $CD56^+$  phenotype made up only a small percentage (1%-2%) of the inflammatory infiltrate.

HLA class I antigens were detected in the form of tiny, granular deposits on sinusoidal cells of normal liver. They were present as tiny foci of a weak membranous pattern. In chronic hepatitis B and C the sinusoidal pattern of HLA class I molecule expression was also observed, irrespective of inflammatory activity. This was accompanied by the expression of these molecules on inflammatory and sinusoidal cells. The intensity of HLA class I expression in sinusoids was much stronger in comparison with the normal liver, not only because of their sinusoidal expression, but also because of their presence on inflammatory cells.

Expression of HLA class II molecules: DR  $\alpha$ -chain and DP, DQ, DR  $\beta$ -chain in normal liver was detected on sinusoidal cells and in the form of granular deposits of a sinusoidal pattern. Single mononuclear cells in sinusoids and portal tracts also showed  $\alpha$ - and  $\beta$ -chains of HLA class II expression. HLA class II molecule expression in chronic hepatitis B and C was detected as a sinusoidal pattern, and on most inflammatory cells in the portal tracts, in foci of piecemeal and spotty necrosis and in areas of bridging necrosis. Cells of lymphoid follicles in portal tracts showed a strong expression of these molecules. In most cases, HLA class II molecule expression on the surface of a hepatocyte was not observed.

**Table 1 Expression of viral antigens in the liver (total number of patients 217)**

Patients	HBsAg	HBcAg	HCVAg	HDVAg
Patients with chronic hepatitis B ( <i>n</i> = 72)	69 (95.83%)	43 (59.72%)	-	-
Patients with chronic hepatitis C ( <i>n</i> = 137)	-	-	67 (48.9%)	-
Patients with chronic hepatitis of mixed etiology ( <i>n</i> = 8)	8 (100%)	4 (50%)	4 (50%)	1 (12.5%)

**Figure 2** A: Expression of HCV antigens in the lymph follicle in the portal tract and in the peripheral hepatocyte (EnVision,  $\times 200$ ); B: Honeycomb pattern of HBsAg expression. No inflammatory reaction (EnVision,  $\times 400$ ); C: Inflammatory infiltrates around hepatocytes containing HBcAg: nuclear and cytoplasmatic expression of HBcAg (EnVision,  $\times 400$ ).

#### The formation of lymphoid follicles in chronic B and C hepatitis

Lymphoid follicles in portal tracts were present in both hepatitis B and C.

The dense clusters of mononuclear cells (follicles) were considered as primary (without germinal centers) or secondary (with germinal centers). Secondary follicles were quite rare—they were seen in 3 cases of chronic B and in 5 cases of chronic C hepatitis. Liver lymphade-

noplasia was seen more often in hepatitis C: 75 patients (54.7%) than in hepatitis B: 22 patients (30.6%); additionally, it was observed in 1 case of hepatitis B + D.

The occurrence of lymphoid follicles in chronic hepatitis B and C correlated with inflammatory activity. The phenotype of cells composing lymphoid follicles was also analyzed. Primary follicles were formed by B lymphocytes ( $CD20^+$ ), T lymphocytes ( $CD4CD45RA^+$  and  $CD4CD45RO^+$ ) of both naive and memory type, and  $CD8^+$  T lymphocytes. Macrophages ( $CD68$ ) and NK cells ( $CD56$ ) were scarce.

Secondary follicles contained germinal centers with B ( $CD20^+$ ) and with T ( $CD4CD45RO^+$ ) lymphocytes. Lymphoid follicles cells showed expression of histocompatibility antigens (HLA-II and HLA-I). We found also expression of HCV antigens inside germinal centers in the portal tract (Figure 2A). Outside follicles, there was a mixture of mononuclear cells, including T cells (also  $CD8^+$ ), macrophages, NK cells and scarce plasma cells.

#### The correlation of inflammatory infiltrate with HBV viral antigens expression in chronic B hepatitis

HBs antigen in liver tissue presented as cytoplasmic droplets, ‘festones’, cytoplasmic embeddings and as a honeycomb pattern. Although HBsAg expression usually did not correlate with the presence of inflammatory infiltrate (Figure 2B), in some cases an inflammatory response was present in the vicinity of hepatocytes with HBsAg expression. Intense and diffuse HBsAg expression was not accompanied by any inflammation, but the inflammatory reaction was related to focal and weak HBsAg expression. No strong correlation was noted between the pattern of HBsAg expression (droplets, festones, honeycomb pattern) and inflammatory activity. A negative correlation, however, was found between the intensity of HBsAg expression localized on membranes of hepatocytes (honeycomb pattern) and the activity of the inflammatory process.

In 43 cases (59.7%), HBcAg was detected in nuclei and/or cytoplasm of hepatocytes as well as on cellular membranes (Figure 2C). Table 1 presents expression of viral antigens in liver. HBcAg presence in relation to overall inflammatory activity was found in 2 patients (4.7%) with chronic hepatitis of minimal activity, 24 (55.8%) with hepatitis of mild activity, 12 patients (28%) with moderate activity, and in 5 patients (11.6%) with severe activity.

In 29 patients (40.3%) HBcAg was not detected. Among those 29 patients, in 15 (51.7%) there was minimal inflammatory activity, in 12 (41.4%) mild activity, while 1 case (3.5%) each of moderate and severe activity was found. To summarize, HBcAg was found predomi-

nantly in patients with chronic hepatitis of moderate and severe activity; only in 2 out of 19 such cases (10.5%) expression of HBcAg was not found. However, localization of HBcAg in the nuclei or cytoplasm of hepatocytes did not correlate directly with the inflammatory infiltrate at those sites. There were foci where inflammatory cells surrounded hepatocytes containing HBcAg, but there was no direct relation between the pattern of HBcAg expression and the presence or lack of inflammatory infiltrate. In addition, no correlation was found between the pattern of HBV antigen expression and the type of hepatocyte necrosis.

#### **The correlation of inflammatory infiltrate with HCV viral antigens expression in chronic C hepatitis**

HCV antigen (HCVAg) was detected in 67/137 patients (49%), and exclusively in the cytoplasm of hepatocytes as granules or amorphous deposits. There was a correlation between HCV antigen expression and inflammatory infiltrates within lobules and in areas of piecemeal necrosis. Furthermore, a positive correlation between the number of hepatocytes containing HCVAg deposits and inflammatory activity was found. A particularly strong expression of HCVAg was detected in hepatocellular carcinoma cells in a patient with liver cirrhosis.

A comparison was made between the inflammatory activity of chronic C hepatitis with or without HCVAg expression in the liver. It was observed that overall inflammatory activity did not correlate with the presence of HCVAg, partly because of the fact that detection of this antigen was dependent on the amount of sections investigated.

## **DISCUSSION**

The analysis of inflammatory infiltrate phenotype in this study showed that the proportions of mononuclear cell composition were similar, irrespective of the etiology and activity of chronic hepatitis. The most numerous were CD45RO<sup>+</sup> lymphocytes—they made up 75% of all inflammatory cells. B lymphocytes constituted 15% of inflammatory infiltrate and other cells (including NK cells) 10%. The CD4/CD8 ratio was > 1.5.

The results presented in this study are in accordance with those obtained by Volpes *et al* in 17 biopsy specimens from chronic hepatitis B and chronic hepatitis C and 5 specimens from acute hepatitis B and acute hepatitis C<sup>[21]</sup>. In all these cases, CD45RO<sup>+</sup> lymphocytes dominated in inflammatory infiltrate. Analysis of the relative composition of inflammatory infiltrate of chronic hepatitis C in children by Woźniakowska-Gesicka established that CD45RO<sup>+</sup> comprised 66%-75% and CD8<sup>+</sup> lymphocytes up to 33% of inflammatory cells. B lymphocytes (CD20<sup>+</sup>) made up 10%-33% of the infiltrate. The results of the present study correspond with those obtained as Woźniakowska-Gesicka *et al* reported<sup>[22]</sup>.

It is assumed that CD4<sup>+</sup> T lymphocytes recognize antigens that are presented by antigen-presenting cells, APC (macrophages, dendritic cells, B lymphocytes) with HLA class II molecules and thus take part in the local

inflammatory reaction<sup>[23]</sup>. The majority of liver infiltrating cells were of the CD45RO<sup>+</sup>CD4<sup>+</sup> phenotype. Furthermore, the proportion of T helper to T suppressor cells in liver tissue was ~2.0. This reflects the pathophysiological conditions of the inflammatory process in the liver. Considering the results of this study, a conclusion can be drawn that proportions of cells in normal and in hepatitis liver are fairly stable. Lukomska *et al* showed that cytotoxic lymphocytes in liver sinusoids derive from peripheral blood, and their number increases during inflammation due to *in situ* divisions<sup>[24]</sup>. This may suggest that the increase of other cellular elements during inflammation may reflect the same kind of divisions at inflammatory sites. CD4 effector cells coordinate the immune response by recognition of foreign antigens, but also by secretion of cytokines which act on other cells<sup>[25]</sup>.

The recognition of foreign antigens by effector cells is crucial for any attempts to eliminate viruses. We have compared the intensity of expression and localization of HLA class I and II molecules with different degrees of activity of hepatitis. HLA class I molecules appeared on the surface of hepatocytes both in the normal liver and in chronic hepatitis. The sinusoidal pattern and very delicate focal membranous expression on the surface of a few hepatocytes were seen in the normal liver. A more intensive expression was observed in cases of hepatitis. The simultaneous expression of viral antigens and HLA molecules on the surface of hepatocytes may certainly indicate the presence of viral antigens, but such expression was not always accompanied by inflammatory infiltrate. This may reflect the status of local tolerance to these antigens. Different intensities of HLA molecules were observed in serial staining of specimens, while the difference in specimen thickness did not exceed 0.5 μm. The other technical parameters, such as incubation time with antibodies or reaction time, did not differ by more than a few seconds. Altogether, localization of the molecule expression was repeatable, and this allowed us to draw conclusions.

A strong association was found between HLA class I expression and HBsAg presence on the surface of hepatocytes in the foci of piecemeal necrosis, with accompanying CD8<sup>+</sup> lymphocyte infiltrate. Senaldi *et al* studied isolated hepatocytes from the livers of children with suspected hepatitis and found HLA class I expression on the surface of 85%-100% hepatocytes<sup>[26]</sup>. Later, Fiore *et al* showed HLA class I expression on the hepatocytes of all chronic hepatitis C (CHC) cases studied, but found no association between the intensity of expression of these molecules and inflammatory activity<sup>[27]</sup>. Van den Oord *et al* proved that the pattern of expression of HLA class I molecules was independent of inflammatory activity, but in areas of spotty necrosis the expression had a focal membranous pattern<sup>[28]</sup>. The results of our study fit the data obtained by the last two authors. The expression patterns of HBV and HCV antigens and the activity of hepatitis showed only a partial association in the current study.

In this study, a granular pattern of HLA class II molecule expression on the surface of sinusoidal cells (macro-

phages, endothelial cells and most inflammatory cells) was found. HLA class II molecules were also found on cells comprising lymphoid aggregates in portal tracts and, less frequently, on the surface of follicular dendritic cell extensions. In a few cases, small groups of hepatocytes with the membranous type of HLA class II molecule expression were found. In most cases in this study, no expression of HLA-DR on hepatocytes was found, a finding that does not support the presumed role of hepatocytes as antigen presenting cells in the inflammatory process<sup>[28-30]</sup>. Using double immunohistochemical staining, Liang *et al* similarly did not find any association between HBcAg and HLA class II molecule expression<sup>[31]</sup>.

Infection with HBV and HCV caused inflammation in liver tissue and formation of lymphoid follicles in the liver. Lymphoid follicles were found more often in chronic hepatitis C (~55%) than in chronic hepatitis B (~31%).

Immunomorphological analysis of lymphoid follicles in chronic hepatitis B and C supports the hypothesis that they arise in portal tracts as a result of chronic local antigen stimulation. Taking into account the fact that lymphadenoplasia is considered as a humoral T-dependent B-cell reaction in chronic local antigenic stimulation, we may conclude that in many cases of chronic hepatitis a local humoral reaction takes place. This may influence the course of disease.

The degree of inflammatory activity did not correlate with the intensity of HBsAg expression in hepatocytes in this study. However, an inverse relationship between the degree of diffuse membranous HBsAg expression and inflammatory local response in chronic hepatitis B (CHB) of minimal and mild activity was established. Nuclear and/or cytoplasmic HBcAg expression in hepatocytes was frequently found in CHB of moderate and severe activity. There was no positive association between the degree of inflammation and the expression of HCV antigens in CHC. However, in comparison to CHB, focal expression of HCV antigens was frequently accompanied by inflammatory infiltrate. The lack of a close relationship between inflammatory cellular reaction and viral antigen expression may suggest that viral antigens are not the only components that take part in the inflammatory reactions *in situ*.

The mechanism of focal tolerance to viral antigens in the liver observed in this study-lack of cellular reaction in spite of intense and diffuse viral antigen expression-is unclear. A small number of CD56(+) NK cells may indicate the impairment of self *vs* non-self recognition, and may influence immunological response and elimination of the virus. In chronic inflammatory reaction, secondary immune response is more specific and therefore more efficient than natural immunity. The presence of lymphoid follicles in some portal tract reflects T-cell dependent B-cell reaction found in e.g. autoimmune inflammatory diseases, self perpetuating processes. In chronic viral hepatitis we observe both cellular and humoral reactions *in situ*. Detailed analysis of cellular reaction in the liver and of the topographic relations of inflammatory cells and viral antigen expression could

contribute significantly towards a better understanding of the immunopathogenesis of chronic hepatitis.

## COMMENTS

### Background

Infection with hepatotropic viruses such as hepatitis C virus (HCV) and hepatitis B virus (HBV) can result in chronic infection, which leads to liver cirrhosis and hepatocellular carcinoma. Immunological mechanisms against viral infections are responsible for damage and necrosis of hepatocyte. Inflammatory infiltrate present in a needle biopsy specimen is evidence of immunological processes *in situ*, as a reaction to viral protein expression. The aim of this study was to evaluate the relationship between viral antigen expression and inflammation. The pattern of immunological response may bring the insight into etiopathogenesis of chronic viral hepatitis and mechanisms of immune reactions *in situ*.

### Research frontiers

The aim of this study was to determine the composition of liver inflammatory infiltrate in biopsy material from patients chronically infected with hepatotropic viruses and to evaluate the correlation of inflammatory infiltrate with HBV and HCV viral antigen expression in specimens of minimal, mild, moderate and severe chronic B and C hepatitis. Irrespective of the etiology and activity of hepatitis, components of the inflammatory infiltrate in liver were the same.

### Innovations and breakthroughs

The correlation between HBV antigens and HCVAg expression in liver and inflammatory infiltrate was investigated. Overall inflammatory activity did not correlate with the expression of HBsAg and HCVAg; however, HBcAg expression accompanied chronic hepatitis B of moderate and severe activity. The study was undertaken on a large amount of clinicopathological material consisting of 217 biopsy specimens (137 from hepatitis C, 72 from hepatitis B and 8 from mixed etiology). The innovative parts of this study were findings of HLA class I, HLA class II (connected with the antigen presentation), CD4 and CD8, and B lymphocytes in the vicinity of infected hepatocytes. T lymphocytes CD4 and CD8 were most often of CD 45 RO+, phenotype of the memory type.

### Application

The study offers precise immunohistochemical/ histopathological diagnosis of liver biopsy. It can bring along many mixed infections, detected not so often before. This offers the clinician the unique opportunity to compare the results of treatment with the previous picture.

### Peer review

This study described the composition of liver inflammatory infiltrate in biopsy materials and the correlation of inflammatory infiltrate with HBV and HCV viral antigen expression. The use of many liver biopsy samples is a strength point of the manuscript. The authors concluded that the components of inflammatory infiltrates in the liver were similar irrespective of the etiology and activity of hepatitis. This observation seems interesting for understanding the immunopathogenesis of viral hepatitis.

of severe co-morbidity ( $P < 0.0001$ ) were related to mortality. In multivariate analysis, only the presence of severe co-morbidity was independently related to mortality ( $P = 0.032$ ).

**CONCLUSION:** While rebleeding and emergency surgery rates are relatively low in octogenarians with AUGIB, the presence of severe co-morbidity is the main factor of adverse outcome.

## Abstract

**AIM:** To evaluate the aetiology, clinical outcome and factors related to mortality of acute upper gastrointestinal bleeding (AUGIB) in octogenarians.

**METHODS:** We reviewed the records of all patients over 65 years old who were hospitalised with AUGIB in two hospitals from January 2006 to December of 2006. Patients were divided into two groups: Group A (65-80 years old) and Group B (> 80 years old).

**RESULTS:** Four hundred and sixteen patients over 65 years of age were hospitalized because of AUGIB. Group A included 269 patients and Group B 147 patients. Co-morbidity was more common in octogenarians ( $P = 0.04$ ). The main cause of bleeding was peptic ulcer in both groups. Rebleeding and emergency surgery were uncommon in octogenarians and not different from those in younger patients. In-hospital complications were more common in octogenarians ( $P = 0.05$ ) and more patients died in the group of octogenarians compared to the younger age group ( $P = 0.02$ ). Inability to perform endoscopic examination ( $P = 0.002$ ), presence of high risk for rebleeding stigmata ( $P = 0.004$ ), urea on admission ( $P = 0.036$ ), rebleeding ( $P = 0.004$ ) and presence

## INTRODUCTION

Despite considerable advances during the last decades, acute upper gastrointestinal bleeding (AUGIB) remains one of the most serious and potentially life-threatening medical cases that require hospitalization and careful monitoring of the patients. Bleeding may be caused by many different lesions of variable prognostic importance. Peptic ulcers and varices are the main and more significant causes of AUGIB. Approximately 45%-60% of the admissions for AUGIB worldwide are due to peptic ulcers<sup>[1-5]</sup>.

The percentage of older patients suffering from AUGIB has been increasing rapidly over the last years

in the Western World; the main reasons are the increase in life expectancy and the increased consumption of many drugs, such as non-steroidal anti-inflammatory drugs (NSAIDs) in this subgroup of patients. These drugs have characteristic side effects. They provoke ulcerogenesis and simultaneously increase the risk of peptic ulcer complications, mainly bleeding, in patients with a peptic ulcer history<sup>[6,7]</sup>.

Elderly patients constitute a subgroup with special characteristics who need careful handling during their hospitalization, because it is a population with considerable co-morbidity, higher medication use and greater risk for further complications. Age has been established as an independent significant risk factor for poor clinical outcome in patients with AUGIB. Mortality rates ranging from 12% to 35% for those aged over 60 years, compared with less than 10% for patients younger than 60 years of age, have been reported in previous studies<sup>[2,8,9]</sup>.

There has been limited information on the clinical outcome of the very elderly patients with AUGIB. The aim of this study was to evaluate the clinical outcome of very elderly patients being presented with AUGIB (those over 80 years old), and also to determine if there were differences in causes and clinical outcome of AUGIB in octogenarians in comparison with those younger than 80 years old. Finally, we aimed at examining factors related to mortality in octogenarians with AUGIB.

## MATERIALS AND METHODS

We retrospectively reviewed the records of all patients older than 65 years of age with AUGIB hospitalized in two hospitals from January to December of 2006. The patients were divided by age into two groups: Group A patients between 65 and 80 years old and Group B patients older than 80 years of age. We included both outpatients and bleeding episodes of the upper gastrointestinal (GI) tract that occurred in already hospitalized patients (inpatients). AUGIB was diagnosed when hematemesis, bloody nasogastric aspiration, or melena as well as other clinical or laboratory evidence of acute blood loss from the upper GI tract were present.

Bleeding patients were treated according to well established guidelines of the British Society of Gastroenterology Endoscopy Committee<sup>[10]</sup>. Management was in general the same and similar to that in the younger patients. The first steps, which are required, are clinical evaluation and resuscitation. According to the general practice, emergency endoscopy was performed in the 1st 24-hour of admission in the majority of patients, or immediately after resuscitation in patients with massive bleeding. In the majority of patients supplemental oxygen was provided during endoscopy. All patients were given topical pharyngeal anesthesia with 10% lidocaine spray. In most cases, sedation was avoided because of the risk of complications. When sedation was needed, titration of the doses was usually necessary.

Injection hemostasis with adrenaline diluted at 1:10.000 in saline 0.9% was the first line treatment in

patients with active peptic ulcer bleeding or ulcers with stigmata of recent bleeding. The use of endoclips and the application of thermal contact treatment, such as argon plasma coagulation (APC) were added to adrenaline injection in selected cases. In patients with esophageal variceal bleeding band ligation was widely used. Sclerotherapy with histoacryl injection was used for hemostasis in cases of fundic variceal bleeding. Medical treatment was the same for all patients, consisting of Proton Pump Inhibitors (PPIs) given intravenously in usual doses. Vasoactive drugs (somatostatin iv 250 mg bolus injection followed by 24-hour infusion of 250 µg/h for 5 d) were added to endoscopic treatment in patients with variceal bleeding.

Demographic and clinical characteristics of octogenarian patients were recorded and compared with those of younger patients. Each patient's age, gender, recent consumption of non-steroidal anti-inflammatory drugs (NSAIDs), oral anticoagulants and antiplatelet drugs, routine laboratory tests (hematocrit, urea, creatinine) and the presence of shock during admission, co-existing illnesses, the history of admissions in the past for gastric surgery or peptic ulcer complications, endoscopic diagnoses and clinical outcome have been registered in standardized database categories. Shock or hemodynamic instability was defined as systolic blood pressure less than 100 mmHg and a pulse rate of more than 100 beats/min.

Medical history of co-existing illnesses has been encountered as follows. The patients were separated into three categories, depending on the condition of the patient in the admittance. We categorized as stage 1 patients with no serious illnesses (hypertension, endocrine, orthopaedic diseases, etc.), in a rather good condition. As stage 2, we categorized patients with illnesses that need more careful monitoring than those in stage 1, as they ran the risk of destabilization (diabetes mellitus, cardiac problems, compensated cirrhosis, cancer in a stabilized condition), and finally we referred to stage 3 patients as those suffering from major health problems (such as recent myocardial infarction, decompensated cirrhosis, cancer with metastases)<sup>[11]</sup>.

Stigmata of active or recent bleeding were classified according to the Forrest Classification: Forrest Ia: active spurting bleeding; I b: active oozing bleeding; II a: non-bleeding visible vessel (NBVV); II b: adherent clot; II c: spots, a NBVV was defined as a raised red spot resistant to washing, III: no spots, ulcer with a clean base. Then we differentiated into two subgroups, depending on the need to administer endoscopic therapy or not: as high risk stigmata we named the peptic ulcers with Forrest Ia-Forrest II a, which are at greatest risk of rebleeding in comparison with the peptic ulcers with low risk stigmata Forrest II b-III.

The clinical outcome was analyzed according to the duration of hospitalization, the complications during hospitalization, the number of transfused blood units per patient, the rate of rebleeding, the need for emergency surgical hemostasis and mortality, defined as death within the hospitalization period and encountered

AUGIB: Acute upper gastrointestinal bleeding; NSAIDs: Non-steroidal anti-inflammatory drugs; NS: No significance.

the causes of death in these patients.

Continuous variables were expressed as mean ± SD and were compared by using Student's *t* test. Categorical variables were expressed as percentages and the differences between the groups were tested for significance by using the chi-squared test. Clinical, biochemical and endoscopic factors that might have contributed to the mortality were evaluated. All these parameters were correlated with in hospital mortality initially by using univariate analysis. Variables found to be significant in the univariate analysis ( $P < 0.05$ ) were included in a multivariate stepwise logistic regression model. All analyses were conducted by using statistical software (SPSS, version 10.0).

## RESULTS

From the total number of 638 patients with acute upper gastrointestinal bleeding hospitalized during the year 2006 in both hospitals, 416 patients (268 males and 148 females) were over 65 years (65.2%). Among these patients 269 (64.7%) were between 65 and 80 years of age (Group A) and 147 (35.3%) were over 80 years (Group B, Table 1). Endoscopy was performed in the majority of patients in both groups. In only 17 patients endoscopy was impossible (15/147 in Group B and 2/269 in Group A,  $P < 0.0001$ , Table 2). Endoscopy was not performed in these patients due to the presence of concomitant severe disease (12/15 in Group B and 1/2 in Group A), their personal or family disagreement (3/15 in Group B and 1/2 in Group A).

### Demographic-clinical characteristics of patients

The percentage of female patients in the octogenarians' group (Group B) was significantly higher than that in Group A (44.2% vs 30.8%,  $P = 0.009$ ). There was no statistically significant difference in the history of previous ulcer between the two groups (Table 1).

The presence of hematemesis before admission was less common in older than in younger patients (14.3% vs 25.3%,  $P = 0.012$ ). Mean hematocrit during admission was less in octogenarians ( $P = 0.047$ ), while mean creatinine and urea levels were higher in comparison with those in Group A ( $P < 0.01$ , Table 1).

The percentage of patients taking NSAIDs and antiplatelet drugs before the bleeding episode wasn't different between the two groups, but the combined use of both drugs was less common in octogenarians (2.0% in Group B vs 10.4% in Group A,  $P = 0.004$ , Table 1).

The percentage of patients with coexisting diseases was higher in octogenarians (Group B) in comparison with Group A, reaching a statistically significant level (94.6% vs 87.7%,  $P = 0.04$ , Table 3). The proportions of patients having hypertension (42.8% vs 32.3%,  $P = 0.04$ ) and cardiovascular diseases (59.2% vs 46.8%,  $P = 0.02$ ) were higher in Group B than in Group A, while that of cirrhotic patients was less frequent (2.0% in Group B vs 7.0% in Group A,  $P = 0.05$ , Table 3).

### Causes of bleeding-endoscopic findings

The main cause of bleeding in both groups was peptic ulcer (51.5% in Group B vs 52.8% in Group A,  $P > 0.05$ , Table 2). Variceal bleeding was statistically less frequent in octogenarians than in younger patients (0.7% vs 7.4%, respectively,  $P = 0.0094$ ) but esophagitis (6.8% vs 1.8%,  $P = 0.025$ ) and vascular diseases such as angiodysplasia (9.0% vs 2.2%,  $P = 0.005$ ) were more common in the octogenarians group. High risk of active stigmata or recent bleeding in peptic ulcer bleeding patients were less common in Group B (17.6%) as compared to younger patients (25.5%), but this difference did not reach statistical significance. Endoscopic hemostasis was administered to 78 patients in the octogenarians' group and was helpful in stopping bleeding and/or preventing rebleeding. There was no complication directly related to diagnostic or therapeutic endoscopy.

Renal disease	12/269 (4.4)	11/147 (7.5)	NS

NS: No significance.

### Clinical outcome

Blood transfusion requirements (red blood cell units per patient) were not significantly different between the two groups ( $2.9 \pm 3.2$  in Group B vs  $2.6 \pm 3.2$  in Group A,  $P > 0.05$ ), while octogenarians required more hospitalization days ( $8.1 \pm 5.5$  d vs  $6.9 \pm 4.1$  d,  $P = 0.013$ ).

Rebleeding rates after endoscopic hemostasis in octogenarians were low and not different from those in younger patients (7.5% vs 6.7%). Eleven patients rebled in the octogenarians' group and a second course of endoscopic hemostasis was successful in 5 out of 6 patients. Emergency surgical hemostasis for continuing or recurrent bleeding was rare in bleeding patients and was not different between the two groups (2.7% in Group B vs 2.6% in Group A).

In-hospital complications were more common in octogenarians (38.1% vs 28.3%,  $P = 0.05$ ), whilst there were no significant differences between octogenarians and younger patients in the proportions of the main complications observed; infection (27.9% vs 19.7%), oligemic shock (4.1% vs 1.1%), ischemic episode (6.8% vs 8.9%) and mental status deterioration (3.4% vs 2.2%), for groups B and A, respectively.

More patients died in the group of octogenarians compared with the younger age group (12.2% in Group B vs 5.2% in Group A,  $P = 0.02$ ). There was no significant difference in the reasons of death between the two groups; cardiovascular/cerebrovascular disease (38.9% in Group B vs 42.8% in Group A), malignancy (22.2% vs 28.6%), septic shock (22.2% vs 7.1%), oligemic

shock (16.7% vs 4.3%), whilst one patient in Group A died from hepatorenal syndrome.

In univariate analysis, factors related to mortality in octogenarians were no endoscopic examination ( $P = 0.002$ ), presence of high risk for rebleeding stigmata ( $P = 0.004$ ), urea on admission ( $P = 0.036$ ), rebleeding ( $P = 0.004$ ) and presence of severe coexisting disease ( $P < 0.0001$ ). In multivariate analysis, only the presence of severe co-morbidity was independently related to mortality ( $P = 0.032$ ).

## DISCUSSION

Demographic features and pattern of illness in patients hospitalized with AUGIB have changed during the last decades. A fall in the incidence of AUGIB during the last years has been reported, as well as a striking increase in the proportion of older patients being presented with AUGIB<sup>[11,12]</sup>. About 35%-45% of all patients presented with AUGIB were over 60 years old in previous studies<sup>[13-15]</sup>. In our study this proportion is even higher. Patients over 65 years of age constitute 65.2% of the total population with AUGIB. Additionally, more than a quarter of patients were over 80 years of age. Ten years earlier in our area this percentage was 9.8%<sup>[16]</sup>. It is clear therefore that now we have to deal with an older population with a higher risk of deterioration due to the presence of higher co-morbidities, making their management a clinical challenge.

This shift to older ages is related not only to the increased life expectancy in the western population, but also to changes in the epidemiology of peptic ulcer disease.

Over half of the cases of AUGIB are due to peptic ulcer bleeding irrespective of the patients' age. Increased use of NSAIDs in the elderly, reduced incidence of non-NSAIDs related peptic ulcers as well as better management of the chronic peptic ulcer disease, especially in younger patients, have contributed to this shift. Eradication of *H pylori*, which can be achieved in over 90% of patients with peptic ulcer, reduces ulcer recurrences as well as ulcer bleeding and rebleeding rates in young patients with idiopathic peptic ulcer disease<sup>[17,18]</sup>.

On the other side, indications of aspirin or non-aspirin non-steroidal anti-inflammatory drugs have been increasing during the last years and this has had detrimental consequences, mainly to the elderly. Age is an independent risk factor for NSAID related GI tract toxicity and ulcer formation. In older patients the risk of serious adverse events, such as peptic ulcer bleeding while taking NSAIDs, is 5.5 times that of controls, whereas in younger patients it is only 1.5 times<sup>[19]</sup>. Moreover, concurrent use of NSAIDs and antiplatelet drugs or oral anticoagulants, often used for thromboembolic prophylaxis in the geriatric population, increases the risk of bleeding<sup>[20]</sup>. Two thirds of our patients had taken NSAID and/or oral-anticoagulant or antiplatelet drugs. In a recently published British study, prescriptions for NSAID have been increased by about 13%, aspirin 75 mg by 460% and the prescriptions for

oral anticoagulants by 200% between 1990 and 1999 in the general population<sup>[14]</sup>. Despite the preventive effects of proton pump inhibitors on gastrointestinal toxicity from NSAIDs, it has been found that 70%-80% of users at risk for gastroduodenal complication does not receive gastroprotection<sup>[21,22]</sup>. The increased use of NSAIDs by the elderly explains partly the increased frequency observed in females in these ages in comparison with younger patients<sup>[23]</sup>.

Severity of bleeding does not seem to be higher in the octogenarians group. Prognostic factors of rebleeding, rates or need for emergency surgical hemostasis in our study were not more frequent in the very elderly. Variceal bleeding, which is characterized by high rebleeding rates and high mortality rate, is rare in this group. On the other hand, angiodysplasia and esophagitis, which were more frequent causes of bleeding in the very elderly, rarely produce life threatening bleeding and currently they are easily controlled endoscopically<sup>[24,25]</sup>.

In our study, endoscopy was performed on approximately 90% of patients over 80 years of age, endoscopic hemostasis was successfully applied to our patients without complications and the majority of rebleeding cases were treated with a second endoscopic hemostasis. Except for the endoscopy itself, endoscopic treatment seems also to be an effective and generally safe treatment even when it is performed in the elderly<sup>[26,27]</sup>. In a previous study in elderly patients with peptic ulcer bleeding, no rebleeding or morbidity occurred when endoscopic treatment was performed early but there was a significantly greater risk of further bleeding and treatment related morbidity when treatment was performed after the onset of rebleeding<sup>[28]</sup>. On the other side, from the existing data, there is no evidence that peptic ulcer bleeding is more resistant to endoscopic therapy due to possible atherosclerosis of the underlying artery. In contrast, vessels eroded by NSAIDs-related ulcers may be more amenable to endoscopic hemostasis than those eroded by chronic duodenal ulcers. Chronic duodenal ulcers, in contrast to acute ulcers, produce destruction of the duodenal bulb and erode deeper and larger vessels that bleed more severely and make endoscopic hemostasis difficult or even impossible<sup>[29]</sup>. Moreover, in a recently published study, mild to moderate anticoagulation did not increase the rebleeding rates after endoscopic hemostasis, meaning that endoscopic hemostasis is effective in anticoagulated patients admitted to hospital with AUGIB<sup>[30]</sup>.

Blood loss and emergency surgery is poorly tolerated by elderly patients with increased co-morbidity. Successful endoscopic therapy reduces the rebleeding rates and the need for emergency surgical hemostasis, which is a known risk factor for mortality especially in the elderly, due to high rate of co-morbidity in these patients. Only 4 out of 147 patients over 80 years of age required emergency surgical intervention in our study. Despite this, overall mortality was significantly increased in octogenarians in comparison to younger patients; this is due to the higher co-morbidity in these patients. In a recent multicenter study from France, no difference in

overall mortality was found among patients over and less than 75 years old, but in this study only patients with AUGIB subjected to endoscopy were included<sup>[31]</sup>. The percentage of deaths related directly to bleeding was generally low even in the very elderly, and the majority of elderly patients with AUGIB died of unpreventable causes. Stable elderly patients with AUGIB and no significant co-morbid illnesses and low risk endoscopic findings can even be managed safely as outpatients, as reported in a previous study<sup>[32]</sup>.

In conclusion, currently more than half of the patients hospitalized with AUGIB are over 65 years old and a quarter more than 80 years. Severity of bleeding in octogenarians is not different in comparison with younger patients, rebleeding is uncommon and the need for emergency surgical hemostasis rare. Mortality is higher than in the younger population and the presence of severe co-morbidity is the main adverse factor of clinical outcome.

## COMMENTS

### Background

The increase in life expectancy and increased consumption of many drugs by older people, such as non-steroidal anti-inflammatory drugs, have resulted in a rapidly increasing incidence of acute upper gastrointestinal bleeding (AUGIB) in older patients in recent years in the Western World.

### Research frontiers

Elderly patients constitute a subgroup with special characteristics, such as considerable co-morbidity, higher medication use and greater risk for further complications, making their management a clinical challenge. There has been limited information on the clinical outcome of the very elderly patients with AUGIB.

### Innovations and breakthroughs

This study shows that severity of bleeding in octogenarians is not different in comparison with younger patients, rebleeding is uncommon and the need for emergency surgical hemostasis rare. Mortality is higher than the younger population and the presence of severe co-morbidity is the main adverse factor of clinical outcome.

### Applications

Very old patients suffering from AUGIB should be managed as younger patients, but clinicians should have in mind that their patients with severe co-morbidity are at increased risk of adverse outcome.

### Peer review

This paper describes causes and clinical outcome of upper GI bleeding in elderly patients. More specifically, the age groups 65-80 and 80+ are compared. The numbers are quite large (269 vs 147) and some striking differences between the groups were noted.

Successful outcomes of EMR-L with 3D-EUS for rectal carcinoids compared with historical controls. *World J Gastroenterol* 2008; 14(25): 4054-4058 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4054.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4054>

### Abstract

**AIM:** To assess the results of endoscopic mucosal resection with a ligation device (EMR-L) combined with three dimensional endoscopic ultrasonography (3D-EUS) using an ultrasonic probe for rectal carcinoids. In addition, diagnosis of the depth and size of lesions by EUS was evaluated.

**METHODS:** Between January 2003 and March 2007, 20 patients underwent EMR-L with 3D-EUS using an ultrasonic probe (group A). 3D-EUS was combined with EMR-L at the time of injection of sterile physiological saline into the submucosal layer. For comparison, 14 rectal carcinoids that had been treated by EMR-L without 3D-EUS between April 1998 and December 2002 were evaluated as historical controls (group B). EUS was conducted for all of the patients before treatment to evaluate tumor diameter and depth of invasion. The percentage of complete resection and the vertical resection margin were compared between the two groups.

**RESULTS:** The depth of invasion upon histopathological examination was in complete agreement with the pre-operative findings by EUS. The tumor diameter determined by EUS approximated that found in the tissue samples. There were no significant differences in the gender, tumor sites or tumor diameters between the two groups. The rate of complete resection for groups A and B was 100% and 71%, respectively ( $P < 0.05$ ). The vertical resection margin of group A was longer than that of group B.

**CONCLUSION:** EMR-L is effective as an endoscopic

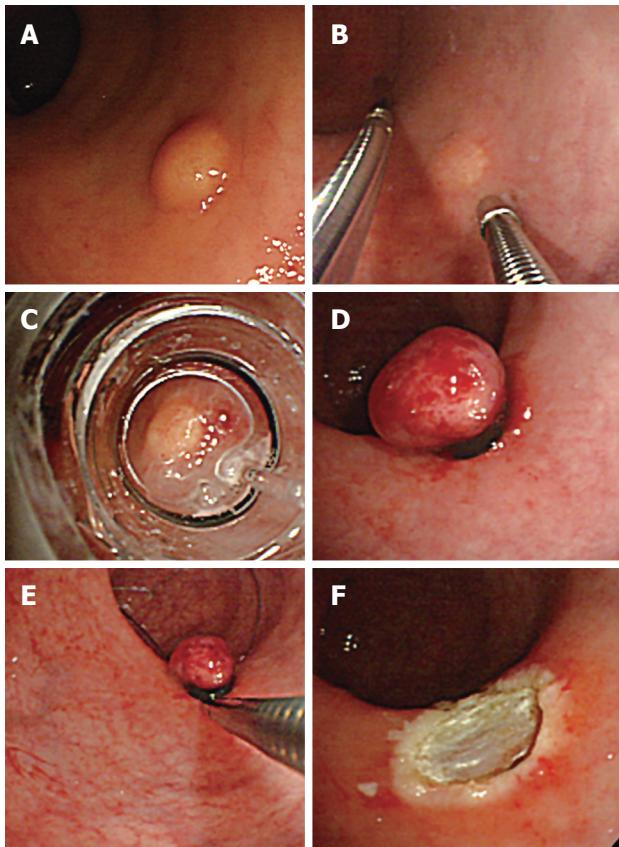

### INTRODUCTION

Recent progress in colonoscopy has facilitated the diagnosis of many rectal carcinoids at an early stage. Rectal carcinoids  $\leq 1$  cm in diameter and a depth of invasion to the submucosal layer are adequately treated by local excision<sup>[1-4]</sup>.

Conventional snare polypectomy or endoscopic mucosal resection (EMR) often result in unsatisfactory complete resection of colonic carcinoids<sup>[1,4-6]</sup>. Although various methods, including EMR with a ligation device (EMR-L), have been developed, problems still remain. We developed a resection technique of EMR-L combined with three-dimensional endoscopic ultrasonography (3D-EUS) using an ultrasonic probe, to confirm accurate injection of saline into the submucosal layer beneath the tumor, for more assured resection. The current study was conducted to evaluate the efficacy of EMR-L in combination with 3D-EUS for endoscopic resection of rectal carcinoids, compared with EMR-L alone.

### MATERIALS AND METHODS

Between April 1998 and March 2007, 36 cases (36 le-

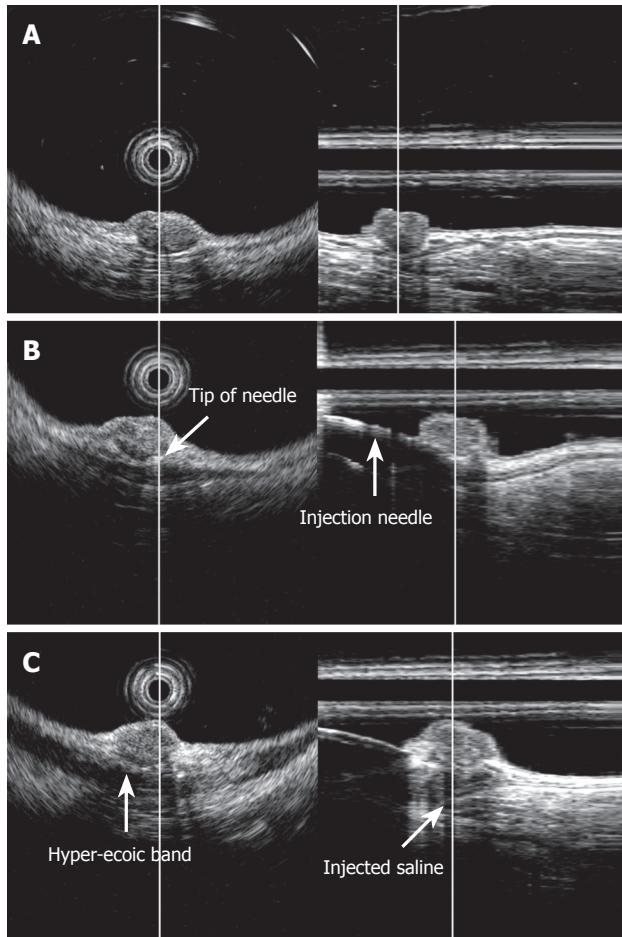

**Figure 1** EMR-L combined with 3D-EUS using an ultrasonic probe. **A:** Endoscopic view of rectal carcinoid; **B:** 3D-EUS was performed at the same time as saline injection into the submucosal layer; **C:** Aspiration of the tumor into the ligation device; **D:** Tumor ligated with the elastic band; **E:** Snaring below the elastic band; **F:** Ulcer after resection.

sions) of rectal carcinoid underwent colonoscopy, and their histopathological appearance was thoroughly examined at our institution. Following observation by conventional colonoscopy, EUS was performed to determine the depth of invasion, tumor size and possible metastasis to the surrounding lymph nodes. To rule out distant metastasis, the procedures were followed by abdominal ultrasonography or CT examination. Those with hepatic metastases, or a complication with severe ulcerative colitis (one case each), were treated surgically. The subjects of the current study were the remaining 34 patients with a tumor diameter  $\leq 10$  mm and a tumor depth that reached the submucosal layer, who underwent EMR-L.

Between January 2003 and March 2007, 20 patients underwent EMR-L combined with 3D-EUS using an ultrasonic probe (group A). For comparison, 14 patients with rectal carcinoids treated by EMR-L alone between April 1998 and December 2002 were included in this study as historical controls (group B).

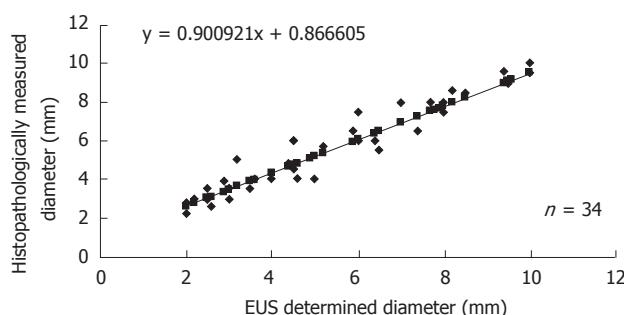

EMR-L, conducted according to Motohashi *et al*<sup>[7]</sup>, was performed as follows: using a small-diameter colonoscope (CF-SV, Olympus, Tokyo Japan) with a ligation device for the treatment of esophageal varices, physiological saline was injected into the submucosal layer. After aspirating as much lesion as possible into the ligation device, the tumor was ligated with an elastic

**Figure 2** EUS image of rectal carcinoid (radial and linear image). **A:** Carcinoid was imaged as a low-echoic region with a depth of invasion to the third layer, i.e. the submucosal layer; **B:** Image upon saline injection into the submucosal layer. The tip of the injection needle was located beneath the tumor in the submucosal layer; **C:** Image after saline injection into the submucosal layer. The injected saline was imaged as a low-echoic area beneath the tumor in the submucosal layer.

band. The section immediately below the elastic band was constricted by snare wire and resected using a high-frequency cutting current.

3D-EUS was combined with EMR-L at the time of injection of sterile physiological saline into the submucosal layer (Figure 1). Specifically, one channel of the two-channel colonoscope (CF-2T230, Olympus) was used for the saline injection, while the 3D ultrasonographic probe (UM-DP20-25R, 20 MHz; Olympus) was inserted through the other channel for scanning. At the time of saline injection, the tip of the injection needle was inserted while observing the ultrasonic radial and linear images, so that it would be located in the middle of the submucosal layer beneath the tumor. By recognizing the rise of the tumor caused by the injection and the adhesion of a hyper-echoic band directly beneath it, the tumor and its dissociation from the muscularis propria were confirmed (Figure 2). We used water-filling methods during EUS examination. For image processing, software for a three-dimensional image display (MAJ 1330, Olympus) was used. For observation of the images, dual plain reconstruction was employed. We com-

pared tumor diameter and depth, determined by EUS, and the complete resection rate and vertical margin between the two groups.

All resected samples were stained with hematoxylin-eosin for histopathological diagnosis. When the tumor tissue was exposed at the deeper edge of the resected sample, or when evaluation of this section was not possible due to thermal degeneration, a judgment of "positive at the edge" was made. If adhesion of the normal submucosal layer was noted at the lower section of the tumor, it was classified as "negative at the edge". The major axis was measured and recorded as the tumor diameter. The vertical margin was defined as the distance between the tumor and the edge of the specimen. We considered that the vertical margin of positive cases was 0  $\mu$ m.

Following treatment, the patients were followed-up with colonoscopy, EUS and abdominal CT for 6 mo immediately following the treatment, and yearly thereafter.

For statistical analyses, the measured variables were expressed as mean  $\pm$  SD. For group comparisons, the  $\chi^2$  test, Fisher's exact test and Mann-Whitney *U* test were conducted. A corrected  $P < 0.05$  was considered to indicate statistical significance.

## RESULTS

The EUS diagnosis before treatment determined that the tumor had reached deep into the submucosal layer in all 34 subjects. Histopathological examination also found tumor involvement in the submucosal layer in all cases, which demonstrated 100% diagnostic accuracy of EUS. A strong correlation was noted between EUS-determined and histopathologically measured tumor diameters (Figure 3). The two findings were very similar, with the difference between them being  $< 1$  mm in 29 patients (85%) (Table 1).

When two groups were divided according to the method of treatment, there were no significant differences in age, gender or site of involvement and tumor diameter. Group B included four patients with "positive at the edge" and 10 with "negative at the edge," with the rate of complete resection being 71%. All 20 subjects in group A were "negative at the edge" and the complete resection rate was significantly higher when compared with that in group B (Table 2). Mean tumor diameters between

**Table 1 Difference in tumor diameter determined by EUS and histopathology**

Difference in diameter (mm)	Cases ( <i>n</i> = 34)
0-0.5	20
1.0	9
1.5	4
2.0	1

**Table 2 Comparative evaluation and complete resection rate of both groups**

	Group A ( <i>n</i> = 20)	Group B ( <i>n</i> = 14)	<i>P</i> value
Gender (M/F)	11/9	6/8	NS
Age (mean $\pm$ SD)	58.7 $\pm$ 8.7	57.3 $\pm$ 11.3	NS
Location (Rb/Ra)	14/6	11/3	NS
Tumor diameter, mm (mean $\pm$ SD)	6.1 $\pm$ 2.3	5.9 $\pm$ 2.3	NS
Complete resection rate, % (cut edge positive)	100 (0)	71.4 (4)	< 0.05

NS: No statistical significance demonstrated.

positive and negative at the edge in group B were  $5.3 \pm 1.7$  mm and  $6.7 \pm 2.3$  mm. Cases with incomplete resection were found in group B, regardless of tumor diameter. Mean vertical margin of group A was  $1231 \pm 120.87$   $\mu$ m and that of group B was  $634 \pm 147.13$   $\mu$ m.

No procedure-related complications, such as hemorrhage and perforations, were found in either group.

Two patients had severe renal failure and another two did not agree to additional surgery. Therefore, the cases that were "positive at the edge" in group B underwent additional endoscopic treatment by conventional EMR and argon plasma coagulation. None of the additional resected specimens included tumor cells. No local recurrence or lymph node or hepatic metastases were noted in either group during a mean observation period of 48.7 mo.

## DISCUSSION

The word carcinoid was first proposed by Oberndorfer in 1907<sup>[8]</sup>. Currently, carcinoids are characterized as slow-growing malignant neoplasms<sup>[9]</sup>, which are epithelial tumors composed of endocrine cells with a unique histological pattern. In Japan, carcinoids of the digestive tract are frequently seen in the colorectal region, especially in the rectum, within 10 cm from the dentate line<sup>[10]</sup>. With the advancement and mounting popularity of colonoscopy, carcinoid of the digestive tract is being discovered more frequently.

In deciding on treatment for rectal carcinoids, the presence of metastases to lymph nodes or other organs is important. If the tumor is located in the muscularis propria, the rate of lymph node metastasis increases<sup>[11]</sup>. When the tumor diameter is  $\leq 10$  mm, the lesion has most often reached as far as the submucosal layer. For lesions with a diameter  $\leq 10$  mm, the metastatic rate is

significantly lower than for those lesions with diameters  $\geq 11$  mm<sup>[12]</sup>. Therefore, for those lesions with a diameter of  $\leq 10$  mm and a depth that reaches the submucosal layer, local incision, especially endoscopic treatment, is frequently selected.

EUS is useful for measuring the diameter or depth of rectal carcinoids. Carcinoids are imaged by EUS as a low echoic region with a clear surrounding area<sup>[13]</sup>. It has been said that the tumor diameter determined by EUS rarely differs from the actual measurement<sup>[14]</sup>. The capacity of EUS to depict the intramural structure is outstanding, and its usefulness in determining tumor depth has already been widely recognized<sup>[3,13-16]</sup>. The accuracy of the pre-operative depth determination was 100% in the current study.

In endoscopic resection of rectal carcinoids, the complete resection rate for standard snare polypectomy or EMR is often low<sup>[4-6]</sup>. Therefore, various innovations have been made for complete resection. Resection using a two-channel scope<sup>[3,17]</sup>, aspiration lumpectomy<sup>[18-20]</sup>, and EMR-L have been utilized and their efficacy has been reported<sup>[7,21,22]</sup>. Ono *et al* have applied EMR-L to fourteen patients<sup>[22]</sup> and Sakata *et al*<sup>[23]</sup> to eight, and all resulted in complete resection, which testifies to the efficacy of the method.

At our institution, prior to 1998, we resected rectal carcinoids by conventional polypectomy or using a two-channel scope, and EMR-L was adopted in 1998. We had initial success in complete resection in all cases<sup>[24]</sup>, therefore, total complete resection rate has increased. But as the number of cases treated in this manner has increased, we have experienced a few cases with positive margin.

Aspiration lumpectomy can be used for resection from the deep submucosal layer<sup>[25]</sup>. By adding a ligation process with the aid of an elastic band, in theory, EMR-L should be able to reliably and safely resect the lesion and submucosal layer. Motohashi *et al* have stated that a sufficient quantity of saline injected into the submucosal layer results in safe ligation and resection<sup>[7]</sup>. Ono *et al* have reported that the vertical resection margin is greater using the EMR-L technique, however, there are still certain cases that exhibit positive margins regardless of the tumor diameter. It seems that these positive margins are due to technical factors. Moon *et al* have reported a procedure in which a snare device is left under the elastic band, so that the lesion can be ligated to include the deeper submucosal tissue and be resected more completely<sup>[26]</sup>.

We believed that the accurate injection of saline into the submucosal layer beneath the tumor is necessary to elevate it upward, achieve effective ligation of the base of the lesion, and to resect the deep submucosal layer. Therefore, 3D-EUS was utilized to assist with the procedure at the time of the saline injection. While observing radial and linear ultrasonic images in real time, we objectively confirmed the insertion of a puncture needle into the middle section of the submucosal layer beneath the tumor, injection of physiological saline, elevation of the tumor, adhesion of a high-echoic band directly beneath

the tumor, and dissociation from the muscularis propria. The lesion was constricted with a snare and resected. All the patients for whom EMR-L was combined with 3D-EUS exhibited negative margins, and compared with those without 3D-EUS, the rate of complete resection was significantly higher. This procedure tended to provide a deeper vertical resection margin.

There have been reports that confirm the dissociation of tumor from the muscularis propria by two-dimensional EUS (2D-EUS) during endoscopic treatment of submucosal tumors<sup>[27,28]</sup>. The state of rectal carcinoid following a local injection may be confirmed by 2D-EUS<sup>[16]</sup>. When 2D-EUS is employed, the scope or probe must be moved while scanning to observe the entire lesion. Thus, a local saline injection to the submucosal layer cannot be conducted simultaneously with ultrasonic observation of the lesion. By employing 3D-EUS, on the other hand, both radial and linear images may be examined in real time while the injection is being administered. In this manner, the location of the tip of the local injection needle can be instantly confirmed or corrected. Furthermore, the state of the tumor being raised following the injection can be analyzed in three dimensions, which proves the efficacy of 3D-EUS.

Onozato *et al* have reported the use of endoscopic submucosal dissection (ESD) for rectal carcinoids<sup>[29]</sup>. However, the indication criteria for endoscopic treatment for rectal carcinoids included size  $\leq 10$  mm, and there is currently no significant difference between ESD and EMR-L for small rectal carcinoids in terms of complete resection rate. In the present study, the number of patients who underwent EMR-L with and without 3D-EUS was small, and the volume of injection was not compared between the two groups. This is a limitation of our retrospective study. Further studies are required to assess the volume of injection, long-term recurrence and patient survival. Also, the difference between ESD and EMR-L combined with 3D-EUS needs to be further evaluated.

EMR-L is significantly beneficial for endoscopic resection of rectal carcinoids. With the aid of 3D-EUS during the procedure, safe and complete resection is assured.

## ACKNOWLEDGMENTS

The authors thank Professor Emeritus Sakai Yoshihiro for his helpful suggestions regarding the manuscript.

## COMMENTS

### Background

Recent progress in colonoscopic examination has facilitated the diagnosis of many rectal carcinoids at an early stage. Conventional snare polypectomy or EMR often yields unsatisfactory results in terms of complete resection of colonic carcinoids.

### Research frontiers

Various endoscopic treatments for colonic carcinoids were demonstrated.

### Innovations and breakthroughs

EMR-L is as effective as endoscopic treatment for rectal carcinoids. In combination with 3D-EUS, safe and complete resection is assured.

## Applications

Further studies are required to assess long-term recurrence and patient survival, and the difference between ESD and EMR-L combined with 3D-EUS needs to be further evaluated in a prospective study.

## Terminology

EMR-L is endoscopic mucosal resection with a ligation device. 3D-EUS is three-dimensional endoscopic ultrasonography.

## Peer review

This very interesting study assessed the results of EMR-L combined with 3D-EUS using an ultrasonic probe for rectal carcinoids. When comparing EMR-L with and without 3D-EUS, the volume of injection should be compared between the groups.

Rebamipide enema therapy for left-sided ischemic colitis patients accompanied by ulcers: Open label study. *World J Gastroenterol* 2008; 14(25): 4059-4064 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4059.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4059>

## Abstract

**AIM:** To attempt rectal administration of rebamipide in the treatment of ischemic colitis patients with ulcers, and evaluate its effects.

**METHODS:** We compared 9 ischemic colitis patients (2 men, 7 women) with ulcers treated by bowel rest only from 2000 to 2005 (conventional therapy group), with 6 patients (2 men, 4 women) treated by rebamipide enema therapy in 2006 (rebamipide enema therapy group) and analyzed the mean duration of fasting and hospitalization, degree of ulcer healing, and decrease in WBC count for the two groups.

**RESULTS:** The mean duration of fasting and hospitalization were  $2.7 \pm 1.8$  d and  $9.2 \pm 1.5$  d in the rebamipide group and  $7.9 \pm 4.1$  d and  $17.9 \pm 6.8$  d in the control group, respectively, and significantly reduced in the rebamipide group ( $t = -2.915$ ;  $P = 0.0121$  and  $t = -3.054$ ;  $P = 0.0092$ ). As for the degree of ulcer healing at 7 d after admission, the ulcer score was reduced by  $3.5 \pm 0.5$  (points) in the rebamipide group and  $2.8 \pm 0.5$  (points) in the control group ( $t = 1.975$ ;  $P = 0.0797$ ), while the decrease in WBC count was  $120.0 \pm 55.8 (\times 10^3/\mu\text{L})$  in the rebamipide group and  $85.9 \pm 56.8 (\times 10^3/\mu\text{L})$  in the control group ( $t = 1.006$ ;  $P = 0.3360$ ).

**CONCLUSION:** In left-sided ischemic colitis patients with ulcers, rebamipide enema therapy significantly reduced the duration of fasting and hospitalization, recommending its use as a new and effective therapeutic alternative.

## INTRODUCTION

Ischemic colitis was described in 1963 by Boley *et al*<sup>[1]</sup> as reversible occlusion of the blood supply to the colon. In 1966, Marston *et al*<sup>[2]</sup> proposed the term ischemic colitis, establishing it as a definite disease entity, and classified the condition into 3 types namely, transient, stricture, and gangrenous. Today, ischemic colitis is considered to be a common disease of the large intestine, and is thought to be caused by various factors including vascular factors such as ischemia and embolism<sup>[3-5]</sup>, and intestinal factors such as constipation<sup>[6,7]</sup>, irritable bowel syndrome<sup>[8,9]</sup>, and history of intestinal surgery<sup>[10,11]</sup>. Endoscopically, ischemic colitis is characterized by edema, erythema, erosion, and ulceration of the colonic mucosa, and pathologically the condition is characterized by diffuse hemorrhage and edema in the submucosal layer, degeneration, desquamation and necrosis of the mucosal epithelium, congestion of the lamina propria, fibrin thrombi in the capillaries, and slight neutrophilic infiltration. According to Reeders *et al* ischemic colitis involves the left colon in 75% of the cases and the right colon in 8%<sup>[12]</sup>.

While surgery is indicated for treatment of the gangrenous type of ischemic colitis, many patients with the transient or stricture types of the disease improve with bowel rest by fasting and parenteral fluid administration alone. However, healing is frequently delayed in patients with ulcerative lesions. We previously reported that ischemic colitis patients with ulcerative lesions require a significantly longer fasting period and

duration of hospitalization as compared with those without ulcerative lesions<sup>[13]</sup>. A longer fasting period and longer duration of hospitalization pose problems, including stress associated with fasting and a high cost of long-term hospitalization.

Rebamipide is an anti-ulcer drug launched in various Asian countries, that has been reported to have ulcer healing effects<sup>[14,15]</sup>, anti-inflammatory effects<sup>[15]</sup>, suppressant effects against free radical production<sup>[16-19]</sup> and mucin secretion-inducing effects<sup>[20,21]</sup>. Recently, the efficacy of rebamipide enema in the treatment of ulcerative colitis has been reported in Japan<sup>[22-25]</sup>.

In this retrospective cohort study, we evaluated the therapeutic effects of rebamipide solution administered as an enema in ischemic colitis patients with ulcerative lesions, with special attention paid to the fasting period and duration of hospitalization.

## MATERIALS AND METHODS

Fifteen ischemic colitis patients (4 men, 11 women; mean age, 68 years) with ulcerative lesions who were admitted to our hospital during the 7 years between 2000 and 2006 were investigated in a non-randomized study. Nine ischemic colitis patients (2 men, 7 women; mean age, 68 years) with ulcerative lesions were treated by fasting and parenteral fluid administration during the 6 years between 2000 and 2005 (conventional therapy group). Six ischemic colitis patients (2 men, 4 women; mean age, 69 years) with ulcerative lesions were assigned to rebamipide enema therapy in addition to conventional therapy in 2006 (rebamipide enema therapy group). Patients who were admitted for other diseases but developed ischemic colitis during the course of those diseases were excluded. The diagnosis of ischemic colitis was made based on colonoscopic and histopathologic findings in biopsy specimens combined with the following three essential criteria: absence of prior antibiotics, negative cultures of feces or biopsy specimens for bacteria, and absence of history of inflammatory bowel disease (IBD). The age at onset, mode of onset, symptoms, and the location of the lesions were used as supplemental information.

Conventional therapy and rebamipide enema therapy groups were compared with respect to age, gender, location of lesions, hematological and blood chemistry findings, performance status (0-4 based on the WHO performance scale: 0, asymptomatic; 1, symptomatic but completely ambulant; 2, symptomatic, up and about > 50% of waking hours; 3, symptomatic, confined to bed or chair > 50% of waking hours, but not bed- or chair-bound; 4, bed- or chair-bound), prevalence of underlying diseases (hypertension, hyperlipidemia, diabetes mellitus, chronic atrial fibrillation, cerebral infarction, constipation, history of abdominal surgery), oral medication, mean fasting period, mean duration of hospitalization, degree of ulcer healing, and decrease in WBC count. The breakdown of the oral medication was: antihypertensive agent 5 cases, digitalis 1 case in the conventional therapy group, and antihypertensive agent 1 case, diuretic 1 case

**Table 1 Stage classification of gastric ulcer by Sakita-Miwa and its translation into numerical expression<sup>[26]</sup>**

Stages	Manifestation
Active stage	A1 (6p) The surrounding mucosa is edematosly swollen and no regenerating epithelium is seen endoscopically
	A2 (5p) The surrounding edema has decreased, the ulcer margin is clear, and a slight amount of regenerating epithelium is seen in the ulcer margin. A red halo in the marginal zone and a white slough circle in the ulcer margin are frequently seen. Usually, converging mucosal folds can be followed right up to the ulcer margin
Healing stage	H1 (4p) The white coating is becoming thin and the regenerating epithelium is extending into the ulcer base. The gradient between the ulcer margin and the ulcer floor is becoming flat. The ulcer crater is still evident and the margin of the ulcer is sharp. The diameter of the mucosal defect is about one-half to two-thirds that of A1
	H2 (3p) The defect is smaller than in H1 and the regenerating epithelium covers most of the ulcer floor. The area of white coating is about a quarter to one-third that of A1
Scarring stage	S1 (2p) The regenerating epithelium completely covers the floor of ulcer. The white coating has disappeared. Initially, the regenerating region is markedly red. Upon close observation, many capillaries can be seen. This is called "red scar"
	S2 (1p) In several months to a few years, the redness is reduced to the color of the surrounding mucosa. This is called "white scar"

in the rebamipide enema therapy group. For evaluation of the degree of ulcer healing, the ulcerative lesions were classified into stages according to the Sakita-Miwa classification of gastric ulcers<sup>[26]</sup> (Table 1), then the stage was converted into numerical scores as follows: A<sub>1</sub>: 6 points, A<sub>2</sub>: 5 points, H<sub>1</sub>: 4 points, H<sub>2</sub>: 3 points, S<sub>1</sub>: 2 points, S<sub>2</sub>: 1 point. The difference between the score at baseline (time of diagnosis) and the score at the follow-up examination was calculated and divided by the number of days between the baseline and the follow-up examinations for evaluation of the therapeutic effects. The result was corrected to the value at 7 d from the baseline and used for the analysis. To further strengthen the objectivity of the evaluation, the decrease in WBC count was calculated by subtracting the WBC count at the follow-up examination from that at the baseline, and divided by the number of days between the baseline and follow-up examinations. The value obtained was corrected to the value at 7 d from the baseline for use in the analysis.

Colonoscopy was performed in all the patients within 3 d of admission or within 5 d of onset of the symptoms. Colonoscopic follow up was conducted in a total of 11 patients, including all the patients in the rebamipide group. Treatment included bowel rest by fasting and parenteral fluid administration in all the patients, oral antiflatulent agents in 4 patients (23.5%), and administration of antibiotics in 4 patients (23.5%); none of the patients needed intravenous hyperalimentation. Treat-

**Table 2 Clinical features of the ischemic colitis patients: Comparison between the rebamipide and conventional therapy groups**

	Conventional group (n = 9)	Rebamipide group (n = 6)	Statistical significance
Age (mean, range, yr)	68 ± 19 (35-87)	69 ± 16 (41-85)	NS
Percentage of females (%)	77.8	66.7	NS
Lesion location: left colon (%)	88.9	100	NS
Performance status 0-1 (%)	77.8	100	NS
WBC count ( $\times 10^3/\mu\text{L}$ )	12.3 ± 4.7	13.5 ± 5.3	NS
CRP (mg/dL)	2.6 ± 4.1	1.7 ± 1.8	NS
K (mEq/L)	3.8 ± 0.4	4.2 ± 0.5	NS
Total cholesterol (mg/dL)	179.3 ± 30.6	191.2 ± 63.0	NS
TG (mg/dL)	93.3 ± 41.0	131.2 ± 74.2	NS
LDH (IU/L)	190.0 ± 42.8	202.8 ± 18.2	NS
CPK (IU/L)	80.7 ± 38.9	118.0 ± 76.6	NS

Values are the mean ± SD. The percentage of females and the lesion location were evaluated by the Fisher's exact test. Other data were evaluated by Student's *t*-test after skewing the values by log transformation. WBC: White blood cell; CRP: C-reactive protein; K: Potassium; TG: Triglyceride; LDH: Lactate dehydrogenase; CPK: Creatinine phosphokinase.

ment was provided in all patients within 5 d of onset of the symptoms. Oral food intake was allowed when the abdominal pain resolved. If no symptomatic recurrence was noted after the start of oral food intake, the patient was discharged.

For rebamipide enema therapy, 150 mg of rebamipide was suspended in 60 mL of warm water and administered through Nelaton's catheter once daily. The subjects remained in the left lateral decubitus position for 30 min. The period of administration varied depending on individual patient needs. The mean duration of treatment was 7 ± 1.6 d in the rebamipide enema therapy group. This study was allowed by the institutional ethical committee. Prior to the administration of rebamipide enema, all the patients were provided with a thorough explanation of the treatment, and informed consent was obtained from each of them.

### Statistical analysis

Data are expressed as mean ± SD or percentage. The percentage of females and the distribution of the lesion location, performance status, and underlying systemic diseases in the two groups were evaluated by the Fisher's exact test. Other data were evaluated by Student's *t*-test after log-transformation of skewed variables. All data analyses were performed with the StatView 5.0. Statistical significance was set at  $P < 0.05$ .

## RESULTS

Fifteen patients (4 men, 11 women; mean age, 68 years) were eligible for the analyses. The location of the lesions with allowance given for partial overlapping of the lesions, was the sigmoid colon in 66.7%, descending colon in 66.7%, transverse colon in 20.0%, and the rectum or ascending colon in 0% of the patients. In relation to the number of episodes of ischemic colitis experienced by

**Table 3 Underlying disease: Comparison between the rebamipide and conventional therapy groups n (%)**

	Conventional group (n = 9)	Rebamipide group (n = 6)	Statistical significance
Hypertension	6 (66.7)	2 (33.3)	NS
Hyperlipidemia	0	3 (50.0)	NS
Diabetes mellitus	1 (11.1)	1 (16.7)	NS
Atrial fibrillation	1 (11.1)	0	NS
Cerebral infarction	1 (11.1)	0	NS
Chronic constipation	5 (55.6)	1 (16.7)	NS
Medications			
Antihypertensive agents	5 (55.6)	1 (16.7)	NS
Others	1 (11.1)	1 (16.7)	NS
History of abdominal surgery	4 (44.4)	3 (50.0)	NS

Values are expressed in percentages. Percentages were evaluated by the Fisher's exact test.

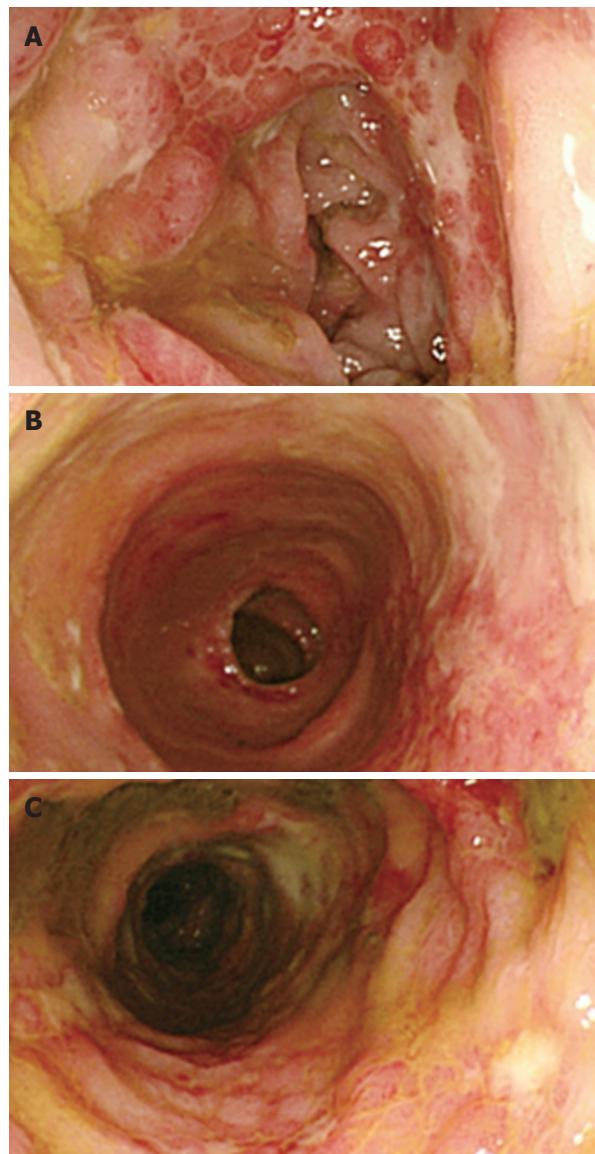

the patients, 93.3% of the patients had suffered from one episode and 6.7% had suffered from two episodes.

The rebamipide enema therapy group consisted of 6 patients (2 men, 4 women), with an average age of 69 years (41-85), and the lesion was located in the left colon in all the patients. The conventional therapy group consisted of 9 patients (2 men, 7 women), with an average age of 68 years (35-87), and the lesion was located in the left colon in 8 patients. There were no statistically significant differences in any of the background factors between the groups, including the prevalence of hypertension, hyperlipidemia, diabetes mellitus, atrial fibrillation, cerebral infarction and chronic constipation, history of abdominal surgery, oral medication, performance status, and hematological and blood chemistry findings (Tables 2 and 3).

The mean fasting period and mean duration of hospitalization were 2.7 ± 1.8 d and 9.2 ± 1.5 d respectively, in the rebamipide enema therapy group, as compared with 7.9 ± 4.1 d and 17.9 ± 6.8 d respectively, in the conventional therapy group. Both the fasting period ( $P = 0.0121$ ) and the duration of hospitalization ( $P = 0.0092$ ) were significantly shorter in the rebamipide enema therapy group (Table 4). As for the degree of ulcer healing, the ulcer score was reduced by 3.5 ± 0.5 (points) in the rebamipide enema therapy group and 2.8 ± 0.5 (points) in the conventional therapy group ( $P = 0.0797$ ), with the interval between the baseline and follow-up examinations being 6.5 ± 0.8 d and 7.7 ± 2.7 d respectively ( $P = 0.3293$ ). The WBC count was decreased by 12.0 ± 5.6 ( $\times 10^3/\mu\text{L}$ ) in the rebamipide enema therapy group and 8.6 ± 5.7 ( $\times 10^3/\mu\text{L}$ ) in the conventional therapy group ( $P = 0.3360$ ), with the interval between the baseline and follow-up examinations of 5.8 ± 1.7 d and 5.4 ± 1.5 d, respectively ( $P = 0.7515$ ). Thus, both the degree of ulcer healing and the decrease in WBC count tended to be favorable in the rebamipide enema therapy group compared to the conventional therapy group, but there was no significant difference in either parameter between the two groups (Table 4). No adverse events were noted in any of the patients.

**Figure 1** Colonoscopic findings at the time of diagnosis of ischemic colitis. **A:** Transverse colon; **B:** Descending colon; **C:** Sigmoid colon.

**Figure 2** Colonoscopic findings at the time of evaluation at 1 wk after the start of rebamipide enema therapy. **A:** Transverse colon; **B:** Descending colon; **C:** Sigmoid colon.

**Table 4 Duration of fasting, duration of hospitalization and reduction in the ulcer score: Comparison between the rebamipide and conventional therapy groups**

	Conventional group (n = 9)	Rebamipide group (n = 6)	Statistical significance
Duration of fasting (d)	7.9 ± 4.1	2.7 ± 1.8	P = 0.0121
Duration of hospitalization (d)	17.9 ± 6.8	9.2 ± 1.5	P = 0.0092
Degree of ulcer healing <sup>1</sup> (points) (n = 5)	2.8 ± 0.5	3.5 ± 0.5	P = 0.0797
WBC decrease <sup>2</sup> (× 10 <sup>3</sup> /μL)	8.6 ± 5.7	12.0 ± 5.6	P = 0.3360

Values are the mean ± SD. <sup>1</sup>The ulcer lesion was scored according to the Sakita-Miwa classification of the stage of gastric ulcer, then the difference between the baseline score (at the time of diagnosis) and at the time of the follow-up colonoscopy was divided by the number of days between the baseline and the follow-up examination, to correct the results to the value on d 7 (A1: 6 points, A2: 5 points, H1: 4 points, H2: 3 points, S1: 2 points, S2: 1 point). <sup>2</sup>Difference in value between that measured at admission and that measured at the time of the follow-up was divided by the number of days between the two examinations to correct the results to the value on d 7.

In a representative case of a 41-year-old man with ischemic colitis with ulcerative lesions located in the transverse colon, descending colon and sigmoid colon, who was treated by rebamipide enema for 7 d, the fasting period was 6 d and the duration of hospitalization was 10 d (Figures 1 and 2).

## DISCUSSION

With the aging of population in Japan and around the world, atherosclerosis and malignancy are two of the major diseases facing our nation. Epidemiological data in Japan reveal that malignant neoplasms rank first as the cause of death, while heart diseases and cerebrovascular diseases together account for about 30% of all deaths, which represents the percentage of deaths caused by malignant neoplasms. Since the prevalence of atherosclerotic diseases may be expected to increase further with the accelerated aging of populations, an increase in the incidence of ischemic colitis is also

inevitable. In fact, we have documented an annual increase in the prevalence of ischemic colitis in our care-providing area.

We previously reported that the fasting period and the duration of hospitalization were significantly prolonged in ischemic colitis patients with ulcerative lesions<sup>[13]</sup>, and sought suitable treatment methods to shorten these parameters. In this study, we evaluated the effects of rebamipide enema therapy in these patients. Rebamipide is an anti-ulcer drug used to treat peptic ulcer, that has been demonstrated to enhance the production of endogenous prostaglandin E2 via COX-2 and thereby act as a gastric mucosal protectant<sup>[27-29]</sup>, to promote mucin production<sup>[20,21]</sup>, and to suppress the production of free radicals, such as hydroxyl radicals and superoxide ions<sup>[16-19]</sup>. Farhadi *et al* reported that rebamipide suppressed the production of reactive oxygen species by neutrophils in the presence of plasma and rectal perfusate in patients with ulcerative colitis<sup>[30]</sup>. It has been reported that in ulcerative colitis, excessive oxygen and free radicals produced by activated neutrophils and macrophages intensify the microcirculatory disorder and lipid peroxidation to aggravate the intestinal mucosal disorder; thus they play important roles in the mechanism of development of inflammation in this disease. Makiyama *et al* reported that the use of rebamipide enema therapy in addition to conventional therapy in patients with ulcerative colitis yielded favorable responses, and classified this therapy as a promising new strategy for the treatment of moderate or less than severe distal colitis or as a supplemental therapy during steroid withdrawal<sup>[22,23]</sup>. Furuta *et al* and Miyata *et al* likewise reported that rebamipide enema therapy was effective in patients with ulcerative colitis<sup>[24,25]</sup>. Oral administration of rebamipide at a dose of 300 mg daily has also been reported to result in remarkable improvement in patients with multiple small intestinal erosions<sup>[31]</sup>.

Limited studies have discussed the mechanism of development of ischemic colitis. Ichihara *et al* produced an experimental model of ischemic colitis in rats, and reported that the development of lesions was clearly suppressed when the superoxide scavenger, liposomal-encapsulated superoxide dismutase (L-SOD), was administered. Based on this they suggested that the production of superoxide anions may be closely involved in the pathogenesis of ischemic colitis<sup>[32]</sup>. In hydrogen peroxide-induced hemorrhagic lesions of the gastric mucosa in the rat, rebamipide suppressed inactivation of SOD activity in a dose-dependent manner<sup>[33]</sup>, suggesting that rebamipide might contribute to healing in ischemic colitis by suppressing the production of free radicals.

This study is an open label study by the non-randomization, and the small study population may be a weak point. In this study, the degree of ulcer healing and decrease in WBC count were used as objective indicators in the evaluation of healing. No significant difference in either parameter was observed between the treatment and previously untreated groups. However, the results did suggest that the healing of the lesions was accelerated to a greater extent in the rebamipide enema therapy

group compared to the conventional therapy group.

The mechanism underlying the efficacy of rebamipide in the treatment of ischemic colitis remains unclear; however, it is assumed that the effect of the drug in suppressing free radical production and accelerating ulcer healing account for its efficacy in patients of ischemic colitis with ulcerative lesions.

Figures 1 and 2 show colonoscopic photographs of the large intestine in a patient who responded to rebamipide enema therapy. In this patient, skip ulcer lesions were present extending from the transverse to the sigmoid colon. Comparison of colonoscopic images of the large intestine obtained at the time of diagnosis (Figure 1) with those obtained at the time of follow-up 7 d after the initiation of rebamipide enema therapy (Figure 2) clearly revealed a more pronounced healing tendency toward the anal end. In regard to the effect of 5-ASA enema therapy and the site of the colon reached by the drug given as an enema in patients with ulcerative colitis, Bodegraven *et al*<sup>[34]</sup> and Otten *et al*<sup>[35]</sup> reported that following administration of 60 mL and 50 mL of 5-ASA, respectively, the drug reached between the sigmoid colon and the descending colon. The present results of rebamipide enema therapy are considered to be related to its effect of accelerating ulcer healing within the range of the colonic segments reached by the drug. As for the dosage of rebamipide, the dose was set at 150 mg in this study, although a dose finding study may be necessary in the future.

In conclusion, rebamipide enema therapy significantly shortened the fasting period and the duration of hospitalization in left-sided ischemic colitis patients with ulcerative lesions. Based on these findings, rebamipide enema therapy appears to be a promising new therapy in ischemic colitis patients with ulcerative lesions.

## COMMENTS

### Background

Authors have recently reported that the duration of fasting and hospitalization were significantly prolonged in ischemic colitis patients with ulcers.

### Research frontiers

In this study, the authors attempted rectal administration of rebamipide for the treatment of ischemic colitis patients with ulcers, and evaluated its effects, including on the duration of fasting and hospitalization.

### Applications

Rebamipide enema therapy shortened the fasting and hospitalization period in left-sided ischemic colitis patients with ulcerative lesions. We recommend rebamipide enema therapy in left-sided ischemic colitis patients with ulcerative lesions.

### Peer review

This is a retrospective study involving a small number of patients with left-sided ischemic colitis with ulcer, collected over a period of 5-6 years, compared with rebamipide therapy. The study shows promising results. It's an interesting paper.

## Abstract

**AIM:** To investigate the feasibility and safety of monopolar electrocautery shovel (ES) in laparoscopic total mesorectal excision (TME) with anal sphincter preservation for rectal cancer in order to reduce the cost of the laparoscopic operation, and to compare ES with the ultrasonically activated scalpel (US).

**METHODS:** Forty patients with rectal cancer, who underwent laparoscopic TME with anal sphincter preservation from June 2005 to June 2007, were randomly divided into ultrasonic scalpel group and monopolar ES group, prospectively. White blood cells (WBC) were measured before and after operation, operative time, blood loss, pelvic volume of drainage, time of anal exhaust, visual analogue scales (VAS) and surgery-related complications were recorded.

**RESULTS:** All the operations were successful; no one was converted to open procedure. No significant differences were observed in terms of preoperative and postoperative d 1 and d 3 WBC counts ( $P = 0.493$ ,  $P = 0.375$ ,  $P = 0.559$ ), operation time ( $P = 0.235$ ), blood loss ( $P = 0.296$ ), anal exhaust time ( $P = 0.431$ ), pelvic

## INTRODUCTION

Since the successful introduction of laparoscopic colectomy by Jacobs *et al*<sup>[1]</sup>, laparoscopic surgery, especially laparoscopic rectal surgery has been developed considerably<sup>[2-6]</sup>. Laparoscopic total mesorectal excision (TME) for rectal cancer whether hand-assisted, laparoscopy-assisted or robotic-assisted laparoscopic technique can offer advantages over open TME,

such as greater comfort and an earlier return to daily activities while preserving the oncologic radicality of the procedure<sup>[7-10]</sup>. Moreover, the laparoscopy allows good exposure of the pelvic cavity because of magnification and good illumination. The laparoscope seems to facilitate pelvic dissection including identification and preservation of critical structures such as the autonomic nervous system<sup>[11-12]</sup>. Laparoscopic TME for rectal cancer is feasible and safe; the short-, mid- and long-term outcomes of the operation are favorable compared with those of conventional open surgery<sup>[13-17]</sup>. However, the laparoscopic TME for rectal cancer is complicated and has some technical difficulties during operation; surgeons had to invent some methods to resolve the problem<sup>[18-22]</sup>. As ultrasonically activated scalpel (US) is able to grasp and divide tissues while sealing small vessels, the laparoscopic operation has become simpler, but the expensive medical instrument and high costs of the disposable materials can greatly increase the cost of laparoscopic TME for rectal cancer<sup>[23-25]</sup>. In order to reduce the cost of the operation, we tried to use monopolar electrocautery shovel (ES) in laparoscopic TME with anal sphincter preservation for rectal cancer, and compared it with US.

## MATERIALS AND METHODS

### **Patients**

Forty-two rectal cancer patients who were treated between June 2005 and June 2007 were chosen prospectively. The inclusion criteria are: patients with confirmed diagnosis of rectal cancer, non-emergency surgery, the tumor margin from the anal margin being more than 5 cm, no preoperative examination of liver, and other distant organ metastasis, and suitable for sphincter-saving surgery. Removal criteria are: patients whose tumor involved the bladder, uterus or pelvic metastasis, and not suitable for radical surgery. One patient in each group was excluded according to the removal criteria. The patients were randomly divided into laparoscopic US group and laparoscopic ES group.

### **Surgical techniques**

The two groups of patients used the same method for preoperative preparation. All the procedures were performed by the same operation team. Each of them conformed to the radical treatment principles including en bloc resection, no-touch isolation technique, proximal lymph-vascular ligation, complete lymphadenectomy, wound protection, and adequate resected margin of the rectum and TME for rectal cancer.

### **Study parameters**

The following parameters were measured prospectively in the two groups: white blood cells (WBC) in the peripheral blood before and after operation, the operative time, blood loss, postoperative pelvic drainage volume and the time of anal exhaust. The pain degree of patients after operation was assessed by visual analogue scales (VAS), "0" represents painless, and the "10" represents the most intense pain<sup>[26]</sup>.

**Table 1 Demographic data of ES and US groups (*n* = 20, %)**

Parameters	ES group	US group	$\chi^2$ or <i>t</i>	P
Mean age (yr)	59.2 ± 12.6	58.8 ± 14.9	0.080	0.937
Gender				
Male	14 (70)	11 (55)		
Female	6 (30)	9 (45)	0.960	0.327
Distance from tumor to anal margin				
5-10 cm	13 (65)	12 (60)		
> 10 cm	7 (35)	8 (40)	0.107	0.744
Dukes' stage				
A, B	7 (35)	9 (45)		
C	13 (65)	11 (55)	0.417	0.519

### **Statistical analysis**

All the statistical analyses were performed using SPSS 11.5 software package. The data were expressed as mean ± SD. Student's *t* test was used to analyze quantitative variables and  $\chi^2$  test was used to analyze qualitative variables. *P* < 0.05 was considered statistically significant.

## RESULTS

### **Comparison of demographic data**

The demographic data of the two groups are shown in Table 1. There was no significant difference in age, gender, tumor location of rectum and Duke's staging.

### **Comparison of surgical safety and postoperative recovery between ES group and US group**

Comparison of the WBC counts before operation between ES group and US group showed no significant differences. The WBC counts of the two groups in postoperative d 1 and d 3 were higher than that of preoperation, but without significant difference. There was no significant difference between ES group and US group in operation time, blood loss, the anal exhaust time, the pelvic drainage volume, postoperative d 1 and d 3 VAS and postoperative complications such as anastomotic fistula and the occurrence of wound infection (Table 2).

## DISCUSSION

The electric power can be converted to mechanical energy by ultrasound frequency generator in US, which can generate 55.5 kHz mechanical oscillation. By the oscillation, the tissues can be cut and coagulated and vascular closure can be made. US can precisely cut and stop bleeding and produce less heat, thus not damaging the surrounding tissues because of the small thermal spread. When US produces less smog and less eschar, the operative field become more clearly. But US also has obvious drawbacks: US instrument is expensive, needs disposable material; and significantly increases costs of the laparoscopic operation<sup>[23,27,28]</sup>. In clinical practice, we found that the laparoscopic rectal cancer operation can almost be conducted at the same anatomical space of rectum; monopolar electrocautery can also be applied in

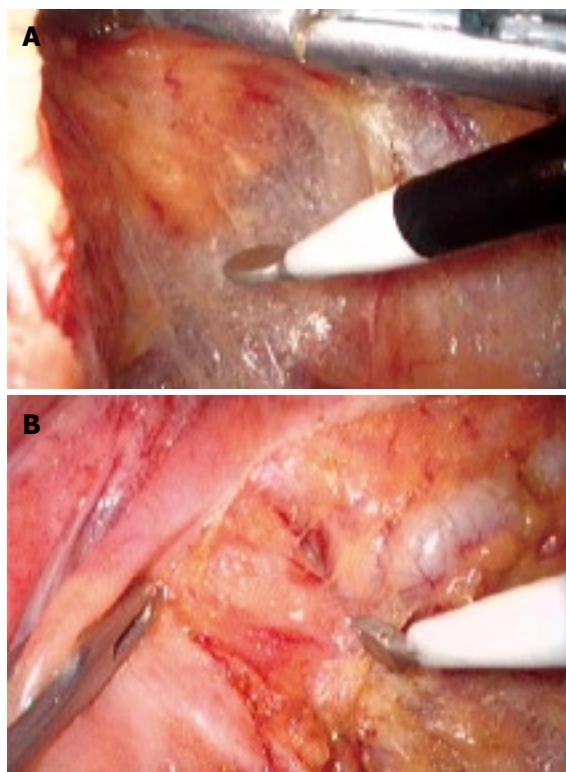

**Table 2 Comparison of surgical safety and postoperative recovery (*n*= 20, mean  $\pm$  SD)**

Parameters	ES group	US group	$\chi^2$ or <i>t</i>	<i>P</i>
WBC counts ( $\times 10^9/L$ )				
Preoperative	5.37 $\pm$ 0.84	5.55 $\pm$ 0.76	0.693	0.493

Wound infection ( <i>n</i> )	1	1	0.00	1.00

laparoscopic TME with anal sphincter preservation for rectal cancer because there is no large blood vessel in the space around the rectum.

The electric current through the tissue can produce high temperature from 100°C to 200°C because the resistance of tissues, the tissue degeneration, necrosis, drying, evaporation, carbonation, eschar, monopolar electrocautery can cut or stop bleeding<sup>[29,30]</sup>. The laparoscopic surgery, according to different operations, can choose different shaped monopolar electrocautery components such as monopolar electrocautery knife, monopolar electrocautery hook, monopolar electrocautery scissors and monopolar ES. ES is particularly suitable for laparoscopic TME with anal sphincter preservation for rectal cancer. First of all, the metal tip of ES only exposes a small area, it has a complete laparoscopic vision so as to avoid injuring the tissues outside the vision during operation in the narrow pelvic space, therefore, the laparoscopic operation has become more secure. Secondly, ES with blunt tip and a flat disk shape, can be used for blunt dissection without electricity supply and sharp dissection with electricity supply, avoiding frequent exchange of surgical instruments through trocars, so it is very suitable for dissection in the space around the rectum. Finally, the relatively sharp edge of ES can be used for sharp dissection, the disk of ES can oppress the bleeding point and achieve electrocoagulation when the tissue was bleeding, it has a good hemostatic effect. During the laparoscopic operation, ES should always use electrocoagulation in order to reduce the smog and extravasate from space wound. This study showed no significant difference in the blood loss, the pelvic drainage volume, the time of anal exhaust flow with defecation, the VAS and WBC counts between the ES group and the US group, indicating that the local and systemic impact of the body due to ES had no significant difference compared with US in laparoscopic TME with anal sphincter preservation for rectal cancer.

ES can produce a higher surface temperature when managing the tissues; the theoretical distance of thermal conduction is longer than that of US, which makes it

**Figure 1** Intraoperative photograph. **A:** Showing monopolar ES dissect the space around the rectum; **B:** Showing monopolar ES dissect the seminal vesicle and the rectum.

easy to damage the surrounding tissues<sup>[31]</sup>. Therefore, it is particularly important for surgeons to understand how to use ES in laparoscopic TME with anal sphincter preservation for rectal cancer. The correct method is to maintain a certain tension on both sides of the separation space; let the ES slightly contact the tissue with its sharp edge, and then gently slide along the surface of tissue in order to form a large space (Figure 1A). The tissue was cut immediately into slide aside to expose deep layer tissue and the important organs in the deep layer tissue can easily be uncovered and avoid injury, thus reducing the possibility of the surrounding tissue necrosis due to “heat chemotactic effect”. At the important anatomical position, the operative speed must be slow, use “mm-class” dissection and sharp dissection in combination with blunt dissection in order to reduce bleeding and avoid injury of major blood vessels and organs (Figure 1B). There was no significant difference in postoperative complications such as anastomotic leakage and wound infection between ES group and US group in our study, indicating that ES is as safe as US in laparoscopic TME with anal sphincter preservation for rectal cancer. The operative time was almost the same between the two groups, although the cutting speed of ES was faster than that of US. On the other hand, the intraperitoneal CO<sub>2</sub> must be exchanged regularly due to heavy smog generated by ES in order to maintain the clarity of operative vision, although it might slow the operative speed of ES in a certain extent. During operation, it must rely on the movement of metacarpophalangeal joint opening and closing repeatedly in order to control US. But in ES

operation, surgeons might feel more comfortable as they can grasp ES, and rely on the push-pull movement of the arm, and the hand movement intensity might significantly decrease. Compared with US, ES has prominent advantages, including sturdiness, durability, low cost, and being suitable for laparoscopic TME with anal sphincter preservation for rectal cancer in less developed settings.

In conclusion, ES is a safe and feasible tool similar to US used in laparoscopic TME with anal sphincter preservation for rectal cancer on the basis of skillful laparoscopic technique and complete understanding of laparoscopic pelvic anatomy. Application of ES can not only reduce the operation costs but also benefit the popularization of laparoscopic operation for rectal cancer patients.

## COMMENTS

### Background

Since the successful introduction of laparoscopic colectomy by Jacobs et al, laparoscopic surgery, especially laparoscopic rectal surgery has been developed considerably. Compared with open operation, the laparoscopic operation has many advantages such as less pain, little blood loss, small incision, good exposure of the pelvic cavity, an earlier return to daily activities, etc. while preserving the oncologic radicality of the procedure. However, the laparoscopic operation is more difficult than the open operation. Ultrasonically activated scalpel (US) is able to grasp and divide tissues while sealing small vessels, making the laparoscopic operation simpler, whereas the expensive medical instrument and high costs of the disposable materials can greatly increase the cost of laparoscopic rectal cancer operation.

### Research frontiers

It has been shown that the laparoscopic rectal cancer operation had the same short-term and long-term outcomes compared with open surgery, so how to overcome the operation difficulty and reduce the cost of laparoscopic rectal operation has become hotspots in laparoscopic surgery.

### Innovations and breakthroughs

In this study, authors tried to use cheap and durable monopolar electrocautery shovel (ES) in laparoscopic operation for rectal cancer in order to reduce the cost of the laparoscopic operation, they also summarized the technique and skill of using monopolar ES, and compared with US.

### Applications

ES is a safe and feasible tool similar to US used in laparoscopic TME for rectal cancer on the basis of skillful laparoscopic technique and complete understanding of laparoscopic pelvic anatomy. Application of ES can not only reduce the operation costs but also facilitate the popularization of laparoscopic operation for rectal cancer.

### Terminology

US is an expensive medical instrument which can incise tissue and seal small vessels, it is often used in complicated laparoscopic operations, but it costs high for the disposable materials. So in laparoscopic operation, US can greatly increase the cost of operation. ES is often used in simple laparoscopic operations because it is not as good as US for hemostasis, but it is cheap and durable.

### Peer review

This is an interesting manuscript looking into two different methods of dissecting the rectum laparoscopically. It is a good paper.

reactions (PCR) were performed, and microsatellite analysis was carried out.

**RESULTS:** No statistically significant difference was found in microsatellite instability (MSI) and loss of heterozygosity (LOH) of un-diluted DNA between SCC and ADC. The levels of MSI and LOH were high in the metaplasia-dysplasia-adenocarcinoma sequence of diluted DNA. The more the diluted DNA was, the higher the rates of MSI and LOH were at the above 7 loci, especially at D3S1616, D5S346, D2S123, D3S1300 and D18S58 loci.

**CONCLUSION:** The sequence of metaplasia-dysplasia-adenocarcinoma is associated with microsatellite alterations, including MSI and LOH. The MSI and LOH may be the early genetic events during esophageal carcinogenesis, and genetic alterations at the D3S1616, D5S346 and D3S123 loci may play a role in the progress of microsatellite alterations.

## INTRODUCTION

Barrett esophagus, thought to be primarily due to uncontrolled gastric acid and biliopancreatic reflux into the esophagus, is a precancerous condition<sup>[1,2]</sup>. It is estimated that the risk of neoplasia in Barrett esophagus, through the intermediate step of dysplastic

transformation of the columnar epithelium, is 125-fold higher than that in general population<sup>[1]</sup>. There is evidence that adenocarcinoma (ADC) of the esophagus arises in similar metaplastic epithelium, which has been termed “short segment Barrett esophagus” by some investigators<sup>[3,4]</sup>. However, this etiology alone is insufficient to explain the rising incidence of this highly lethal form of cancer<sup>[5,6]</sup>. Although several studies focusing on the squamous cell carcinoma (SCC) and the advanced stages of progression from dysplasia to ADC have investigated the role of genetic alterations in esophageal cancer (EC)<sup>[7-10]</sup>, scarce data are available on genetic alterations occurring in metaplasia-dysplasia-adenocarcinoma sequence of Barrett esophagus. To better understand the pathogenesis of esophageal ADC, we investigated the microsatellite alterations in these lesions. We dissected Barrett esophageal columnar epithelium (metaplasia) adjacent to dysplastic and neoplastic changes, dysplasia, and ADC, from the formalin-fixed, paraffin-embedded tissue blocks. Microsatellite alterations were evaluated at D2S123, D3S1616, D3S1300, D5S346, D17S787, D18S58 and BATRII loci, using the technique of dilution polymerase chain reaction (PCR). Our aim was to assess the early microsatellite alterations characterizing Barrett esophagus.

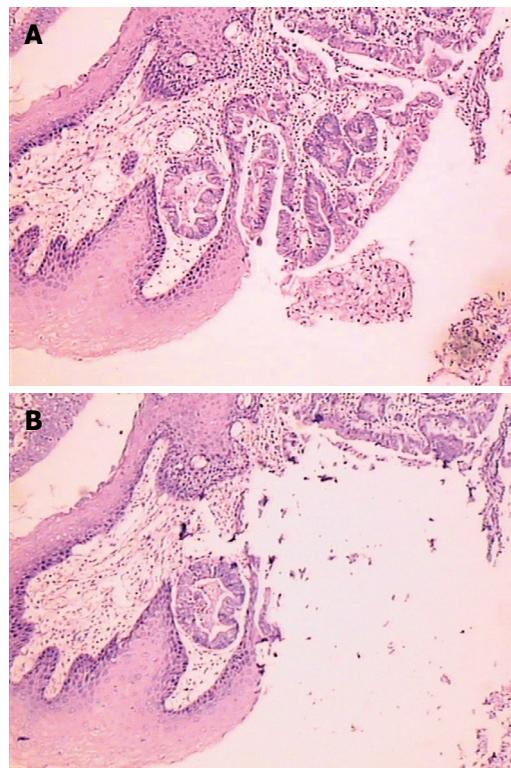

## MATERIALS AND METHODS

### Tissue specimens

Forty-one specimens were obtained from EC patients identified from Xiamen First Hospital affiliated to Fujian Medical University, Fujian Province, China, during 2002-2005. All the patients did not receive chemotherapy or radiation before surgery. Formalin-fixed, paraffin-embedded archival esophageal tissue specimens from 41 EC patients were accrued according to the guidelines established by the Ethics Committee of Xiamen First Hospital Affiliated to Fujian Medical University. Histopathological assessment identified 23 SCC and 18 ADC, including only 8 ADC with metaplasia and dysplasia adjacent to ADC. Strict criteria were used to diagnose ADC of primary esophageal origin as previously described<sup>[11]</sup>. Briefly, these included the presence of Barrett epithelium and dysplasia adjacent to ADC, at least 75% of tumor mass located in the distal one third of esophagus, invasion of periesophageal tissue, minimal gastric involvement, and clinical symptoms of dysphagia due to esophageal obstruction. Tissue histopathology was reviewed independently by 2 gastrointestinal pathologists.

### Tissue cellularity, DNA isolation and DNA dilution

Paraffin-embedded normal squamous epithelium, Barrett esophageal columnar epithelium (metaplasia), dysplasia and esophageal tumor tissues were dissected from the surrounding tissues under microscopic guidance in order to enrich the appropriate cell population for subsequent DNA extraction (Figure 1). All the hematoxylin-eosin

**Figure 1** Photomicrograph of epithelial dysplasia (HE,  $\times 200$ ) in Barrett esophagus (A) and after dissected under microscopic guidance (B).

(HE) stained sections of the above tissues from each EC patient were reviewed and cellularity was determined by estimating the relative density of neoplastic cells to normal tissue components (infiltrating stroma, muscle cells, white blood cells) per microscopic field. For the majority of cases, carcinoma specimens with at least 75% neoplastic cellularity were selected for microsatellite analyses. A series of unstained 10  $\mu\text{m}$ -thick sections of the above tissues were prepared from the corresponding paraffin-embedded tissue block with the microtome appropriately cleaned between cases in order to prevent tissue contamination. Previously selected areas on HE stained sections were then properly oriented and traced carefully on the corresponding unstained sections using a mark pen. Paraffin shaving from the unstained 10  $\mu\text{m}$ -thick sections was collected and pooled together in 0.5 mL Eppendorf tubes and DNA was extracted using proteinase K digestion buffer (10 mmol/L Tris-HCl, pH 8.0, 100 mmol/L KCl, 2.5 mmol/L MgCl<sub>2</sub>, 0.45% Tween20 and 2.5 mg/mL proteinase K) as previously described<sup>[12]</sup>. Briefly, samples were deparaffinized at 95°C for 10 min, cooled 1 h to room temperature and incubated at 65°C for 1 h with the proteinase K digestion buffer (100-200  $\mu\text{L}$ ). Samples were then denatured at 95°C for 10 min to remove excess proteinase K. The mixture was centrifuged at 5000 r/min for 5 min and the supernatant was carefully transferred by aspiration to a clean microcentrifuge tube. The quality of DNA was 1.07-1.24 ( $A_{260}/A_{280}$ ), the quantity of DNA was 255.4-407.0 ng/ $\mu\text{L}$ . To increase its sensitivity, DNA samples were diluted at 1:100, 1:1000, 1:5000, 1:10 000 and 1:50 000, respectively.

### Dilution PCR and microsatellite analysis

Seven microsatellite markers (D2S123, D3S1616, D3S1300, D5S346, D17S787, D18S58 and BATRII loci) were used in this study. The oligonucleotide primers used for PCR amplifications were obtained from Research Genetics (Huntsville, AL). Each PCR reaction contained 1 μL of DNA samples each diluted at 1:100, 1:1000, 1:5000, 1:10000 or 1:50000, respectively, 0.4 μCi [r-<sup>32</sup>p] ATP-radiolabeled microsatellite primer, 0.2 mmol/L dNTP, 10 mmol/L Tris-HCl (pH 8.3), 1.5 mmol/L MgCl<sub>2</sub>, 50 mmol/L KCl, and 0.4 units of Taq polymerase in a total reaction volume of 10 μL (that was called dilution PCR). The hot start PCR was used to eliminate nonspecific amplification. The samples underwent 35 cycles of PCR amplification (95°C for 30 s, 58°C for 40 s, and 72°C for 60 s) followed by an extension at 72°C for 2 min. Several PCR amplifications were performed for each DNA dilution. PCR products were diluted at 1:1 in a formalin loading buffer containing 95% formalin, 0.05% bromophenol blue, 0.05% xylene cyanol and 20 mmol/L EDTA, and 5 μL aliquots of PCR products was electrophoresed on 7% denaturing polyacrylamide gels (19:1 acrylamide:bisacrylamide) containing 5.6 mol/L urea, 32% formamide and 1 × TBE [0.089 mol/L Tris (pH 8.3)], 0.089 mol/L borate and 0.002 mol/L EDTA] at 75 W for 2-4 h. Gels were vacuum-dried at 80°C and exposed to a Kodak MR film (Kodak, Xiamen, China) for 6-24 h. Microsatellite analysis was carried out. A sample was scored positive for microsatellite instability (MSI) if additional new alleles were observed in Barrett esophageal epithelium or dysplasia or tumor DNA compared to control DNA from the same individual. Loss of heterozygosity (LOH) was defined as a visible reduction (at least 2 folds or more) in the ratio of signal intensities of the 2 alleles in metaplasia or dysplasia or tumor DNA relative to that observed in the corresponding normal DNA of the same individual. In all positive results analyzed, since

losses were readily visible or obvious, quantification was unnecessary. To ensure that the allele in intensities was identified in microsatellite analysis, multiple exposures of each autoradiograph were carried out. The autoradiographs were independently scored by JCC and HPZ.

### Statistical analysis

Fisher's exact test was performed to assess any statistically significant correlation of the frequency of the 2 histological subtypes (SCC vs ADC) or 2 subgroups (un-dilution vs dilution) by SPSS 10.0. P < 0.05 was considered statistically significant.

## RESULTS

### Microsatellite alterations in undiluted DNA of SCC and ADC

A varying level of MSI, ranging from 0% (0/23) to 28.6% (6/23) at the 7 loci tested, was detected in 23 SCC. The rate of MSI was 25% (3/18) at the D2S123 or D3S1616 or D5S346 locus in 18 ADC. The rate of MSI was 0 at the D3S1300, D17S787, D18S58 and BAT-R II loci in 18 ADC. Only informative cases (heterozygous for the microsatellite markers used) were considered for LOH analysis. The rate of LOH was 23.5% (4/17 informative cases) at the D3S1300 locus, and very low for the other loci in 23 SCC. The rate of LOH was 10.0% (1/10 informative cases) at the D2S123 or D3S1300 or D3S1616 locus, the others were 0 in 18 ADC. The results of the microsatellite analysis are summarized in Tables 1 and 2. No statistically significant difference was found in the rate of MSI and LOH at one or more positive loci, or at two or more positive loci between SCC and ADC.

### Microsatellite alterations in diluted DNA of phenotypically normal esophageal squamous epithelium and metaplasia-dysplasia-adenocarcinoma sequence

Dilution PCR showed that the more sensitive strategy

for analyzing microsatellite changes was developed, reasoning that if a rare cell in a population harbored microsatellite alterations, the new microsatellite alleles would not be detected amid the large background of normal alleles<sup>[13,14]</sup>. High levels of MSI and LOH were very commonly found in phenotypically normal esophageal squamous epithelium and metaplasia-dysplasia-adenocarcinoma sequence of diluted DNA. The more the dilution of DNA (up to 1:5000) was, the higher the rates of MSI and LOH were at the above 7 loci, especially at D3S1616, D5S346, D3S123, D2S1300 and D18S58 loci. However, the rates of MSI and LOH were low when DNA was diluted at 1:10 000 and up, because most PCR products were not available. The data described here could document a profound microsatellite alteration in phenotypically normal esophageal squamous epithelium and metaplasia-dysplasia-adenocarcinoma sequence, although un-diluted DNA was not discovered. The results of microsatellite analysis are summarized in Tables 1, 2 and Figure 2.

## DISCUSSION

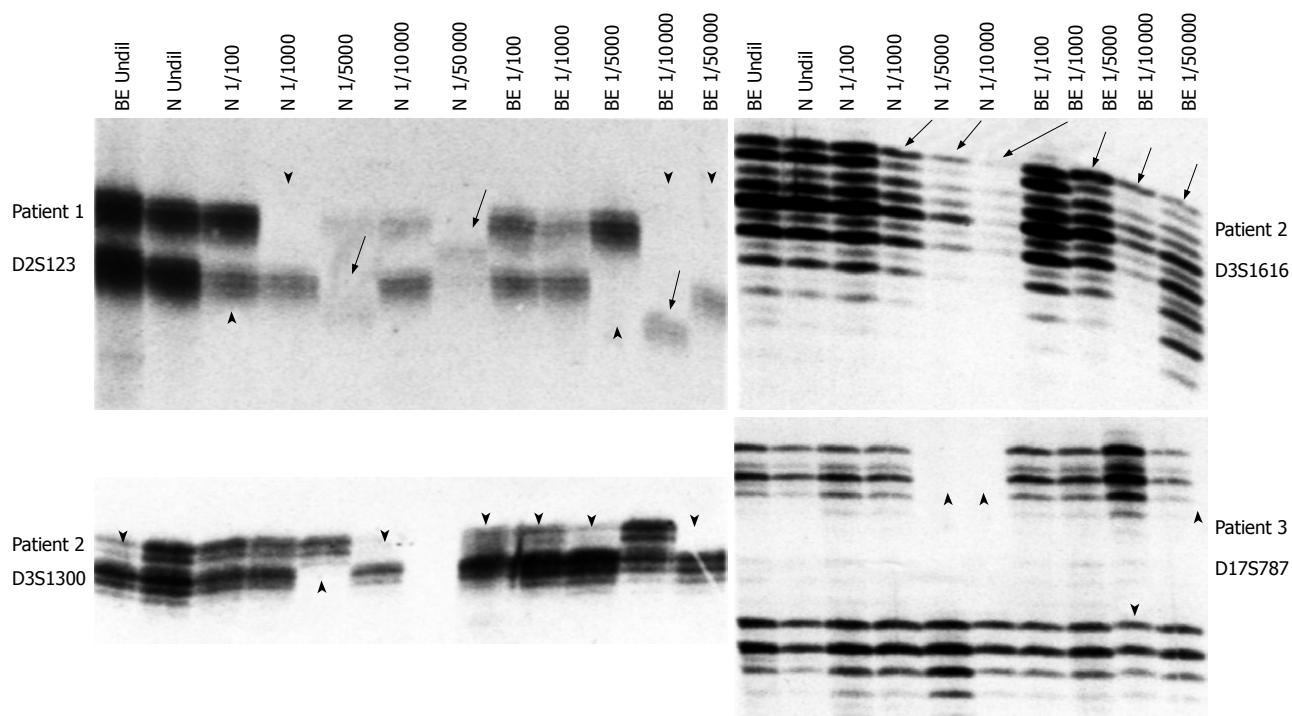

Tumor of Barrett esophagus occurs via a multi-step pathway, and is histopathologically recognized as a metaplasia-dysplasia-adenocarcinoma sequence<sup>[15]</sup>. DNA and certain molecular abnormalities under the form of proto-oncogene alterations, LOH and mutations of tumor suppressor genes are thought to represent the genetic background of metaplastic and dysplastic changes<sup>[16-19]</sup>. In recent years, frequent or infrequent MSI at multiple microsatellite loci corresponding to diverse tumor suppressor genes has been demonstrated in ADC of colon and rectum, small intestine, stomach, gallbladder and esophagus<sup>[20-24]</sup>. However, few data are available on the correlation between microsatellite alterations and metaplasia-dysplasia-adenocarcinoma sequence in Barrett esophagus, especially in normal squamous epithelium and metaplastic tissue adjacent to dysplasia and neoplasm.

Our study was to assess the microsatellite alterations in metaplasia-dysplasia-adenocarcinoma sequence of Barrett esophagus, as well as in normal squamous epithelium adjacent to metaplastic tissue. Tissue was dissected under microscopic guidance with a new technique which ensures enrichment and purity of the tissues to be studied and the specificity of the molecular event encountered.

In this study, the frequency of MSI was investigated in 23 SCC and 18 ADC, including 8 ADC with Barrett esophageal columnar epithelium and dysplasia. MSI of at least one microsatellite locus was detected in 10 out of 23 SCC (47.6%) and 5 out of 18 ADC (41.7%). MSI of two or more microsatellite loci was found in 5 out of 23 SCC (23.8%) and 3 out of 18 ADC (25.0%). MSI was found in 1 out of 8 Barrett esophageal columnar epithelium tissue samples, 2 out of 8 dysplasia tissue samples adjacent to ADC only at one microsatellite locus. Although no significant difference was found in the frequency of MSI between SCC and ADC in this study, the results are in agreement with the findings of some previous studies showing frequent MSI in EC<sup>[25-28]</sup>, but not consistent with some recent reports showing infrequent MSI in EC<sup>[24,29]</sup>.

It was reported that tumors develop *via* a process of clonal expansion resulting from the selection of increasingly abnormal sub-populations<sup>[10]</sup>. According to this theory, microscopic tumor usually represents the clonal expansion of one or a few cells, indicating that cells of a given neoplasm should share some common genetic abnormalities<sup>[10]</sup>. In order to find whether microsatellite alterations are an early event in esophageal ADC, we diluted DNA of metaplasia, dysplasia, ADC and normal esophageal squamous epithelium from the same 8 patients, and performed dilution PCR which showed surprisingly high levels of MSI and LOH expression at the early stage of metaplasia-dysplasia-adenocarcinoma sequence.

However, some studies also suggested that PCR

**Figure 2** Microsatellite alterations in diluted DNA. Arrow and arrowhead indicate MSI and LOH, respectively. N: Normal esophageal squamous epithelium DNA; BE: Barrett esophageal columnar epithelium (metaplasia) DNA; Undil: Un-diluted; 1/100-1/50 000: Dilution fold.

artifacts are found when paraffin-embedded tissues are used, especially when the number of cells analyzed is small<sup>[30,31]</sup>. With a larger number of target cells, enough non-damaged templates dominate the amplification process. With a smaller amount of cells, only fragmented DNA presents and requires a few PCR cycles to achieve an *in vitro* repaired template that would yield an exponential amplification<sup>[30,31]</sup>. Thus, to minimize the potential for artificial microsatellite alterations resulting from the diluted DNA, DNA was diluted at 1:100 to 1:50 000 for the dilution PCR. The concentration was estimated to be 25.5-40.7 pg/µL DNA when diluted at 1:10 000. PCR amplification was performed for each diluted DNA. For example, in patient 1, a concentration of 34.3-40.7 pg/µL DNA diluted at 1:10 000 was used.

Interestingly, microsatellite alterations were detected in all the eight patients having the “sequence” of metaplasia-dysplasia-adenocarcinoma at each representative DNA dilution. Similarly, microsatellite alterations were detected both in metaplasia and in dysplasia adjacent to ADC at the 7 microsatellite loci. The more the dilution of DNA was, the higher the rate of microsatellite alterations was at the D3S1616, D5S346, D2S123, D3S1300 and D18S58 loci depending on development of the metaplasia-dysplasia-adenocarcinoma sequence, clearly revealing that there are extensive microsatellite alterations at the D3S1616, D5S346, D2S123, D3S1300 and D18S58 loci in the metaplasia-dysplasia-adenocarcinoma sequence of Barrett esophagus, even in the histopathologically normal esophageal squamous epithelium. The observations of shared molecular abnormalities in metaplasia, dysplasia and ADC suggested a process of

colonial expansion in the proposed histological pathway of tumor development, which may be partly interpreted by the fact that only partial cells undergo molecular alterations under a similar circumstance.

In conclusion, high levels of MSI and LOH are frequently found in metaplasia, dysplasia and adenocarcinoma. Development of esophageal ADC is associated with microsatellite alterations, including MSI and LOH. These alterations occurring in recognized precursor lesions provide evidence for support of the proposed metaplasia-dysplasia-adenocarcinoma sequence in Barrett esophagus. MSI and LOH may be the early genetic events during esophageal carcinogenesis. Additional genetic alterations at the D3S1616, D5S346 and D3S123 loci probably play a role in the progression of these diseases. D3S1616, D5S346, D2S123, D3S1300 and D18S58 loci may be used as predictive markers for the early detection of esophageal ADC.

## COMMENTS

### Background

It is estimated that the risk of neoplasia in Barrett esophagus is 125-fold higher than that in the general population, through the intermediate step of dysplastic transformation of the columnar epithelium. There is evidence that adenocarcinoma (ADC) of the esophagus arises in metaplastic epithelium, termed “short segment Barrett esophagus”. However, this etiology alone is insufficient to explain the rising incidence of this highly lethal form of cancer.

Although several studies focusing on the squamous cell carcinoma (SCC) and the advanced stages of progression from dysplasia to ADC, have investigated the role of genetic alterations in esophageal cancer (EC), scarce data are available on genetic alterations occurring in metaplasia-dysplasiaadenocarcinoma sequence of Barrett esophagus.

### Research frontiers

Tumor occurring in Barrett esophagus via a multi-step pathway is histopathologically recognized as a metaplasia-dysplasia-adenocarcinoma sequence. Certain molecular abnormalities in the form of proto-oncogene alterations, loss of heterozygosity (LOH) and mutations of tumor suppressor genes are thought to represent the genetic background of metaplastic and dysplastic changes. In recent years, frequent or infrequent microsatellite instability (MSI) at multiple microsatellite loci corresponding to the diverse tumor suppressor genes has been found in ADC of colon and rectum, small intestine, stomach and esophagus. However, few data are available on the correlation between microsatellite alterations and metaplasia-dysplasia-adenocarcinoma sequence in Barrett esophagus, especially in normal squamous epithelium and metaplastic tissue adjacent to dysplasia and neoplasm.

### Innovations and breakthroughs

Dilution polymerase chain reaction (PCR), the more sensitive strategy for analyzing microsatellite changes, was developed, reasoning that if a rare cell in a population harbored microsatellite alterations, the new microsatellite alleles would not be detectable amid the large number of normal alleles. High levels of MSI and LOH are frequently found in phenotypically normal esophageal squamous epithelium and metaplasia-dysplasia-adenocarcinoma sequence of diluted DNA in this study.

### Applications

MSI and LOH might be the early genetic events during esophageal carcinogenesis. Additional genetic alterations at the D3S1616, D5S346 and D3S123 loci may play a role in progression of ADC. The microsatellite markers (D3S1616, D5S346, D2S123, D3S1300 and D18S58 loci) may be used as predictive markers in the early detection of esophageal ADC.

### Terminology

Dilution PCR refers to diluted DNA of metaplasia, dysplasia, ADC and normal esophageal squamous epithelium in the same patient before PCR is performed.

### Peer review

The study was well designed and provided a great finding at metaplasia-dysplasia-adenocarcinoma sequence in Barrett esophagus. It is interesting.

group ( $t = 5.254, 3.438$  and  $3.527, P < 0.001$ ). SOD of the reflux group was shorter than the control group ( $t = 2.049, P < 0.05$ ). The level of serum gastrin and plasma motilin of the reflux group was much lower than the control group ( $t = -2.230$  and  $-2.235, P < 0.05$ ). There was positive correlation between the level of plasma motilin and SOBP and between the level of serum gastrin and SOBP and CBDP.

**CONCLUSION:** About 35.9% of the patients with a T tube after cholecystectomy and choledochotomy have duodenal-biliary reflux. Most of them have sphincter of Oddi hypomotility and the decreased level of plasma motilin and serum gastrin. The disorder of gastrointestinal hormone secretion may result in sphincter of Oddi dysfunction. There is a close relationship between sphincter of Oddi hypomotility and duodenal-biliary reflux.

Sphincter of Oddi hypomotility and its relationship with duodenal-biliary reflux, plasma motilin and serum gastrin. *World J Gastroenterol* 2008; 14(25): 4077-4081 Available from: URL: <http://www.wjnet.com/1007-9327/14/4077.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4077>

## Abstract

**AIM:** To detect whether patients with a T tube after cholecystectomy and choledochotomy have duodenal-biliary reflux by measuring the radioactivity of Tc99m-labeled diethylene triamine penta-acetic acid (DTPA) in the bile and whether the patients with duodenal-biliary reflux have sphincter of Oddi hypomotility, by measuring the level of plasma and serum gastrin of the patients. Finally to if there is close relationship among sphincter of Oddi hypomotility, duodenal-biliary reflux and gastrointestinal peptides.

**METHODS:** Forty-five patients with a T tube after cholecystectomy and choledochotomy were divided into reflux group and control group. The level of plasma and serum gastrin of the patients and of 12 healthy volunteers were measured by radioimmunoassay. Thirty-four were selected randomly to undergo choledochoscopy manometry. Sphincter of Oddi basal pressure (SOBP), amplitude (SOCA), frequency of contractions (SOF), duration of contractions (SOD), duodenal pressure (DP) and common bile duct pressure (CBDP) were scored and analyzed.

**RESULTS:** Sixteen (35.6%) patients were detected to have duodenal-biliary reflux. SOBP, SOCA and CBDP in the reflux group were much lower than the control

## INTRODUCTION

Endoscopic sphincterotomy (EST) is an important surgery to treat choledocholithiasis. About 50% of the patients after EST had biliary gas indicating reflux of duodenal contents<sup>[1]</sup>. The duodenal-biliary reflux rate was as high as 100% in the patients after EST<sup>[2]</sup>. The stone recurrence rate was 9.8% in the patients with EST<sup>[3]</sup>, but in the patients after cholecystectomy for gallbladder stones, the choledocholithiasis recurrence rate was only about 2.5%<sup>[4]</sup>. Thus, EST destroyed the sphincter of Oddi, resulting in duodenal-biliary reflux which may have close relationship with the recurrence of choledocholithiasis.

The stone recurrence rate was about 10.3% in the patients with T tubes after cholecystectomy and choledochotomy without apparent difference from that of patients after EST<sup>[3]</sup>. To understand whether sphincter of Oddi hypomotility and duodenal-biliary reflux existed in these patients and if these patients had abnormal secretion of gastrointestinal hormones it needs further studies. To detect if the duodenal-biliary reflux existed the radioactivity of Tc99m-labeled diethylene triamine pentaacetic acid (DTPA) in the bile from the T tubes. Besides, we investigated whether the patients with duodenal-biliary flux had sphincter of Oddi hypomotility and we measured the level of plasma motilin and serum gastrin of the patients. Finally, we discuss the relationship of duodenal-biliary flux with sphincter of Oddi hypomotility, serum gastrin and plasma motilin.

## MATERIALS AND METHODS

### **Patients**

Forty-five patients (16 men, 29 women, and mean age 58.9 years), who underwent cholecystectomy and choledochotomy at least 1.5 mo (mean 2.5 mo) after T tube drainage, were selected at the Second Affiliated Hospital of China Medical University between April 2004 and August 2005. They were divided into reflux group and control group. The amount of radioactivity of DTPA in the bile was measured and their blood was taken at fasting state in the morning for detecting serum gastrin and plasma motilin. The blood of 12 healthy volunteers (9 men, 3 women and mean age 51.6 years) was taken as control. Thirty-four patients (12 men, 22 women, and mean age 58.3 years) were selected for sphincter of Oddi manometry randomly and double-blindedly.

### **Observation of duodenal-biliary reflux**

The patients were fasted overnight and took 1 mL water orally containing 185 MBq (5mCi) <sup>99m</sup>Tc-DTPA, then drunk 240 mL water and took a prostrate position. The bile of 2 h was collected and 20 mL of the bile were taken for detection. The intensity of radioactivity was counted in the RM905 radioactivity-detecting meter. Patient was thought to have duodenal-biliary reflux when radioactivity was detected in the bile. <sup>99m</sup>Tc-DTPA was prepared just before administration and radiochemical purity was detected by radiochromatography. The radiochemical purity of <sup>99m</sup>Tc-DTPA was more than 99% while the free <sup>99m</sup>Tc was less than 1%.

### **Detection of plasma motilin and serum gastrin**

Four mL vein blood was obtained from the patients and healthy volunteers in the early morning and was put into two test tubes undividedly. One of them was filled with 30 μL 10% ethylene diamine tetraacetic acid disodium and 30 μL aprotinin. Then they were centrifuged at 1500 r/min for 15 min, serum and plasma isolated were put into Eppendorf tubes and stored in freezing refrigerator at -70°C.

Plasma motilin and serum gastrin were measured by radioimmunoassay. The sample of serum, plasma misce bene was collected before measurement, then

centrifuged at 1500 r/min for 15 min, The supernatant was taken and tested. The motilin radioimmunoassay kit was supplied by Peking Huaying Biotechnology Research Institute. The gastrin radioimmunoassay kit was provided by Isotope Research Center of the China Atomic Energy Academy.

### **Method and apparatus of sphincter of Oddi manometry**

A triple lumen polyethylene manometry catheter 200 cm in length with an outer diameter of 1.7 mm was used for manometry. The three side holes in the distal end were located 2 mm apart. Sterile water was infused through the catheter at a flow rate of 0.5 mL/min by a hydraulic capillary infusion system. PC polygraph HR (Swedish CTD-Synectics Medical Company) and relevant program were used to record and analyze the tracings. Manometry was performed after all the stones were removed from the common bile duct. The catheter was introduced via the side-pore of choledochoscope into duodenum directly, when the pressure was stable, duodenal pressure-curve was recorded. It was then withdrawn in a stepwise fashion; the position of catheter in the sphincter could be confirmed by direct observation under choledochoscope or by the characteristic pressure changes on the screen. The Oddi's sphincter and common bile duct motility tracings were recorded respectively.

Sphincter of Oddi basal pressure (SOBP), amplitude of phasic contractions (SOCA), frequency of phasic contractions (SOF), duration of phasic contractions (SOD), duodenal pressure (DP) and common bile duct pressure (CBDP) were recorded and analyzed with a special computer program.

Statistical analysis was carried out using Student's *t* test. Data were analyzed with software SPSS11.5. The results were expressed as mean ± SD. Levene's test was used to test the homoscedasticity of the data; *t* test would be used when data had no homoscedasticity. A two-tailed *P* value of < 0.05 was considered significant statistically. Pearson correlation test was used to test correlation of the data.

## RESULTS

### **Duodenobiliary reflux**

There were 16 (35.6%) patients with duodenal-biliary reflux among 45 patients who underwent cholecystectomy, choledochotomy and T tube drainage. The mean technetium count of the bile was 132.73 ± 246.07 KBq (counting performed at the second hour after the isotope ingested). The rest 29 bile samples detected had no radioactivity.

### **Plasma motilin and serum gastrin**

Plasma motilin (377.54 ± 130.44) and serum gastrin (68.33 ± 28.56) of the reflux group is apparently lower than that of the control group and the non-reflux group (Table 1).

### **Manometry of SO**

Thirty-four patients were selected (12 men, 22 women,

**Table 1** Plasma motilin and serum gastrin of patients with a T tube after cholecystectomy and choledochotomy (pg/mL)

	Cases	Level of plasma motilin	Level of serum gastrin
Reflux group	16	377.54 ± 130.44 <sup>a,d</sup>	68.33 ± 28.56 <sup>a,d</sup>
Non-reflux group	29	525.37 ± 184.47	97.64 ± 26.93
Control group	12	499.02 ± 157.77	92.95 ± 25.67

<sup>a</sup>P < 0.05 vs the control group; <sup>d</sup>P < 0.01 vs the nonreflux group.

and mean age 58.3 years) for sphincter of Oddi manometry randomly and double-blindedly. Among them 13 were classified into the reflux group and 21 into the control group (Table 2).

The sphincter of Oddi's basal pressure, amplitude, common bile duct' pressure in the reflux group were significantly lower than that of the control group ( $P < 0.001$ ), the duration of contractions of the reflux group was shorter than that of control group while there was no significant difference in the frequency of contractions and duodenal pressure between the two groups. The change of SOCA was most remarkable; and the mean value of the reflux group was lower than that half of the control group. In the reflux group, there were 10 (76.9%) patients with DP higher than SOBP and 8 (61.5%) patients with DP higher than CBDP while no patient with DP higher than SOBP and only 2 (9.5%) patients with DP higher than CBDP in the control group (Table 2).

#### Pearson correlation test

There was no evident correlation between plasma gastrin and serum motilin (the Coefficient of Correlation was 0.146) while plasma motilin showed obviously positive correlation with sphincter of Oddi basal pressure (the Coefficient of Correlation was 0.366) ( $P < 0.05$ ). Moreover serum gastrin showed apparent positive correlation with sphincter of Oddi basal pressure (the Coefficient of Correlation is 0.429) ( $P < 0.05$ ) and common bile duct pressure (the Coefficient of Correlation is 0.359) ( $P < 0.05$ ).

## DISCUSSION

Sphincter of Oddi was at the lower end of the bile duct and pancreatic duct. It plays a major role in controlling bile and pancreatic juice flowing into the duodenum and equally importantly to prevent reflux of duodenal contents into the biliary and pancreatic duct. One-hundred years ago, a variety of names were given to malfunction of sphincter of Oddi, including odditis, biliary dyskinisia, postcholecystectomy and sphincter of Oddi stenosis. Now based on manometry, sphincter of Oddi dysfunction was subdivided into two groups; one of a stenotic pattern and the other a dyskinetic pattern<sup>[5]</sup>. Reports about sphincter of Oddi hypomotility and sphincter of Oddi dilation were rare. Does sphincter of Oddi hypomotility exist? Does it have close relationship with duodenal-biliary reflux? Does it have close relationship with recurrent cholangitis and recurrent gallstone? Our

study would discuss these questions profoundly.

Digestive juice reflux is an abnormal phenomenon of the digestive tract. Duodenal-gastric reflux and gastric-esophagus reflux were most common among them which would result in reflux gastritis and esophagitis<sup>[6,7]</sup>. Under some conditions, such as after intestinal anastomosis and EST, duodenobiliary reflux may occur, resulting in ascending cholangitis. But whether duodenobiliary reflux existed in patients with gallstones and without EST and in healthy people, has been rarely studied. Feng *et al*<sup>[8]</sup> found only two of 30 patients with gallbladder stones had duodenobiliary reflux. Wang *et al*<sup>[9]</sup> studied 53 patients who suffered from the recurrent inflammation of biliary duct after operation and found that the incidence rate of duodenobiliary reflux was as high as 66.67%. The change of biliary tract anatomy could result in pneumatosis of the duct of Wirsung, suggesting duodenopancreas reflux<sup>[10]</sup>. Li *et al*<sup>[11]</sup> found that there was apparent duodenobiliary reflux during the process of T tube drainage and the main bacterium infecting bile was G<sup>-</sup> bacterium (especially the *E. coli*). We employ <sup>99m</sup>Tc-DTPA for the first time to determine duodenobiliary reflux in patients undergoing choledocholithotomy plus T-tube drainage. The only machine used was RM905 radioactivity meter. For its high molecular weight, <sup>99m</sup>Tc-DTPA had no other pathway to enter into the bile and it was hard for it to penetrate the intestinal mucosa<sup>[12]</sup>. If there was radioactivity detected in patients' bile, we could infer they had duodenobiliary reflux. The method was simple, less expensive and safe. It was easy to repeat within a short period for the short half-life of the technetium. The results could be easily understood. It had a high specificity (100%), and the sensibility was still unknown since the occurrence of duodenobiliary reflux also could be influenced by many factors, such as the state of the sphincter of Oddi. This means the real duodenobiliary reflux incidence among patients undergoing choledocholithotomy may be higher than our results. We found that the morbidity of duodenobiliary reflux among these people was 35.9% (28/78). It was so high, resulting in bacterial infection and recurrence of stone.

As a valve to prevent duodenal juice reflux, does state of Oddi sphincter have intimate relationship with duodenobiliary reflux? There were numerous and thorough researches on sphincter of Oddi disorder<sup>[13-17]</sup>, but reports about sphincter of Oddi hypomotility and sphincter of Oddi dilation were relatively rare. Early in the 1890, Courvoisier found that 14% of the patients with common bile duct stones had dilation of the duodenal ampulla. Deng *et al*<sup>[18]</sup> found that the mean contraction period was shortened ( $P < 0.02$ ), and that the frequency ( $P < 0.005$ ) and amplitude ( $P < 0.001$ ) of sphincter phasic waves during phase III were decreased in the patients with proximal duodenal transection performed during gastrectomy; this suggested that duodenal transection produced significant changes in interdigestive sphincter of Oddi motility, possibly contributing to augmented duodenobiliary reflux and then lithogenesis. There were many case reports about

**Table 2 Results of sphincter of Oddi manometry of patients with a T tube after cholecystectomy and choledochotomy (mmHg)**

Groups	n	M/F	Age (yr)	SOBP	SOCA	SOD	SOF	CBDP
Reflux group	13	7/6	62.4 ± 8.4	-3.48 ± 4.77	33.81 ± 29.51	4.34 ± 1.26	7.46 ± 2.80	-1.64 ± 4.91
Control group	21	6/15	55.7 ± 14.2	12.26 ± 10.08 <sup>b</sup>	91.40 ± 66.97 <sup>b</sup>	5.27 ± 1.31 <sup>b</sup>	7.08 ± 2.78	6.70 ± 7.58 <sup>b</sup>

<sup>b</sup>P < 0.01 vs control group.

patients who had sphincter of Oddi hypomotility which expressed pneumobilia, lower SOBP and SOCA (patients with chronic intestinal pseudo-obstruction<sup>[19]</sup>, common bile duct stones<sup>[20]</sup> and progressive systemic sclerosis<sup>[21]</sup>). Factors correlated to sphincter of Oddi hypomotility including dragging of SO by postoperative adhesion, intra-abdominal abscess, pancreatitis, incompetence of SO resulting from tumors, retrograde peristalsis of duodenum, functional disorder of nerves of the sphincter, passing of stones and actions of drugs.

We found that 16 patients had duodenal-biliary reflux among 45 patients who underwent cholecystectomy and T tube drainage (35.6%), a large number of whom had sphincter of Oddi hypomotility. There were ten (76.9%) patients with DP higher than SOBP and 8 (61.5%) patients with DP higher than CBDP (61.5%) while no patient with DP higher than SOBP and only two (9.5%) patients with DP higher than CBDP (9.5%) in the control group. Sphincter of Oddi structure of human is resembled to that of cats. The bile flow stopped at the contraction state while expelling to the duodenum in the intervals of contraction, but the sphincter of opossum can expel bile during the contraction stage. Sphincter of cats and opossums could expel bile into the duodenum when the duodenum pressure was as high as 45 cmH<sub>2</sub>O and no duodenobiliary reflux occurred<sup>[22]</sup>. Sphincter of Oddi function played an important role in preventing the occurrence of duodenobiliary reflux. It would lose its function of non-return valve in the hypomotility state and could not prevent the duodenal fluid refluxing into the biliary duct and pancreatic duct.

It has been verified that when duodenal juice was added to lithogenic bile, gallstones formed<sup>[23]</sup>. Bacterial pathogens gained access into the biliary system by descending *via* the portal venous circulation or through the sphincter of Oddi. Bacteria thrived as glycocalyxenclosed microcolonies, coalescing to form an adherent biofilm. The establishment of biofilm was a key event in the formation of biliary sludge and pigment gallstones<sup>[24]</sup>. There were about 35.9% of the patients with a T tube after cholecystectomy and choledochotomy who had duodenal-biliary reflux. Most of them had sphincter of Oddi hypomotility. We thought that sphincter of Oddi hypomotility may be one of the most important factors which would result in duodenal-biliary reflux, and reflux of duodenum juice into biliary duct is a main cause of stone recurrence.

Motilin is a kind of multiple peptide hormones which contains 22 amino acids and is secreted by the endocrine cells of gut (mainly produced by cells of sinus ventriculi, duodenum and upper part of small intestine).

It had the effect of strongly stimulating the contraction of the upper digestive tract and physiological myoelectric activity of its smooth muscle cells. Motilin can invoke contractions of smooth muscle of gallbladder and stimulate secretions of bile. Motilin had prokinetic effect on the sphincter of Oddi and its function had intimate relationship with the dosage used<sup>[25-27]</sup>. When large dose of motilin used, the sphincter of Oddi of animals contracted, even spasmed. Gastrin is a kind of gastrointestinal hormone, which has been studied earlier and intensively. It is mainly secreted by the G cells of the sinus ventriculi mucosa and small intestines. The researches about effect of gastrin on sphincter of Oddi are rare<sup>[28-30]</sup>. A few reports showed gastrin could increase SOBP and SOCA. Chen suggested that the patients with post-cholecystectomy pain had sphincter of Oddi dysfunction with characteristics of high tension and it was related to elevation of serum gastrin<sup>[31]</sup>. Our study found that many patients with a T tube after cholecystectomy and choledochotomy had duodenal-biliary reflux. Most of them had sphincter of Oddi hypomotility, and decreased plasma motilin and serum gastrin. Plasma motilin showed obviously positive correlation with sphincter of Oddi basal pressure while serum gastrin showed apparent positive correlation with sphincter of Oddi basal pressure and common bile duct pressure. Disorder of gastrointestinal hormone secretion might result in sphincter of Oddi dysfunction and the sphincter of Oddi hypomotility caused by it had intimate relationship with duodenal-biliary reflux and recurrence of gallstones.

## COMMENTS

### Background

Sphincter of Oddi is at the lower end of the bile duct and pancreatic duct. It plays a major role in controlling the flowing of bile and pancreatic juice into the duodenum and equally importantly to prevent the reflux of duodenal contents into the biliary and pancreatic duct. Based on manometry, sphincter of Oddi dysfunction was subdivided into two groups; one characterized by a stenotic pattern and the other a dyskinetic pattern. The reports about sphincter of Oddi hypomotility and sphincter of Oddi dilation are fairly rare.

### Research frontiers

Whether sphincter of Oddi hypomotility and duodenal-biliary reflux existed in patients with a T tube after cholecystectomy and choledochotomy and if they had abnormal secretion of gastrointestinal hormones needed further researches. Does sphincter of Oddi hypomotility exist? Does it have close relationship with duodenal-biliary reflux? Does it have close relationship with recurrent cholangitis and recurrent gallstone? This study discussed these questions profoundly.

### Innovations and breakthroughs

This study found many patients with a T tube after cholecystectomy and choledochotomy had duodenal-biliary reflux. Most of them had sphincter of Oddi hypomotility, plasma motilin and serum gastrin of them decreased. The disorder

of gastrointestinal hormone secretion might result in sphincter of Oddi dysfunction and sphincter of Oddi hypomotility caused by it had intimate relationship with duodenal-biliary reflux and recurrence of gallstones.

### Applications

The reports about sphincter of Oddi hypomotility and sphincter of Oddi dilation are relatively rare. Authors found the disorder of gastrointestinal hormone secretion might result in sphincter of Oddi dysfunction and sphincter of Oddi hypomotility caused by it had intimate relationship with duodenal-biliary reflux and recurrence of gallstones. So regulating the level of hormones might be helpful in the treatment of sphincter of Oddi dysfunction.

### Peer review

It is a very interesting study, and the presentation of manuscript is good. Title accurately reflects the major topic and contents of the study. Although it is not a multi-center study the results are very interesting because they demonstrated more about the function of the Sphincter of Oddi. Discussion is well organized, and references are appropriate and relevant.

### Abstract

**AIM:** To explore the relationship between serum p53 antibodies (p53-Abs) and clinicopathological characteristics and therapeutic effect in patients with esophageal carcinoma (EC), and to investigate sequential changing regularity of serum p53-Abs after radiotherapy.

**METHODS:** The serum p53-Ab levels were detected in 46 EC patients and 30 healthy adults by enzyme linked immunosorbent assay (ELISA). The blood samples were collected on the day before radiotherapy and on the administration of an irradiation dose of 20 Gy/10 f/12 d, 40 Gy/20 f/24 d and 60 Gy/30 f/36 d after radiotherapy.

**RESULTS:** The level and positive rate of serum p53-Abs in EC patients were significantly higher than those in normal individuals ( $P < 0.05$ ). Serum anti-p53 antibodies were positive in 18 of 46 EC patients (39.1%). The positive rate of p53-Abs in EC was related to histological grade, disease stage and lymph node metastasis ( $P < 0.05$ ), but it was not significantly related to sex, age and to the size and site of tumor. The level and positive rate of p53-Abs had significant differences between before radiotherapy and after administration of an irradiation dose of 40 Gy/20 f/24 d and 60 Gy/30 f/36 d ( $P < 0.05$  or  $P < 0.01$ ). The positive rate of p53-Abs in EC patients with effect was significantly lower than that in those without effect after radiotherapy ( $P < 0.0001$ ).

**CONCLUSION:** Detection of serum p53-Abs is helpful to the diagnosis of esophageal carcinoma. Monitoring for sequential change of serum p53-Abs before and after radiotherapy in patients with esophageal carcinoma is also useful to evaluate the response to the treatment and prognosis of the patients.

Changes of serum p53 antibodies and clinical significance of radiotherapy for esophageal squamous cell carcinoma. *World J Gastroenterol* 2008; 14(25): 4082-4086 Available from: URL: <http://www.wjnet.com/1007-9327/14/4082.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4082>

### INTRODUCTION

Esophageal carcinoma (EC) is one of the most common malignant diseases in China. The prognosis of this disease is unfavorable in spite of advances in therapies. Mutations of the p53 gene are common gene alterations in most malignant tumors, including EC. Mutant p53 protein is accumulated in cells because of its longer half-life compared with wild-type protein. Therefore, p53 overexpression can be detected by immunohistochemical staining for p53. The anti-p53 antibody (p53-Ab) assay is based on the initial results of Crawford *et al*<sup>[1]</sup> who detected p53-Abs in the sera of patients with breast carcinomas. Because mutation in the p53 gene and the consequent overexpression of p53 are associated with tumor tissues, both wild type and mutant p53 may act as targets of tumor specific humoral and cellular immune responses<sup>[2,3]</sup>. The presence of p53-Abs in the sera of patients has been noted in various types of carcinomas. Non-carcinoma patients do not exhibit such antibodies<sup>[4-7]</sup>. Close correlations were observed between the presence of such antibodies and other factors related to a poor prognosis, such as high histological grade and

the absence of hormone receptors<sup>[3,8]</sup>. The presence of serum p53-Abs was reported to be an independent prognostic factor for breast carcinoma<sup>[9]</sup>. Studies have revealed that overexpression of p53 protein closely related to induction of drug resistance in cancer patients and it can be used as a predictor for chemosensitivity of tumor. Specific p53-Ab was found in the sera of cancer patients with p53 protein overexpression. Furthermore, the presence of serum p53-Ab is closely correlated with p53 protein overexpression<sup>[10,11]</sup>. Thus, serum p53-Ab could theoretically be useful in predicting radiosensitivity in cancer patients. However, the clinical relevance of p53-Ab and radiotherapy for EC has not been fully studied. In the present study, the serum p53-Ab level was detected in 46 EC patients and 30 healthy adults as control by enzyme linked immunosorbent assay (ELISA). We explored the relationship between serum p53-Abs and clinicopathological characteristics and therapeutic effect in EC patients, and investigated the sequential changing regularity of serum p53-Abs after radiotherapy.

## MATERIALS AND METHODS

### Clinical data

A total of 46 consecutive patients with primary EC were enrolled in this study. They consisted of 38 males (82.6%) and 8 females (17.4%), with a mean age of 56.4 years (range, 46-70 years), who were treated at Gansu Provincial Tumor Hospital between April 2005 and June 2007. The patients' eligibility for this study was as follows: (1) Primary lesion was squamous carcinoma in histology. There was no previous malignant disease or clinical evidence of a second primary tumor elsewhere; (2) Karnofsky performance status  $\geq 70$ , white blood cell and hemoglobin levels within the normal range; and (3) Having not received radiotherapy, chemotherapy and operation. Tumor, nodes and metastasis (TNM) classification was established on the basis of pathologic examinations of biopsied specimens. Lymph node status in the patients was determined by computed tomography (CT). According to the UICC (2002) classification, 10 patients were in stage I, 17 in stage II, 14 in stage III and 5 in stage IV. Twenty-eight patients had no signs of lymph node metastasis, and the other 18 patients had metastasis of mediastinal and/or supraclavicular lymph nodes. Thirty-two had primary lesions  $< 6$  cm and 14 were  $\geq 6$  cm in size. Five tumors were located in the upper thorax, 21 in the middle thorax and 20 in the lower thorax. To compare the reliability of seronegative testing, a total of 30 healthy volunteers, 19 males and 11 females, with a mean age of 36 years (range, 21-62 years) from our hospital staff and medical students served as controls. Informed consent was obtained from all patients. The blood samples were collected on the day before radiotherapy and on the administration of an irradiation dose of 20 Gy/10 f/12 d, 40 Gy/20 f/24 d and 60 Gy/30 f/36 after radiotherapy, and stored at -80°C until Assay.

### Radiotherapy

Radiation source was a 6MV linear accelerator. The

design of the radiation fields was based on the diagnosis by CT and barium examination. For all patients, a three-field approach was administered: one anterior and two posterior oblique portals. The width of the fields was adjusted to cover gross tumors with 3-4 cm extended margins so as to include subclinical lesions. The length of the field covered clinical tumors with a 3-5 cm extended margin at both ends of the lesion. All patients received conventional fractions, 2.0 Gy per fraction, five fractions per week. The total dose given to the tumor was 60-70 Gy/6-7 W.

### Assay of serum anti-p53 antibodies

Anti-p53 antibodies in sera of patients was detected using a commercially available sandwich enzyme-linked immunosorbent assay kit (Immunotech, France). The assay was done according to the manufacturer's instructions, with the following specifications: patient serum was added for 60 min at 37°C to microtiter wells coated with recombinant wild type human p53 protein to detect specific anti-p53 antibodies or with a control protein to detect nonspecific interactions. After washing, goat antihuman immunoglobulin G (IgG) antibody conjugated with peroxidase was added and stayed for 60 min at 37°C. Next, the substrate 3,3,5,5-tetramethyl benzidine (TMB) was added for 10 min. The enzymatic process was halted by adding 2N hydrogen chloride. Light absorption was measured at 450 nm using a photospectrometer. Because human serum may give rise to variable background signals, an internal control was used to measure the nonspecific background of each sample. This background reflects nonspecific interactions of serum components either with the plastic or with the components used in the ELISA. In the assay, the nonspecific background corresponds to the absorbance measured on wells coated with control protein. The presence of anti-p53 antibodies in a sample is determined by different parameters, i.e., for the specific signal of the sample, index = specific signal of the positive control (low); for p53 net absorbance of the sample, ratio of net absorbance = control protein net absorbance of the sample. An index of 1.1 and a ratio of net absorbance of 1.6 were determined to be positive for the presence of anti-p53 antibodies.

### Clinical evaluation of radiation response

At the end of RT, all patients received esophageal barium examination and the clinical radiation response was evaluated according to standard X-ray diagnosis of EC after radiotherapy<sup>[12]</sup>. A complete response (CR) was defined as the disappearance of the mass shadow, no narrowing observed in the esophageal lumen, and none or slight rigidity of the esophageal wall without residual ulceration. Partial response (PR) was > 50% reduction in tumor bulk, but < 100% resolution of the disease and a residual shallow ulcer with a diameter  $< 1.5$  cm, despite the disappearance of the mass shadow. No response (NR) was defined as no improvement in the X-ray findings, with a deep and large residual ulcer or complete

obstruction of the esophageal lumen, regardless of the residual state of the mass shadow.

### Statistical analysis

The Statistical Package for Social Sciences, version 10.0 was used for statistical analysis. Serum p53-Abs levels were expressed as means ± SD. Student's *t* test, Pearson Chi-square and logistic analysis were used to determine the significance of difference between the two groups. A *P* value < 0.05 was considered significant.

## RESULTS

### Comparison of index and ratio of serum p53-Abs

The index and ratio of serum p53-Abs for EC patients were  $1.5847 \pm 0.5133$  and  $3.0293 \pm 0.7013$ , and those for healthy controls were  $0.2418 \pm 0.1438$  and  $1.0361 \pm 0.2175$ , the former was higher than the latter (*P* < 0.0001).

### Comparison of positive rate of serum p53-Abs

The positive rate of serum p53-Ab was 39.1% (18 of 46)

**Table 3 Logistic analysis on the relationship between positive rate of serum p53-Abs and clinical pathophysiological characteristics in EC patients**

Variables	B	OR	95% CI	P
Age	0.0241	1.0237	0.9583-1.0816	0.4659
Sex	-0.6230	0.5363	0.0863-3.3401	0.5165
TNM stage	1.8389	6.2899	2.4658-3.8954	0.0248
Histological grade	-4.1430	0.0159	0.0039-0.5867	0.0156
Lymph node metastasis	-0.4891	0.5973	0.3327-1.1406	0.1314
Size of tumor	0.6954	1.8924	0.7859-4.5968	0.1602
Site of tumor	-0.0695	0.9530	0.3240-2.6575	0.7986

for EC patients and 0% (0 of 30) for healthy controls, with a significant difference (*P* < 0.0001). The sensitivity, specificity, accurate rate, positive predictive value and negative predictive value of p53-Ab detection in EC were 39.1%, 100%, 63.2%, 100% and 52%, respectively.

### Comparison of before and after radiotherapy sequential change

The level and positive rate of serum p53-Abs had significant differences between before radiotherapy, after administration of an irradiation dose of 40 Gy/20 f/24 d and after administration of an irradiation dose of 60 Gy/30 f/36 d (Table 1).

### Relationship between positive rate of serum p53-Abs and clinical pathophysiological characteristics

The positive rate of serum p53-Abs in EC was related to histological grade, disease stage and lymph node metastasis, but it was not significantly related to sex, age and to the size and site of tumor (Table 2).

### Logistic analysis

Logistic analysis showed that the positive rate of serum p53-Abs in EC had positive correlation with disease stage, negative correlation with histological grade and independence with sex, age and with the size and site of tumor (Table 3).

### Clinical response to RT and serum p53-Abs

At the end of RT, CR was achieved in 21 patients, RR in 18 and NR in 7. In patients with CR plus PR, 61.1% (11/39) were positive for serum p53-Abs, but 100% (7/7) of patients with NR were positive for serum p53-Abs. The positive rate of serum p53-Abs in EC patients with effect was significantly lower than those without effect after radiotherapy (*P* < 0.0001).

## DISCUSSION

p53 protein plays a crucial role in the regulation of the cell cycle and has been implicated in cell differentiation, apoptosis, DNA synthesis, and repair<sup>[13,14]</sup>. This nuclear protein, because of its critical function in triggering cell death via apoptosis in cells affected by irreparable genomic damage, has been designated as the "guardian of the genome" by Lane<sup>[15]</sup>.

Mutations in the p53 tumor suppressor gene are

among the most common genetic alterations in human malignancies. In ovarian carcinoma, alterations in this tumor suppressor gene occur in approximately 50% of cases<sup>[16-18]</sup>. The commonly termed overexpression of p53 corresponds to a cellular accumulation of a biologically inactive protein stabilized either by a decreased rate of degradation of mutated gene product or by complex formation with certain proteins, such as viral oncoproteins or heat-shock protein 70<sup>[14,19,20]</sup>. In normal cells, p53 protein, through its short half-life, is present at such low levels that it is undetectable by conventional immunohistochemical methods. However, the results obtained in a number of studies on the prognostic impact of overexpression of p53 protein in ovarian carcinoma tissue were controversial. Whereas some investigators reported impaired clinical outcome in patients with p53 overexpressing tumors<sup>[21-23]</sup>, others failed to demonstrate a relation between the course of the disease and p53 expression<sup>[16,24]</sup>.

Recently, circulating p53-Ab has been detected in the serum or plasma of patients with various carcinomas. Detection is made by a simple and rapid ELISA procedure. The positive rate for p53-Ab was reported to be 24% for lung cancer, 19% for pancreatic cancer and 25% for colorectal cancer. The frequency of positive p53-Ab in patients with EC ranges from 25% to 53% in the literature. Our study detected p53-Ab in 18 (39.1%) of the 46 patients with EC, while it was not detected in any of the 30 healthy subjects. This positive rate for p53-Ab in esophageal cancer patients is thus similar to that in the published literatures<sup>[25,26]</sup>. The index and ratio of serum p53-Abs for patients with EC before radiotherapy were obviously higher than those for healthy controls ( $P < 0.05$ ). This suggests that the detection of serum p53-Ab in patients with EC is helpful to its diagnosis. We also found that the positive rate of serum p53-Abs in EC was related to the histological grade, disease stage and lymph node metastasis ( $P < 0.05$ ), but it was not significantly related to sex, age and the size and site of tumor ( $P > 0.05$ ). The lower the histological grade and clinical stage, the higher the level and positive rate of serum p53-Abs in EC, indicating that the positive serum p53-Abs is a poor characteristic and identifying marker of unfavorable prognosis for patients with EC.

At the end of RT, CR was achieved in 21 patients, RR in 18 and NR in 7. In patients with CR plus PR, 61.1% (11/39) were positive for serum p53-Abs, but 100% (7/7) of patients with NR were positive for serum p53-Abs. The positive rate of serum p53-Abs in EC patients with effect was significantly lower than those without effect after radiotherapy. This suggests that serum p53-Ab overexpression can be one of the reference indicators for predicting radiosensitivity in patients EC. Future studies will be required to reveal and confirm the correlation between radiosensitivity and serum p53-Abs.

We also found that the serum p53-Abs level was useful for the monitoring of treatment. In the present study, the level and positive rate of serum p53-Abs had significant differences between before radiotherapy,

after administration of an irradiation dose of 40 Gy/20 f/24 d and after administration of an irradiation dose of 60 Gy/30 f/36 d. It was reported that the presence of p53-Ab correlates closely with p53 overexpression and/or mutation<sup>[2,27]</sup>. This suggests that the p53 immune response in the patients can be attributed to accumulation of mutant p53 in the nucleus of tumor cells. The p53 protein was decreased and the tumor cell was destroyed through effective radiotherapy, the source of mutation of the p53 gene was eliminated, and then the immune response was weakened. Thus, monitoring of sequential change of serum p53-Abs before and after radiotherapy in patients with EC is helpful to evaluating the response to treatment and prognosis. A larger series of studies will be required to reveal and confirm the correlation between radiosensitivity and serum p53-Abs.

## COMMENTS

### Background

Mutations of the p53 gene are common gene alterations in most malignant tumors, including esophageal carcinoma. Mutant p53 protein is accumulated in the cell because of its longer half-life compared with wild-type protein. p53 protein plays a crucial role in the regulation of the cell cycle and has been implicated in cell differentiation, apoptosis, DNA synthesis and repairment. In addition, it has been shown that patients with various types of neoplasias have p53 antibodies in their sera. ELISA was used to detect anti-p53 antibodies in the sera. The authors explored the relationship between serum p53-Abs and clinicopathological characteristics and therapeutic effect in patients with esophageal carcinoma, and investigated the sequential changing regularity of serum p53-Abs after radiotherapy.

### Research frontiers

Studies have revealed that overexpression of p53 protein is closely related to induction of drug resistance in cancer patients and it can be used as a predictor for chemosensitivity to tumor treatment. Specific p53-Ab was found in the sera of cancer patients with p53 protein overexpression. Furthermore, the presence of serum p53-Ab is closely correlated with p53 protein overexpression. Thus, serum p53-Ab could theoretically be useful in predicting radiosensitivity in cancer patients. However, the clinical relevance of p53-Ab and radiotherapy for esophageal carcinoma has not been fully studied.

### Innovations and breakthroughs

From the results of this study, the following conclusions can be drawn that the positive rate of serum p53-Abs in esophageal carcinoma is related to histological grade, disease stage and lymph node metastasis, but it is not significantly related to sex, age and the size and site of tumor. The level and positive rate of serum p53-Abs had significant differences between before radiotherapy, after administration of an irradiation dose of 40 Gy/20 f/24 d and after administration of an irradiation dose of 60 Gy/30 f/36 d. The positive rate of serum p53-Abs in esophageal carcinoma patients with effect is significantly lower than those without effect after radiotherapy.

### Applications

Detection of serum p53-Abs is helpful to diagnosis of esophageal carcinoma. Monitoring of sequential change of serum p53-Abs before and after radiotherapy in patients with esophageal carcinoma is also useful in evaluating the response to the treatment and prognosis of the patients.

### Peer review

The authors detected the serum p53 antibody level in patients with esophageal

squamous cell carcinoma and its sequential changes before and after radiotherapy. The results showed that changes of serum p53-Abs are helpful to the diagnosis of esophageal carcinoma. Monitoring of sequential change of serum p53-Abs before and after radiotherapy in patients with esophageal carcinoma is helpful to evaluating the response to the treatment and prognosis of the patients. Therefore, this study has values in clinical management of the patients.

## INTRODUCTION

Takayasu's arteritis is a granulomatous panarteritis affecting large vessels, namely the aorta and its main branches, pulmonary and coronary arteries. It is characterised by stenotic and, occasionally, aneurysmal lesions. Manifestations of the disease range from no symptoms, to bruits, hypertension, cerebrovascular events, congestive heart failure and blindness<sup>[1]</sup>. Takayasu's arteritis classically progresses through three stages, namely a systemic non-vascular phase, a vascular inflammatory phase and a quiescent "burnt out" phase<sup>[1]</sup>. First described by Yamamoto in 1830<sup>[1]</sup>, the disease has a worldwide distribution, although it is most commonly diagnosed in young women of Asian decent. The incidence in North America has been estimated at 2.6 cases per million<sup>[2]</sup>.

Crohn's disease is a chronic, relapsing, transmural inflammatory disease, affecting primarily the gastrointestinal mucosa. The incidence of Crohn's disease is approximately 2 in 100 000, and its prevalence is 50 in 100 000<sup>[3]</sup>, with geographical and ethnic variation, most commonly seen in Caucasian populations. There is a slight female preponderance, with a peak onset of disease around 20 years of age, with another peak occurring between 50 and 70 years of age<sup>[4]</sup>.

Both Takayasu's arteritis and Crohn's disease are chronic granulomatous inflammatory processes involving different target organs, namely large elastic arteries and the gastrointestinal tract respectively. They may coexist and in 29 reported cases, Crohn's disease

## Abstract

Takayasu's arteritis and Crohn's disease are chronic inflammatory diseases of uncertain aetiology. They rarely occur together, with only twenty nine cases of co-existent Takayasu's arteritis and Crohn's disease reported in the literature. In 88% of these cases, Takayasu's arteritis was diagnosed simultaneously or following a diagnosis of Crohn's disease. We present a case of a young Caucasian medical student, incidentally found to have bilateral carotid bruits on auscultation by a colleague. Magnetic resonance angiography revealed stenoses of the common carotid arteries with established collaterals, and a diagnosis of Type 1 Takayasu's arteritis was made. An <sup>18</sup>F-fluorodeoxyglucose positron emission tomography scan revealed no active disease. Nine months later, she presented with a short history of abdominal pain, vomiting and abdominal distension. Barium follow-through and computer tomography revealed a terminal ileal stricture and proximal small bowel dilation. An extended right hemicolectomy was performed and histopathology supported a diagnosis of Crohn's disease. This case report is presented with a particular focus on the temporal relationship between these two disease processes and explores whether their concurrence is more than just co-incidence.

preceded Takayasu's arteritis in 88% cases, raising the possibility that it could be regarded as an extraintestinal manifestation of Crohn's disease. In contrast, herein we present a rare case of Crohn's disease in a patient with clinically inactive Takayasu's arteritis.

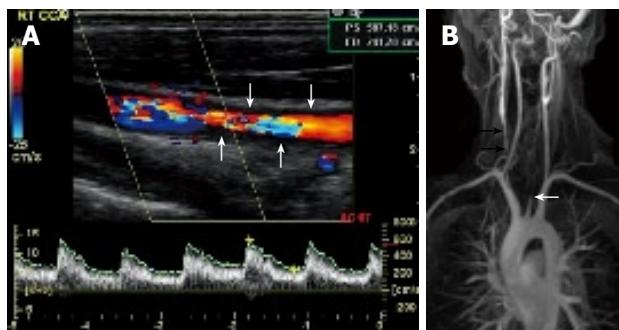

## CASE REPORT

A 24-year-old Caucasian medical student was found incidentally to have bilateral carotid bruits whilst practising for final clinical examinations. Her past medical history was unremarkable. Physical examination revealed normal peripheral pulses, equal normal blood pressure in both arms and no cardiac murmurs. A C-reactive protein of 13 mg/L, haemoglobin of 11.8 g/dL and a plasma viscosity of 1.73 mmHg were recorded.

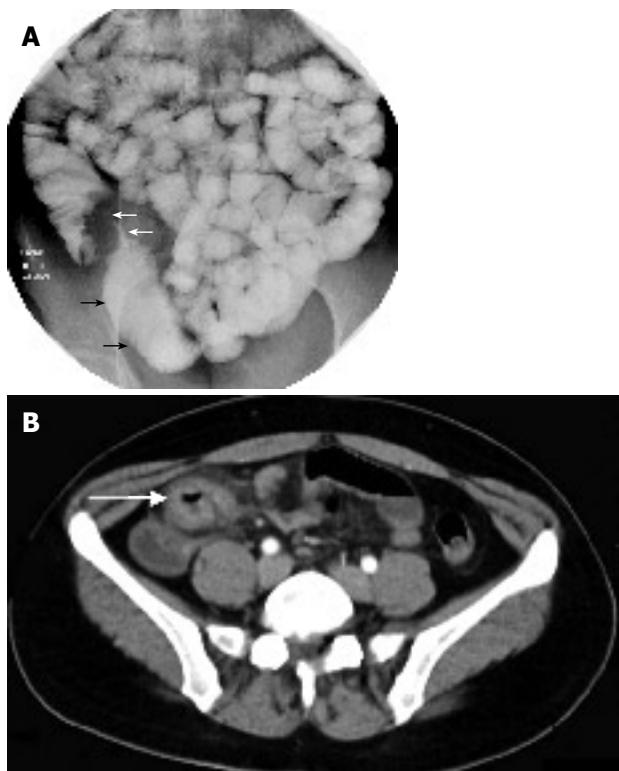

A duplex scan showed thickening of the proximal common carotid with severe stenoses in the mid common carotid arteries bilaterally (Figure 1A). Reduced internal carotid flow was compensated by retrograde flow in both external carotid arteries. Gadolinium-enhanced magnetic resonance angiography confirmed these findings along with a normal aortic arch, prominent bilateral vertebral arteries, mild irregularity in the right subclavian artery and collaterals feeding both external carotid arteries (Figure 1B). These findings led to the diagnosis of Type I Takayasu's arteritis<sup>[1]</sup>. Subsequent echocardiography confirmed the absence of aortic regurgitation and computer tomography-angiography of the subdiaphragmatic aorta was unremarkable. A normal full body  $^{18}\text{F}$ -fluorodeoxyglucose positron emission tomography ( $^{18}\text{F}$ -FDG-PET) scan revealed no active disease.

Nine months later, she presented with a short history of colicky abdominal pain, vomiting and abdominal distension. Barium studies and a computer tomography scan revealed a terminal ileal stricture and proximal small bowel dilation (Figure 2). At operation, the obstructing lesion was found to have extended to the ileocaecal valve with tethering to the proximal transverse colon. A laparoscopic extended right hemicolectomy was performed with a primary anastomosis, from which a full recovery was made and the patient remains symptom free.

The resected specimen showed a three-centimetre long stricture at the distal ileum extending to the ileocaecal valve (Figure 3A), and the strictured bowel had a thickened wall with fat wrapping. Along the stricture, the small bowel mucosa was replaced by intensely inflamed granulation tissue and inflamed transmural fibrous tissue focally replaced the muscularis propria (Figure 3A). Within this tissue, there were scattered medium-sized blood vessels showing intramural chronic inflammation with focal obliteration. In addition, one blood vessel showed a cluster of multinucleated giant cells along the outer edge of the media (Figure 3D). However, the majority of similarly-sized vessels at and around the stricture and the ileocolic artery were normal. The ileum just proximal to the stricture showed focal ulceration, transmural chronic inflammation and ulcer-associated cell lineage (also known as gastric pyloric gland metaplasia) (Figure 3C). Well-formed granulomas were present in the

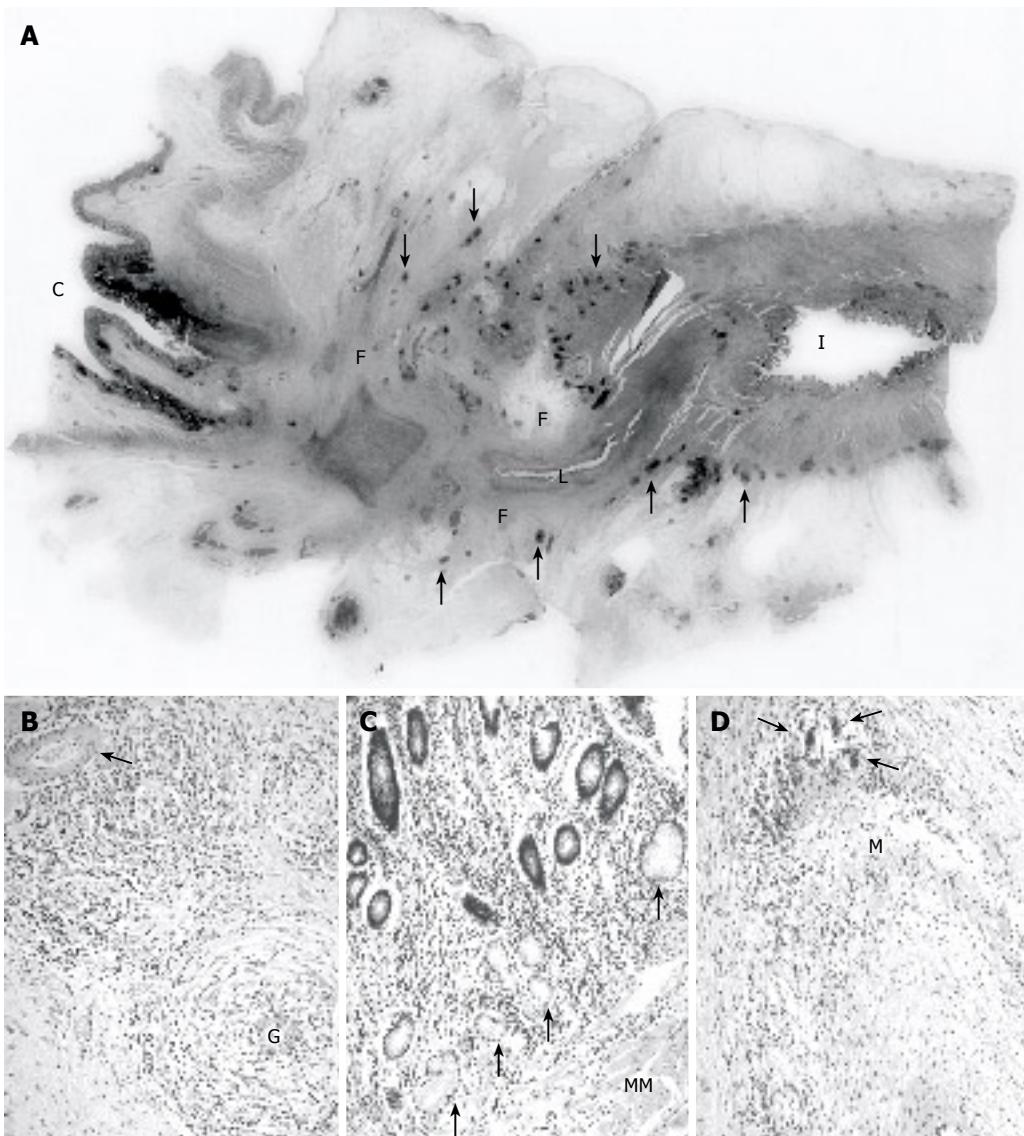

**Figure 1** Ultrasound image of the right common carotid artery showing wall thickening (arrows) and blood flow with a significantly enhanced peak systolic velocity (PS  $> 587 \text{ cm/s}$ ), indicating a severe stenosis (A) and magnetic resonance angiography showing occlusion of the left common carotid (white arrows) and stenosis of the right common carotid (black arrows) arteries (B).

**Figure 2** Barium follow through showing a stricture at the terminal ileum (white arrows) typical of Crohn's disease with dilated ileum just proximal to it (black arrows) (A) and axial CT image showing the thickened terminal ileum (arrow) and associated inflammatory change (B).

caecal submucosa just distal to the stricture and in the subserosal tissues surrounding the stricture (Figure 3B). The presence of a fistula connecting the stricture to the transverse colon was confirmed histologically. Seventeen lymph nodes harvested showed reactive changes only, with no evidence of granulomas. Several features of this specimen strongly support a diagnosis of Crohn's disease. The stricture occurred at a site classically affected by Crohn's disease, and showed several characteristic features of this disease, namely fat wrapping, fistula formation, transmural fibrosis and inflammation, multiple granulomas (which could not be attributed to crypt rupture or extravasated intestinal contents),

**Figure 3** **A:** Whole histological mount of the terminal ileal stricture showing part of its stenosed lumen (L), with the caecum (C) and ileum (I) at either end. The stricture showed transmural chronic inflammation (examples of the numerous lymphoid follicles are arrowed) with extensive fibrosis (F); **B:** Well-formed granulomas (G) with surrounding chronic inflammation in the subserosal tissues around the stricture with no vasculitis in an arrowed small muscular artery; **C:** Ileal mucosa proximal to the stricture showing extensive ulcer-associated cell lineage (arrowed) and chronic inflammation extending into the hypertrophied muscularis mucosae (MM); **D:** A medium-sized muscular artery within the fibrous tissue of the stricture showing chronic inflammation and multinucleated giant cells (arrowed) concentrated around the outer edge of the media (M) and the lumen of the artery in the bottom right corner.

and widespread adjacent ulcer-associated cell lineage. By contrast, there was no evidence that Takayasu's arteritis directly caused the ileal stricture and inflammation. Takayasu's arteritis is a vasculitis of large vessels. If the arteritis involved a large vessel supplying the abnormal terminal ileum, namely the superior mesenteric artery or its proximal branches, the most likely intestinal manifestation would have been infarction, and a much longer segment of bowel. The largest blood vessel included in the resection specimen (i.e. the ileocolic artery) did not show vasculitis. In fact, the only abnormal vessels seen were occasionally inflamed and focally occluded medium-sized arteries around the stricture, and even these were more likely to represent endarteritis obliterans secondary to the inflammation. Finally, 'granulomatous vasculitis', as was seen in one medium-sized artery beside the stricture, is a recognised feature of Crohn's disease.

## DISCUSSION

Co-existence of Takayasu's arteritis and Crohn's disease has previously been reported in 29 cases. The expected prevalence of Crohn's disease in patients with Takayasu's

arteritis, if present by chance alone, is approximately 0.05%-0.2%<sup>[3]</sup>. Thus, it has been suggested that this unexpected association is more than just a coincidence. The epidemiology, aetiology and pathogenesis of these two diseases point to a role of both environmental and hereditary factors, interacting to trigger the inflammatory process.

Takayasu's arteritis and Crohn's disease present more commonly in young females, suggesting a potential hormonal influence. To this end, the oral contraceptive pill has been reported, somewhat controversially, to increase the risk of Crohn's disease<sup>[4]</sup>. Geographically, Takayasu's arteritis is common in Japan, Korea and India, whereas Crohn's disease has a much higher prevalence in Northern Europe and North America<sup>[1,4]</sup>. Such ethnic predilection has led to the investigation of human leucocyte antigens (HLA) in the pathophysiology. However, to date no common HLA genotype links these two disease processes. Likewise infectious agents have been implicated. In particular, mycobacterium tuberculosis (MTB) or autoimmunity evoked by this micro-organism. Although increased reactivity to, and circulating antibodies against mycobacterium heat shock protein, 65 have been identi-

fied in Takayasu's arteritis and Crohn's disease patients, there is no convincing evidence for a role of MTB in the pathogenesis<sup>[5,6]</sup>.

Cell-mediated immunological mechanisms play an important role in both diseases. In Takayasu's arteritis, autoantibodies against aortic endothelial cells may contribute to vascular dysfunction by increasing local cytokine synthesis, cellular adhesion molecule expression and endothelial cell apoptosis<sup>[7]</sup>. Pro-inflammatory cytokines such as tumour necrosis factor (TNF)  $\alpha$ , interleukin (IL)-6, IL-8, IL-12 and IL-18, are common to both, amplifying the inflammatory process<sup>[7,8]</sup>. Moreover, the anti-TNF $\alpha$  monoclonal antibody infliximab is an effective therapeutic agent for both Takayasu's arteritis and Crohn's disease, suggesting the presence of common inflammatory pathways<sup>[3,7]</sup>. Wakefield *et al*<sup>[9]</sup> have found evidence of granulomatous vasculitis, also present in our case, in 15 out of 24 patients when examining resected intestine from patients with Crohn's disease. Granulomatous inflammation is also seen in Takayasu's arteritis<sup>[10]</sup>. Despite these similarities, the question of why the arch of the aorta is the predominant site of tissue injury in Takayasu's arteritis, and the bowel wall in Crohn's disease remains to be answered.

In our patient, Takayasu's arteritis was asymptomatic and the presence of established collaterals, a negative  $^{18}\text{F}$ -FDG-PET scan and no MRA evidence for vascular wall inflammation, suggested that the peak activity was present some years ago. Thus, Crohn's disease appears to have presented apparently independent of Takayasu's arteritis. It was reported that only 3 of 24 previous cases with known details have Takayasu's arteritis preceded Crohn's disease<sup>[3,11-17]</sup>. An association between the conditions may simply reflect two diseases typically presenting in the same age group. However, a shared common cause resulting in a granulomatous vasculitis and end organ damage remains a possible explanation.

In summary, the temporal relationship between Takayasu's arteritis and Crohn's disease remains of interest, with the majority of cases presenting initially with Crohn's disease. Possible explanations for their association have been explored. However, no data can confirm an aetiological link between the two diseases. We present an interesting case of Crohn's disease arising in a patient apparently some years after Takayasu's arteritis, as indicated by the established carotid arterial collaterals. As the active phase of Takayasu's arteritis may be relatively short, and the disease can 'burn out', many cases may go undetected, as would this case had it not been for the astute medical student.

patient admission to the general surgery departments. There are various pathologies which lead to bleeding; however, bleeding due to gastric arterio-venous malformation is not commonly seen. In this article we present a patient with sustained hematemesis, whose medical workup revealed the bleeding source to be the stomach. The bleeding could not be stopped by upper endoscopy. Celiac trunk angiography demonstrated arterio-venous malformation emerging from the splenic artery and embolization of the vessel was performed. A search of the English medical literature for congenital anomalies such as arterio-venous malformations supplied by the splenic artery did not yield any similar descriptions.

## CASE REPORT

A 24-year-old previously healthy male was transferred to our general surgery department due to unsuccessful treatment of acute upper gastrointestinal bleeding. Ten days ago, he had been admitted to hospital due to hematemesis and melena. He underwent an upper endoscopy, which demonstrated a small gastric ulcer covered by a blood clot, without a visible vessel. The ulcer was endoscopically coagulated using Argon beam. Four days later the patient had sustained hematemesis again. He underwent a second endoscopy, which showed a large clot covering a gastric ulcer. During hospitalization he was treated with ten units of packed red blood cells. Due to the relapse of symptoms and massive transfusion of blood products an angiography was performed. An aberrant gastric arterio-venous malformation supplied by the splenic artery was demonstrated. Attempts to embolize the vessel failed and the patient was referred to our institute. Upon arrival, his pulse was 102 bpm, and blood pressure 140/80 mmHg. Blood tests showed hemoglobin level of 10.2 mg/dL. Naso-gastric tube was inserted and drained fresh blood. Celiac trunk angiography was performed and revealed an arterio-venous malformation emerging from the splenic artery (Figure 1). Arterial embolization was achieved by selective injection of embospheres (diameter of 0.5-0.7mm) and placement of several detachable coils until flow arrest was obtained (Figure 2). The procedure was performed without any immediate complications. Two days following the procedure the patient developed a fever of 38°C, and suffered from left

## Abstract

In this case report, we present a patient who suffered from gastrointestinal bleeding. The bleeding source was a gastric arterio-venous malformation emerging from the splenic artery. Attempts to stop the bleeding failed and therapeutic angiography succeeded in occluding the vessel. A search at the literature has not yielded any other case report describing this anatomical anomaly.

## INTRODUCTION

Upper gastrointestinal bleeding is a common cause for

**Figure 1** Arteriography of the celiac trunk demonstrating the arterio-venous malformation emerging from the splenic artery (arrow).

**Figure 2** Embolization of the arterio-venous malformation was achieved using intra-arterial coils (arrow).

upper quadrant abdominal pain, both were attributed to segmental infarction of the spleen. Blood tests showed a constant level of hemoglobin. Eight days after the procedure he underwent elective upper endoscopy which showed mild fundal gastritis without an ulcer. On a six-month follow up, the patient presented no symptoms.

## DISCUSSION

Upper gastrointestinal bleeding is a common cause for admission of patients to emergency departments<sup>[1]</sup>. The most common etiologies are esophageal or gastric varices due to portal hypertension, erosive gastritis, peptic ulcers and gastric benign or malignant tumors. Other rare pathologies are aorto-enteric fistula which can cause massive upper gastrointestinal bleeding, gastric arterio-venous malformation<sup>[2]</sup> which is very common in patients who suffer from end stage renal failure, or Dieulafoy's

syndrome<sup>[3]</sup> which is a congenital dysplastic large caliber artery often lying at the submucosa of the gastric fundus, where erosion of the overlying mucosa is believed to cause significant bleeding. The pathogenesis of arterio-venous malformations of the splenic artery<sup>[4]</sup> is described in the medical literature as a cause of left sided portal hypertension (arterio-venous malformation is caused by blunt or penetrating trauma to the splenic artery which produces a fistula between the artery and the vein). A high flow of blood directly from the artery through the portal venous system elevates the portal blood pressure. Other pathology of the splenic artery which can cause massive upper gastrointestinal or intra-abdominal bleeding, is aneurysm of the artery. Aneurysms are the third most common intra-abdominal aneurysms, they are more common in multi-gravid women or patients with pancreatitis or abdominal trauma, and rarely cause any symptoms. Erosion into the gastric wall initiates gastric bleeding which may be massive.

The arterial supply of the vascular malformation described in this case emerged from the splenic artery, the patient did not sustain any abdominal trauma. It seems that an embryological developmental defect caused this congenital anomaly. Searching the English medical literature for articles describing this rare pathology has not found any similar descriptions. We assume that growing use of angiographic modalities for diagnosis and treatment of pathologies will show in the future more congenital anomalies which have not been characterized yet. The arterio-venous malformation has also supplied part of the spleen. According to this, we recommend not to discharge the patients too early after the procedure because of possible occurrence of complications related to partial infarction of the spleen. Usually such an infarction necessitates only observation and analgesia.

## Abstract

Non-Hodgkin lymphoma is a rare cause of biliary obstruction. To the best of our knowledge, non-Hodgkin lymphoma in the peripancreatic region causing obstructive jaundice with simultaneous portal vein (PV) invasion has not yet been reported. We present a 50-year-old patient with obstructive jaundice whose extrahepatic portal vein was obstructed by the invasion of a peripancreatic non-Hodgkin lymphoma. The patient denied any other symptoms such as recurrent fever, night sweat and loss of body weight. Computed tomography (CT) revealed a 10 cm mass in the retroperitoneal space behind the head of the pancreas causing obstruction of the distal bile duct and the PV. A pylorus-preserving pancreaticoduodenectomy combined with a PV resection was performed. The PV was reconstructed using an autologous right internal jugular vein graft. The resected specimen showed endoluminal invasion of both the bile duct and the PV. Histological examination showed the mass consisting of diffuse sheets of large malignant lymphoid cells. These cells were positive for CD20 and CD79a, partially positive for CD10, and negative for CD3, CD4, CD5, CD8 and CD30. The pathologic diagnosis was diffuse large B-cell type non-Hodgkin lymphoma and the patient was transferred to the Department of Hematology and Oncology for chemotherapy. He received four cycles of combined chemotherapy including cyclophosphamide, doxorubicin, vincristine and prednisone plus rituximab, and three cycles of intrathecal chemoprophylaxis including methotrexate, cytosine arabinoside and prednisone. The patient is alive with

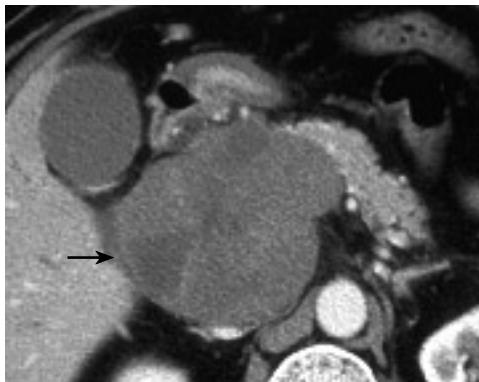

## INTRODUCTION

Non-Hodgkin lymphoma is a rare cause of biliary obstruction<sup>[1,2]</sup>. In a retrospective study, biliary obstruction secondary to non-Hodgkin lymphoma was found in 3 (0.3%) of 1123 patients with malignant biliary obstruction, and obstructive jaundice was found in one of them<sup>[1]</sup>. On the other hand, vascular invasion due to non-Hodgkin lymphoma has been described only as case reports including a case of primary non-Hodgkin lymphoma of the liver with bile duct invasion and portal venous tumor thrombus<sup>[3,4]</sup>.

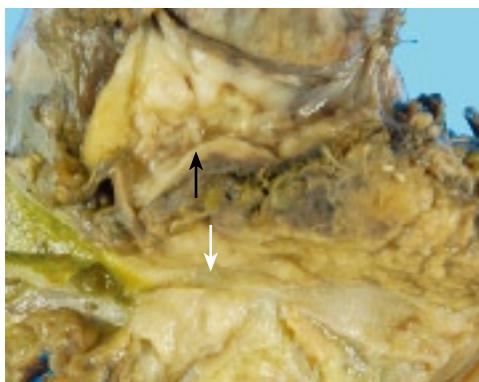

To the best of our knowledge, non-Hodgkin lymphoma in the peripancreatic region causing obstructive jaundice with simultaneous portal vein (PV) invasion has not yet been reported. Here we present a patient with obstructive jaundice whose extrahepatic PV was obstructed by a peripancreatic non-Hodgkin lymphoma.

## CASE REPORT

A 50-year-old man was reported to have an elevated serum lactate dehydrogenase (LDH) level (269 IU/L)

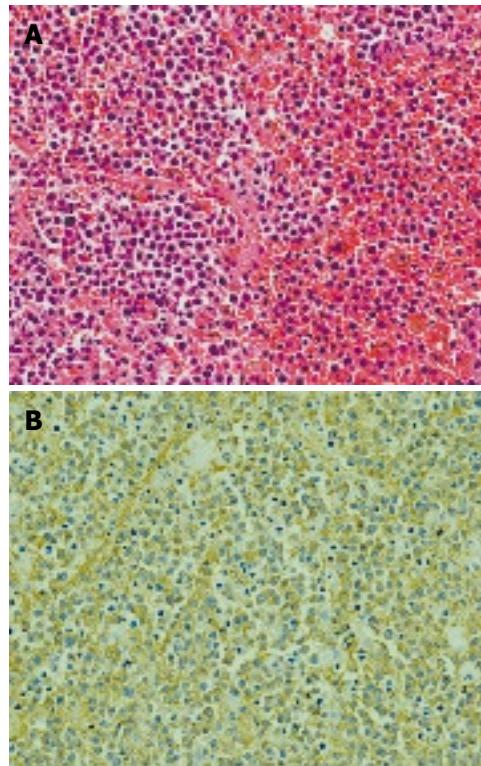

**Figure 1** Preoperative enhanced computed tomography. A low density mass (arrow), 10 cm in diameter, can be seen in the retroperitoneal space behind the pancreas head.

**Figure 2** A photograph of the resected specimen. Endoluminal invasion of both the bile duct (white arrow) and the portal vein (black arrow) can be observed.

by medical checkup in July 2007. He consulted with a physician in the following month. Serum LDH level continued to increase (313 IU/L). Abdominal ultrasonography was scheduled but he did not show up. On October 9, 2007, he presented with jaundice and was referred to our hospital on the next day. The patient denied any other symptoms such as recurrent fever, night sweat, and loss of body weight. His past history was unremarkable excluding a history of nephritis in his childhood. He had smoked 30 cigarettes per day, and was not alcoholic. His height was 173 cm and body weight 73 kg, blood pressure 124/79 mmHg and pulse rate 68 beats/min. No superficial lymphadenopathy was palpable. Computed tomography (CT) revealed a low-density mass, 10 cm in diameter, in the retroperitoneal space behind the pancreas head (Figure 1), due to which the distal bile duct and the PV were obstructed.

On October 22, 2008, a pylorus-preserving pancreaticoduodenectomy combined with a PV resection was performed. The PV was reconstructed using an autologous right internal jugular vein graft. The resected specimen showed endoluminal invasion of both the bile duct and the PV (Figure 2). Histological examination showed the mass consisting of diffuse sheets of large malignant lymphoid cells (Figure 3A). Immunohistochemical studies revealed that these cells were positive for CD20 (B-cell associated antigen, Figure 3B) and CD79a (B-cell associated

**Figure 3** Photomicrographs of the tumor. A: The tumor consists of diffuse sheets of large malignant lymphoid cells (HE, x 20); B: Immunostaining of the tumor. The tumor cells are positive for CD20 (immunostaining, x 20).

antigen), and partially positive for CD10 (B-cell associated antigen), and negative for CD3 (T-cell associated antigen), CD4 (T-cell associated antigen) CD5 (T-cell associated antigen), CD8 (T-cell associated antigen) and CD30 (a universal feature of anaplastic large cell lymphoma). The pathologic diagnosis was diffuse large B-cell type non-Hodgkin lymphoma. The patient was transferred to the Department of Hematology and Oncology.

On January 9, 2008, combined chemotherapy including cyclophosphamide, doxorubicin, vincristine, and prednisone plus rituximab (CHOP-R) was started. During the next 4 mo, he received 4 cycles of CHOP-R, and 3 cycles of combination of intrathecal chemoprophylaxis including methotrexate, cytosine arabinoside, and prednisone. The patient is alive with no evidence of the disease for 7 mo after the operation, and will receive additional courses of chemotherapy.

## DISCUSSION

Because of its rarity, non-Hodgkin lymphoma is seldom considered as a differential diagnosis in patients presenting with jaundice<sup>[2]</sup>. In one retrospective study by Ravindra *et al*, 6 of 9 patients with non-Hodgkin lymphoma presenting obstructive jaundice underwent laparotomy before the diagnosis was made as in the present case<sup>[2]</sup>, whereas, the other 3 patients were diagnosed by biopsy and could avoid laparotomy due to the following clinical features. The first patient with obstructive jaundice also had cervical lymphadenopathy, and cervical lymph node biopsy was performed, the second patient was considered too old to withstand the operation, and un-

derwent an ultrasonographically guided percutaneous biopsy, and the third patient had a history of lymphoma and jaundice 1 year after complete remission, which suggested recurrence<sup>[2]</sup>. In our case, the patient had none of such clinical findings as described above. Furthermore, our case presented with not only obstructive jaundice but also simultaneous portal venous obstruction. Such clinical features were not observed in the Ravindra's cases<sup>[2]</sup>. The common etiology of malignant biliary obstruction occurring simultaneously with extrahepatic PV invasion is generally pancreatic carcinoma or cholangiocarcinoma<sup>[5]</sup>, and we had no idea of lymphoma for a differential diagnosis in this case before operation.

Chemotherapy is the mainstay of treatment for non-Hodgkin lymphoma<sup>[6,7]</sup>. Surgical intervention delayed the initiation of chemotherapy in the present case, which could miss an opportunity to cure the disease. Although it remains unclear whether chemotherapy should precede the biliary drainage procedures in patients with non-Hodgkin lymphoma presenting with jaundice, chemotherapy alone usually alleviate the obstructive jaundice without biliary drainage<sup>[7]</sup>. Dudgeon *et al* described five patients with non-Hodgkin lymphoma causing obstructive jaundice, who were treated with combined chemotherapy without prior surgical or endoscopic biliary decompression, or radiation therapy. Jaundice was relieved rapidly (within 2-59 d) in all the patients with acceptable toxic effects, and all the five patients achieved remissions<sup>[8]</sup>.

Fine needle aspiration (FNA) with percutaneous or endoscopic ultrasound (EUS) guidance should precede the operation in the present case. FNA with percutaneous or EUS guidance permits both morphologic and cytologic analysis of lesions at various locations such as within or adjacent to the gastrointestinal tract, and intra-abdominal and retroperitoneal masses<sup>[9-11]</sup>. Erickson and colleagues studied 18 patients with retroperitoneal lesions who underwent EUS and EUS-guided FNA<sup>[9]</sup>. EUS-guided FNA was done in 15 (83%) of the 18 patients, among whom four were diagnosed as having lymphomas and avoided surgical intervention<sup>[9]</sup>, whereas, one patient ultimately had to have exploratory surgery for biopsy because neither EUS-guided FNA nor CT-guided percutaneous biopsy could provide enough tissues for definitive classification of a follicular centroblastic centrocytic lymphoma<sup>[9]</sup>. Similarly, in one retrospective study, 9 patients with non-Hodgkin lymphoma presented with obstructive jaundice<sup>[2]</sup>. Among them, two underwent percutaneous biopsy, and both avoided laparotomy.

One disadvantage of FNA with percutaneous or EUS guidance is a risk of complications. The possible complications associated with FNA included infection, intracystic hemorrhage, retroperitoneal hematoma, and pancreatitis<sup>[10,11]</sup>. Eloubeidi *et al* studied 547 patients who underwent EUS-guided FNA in the preoperative evaluation of suspected pancreatic cancer<sup>[10]</sup>. In their report, 11 (2%) patients developed a major complication, and one patient required surgical debridement for necrosis<sup>[10]</sup>. Guo *et al* reported that one (1.5%) of 68 patients had a minor complication (hematoma) from the radiologically guided percutaneous FNA biopsy of pelvic and retro-

peritoneal masses<sup>[11]</sup>.

Another disadvantage of FNA with percutaneous or EUS guidance is a risk of tumor seeding along a needle tract<sup>[12,13]</sup>. Although the EUS-guided FNA is considered to have a lower risk of peritoneal carcinomatosis compared with percutaneous one<sup>[12]</sup>, a case of tumor seeding of a pancreatic adenocarcinoma because of EUS-guided FNA has been reported<sup>[13]</sup>. Therefore, FNA with percutaneous or EUS guidance should be indicated only when additional information accessible by the procedure significantly affects the subsequent management of patients.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London, The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

#### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjnet.com](mailto:submission@wjnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L;  $\text{CO}_2$  volume fraction, 50 mL/L  $\text{CO}_2$ , not 5%  $\text{CO}_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *KhoI*, *KpnI*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903  
Ocean International Center, Building D  
No. 62 Dongsihuan Zhonglu  
Chaoyang District, Beijing 100025, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>  
Telephone: +86-10-59080039  
Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

### Abstract

Iron is a critical micronutrient, and iron derived from heme contributes a large proportion of the total iron absorbed in a typical Western diet. Heme iron is absorbed by different mechanisms than non-heme iron, but despite considerable study over many years these mechanisms remain poorly understood. This review provides an overview of the importance of heme iron in the diet and discusses the two prevailing hypotheses of heme absorption; namely receptor mediated endocytosis of heme, and direct transport into the intestinal enterocyte by recently discovered heme transporters. A specific emphasis is placed on the questions surrounding the site of heme catabolism and the identity of the enzyme that performs this task. Additionally, we present the hypothesis that a non-heme iron transport protein may be required for heme iron absorption and discuss the experiences of our laboratory in examining this hypothesis.

### THE IMPORTANCE OF DIETARY IRON AND HEME

Iron is a vitally important element in biological terms (for review see<sup>[1]</sup>). Iron is a transition metal with the ability to readily accept and donate electrons, allowing it to function as an oxidant or reductant in a large number of biochemical reactions. In mammals, iron is notably required for oxygen transport as a component of hemoglobin, DNA synthesis as a component of ribonucleotide reductase, and as an electron acceptor/donor in the cytochromes that are essential for energy transduction. Currently, iron deficiency is the most common diet related health problem in the world<sup>[2]</sup>, and the effects on human health are wide ranging. Iron deficiency manifests as anaemia in up to 2 billion people, impairs physical and mental development in children, and can exacerbate many other health problems.

Heme is a biologically important iron containing compound and a key source of dietary iron. Historically, it was doubted that heme iron could be absorbed by the enterocyte and it was not until 1955 that the absorption of heme-derived iron was demonstrated for the first time<sup>[3]</sup>. Currently, the importance of heme iron in the diet cannot be underestimated. Studies estimate that in Western societies, iron derived from heme sources such as myoglobin and hemoglobin make up two-thirds of the average person's total iron stores despite only constituting one-third of the iron that is actually ingested<sup>[4-6]</sup>. This likely explains why vegetarians are more prone to iron deficiency than those who regularly consume red meat<sup>[7]</sup>.

The relative importance of dietary heme is attributable to its high bioavailability compared with

**Figure 1** Summary diagram of established and putative iron absorption pathways in the intestinal enterocyte. Non-heme iron: All non-heme iron is ultimately taken up from the lumen by DMT1 situated on the microvillus membrane, before joining the labile iron pool in the cytoplasm. Ferric iron must first be reduced to the ferrous form by DcytB before uptake. Ferrous iron in the labile iron pool is then transferred to the circulation by FPN1, which requires hephaestin for oxidation to the ferric form in order to bind to circulating apotransferrin. Heme iron: Heme iron is hypothesized to be taken up by receptor mediated endocytosis. Internalised heme is degraded by HO-2 inside the vesicles, releasing non-heme iron and generating biliverdin. The non-heme iron is then transported to the cytoplasm by DMT1. Heme iron may also be taken up by PCFT/HCP1 directly into the cytoplasm. Intact heme may be transported across the basolateral membrane by FLVCR where it binds circulating hemopexin. Alternatively, heme may be catabolized to non-heme iron and biliverdin by HO-1 located on the endoplasmic reticulum. Any iron released from heme inside the enterocyte, regardless of the mode of uptake, ultimately joins the labile iron pool and is transferred to the bloodstream by FPN1 in the same fashion as non-heme iron.

non-heme iron in the predominantly alkaline conditions found in the lumen of the small intestine. In aqueous solutions at or above pH 7.0, non-heme iron is present as Fe(II) and Fe(III). Fe(II) readily oxidizes to Fe(III) which precipitates from solution as ferric hydroxide or forms soluble hydroxyl-iron dimers which are not directly available for absorption<sup>[8]</sup>. Further, many dietary components (particularly humic substances such as tannins and phytate) can chelate iron making it non-

bioavailable<sup>[9-11]</sup>, while only select reductants in the diet (such as ascorbate) can act as solubilizing agents<sup>[12]</sup>.

In contrast polymerization of heme, which reduces its absorption, is minimised in alkaline conditions<sup>[13]</sup> while humic substances<sup>[14,15]</sup> and chelators such as desferrioxamine<sup>[16,17]</sup> do not reduce heme bioavailability. Heme solubility is also increased significantly by the presence of protein<sup>[13,18-20]</sup> which is important considering heme-rich foods typically contain high quantities of protein. Paradoxically, the absorption of heme iron cannot upregulate to the same extent as non-heme iron during iron deficiency<sup>[14,15,21-25]</sup>. This is possibly due to rate limitations at the step of heme catabolism (see 'Heme Catabolism' below) although the extent to which enterocyte adaptation (particularly transfer to the circulation by ferroportin<sup>[26-29]</sup> and humoral regulation by hepcidin<sup>[30-33]</sup>) affects heme iron absorption is very poorly characterised compared to non-heme iron.

Despite the clear importance of dietary heme as a source of body iron, the mechanism by which the enterocyte takes up heme and catabolizes it to utilise the iron is still poorly understood. Heme is taken up as an intact metalloporphyrin<sup>[34,35]</sup> and comparative studies show that a molecule with a similar size, structure, and ionic charge to heme (namely Vitamin B12) was not absorbed by enterocytes because of the absence of specific carriers on the apical membrane, whereas in identical conditions up to 19% of an equivalent dose of heme was absorbed<sup>[36]</sup>. This strongly suggests that heme uptake is a facilitated process, as opposed to simple diffusion.

Currently, there are two prevailing hypotheses explaining the mechanisms of this process; firstly, a long-standing hypothesis that heme is taken up by receptor mediated endocytosis; secondly, the recent discovery of a heme transporter that may have the capability of transferring heme from the small intestinal lumen directly into the cytoplasm. These pathways are summarised in Figure 1 and discussed in detail below.

## HEME RECEPTOR MEDIATED ENDOCYTOSIS

The hypothesis of heme uptake by receptor mediated endocytosis originated in 1979 from the discovery of a heme binding protein on the microvillus membrane of the upper small intestine of both pigs and humans<sup>[37]</sup>. Characterisation of this binding protein demonstrated that it was not albumin, hemopexin, glutathione-S-transferase, or aggregated heme<sup>[38]</sup>. The dissociation constant for the binder/heme complex was found to be  $10^{-6}$  to  $10^{-7}$  mol/L using radioactive ligands, and  $10^{-9}$  mol/L in spectral studies<sup>[39]</sup>. This high affinity binding, along with loss of binding capacity with trypsin digestion, indicated the presence of a protein receptor for heme on the microvillus membrane. Heme uptake by rat duodenal enterocytes increases with iron deficiency and correlates with a modest but statistically significant increase in heme binding capacity<sup>[36]</sup>, suggesting that the quantity of

receptor present on the microvillus membrane contributes to regulation of heme iron absorption.

A heme binding protein has also been characterised on the membrane of erythroleukemia cells with very similar properties to that observed in the duodenum<sup>[40]</sup>. These cell types are capable of internalising heme intact, as evidenced by the binding and uptake of heme-embedded latex beads<sup>[41,42]</sup>. Heme uptake is also temperature<sup>[43]</sup> and ATP<sup>[44]</sup> dependent, and these combined data provide strong evidence for the ability of cells to actively take up heme by endocytosis.

Morphological evidence corroborates this assessment. In two similar studies, heme or hemoglobin were administered into closed duodenal loops of rats or dogs, and duodenal tissue samples collected over a time period of up to 3 h thereafter<sup>[45,46]</sup>. Heme in the duodenal mucosa was reacted with DAB to produce an electron dense precipitate that was then observed by electron microscopy. Both studies reported the appearance of heme initially on the microvillus membrane, then within tubulovesicular structures in the apical cytoplasm, before collecting in vesicles identified as secondary lysosomes<sup>[46]</sup>. Heme disappeared from within these vesicles approximately 2–3 h after the initial dose. There was no heme observed in the basal cytoplasm or the extracellular space, consistent with heme uptake at the microvillus membrane by an endocytotic pathway and its catabolism within the apical cytoplasm of the cell.

One important criticism of the receptor mediated endocytosis hypothesis is that it assumes iron released from heme is transported out of the internalised vesicles in order to join the labile iron pool. Currently, no such transport process has been identified. However, it is possible that divalent metal transporter 1 (DMT1) may fulfil this role in a manner analogous to its role in the transferrin receptor cycle<sup>[47–50]</sup> (see ‘A Possible Role for DMT1?’ below).

## HEME TRANSPORTERS

In recent years, two mammalian heme transporters have been discovered, namely PCFT/HCP1<sup>[51,52]</sup> and FLVCR<sup>[53]</sup>. These appear to function independently of the putative heme receptor and receptor mediated endocytosis in that they act as a direct transfer process across plasma membranes. At this early stage the physiological relevance of these transporters to intestinal heme iron absorption is unclear, but the information that is available will be considered below.

The PCFT/HCP1 cDNA was initially isolated by the subtractive suppressive hybridisation of ileal cDNA from duodenal cDNA in hypotransferrinaemic mice<sup>[51]</sup>. Heme transport capability by PCFT/HCP1 has been demonstrated *in vitro*, with expression in Xenopus oocytes and the HeLa cell line resulting in a 2-fold to 3-fold increase in heme uptake. Heme uptake by HeLa cells expressing PCFT/HCP1 was greatly reduced at 4°C compared to 37°C which was interpreted as energy dependence, although without the specific use of metabolic inhibitors to distinguish between temperature

dependent kinetic properties of the transporter and a requirement for metabolic fuels, this interpretation is ambiguous.

Uptake of radio-labelled heme by transfected CHO cells was competitive with the uptake of unlabelled heme, zinc protoporphyrin, and protoporphyrin suggesting that transport is selective for the porphyrin ring, although no non-porphyrin competitors appear to have been assessed. However, the addition of PCFT/HCP1 siRNA to CHO cells did not reduce the substantial basal heme uptake of control cells<sup>[51]</sup>. Clearly, CHO cells have significant pre-existing heme acquisition pathways that are not related to PCFT/HCP1. *In vivo*, heme uptake from closed duodenal loops in normal and hypoxic mice was modestly reduced (30%–40%) by the addition of a PCFT/HCP1 antibody but no decrease was seen with pre-immune serum. PCFT/HCP1 gene expression was significantly increased by hypoxia but was not significantly altered by iron deficiency which appears contrary to the upregulation of heme binding and uptake shown in other studies<sup>[36]</sup>, although regulation of heme transport may instead be regulated by the sub-cellular location of PCFT/HCP1.

PCFT/HCP1 has been independently characterised as a folate/proton symporter and appears to play a key role in intestinal folate absorption<sup>[52,54]</sup>. This is evidenced by a 55%–80% reduction in pH dependent folate uptake in the enterocyte-like CaCo-2 cell line following RNA interference for PCFT/HCP1. Additionally, human patients diagnosed with hereditary folate malabsorption carry a point mutation to PCFT/HCP1 that results in the formation of a non-functional splice variant. Interestingly, the folate transport capabilities of PCFT/HCP1 are at least an order of magnitude higher than that observed for heme, suggesting that folate may be the more physiologically relevant target of this transport protein. It is clear that the generation of a knockout model for PCFT/HCP1 is required to assess the importance of this heme/folate transporter *in vivo*.

FLVCR was initially characterised as the cell surface protein receptor for feline leukaemia virus subgroup C which causes severe anaemia in infected cats<sup>[55,56]</sup>. It has since been demonstrated that loss of FLVCR function in erythropoietic cells is associated with impairment of erythroid maturation and increased apoptosis, and that heme content of erythropoietic primary cultures is dependent upon FLVCR expression<sup>[53]</sup>. Since cells expressing FLVCR are capable of actively exporting heme, it was concluded that FLVCR acts as an overflow valve for excess manufactured heme that would otherwise result in cellular toxicity by producing oxidative stress before it can bind to globins for hemoglobin production.

With regard to intestinal heme iron absorption, no studies have yet directly examined FLVCR function *in vivo*, though the polarized intestinal cell line CaCo-2 does express the protein<sup>[53]</sup>. It has also been demonstrated that CaCo-2 cells are capable of heme transport in both directions, equivalent to both absorption and secretion *in vivo*, and that the secretory pathway is significantly

more active under control conditions<sup>[57]</sup>. Presumably, FLVCR is acting on the basolateral membrane to regulate heme content when heme synthesis rates are at their peak just prior to differentiation, and the potential for cell damage from oxidative stress is greatest if HO-1 activity is impaired<sup>[58-60]</sup> (see 'Heme Oxygenase' below). In this case it is highly unlikely that FLVCR is involved with heme uptake at the apical membrane. Studies of FLVCR *in vivo* are required to confirm this assessment.

## HEME CATABOLISM IN THE ENTEROCYTE

It was initially hypothesized that following uptake, heme passed directly into the portal circulation where it bound hemopexin and was most likely sequestered by hepatocytes using the hemopexin receptor and degraded, based on early observations in guinea pigs<sup>[23]</sup>. However, this theory is questionable for other species, with strong evidence that heme is catabolized within the enterocyte in most omnivorous and carnivorous mammals. This is best demonstrated by experiments in which dogs were administered an intragastric dose of radio-labelled hemoglobin, and 90% of the recoverable radioactivity in samples of portal blood over a period of 3 h was present as non-heme iron<sup>[35]</sup>. Similar observations have been made in human<sup>[14,34]</sup> and rat<sup>[17]</sup> experiments.

The presence of a heme splitting substance in the mucosa was first demonstrated in 1968<sup>[61]</sup>. The high molecular weight of this substance (MW about 64 kDa) and the kinetic properties of the reaction indicated that the heme splitting substance was an enzyme. Initial studies suggested that xanthine oxidase could play a role by generating hydrogen peroxide to chemically degrade heme, resulting in iron release and a non-specific mixture of four bilirubin isomers<sup>[62-64]</sup>. However, this hypothesis was problematic since *in vivo* heme degradation typically results in a single dominant isomer, namely bilirubin IX- $\alpha$ <sup>[65,66]</sup>.

Further research generated a strong case that the heme splitting substance in the mucosa was microsomal heme oxygenase<sup>[24]</sup>. This is based on the fact that heme oxygenase almost exclusively generates the expected bilirubin IX- $\alpha$  isomer and that heme oxygenase activity is highest in the location where heme iron absorption is highest, the duodenum<sup>[17,23,37]</sup>. In addition, iron deficiency results in an increase in both heme iron absorption and mucosal heme oxygenase activity, whereas xanthine oxidase activity decreases dramatically.

Based on morphological studies, it appears that heme is degraded inside internalised vesicles within 2-3 h of heme uptake by receptor mediated endocytosis<sup>[45,46]</sup>. Acid ferrocyanide staining, which exclusively detects non-heme iron, indicates that iron is released from heme inside the vesicle, before transport to the labile iron pool by unknown mechanisms (see 'A Possible Role for DMT1?' below). The iron is then thought to undergo identical transport through the enterocyte and into the circulation as for internalised non-heme iron.

A study tracking the absorption of <sup>59</sup>Fe-hemoglobin in closed duodenal loops has suggested that heme degradation is the rate limiting step in heme iron absorption, as opposed to hemoglobin degradation, heme uptake or iron transfer to the circulation<sup>[67]</sup>. This is based on increasing doses of hemoglobin resulting in the accumulation of <sup>59</sup>Fe-heme, but not <sup>59</sup>Fe, within the mucosa. However, since this study utilized whole-mucosal homogenates to assess relative heme and non-heme iron content there may not be sufficient sensitivity to detect the possible accumulation of non-heme iron inside endocytotic vesicles which would result in decreased heme oxygenase activity by end-product inhibition<sup>[61]</sup>. Nonetheless, the hypothesis that heme oxygenase is limiting for heme iron absorption is consistent with the decrease in absorption that is observed with inhibitors of heme oxygenase activity<sup>[68]</sup>.

## HEME OXYGENASE

Heme oxygenase is a microsomal enzyme (corresponding to the endoplasmic reticulum *in vivo*) that catalyses the mixed function oxidation of heme using cytochrome P-450, NADPH and molecular oxygen producing CO, iron and biliverdin IX- $\alpha$  which is rapidly reduced to bilirubin IX- $\alpha$ <sup>[69-71]</sup>. There are two well characterised isoforms of heme oxygenase, referred to as HO-1 and HO-2<sup>[72,73]</sup>, and these isoforms are products of different genes<sup>[74,75]</sup>. A third isoform has been described as HO-3<sup>[76]</sup>, but this appears to be a brain-specific pseudogene derived from HO-2<sup>[77]</sup>.

HO-1 expression is induced by numerous factors including oxidative stress, inflammation, cytokines, nitric oxide, prostaglandins, an elevated level of substrate, iron deficiency, metals including Cd, Co, Cr, Cu, Fe, Hg, Ni, Pd, Pt, Sn and Zn, hyperoxia, and exposure to UV light (for review see<sup>[78]</sup>). HO-1 is also induced by hyperthermia, leading to the use of the alternate name heat shock protein 32<sup>[79]</sup>. Considering these combined factors, induction of HO-1 expression appears to be related to preventing cell damage under many circumstances by reducing levels of the pro-oxidant heme and generating the antioxidant bilirubin<sup>[80]</sup>. This assessment is confirmed by genetic knockout of HO-1 in mice<sup>[81]</sup>, and humans with impaired HO-1 expression<sup>[82-84]</sup>, which present with reduced defence against external stresses.

In contrast, HO-2 expression is not inducible<sup>[79,85]</sup>. HO-2 is primarily found in the brain<sup>[86]</sup> and testis<sup>[85]</sup> and appears to function as a sensor for O<sub>2</sub>, CO, and NO<sup>[87-90]</sup>. In the intestine these functions are relevant in the interstitial cells of Cajal, where HO-2 regulates levels of CO, which in turn affects potassium currents and resting membrane potential of intestinal smooth muscle, and thus intestinal motility (for review see<sup>[78]</sup>).

In relation to the catabolism of dietary heme, most work regarding heme oxygenase was performed before the different isoforms were known. As such, the specific isoform involved with heme iron absorption has not been established with certainty. However, it has long

been assumed that HO-1 is the key player<sup>[91]</sup> based on corroboration of physiological evidence; specifically, HO-1 and heme iron absorption both upregulate in iron deficiency<sup>[92]</sup>. Further, HO-1 activity<sup>[24]</sup> and heme iron absorption<sup>[17,23,37]</sup> are both highest in the duodenum, which is also the site of highest expression of the putative heme receptor and PCFT/HCP1<sup>[37,51,52]</sup>.

However, HO-1 is generally considered to be a membrane bound protein associated with microsomes<sup>[69]</sup> with a cytoplasmic catalytic site<sup>[93]</sup>. Thus under normal circumstances HO-1 would have no topological association with the vesicles that are thought to contain internalised heme, namely endosomes and/or lysosomes. As such, the possibility that HO-2 plays a role in heme iron absorption should be strongly considered, since both HO-1 and HO-2 generate the appropriate isoform of bilirubin<sup>[72]</sup>. Further, the participation of a non-inducible enzyme could explain why the ability to upregulate heme iron absorption is limited compared to non-heme iron<sup>[14,15,21-25]</sup>, and heme splitting is speculated to be rate limiting<sup>[67]</sup>.

In a recent study our laboratory examined the sub-cellular location of HO-1 and HO-2 in enterocytes in relation to endocytotic markers during the course of heme iron absorption<sup>[94]</sup>. We observed that HO-1 was distributed evenly throughout the cytoplasm of enterocytes and did not co-localise with endocytotic markers. In contrast, HO-2 presented as a dense band in the apical cytoplasm that co-localised extensively with endosomes. This strongly suggests that HO-2 could be exposed to all heme taken up by the enterocytes, either by way of receptor mediated endocytosis or by transport directly into the cytoplasm. Clearly, the role of HO-2 in heme iron absorption needs to be investigated further using more direct methods, particularly using knockout models for HO-1 and HO-2.

## A POSSIBLE ROLE FOR DMT1?

The uptake of non-heme iron by the enterocytes occurs through the function of DMT1<sup>[95,96]</sup>. DMT1 is also capable of transporting other divalent cations<sup>[96-98]</sup> and is responsible for cellular iron acquisition during the transferrin receptor cycle<sup>[47-50]</sup>. DMT1 functions as a Fe(II)/proton symporter<sup>[96]</sup> and is highly expressed in the duodenum during iron deficiency<sup>[99]</sup>. This is consistent with the duodenum being the principal site of iron absorption<sup>[100]</sup> and the least alkaline section of the small intestine due to the close proximity to acidic gastric secretions. Ultimately, Fe(III) is also transported by DMT1 after reduction to Fe(II) by DcytB<sup>[101]</sup>, although the physiological significance of this pathway is the subject of continued debate<sup>[102,103]</sup>.

The physiological relevance of DMT1 in iron metabolism, including iron absorption, is confirmed in the Belgrade (*b*) rat and *mk* mouse which both exhibit a microcytic, hypochromic anaemia due to a G185R mutation to DMT1, resulting in a dramatic decrease in DMT1 function<sup>[47,104-106]</sup>. Considering *b/b* rats, the primary symptoms are mostly attributable to

decreased iron uptake by reticulocytes<sup>[107,108]</sup> and earlier erythroid precursors<sup>[109]</sup>. Further research has shown that endosomal iron transport during the transferrin receptor cycle is significantly reduced in *b/b* rats<sup>[108,110-112]</sup>, and these findings are entirely consistent with the functional role<sup>[47,105]</sup> and sub-cellular location<sup>[48,50]</sup> of DMT1 in relation to the transferrin receptor cycle.

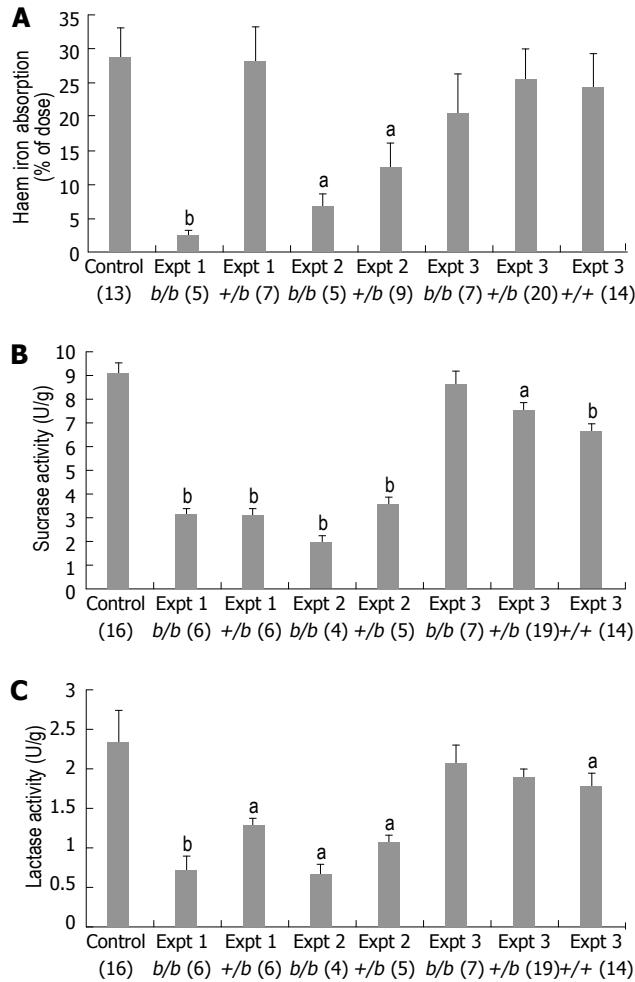

In addition to the striking effects on reticulocyte development, *b/b* rats also exhibit a significant decrease in the quantity of megakaryocytes in their bone marrow<sup>[113]</sup>, and their overall hematological status is similar to that observed in a rare preleukaemic syndrome<sup>[114]</sup>. The subsequent high clearance rates of prematurely senescent erythrocytes in turn causes splenomegaly. Aside from hematological factors, *b/b* rats exhibit a universal reduction in iron uptake by body tissues<sup>[115]</sup>, including the brain<sup>[116]</sup>. The extent to which this affects overall health and development, independent of hematological parameters, is not currently known.

The final important aspect of defective iron metabolism by Belgrade rats is their decreased dietary non-heme iron absorption at the stage of uptake into the enterocytes<sup>[115,117]</sup>. This is consistent with the location<sup>[99]</sup> and function<sup>[95]</sup> of DMT1 on the microvillus membrane of enterocytes. Decreased iron absorption can be viewed as the 'second hit' for iron deficiency anaemia in *b/b* rats. However, the residual activity of mutated DMT1 means that appropriate dietary iron supplementation and iron dextran injections can improve general health and survival rates without returning hematological status to normal<sup>[118]</sup>.

Over the past few years our laboratory has been using the Belgrade rat to examine whether DMT1 is the transporter required to utilise the iron released from heme during receptor mediated endocytosis. This hypothesis suggests that the function of DMT1 is directly comparable to its role in the transferrin receptor cycle<sup>[47-50]</sup> and that *b/b* rats would exhibit decreased heme iron absorption compared with *+/b* and control rats due to a reduced ability to transport iron out of internalised vesicles.

## THE BELGRADE RAT AND HEME IRON ABSORPTION

In preliminary experiments, *b/b* rats exhibited a statistically significant decrease in hemin chloride, hemoglobin, and ferrous iron absorption when compared with *+/b* and Wistar (*W*) rats, as assessed by whole body retention of an oral gavage of radio-labelled iron. This strongly suggested that there was a requirement for DMT1 in heme iron absorption (see Expt 1 in Figure 2A). However, it was unclear whether this effect was due to a reduction of DMT1 function across the membranes of endocytotic vesicles, or was secondary to pathological effects of the iron deficiency and anaemia experienced by *b/b* rats. A general defect in the mucosal biology of *b/b* rats may have consequences for other proteins and biosynthetic processes including

**Figure 2** Results from Belgrade rats for heme iron absorption (A), sucrase activity (B) and lactase activity (C) over a series of experiments. Figures in brackets indicate n values, and data is mean  $\pm$  SE. Groups marked with 'a' or 'b' are significantly different from the control group (1-way ANOVA  $^aP < 0.05$  and  $^bP < 0.005$ , respectively). In early experiments 1 and 2, b/b and +/b rats had significantly lower heme iron absorption than Wi controls, initially suggesting a possible role for DMT1. However, sucrase and lactase activity was also lower in b/b and +/b rats indicating a more general defect in the mucosa of the Belgrade strain. In experiment 3, +/+ rats were used as an improved control to account for strain differences between Wi and Belgrade strains, but in this (and subsequent) experiments there was an apparent recovery in both heme iron absorption as well as sucrase and lactase activities. We could find no explanation for this dramatic phenotypic change, making it difficult to correlate DMT1 function with heme iron absorption.

reduced expression of the heme receptor and/or heme transporters, reduced capacity to internalise a heme/receptor complex and reduced heme oxygenase activity -all of which would affect heme iron absorption.

It was observed that in addition to reduced heme iron absorption both b/b and +/b rats also exhibited significantly lower activity of sucrase and lactase<sup>[119]</sup> when compared with Wistar rats (see Expt 1 in Figure 2B, C). Previous studies examining the Belgrade strain have only observed phenotypic differences in b/b rats, whereas +/b rats appear identical to control laboratory rat strains such as Wistar and Sprague-Dawley for all measured parameters<sup>[115,117,120,121]</sup>. This raised the strong possibility that there are as yet uncharacterized strain differences between Belgrade and other laboratory

rat strains that are unrelated to reticulocyte iron uptake and non-heme iron absorption.

Experiments assessing heme iron absorption and the expression of sucrase and lactase were repeated shortly after with similar results; b/b rats again exhibited significantly decreased heme iron absorption compared to Wi, but so did +/b rats contrasting with the previous experiment. Further, both b/b and +/b rats had significantly decreased sucrase and lactase activities compared to Wi controls, making it difficult to correlate DMT1 function with heme iron absorption (see Expt 2 in Figure 2A-C). At this time it was decided to use a more appropriate control than Wi rats in order to account for any strain differences, thus we established a breeding program that would generate b/b, +/b and +/+ Belgrade rats. We concurrently began genotyping all experimental rats by sequencing reverse transcribed DMT1 mRNA; in all cases the measured genotype matched the observed phenotype.

The experiment including +/+ rats yielded unexpected and conflicting results. b/b rats demonstrated a dramatic recovery of both heme iron absorption and sucrase and lactase activity, such that they were directly equivalent to +/b and +/+ rats, and approximately comparable to Wi controls from previous experiments (see Expt 3 in Figure 2A-C). Subsequent experiments were able to replicate this recovery (data not shown). The dramatic phenotypic change in the Belgrade rat strain could not be attributable to any gross developmental characteristics including body mass, spleen mass and mucosa mass, nor any change in the measures of iron deficiency and anaemia. Additionally, we were unable to find evidence for the contraction of a chronic infection, significant changes in other external factors or any variation in our well-controlled measurement of heme iron absorption and enzyme activity.

Thus the colony of Belgrade rats available to us has been unable to provide any conclusive evidence for a role of DMT1 in heme iron absorption. Similarly, we were not able to observe any relocation of DMT1 to endosomes or lysosomes during the course of heme iron absorption using confocal microscopy<sup>[94]</sup>. However, bearing in mind that there are still large deficiencies in the understanding of heme iron absorption, we feel that a potential role for DMT1 should still be seriously considered in the future. This will require more reliable animal models than the Belgrade rat, possibly including the mk mouse or the *Slc11a2<sup>int/int</sup>* mouse which exhibits selective knockout of intestinal DMT1<sup>[95]</sup>. Further, it would be highly desirable to use more sensitive techniques than confocal microscopy (such as immunoelectron microscopy) to determine whether DMT1 is internalised to endosomes or lysosomes during heme iron absorption.

## CONCLUSION

Since the discovery of DMT1 in 1997 iron metabolism has experienced a renaissance, and the subsequent discovery of ferroportin and the humoral regulator

hepcidin have provided a very solid and complete theory for the mechanisms of non-heme iron absorption. The absorption of heme iron has yet to undergo a similar revolution, and considerably more work needs to be done in the future for a complete understanding of the absorption of this critical micronutrient. Primarily, the physiological relevance of recently discovered heme transporters will need to be confirmed *in vivo*, along with continued searching for additional heme transporters and receptors. Concurrent efforts to explicitly identify the enzyme responsible for heme catabolism, as well as the sub-cellular location of this enzyme's catalytic site, will help ascertain whether heme is taken up by receptor mediated endocytosis or is transported directly into the cytoplasm of enterocytes. Finally, the potential role of iron transporters such as DMT1 in heme iron absorption will need to be investigated further; particularly if receptor mediated endocytosis proves to be an important heme uptake pathway.

viral hepatitis, alcohol intake, nonalcoholic fatty liver disease, autoimmune liver diseases and hereditary diseases such as hemochromatosis,  $\alpha_1$ -antitrypsin deficiency and Wilson's disease. Many patients with liver injury are likely to be treated with several drugs, increasing the possibility that their liver injuries are drug-induced. Some patients with liver injury, however, have underlying systemic diseases, which may also affect their livers. Knowledge of liver involvement in systemic diseases is important for the accurate diagnosis of liver injury and to avoid unnecessary examination and treatment. This review will describe liver injury caused by various systemic diseases.

### Abstract

Potential causes of abnormal liver function tests include viral hepatitis, alcohol intake, nonalcoholic fatty liver disease, autoimmune liver diseases, hereditary diseases, hepatobiliary malignancies or infection, gallstones and drug-induced liver injury. Moreover, the liver may be involved in systemic diseases that mainly affect other organs. Therefore, in patients without etiology of liver injury by screening serology and diagnostic imaging, but who have systemic diseases, the abnormal liver function test results might be caused by the systemic disease. In most of these patients, the systemic disease should be treated primarily. However, some patients with systemic disease and severe liver injury or fulminant hepatic failure require intensive treatments of the liver.

### INTRODUCTION

Potential causes of abnormal liver function tests include

### CARDIOVASCULAR DISEASES

#### *Ischemic hepatitis*

The pathophysiology of ischemic hepatitis, also known as "shock liver", is poorly understood<sup>[1]</sup>. Patients usually show rapid (within 24-48 h) and dramatic transient increases in serum aminotransferase, lactate dehydrogenase (LDH) levels and bilirubin following periods of hemodynamic instability or hypoxia. Three features distinguish ischemic hepatitis from acute viral hepatitis: LDH elevation is more marked in ischemic than in viral hepatitis; serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) concentrations rapidly return to normal in ischemic hepatitis, usually within 7-10 d; and ischemic hepatitis is more often complicated by renal damage<sup>[2]</sup>. Ischemic hepatitis has several etiologies (Table 1)<sup>[2]</sup>.

#### *Liver congestion*

Liver congestion is caused by acute or chronic right-sided heart failure and is manifested by hepatomegaly (95%-99%), ascites (7%-49%), splenomegaly (12%-25%) and/or jaundice (< 20%)<sup>[3,4]</sup>. In addition, patients often show signs indicative of heart failure, including peripheral edema and pleural effusion. Liver function tests show that serum bilirubin is elevated, usually to 1-5 mg/dL and mostly in the unconjugated form, in 24%-81% of patients, depending on the severity of heart failure<sup>[3-5]</sup>. Bilirubin concentrations rapidly return to normal 3-7 d after improvement of right-sided heart failure. In addition, 3%-50% of patients with heart failure show elevated levels of serum aminotransferases, with the elevation of AST more marked than that of ALT<sup>[3-5]</sup>. Elevated serum alkaline phosphatase (ALP) is observed in 10%-20% of patients with right-sided heart failure, but these levels return to normal within 1 wk after improvement of heart failure<sup>[3-5]</sup>.

**Table 1 Etiologies of ischemic hepatitis<sup>[2]</sup>**

<b>Etiologies of ischemic hepatitis</b>
Left ventricular failure
Acute myocardial infarction
Cardiac arrhythmia
Prosthetic valvular dysfunction
Cardiomyopathy
Pericardial tamponade
Other causes of shock
Trauma
Burns
Dehydration
Hemorrhage

### Cardiac cirrhosis

Cardiac cirrhosis may occur after longstanding hepatic congestion, but its incidence is relatively low. Although liver cirrhosis has no characteristic biochemical markers, a multivariate analysis found that elevated concentrations of AST and bilirubin are prognostic of poor outcome<sup>[6]</sup>.

### HEATSTROKE

The liver is extremely sensitive to thermal injury and is a frequent site of tissue injury in patients with heatstroke, with almost all of these patients experiencing liver injury<sup>[7]</sup>. Elevated serum ALT concentration is the most common feature in patients with heatstroke, and may lead to acute hepatic failure<sup>[8]</sup>. Liver function tests usually return to normal after 2 wk, but may remain elevated after 1 mo<sup>[9]</sup>.

### CONNECTIVE TISSUE DISEASES

Connective tissue diseases often involve the liver, and various forms of hepatic involvement have been reported. Laboratory markers and liver diseases associated with connective tissue diseases are summarized in Table 2<sup>[10,11]</sup>. For example, liver disease has been shown to be a common complication of systemic lupus erythematosus (SLE). Elevated serum ALT has been observed in 21% of patients with SLE<sup>[12]</sup>, and 4.4% of patients with SLE may have serious chronic liver diseases, including chronic active hepatitis and liver cirrhosis<sup>[13-16]</sup>. The most common liver histologic manifestation of SLE is steatosis, which may not be associated with corticosteroid therapy<sup>[17]</sup>. It is important to distinguish lupus-related chronic hepatitis from autoimmune hepatitis (AIH), because patients with the latter often rapidly progress to liver cirrhosis unless they are treated with appropriate and sufficient doses of corticosteroids. Inasmuch as corticosteroid treatment can improve liver biochemical abnormalities in either disease, a response to the drug does not contribute to the differential diagnosis. The presence of anti-smooth muscle antibody, which is found in patients with AIH but not in those with lupus-related liver disease, may be helpful for distinguishing these two diseases<sup>[18]</sup>. There have been reports of patients with overlapping SLE and autoimmune hepatitis<sup>[13-16]</sup>, thus confusing the diagnosis

**Table 2 Connective tissue disease-associated abnormal liver function tests and liver diseases<sup>[10,11]</sup>**

<b>Connective tissue disease</b>	<b>Abnormal liver function tests</b>	<b>Liver disease or histology</b>
Juvenile rheumatoid arthritis	Elevated aminotransferases	Drug hepatotoxicity Massive hepatomegaly Infiltration of portal tracts by chronic inflammatory cells Acute necro-inflammatory disease
Felty syndrome	Elevated ALP and aminotransferases	Chronic hepatitis Drug hepatotoxicity Nodular regenerative hyperplasia Portal fibrosis Sinusoidal lymphocytosis Amyloidosis Macronodular cirrhosis Hepatomegaly
Rheumatoid arthritis	Elevated ALP, correlate with severity of arthritic activity	Drug hepatotoxicity Autoimmune chronic hepatitis (type 1) Nodular regenerative hyperplasia Primary biliary cirrhosis Amyloidosis Spontaneous hepatic rupture/ Necrotizing arteritis Steatosis
Polymyalgia rheumatica	Elevated ALP and aminotransferases	Drug hepatotoxicity Steatosis Lymphocytic infiltration of portal tracts Granulomas Hyperplasia of perisinusoidal stellate cells Primary biliary cirrhosis
Sjögren's syndrome	Elevated ALP and aminotransferases	Primary; 7% have liver dysfunction, mostly PBC Secondary; 40%-70% have PBC
Scleroderma	Hepatic involvement is low; Elevated ALP, mild elevation of aminotransferases and bilirubin	Drug hepatotoxicity CREST syndrome (PBC) Spotty calcification Idiopathic portal hypertension Cirrhosis Nodular regenerative hyperplasia Hepatomegaly
Systemic lupus erythematosus	Elevated aminotransferases in up to 50% of patients	Drug hepatotoxicity Autoimmune chronic hepatitis (type 1) Venous congestion Nodular regenerative hyperplasia Hepatic infarction Steatosis Venous thrombosis Granulomatous hepatitis Centrilobular necrosis Cirrhosis
Adult Still's disease	Elevated ALP and aminotransferases	Moderate portal mononuclear cell infiltration with occasional focal hepatocyte necrosis

of liver disease in SLE patients. Criteria are needed for the differential diagnosis of AIH and lupus-related liver disease in patients with SLE.

## HEMATOLOGICAL DISEASES

### Hodgkin disease

Liver infiltration of malignant cells has been reported in 14% of patients with Hodgkin disease, and hepatomegaly in 9% of patients with stage I-II and in 45% of patients with stage III-IV disease<sup>[17]</sup>. In addition, mild elevations of aminotransferases and moderate elevation of ALP can occur, due to tumor infiltration or extrahepatic bile duct obstruction<sup>[17]</sup>. However, cholestasis in zone 3, which was not associated with extrahepatic obstruction or tumor infiltration, has been described; this cholestasis may be due to vanishing bile duct syndrome<sup>[18]</sup>.

### Non-Hodgkin lymphoma

Lymphoma cell infiltration of the liver is more common in non-Hodgkin than in Hodgkin disease, with 16%-43% of non-Hodgkin patients showing hepatic involvement<sup>[17]</sup>. Extrahepatic obstruction is also more common in non-Hodgkin than in Hodgkin disease. Moreover, hepatic infiltration is more common in low-grade B-cell lymphomas (small cell) than in high-grade (diffuse large B-cell, T-cell histiocytic) lymphomas<sup>[19]</sup>. Liver function tests show mild to moderate elevations in serum ALP, and hepatomegaly may occur<sup>[17]</sup>. Although liver involvement in both Hodgkin and non-Hodgkin lymphomas may present as acute hepatic failure<sup>[20-25]</sup>, liver transplantation should be avoided<sup>[26]</sup>. Jaundice due to non-Hodgkin lymphoma can be distinguished from that due to viral hepatitis or drug hepatotoxicity by the presence of liver enlargement and lactic acidosis in lymphoma<sup>[27]</sup>.

### Chronic lymphoid leukemia (CLL)

Patients with CLL often show mild to moderate liver enlargement and extensive lymphocytic infiltration in the portal tracts, with functional impairment of the liver in late stages<sup>[28,29]</sup>.

### Hairy cell leukemia

Leukemia cells often infiltrate the liver, in both the portal tracts and sinusoids, and liver enlargement has been observed in up to 40% of patients with this disease<sup>[30]</sup>.

### Acute leukemia

Although hepatic involvement in acute leukemia is usually mild and silent at the time of diagnosis<sup>[27]</sup>, a post mortem study showed liver infiltration in > 95% of ALL and up to 75% of AML patients<sup>[31]</sup>. In ALL, infiltration was confined to the portal tracts, whereas, in AML, infiltration was observed in both portal tracts and sinusoids. Massive leukemic cell infiltration of the liver may present as fulminant hepatic failure<sup>[32]</sup>. In patients with acute leukemia, drug-induced liver injury and bacterial or fungal infections may also affect the liver.

### Multiple myeloma

Hepatomegaly has been observed in 15%-40% of patients with multiple myeloma and may sometimes be accompanied by splenomegaly<sup>[33,34]</sup>.

### Primary myelofibrosis

Liver involvement is common in patients with primary myelofibrosis, and liver enlargement is observed in almost all patients. The mechanisms of liver involvement have been associated with extramedullary hematopoiesis, increased hepatic blood flow and hemosiderosis caused by multiple blood transfusions<sup>[27]</sup>. Ascites and esophageal varices secondary due to portal hypertension has been found in 7% of these patients<sup>[35,36]</sup> and nodular regenerative hyperplasia of the liver following obstruction of intrahepatic portal vein branches may augment the portal hypertension<sup>[37]</sup>. The most common liver function abnormality in patients with primary myelofibrosis is elevated ALP, which has a frequency of 40%-60% and which may be associated with the severity of sinusoidal dilatation<sup>[38]</sup>.

### Polycythemia vera

Although direct liver involvement is uncommon, some patients may present with acute or chronic Budd-Chiari syndrome<sup>[39]</sup>.

### Chronic myeloid leukemia (CML)

About 50% of patients with CML show mild to moderate hepatomegaly at presentation, with no liver function abnormalities<sup>[40]</sup>. At the time of blastic crisis, however, liver sinusoidal infiltration by immature cells may lead to liver enlargement and elevated serum ALP levels<sup>[41]</sup>.

### Myelodysplasias

In patients with sideroblastic or refractory anemia, iron deposition in the liver may occur due to repeated transfusion or decreased iron utilization by bone marrow<sup>[27]</sup>.

### Sickle-cell disease

The liver is commonly involved in sickle-cell disease. This may be due to iron overload caused by multiple blood transfusions, gallstones, or cardiac dysfunction due to secondary hemochromatosis<sup>[42]</sup>.

### Thalassemia

The major cause of liver injury in patients with thalassemia is hemochromatosis due to ineffective erythropoiesis, with massive iron deposits found in the liver<sup>[27]</sup>.

## LUNG DISEASES

### Pneumonia

Lobar pneumonia caused by *Legionella pneumophila*, *Mycoplasma pneumoniae* or *Pneumococcus* may be associated with elevated concentrations of serum aminotransferase and bilirubin<sup>[43]</sup>.

Jaundice has been observed in 3%-25% of patients with *Pneumococcus* pneumonia<sup>[44]</sup>, often developing between days 3 and 6 of illness.

In *Legionnaire's* disease, liver function tests are likely to show abnormalities, with elevated concentration

of serum ALP and aminotransferase in up to 50% of patients<sup>[45]</sup>.

*Mycoplasma pneumoniae* is a frequent cause of community-acquired pneumonia. Liver involvement is not common, but some patients may have elevated levels of serum aminotransferases<sup>[43]</sup>. Cholestatic hepatitis and mild hepatitis without pneumonia have been described<sup>[43]</sup>.

Cytomegalovirus pneumonia can also result in jaundice and elevated levels of ALP and aminotransferases<sup>[46]</sup>.

### Chronic pulmonary disease

Serum bilirubin, ALT,  $\gamma$ -glutamyl transpeptidase (GGT) and ALP may be elevated in patients with chronic pulmonary disease or status asthmatics<sup>[47-49]</sup>, and these liver abnormalities may be associated with secondary heart failure or hypoxia.

## RENAL DISEASES

Even in the absence of liver metastasis, renal cancer causes hepatomegaly and abnormal liver function test results. Following tumor resection, however, these liver abnormalities return to normal, suggesting that the previously observed abnormalities were caused by a hepatotoxic hormone secreted from the tumor<sup>[50]</sup>.

## SYSTEMIC INFECTION-BACTEREMIA AND SEPSIS

Cholestasis is a common complication in patients with extrahepatic bacterial infection and sepsis, regardless of whether the infectious agent is gram-negative (*E.coli* and *Klebsiella*) or gram-positive (*S aureus*)<sup>[51,52]</sup>. Proinflammatory cytokines, including tumor necrosis factor-alpha (TNF- $\alpha$ ) and interleukin-6 (IL-6), as well as nitric oxide, are thought to induce cholestasis by inhibiting the canalicular excretion of conjugated bilirubin<sup>[53]</sup>. Liver biopsy may show mild portal inflammation, but bile ducts often appear normal and there is usually no cholangitis<sup>[54]</sup>.

Laboratory findings in sepsis include mild elevation of ALP (mostly 1 to 3 times the ULN) and modest elevation of ALT. Peak serum bilirubin concentrations typically range from 5 to 10 mg/dL, but levels as high as 30 to 50 mg/dL have been reported<sup>[51]</sup>. Importantly, the serum concentrations of ALP and bilirubin may be discordant, with deeply jaundiced patients often having normal ALP levels, while anicteric patients may show marked elevation of ALP or GGT<sup>[55-57]</sup>. Compared with infected patients without bacteremia, those with bacteremia had significantly higher serum levels of GGT and ALP and significantly lower serum concentrations of albumin, cholesterol and cholinesterase. These alterations were observed within several days after the onset of bacteremia, but concentrations returned to normal following adequate treatment of the infection<sup>[52]</sup>. Although the major pathogens were *S aureus* and *E.coli*, *P aeruginosa* infection may cause cholestasis more frequently than other organisms, with 26% to 52%

of patients severely infected with *P aeruginosa* having jaundice<sup>[58]</sup>. At autopsy, these patients showed periportal cholestasis with minimal liver cell damage.

## LIVER DAMAGE IN INFECTION BY SPECIFIC PATHOGENS

### *Clostridium perfringens* infection

*C perfringens* may directly affect the liver by forming an abscess or causing necrotizing massive gas gangrene of the liver, leading to fulminant hepatic failure<sup>[59]</sup>.

### *Salmonella typhi* infection

While sepsis can cause liver dysfunction, it can also occur following *Salmonella typhi* infection, a condition known as *Salmonella* hepatitis<sup>[60]</sup>. Although severe elevation of liver function tests is rare, jaundice has been observed in 33% of these patients. Although the clinical features of *Salmonella* hepatitis may be identical to those of acute viral hepatitis, these diseases may be distinguished by the ALT/LDH ratio, which is < 4.0 in *Salmonella* hepatitis, significantly lower than the ratio in acute viral hepatitis, > 5.0<sup>[61]</sup>.

### Lyme disease

Hepatic involvement is common in Lyme disease caused by *Borrelia burgdorferi*, and mild elevations of GGT and aminotransferase are commonly observed especially in patients with early stage disease<sup>[62,63]</sup>.

### Q fever

Nearly 50% of patients with Q fever had accompanying hepatitis, but the liver function abnormalities were nonspecific. Although these patients usually show anicteric hepatitis, one third may have jaundice if the disease is prolonged<sup>[64]</sup>.

### Syphilis

Acute cholestatic syphilitic hepatitis, sometimes accompanied by jaundice, has been reported in patients with secondary syphilis<sup>[65]</sup>. Patients with tertiary syphilis may present with gummas formation in the liver, which resemble metastatic tumors<sup>[66]</sup>.

### *Campylobacter* infection

Mild to severe liver biochemical abnormalities have been observed following infection with *Campylobacter* organisms<sup>[67]</sup>.

### *Chlamydia* or *Neisseria* infection

Perihepatitis has been observed in patients infected with *Chlamydia trachomatis*<sup>[68]</sup> and *Neisseria gonorrhoeae*<sup>[69]</sup>, with the formation of liver granulomas in the former<sup>[65]</sup>.

### HIV infection

Liver injury in patients with HIV infection can be caused by HIV itself, by coinfection with hepatitis viruses such as HBV and HCV, or by hepatic involvement of

**Table 3 Liver involvement in deep fungal infections<sup>[73]</sup>**

Liver involvement in deep fungal infections
Opportunistic mycoses
Candidiasis-includes hepatosplenic candidiasis
Cryptococcosis
Less common: aspergillosis, mucormycosis, trichosporonosis
Pathogenic mycoses
Histoplasmosis-disseminated histoplasmosis
Paracoccidioidomycoses
Less common: coccidioidomycosis, african histoplasmosis, blastomycosis, penicilliosis

systemic infections, including *M tuberculosis*, *M avium complex*, *Toxoplasma gondii*, or *Cryptosporidium*. In addition, liver injury in HIV-infected patients may be due to the toxicities of drugs prescribed for the treatment of HIV or coinfecting microbes. In addition, biliary tract injuries caused by tuberculosis, *M avium* and *Cryptosporidium* have been reported<sup>[70]</sup>.

#### ***Mycobacteria infection***

Liver involvement is frequent in patients with mycobacterial infections, not only with *Mycobacterium tuberculosis* infection, but also with *M avium intracellulare* or *M genavense* infection<sup>[65]</sup>. The clinical spectrum of liver disease due to *Mycobacterium spp.* ranges from the absence of symptoms to liver failure, with multiple granulomas in the parenchyma of the liver being the most common lesion<sup>[71]</sup>. These patients show elevated serum ALP concentrations and hepatomegaly. Although the number of intrahepatic granulomas is greater in patients with than without disseminated military tuberculosis, hepatic tuberculosis can occur, even in the absence of apparent tuberculosis elsewhere<sup>[72]</sup>.

#### ***Fungal infection***

The liver is often involved in deep fungal infections, possibly due to enrichment of the blood flow through the liver or the invasion of fungi, including *C albicans* and *C tropicanus*, into the liver from the gut by penetrating through degenerated barriers of gastrointestinal mucosa<sup>[73]</sup>. Patients with liver involvement of fungal infection may show elevated serum concentrations of ALP and GGT, due to the formation of multiple small abscesses or granulomas in the liver. Liver involvement following deep fungal infections is summarized in Table 3<sup>[73]</sup>.

### **ACUTE HEPATIC FAILURE CAUSED BY VIRUSES OTHER THAN HEPATITIS A TO E**

The major causes of acute hepatic failure include drugs, hepatitis A, hepatitis B, and hepatitis E. Although Epstein-Barr virus and cytomegalovirus can also cause severe hepatitis during primary infection, other microbes, which mainly affect other organs, can cause acute hepatic failure. Among these are *Salmonella paratyphi A*<sup>[74]</sup>, herpes simplex virus<sup>[75,76]</sup>, parvovirus B19<sup>[77]</sup>, coxsackie virus B2<sup>[78]</sup>, human herpesvirus-6<sup>[79]</sup>, Varicella-Zoster

virus<sup>[80]</sup>, and Dengue virus<sup>[81]</sup>. Parvovirus B19 and human herpesvirus-6 are often found in patients with non-A to non-E acute hepatic failure.

### **TOTAL PARENTERAL NUTRITION (TPN)**

TPN may cause steatosis or cholestasis, and liver disease is more severe in infants than in adults. Elevated serum aminotransferase concentrations are common during the first 1-3 wk of TPN, and bilirubin increases in some adults after 10 wk or more of TPN<sup>[82-84]</sup>. Chronic cholestasis has been observed in 55% of patients receiving TPN for at least 2 years<sup>[85]</sup>, and cholestasis can lead to acalculous and calculous cholecystitis or TPN-induced cholelithiasis<sup>[86]</sup>.

### **ENDOCRINE DISEASES**

#### ***Thyroid disease***

Patients with hyperthyroidism frequently experience liver injury, which may be caused by increased hepatocyte oxygen demand without an associated increase in hepatic blood flow. Liver injury can be either cholestatic or hepatocellular. Up to 64% of these patients show elevated serum ALP, and up to 35% show elevated ALT. Interestingly, only 17% of these patients show elevated GGT<sup>[17]</sup>, and most of the increased ALP is bone-derived<sup>[87]</sup>.

In contrast to hyperthyroidism, liver biochemistry abnormalities are less prominent in patients with hypothyroidism. However, modest elevations in serum AST and ALT have been reported in 84% and 60%, respectively, of patients with hypothyroidism<sup>[88]</sup>. Some patients may show low serum ALP<sup>[87]</sup>, but their most characteristic symptom is ascites, which is caused by unknown mechanisms<sup>[87]</sup>. In addition, cholestatic jaundice has been described in case reports of patients with severe hypothyroidism<sup>[17]</sup>.

#### ***Cushing syndrome***

Hypercortisolism causes fatty infiltration of the liver in half of the patients, which may progress to NASH. The prevalence of NASH in these patients has been estimated to be 20% to 50%<sup>[89]</sup>.

#### ***Adrenal insufficiency***

Elevated serum aminotransferase concentrations have been reported in patients with adrenal insufficiency; these abnormalities usually resolve with appropriate hormone replacement<sup>[90,91]</sup>.

#### ***Diabetes mellitus***

Elevated liver chemistries have been observed in 10%-20% of patients with DM<sup>[92,93]</sup>, more frequently in patients with type 2 than type 1 DM<sup>[94]</sup>. One study reported that 16.5%, 9%, 11% and 6% of these patients had elevations in serum GGT, ALP, ALT and AST, respectively. Non-alcoholic fatty liver disease is a complication in 32% to 78% of patients with type 2

DM, and 50% of these patients may have non-alcoholic steatohepatitis (NASH)<sup>[95,96]</sup>. NASH in DM patients may lead to liver cirrhosis and eventually to hepatocellular carcinoma<sup>[94,97]</sup>.

## POSTOPERATIVE JAUNDICE

Jaundice often occurs after surgery, especially after cardiac surgery; of the latter, approximately 26.5% show conjugated hyperbilirubinemia<sup>[98]</sup>. Factors thought to contribute to the development of jaundice after surgery include: (1) Liver congestion due to preexisting right-sided heart failure; (2) Degree of perioperative hypotension and hypoxia; (3) Destruction of transfused erythrocytes; (4) Hemolysis secondary to mechanical prostheses; (5) Type of operation-The incidence of postoperative jaundice is dependent on the type of operation. For example, patients who underwent mitral valve replacement or multiple valve surgery had a higher rate of jaundice than those who underwent coronary bypass graft surgery; (6) Perioperative infection; (7) Resorption of hematoma; (8) Worsening of jaundice in Gilbert's syndrome-Gilbert's syndrome is the most common form of inherited hyperbilirubinemia, with 5% to 10% of Caucasians and Japanese estimated to have this syndrome. Although serum bilirubin levels are usually below 3 mg/dL, with the unconjugated form being dominant, jaundice may be worsened by a stress caused by surgery or infection; (9) Total parenteral nutrition; (10) Drug-induced liver injury, and (11) Benign postoperative intrahepatic cholestasis.

Postoperative jaundice usually occurs within 1-2 wk after major surgery. Serum concentrations of mainly conjugated bilirubin may increase to 40 mg/dL, but these resolve within a few days to weeks without specific treatment<sup>[99]</sup>.

## GASTROINTESTINAL DISEASES

Abnormal liver function test results are observed in over 50% of patients with inflammatory bowel diseases requiring surgery. The hepatobiliary diseases accompanying ulcerative colitis and Crohn's disease are shown in Table 4<sup>[100]</sup>.

Patients who undergo jejunoileal resection for the treatment of severe obesity may experience liver damage<sup>[101]</sup>. The liver often shows NASH, leading to liver cirrhosis and liver failure. Similar liver injuries have been observed in patients undergoing gastrectomy via Billroth-II reconstruction. Bacterial overgrowth in the blind-loop of the intestine can induce endotoxin and intrinsic ethanol<sup>[102,103]</sup>, leading to Kupffer cell activation and hepatocyte damage.

## GRANULOMA FORMATION IN THE LIVER

Several systemic diseases and drugs have been shown to induce granulomas in the liver, causing liver enlargement. The most consistently abnormal liver biochemistry result is elevated serum ALP. The diagnosis and causes of hepatic granulomas may be determined by

**Table 4 Hepatobiliary disorders associated with inflammatory bowel disease<sup>[100]</sup>**

Hepatobiliary disorders	Ulcerative colitis	Crohn's disease
Primary sclerosing cholangitis (PSC)	+	+
Large duct PSC	+	+
Small duct PSC (pericholangitis)	+	+
Cirrhosis	+	+
Hepatocellular carcinoma	+	+
Cholangiocarcinoma	+	+
Miscellaneous disorders		
Fatty liver	+	+
Granulomas		+
Amyloidosis		+
Hepatic abscess		+
Gallstones		+
Autoimmune hepatitis	+	

a histological examination of the liver. Five etiological categories have been identified<sup>[104]</sup>: (1) Immunological: Sarcoidosis, primary biliary cirrhosis, giant cell hepatitis, Wegener's granulomatosis, chronic granulomatous disease and allergic granulomatosis; (2) Infectious: Hepatitis C virus, cytomegalovirus, Epstein-Barr virus, tuberculosis, *Mycobacterium avium-intracellulare* in patients with HIV infection, leprosy, brucellosis, typhoid fever, Whipple's disease, tularaemia, yersiniosis, cat-scratch disease, histoplasmosis, blastomycosis, coccidiomycosis, candidiasis, Q fever, leishmaniasis, toxoplasmosis, syphilis, and schistosomiasis; (3) Medications: Penicillins, diphenylhydantoin and allopurinol; (4) Neoplastic: Hodgkin's disease and hypernephroma, and (5) Foreign body: Beryllium, suture material used in operation and thorotrast.

## AMYLOIDOSIS

Hepatic involvement has been demonstrated in about one-fifth of patients with AA amyloidosis and about half of those with the AL type, and liver function tests can remain normal even in patients with substantial amyloid deposits and hepatomegaly. Elevated serum ALP and GGT occur first in patients with massive amyloid deposits, followed by modest elevations of serum AST and ALT<sup>[105]</sup>.

## CONCLUSION

Abnormal liver function often occurs in patients without hepatitis virus infection and without excessive alcohol intake. Although US, CT or MR imaging should be used to assess the occurrence of fatty liver disease, hepatobiliary malignancies or infection and gallstones, diagnosis of autoimmune liver disease, especially with atypical presentation, is sometimes difficult. Moreover, intake of drugs including herbal medicines or supplemental nutrients may cause liver injury. However, abnormal liver function tests do not necessarily indicate serious liver disease. Asymptomatic patients with isolated, mild elevation of unconjugated bilirubin (e.g. Gilbert's syndrome) or GGT generally do not have liver disease and do not require further examination<sup>[106]</sup>. In

contrast, the liver may be involved in systemic diseases that mainly affect other organs. Therefore, in patients without etiology of liver injury by screening serology and diagnostic imaging, but who have systemic diseases, the abnormal liver function test results might be caused by the systemic disease. In most of these patients, the systemic disease should be treated primarily. However, some patients with systemic disease and severe liver injury or fulminant hepatic failure require intensive treatments of the liver.

### INTRODUCTION

Both hepatitis C infection and non-alcoholic fatty liver disease (NAFLD) are major causes of liver related morbidity and mortality. Hepatitis C virus (HCV) is a major cause of chronic liver disease with about 170 million people infected worldwide. The severity of disease varies widely from asymptomatic chronic infection to cirrhosis and hepatocellular carcinoma (HCC)<sup>[1]</sup>.

NAFLD represents a spectrum of liver diseases characterized mainly by macrovesicular steatosis that occurs in the absence of alcoholic consumption. The hepatic histology varies from isolated hepatic steatosis alone “first hit” to fatty liver accompanied by hepatocellular damage plus inflammation known as steatohepatitis “second hit” which is followed by the development of fibrosis.

Adipose tissue is now recognized as not simply a storage depot for excess energy, but rather an active endocrine organ that secretes a number of molecules termed, adipocytokines. A number of these adipocytokines have been linked to alterations in insulin sensitivity, including adiponectin, leptin, resistin, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )<sup>[2,3]</sup>.

Insulin resistance (IR) is a major pathogenic feature leading to hepatic fat accumulation. In the meantime, hepatitis C infection promotes IR. Two types of IR are found in chronic hepatitis C patients: “viral” and “metabolic” IR. IR in chronic hepatitis C is relevant because it promotes steatosis and fibrosis<sup>[4]</sup>. Metabolic IR is thought to be triggered by hepatic FFA accumulation that may exacerbate overall IR<sup>[5]</sup>.

### METABOLIC SYNDROME

Metabolic Syndrome (X-syndrome) is a cluster of disorders including central obesity, IR with or without type 2 DM, dyslipidemia and hypertension. Recent findings linking the components of the metabolic syndrome with NAFLD and the progression to non-alcoholic steatohepatitis (NASH), fibrosis and cirrhosis will be reviewed. Metabolic syndrome was first described in 1988 by Reaven GM<sup>[6]</sup>. Whether hepatic IR causes cellular injury and inflammation in the liver or is

### Abstract

Steatosis is a common feature of many liver diseases, namely non-alcoholic steatohepatitis (NASH) and hepatitis C virus (HCV) infection, but the pathogenic mechanisms differ. Insulin resistance (IR), a key feature of metabolic syndrome, is crucial for NASH development, associated with many underlying genetically determined or acquired mitochondrial and metabolic defects and culminates to inflammation and progression to fibrosis. This may have potential implications for new drug therapy. In HCV-related disease, steatosis impacts both fibrosis progression and response to treatment. Steatosis in HCV-related disease relates to both viral factors (HCV genotype 3), and host factors (alcohol consumption, overweight, hyperlipidemia, diabetes). Among others, IR is a recognized factor. Hepatic steatosis is reported to be associated with disturbance in the signaling cascade of interferon and downregulation of its receptors. Thus, hepatic steatosis should not be considered a benign feature, but rather a silent killer.

the result of both inflammation and steatosis is still unrevealed<sup>[7]</sup>. Hepatic steatosis is caused by imbalance between the delivery of fat in the liver and its subsequent secretion or metabolism. In other words, fat accumulates when the delivery of fatty acids to the liver, either from the circulation or by de novo synthesis within the liver, exceeds that capacity of the liver to metabolize the fat by  $\beta$ -oxidation or secrete it as very low-density lipoproteins (VLDL). Derangements in any of these pathways alone or in combination causes fat to accumulate in the liver.

#### **Delivery of fatty acids from peripheral stores to the liver**

Triglycerides (TAG) are stored in adipose tissue and released as FFAs into the circulation through the actions of lipoprotein lipase. FFAs released from peripheral stores are hydrophobic and are strongly bound to circulating albumin. FFAs are transported by albumin to the liver where they can then be used as a substitute for  $\beta$ -oxidation, stored as TAG, or exported as VLDL.

Excess glucose is converted to the liver, the backbone of most amino acids, can be converted to pyruvate and then to acetyl-coenzyme A (acetyl-CoA), which feeds directly into cytosolic fatty acid synthesis.

Processes that can lead to excessive FFAs delivery or impaired  $\beta$ -oxidation or secretion can lead to hepatic steatosis, increased mitochondrial reactive oxygen species (ROS) and lipid peroxidation products<sup>[8,9]</sup>.

#### **Fate of fatty acids in the liver**

In the fasting state, adipocyte TAG is hydrolyzed to release FFAs, which are transported to the liver where they can serve as substrates for mitochondrial  $\beta$ -oxidation.  $\beta$ -oxidation of fatty acids is a major source of energy needed to maintain liver viability during fasting. It is also the source of the ketone bodies, acetoacetate and acetone. These are released into the blood and are essential fuel sources for peripheral tissues, when glucose is in short supply. Defects in hepatic  $\beta$ -oxidation cause microvesicular steatosis of the liver, increase in oxidative stress due to extramitochondrial oxidative stress. ROS and peroxidation products lead to cytotoxic events, release of proinflammatory cytokines and activation of hepatic stellate cells and fibrosis<sup>[8,9]</sup>.

#### **Formation and secretion of VLDL**

In the fed state,  $\beta$ -oxidation of fatty acids is not required as an energy source, and fatty acids delivered to the liver are mainly converted to TAG. Insulin regulates the metabolic path that fatty acids take in the liver. Without insulin, creatinine palmitoyl transferase-I (CPTI) commits fatty acids to mitochondrial  $\beta$ -oxidation; when insulin levels are high, glycerol-3-phosphate acetyltransferase commits fatty acids to the formation of TAG. This bulk of acetyl CoA entering the citric acid cycle, results in delivery of electrons to the respiratory chain, where they generate ROS.

## **DEVELOPMENT OF STEATOHEPATITIS**

Steatosis *per se* does not always lead to hepatocellular injury

suggesting that a two-step model involving additional secondary insults is required for the inflammatory component of steatohepatitis “second hit”<sup>[10]</sup>.

Factors that lead to progressive liver injury are multifactorial and may include increased lipid peroxidation, FA toxicity, mitochondrial impairment, cytokine mediated hepatotoxicity, and oxidative injury. Hyperinsulinemia in the insulin-resistant state leads to increased FA oxidation promoting the development of ROS and oxidative injury<sup>[11-13]</sup>. Although there are no reliable human data supporting a causal role of oxidative injury in human NASH, animal data have suggested a potential role for oxidative injury<sup>[14-16]</sup>.

Excess fat in the liver predisposes to hepatocellular injury. This may be caused by direct cellular cytotoxicity of excess FFAs, oxidative stress, lipid peroxidation or other mechanisms. In the meantime, IR may contribute to hepatic fat accumulation and plays a key role in the development of steatohepatitis and disease progression<sup>[4]</sup>. Furthermore, TNF- $\alpha$  secreted by the macrophages of the adipose tissue which directly impairs insulin signaling and is crucial for the passage of steatosis to steatohepatitis<sup>[17]</sup> through induction of several proinflammatory cytokines. In addition, FFAs may lead to hepatocyte apoptosis which is one mechanism of cell injury in NAFLD<sup>[5]</sup>.

Hepatocellular injury may cause inflammatory response with subsequent cytokine induction, mitochondrial dysfunction and progressive fibrosis in a subset of patients<sup>[10]</sup>.

In animal models, development of steatohepatitis depends on additional factors, such as endotoxin exposure, acute liver injury (for example, ischemia-reperfusion), alcohol, excess dietary polyunsaturated fatty acids, or aging. A unifying hypothesis envisages that all causes capable of changing the redox equilibrium of the hepatocyte may result in liver inflammation and fibrogenesis activation. ROS may promote hepatic stellate cell activation and collagen fiber deposition<sup>[18]</sup>. Lipid peroxidation products may elicit activation of nuclear factors that lead to procollagen type I overexpression<sup>[19]</sup>.

Some investigators have used a taxonomic distinction of secondary NASH, or that attributable to readily identifiable drugs, toxins, or genetic abnormalities, and primary NASH, which is probably related to IR<sup>[20]</sup>.

## **FIBROSIS PROGRESSION IN NASH**

Progression of fibrosis in NASH has been histologically demonstrated in 32%-37% of the patients<sup>[21,22]</sup>. Estimated rates of cirrhosis development over 10 years of 5%-20% have been reported by 3 independent studies<sup>[23-25]</sup>. NASH patients with advanced fibrosis are at risk of developing liver complications<sup>[25]</sup>. Obesity, diabetes, IR and the initial severity of the fibrosis are the factors most conspicuously associated with fibrotic progression<sup>[23-25]</sup>.

The mechanisms by which IR promotes fibrosis progression include: steatosis, hyperleptinemia, increased

TNF production, impaired expression of PPAR- $\gamma$  receptors<sup>[4]</sup>. Hepatic injury in NASH induces oxidative stress, ROS and peroxidation products which lead to cytotoxic events, release of proinflammatory cytokines that activate hepatic stellate cells and deposition of collagen<sup>[8,9]</sup>.

HCC has been detected in several NASH patients, most often at the time of diagnosis, and rarely, during follow up<sup>[23,26,27]</sup>. In the larger Olmsted County Community Study<sup>[26]</sup>, 2 of 420 NAFLD patients developed HCC during a 7-year follow-up period. The estimated rate of liver-related deaths over 10 years was 12% for NASH patients<sup>[24,25]</sup>.

## ROLE OF HYPERTENSION

Hypertension is one of the main components of metabolic syndrome. The renin-angiotensin system (RAS) plays a role in progression of chronic liver disease to fibrosis, and HCC and this action is mediated *via* several mechanisms such as direct effect on activated HSCs and neovascularization<sup>[28]</sup>.

RAS is frequently activated in patients with chronic liver disease. In animal models, evidence has shown that angiotensin 2 receptor antagonist and angiotensin-converting enzyme (ACE) inhibitors display antifibrotic characteristics *via* the hepatic stellate cell proliferation<sup>[29]</sup>. In a pilot study examining the therapeutic efficacy of angiotensin 2 receptor antagonist, losartan was studied in patients with NASH and hypertension. Seven patients were treated with losartan (50 mg/d) for 48 wk. After 48 wk, patients not only showed a significant decrease in blood markers of hepatic fibrosis, but also an improvement in serum aminotransferase levels<sup>[30]</sup>. However, recent evidence that angiotensin 2 receptor antagonists and ACE inhibitors are antifibrotic in animal models of hepatic fibrosis suggests that these agents are worth examining in clinical trials<sup>[29]</sup>. Hypertension should be sought and treated appropriately in patients with NAFLD, particularly those with type 2 DM in whom tight blood pressure control (< 140/80 mmHg) with an ACE inhibitor or a  $\beta$ -blocker significantly reduces the risk of cardiovascular morbidity, sudden death, stroke and peripheral vascular disease<sup>[31,32]</sup>.

## BIOLOGICAL ROLE OF INSULIN

Insulin, after binding its receptor, induces the phosphorylation of receptor substrates in the liver and muscles, and triggers several steps toward the transactivation of glucose transporter-4 (GLUT-4). This increases glucose uptake by cells and its storage as glycogen, and inhibits the net production of glucose by the liver, thus blocking glycogenolysis and neoglycogenesis. Moreover, insulin promotes lipid storage by inhibiting lipolysis. When insulin is unable to induce glucose uptake, pancreatic  $\beta$ -cells increase insulin production and the hyperinsulinemic state prevents hyperglycemia. Thus, IR depends on insulin secretion and insulin sensitivity.

## IR

IR is defined as a condition in which higher-than-normal insulin concentrations are needed to achieve normal metabolic responses or, alternatively, normal insulin concentrations are unable to achieve normal metabolic responses<sup>[33]</sup>.

Hyperinsulinemia appears as a consequence of the inability of insulin to induce its effect on glucose metabolism, and hence, an abnormally large amount of insulin is secreted to achieve a biological response with consequent several abnormalities in target organs such as the liver, endothelium, and kidneys, and this represents the main feature in the metabolic syndrome<sup>[4]</sup>.

IR is measured by many ways. The most accurate is euglycemic-hyperinsulinemic clamp method whereas the less accurate, but widely applied, is Homeostasis Model Assessment (HOMA). Mean HOMA index increases with the stage of fibrosis and could help to differentiate stages of fibrosis<sup>[34]</sup>.

### **Pathogenesis of IR**

Pathogenesis of IR is not fully understood. IR is thought to be the key pathogenic feature leading to hepatic fat accumulation. It causes an increase in FFA influx into the liver that drives hepatic triglyceride production. Increased serum insulin and glucose levels also promote *de novo* lipogenesis by upregulating lipogenic transcription factors. NAFLD may in turn result in hepatic IR, which is thought to be triggered by hepatic FFA accumulation and their metabolites that may exacerbate overall IR<sup>[5]</sup>.

TNF- $\alpha$  is liberated by macrophage of adipose tissues of obese persons and worsens IR. Typically patients with NASH have also low serum adiponectin which is considered a potent insulin enhancer<sup>[17]</sup>.

### **IR in hepatitis C**

HCV directly associates with IR independent of the visceral fat area in non-obese and non-diabetic patients<sup>[35]</sup>. The mechanisms by which hepatitis C induces increased IR and the risk for development of diabetes has not been completely understood. Liver fibrosis progression has been considered, for a long time, responsible for the appearance of IR and type 2 diabetes in patients with chronic liver diseases<sup>[4]</sup>.

Recent data support a connection between HCV replication and IR, and HOMA decreased when the virus was eradicated. Besides, the incidence of diabetes type 2 is different in cured patients than in non-responders, supporting a better control of IR after HCV clearance<sup>[36]</sup>. Therefore, hepatitis C promotes IR and IR induces interferon resistance, steatosis and fibrosis progression in a genotype-dependent manner<sup>[4]</sup>.

Extensive evidence supports a central role of TNF- $\alpha$  and other proinflammatory cytokines in the development of obesity-associated IR and fatty liver<sup>[37]</sup>.

HCV infection promotes IR, mainly by increased TNF- $\alpha$  production together with enhancement of suppressor of cytokine (SOC)-3; both events block PI3K and Akt phosphorylation. Two types of IR can

be found in chronic hepatitis C patients: "viral" and "metabolic" IR<sup>[4]</sup>.

Both HCV and TNF- $\alpha$  downregulate IRS-1, 2 phosphorylation *via* upregulation of SOCS-3, which degrades the insulin receptor. Furthermore, HCV core protein *per se*, or its inflammatory cytokine (TNF- $\alpha$ ), interfere with normal insulin signaling which impairs translocation of GLUT-4 transporters to plasma membrane limiting glucose uptake and increases blood glucose/insulin level leading to IR. In the mean time, TNF- $\alpha$  impairs expression of PPAR- $\gamma$  receptor which in turn, decreases insulin sensitivity<sup>[4]</sup>.

## STEATOSIS IN CHRONIC HEPATITIS C

In chronic hepatitis C patients, the prevalence of steatosis ranges from 40% to 86% (mean, 55%)<sup>[38,39]</sup>. The majority of patients with steatosis (78%) have mild steatosis affecting less than 30% of hepatocytes. Thus, steatosis occurs more frequently in patients with chronic hepatitis C (55%) than in the general population (20%-30%) of adults in the Western world<sup>[40]</sup>. Macrovesicular steatosis is found in the periportal region of the liver-different from the centrilobular distribution characteristic of NASH patients. Mild steatosis had been reported in nearly 40% of patients with HCV genotype 4<sup>[41]</sup>.

Moderate or severe steatosis is significantly less frequent in genotype 4 than 3 chronic hepatitis C patients and similar between genotype 4 and 1. In non-diabetic, overweight patients, moderate or severe steatosis is present in only 10%-15% of genotype 4 or 1 compared with 40% of genotype 3 patients. Thus, hepatic steatosis in genotype 4 is mostly associated with metabolic factors, similar to those in genotype 1<sup>[41,42]</sup>.

It has been shown that HCV genotype 3 is associated with higher quasispecies heterogeneity than genotype 1<sup>[43]</sup>. Serum levels of apolipoprotein B and cholesterol are reduced in patients in whom steatosis responds to antiviral therapy<sup>[44]</sup>. Hypocholesterolemia in patients with chronic hepatitis C (especially genotype 3) has been reported by others<sup>[45,46]</sup>. Instead, after antiviral treatment, virus-related steatosis disappears whereas host associated steatosis remains unaffected<sup>[11]</sup>. Thus the disappearance of steatosis correlates with normalization of apolipoprotein B and cholesterol levels.

### Pathogenesis of steatosis in chronic hepatitis C

IR emerges as a very important host factor, mainly because it has been related to steatosis development, fibrosis progression and non-response to peg-interferon plus ribavirin. HCV directly associates with IR independent of the visceral fat area in non-obese and non-diabetic patients. HCV is directly associated with IR in a dose-dependent manner, independent of the visceral adipose tissue area<sup>[35]</sup>.

Factors associated with steatosis in chronic hepatitis C are: (1) viral factor (HCV genotype 3); (2) host factors (alcohol consumption, overweight, hyperlipidemia, diabetes, insulin resistance), and (3) drug therapy

(corticosteroids, amiodarone, methotrexate, *etc*)<sup>[11]</sup>. The mechanisms underlying the development of parenchymal steatosis in HCV infection are not exactly known<sup>[47]</sup>.

The first mechanism supposes that HCV core protein may block assembly of Apo-A<sub>1</sub>-A<sub>2</sub> with TAG. This will result in decreased export of TAG bound to apolipoprotein- $\beta$  (Apo- $\beta$ ) as VLDL out of hepatocyte, which is corrected by antiviral therapy<sup>[11]</sup>. Others propose that the core protein induces oxidative stress within the mitochondria that contributes to lipid accumulation<sup>[48]</sup>. Though the exact mechanism remains elusive, it seems that HCV itself can directly induce steatosis in genotype 3<sup>[49]</sup> by the cytopathic effect of high titer of intracytoplasmic negative strand HCV RNA<sup>[39]</sup>.

The second proposed mechanism recognizes IR as the major mechanism in the pathogenesis of hepatic steatosis<sup>[49-53]</sup>. It has been reported that IR plays a central role in NAFLD. However, the mechanisms of development of IR in patients with chronic HCV infection are not well understood<sup>[54,55]</sup>. IR causes impaired metabolic clearance of glucose, compensatory hyperinsulinemia, and increased lipolysis. The latter leads to increased plasma FFAs; increased hepatic uptake of FFAs by the liver which results in steatosis<sup>[9]</sup>. Furthermore, it has been suggested that IR may result from excess FFAs, TNF- $\alpha$  and suppressor of cytokine signaling (SOCS) which could downregulate insulin receptor substrate (IRS)-1 signaling<sup>[20]</sup>. This will result in the impaired translocation of GLUT-4 transporters to the plasma membrane which limits glucose uptake; increases blood glucose and cause a compensatory increase in insulin<sup>[56-58]</sup>. Recently, Pazienza *et al* reported that both genotype 3a and 1b downregulates IRS-1 through genotype-specific mechanisms<sup>[59]</sup>. Furthermore, Fartoux L *et al* reported that IR depends mainly on the age of the patient<sup>[34]</sup>. It has been suggested that age associated decline in mitochondrial function could contribute to IR<sup>[34,60]</sup>.

The main deleterious effect of IR in chronic hepatitis C is the ability to promote fibrosis progression. High serum glucose levels have been found associated with an increased rate of fibrosis progression, even greater than overweight<sup>[61]</sup>.

### Steatosis and fibrosis progression in HCV

High levels of TNF- $\alpha$  have also been observed in human chronic hepatitis C patients<sup>[40]</sup>. TNF- $\alpha$  has been shown to induce IR in experimental animals and cultured cells<sup>[62,63]</sup>. Inhibition of tyrosine phosphorylation of IRS 1 and 2 may be one of the mechanisms by which a high level of TNF- $\alpha$  causes IR<sup>[63-65]</sup>. Administration of an anti-TNF- $\alpha$  antibody restores insulin sensitivity<sup>[66]</sup>. These results provide direct experimental evidence for the contribution of HCV in the development of IR. There are experimental arguments for a direct role of insulin in fibrosis progression in HCV infection<sup>[11]</sup>.

Epidemiological studies indicating that the state of IR now associated with NASH is also associated with an increased risk of HCC. It is worth mentioning that diabetes increases the risk of chronic liver disease and HCC<sup>[67]</sup>.

## RESPONSE TO INTERFERON THERAPY IN HCV INFECTION

The current treatment for patients with chronic hepatitis C is the addition of ribavirin to interferon-based therapies for 24 to 48 wk. Unfortunately, a sustained virological response (SVR) is achieved in only 42%-52% of treatment-naïve patients, and the rest either show no response or experience a relapse when therapy is stopped<sup>[68]</sup>.

The mechanisms underlying the failure of interferon therapy are not well understood, but evidence indicates that in addition to viral factors, several host factors are also involved<sup>[69]</sup>. Among host factors, IR has been found to impair virological response to combined therapy in chronic hepatitis C patients<sup>[70]</sup>.

Hyperinsulinemia interferes with IFN signaling cascade<sup>[71]</sup> through upregulation of SOCS and activation of phosphatidylinositol-3-kinase (PI3K) that inhibit phosphorylation of STAT1.

In addition to IR, HCV core protein and TNF- $\alpha$  cytokine, derived primarily from macrophages of adipose tissue, upregulate SOCS-3 which binds to Janus Kinase inhibiting phosphorylation of STAT1, eventually interfering with interferon signaling<sup>[4]</sup>. SOCS-3 also causes degradation of IRS-1, in turn leading further to interference with insulin signaling and hyperinsulinemia that interferes eventually with interferon signaling<sup>[71]</sup>.

Recent data support a connection between HCV replication and IR and HOMA decreased when the virus was eradicated<sup>[4]</sup>. HCV directly associates with IR independent of the visceral fat area in non-obese and non-diabetic patients<sup>[35]</sup>.

In addition to IR, obesity and hepatic steatosis have been recognized as independent risk factors for a poor response to IFN- $\alpha$  therapy<sup>[72,73]</sup>. In obese individuals, subcutaneous fat could cause a reduction in the initial absorption and bioavailability of interferon given subcutaneously<sup>[72]</sup>. In the meantime, obesity and hepatic steatosis impair immune responses to HCV and increase fibrosis progression in obese patients<sup>[73]</sup>.

Furthermore, hyperleptinemia in obese is an independent risk factor for non-response to antiviral therapy<sup>[74]</sup>. Hyperferritinemia downregulates the response to interferon therapy<sup>[75,76]</sup>.

From this review, we have noted that steatosis, either metabolic or cytopathic, contributes to the development of NASH and progression to fibrosis, cirrhosis and HCC. Accordingly, we can conclude with confidence that hepatic steatosis is not a benign disease, but rather a silent killer.

### Abstract

The Crohn's disease activity index (CDAI) has been commonly used to assess the effects of treatment with different agents in Crohn's disease (CD). However, these studies may be compromised, if the results compared to a placebo or standard therapy group (in the absence of a placebo) substantially differ from the expected response. In addition, significant concerns have been raised regarding the reliability and validity of the CDAI. Reproducibility of the CDAI may be limited as significant inter-observer error has been recorded, even if measurements are done by experienced clinicians with expertise in the diagnosis and treatment of CD. Finally, many CDAI endpoints are open to subjective interpretation and have the potential for manipulation. This is worrisome as there is the potential for significant financial gain, if the results of a clinical trial appear to provide a positive result. Physicians caring for patients should be concerned about the positive results in clinical trials that are sponsored by industry, even if the trials involve respected centers and the results appear in highly ranked medical journals.

### INTRODUCTION

The Crohn's disease activity index (CDAI) is a numerical calculation derived from the sum of products from a list of 8 items (Table 1), and multiplied by weighting factors for each item to define the severity of "disease activity" in patients with Crohn's disease (CD)<sup>[1]</sup>. Essentially, the CDAI represents a numerical estimation of a physician's interpretation of patient symptoms. Initially, the CDAI was correlated with a physician's overall global assessment for a group of 112 patients with CD after a total of 186 patient visits done in 13 different hospitals in the United States<sup>[1]</sup>. This instrument was first applied in the National Cooperative Crohn's Disease Study (NCCDS), published in 1979, and used to quantitatively compare the results in a placebo group to groups treated with the following drugs: sulphasalazine, prednisone and azathioprine.

Index values of 150 and below were associated with quiescent or non-active disease (i.e. "remission"). Values over 150 were indicative of active disease, and over 450, extremely severe disease. Of particular note, in patients randomized to placebo in the NCCDS, 32% achieved a spontaneous remission at the end of 17 wk, and 53% of these were still in remission at the end of 24 mo<sup>[2]</sup>. The results of drug treatment using the CDAI in active disease showed that the response to prednisone or sulfasalazine was significantly better than placebo, while the response to azathioprine was better than placebo, but did not reach statistical significance<sup>[3]</sup>. Patients with colonic involvement were especially responsive to sulfasalazine, and those with small bowel involvement were especially responsive to prednisone<sup>[3]</sup>. Since these studies were reported, other publications<sup>[4-7]</sup> have appeared employing the CDAI as well as other indices<sup>[8-12]</sup> to assess disease activity in the evaluation of

**Table 1 CDAI items and weighting factors**

<b>Item (daily sum per week)</b>	<b>Weighting factor</b>
Number of liquid or very soft stools	2
Abdominal pain score in one week (rating, 0-3)	5
General well-being (rating, 1-4)	7
Sum of physical findings per week:	20
Arthritis/arthralgia	
Mucocutaneous lesions (e.g. erythema nodosum, aphthous ulcers)	
Iritis/uveitis	
Anal disease (fissure, fistula, etc)	
External fistula (enterocutaneous, vesicle, vaginal, etc)	
Fever over 37.8°C	
Antidiarrheal use (e.g. diphenoxylate)	30
Abdominal mass (no = 0, equivocal = 2, yes = 5)	10
47 minus hematocrit (males) or 42 minus hematocrit (females)	6
1-x (1-body weight divided by a standard weight)	1

therapeutic effectiveness of different pharmacological and biological agents<sup>[13]</sup>.

## PLACEBO RESPONSE

Knowledge of the expected response to a placebo may be useful, but may not always be available. The NCCDS compared each of the treatment groups to a placebo group. Therapy with a new agent may now require comparison to the standard treatment, instead of a placebo. In part, at least, this relates to the ethical need to ensure that all participants in a clinical trial have access to proven therapy. Placebo alone may be difficult to justify, especially if patients are significantly symptomatic. And, if a new treatment shows a statistically positive result, it could reflect a limited effect of standard treatment (or the placebo). As in day-to-day clinical practice, the standard treatment may not always perform as well (or as badly) in each clinical trial. To best appreciate the results of a clinical trial involving a new agent, the expected response to placebo and treatment groups, as in the NCCDS, may be both important and informative.

## OBSERVER DIFFERENCES

Although the CDAI appeared to correlate with the global clinical assessment in a limited number of CD patients, it was appreciated that the same observer or different observers might derive different results at different times. Thus, efforts were made by the CDAI investigators and later groups to evaluate the reliability and validity of the CDAI. In the initial report of its development<sup>[14]</sup>, the consistency of the CDAI was examined in 2 successive visits for 32 patients. A positive association with the physician global assessment (with some overlap) was noted with a total of 50 index points being the apparent difference between slight clinical improvement (or worsening) and no actual change in symptoms for 2 successive visits. Subsequent studies also suggested that the reliability of the CDAI is within a defined moderate to good range, but not in a defined

very good to excellent range<sup>[15,16]</sup>. Later efforts to recalculate the CDAI by these investigators showed no significant difference from the original estimation, so no further changes in the CDAI were recommended<sup>[16]</sup>.

The CDAI appeared to be relatively reliable if used by these observers well experienced in its application. However, significant inter-observer differences were later noted in a series of separate studies, published as a single paper<sup>[17]</sup>. In one study, the CDAI was calculated from 10 "paper cases" evaluated by 5 consultants in surgery or gastroenterology, and 2 research assistants. Major discrepancies in calculated CDAI values were noted for each of the 7 different cases ranging from 166 to 430 points! In a second study, 15 members of the IOIBD prospectively evaluated a single case. The range of estimated values was 320 to 391, or 71 points. Improvement in observer differences, however, could be achieved with terminology discussion prior to calculation. A final study assessed the ability of 6 experienced gastroenterologists to independently elicit patient data, rather than being provided by the information from the "paper case" format. Wide variations in the estimated CDAI were seen ranging (in 1 case) up to 500 points! "Good agreement" was believed to have been achieved even in the best 2 patients, the difference was over 50 points. In spite of these critical concerns, the CDAI is used today in most clinical trials to evaluate different agent effects on symptom activity in CD.

## OTHER CDAI ISSUES

There are other recognized difficulties with the CDAI *per se*. First, as noted elsewhere<sup>[18]</sup>, a significant component of the total CDAI score is derived from highly subjective items, such as "general well being" and "intensity of abdominal pain". Many symptoms overlap with those that might be ascribed to some other functional causes. To overcome this issue, it has been logically recommended that these patients should be randomly distributed to each of the treatment groups<sup>[18]</sup>. But, in practice, this may be difficult to accomplish and may not be done. Second, the CDAI is computed using a diary card that must be developed by the patient for 7 d prior to submission. In practice, this may be difficult for some patients to prospectively do well without close monitoring which may not be feasible. Some clinical study coordinators apparently assist patients in retrospective completion of 7-d diaries on the study visit<sup>[18]</sup> and this could clearly impact results. As noted<sup>[18]</sup>, there are no data on the prevalence of this practice in clinical trial centers and it is not generally mentioned in the Methods section of the published reports. Third, some symptoms may be difficult to interpret or quantitate easily. For example, "liquid" stools may be difficult to precisely define<sup>[17]</sup>. Finally, even though enterocutaneous fistulae may be very troublesome for the patient, their impact on the CDAI may be limited. "General well being" may be severely impacted by perianal disease, but the patient may be fully functional. As a result, other indices have been developed to directly evaluate this component<sup>[19]</sup>. Even here, however, the endpoint measured may be criticized. For example, an

open fistula may be differentiated from a closed fistula based on expression of purulent material from the tract following application of “gentle pressure”. Data on intra-observer and inter-observer agreement for such endpoints in clinical trials are not available. Moreover, full disappearance of fistula tracts is rarely documented.

## IMPACT OF INDUSTRY

Another significant issue is the impact of the pharmaceutical industry in the conduct of clinical trials. This issue has been addressed in detail elsewhere<sup>[20]</sup>. In 1979, the NCCDS was reported to be largely supported through peer-review national research grant agencies for all patient study costs while the pharmaceutical industry was simply acknowledged for their donation of the study medications. Of course, it is not known if there were other financial benefits provided by industry then since requirements for reporting of industry support were minimal. Now, virtually all clinical trials are conducted almost entirely through industry support, either from private or shareholder-owned public companies. Many clinical trials are largely authored by a select group of “experts”, often, but not always, affiliated with university centers. Some authors are fully employed by the sponsoring industry and have the responsibility of collecting and monitoring all data collected, evaluating results and even drafting the manuscript. Some, but not all, journals require that all investigators declare income received from industry in the form of honoraria and other forms of financial support, although the precise amounts are never disclosed. Others may actually be owners or shareholders of the company concerned. This declaration is meant to alert the reader that the investigator may have a conflict of interest, not increase investigator credibility. If the journal did not require the declaration, it would not be provided. The problem, however, is even deeper. While hospitals involved in provision of research facilities may not be directly involved in conduct of the clinical trial, a “fee” is usually attached to the clinical trial costs for use of facilities, and so, indirectly, the institution (and its reputation possibly earned over many decades) is also being “purchased” by industry. Many teaching institutions, limited in resources, often consider industry funding as a positive asset for faculty members in the promotion process. In everyday clinical practice, it may be difficult to wade through all of these issues. The CDAI provides a simple numerical means to statistically evaluate treatment response, but this measurement has the potential to be manipulated as a positive spin will surely impact the share price in a positive direction.

## TOP-DOWN AND BOTTOM-UP CDAI TRIALS

A recent clinical trial compared infliximab to “conventional therapy” for CD<sup>[21]</sup>. An industry marketing label for these respective approaches has already appeared in the literature: “top-down” and “bottom-up”. In this study, both investigators and patients were aware of the drugs

being used for treatment. The study reported a positive result in favor of infliximab and azathioprine. The potential conflict of interest for a positive study result was clearly evident for all concerned in this open label study. Patients can actively influence the results of open label clinical trials, especially if an ordinarily expensive treatment is offered at no cost. Many of the authors noted financial support from a number of companies, including those with a vested commercial interest in the direct global marketing of infliximab. Even the editorialist<sup>[22]</sup> listed support from the same companies, certainly not an independent view of the data.

This open label study illustrated more about the modern conduct of clinical trials, their potential for conflict of interest and the credibility of the investigators associated with the results of this trial. Clinicians will need to be more suspicious of the results of clinical trials for CD, especially if based partly, or solely, on the CDAI, an index whose reliability and validity may be quite limited. Moreover, as the CDAI was used originally to assess the effectiveness of therapeutic agents having been used by physicians for decades, the present use of the CDAI seems to have evolved from its original intent. Now, potent biologicals (rather than pharmaceuticals) are being explored in clinical trials to determine if CDAI numbers, reflecting clinical symptoms, can be altered sufficiently to produce a statistically relevant result. Interestingly, even in an early report with infliximab in CD, a statistically positive result was observed with a specific dose of the agent, but in the same study, a dose-response could not be defined with higher doses<sup>[13]</sup>. This lack of dose-response with this biological agent was not explained. However, in retrospect, the study design clearly provided an advantage to infliximab treatment. There were three different infliximab groups that could be compared to only one placebo group. A statistically significant result for any one of these infliximab groups compared to the placebo would have been considered positive in favor of the new agent. Also, it was reported that 33% of the infliximab-treated patients had a CDAI-defined remission compared to only 4% for placebo. While statistically different, the remission rate for the infliximab-treated group was remarkably similar to the earlier reported placebo rate in the NCCDS. It is not known if these results reflected, to some degree, the inherent limitations of the CDAI to estimate patient symptoms, even in a blinded clinical trial, and permit comparisons with earlier studies.

Where will this approach related to the “chemotherapy of the CDAI” take us? No one really knows. However, the impact of an investigator bearing therapeutic “gifts” for the patient in a clinical trial, while, at the same time, personally receiving “gifts” from industry should raise concerns among physicians that are responsible for patient care.

## NEED FOR LONG-TERM STUDIES ON NATURAL HISTORY OF CD

A final paragraph might be added to raise a separate issue.

It is probably not sufficient to simply raise criticism and concern regarding the CDAI. Others have explored the use of other indices, some perhaps simpler to apply in a clinical setting. For example, the Harvey-Bradshaw Index<sup>[23]</sup> evaluates symptoms and signs during the preceding 24 h, rather than the previous 7 d, reduces the original 8 items in the CDAI to 5 (i.e. excluding antidiarrheal use, hematocrit and body weight), and eliminates the weighting factor. Its use appears to correlate well with the CDAI<sup>[23,24]</sup>. Another, the Cape Town Index (or South African Index) was developed as another alternative to avoid the “single parameter” bias inherent in the Harvey-Bradshaw Index<sup>[25]</sup>. Another index, the Van Hees Index<sup>[26]</sup> was developed in an attempt to avoid subjective clinical criteria by employing a physician global assessment variable. Most important, each of these different indices really attempts to measure only a very limited temporal window in the clinical course of CD. A longer term view of CD is required<sup>[27,28]</sup> so that objective measurement of the effects of different therapeutic efforts can be seen to positively or negatively alter the natural history of this chronic inflammatory process.

### Abstract

Cholangiocarcinomas arise from the epithelial cells of the bile ducts and are associated with poor prognosis. Despite new diagnostic approaches, the definite diagnosis of this malignancy continues to be challenging. Cholangiocarcinomas often grow longitudinally along the bile duct rather than in a radial direction. Thus, large tumor masses are frequently absent and imaging techniques, including ultrasound, CT, and MRI have only limited sensitivity. Tissue collection during endoscopic (ERCP) and/or percutaneous transhepatic (PTC) procedures are usually used to confirm a definitive diagnosis of cholangiocarcinoma. However, forceps biopsy and brush cytology provide positive results for malignancy in about only 50% of patients. Percutaneous and peroral cholangioscopy using fiber-optic techniques were therefore developed for direct visualization of the biliary tree, yielding additional information about endoscopic appearance and tumor extension, as well as a guided biopsy acquisition. Finally, endoscopic ultrasonography (EUS) complements endoscopic and percutaneous approaches and may provide a tissue diagnosis of tumors in the biliary region through fine-needle aspiration. In the future, new techniques allowing for early detection, including molecular markers, should be developed to improve the diagnostic sensitivity in this increasing tumor entity.

### INTRODUCTION

Cholangiocarcinomas are topographically categorized as intrahepatic or extrahepatic carcinomas. Extrahepatic cholangiocarcinomas are further subdivided into hilar, middle and distal carcinomas. The most common type of hilar cholangiocarcinoma is classified into 4 stages according to the bismuth classification<sup>[1]</sup>. Surgery is the only curative treatment in patients with cholangiocarcinoma. The results are more favourable for patients with early-stage disease. Therefore, a reliable diagnostic procedure is of great importance for these patients. However, confirmation of cholangiocarcinoma can be very difficult because of a wide spectrum of alternative diagnoses, including other carcinomas, metastasis and benign biliary strictures. Therefore, multidisciplinary investigative approaches are needed to overcome this problem. Cholangiocarcinomas often grow longitudinally along the bile duct rather than in a radial direction away from the bile duct. Consequently, imaging techniques including ultrasound, CT, and MRI are of limited sensitivity for the detection of cholangiocarcinoma<sup>[2]</sup>. Biliary tissue collection during endoscopic procedures is widely used for distinction between benign and malignant strictures and provides the only definitive diagnosis that can be used for establishing therapeutic strategies. To obtain tissue samples, brush cytology and/or forceps biopsy were routinely performed in patients with suspected malignant biliary strictures.

### BIOCHEMICAL INVESTIGATIONS

Obstructive jaundice is typically associated with an increase of serum bilirubin, alkaline phosphatase and gamma-

glutamyl transpeptidase. These laboratory parameters are unspecific and do not allow a distinction between benign and malignant bile duct strictures. The most widely studied tumor markers are carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA). Both tumor markers may be elevated in cholangiocarcinoma<sup>[3-5]</sup>. However, CA19-9 and CEA are not specific for cholangiocarcinoma. CA19-9 is also raised in pancreatic cancer, colorectal cancer, gastric cancer, and gynaecological malignancies<sup>[6]</sup>. Additionally, CA19-9 may be elevated in patients with acute cholangitis<sup>[7]</sup>. In a series of patients without primary sclerosing cholangitis, the sensitivity of a serum CA19-9 level of more than 100 U/mL in diagnosing cholangiocarcinoma was 53%<sup>[3]</sup>. Furthermore, the authors reported in patients with unresectable cholangiocarcinoma a significantly greater mean CA19-9 concentration compared to patients with resectable cholangiocarcinoma. Recently, John *et al*<sup>[8]</sup> reported that sensitivity and specificity were 67.5% and 86.8%, respectively, when using a cut-off value of 100 U/mL. In another report that included 37 patients with primary sclerosing cholangitis, a serum CA19-9 concentration above 100 U/mL sensitivity was 89% and specificity was 86% for the diagnosis of cholangiocarcinoma<sup>[4]</sup>. CEA also has unsatisfactory diagnostic sensitivity and specificity for cholangiocarcinoma<sup>[9]</sup>. In conclusion, the diagnostic value of tumor markers in cholangiocarcinoma is limited. However, CA19-9 is useful in following the effect of treatment and to detect disease recurrence.

## IMAGING

### Ultrasonography

Patients suffering from jaundice usually undergo transabdominal ultrasonography to evaluate the bile duct diameter and hepatic parenchyma. Furthermore, gallstones can be excluded. In most patients cholangiocarcinomas are not directly detectable, but indirect signs are visible in the majority of patients. Distal lesions cause dilation of both intrahepatic and extrahepatic bile ducts, whereas proximal lesions only cause dilation of intrahepatic bile ducts. The localization of the bile duct lesion can be suggested if there is an abrupt change in ductal diameter. The diagnostic accuracy of ultrasonography was investigated in 429 patients with obstructive jaundice. In this series ultrasonography demonstrated ductal obstruction in 89%, and the sensitivity for localizing the site of obstruction was 94%<sup>[10]</sup>. The sensitivity and specificity of ultrasonography depends on tumor localization, the quality of the equipment and the experience of the investigator<sup>[11]</sup>. Ultrasound findings are limited in patients with liver cirrhosis and primary sclerosing cholangitis due to a lack of visible dilated bile ducts. Doppler ultrasonography provides information on hepatic and portal vessel patency. Recent studies reported that contrast enhanced ultrasonography provides sensitive and specific criteria for the differentiation between malignant and benign liver lesions<sup>[12-15]</sup>. Preliminary

data for cholangiocarcinoma suggest a behavior that is not dissimilar to metastatic lesions<sup>[14,16]</sup>. However, the limited number of cases in the reported series does not allow conclusive considerations for cholangiocarcinoma. Therefore, further studies with appropriate numbers of patients are needed.

### Computed tomography

Computed tomography (CT) is a commonly used approach for the detection and staging of cholangiocarcinoma. The radiological findings depend on localization and morphology of the tumor. CT scan permits identification of bile duct dilatation as well as assessment of lymph node, liver parenchyma, vascular encasement and metastasis<sup>[17]</sup>. Additionally, computed tomography is useful for detecting the presence of liver atrophy. Dilatation of bile ducts combined with atrophy suggests the obstruction of the portal vein<sup>[18]</sup>. However, conventional computed tomography is limited in the ability to estimate the extent of cholangiocarcinoma and resectability. Tillich *et al*<sup>[17]</sup> reported a series of 29 patients with hilar cholangiocarcinoma who underwent multiphasic helical CT, including arterial and portal venous phase. In these patients resectability was correctly predicted in only 60%. In another series, Yamashita *et al*<sup>[19]</sup> reported only 59% sensitivity in identifying a primary lesion by using contrast-enhanced computed tomography. Recently, the accuracy of preoperative high-resolution computed tomography to determine resectability in patients with hilar cholangiocarcinoma was evaluated<sup>[20]</sup>. In this series negative and positive predictive values of high-resolution computed tomography to determine resectability were 92% and 85%, respectively. Thus, only new CT scanning techniques should be taken into account since radiological procedures have had a considerable improvement in the last years.

### Magnetic resonance imaging and magnetic resonance cholangiopancreatography

In recent years, magnetic resonance imaging (MRI), especially in combination with magnetic resonance cholangiopancreatography (MRCP) has improved diagnosing cholangiocarcinoma and determining resectability<sup>[21-23]</sup>. Magnetic resonance imaging can assess the local tumor extension, lymph nodes, metastasis and liver parenchyma. It is important to use sequences with thin-slice thickness (3-4 mm) that provide sufficient signal to obtain good quality images and are sufficiently thin to detect subtle abnormalities. At present, good quality MRI in the hands of experienced centers, can be an excellent imaging approach for the diagnosis and staging of cholangiocarcinoma<sup>[24]</sup>. Moreover, magnetic resonance angiography (MRA) provides good assessment for infiltration of blood vessels. Magnetic resonance cholangiography can provide a three-dimensional reconstruction of the biliary tree without injection of intravenous and biliary contrast fluid. Therefore, the risk for cholangitis is reduced<sup>[21]</sup>, and additionally there is no

risk for contrast induced nephropathy. MRCP allows the assessment of bile ducts above and below a total obstruction. Therefore, MRCP should be considered for planning the treatment of patients suffering from cholangiocarcinoma. Zidi *et al*<sup>[25]</sup> reported a correct malignant hilar tumor stage using MRCP in 78% of the investigated patients. Furthermore, in this series an underestimated tumor extension was reported in 22%<sup>[25]</sup>. Biliary stent placement and percutaneous drainage results in mild inflammation of bile duct walls, which appears as an increased gadolinium enhancement with an appearance indistinguishable from the superficial spread of cholangiocarcinoma. To avoid this problem MRI and MRCP should be performed before endoscopic stenting and percutaneous transhepatic drainage<sup>[23]</sup>.

### **Positron emission tomography (PET)**

Several studies reported intensive accumulation of nucleotide tracer 18-fluorodeoxyglucose (FDG) in cholangiocarcinoma<sup>[26-28]</sup>. PET scanning with focal FDG accumulation permits visualization of cholangiocarcinomas. PET scan can detect cholangiocarcinomas as small as 1 cm<sup>[29,30]</sup>. FDG-PET is of value for staging of bile duct cancers, especially for discovering distant metastasis and malignant lymph nodes. In one series, PET led to a change of therapeutic management in 30% of patients suffering from cholangiocarcinoma because of detection of primary unsuspected metastases<sup>[26]</sup>. The limitation of FDG-PET is false positive results in patients with biliary tract infections, primary sclerosing cholangitis, and biliary stenting via endoscopic retrograde cholangiography (ERC) and PTBD<sup>[26,31]</sup>. The diagnostic sensitivity can be increased by using 18-fluorodeoxyglucose (FDG) in combination with CT scanning (FDG-PET/CT). Reinhardt *et al*<sup>[28]</sup> evaluated the effectiveness of this new dual-modality technique for noninvasive differentiation of extrahepatic bile duct strictures. This series included 14 patients with histological proven cholangiocarcinoma and 8 patients with benign bile duct strictures. In this series, all patients with cholangiocarcinoma presented with focal increased tracer uptake compared to patients with benign bile duct stricture. Overall, our experience is that <sup>18</sup>F-FDG PET/CT does not provide high accuracy for noninvasive detection of perihilar cholangiocarcinoma in extrahepatic bile duct strictures, which may be mainly due to the small size of the tumors.

## **ENDOSCOPIC APPROACHES**

### **Endoscopic retrograde cholangiography**

Retrograde injection of contrast fluid into the biliary tract allows the assessment of localization and morphology of bile duct strictures. Malignancy is suggested when there are findings of asymmetric, irregular strictures. Moreover, resectability can be evaluated. However, the differentiation in benign and malignant bile duct stricture may be difficult. Park *et al*<sup>[32]</sup> identified 20 out of 27 malignant bile duct strictures using ERC alone. In this series diagnostic

sensitivity and specificity for endoscopic retrograde cholangiography was 74% and 70%, respectively. Other authors have reported similar results for detecting malignant bile duct strictures by direct cholangiography<sup>[33]</sup>. Compared to non-invasive imaging techniques, endoscopic retrograde cholangiography allows tissue collection for cytological and histological investigation. Additionally, ERC allows biliary stent implantation for palliative treatment in irresectable tumors.

### **Percutaneous transhepatic cholangiography (PTC)**

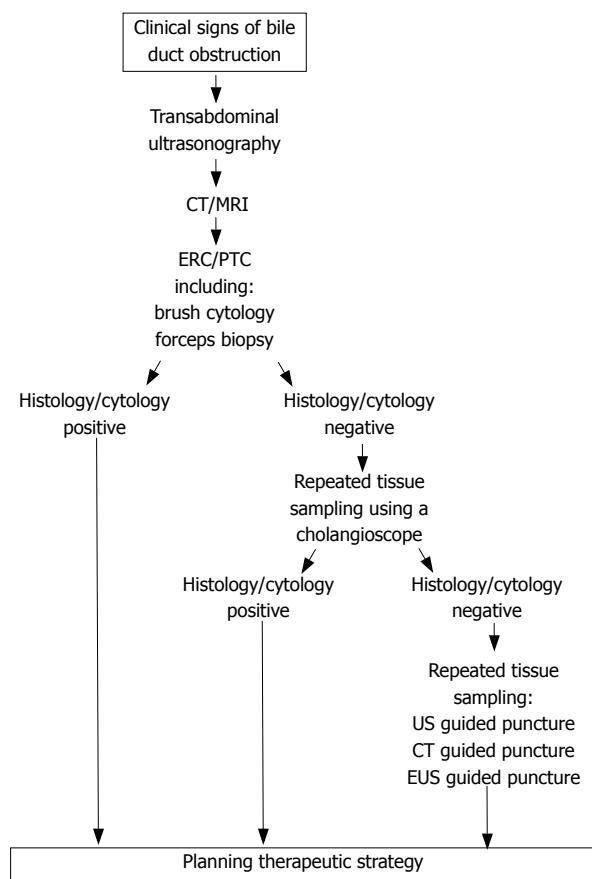

In patients with difficult bile duct access percutaneous transhepatic approaches offer a valuable alternative for bile duct access. The effectiveness of this procedure in diagnostic and therapy of complex biliary obstruction has been well documented<sup>[34,35]</sup>. Because percutaneous transhepatic bile duct access is an invasive technique, potential complications including bleeding, cholangitis, biliary leakage, duodenal perforation and death can occur. In previous series, procedure related death ranging from 0.6% to 5.6% was reported<sup>[36-39]</sup>. Therefore, endoscopic retrograde cholangiography is usually favoured above percutaneous transhepatic cholangiography. Percutaneous transhepatic approaches also allow tissue collection and biliary drainage.

### **Cholangioscopy**

Cholangioscopy using fiber-optic techniques provide direct visualization of the biliary tree. Differentiation between benign and malignant bile duct stricture using a cholangioscope has not been well defined. However, typical signs for malignancy including mucosal ulcerations, irregular mucosa and asymmetric stricture may be visible. Moreover, cholangioscopic guided forceps biopsy and brush cytology may enhance the diagnostic accuracy of tissue diagnosis. The most common approach is percutaneous transhepatic cholangioscopy. Another possibility is to perform peroral transpapillary cholangioscopy using a mother baby endoscope. Fukuda *et al*<sup>[40]</sup> evaluated the utility of peroral cholangioscopy for distinguishing malignant from benign biliary disease. The authors identified 22 out of 38 malignant bile duct strictures using ERC in combination with tissue sampling. The addition of peroral cholangioscopy correctly identified all 38 malignant strictures in this series.

### **Intraductal ultrasonography**

Intraductal ultrasonography (IDUS) is a promising imaging modality for the evaluation of a variety of biliary disorders<sup>[41,42]</sup>. Intraductal ultrasonography does not provide definite diagnoses. However, the characterization of biliary structures provided by IDUS can be used in combination with other diagnostic approaches to develop appropriate therapeutic strategies. Intraductal ultrasonography can provide the local staging to select patients with cholangiocarcinoma who benefit from surgical resection<sup>[43-46]</sup>. Recently, Stavropoulos *et al*<sup>[47]</sup> reported that intraductal ultrasonography increased the

**Figure 1** The diagnostic algorithm in patients with suspected extrahepatic bile duct obstruction.

accuracy of ERCP in distinguishing between benign and malignant strictures from 58% to 90%. This high rate of diagnostic accuracy using intraductal ultrasonography has been confirmed by others<sup>[48,49]</sup>.

#### EUS guided fine-needle aspiration

Endoscopic ultrasonography (EUS) complements the role of endoscopic and percutaneous transhepatic approaches and may provide a tissue diagnosis through fine-needle aspiration (FNA). The yield of EUS-FNA in patients with suspected cholangiocarcinoma was evaluated by Eloubeidi *et al*<sup>[50]</sup>. The authors reported a diagnostic sensitivity of 86%. However, another group reported lower rates of diagnostic sensitivity (45%) for detection of bile duct lesions by using ultrasound guided fine needle aspiration<sup>[51]</sup>. EUS-FNA may represent an alternative approach in the diagnosis of cholangiocarcinoma, especially in patients with negative brush cytology and forceps biopsy findings. One of the major limitations of endoscopic brush cytology from bile duct strictures is the poor quality of cytologic samples. Therefore, negative cytological results do not permit reliable exclusion of malignancy.

#### Brush cytology and forceps biopsy

Tissue collection during endoscopic and/or percutaneous transhepatic procedures are the most common techniques for providing a definitive diagnosis of

cholangiocarcinoma<sup>[52]</sup>. Brush cytology, first described in 1975, is the most common tissue sampling technique in patients with suspected bile duct strictures<sup>[53]</sup>. It is generally safe, requires little time, and is technically easier compared to forceps biopsy. The sensitivity of brush cytology for diagnosis of malignant biliary strictures ranges from 30% to 60% in most published series<sup>[54-56]</sup>. Tissue samples for histological investigation can be obtained from biliary strictures by using forceps. This technique is more time consuming than brushing and is less widely used, but it provides a sample of subepithelial stroma. In patients with malignant biliary stricture the overall cancer detection rate of forceps biopsy is often higher than for brush cytology, ranging from 43% to 81%<sup>[57-59]</sup>. In these published series, the sensitivity of brush cytology and forceps biopsy was evaluated in a heterogeneous patient group with several malignant bile duct strictures. Recently, the diagnostic sensitivity of transpapillary brush cytology and forceps biopsy was evaluated in patients with hilar cholangiocarcinomas<sup>[60]</sup>. In this series, the sensitivity of transpapillary brush cytology was 41.4% and the sensitivity of forceps biopsy was 53.4%. In combined approaches the diagnostic sensitivity increased to only 60.3%.

#### Fluorescence in situ hybridization (FISH)

Recently, investigators have attempted to improve diagnostic assessment with an advanced cytological technique for the detection of malignant pancreaticobiliary strictures<sup>[61]</sup>. Fluorescence *in situ* hybridization (FISH) has been shown to increase the sensitivity for the diagnosis of malignant pancreaticobiliary strictures compared to conventional cytology. Kipp *et al*<sup>[62]</sup> used a multitarget FISH probe set which has previously shown high impact in monitoring recurrent urothelial carcinoma<sup>[63]</sup>. This advanced technique identifies malignant cells by detecting aneusomy and deletion of the locus 9p21. By applying this technique for brush cytology and bile aspirate specimens in 131 patients with bile duct strictures (including 71 with primary sclerosing cholangitis, FISH analysis showed sensitivity of 35% and specificity of 91%. When patients with primary sclerosing cholangitis were excluded, sensitivity for malignancy detection by FISH was 16%<sup>[64]</sup>. This indicates that probe sets specific for biliary neoplasms will be required for higher sensitivity. However, not all malignant tumors present aneusomy or aneuploidy. In the biliary tract, the percentage of cancers displaying aneuploidy has been estimated to be approximately 80%<sup>[65]</sup>.

#### CONCLUSION

Figure 1 demonstrates the diagnostic algorithm used in our hospital for patients with suspected extrahepatic bile duct obstruction. Cholangiocarcinomas are still difficult to diagnose. In the future we need better early detection methods including molecular markers and improved histological techniques. Furthermore, new imaging and endoscopic techniques should be

developed to improve the diagnostic accuracy and tumor extension.

### Abstract

Capsule endoscopy has been shown to detect small bowel inflammatory changes better than any other imaging modality. Selection criteria have been optimized to increase the yield of capsule endoscopy in patients suspected to have Crohn's disease. Capsule endoscopy allows for earlier diagnosis of Crohn's disease of the small bowel and improved diagnosis of colitis in patients where it is unclear if they suffer from Crohn's or ulcerative colitis. A test capsule is available to assess for small bowel strictures and thus avoid capsule retention. A common language has been developed and a new scoring index will be added to capsule software. It is envisioned that the manner in which we treat Crohn's disease in the future will change, based on earlier diagnosis and treatment aimed at mucosal healing rather than symptom improvement.

### INTRODUCTION

Capsule endoscopy (CE) was initially marketed in 2001 and in short time, this procedure gained a reputation for providing state-of-the-art imaging of the small intestine. It is recommended as the third test used in the investigation of obscure gastrointestinal bleeding after colonoscopy and upper endoscopy<sup>[1]</sup>. Capsule endoscopy has also been shown to be of use in patients with suspected Crohn's disease. Many papers have been published on the utility of capsule endoscopy for the diagnosis of Crohn's disease in cases of both suspected and known illness<sup>[2-5]</sup>. In a pooled data analysis, CE had a miss rate for ulcers of 0.5%<sup>[6]</sup>. A meta-analysis of eleven studies including 223 patients, comparing CE to other imaging modalities of the small bowel for inflammatory bowel disease established that CE has an incremental diagnostic yield of 25%-40% over other modalities such as barium studies and CT scanning (Table 1)<sup>[7]</sup>. This ability to visualize ulcers and other subtle inflammatory lesions led to the use of this technology to study the adverse effects of non-steroidal anti-inflammatory drugs (NSAID) on the small intestine<sup>[8]</sup>. The International Conference on Capsule Endoscopy (ICCE) consensus statement concluded that capsule endoscopy identifies small-bowel mucosal lesions not seen with other imaging modalities and may therefore play an important diagnostic role in the evaluation and monitoring of patients with known or suspected Crohn's disease<sup>[9]</sup>. Secondly, they concluded that capsule endoscopy may have a unique role in assessing mucosal healing after medical therapy, for assessing early postoperative recurrence and in guiding therapy, and finally the consensus statement concluded that capsule endoscopy may identify sub-clinical markers in asymptomatic family members and contribute to the understanding of the natural history inflammatory bowel disease (IBD).

### SUSPECTED CROHN'S DISEASE

With capsule endoscopy able to identify mucosal changes before other technologies, it is often used in patients with suspected Crohn's disease. This is a group that previously had not been formally defined. Suspicion of Crohn's disease was previously left to the discretion of the treating physician and usually was considered when a

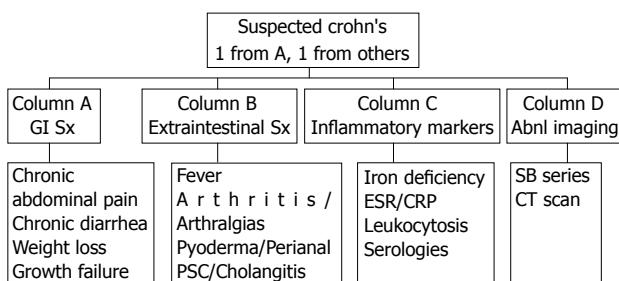

**Table 1** The incremental yield of capsule endoscopy over other testing (Treister *et al*<sup>[7]</sup>)

	Total yield CE (%)	Total yield other modality (%)	% IY for CE (95% CI)
Small bowel series	66	24	42 (0.30-0.54)
Ileoscopy	61	46	15 (0.02-0.27)
CT enterography	75	37	38 (0.23-0.54)
Push enteroscopy	51	7	44 (0.31-0.57)
Small bowel MRI	60	40	20 (0.41-0.81)

patient had either abdominal pain or persistent diarrhea. Yields of capsule endoscopy are low when performed in patients with abdominal pain alone<sup>[10]</sup> and in patients with abdominal pain and diarrhea alone<sup>[11]</sup>. When other criteria are added this yield increases. The addition of a sign or symptom of inflammation increases the yield of capsule endoscopy. In the CEDAP-Plus study of 50 patients with suspected Crohn's disease, signs of inflammation included elevated erythrocyte sedimentation rate, elevated C-reactive protein, thrombocytosis and leukocytosis and one of these markers increased the yield of capsule endoscopy with an odds ratio of 3.2<sup>[12]</sup>. The landmark paper by Fireman enrolled patients with abdominal pain, diarrhea, anemia, and weight loss. These patients had had symptoms for an average of 6.3 years and all had normal colonoscopies, upper endoscopies and small bowel series. Crohn's disease was diagnosed in 12 of the 17 by capsule endoscopy. It is clear that selective criteria were needed. The first consensus statement of the ICCE addressed the proper selection of patients and the group of suspected Crohn's disease was defined<sup>[9]</sup>. More recently, the ICCE convened in part to expand their definition of patients who should be considered as being suspect for Crohn's disease<sup>[13]</sup>. An algorithm was formulated (Figure 1). Patients should be considered for capsule endoscopy to diagnose or exclude the diagnosis of Crohn's disease if they had symptoms plus either extraintestinal manifestations, inflammatory markers or abnormal imaging studies.

## INDETERMINATE COLITIS

Another emerging use of capsule endoscopy in the field of inflammatory bowel disease is in patients with indeterminate colitis. Colonoscopic and pathologic criteria cannot differentiate Crohn's from ulcerative colitis in 10%-15% of colitic cases<sup>[14]</sup>. Proper identification of the disease state is important especially when choosing a surgical intervention. A few studies have examined the potential role of CE to rule out small bowel lesions suggestive of Crohn's disease in the setting of indeterminate colitis. Mow reported finding small bowel lesions in 40% of indeterminate cases<sup>[4]</sup>. Manoury reported 30 patients with indeterminate colitis and negative serologies in whom CE identified 5 cases with Crohn's<sup>[15]</sup>. This problem is especially difficult in children where the diagnosis cannot be assured in up to 30% of cases<sup>[16]</sup>. Use of capsule endoscopy in children has increased. Studies show that swallowing is possible in almost all cases, and in small children, the capsule is placed endoscopically<sup>[17]</sup>.

**Figure 1** Criteria for suspected Crohn's disease (Mergener *et al*<sup>[13]</sup>).

## RETENTION

Despite the ability to identify ulcers where no other technology could, there have been limitations to the application of this new technology. Fear of retention is one. Having a capsule retained in the small bowel remains a major concern for physicians performing capsule endoscopy since it could possibly lead to surgery in a patient who may otherwise have been treated medically for the same illness. This has been felt to be true especially for patients with Crohn's disease or NSAID enteropathy. The ICCE consensus statement on capsule retention reported a 1.5% risk of retention when capsule endoscopy is performed in the setting of suspected Crohn's disease<sup>[18]</sup>. Cheifetz reported retention in 13% of exams performed in the setting of previously known Crohn's disease<sup>[19]</sup>.

The ICCE consensus statement defined capsule retention as having a capsule endoscope remain in the digestive tract for a minimum of two weeks<sup>[18]</sup>. Retention was also defined as the capsule permanently remaining in the bowel lumen unless extracted by endoscopic or surgical methods or if passed as a result of medical therapy. There is no data on the success of medical therapies for retention such as initiating a course of steroids or infliximab, stopping NSAIDs, or using prokinetics or cathartics to aid in passage of the capsule. There is no time limit to institute management for capsule removal and capsules have stayed in patients asymptotically for over 3 years.

It is up to the physician and patient together to decide the best management for capsule retention. The choice of surgical, endoscopic, or medical management once capsule retention has been diagnosed depends on the cause of the retention, the indication for the exam in the first place, and the extent of previous treatment. If retention occurs behind a tumor or mass, surgical intervention is typically pursued quickly. If retention occurs behind a Crohn's stricture and the patient has had pronounced bleeding, again surgical intervention may prove the most efficacious method of not only removing the capsule but also dealing with the cause of hemorrhage. This is equally true for retention in a patient with known Crohn's disease and recurrent symptoms but without documented disease by any other method and failure to respond to medical therapy prior to the capsule exam. Those with known Crohn's disease who have already maximized their treatment with biologics and steroids for ongoing

**Table 2 Parameters and weightings for the capsule endoscopy scoring index (Gralnek *et al*<sup>[26]</sup>)**

	<b>Parameters</b>	<b>Number</b>	<b>Longitudinal extent</b>	<b>Descriptors</b>
First tertile	Villous appearance	Normal: 0	Short segment: 8	Single: 1
		Edematous: 1	Long segment: 12	Patchy: 14
	Ulcer	None: 0	Whole tertile: 20	Diffuse: 17
		Single: 3	Short segment: 5	< 1/4: 9

		Single: 14	Non-Ulcerated: 2	Not traversed: 10
		Multiple: 20		

symptoms are not likely to improve without surgical intervention. Finally, for the patient in whom bleeding is not pronounced or in whom prior disease was only suspected but not treated, capsule retention behind a NSAID or Crohn's stricture can be managed with double balloon enteroscopy<sup>[20]</sup>. This technique allows for capsule retrieval and then the patient can be treated medically for their underlying illness.

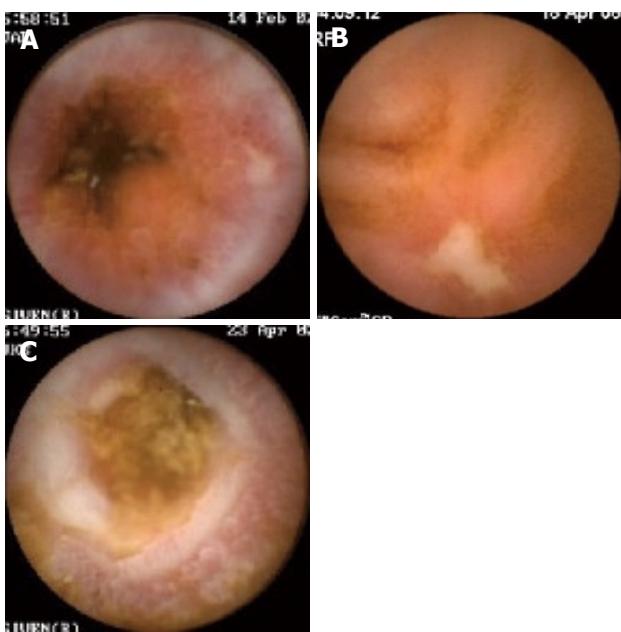

In an effort to avoid such situations, a dissolving test capsule called a patency capsule has been developed<sup>[21]</sup>. This capsule is the same size as a video capsule. It is constructed of cellophane with wax plugs at either end and it contains lactose mixed with 10% barium to make it radio-opaque. The wax plugs have holes that allow sucus entericus to dissolve the lactose and thus collapse the capsule into its various parts. A 2 mm × 10 mm radiotag inside the capsule allows the patient to be scanned externally to see if it is present in the body. Typically the patency capsule is swallowed by the patient and he or she is scanned 30 h after ingestion. At 30 h the capsule begins to dissolve. Thirty-eight percent of patency capsules are dissolved by 35 h and all are dissolved by 36-72 h.

## CAPSULE SCORING INDEX

The other major limitation to the adoption of this technology has been the lack of standardization when describing small bowel inflammatory lesions, in terms of their extent and severity. Specifically, no one language for findings has been developed, and no severity scale of mucosal disease activity or even a threshold for disease diagnosis has been agreed upon. There are many clinical scoring indices for Crohn's disease including the Crohn's

disease activity index (CDAI), the Harvey-Bradshaw and van Hees indices among others<sup>[22]</sup>. Since prior to CE, there has been no good direct measure of mucosal disease activity in the small intestine, these indices are based on clinical symptoms and some laboratory parameters. There is high interobserver variability in these scores due to their subjective nature<sup>[23]</sup>. Capsule endoscopy has provided the ability to detect mucosal inflammatory change of the small intestine often missed by other techniques. Interpretation and comparison of previous reports on the yield of CE have been limited due to the lack of a standardized and validated scoring index. The landmark papers by Fireman and Eliakim describing the yield of CE in suspected Crohn's disease did not outline the findings necessary to make the diagnosis<sup>[2,24]</sup>. Goldstein, who compared the effect of naproxen *versus* celecoxib on the small intestine, counted the number of mucosal breaks to measure adverse drug effects<sup>[8]</sup>. Mow used the cut off of three ulcers of any size to establish a diagnosis of Crohn's disease<sup>[4]</sup>. Fidder defined a positive capsule study for Crohn's disease as four or more ulcers, erosions, or a region with clear exudate and mucosal hyperemia and edema<sup>[25]</sup>. The meta-analysis of CE in the setting of Crohn's disease recognized this lack of a uniform method of categorizing findings at capsule endoscopy<sup>[7]</sup>.

A scoring index has been developed to assess mucosal inflammatory disease in the small bowel detected by CE and this will be included in the next version of capsule endoscopy software (Table 2)<sup>[26]</sup>. This scoring index is based on three capsule endoscopic variables: villous appearance, ulceration and stenosis (Figure 2). In addition, each variable is assessed by other parameters including size and extent of the change. The changes in villous appearance and

**Figure 2** Examples of endoscopic findings of Crohn's disease at capsule endoscopy. **A:** Edema; **B:** Ulceration; **C:** Strictures.

ulceration are assessed by tertiles, dividing the small bowel transit time into three equal time allotments. The stenosis evaluation is done for one entire study. The endoscopic variables have been specifically defined. Villous appearance is defined as edema where villous width is equal or greater than villous height. Villous appearance is based on mucosa distinct and separated from an ulcer rather than contiguous to a mucosal break. Ulcerations are defined as mucosal breaks with white or yellow bases surrounded by red or pink collars. Ulcer size is based on the entire lesion including its surrounding collar and is measured according to the percentage of the capsule image occupied by the ulcerated lesion. Ulcer size is based on the largest ulcer seen in each tertile. The number of lesions was defined as single, few (2-7 lesions) or multiple (8 or more lesions). The index was created in four separate steps. First, as outlined above, the characteristics of inflammatory change in the small bowel were identified. The terminology used accepted structured language developed for capsule endoscopy<sup>[27]</sup>. Second, blinded readers graded the presence or absence of each parameter on de-identified videos prospectively and also graded a perceived global assessment of overall severity of the findings. Third, the individual parameters and their descriptors were ranked in order of severity. In the fourth step, values for each parameter were created using the descent gradient method, a mathematic method to optimize numbers assigned to a rank order of variables. The premise was to assure that a final numerical score reflected the global assessment and that the global assessment agreed with the ranking of finding severity.

The score provides a common language to quantify mucosal changes associated with any inflammatory process. The index does not diagnose or measure a disease; it measures mucosal change. In addition, this scoring index does not have the discriminatory ability to differentiate these illnesses. At the same time however,

the index could be used for a number of different purposes including differentiating normal small bowel from disease states. This scoring index may be able to help establish the diagnosis of small bowel Crohn's disease when combined with other clinical signs/symptoms including patient history, clinical presentation and laboratory values. The index could also be potentially used to measure and document mucosal healing in response to therapy. The CE scoring index can provide one more point of evaluation along with other patient-level data to assist in determining appropriate patient management. Finally, the score could be a standardized method of communication both for treating physicians and for research purposes when assessing therapies and outcomes of patient's with small bowel Crohn's disease.

## THE FUTURE OF CAPSULE ENDOSCOPY IN IBD

Capsule endoscopy has the opportunity to propel a coming paradigm shift in the treatment of Crohn's disease. It is clear that capsule endoscopy identifies the earliest inflammatory changes in the small bowel. At the same time, the average time from the onset of a patient's symptoms until diagnosis historically lags an average of 35 mo<sup>[28]</sup>. Thus capsule endoscopy has the opportunity to diagnose Crohn's disease earlier than ever before. What remains unclear is if early diagnosis provides patient benefit. Does earlier diagnosis and thus earlier intervention change the natural history of the disease? This is not known, though studies in children with fistulous disease had greater response to therapy the earlier they were diagnosed<sup>[29]</sup>. Thus it is theorized that early diagnosis will bring earlier treatment and thus improved outcomes. Another paradigm shift in the making is the method of assessing disease activity. Previously, physicians have used patient symptoms to guide treatment. Unfortunately placebo response rates by symptoms average 18% (0%-50%)<sup>[30]</sup>. Remission has been defined as symptom improvement typically using the CDAI. But remission does not correlate with mucosal healing. In Rutgeerts' trial of 75 patients treated with infliximab, 67% of healed patients were in symptom remission, while 56% of remission patients did not heal<sup>[31]</sup>. Prior to capsule endoscopy there was no reliable method to determine the extent or severity of the disease in the small bowel though colonic evaluation has been available. It has been proposed that in the future, patient management decisions may be based on measures of mucosal healing rather than symptom response<sup>[32]</sup>. A variety of tools are available to assess overall disease activity including fecal and serum biomarkers, endoscopy, radiology, and capsule endoscopy.

In summary, capsule endoscopy has been shown to detect small bowel inflammatory changes better than any other imaging modality. A common language has been developed. It is envisioned that the manner in which we treat Crohn's disease in the future will change, based on earlier diagnosis and treatment aimed at mucosal healing rather than symptom improvement.

## Abstract

We outline probable and possible developments with wireless capsule endoscopy. It seems likely that capsule endoscopy will become increasingly effective in diagnostic gastrointestinal endoscopy. This will be attractive to patients especially for cancer or varices detection because capsule endoscopy is painless and is likely to have a higher take up rate compared to conventional colonoscopy and gastroscopy. Double imager capsules with increased frame rates have been used to image the esophagus for Barrett's and esophageal varices. The image quality is not bad but needs to be improved if it is to become a realistic substitute for flexible upper and lower gastrointestinal endoscopy. An increase in the frame rate, angle of view, depth of field, image numbers, duration of the procedure and improvements in illumination seem likely. Colonic, esophageal and gastric capsules will improve in quality, eroding the supremacy of flexible endoscopy, and become embedded into screening programs. Therapeutic capsules will emerge with brushing, cytology, fluid aspiration, biopsy and drug delivery capabilities. Electrocautery may also become possible. Diagnostic capsules will integrate physiological measurements with imaging and optical biopsy, and immunologic cancer recognition. Remote control movement will improve with the use of magnets and/or electrostimulation and perhaps electromechanical methods. External wireless commands will influence capsule diagnosis and therapy and will increasingly entail the use of real-time imaging. However, it should be noted that speculations about the future of technology in any detail are almost always wrong.

## INTRODUCTION

Wireless capsule is an incompletely developed technology, which may change endoscopy forever and has the capacity to replace a good deal of conventional endoscopy. Will capsule endoscopy replace much of conventional upper gastrointestinal endoscopy and colonoscopy? The answer is probably yes but the time frame is unclear. Will capsule endoscopy be able to deliver therapy? Again, the answer is probably yes.

There are major challenges to the expansion of capsule technology into a position where it can compete with conventional diagnostic gastroscopy and colonoscopy<sup>[1-5]</sup>. The first challenge is power management. At present the Pillcam capsule contains two small 3 volt hearing aid batteries which allow about 8 h of continuous imaging at 2 frames per second. The use of complementary oxide silicone (CMOS) technology for the video has the advantage of requiring extremely low power levels when compared with a charge coupled device (CCD). Slowing the video frame rate to two frames per second also increases the life span of the capsule. The esophageal capsule takes 14 frames a second and has a life span of about 20 min. Recent quite radical design changes have included the development of an esophageal capsule with 18 frames per second and small bowel and colon capsules, both with 4 frames per second, yet with an increase in capsule life to about 11 h. These changes have been accomplished

mainly by more efficient power management. More batteries or increased battery volume may be of help but would increase the size and weight of the capsule. The two small silver oxide batteries in current use are not the most efficient in terms of power to weight ratio, but were chosen because of their safety record. Lithium batteries could run the capsule for longer periods. There have been important "break-throughs" in battery design with the advent of carbon nanotubes and Buckytubes which have the intrinsic characteristics desired in the material used as electrodes in batteries and capacitors, two technologies of rapidly increasing importance. Buckytubes have a tremendously high surface area (approximate 1000 m<sup>2</sup>/g), good electrical conductivity, and their linear geometry makes the surfaces highly accessible to the electrolyte. It may be that better battery design and better power management will give the capsule the power required for additional performance and functions.

The development of external power transmission methods using electrical field induction, radio-frequency, microwaves or ultrasound technology could free the capsule from the requirement for batteries or at least prolong the functional lifespan. This would substantially lighten the capsule, allow space and power for other functions such as biopsy or drug delivery but above all allow the capsule to be powered for indefinite periods which would permit increase in the present rather low frame rate, and in particular make the problem of prolonged or implanted capsule endoscopy and remote controlled therapeutic capsule endosurgery much easier to solve.

The development of the capsule endoscopy was made possible by miniaturization of digital chip camera technology, especially CMOS chip technology. The continued reduction in size, increases in pixel numbers and improvements in imaging with the two rival technologies-CCD and CMOS is likely to change the nature of endoscopy. The current differences are becoming blurred and hybrids are emerging.

The main pressure is to reduce the component size, which will release space that could be used for other capsule functions such as biopsy, coagulation or therapy. New engineering methods for constructing tiny moving parts, miniature actuators and even motors into capsule endoscopes are being developed.

Although semi-conductor lasers that are small enough to swallow are available, the nature of lasers which have typical inefficiencies of 100-1000 percent makes the idea of a remote laser in a capsule capable of stopping bleeding or cutting out a tumour seems to be something of a pipe dream at present, because of power requirements. The construction of an electrosurgical generator small enough to swallow and powered by small batteries is conceivable but currently difficult because of the limitations imposed by the internal resistance of the batteries. It may be possible to store power in small capacitors for endosurgical use, and the size to capacity ratio of some capacitors has

recently been reduced by the use of tantalum. Small motors are currently available to move components such as biopsy devices but need radio-controlled activators. One limitation to therapeutic capsule endoscopy is the low mass of the capsule endoscope (3.7 g). A force exerted on tissue for example by biopsy forceps may push the capsule away from the tissue. Opening small biopsy forceps to grasp tissue and pull it free will require different solutions to those used at flexible endoscopy-the push force exerted during conventional biopsy is typically about 100 g and the force to pull tissue free is about 400 g.

Future diagnostic developments are likely to include capsule gastroscopy, attachment to the gut wall, ultrasound imaging, biopsy and cytology, propulsion methods and therapy including tissue coagulation. Narrow band imaging and immunologically or chemically targeted optical recognition of malignancy are currently being explored by two different groups supported by the European Union as FP6 projects: -the VECTOR and NEMO projects. These acronyms stand for: VECTOR = Versatile Endoscopic Capsule for gastrointestinal TumOr Recognition and therapy<sup>[6]</sup> and NEMO = Nano-based capsule-Endoscopy with Molecular Imaging and Optical biopsy.

Both projects also include the development of remote manipulation methods.

## CHALLENGE TO USING CAPSULE ENDOSCOPY FOR COLONOSCOPY

There are challenges to using wireless capsule endoscopy for colonoscopy but most of these have been solved. Currently the capsule acquires images for 8 h and usually reaches the right side of the colon before the battery expires. The capsule may have to run for 24-48 h in order to perform a complete examination of the colon unless we can speed up the total gut transit. The power problem can be addressed in several ways including the use of more batteries, batteries with a delay mode which are switched on when the capsule reaches the distal small intestine, external power transmission and methods to move the capsule faster in the colon. A very effective timed colon cleaning will be necessary. Deletion of identical frames would make it easier to examine the images since the capsule in the colon may remain stationary for prolonged periods. Currently, wireless capsule colonoscopy has generated images from all areas of the colon and has imaged pathology especially in the right side of the colon, but also in the rectum. Initial clinical studies have provided promising results.

Autonomous wireless capsule laparoscopy is technically feasible and has been tried *in vivo* but needs to develop further and offer advantages over conventional laparoscopy. The obvious advantages might be that port numbers can be reduced for selected laparoscopic operations. It can be used to improve visualization during NOTES, and may allow multiple camera angles

during surgery, and views of structures that are difficult to see with conventional rigid laparoscopes such as the retroesophageal space or the pouch of Douglas. Wireless imaging of cardiac or vascular structures is conceivable, but would require substantial development and control strategies.

Wireless laparoscopy is a desirable extension of wireless capsule endoscopy. This may allow deconstruction of laparoscopes or NOTES platforms, separating the imager from the surgical effectors, thus reducing the outer diameter of trocars, and making surgery less invasive.

The manufacture of an autonomous video capsule the size of a red blood cell as described in Isaac Asimov's "The Fantastic Voyage" and made into a movie in 1966 by Richard Fleischer with Stephen Boyd, Raquel Welsh and Donald Pleasance is some way in the future. Reduction in size by up to an order of magnitude is currently conceivable with available components. It would be relatively easy to reduce by one-half the current dimensions of the capsule.

## **ATTACHMENT OF CAPSULE ENDOSCOPES TO THE GI TRACT**

It may become possible to stitch or clip the capsule to the wall of the stomach so that prolonged examination of bleeding ulcers or varices becomes possible. An on/off radio-controlled command may be helpful to conserve power. Long-term endoscopy with wireless endoscopes attached to the wall of the gut seems an obvious way to improve the management of gastrointestinal bleeding and other disorders.

## **TISSUE INTERACTIVE DIAGNOSTIC METHODS SUCH AS BIOPSY**

At present, the capsule cannot obtain biopsies, aspirate fluid or brush lesions for cytology. These common endoscopic manoeuvres may become possible during capsule endoscopy. These techniques require real-time viewing, as well as radio-controlled triggering and remote controlled capsule manipulation, if they are to be used with precision. Biopsy using a spring loaded Crosby capsule-like device with an evacuated chamber is feasible with existing capsule technology. In preliminary studies, patients were almost always able to retrieve the capsules from the stools using a net and a magnet. Experimental brush, biopsy and radio-controlled release mechanisms which can be used in autonomous capsules have been tested in "*in vivo*" studies. It may become possible to combine capsule technology with "optical biopsy" such as narrow band imaging or pathology-targeted enhanced tissue markers.

## **CAPSULE COAGULATION**

A prototype coagulation capsule has been built and tested which employs an exothermic chemical reaction to

generate heat using the interaction of calcium oxide and water. It seems possible that other thermal therapeutic applications will be added in the future.

## **ELECTRO-STIMULATION FOR PROPELLING CAPSULE ENDOSCOPE**

One way to manipulate a wireless capsule endoscope autonomously in the gastrointestinal tract is to use electro-stimulation to propel the device, for example with a pair of bipolar electrodes at either end of the capsule. This technology has been tested in humans. Electrodes attached to a PILLCAM capsule have been used to propel the device in the porcine esophagus and small intestine, as well as in the human small intestine. A dumb-bell shaped capsule allows the imaging capsule to view the traction capsule. A radio-controlled electro-stimulation capsule has been developed. Radio-commands can be sent from a transmitter to the receiving traction capsule causing it to propel the video capsule forwards or backwards in the human gastrointestinal tract.

Water-jet propulsion has also been used to propel very light weight (3.7 g) capsules in the gastrointestinal tract. The light weight of the capsule compared with the 1.5 kg of a colonoscope makes it possible to think in terms of developing new types of very light weight colonoscopes, which can be passed on a wire through the anus, and would require much less force on the wall of the colon to reach the cecum.

Olympus in a news release (November 30, 2004) announced the following developments in capsule endoscopy: wireless power supply system, capsule guidance system, drug delivery system, body fluid sampling technology, self-propelled capsule and ultrasound capsule. Competition is likely to stimulate new technical developments which may make capsule endoscopy cheaper. Olympus is using CCD technology in their small bowel capsule that was released recently in Europe and USA, with FDA approval and a CE mark. A Chinese wireless small intestinal capsule (OMOM) has gone through 3 technical design changes, with improving image quality, and currently costs less than the other systems. A Korean small intestinal capsule (MIRO) includes some novel technological features including two external electrodes and a single skin electrode to facilitate transmission of image data using the body as an electrical conductor, thus eliminating the need for radiofrequency (wireless) data transmission, and as a result saving power. Recent technical improvements in the Given Imaging capsules (SB2, ESO2, COLON1) include adaptive light control i.e. if a frame is too dark the light emitting diodes will emit more light in subsequent frames. The frame rates of commercially available Given capsules have increased from 2 to 4 frames per second, for prolonged image transmission of up to 11 h and from 14-18 frames per second for rapid esophageal double imager viewing. Additional lenses have been added to the

redesigned optics to increase the depth of focus and widen the angle of view from 140 to 156 degrees which can more than double the surface area of the mucosa examined. The software continues to improve in order to manage the technical advances. Rapid 5, is the most recent version, indicating that the software has been revised 5 times. Real-time viewing has improved and will be increasingly important for new diagnostic and therapeutic options. At the time of writing (May 2008) more than 750 000 wireless capsule endoscopes have been sold since they were first launched in 2001.

## CONCLUSION

Capsule video-enteroscopy has opened up a new world of diagnostic and other possibilities for the gastroenterologist. It is remarkable to see images of small intestinal abnormalities such as an ulcerated Meckel's diverticulum or active bleeding from a tumour in the middle of the small intestine, which was not possible until recently. The development of wireless capsule endoscopy has changed video endoscopy of the small intestine into a much less invasive and more complete examination. The increasing use of these resources and the comfort and ease with which some of these examinations can be performed makes it likely that wireless capsule video imaging will have a substantial impact on the management of small intestinal disease as well as other parts of the body.

It is usually a mistake to try to predict the future

because the chances of error are very high. "It is impossible to predict the future, and all attempts to do so in any detail look ludicrous within a very few years." These are the opening words of "The Profiles of the Future" by Arthur C. Clarke, who wrote an amusing account of eminent scientists predicting that electric light, human flight and space travel were impossible at the same time as Edison perfected the light bulb, the Wright brothers made their first motor powered flight and Yuri Gagarin circled the earth in a sputnik. Einstein who probably knew more than most about the potential impact of physics on the future of mankind was goaded during an interview in 1929 on board the Belgoland into saying "I never think about the future; it comes soon enough".

## Abstract

Video capsule endoscopy is an attractive and patient-friendly tool that provides high quality images of the small bowel. Obscure gastrointestinal bleeding is the primary and most evaluated indication to capsule endoscopy; however, indications are expanding and a small number of preliminary reports have been presented concerning the role of video capsule endoscopy in the diagnosis of celiac disease. The purpose of this review is to update the current knowledge and to hypothesize on future perspectives of the use of video capsule endoscopy in patients with celiac disease.

## INTRODUCTION

Celiac disease is a gluten-dependent enteropathy, characterized by chronic small bowel inflammation

and mucosal atrophy. Up to a few years ago, celiac disease was considered a rare pathology. Today, its prevalence has been estimated ranging between 0.2% and 1% in the United States and European population<sup>[1]</sup>. Although celiac disease was believed to be a pediatric syndrome, it is now recognized mainly as an adult disease that involves multiple organs. Abdominal pain, diarrhea, growth failure and malabsorption are its typical clinical presentation. However, the increased interest for this pathology over the last 2 decades allowed diagnosing celiac disease also in those with the silent or "atypical" form. These patients may present vague and subclinical manifestations such as dyspeptic symptoms or esophageal reflux, irritable bowel syndrome, polyneuropathy or iron deficiency anemia<sup>[2]</sup>. The disease can also be totally asymptomatic and the diagnosis can be accidental. The diagnosis of celiac disease is made by demonstrating the characteristic histopathological changes on intestinal biopsy obtained by esophagogastroduodenoscopy. Villous atrophy on a duodenal biopsy represents the internationally accepted gold standard diagnostic test for celiac disease. Serological tests include antigliadin, antiendomysium and anti-tissue transglutaminase antibodies. These tests are highly reliable for the diagnosis of celiac disease and represent a cheap and non-invasive method to identify patients who will be referred to endoscopy, specifically with the purpose of obtaining duodenal biopsy. The positive and negative predictive value of combining the measurement of antibodies from tissue transglutaminase and antiendomysium has been reported to be greater than 96%<sup>[3]</sup>.

Capsule endoscopy is a well tolerated, minimally invasive method for the visualization of the entire small bowel and is currently used to evaluate patients with obscure bleeding, inflammatory bowel diseases, suspected small bowel tumours, polyposis syndromes, nonsteroidal anti-inflammatory drug injury and complicated celiac disease<sup>[4]</sup>. Video capsule endoscopy is provided with an 8-fold magnification capacity lens optical system that allows a magnification similar to that of dissection microscopy<sup>[5]</sup> and is therefore able to assess the small bowel villous structure. For this reason, video capsule endoscopy could offer an alternative to duodenal biopsy in patients who are unable or unwilling to undergo esophagogastroduodenoscopy. This article reviews the current knowledge and future prospects of the use of video capsule endoscopy in patients affected by celiac disease.

## CRITERIA FOR DIAGNOSIS OF CELIAC DISEASE

The first step in pursuing a diagnosis for celiac disease is a serological test. The immunoglobulin A (IgA) anti-human tissue transglutaminase (t-TG) and IgA endomysial antibody immunofluorescence (EMA) are the best tests available. Although these tests are highly sensitive and specific, small bowel biopsy remains the standard for the diagnosis of celiac disease. Demonstration of hyperplastic villous atrophy of the small bowel and clinical remission when a gluten-free diet is followed represent the diagnostic tests for celiac disease<sup>[6]</sup>.

## ENDOSCOPIC SIGNS IN CELIAC DISEASE

Four endoscopic markers suggestive of villous atrophy have been described in celiac disease: loss or reduction in duodenal Kerkring's folds, mosaic mucosal pattern, scalloped configuration of duodenal folds and micronodular pattern of the mucosa<sup>[7,8]</sup>. These markers should serve as a tool to assist endoscopists in deciding when small bowel biopsies may be indicated. Sensitivity of these markers for the diagnosis of celiac disease has been reported to be between 47% and 100%<sup>[8-10]</sup>. Endoscopic markers overall have a wide range in sensitivity mainly because of their absence when lesser degrees of villous atrophy are present. Therefore, endoscopic evaluation without biopsies is not considered sensitive enough for a diagnosis and is considered inadequate to confirm or to exclude celiac disease<sup>[11]</sup>. However, when endoscopic signs are present, they have a high specificity, ranging between 92% and 100%<sup>[2,10,12]</sup>. For this reason, investigators should be aware of the importance of such markers detected during endoscopy. Recognition of endoscopic signs of celiac disease could help to select patients for biopsy and avoid delays in the diagnosis of the disease, preventing long term complications. Recently, endoscopic approaches for the evaluation of duodenal villous abnormalities have been proposed allowing a direct visualization of the duodenal villous structure during routine upper endoscopy. Endoscopic visualization of intestinal villous pattern with the "immersion technique" provides a sensitivity, specificity, positive predictive value and negative predictive value of 85%, 99%, 99% and 90%, respectively<sup>[11,13]</sup>. Moreover, it has been demonstrated that the new high-magnification and high-resolution endoscopes are able to better evaluate the presence or absence of villous pattern. Sensitivity, specificity, positive predictive value and negative predictive value of endoscopic magnification ( $\times 2$ ) for detection of total villous atrophy were all 100%. Similar results were obtained combining the "immersion technique" with magnification<sup>[14]</sup>. Therefore, theoretically, in patients with suspected celiac disease (EMA+ and/or t-TG antibodies+) using these new endoscopic approaches, the biopsy sampling of the small bowel could be avoided when a flat duodenal mucosa is observed and should be reserved only for those patients in whom villi are observed at endoscopy<sup>[11]</sup>.

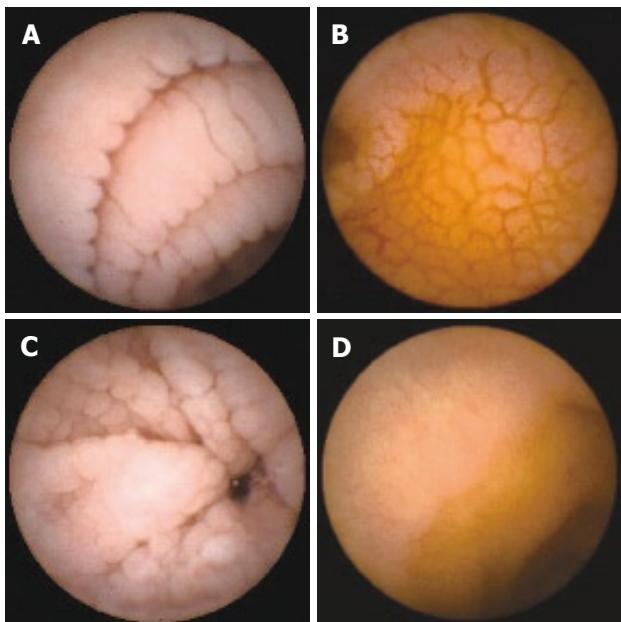

**Figure 1** Normal endoscopic pattern at video capsule endoscopy. Villous pattern can be easily observed.

## CAPSULE ENDOSCOPY

Capsule endoscopy has become an important tool in the investigation of patients with small bowel diseases. Preliminary reports suggest that capsule endoscopy could represent an attractive and non-invasive diagnostic tool in patients with suspected celiac disease<sup>[15-19]</sup>. It can also be used in patients with known celiac disease for monitoring small bowel healing; in patients with alarming symptoms despite a closely followed gluten-free diet and in long-term surveillance to detect malignancies<sup>[20]</sup>. The diagnosis of celiac disease is still based on the recognition of villous atrophy on duodenal biopsy; however duodenal biopsy cannot be considered an optimal gold standard. The major limits are represented by the need to perform an upper gastrointestinal (GI) endoscopy which represents an invasive procedure; the difficulty to obtain proper oriented tissue samples; the occurrence of patchy mucosal lesions that can be missed by the biopsy; and the limited portion of gut examined with the risk of loosing the diagnosis of complications, such as enteropathy-associated T-cell lymphoma and ulcerative jejunileitis. Capsule endoscopy is provided with certain features that may overcome some of the limits of traditional upper GI endoscopy. Capsule endoscopy is a non-invasive, painless and well accepted procedure. The capsule has the magnification power of a dissecting microscope: the optical system has an 8-folds magnification power, therefore the villi can be easily observed (Figure 1). The test is performed without air inflation, with the optical dome of capsule endoscopy close to the mucosa, improving the assessment of the villous architecture. Finally, it allows the visualization of the entire small bowel, providing an estimation of the extent of small bowel involvement and facilitating the diagnosis of complications.

In a preliminary study, Petroniene *et al*<sup>[16]</sup> compared 10 celiac patients with histologically proven villous atrophy (Marsh III) with 10 control patients with normal histology, showing that capsule endoscopy has an excellent accuracy in identifying villous atrophy. When compared to upper GI endoscopy, capsule endoscopy reported an identical specificity (100%); a tendency towards a better sensitivity (70% vs 60%); and a positive

**Figure 2** Endoscopic markers of celiac disease at capsule endoscopy: scalloping (A), mosaic pattern (B), micronodularity (C), and reduction of folds (D).

predictive value and negative predictive value of 100% and 77%, respectively. These data were confirmed by recent studies<sup>[17,19]</sup>. Hopper *et al*<sup>[17]</sup> showed that 17 out of 20 patients with celiac disease had villous atrophy also detected by capsule endoscopy. In this paper, the sensitivity, specificity, positive predictive value and negative predictive value for capsule endoscopy in recognising villous atrophy were 85%, 100%, 100% and 88.9%, respectively. Upper GI endoscopy detected endoscopic markers consistent with celiac disease in 16 out of 20 celiac patients with a sensitivity, specificity, positive predictive value and negative predictive value of 80%, 100%, 100% and 85.7%, respectively. Capsule was more sensitive than conventional endoscopy in identifying endoscopic markers, but the difference observed did not achieve statistical significance. In the largest presented series, Rondonotti *et al*<sup>[19]</sup> reported on 43 consecutive patients with signs and/or symptoms suggestive of celiac disease and positive serological markers who underwent upper GI endoscopy and video capsule endoscopy. 87.5% of patients who had characteristic histological changes were diagnosed with celiac disease by capsule endoscopy. Overall, capsule endoscopy was reported to have a sensitivity of 87.5%, a specificity of 90.9%, a positive predictive value of 96.5%, a negative predictive value of 71.4% and positive and negative likelihood ratios of 9.6 and 0.14, respectively. Capsule endoscopy appeared highly performing in patients with Marsh III lesions, as it is able to correctly diagnose 89% of patients with this type of histological change.

Such promising data are not confirmed in the series presented by Biagi *et al*<sup>[5]</sup>. In this series, the authors classified the mucosal appearance as seen at capsule endoscopy as normal, hypotrophic and atrophic and

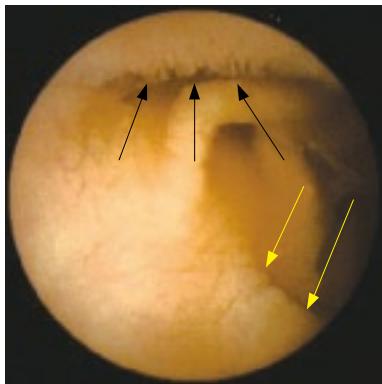

**Table 1** Sensitivity, specificity, PPVs and NPVs of capsule endoscopy in celiac disease from referenced articles (%)

Ref.	Sensitivity	Specificity	PPV	NPV
Petroniene <i>et al</i> <sup>[16]</sup>	70	100	100	77
Biagi <i>et al</i> <sup>[5]</sup>	90.5-95.2	63.6	100	77.8-87.5
Hopper <i>et al</i> <sup>[17]</sup>	85	100	100	88.9
Rondonotti <i>et al</i> <sup>[19]</sup>	87.5	90.9	96.5	71.4

evaluated whether there was a correlation between the degree of villous atrophy at the histology and capsule endoscopy results. Video capsule findings regarding the degree of small bowel mucosal atrophy showed only a moderate agreement with the histologic pattern, with a high sensitivity (range, 90.5%-95.2%), but a low specificity (63.6%). Positive predictive value was 100% and negative predictive value ranged between 77.8% and 87.5%.

Overall, capsule endoscopy seems to be able to recognize the endoscopic markers of celiac disease described in the literature<sup>[15,16,21]</sup>. Scalloping, mosaicism, micronodularity and reduction of folds (Figure 2) can all be seen by capsule endoscopy<sup>[16,19,22]</sup>. In addition to general mucosal pattern, capsule endoscopy can easily recognize finger-like villi (Figure 1)<sup>[16,17]</sup>. Table 1 shows the literature data on sensitivity, specificity, positive predictive value and negative predictive value of capsule endoscopy in celiac disease. Capsule endoscopy has a high sensitivity (range, 70%-95.2%), even better than that of upper GI endoscopy, an overall high specificity (range, 63.6%-100%) and high positive predictive value and negative predictive value, respectively between 96.5%-100% and 71.4%-88.9%. This means that when an atrophic pattern is observed by capsule endoscopy, patients have a very high probability to have celiac disease. However, the relatively low negative predictive value suggests that a normal capsule endoscopy pattern can not exclude definitively villous atrophy.

The accuracy obtained by capsule endoscopy is similar to that of magnification endoscopy or of endoscopy with the "immersion technique"<sup>[11,13]</sup>, however capsule endoscopy has the great advantage of being a non-invasive technique and to visualize the entire small bowel<sup>[15]</sup>. Overall, interobserver agreement was moderate to high in the detection of villous atrophy and ranged between 0.41 and 0.87<sup>[16,19]</sup>. The interobserver agreement is an important factor in assessing the accuracy of the tests employing subjective visual evaluation. Agreement between investigators for the diagnosis of specific endoscopic markers is different: while it is low for erosions ( $\kappa$ , 0.27-0.72) and reduction in the number or loss of duodenal folds ( $\kappa$  = 0.41 and 0.59, respectively), it is good for mosaic pattern ( $\kappa$  = 0.76) and scalloped folds ( $\kappa$  between 0.65 and 0.85)<sup>[5,16,19]</sup>. The lack of an overall high degree of agreement between investigators could mean that the correct visualization of villous atrophy is difficult even for physicians with long-term experience in capsule endoscopy. It has been demonstrated that the interobserver agreement varies significantly between investigators ranging from poor to perfect ( $\kappa$ , 0.26-1.0). The agreement is perfect between experts who have

**Figure 3** "Patchy" atrophy detected by capsule endoscopy. Capsule endoscopy shows a normal villous pattern in the upper part of the image (black arrows) and villous atrophy in the lower part (yellow arrows).

extensive experience with capsule endoscopy<sup>[16]</sup>. Familiarity with capsule endoscopy may be an important factor affecting the accuracy of the procedure and training sessions are needed for those endoscopists who are interested in capsule endoscopy. In fact, with physicians more experienced in evaluating patients with suspected or known celiac disease, an overall improvement in the interobserver agreement may be expected<sup>[19]</sup>.

Capsule endoscopy also provides information on how much bowel is involved by the celiac disease, allowing the visualization of portions of the small bowel not accessible by other traditional endoscopic methods. Although precise evaluation of the extent of the affected bowel is not possible, it is, however, possible to determine whether the disease is confined to the duodenum, to the proximal part of the jejunum or whether it extends throughout the whole of the small bowel. Rondonotti *et al*<sup>[19]</sup> showed that 66.6% of patients had an extension of the mucosal changes seen at capsule endoscopy beyond the proximal small bowel, and 11.1% had lesions that involved the small bowel entirely. The significance of the extent of involvement of the small bowel in patients with celiac disease is still unclear. However, available data suggest that there is a trend in correlation between the severity of symptoms and the degree of small bowel involvement<sup>[16,19]</sup>. This could be an interesting and important topic for future research. Moreover, evaluation of the entire small bowel may reveal mucosal changes undetected by traditional endoscopy in case of a "patchy" distribution (Figure 3). Rondonotti *et al*<sup>[19]</sup> reported of a patient who had a normal mucosa at upper GI endoscopy and scalloping of folds in the distal part of duodenum at capsule endoscopy. Authors argued that the normal duodenal histology in this patient was a sampling error and the capsule findings were compatible with a "patchy" distribution of mucosal changes.

Celiac disease may be complicated by a variety of pathologies, including small bowel adenocarcinoma, intestinal T-cell lymphoma and ulcerative jejunitis. These complications are often not identifiable by conventional imaging modalities as they are located beyond the site reachable by traditional endoscopy. Capsule endoscopy has

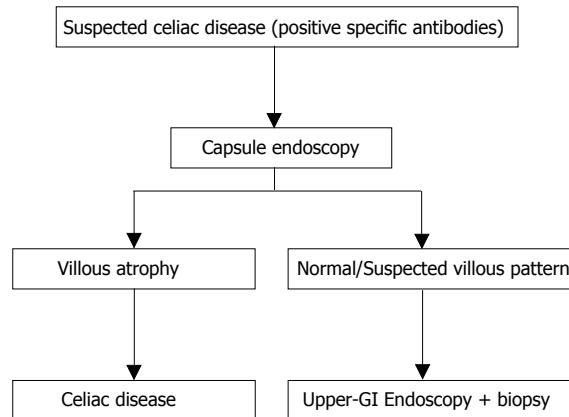

been reported to be able to demonstrate intussusception, ulcerative jejunoileitis, lymphoma and adenocarcinoma in patients with celiac disease<sup>[23-27]</sup>. In a series of 47 celiac patients with a high risk of complication (persistent unexplained abdominal pain, weight loss, history of small bowel neoplasia, long-standing celiac disease, positive faecal occult blood test or iron deficiency anaemia unresponsive to iron supplementation), lesions were detected in about 50% of cases<sup>[20]</sup>. These data support the role of capsule endoscopy in patients who have complicated disease, who present alarm symptoms or who do not respond to a gluten-free diet<sup>[28]</sup>. In this group of patients, capsule endoscopy should be promptly performed as it avoids several unnecessary diagnostic tests, it permits to visualize small bowel complications that generally are diagnosed late, and it allows initiation of specific therapies.

Unsuspected celiac disease can also be diagnosed during capsule endoscopy performed for other indications including abdominal pain, gastrointestinal bleeding, and dyspepsia<sup>[22,29,30]</sup>. In these cases, findings evocative for celiac disease should suggest the performance of additional testing to rule out celiac disease. For this reason, recognition of endoscopic markers for celiac disease and villous atrophy is mandatory for physicians who perform capsule endoscopy.

Data presented in the literature are interesting and they make us optimistic about the role of capsule endoscopy in the evaluation of patients with celiac disease. However, some issues remain still open and need to be clarified. In all the studies presented, patients had a high pre-test probability (EMA and/or t-TG positive) of having celiac disease. This may provide an over estimation of the performance of capsule endoscopy in the detection of endoscopic markers and villous atrophy. A further limitation is represented by patients with less severe histological changes (Marsh I and II). In fact, it is demonstrated that capsule endoscopy is able to detect the majority of Marsh III lesions, which are associated with evident mucosal abnormalities; however, it may not distinguish patients with Marsh I and II lesions as they may have a normal villous pattern. Furthermore, the role of capsule endoscopy in screening or surveillance for malignancies in patients with celiac disease should be clarified. It is unclear what group of patients should be screened or should undergo surveillance to detect small bowel malignancies<sup>[23]</sup>. Finally, it should be clarified whether capsule endoscopy could play a role in diagnosing celiac disease in patients with positive serologic tests and negative biopsies.

## FUTURE PERSPECTIVES

Recently, new endoscopic approaches and technologies that allow a direct visualization of the duodenal villous structure with high accuracy have been proposed<sup>[11,13,31,32]</sup>. Using these new procedures, it is possible to detect the presence of the intestinal villi or to suggest their absence. These observations led the Authors to propose a new diagnostic approach to celiac disease avoiding the biopsy

**Figure 4** Possible algorithm in the diagnostic work-up of celiac disease.

sampling. All these new methods still require "standard" endoscopy which is an invasive procedure, it is not well tolerated by patients and it only reaches the proximal part of the small bowel. Capsule endoscopy offers several advantages over standard endoscopy: it is a non-invasive procedure; it is well tolerated by patients; and it allows the visualization of the entire small bowel. Moreover, the optical system of the capsule allows an 8-fold magnification, providing a good visualization of small bowel villous pattern. Therefore, if a biopsy-avoiding approach using new endoscopic methods (such as the "immersion" technique or high-resolution and magnifying endoscope) seems reasonable, it appears more and more rational to obtain the same information recurring to a non-invasive procedure, that allows to explore all the small bowel. It is our feeling that in the next few years the diagnostic approach to celiac disease will change if larger studies will confirm the results published to date regarding the role of capsule endoscopy in celiac disease (Figure 4). "High risk" patients for celiac disease (positive specific antibodies)<sup>[3]</sup> will avoid traditional endoscopy and undergo capsule endoscopy directly; only those patients with a normal or suspected villous pattern at capsule endoscopy will undergo standard upper GI endoscopy with duodenal biopsy. Several studies are needed to confirm these new approaches.

## CONCLUSION

The essential requirement for the diagnosis of celiac disease is the histopathologic demonstration of villous atrophy. For this reason, endoscopy plays a critical role as it permits to obtain duodenal specimens. Video capsule endoscopy provides good quality images of the small bowel mucosa, including well-defined villous pattern in patients with celiac disease. At present, capsule endoscopy may be an alternative to traditional endoscopy and duodenal biopsy in patients with suspected celiac disease who are unable or unwilling to undergo conventional upper GI endoscopy for confirmation of villous atrophy. Capsule endoscopy also provides information on the extent of the small bowel involved, but the meaning of this data is still unknown. Other potential indications for

capsule endoscopy include complications related to celiac disease, refractory patients and long-term surveillance to detect malignancies. Further prospective studies are needed to confirm these preliminary results and to investigate if capsule endoscopy could represent a first line approach in patients with suspected celiac disease.

## Abstract

Wireless capsule endoscope (WCE) for the investigation of the small bowel is an approved technique both in adults and children (more than 10 years old). The present review provides data on the indications, diagnostic yield, adverse events and limitations of the WCE technique in children and tries to predict the future of WCE usage in this population of patients.

## INTRODUCTION

The concept of a wireless capsule endoscope (WCE) for the investigation of the small bowel, was introduced in 2000<sup>[1]</sup>, soon to be followed by a commercially available product both in Europe and the USA<sup>[2]</sup>.

Soon after its first reports in adult patients, the advantages of this imaging technique turned WCE into an experimental and later an approved technique in the

diagnostic arsenal of pediatric gastroenterology (from the age of 10 years old) worldwide.

The present review will provide data on the indications, diagnostic yield, adverse events and limitations of PillCam SB technique in children and try to predict the future of WCE. An electronic search of MEDLINE was done (up to May 15, 2007), limiting full citations to papers published in English while reviewing abstracts in any language.

## PEDIATRIC PATIENTS AND WCE

### Age range

In 2001, the Food and Drug Administration approved WCE, then referred to as M2A, and now PillCam SB (Given Imaging, Yoqneam, Israel) as an adjunct tool for the evaluation of small-intestinal disorders and later (2003) as a first line modality for the evaluation of small-intestinal disorders. In 2004, WCE was approved as a diagnostic tool for children not younger than 10 years of age. As will be discussed later, the main limitation in children is the need to swallow this 27 mm × 11 mm relatively large pill. Using any of the traditional endoscopy assisted methods of ingestion, successful WCE examinations were reported in children as young as 2.5 years and 3 years of age<sup>[3,4]</sup>. Interestingly, in a recent report from China, 6 out of 16 pediatric studies (37%), were done in children younger the 10 years<sup>[5]</sup>.

### Clinical indications

The literature on the use of WCE in children is limited. In adults, the main indications include obscure gastrointestinal bleeding (OGIB), iron deficiency anemia, suspected Crohn's disease, small intestinal tumors and refractory celiac disease. Nevertheless, any small bowel disease/pathology manifested beyond the reach of the endoscope might be an indication for WCE. Similarly, in children, the main indications include OGIB and suspected Crohn's disease, though many other indications for the use of WCE were described and are summarized in Table 1. In this review we evaluated the available literature on the use of WCE in children on these two main topics (suspected intestinal inflammation and OGIB) and mention some others.

### Intestinal inflammation Crohn's disease

There are 5 studies in the pediatric literature looking at suspected Crohn's disease. A prospective pediatric study

evaluating small bowel pathologies<sup>[6]</sup> found that, among 10 out of 20 patients, multiple lesions consistent with Crohn's disease were found using PillCam SB. Not less important, small-bowel Crohn's disease was ruled out in 8 patients. In another study<sup>[7]</sup>, WCE was used in 12 patients with suspected Crohn's disease not diagnosed by gastroscopy, colonoscopy, and small-bowel follow-through examinations that were carried out in all of the patients. Here too, WCE identified lesions suggestive of Crohn's disease in seven of the 12 (58.3%), the majority of the lesions being in the ileum. In a prospective cohort of children<sup>[8]</sup>, 16 patients with suspected small bowel Crohn's disease (10 newly diagnosed; 6 known cases), underwent WCE which was compared with standard investigation. All of the patients had preceding upper gastrointestinal endoscopy and ileocolonoscopy, and the majority had a barium meal and follow-through. In all patients with CD who had successful WCE studies (12/16), small bowel disease was identified (11/12 active disease, 1/12 chronic disease) by PillCam SB. In this study, ileocolonoscopy and WCE complemented each other with respect to the extent of the disease. In a retrospective review of 46 WCE studies in children<sup>[9]</sup> (a denominator was not provided), among 9 children with newly diagnosed small intestinal Crohn's disease, seven (78%) had their treatment changed after WCE was done. Finally, PillCam SB was able to suggest the diagnosis of Crohn's disease in 2 adolescents with abdominal pain, protein loosing enteropathy and anemia with negative radiologic and endoscopic evaluation<sup>[10]</sup>.

In accordance with adult studies and some of the studies cited, the North American Society for Gastroenterology Hepatology and Nutrition<sup>[11]</sup> concluded that WCE is increasingly being used in the detection of obscure small bowel lesions and now has a proven role in the identification of Crohn's disease of the small intestine. It was concluded that the sensitivity of WCE at identifying small bowel ulceration or stricture appears to be superior to conventional barium radiography and enteroclysis, but this conclusion was made based on adult literature<sup>[12,13]</sup>.

From adult studies, it is clear that WCE may have other important roles such as the assessment of mucosal healing of the small intestine, defining the extent of disease and providing evidence for distinction between Crohn's and UC in patients with indeterminate colitis<sup>[2]</sup>.

### Celiac disease

Endoscopy with intestinal mucosa biopsies is still considered the gold standard in diagnosing celiac disease. However, in adults, there is mounting evidence that WCE may be useful in the evaluation of patients with already diagnosed celiac disease<sup>[14]</sup>. In a recent study, in adults, evaluating the role of WCE in the diagnosis of celiac disease, findings regarding the degree of intestinal mucosal atrophy showed only moderate agreement with the histologic pattern<sup>[15]</sup>. The authors concluded that WCE cannot be an alternative to biopsy, but a duodenal biopsy should be done when an atrophic mucosal pattern is observed in patients undergoing WCE for other

**Table 1 Pediatric indications for the use of WCE**

Pediatric indications for the use of WCE
Intestinal inflammation
Crohn's disease
Celiac disease
Occult or obscure intestinal bleeding
Vascular malformations
Vasculitis (Henoch-Schönlein Purpura)
Meckel's diverticulum
Protein-losing enteropathies
Intestinal lymphangiectasia
Miscellaneous
Peutz-Jeghers syndrome
Familial and nonfamilial polyposis
Eosinophilic enteropathy
Food allergy
Mucosal injury
Drugs
Chemotherapy
Radiotherapy
Graft versus host disease
Malignancy
Chronic abdominal pain

reasons. In adults, a consensus expert panel suggested that WC endoscopists should be able to recognize celiac disease, and for the time being, WCE might be an option in patients unable or unwilling to undergo conventional upper GI endoscopy<sup>[16]</sup>. Data in children are lacking to evaluate and apply these statements in children.

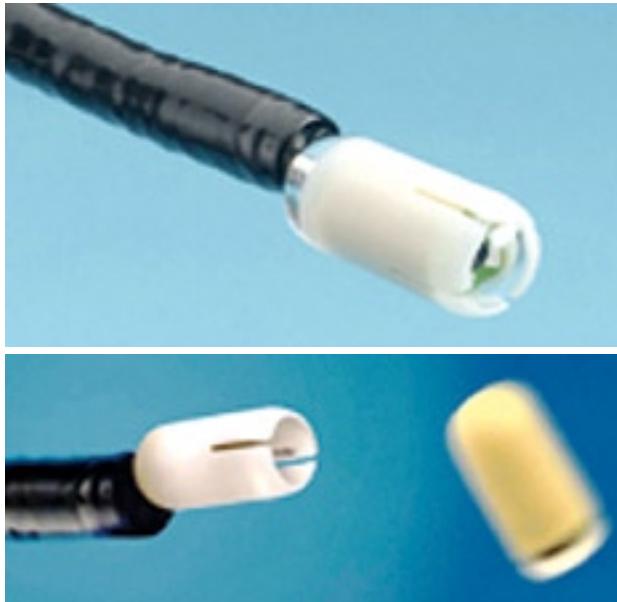

### Obscure gastrointestinal bleeding and other sources of bleeding

WCE is the imaging method of choice in adults with OGIB<sup>[17]</sup>. In a cohort of patients from Canada, among four patients with obscure bleeding, WCE confirmed a diagnosis of vascular malformations in three. In that study, WCE was more accurate identifying the precise source of bleeding compared with angiography<sup>[6]</sup>. In another study from England<sup>[8]</sup> a possible source of bleeding was identified in all 6 patients suffering from chronic anemia and OGIB. In that study, WCE had a higher diagnostic yield compared to a combination of gastroduodenoscopy and ileocolonoscopy.

WCE was reported to be helpful in evaluating and directing treatment options in chronic Henoch-Schonlein Purpura vasculitis<sup>[18]</sup>. Similarly, it has been found helpful in monitoring the effect of therapy in patients with blue rubber bleb nevus syndrome<sup>[19]</sup>. Other miscellaneous diagnoses of PillCam SB are bleeding varices, angiodysplastic lesions, jejunal hemangioma, Meckel's diverticulum and bleeding lymphonodular hyperplasia<sup>[20-23]</sup>.

### Miscellaneous

As reviewed recently<sup>[20]</sup>, WCE is used to diagnose and survey small bowel polyps in children with familial polyposis and those with Peutz-Jeghers syndrome. It may also be used to diagnose malignancies<sup>[24]</sup>, intestinal lymphangiectasia<sup>[25]</sup>, as well increasing number of entities summarized in Table 1. It is clear that with time,

**Figure 1** An introducing device for the capsule endoscope.

many of these entities will become more established indications for performing WCE. Future studies should delineate the role of WCE compared to other imaging modalities for some of these entities.

#### Advantages and limitations

WCE is clearly advantageous for evaluating small bowel pathologies when the child is able to swallow the capsule as it is a procedure that is free of anesthesia and its risks. Often, we are able to select those patients who will readily swallow the capsule (using candies of increasing sizes) and train some who were afraid to swallow big candies<sup>[26]</sup>. When the patient can not swallow the capsule due to any reason (including swallowing disorders, dysphagia, gastroparesis) the capsule can be safely introduced to the duodenum using various techniques and a standard endoscope (Figure 1)<sup>[20,27]</sup>.

The main adverse event when using the capsule is capsule retention mainly due to strictures. Studies in adults have demonstrated the usefulness of using a Patency capsule (see accompanying article) and predicting the uneventful passage of the capsule using a Patency capsule has also been reported in children<sup>[6, 20]</sup>. In adults, capsule retention was reported in 13% (95% CI, 5.6%-28%) of patients with known CD, but only in 1.6% (95% CI, 0.2%-10%) with suspected Crohn's disease<sup>[28]</sup>. Capsule retention occurred in children, but not in adults with suspected Crohn's disease. In a cohort of 45 children undergoing WCE, nine subjects (20%) had adverse events<sup>[19]</sup>. Of these patients, five had delayed passage from the stomach with 2 patients requiring endoscopic retrieval and 4 had delayed passage from the small intestine (more than 5 d). Three of the 4 patients with intestinal retention underwent surgery (one underwent ileocolic resection 2 mo later) and one responded to steroids. In the study from Canada<sup>[6]</sup>, all 30 capsule studies were well tolerated, although 1 capsule was retained owing to an inflammatory stenosis. The capsule was eventually ex-

**Figure 2** A device used to introduce the capsule endoscope into the stomach.

peled after corticosteroid therapy. No capsule retention occurred in a Chinese series of 16 patients<sup>[5]</sup>. Figure 2 shows a device used to introduce the capsule endoscope to the stomach.

#### CONCLUSION

The North American Society for Gastroenterology Hepatology and Nutrition recently stated that regarding WCE in Crohn's disease, "Drawbacks of WCE include the cost of the test, as well as the potential risk of capsule impaction in strictured areas of the small bowel. Future studies may determine whether capsule endoscopy should be performed as a routine examination on new-onset patients with colitis and normal contrast studies. At this time, we recommend that this test be used primarily when CD of the small bowel is strongly suspected but cannot be documented by other modalities"<sup>[11]</sup>.

Thus, in summary, WCE is a promising diagnostic tool for small bowel imaging both in adults and children. A smaller capsule may allow younger children to use it without the need of traditional endoscopy.

## Abstract

**AIM:** To gain mechanistic insights into the role played by epidermal growth factor receptor (EGFR) in the regulation of vascular endothelial growth factors (VEGFs) in colorectal cancer (CRC).

**METHODS:** The impact of high-level expression of the growth factor receptors EGFR and VEGF receptor (VEGFR)3 and the VEGFR3 ligands VEGF-C and VEGF-D on disease progression and prognosis in human CRC was investigated in 108 patients using immunohistochemistry. Furthermore, the expression of the lymphangiogenic factors in response to the modulation of EGFR signalling by the EGFR-targeted monoclonal antibody cetuximab was investigated at the mRNA and protein level in human SW480 and SW620 CRC cell lines and a mouse xenograft model.

**RESULTS:** Human CRC specimens and cell lines displayed EGFR, VEGF-C and VEGF-D expression with varying intensities. VEGF-C expression was associated with histological grade. Strong expression of VEGF-D was significantly associated with lymph node metastases and linked to a trend for decreased survival in lymph node-positive patients. EGFR blockade with ce-

tuximab resulted in a significant decrease of VEGF-D expression *in vitro* and *in vivo*.

**CONCLUSION:** In conclusion, the expression of VEGF-D in colorectal tumours is significantly associated with lymphatic involvement in CRC patients and such expression might be blocked effectively by cetuximab.

## INTRODUCTION

Globally, colorectal cancer (CRC) is one of the three most commonly diagnosed malignancies<sup>[1]</sup>. For patients with metastatic disease, systemic cytotoxic chemotherapy has been shown to clearly improve survival<sup>[2-5]</sup>. More recently, the addition of therapeutic antibodies including cetuximab<sup>[6-8]</sup> and bevacizumab<sup>[9,10]</sup> to such cytotoxic regimens has been shown to further improve outcomes in first- and second-line settings.

The mode of action of the new therapeutic antibody cetuximab is thought to be based primarily upon perturbation of epidermal growth factor receptor (EGFR)-ligand interactions<sup>[11]</sup>. Binding of cetuximab blocks EGFR-associated cellular signal transduction cascades, which govern processes such as tumour cell survival, proliferation, invasion and metastasis<sup>[12-16]</sup>. Since high-level expression of the EGFR gene has been associated with reduced survival in a range of malignancies, targeting growth factor receptor signalling

cascades is a promising anticancer strategy<sup>[17-24]</sup>. Even more, an additional mode of action of cetuximab has been suggested which relates to tumour cell binding inducing an antibody-dependent cell-mediated cytotoxicity reaction<sup>[25,26]</sup>.

However, even if a number of such molecular tumour characteristics appeared to be associated with the antitumor efficacy of EGFR-targeted agents<sup>[27]</sup>, it remains a matter of debate as to whether the intensity or extent of immunohistochemical detection of EGFR expression in the tumour correlate with prognosis and response to EGFR-targeted agents<sup>[28,29]</sup>.

The hypothesis that growth and spread of tumours are dependent on their vascular and lymphatic systems was proposed several decades ago<sup>[30]</sup>. Interest in this concept has recently been rekindled following the molecular identification of regulators of (lymph-) angiogenesis such as the vascular endothelial growth factor (VEGF) family, including the ligands VEGF-A, -B, -C and -D, and the VEGF receptors VEGFR1 (FLT1), VEGFR2 (KDR) and VEGFR3 (FLT4)<sup>[31]</sup> and their clinical utilization by recombinant strategies for targeting angiogenesis, such as the anti-VEGFA antibody, bevacizumab<sup>[9]</sup> and the decoy receptor, VEGF Trap<sup>[32]</sup>. Interestingly, VEGF-C and VEGF-D, signalling through VEGFR3, have been identified as key regulators of lymphangiogenesis<sup>[33-36]</sup>. Data from *in vitro* and murine tumour models further support the key role of VEGF-C and VEGF-D in malignancy. For many tumour types, clinical studies have revealed a correlation between VEGF-C, VEGF-D and VEGFR3 expression and lymphatic spread, tissue invasion or poor prognosis<sup>[37-41]</sup>. However, in other studies, clear associations were not identified<sup>[42,43]</sup> or low levels of VEGF-D were correlated with an increased risk of metastasis and reduced survival<sup>[44]</sup>. Similar data have also been reported for CRC. In one study, VEGF-C and VEGF-D expression correlated with the tumour invasion, lymphatic and venous involvement, lymph node metastasis and liver metastasis, and reduced survival time<sup>[45]</sup>. A second study also reported that high-grade VEGF-D expression was associated with lymphatic involvement and poor patient survival<sup>[46]</sup>, while a third confirmed that VEGF-D expression correlated with the depth of tumour invasion, lymph node metastasis and reduced survival time<sup>[47]</sup>. However, in other analyses VEGF-D expression at the mRNA-level was reported to be downregulated in CRCs with lymphatic spread<sup>[48]</sup> and appeared to be lower at the leading edge of tumours in which lymphatic vessels were present<sup>[49]</sup>.

Given that lymphangiogenesis is increasingly recognized as a critical component of tumourigenesis and that EGFR signalling, a key regulator of tumourigenesis in CRC, possibly acts to some extent through regulation of VEGF-C and VEGF-D expression, we evaluated the co-expression profiles of EGFR, VEGF-C and VEGF-D in human CRC specimens. Results were correlated with the patients' clinicopathological parameters and survival. Furthermore, in order to gain mechanistic insights into the role played by EGFR in the regulation of VEGF-D in colorectal cancer, we analyzed the effect of cetuximab *in*

*vitro* and *in vivo* on the expression of VEGF-D in SW480 and SW620 human colon cancer cell and xenograft models of CRC. We thus showed that expression of VEGF-D is prognostically relevant in CRC and for the first time provided experimental evidence that EGFR-targeted antitumor therapy exerts its effect in part through suppressing lymphangiogenesis by downregulating VEGF-D.

## MATERIALS AND METHODS

### Tissue samples and patient characteristics

All tissues investigated in this study were obtained from patients ( $n = 108$ ) who underwent colectomy between 1995 and 2003 at the Department of Abdominal Surgery, University Hospital Mainz, Germany. Written informed consent for experimental immunohistochemistry was obtained from all patients before analysis. Expression of EGFR was analyzed in all patients, with assessment of VEGF-C and VEGF-D conducted in 102 cases and 104 cases, respectively, because of limited availability of tumour material.

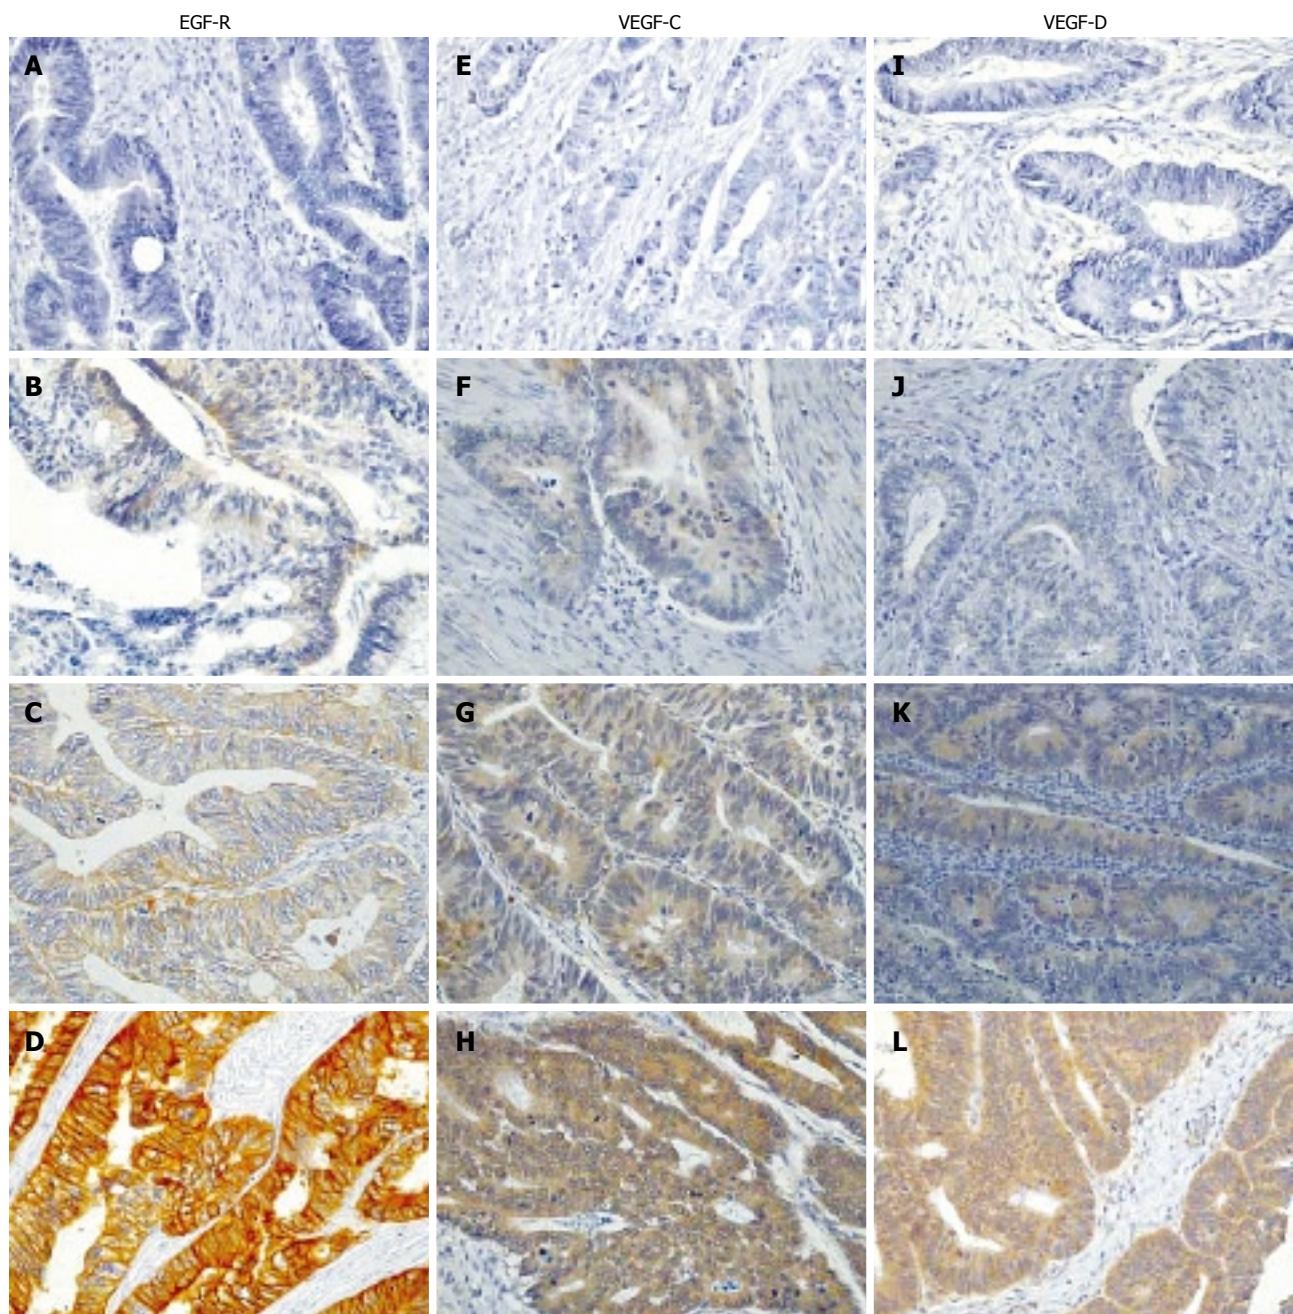

Patient age at the time of primary surgery ranged from 36.2 years to 83.1 years ( $63.6 \pm 10.45$  years). Seven patients were lost to follow up and were therefore censored at the time of last contact ( $34.86 \pm 4.18$  mo). Staging and diagnosis of CRC was assessed according to the World Health Organization classification and the TNM classification as set out by the International Union Against Cancer [Union International Contre le Cancer (UICC)]. After resection, patients were followed up every 6 mo. Patients with synchronous or metachronous metastasis underwent additional restaging every 3 mo during chemotherapy.

### Immunohistochemical (IHC) staining

Formalin-fixed paraffin-embedded tissues of patients with CRC from the Department of Pathology, University Hospital Mainz, Germany, were used in this study. Tissue sections (4  $\mu$ m) were cut from these blocks and used for IHC staining. All tissue sections were deparaffinized in xylene and rehydrated in a graded ethanol series.

Staining for EGFR was performed using the commercially available EGFR pharmDx kit (DakoCytomation, Carpinteria, CA, USA), which includes the pharmDx mouse anti-EGFR monoclonal antibody (clone 2-18C9), a negative control reagent (a mouse monoclonal antibody for an enzyme that is not expressed in mammalian tissue), and positive and negative control cancer cell preparations (CAMA-1 breast cancer and HT29 colon cancer cell lines). IHC staining was performed according to the manufacturer's instructions.

Staining for VEGF-C and VEGF-D was carried out following antigen retrieval. Sections were heated in citrate buffer and then cooled for 20 min. Endogenous peroxidase was blocked in 3% hydrogen peroxide in methanol for 15 min. To block nonspecific binding, prior to incubation with the primary antibody, tissue sections were incubated with serum-free DAKO Antigen-Block for 30 min. Primary antibodies specific for VEGF-C

**Figure 1** Immunohistochemical analysis of the expression levels of EGFR (A-D), VEGF-C (E-H) and VEGF-D (I-L) in human colorectal cancer sections ( $\times 400$ ). A, E and I: No expression; B, F and J: Weak expression; C, G and K: Moderate expression; D, H and L: Strong expression.

(sc-9047, Santa Cruz Biotechnology Inc. CA, USA) and VEGF-D (sc-13085, Santa Cruz Biotechnology Inc.) and were diluted 1:50 in DAKO ChemMate antibody diluent and sections were incubated for 16 h at  $4^{\circ}\text{C}$  (VEGF-C) or 2 h at room temperature (VEGF-D). After incubation with an anti-rabbit secondary antibody for 30 min, bound complex was visualized by using diaminobenzidine (ChemMateTM DAKO EnVisionTM Detection Kit). Sections were counterstained with Mayer's hematoxylin and mounted. Between all incubations, sections were washed in phosphate-buffered saline (PBS). Foetal kidney was used as a positive control. Negative controls were prepared by omitting primary antibody from the process (data not shown).

#### Evaluation of immunostaining

Immunostaining was independently evaluated by 4 authors who were blinded to patient outcome and all clinicopathological findings. EGFR-staining was interpreted according to standard parameters (EGFR pharmDx™ Interpretation Manual, DAKO). The staining intensities (Figure 1) were scored as negative, weak, moderate or strong. To unequivocally categorize cases into two groups, each sample was defined as EGFR-negative or EGFR-positive when  $< 1\%$  or  $\geq 1\%$  of the tumour cells respectively showed an EGFR-immunospecific membranous brown staining.

Staining results for VEGF-C and VEGF-D were similarly classified by estimating both the staining intensity

and the percentage of epithelial cells showing specific immunoreactivity. Staining intensities were not always homogeneous across individual tumour samples (as shown in Figure 1). All results showing more than 25% of tumour cells stained (with weak to strong positivity) were considered to represent biologically relevant levels of expression of these proteins and, for the purposes of statistical analysis, were counted as positive results.

### **Cell lines**

The colon carcinoma cell lines SW480 and SW620 were obtained from the American Type Culture Collection (Manassas, VA, USA) and maintained in RPMI 1640 media (Invitrogen, Carlsbad, CA, USA), supplemented with 10% foetal calf serum (FCS; PAA Laboratories, Pasching, Austria). Cells were cultured at 37°C in a 5% CO<sub>2</sub> atmosphere and passaged routinely using Trypsin-ethylenediaminetetraacetic acid (PAA Laboratories) treatment.

### **Cetuximab**

Clinical grade anti-EGFR monoclonal antibody cetuximab (Erbitux®) was supplied by Merck KGaA (Darmstadt) at a concentration of 2 mg/mL in a buffer consisting of 10 mmol/L sodium phosphate and 145 mmol/L sodium chloride at pH 7.

### **Stimulation assay**

SW480 and SW620 cells were seeded at  $3 \times 10^5$  cells/well in a 6-well tissue culture plate with media containing 10% FCS. After 24 h, cells were starved by incubation in media with a reduced FCS level (0.5%) for an additional 24 h. Afterwards, cells were incubated in medium plus 0.5% FCS supplemented either with 5 ng/mL epidermal growth factor (EGF, Sigma Chemical Co., St. Louis, MO, USA) for 20 min followed by 20 µg/mL cetuximab, or alternatively, the same medium supplemented with one or other of these substances. After culturing for another 24 h, monolayers were washed with icecold PBS, centrifuged and pellets were frozen for RNA isolation. The cell culture experiments were independently repeated at least two times.

### **RNA isolation and quantitative real time RT-PCR**

RNA isolation was performed using the RNeasy Kit according to the manufacturer's recommendations (Qiagen, Hilden, Germany). Transcription of the housekeeping gene glyceraldehyde-3-phosphate-dehydrogenase (GAPDH), VEGF-D and VEGFR3 was analyzed by a one-step reverse transcriptase-polymerase chain reaction (RT-PCR) using a LightCycler 2.0 system (Roche). RT-PCR was performed with 0.1 µg of RNA in a 35 cycle reaction (20 µL total volume; QuantiTect SYBRGreen RT-PCR, Qiagen) according to the recommendations of the manufacturer. All RT-PCR reactions were done in 2 replicates. All PCRs were established with an exponential phase efficiency of 2 to guarantee that the data were comparable. The evaluation of the expression of the target genes was performed relative to the expression of GAPDH. Control and test

samples in the EGF/cetuximab and xenograft analyses were compared using the  $\Delta\Delta Ct$  approach ( $\Delta\Delta Ct = 2^{-(Ct_{target\ gene\ control} - Ct_{GAPDH\ control}) - (Ct_{target\ gene\ test\ condition} - Ct_{GAPDH\ test\ condition})}$ ). From this formula, for the test compared with the control condition, a  $\Delta\Delta Ct$  over 1 indicated an increase of a target gene expression and a  $\Delta\Delta Ct$  of less than 1 indicated a lower expression of the target gene relative to the housekeeping gene GAPDH.

RT-PCR primers used were: GAPDH, forward: 5'-CC CATCACCATCTCCAGGAGCG-3' and reverse 5'-CA TGCCAGTGAGCTTCCCGITCA-3' (476 bp product); EGFR, forward: 5'-TCTCAGCAACATGTCGATGGA-3' and reverse 5'- GCACTGTATGCACTCAGAGTT-3' (92 bp product), VEGF-D, forward: 5'-GTATGGACTCTCGCTCAGCAT-3' and reverse: 5'-AGGCTCTCTCATGCAACAG-3' (225 bp product), VEGFR3, forward and reverse; QuantiTect Primer Assay: FLT4 (VEGFR3, 127 bp product, Qiagen). Cycle conditions of the one-step real time LightCycler RT-PCRs were as follows: for reverse transcription, 20 min at 50°C. The subsequent PCR reaction was characterized by: initial denaturation (15 min at 95°C) followed by the respective number of cycles (GAPDH: 25, VEGF-D: 35, VEGFR3: 40, EGFR: 35) of: denaturation (15 s at 94°C), annealing (25 s: GAPDH; 63°C, VEGF-D; 61°C, VEGFR3; 55°C, EGFR; 61°C) and elongation (35 s at 72°C). After the last cycle, a melting curve was plotted to confirm the amplification of a single specific RT-PCR product.

### **Western blotting**

SW480 and SW620 cells were plated at  $2.5 \times 10^6$  cells/well in 6 wells. Cells were harvested and lysed in RIPA buffer<sup>[50]</sup>. For EGFR, VEGF-D, VEGFR3 and α-tubulin analysis, 50 µg of cleared lysates were separated on 10.0% sodium dodecyl sulphatepolyacrylamide gels, blotted to nitrocellulose transfer membranes (Schleicher & Schuell) and blocked for 1 h in 5% non-fat dry milk, incubated with a specific primary antibody: antihuman EGFR sc-03, antihuman VEGF-D sc-13085, VEGFR3 sc-321 (Santa Cruz Biotechnology Inc: all antibodies were diluted 1:200 in 5% bovine serum albumin) or anti-α-tubulin (Sigma: diluted 1:10000 in 5% non-fat dry milk). Detection of bound antibody was performed using a peroxidase-conjugated secondary goat anti-rabbit antibody (sc-2030; Santa Cruz Biotechnology Inc.) diluted 1:2000 in 5% non-fat dry milk and an ECL chemiluminescence detection kit (Perkin Elmer).

### **Animals**

Female NOD/SCID -/- mice were purchased from the central animal facility (ZVTE, University of Mainz, Germany). The mice were maintained in a laminar airflow cabinet under pathogen-free conditions and used at 7-10 wk of age. Mice were housed in microisolator cages with laboratory chow.

### **Treatment of subcutaneous colorectal carcinoma xenografts**

Colon carcinoma tumours were established as xenografts

by injecting  $1 \times 10^7$  SW480 cells, mixed in PBS : medium (1:1), subcutaneously into the left flank of eight NOD/SCID -/- mice. Ten days after cell injection, all mice bore a tumour with a minimum diameter of 4 mm. The mice were randomized into two groups of four animals. They were treated with either saline or cetuximab at 1 mg/dose every three days. Cetuximab and the saline placebo were administered intraperitoneally at a constant volume of 0.5 mL/injection. Treated animals were checked daily. After 5 wk of treatment, tumours were isolated and processed with a disperger to enhance subsequent RNA isolation with the RNeasy Kit (Qiagen, Hilden, Germany).

### Statistical analysis

The association of staining intensity with clinicopathological patterns was assessed with the  $\chi^2$  test and with the unpaired Student *t*-test, where appropriate. Differences in migration were evaluated with the unpaired Student's *t*-test. Survival rates were visualized applying the Kaplan-Meier curves and log rank test. *In vitro* and *in vivo* real time gene expression medians were compared using Mann-Whitney *U* test.  $P < 0.05$  was considered significant and  $P < 0.001$  highly significant in all statistical analyses.

## RESULTS

### Patient profiles and tumour characteristics

Disease characteristics for the group of 108 patients selected are representative of CRC patient populations in industrialized countries, except for a lower percentage of T3 cancers (Table 1). The mean age of the patient cohort at the time of primary surgical intervention was 63.8 years (SD, 10.45 years). Tumour stage was distributed as follows: UICC stage I was found in 14%, stage III in approximately a fifth and stages II, and IV, each in approximately a third of all patients (Table 1). The most common histopathological grading was pG2, which was reported for nearly 80% of cases. Approximately half of all patients had positive lymph node status. The UICC stage dependent survival rates after 3 years were 100% for stage I, 92% for stage II, 78% for stage III and 44% for stage IV, which were similar to those reported for other large CRC population series<sup>[51]</sup>. Expression was studied in specimens taken from all 108 CRC patients.

### Expression of EGFR, VEGF-C and VEGF-D in CRC specimens

The expression of EGFR, which could be assessed by IHC staining for all 108 samples, exhibited a predominantly membranous subcellular localization. In a few specimens, an additional weak cytoplasmic localization was found, which was not scored as indicative of positive staining for EGFR (Figure 1 A-D). EGFR expression in CRC specimens was distributed as follows: in 59 cases (54.6%), the specimen showed no positive staining for EGFR, while in 49 patients (45.4%) the specimen showed a positive membranous staining, including 31 patients (28.7%) where staining

**Table 1 Baseline characteristics of the colorectal cancer patients ( $n = 108$ )**

	<i>n</i>	%

pN 1	21	19.4
pN 2	34	31.5

was weakly positive and 9 patients (8.3%) each with moderately or strongly positive staining. No statistically significant correlation was identified between EGFR staining and the UICC stage, grading, tumour invasion or lymph node metastasis (Table 2). Comparison with the histopathological grading of the tumour cells however showed a trend towards the expression of EGFR in less well differentiated lesions. Thus, the prognostic value of IHC-determined EGFR expression status in relation to the prediction of poor survival<sup>[52-56]</sup> could not be confirmed in the current CRC population, again arguing to successfully integrate the anti-EGFR monoclonal antibody cetuximab into therapeutic regimens for patients whose tumours do not appear to express EGFR<sup>[57,58]</sup>.

The staining for VEGF-C and VEGF-D was predominantly cytoplasmic (Figure 1 E-H and I-L, respectively). VEGF-C expression could be assessed in 102 specimens, with 74 specimens (68.5%) staining positive for VEGF-C and 28 specimens (25.9%) being negative. Twenty-five percent of the G1 tumours ( $n = 4$ ) were positive, while 70.6% of G2 tumours, 70.6% of G3 tumours, and 50.0% of G4 graded tumours were positive for VEGF-C. Thus even if statistically significant (Table 2) but only 4 patients were G1, a clinical clear cut comparison of well versus not well differentiated tumours may not be done. However, another finding was the borderline significant correlation between tumour invasion and VEGF-C expression ( $P = 0.050$ ). Only 11 (55.0%) of the pT1 and pT2 graded tumours were positive for VEGF-C compared with 63 (76.8%) of the tumours with deeper invasion. No statistically significant correlation was apparent with the other clinicopathological parameters including UICC stage and lymph node status (Table 2).

VEGF-D expression was analyzed in 104 available specimens, with 70 (64.8%) staining positive and 34 (31.5%) staining negative. Interestingly, VEGF-D staining was associated with UICC tumour stage ( $P = 0.048$ ). Nine of 14 (64.3%) specimens from patients with UICC stage I tumours stained positive, while 27 (77.1%) of the UICC stage II, 9 (42.9%) of the UICC stage III and 25 (73.5%) of the UICC stage IV tumours stained positive for VEGF-D. No significant association

<sup>1</sup>Percentages relate to number of positive tumours out of total number of cases in the subclass.

was found with several other parameters including grading, tumour invasion and pN status (Table 2). Again, the comparative analyses of the combined VEGF-C and VEGF-D co-expression with well *versus* not well differentiated tumours were statistically significant ( $P = 0.022$ ), but possibly not clinically clear cut significant due to the low patient number analysed.

However, when VEGF-D staining was analyzed in relation to the number of tumour positive lymph nodes, there was a statistically significant overall association between the number of lymph node metastases and VEGF-D positivity of the primary tumour ( $P = 0.025$ ). The patient cohort was stratified into patients with no lymph node metastases ( $n = 51$ ), with up to 6 lymph node metastases ( $n = 36$ ), and with more than 6 lymph node metastases ( $n = 17$ ). Among those from patients with up to 6 lymph node metastases, 18 (50.0%) stained positive for VEGF-D, and among the patients with more than 6 lymph node metastases, 14 (82.4%) stained positive for VEGF-D.

When VEGF-D staining was analyzed in relation to the survival of lymph node positive patients, there was a trend ( $P = 0.067$ ) between the VEGF-D positive and negative groups (Figure 2). The patients with lymph node metastases whose tumours were VEGF-D positive had a 30% lower chance of survival at 36 mo in comparison to the patients with VEGF-D negative tumours. Kaplan Meier analysis also indicated highly statistically significant correlations between the number of lymph node metastases and UICC stage and overall survival (in both cases, log rank test  $P < 0.001$ ; Figure 2). It was also noteworthy that in several specimens, VEGF-C and VEGF-D were strongly expressed at the tumour invasion front (data not shown). Consistently, the further comparison of VEGF-C and VEGF-D combined staining profiles in relation to survival, double VEGF-C and VEGF-D positive patients had a trend to an unfavorable 5 years prognosis compared

to the negative group (log rank test  $P = 0.2$ ), whereas triple EGFR, VEGF-C and VEGF-D positivity did not influence survival in these two cohorts (data not shown).

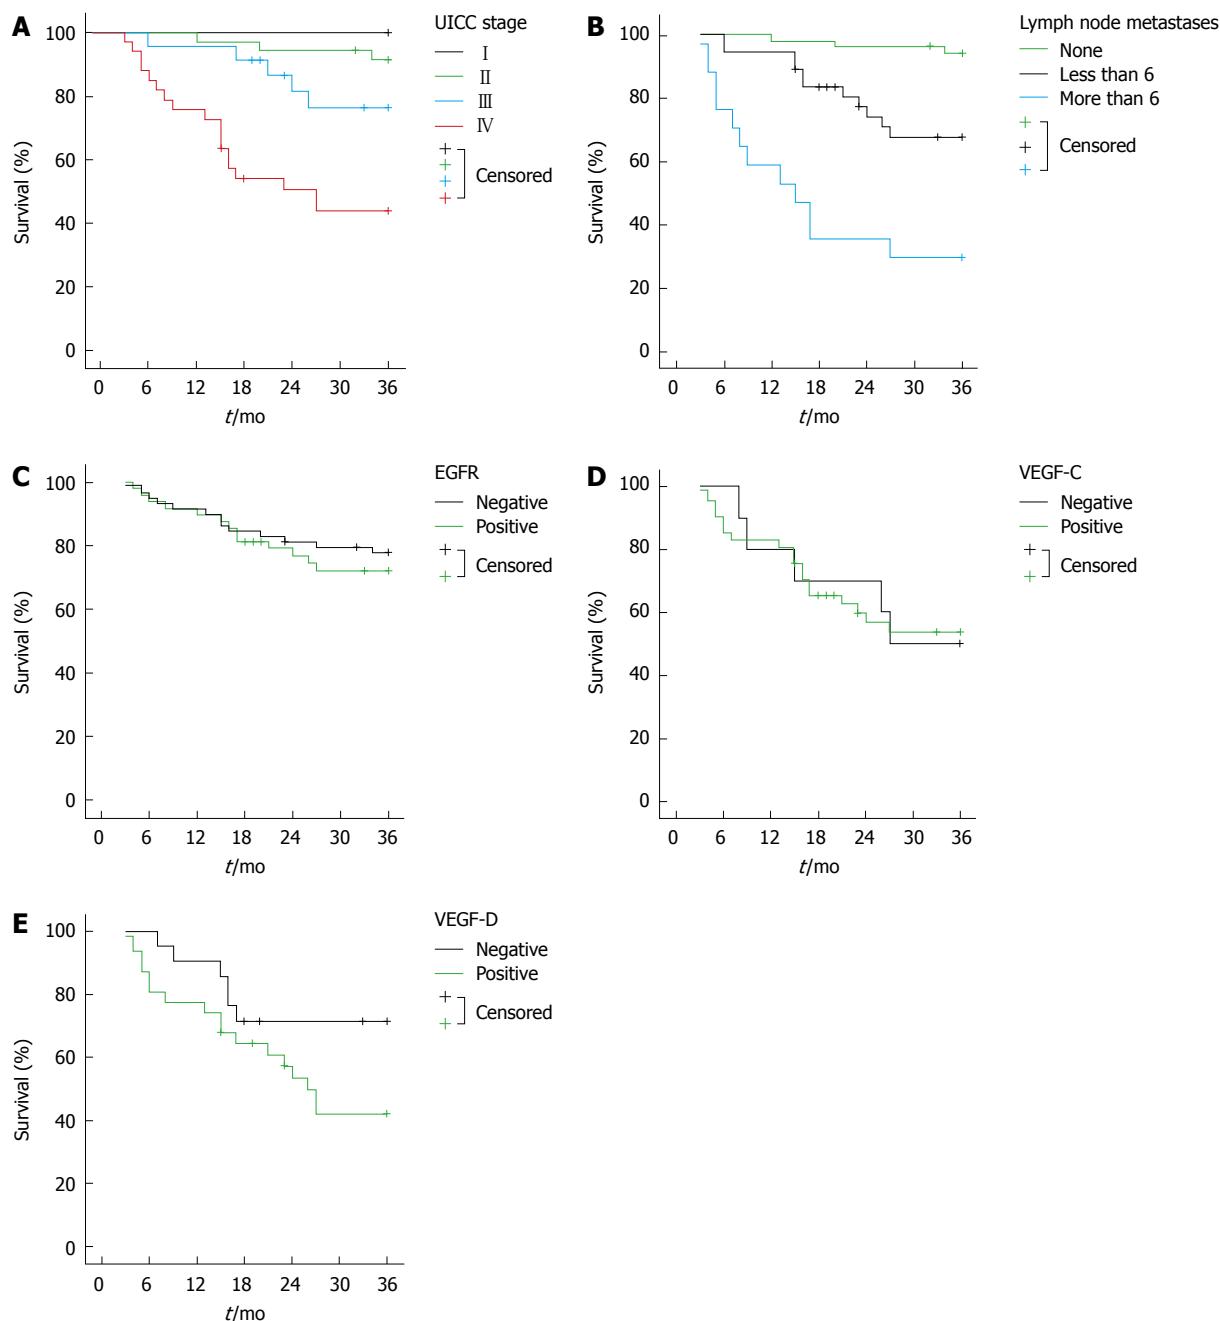

#### **EGFR, VEGF-C, VEGF-D and VEGFR3 expression in colorectal carcinoma cell lines**

Real time RT-PCR assays and Western blotting were used to measure transcript and protein levels in experimental analyses. Whereas VEGF-D transcripts and protein were expressed at moderate levels in both SW480 and SW620 CRC cell lines, a similar analysis of expression of EGFR and VEGFR3 yielded varying results. EGFR mRNA and protein levels were high in SW480 and markedly lower in SW620 cells. Though mRNA levels of VEGFR3 were high in SW480 and moderate in SW620, the protein levels of VEGFR3 were also higher in SW480 than in SW620 cells (Figure 3).

#### **Effect of cetuximab in CRC cell lines and a xenograft model**

In order to analyze the effect of cetuximab on VEGF-D and VEGFR3 transcription, SW480 cells were treated for 24 h with either EGF or cetuximab alone or a combination of these two agents. Incubation of the cells with EGF was associated with a marked relative increase in VEGF-D and VEGFR3 mRNA levels compared with control (0.5% FCS) values. Conversely, incubation with EGF and cetuximab simultaneously resulted in a highly statistically significant ( $P = 0.004$ ) suppression of this inductive effect, for both genes (Figure 4A). There were similar highly statistically significant ( $P = 0.004$ ) differences in the levels of VEGF-D and VEGFR3 expression in the EGF *versus* cetuximab treated cells. Incubation with cetuximab alone also resulted in a decreased level of VEGF-D mRNA compared to the control. This effect was not seen for VEGFR3. In the EGFR negative cell line SW620 no such effects were detectable (data not shown).

In the *in vivo* xenograft model, treatment with either

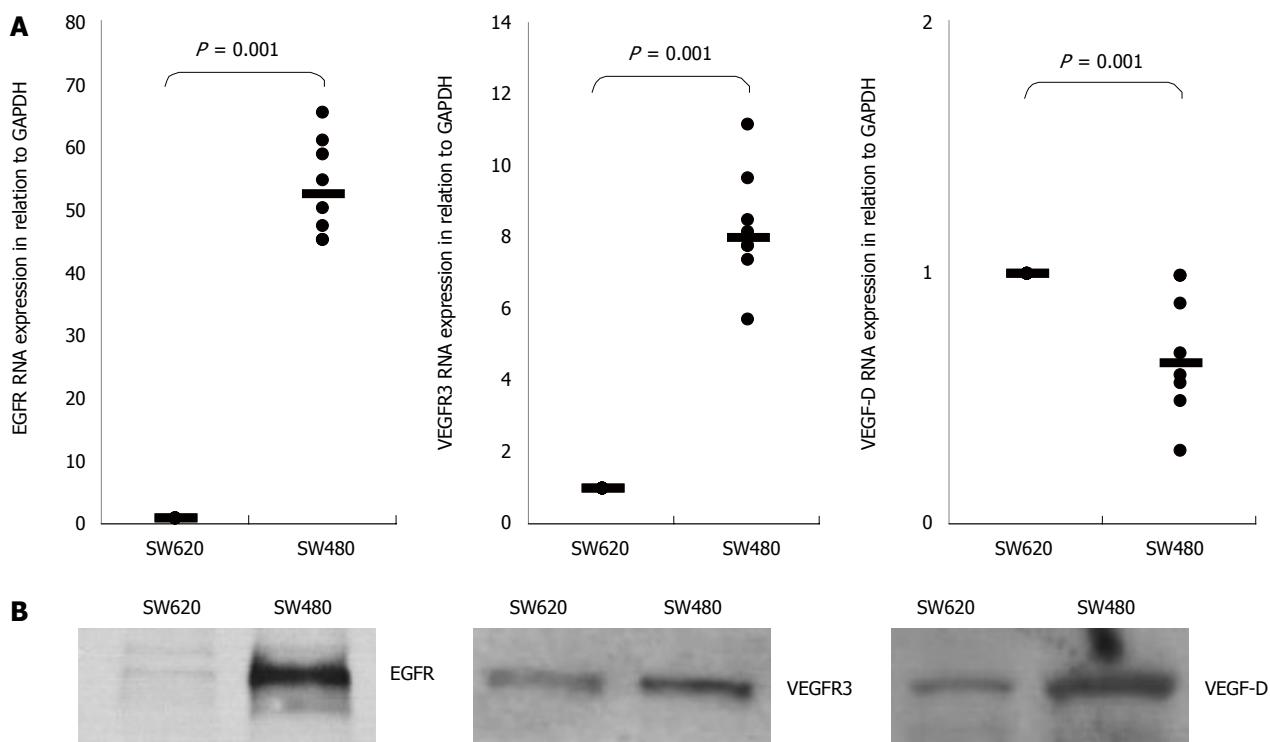

**Figure 2** Kaplan Meier survival analyses of colorectal cancer subgroups in relation to baseline disease characteristics and EGFR, VEGF-C or VEGF-D expression. **A-C:** Survival analysis for all patients in relation to UICC stage ( $P < 0.001$ ), the number of metastases ( $P < 0.001$ ) and EGFR staining ( $P = 0.546$ ), respectively; **D** and **E:** The 3 years survival in patients with lymph node metastasis in relation, respectively, to the expression of VEGF-C ( $P = 0.967$ ) and VEGF-D ( $P = 0.067$ ).

cetuximab or saline placebo was administered over a period of 28 d. After this period, the mRNA level of VEGF-D was highly statistically significantly ( $P = 0.004$ ) reduced in the tumour tissue of mice which had received cetuximab compared with those that had received saline. No such effect could be detected for VEGFR3 ( $P = 0.577$ , Figure 4B).

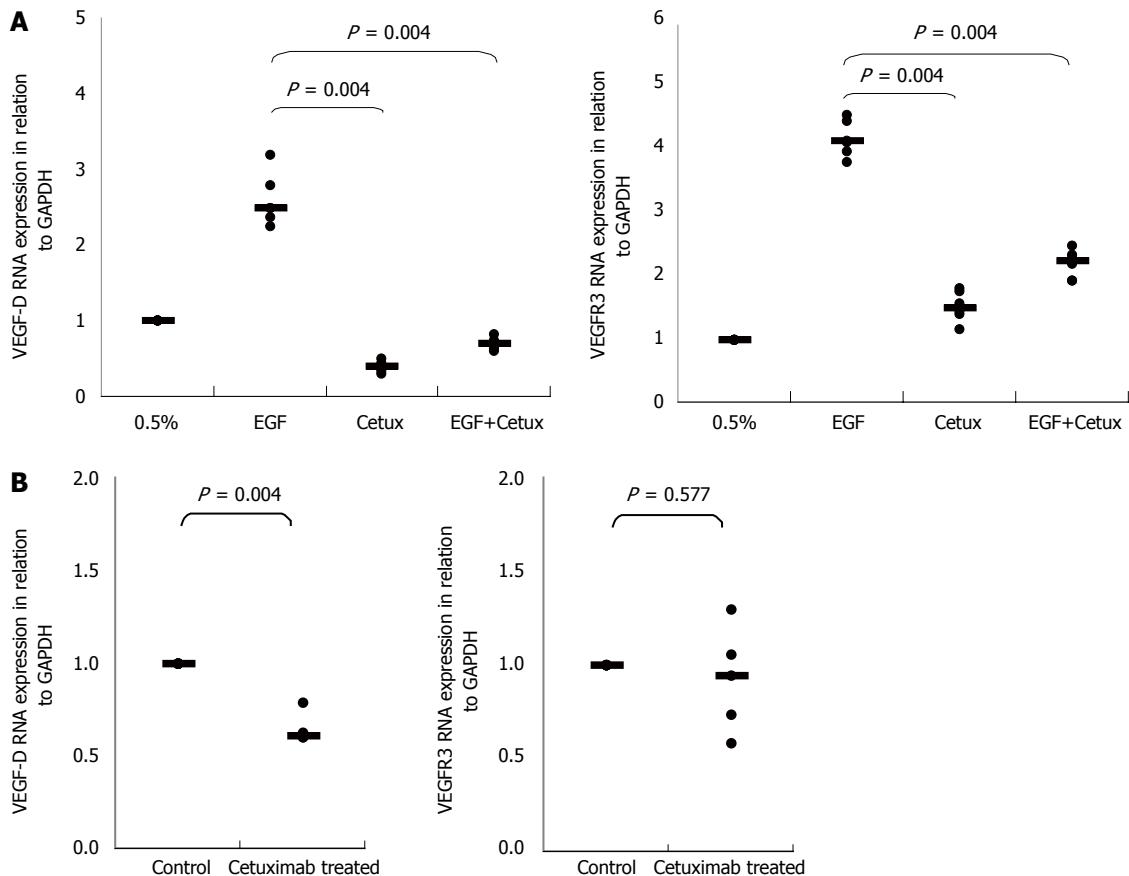

## DISCUSSION

A significant proportion of patients with advanced but non-metastatic CRC which has seemingly been curatively resected experience disease recurrence<sup>[52,53]</sup>. In order to identify high-risk patients at an early stage, it

is important to understand the molecular mechanisms behind the behaviour of these tumour types<sup>[54,55]</sup>. Herein, activation of EGFR-mediated signalling cascades has been identified in promotion of cell proliferation, malignant transformation, angiogenesis and metastatic dissemination<sup>[54,56]</sup>. In addition, lymphangiogenesis, mediated through tumour-derived VEGF-C and VEGF-D, gained attention in relation to the facilitation of lymph node metastasis and tumour spread<sup>[37,39,40,57]</sup>. Recent data from clinical studies suggest that VEGF-C and/or VEGF-D expression in tumour tissue might be prognostic factors for lymphatic spread, tumour invasion and/or poor prognosis in a variety of cancers including gastric, colorectal, endometrial and breast<sup>[37,39,40,45,46]</sup>.

**Figure 3** Quantitative EGFR, VEGFR3 and VEGF-D mRNA expression (A) and Western blot analysis (B) of untreated SW480 and SW620. The  $\alpha$ -tubulin signal served as a control to confirm the loading of equivalent amounts of protein per track.

**Figure 4** Effect of cetuximab on (A) the expression of VEGF-D and VEGFR3 in SW480 cells cultured in the presence and absence of EGF and (B) the *in vivo* levels of VEGF-D and VEGFR3 in a NOD/SCID mouse xenograft model.

To our knowledge, this is the first study analyzing concurrently the expression profiles of EGFR and the

lymphangiogenic ligands VEGF-C and VEGF-D in a large series of human CRC specimens. With a relatively

low patient numbers used for well differentiated tumors, the statistical correlations of this current study between the histopathological grading and VEGF-C, but not VEGF-D expression levels may only be assumed to hold true for a larger clinical setting. However most interestingly, the comparison of the expression profile of VEGF-D in the colorectal tumour series with clinicopathological parameters revealed a significant association between VEGF-D and the number of lymph node metastasis. Moreover, we show with a clear trend that patients in a pN+ setting and positive VEGF-D expression define a subgroup with shorter survival. These data are consistent with previous analyses in a range of other cancers. Furthermore, they are in agreement with the established clinical observation that lymphatic dissemination in particular the number of metastatic lymph nodes is closely related to the clinical outcome/prognosis of patients with CRC<sup>[59]</sup>.

Signal transduction *via* the ligands VEGF-C and -D and VEGFR3 triggers lymphatic endothelial cell growth and migration<sup>[34-36]</sup>. Thus, it is noteworthy that in our specimens VEGF-C and VEGF-D were also strongly expressed at the tumour invasion front. We have previously shown that VEGFR3 is expressed in 67% of primary gastric cancers<sup>[60]</sup>. Data on animal models suggest that VEGF-C/VEGF-D/VEGFR3 signalling can promote tumour lymphangiogenesis and the metastatic spread of tumour cells<sup>[35,61-63]</sup>. Indeed, it has been suggested that primary tumours may prepare their future metastasis site by producing lymphangiogenic factors that mediate their efficient transport to the sentinel node<sup>[64]</sup>. Data from Jia *et al* suggested that VEGF-C expression may induce lymphangiogenesis in CRC and as a result, tumour cells could perhaps enter lymphatic vessels more easily<sup>[57,65]</sup>. These processes could be blocked by inhibition of VEGFR3 signalling by systemic delivery of a soluble VEGFR3-immunoglobulin fusion protein. However, lymph node metastasis was not suppressed if such treatment was started later, after tumour cells had already disseminated, suggesting that tumour cell entry into the lymphatic vessels is a key step during the metastatic process<sup>[66]</sup>. Consistently with these findings, our double VEGF-C and VEGF-D positive patients had unfavorable survival prognosis compared to the negative groups in the Kaplan-Meier analysis, again arguing for a large analysis of these markers in colorectal cancer patients with chemotherapy and/or cetuximab-based adjuvant therapy.

We further explored whether EGFR blockade influenced the expression of VEGF-D and VEGFR3 using *in vitro* and *in vivo* models. While treatment of the EGFR-expressing CRC cell line SW480 with EGF resulted in an increase in the transcript levels of both genes, there was a highly significant reduction in those induced mRNA levels when cetuximab was added. These data suggest that cetuximab, by blocking EGFR-associated signalling, might act as an inhibitor of VEGF-D expression, and consequently, of lymphangiogenesis. In contrast with an earlier report of another EGFR-specific antibody (ICR62)

stimulating VEGF-D<sup>[67]</sup>, cetuximab blocks additionally the production of pro-angiogenic factors such as VEGF and IL-8<sup>[12-14,68-70]</sup>. Although complete inhibition of VEGF-D expression was not achieved in our model systems the effect of cetuximab was nevertheless dramatic. In a therapeutic context, cetuximab, might also therefore induce a clinically-relevant reduction in tumour lymphangiogenesis. Given that the induction of lymphangiogenesis appears to be one of the early events in the progression of cancer<sup>[57]</sup>, a therapy targeting such processes would have a clear role in (neo-)adjuvant chemopreventive settings. Further preclinical and clinical studies are therefore warranted to explore these issues.

In conclusion, immunohistochemical staining of VEGF-D coupled with the examination of lymph node status may aid in the definition of patient subpopulations with more aggressive tumours. A cetuximab-based adjuvant therapy might then improve overall survival in these patients. Still, the link between prognostic markers and response to a certain treatment remains elusive. However, the new data in the current paper suggest that the inhibition of VEGF-D signalling might contribute to the widely demonstrated clinical activity of cetuximab in the treatment of CRC.

## ACKNOWLEDGMENTS

The authors thank Merck KGaA, Darmstadt for an educational grant, as well as providing the EGFR DAKO kits and the EGFR antibody cetuximab for the experiments. The authors would also like to thank all colleagues and assistants of the animal core facility of Mainz University as well Dr. Andreas Teufel for administrative help with the xenograft models. The results of the manuscript are part of the MD and PhD theses of Christian Frings and Annett Mueller, respectively.

## COMMENTS

### Background

Since the use of new biologic agents, such as epidermal growth factor receptor (EGFR)-targeted agents may improve our current therapeutic approaches for advanced human colorectal cancer (CRC) which seeds quite often metastatic tumor cells in the lymphatic glands, is of high interest to analyse prognostic and predictive expression markers for lymphangiogenic tumor spread, particularly in view of the possible modulation of these factors by the EGFR-targeted agents cetuximab and panitumumab.

### Research frontiers

Our clinical human colon cancer specimens displayed these markers EGFR, vascular endothelial growth factor (VEGF)-C and VEGF-D expression. Strong expression levels of VEGF-D were associated with lymph node metastasis and linked to decreased survival in lymph node-positive colon cancer patients. In tumor models, the new antibody for EGFR blockade cetuximab resulted in a highly significant decrease of VEGF-D expression.

### Innovations and breakthroughs

The lymphangiogenic marker VEGF-D thus associated with lymph node metastasis and is linked to a decreased survival in lymph node-positive patients. The EGFR blockade with cetuximab resulted in a significant decrease of VEGF-D expression, particularly favouring these EGFR-targeted agents as treatment options of lymph node-positive colorectal cancer.

### Applications

Patients with advanced lymph node-positive colorectal cancer might better be

selected as well as better be treated in the near future.

#### Peer review

Immunohistochemical staining of VEGF-D coupled with the examination of lymph node status may define patient subpopulations of with more aggressive colorectal cancers. Since the EGFR blockade with cetuximab resulted in a significant decrease of VEGF-D, EGFR-targeted agents may improve the overall survival, particularly as a new treatment option of lymph node-positive colorectal cancer.

**METHODS:** Five patients each with ALF and ACLF in grade 3 or 4 hepatic encephalopathy and with clinical signs of raised intracranial pressure were studied along with five healthy volunteers. After baseline MRI, an intravenous bolus of 20% mannitol solution was given over 10 min in controls as well as in patients with ALF and ACLF. Repeat MRI for the same position was acquired 30 min after completing the mannitol injection.

**RESULTS:** No statistically significant difference was observed between controls and patients with ALF and ACLF in metabolite ratios, DTI metrics and brain volume or CSF volume following 45 min of mannitol infusion. There was no change in clinical status at the end of post-mannitol imaging.

**CONCLUSION:** The osmotic effect of mannitol did not result in significant reduction of brain water content, alteration in metabolite ratios or any change in the clinical status of these patients during or within 45 min of mannitol infusion.

## Abstract

**AIM:** To evaluate the effect of an intravenous bolus of mannitol in altering brain metabolites, brain water content, brain parenchyma volume, cerebrospinal fluid (CSF) volume and clinical signs in controls and in patients with acute liver failure (ALF) and acute-on-chronic liver failure (ACLF), by comparing changes in conventional magnetic resonance imaging (MRI), *in vivo* proton magnetic resonance spectroscopy (PMRS) and diffusion tensor imaging (DTI) before and after its infusion.

## INTRODUCTION

Liver failure is a life-threatening condition following

severe hepatocellular injury that affects many other organ systems, most notably the brain and kidneys<sup>[1]</sup>. Liver failure may develop in the absence of pre-existing liver disease i.e. acute liver failure (ALF) or when an acute insult is superimposed on a chronic liver disorder [acute-on-chronic liver failure (ACLF)<sup>[2,3]</sup>]. Cerebral edema leading to raised intracranial pressure (ICP) is known to be a major complication in patients with ALF<sup>[4]</sup>. The pathophysiological mechanisms underlying development of cerebral edema and ICP in ALF are multifactorial<sup>[5,6]</sup>. Though the occurrence and nature of cerebral edema in ACLF is not well studied, anecdotal evidence from patients with ACLF suggests that hyponatremia is implicit in the progression to cerebral edema<sup>[7]</sup>.

Presently, osmotic therapy is widely used to control cerebral edema and raised ICP. Mannitol is the most frequently used osmotically active agent in clinical practice<sup>[8]</sup>. It acts by increasing blood osmolarity, thereby establishing a concentration gradient across the intact blood-brain barrier (BBB) that forces movement of water from the edematous brain tissue to the intravascular space<sup>[9]</sup>. In controlled trials, mannitol has been shown to decrease the raised ICP level in ALF patients and is associated with improved survival<sup>[10]</sup>. Other experimental studies have suggested that mannitol infusion reduces the water content and volume of normal, but not of infarcted brain tissue<sup>[11,12]</sup>.

Noninvasive imaging techniques such as magnetic resonance imaging (MRI) and computed tomography (CT) have been used to evaluate the brain water content changes after mannitol administration. Increased brain density of both edematous peritumoral white matter as well as normal gray and white matter on CT scans has been attributed to mannitol induced reduction in brain water content in patients with cerebral tumors<sup>[13]</sup>. Similarly, MR scans in patients with cerebral tumors detect reduced longitudinal relaxation time (T1) in edematous peritumoral white matter after mannitol infusion, which correlates with decrease in water content<sup>[14]</sup>.

Newer MR imaging techniques such as proton magnetic resonance spectroscopy (PMRS) and diffusion tensor imaging (DTI) are considered to be more sensitive and accurate in assessing the changes in brain metabolites and brain water content within the intracellular and extracellular compartments<sup>[15]</sup>. Changes in brain osmolytes detected by the PMRS are indirect or proxy evidence for cerebral edema. PMRS changes (i.e. reduction of choline, myoinositol and N-acetyl aspartate peaks and increase in Gln-Glx peak) are well-known in liver cirrhosis and chronic liver failure, conditions where there is sufficient time for organic osmolytes to compensate for increased intracellular osmolarity caused by astrocytic accumulation of glutamine<sup>[16]</sup>. PMRS changes in ALF are not well documented and are unlikely to be so clear-cut since rapid onset of the syndrome does not allow sufficient time for compensatory mechanisms to counterbalance rapid changes in osmolarity due to rapid and massive accumulation of astrocytic glutamine in this condition<sup>[17]</sup>. In patients with hyponatremia,

PMRS has revealed significantly lower levels of the organic osmolyte myoinositol which would normally compensate for the rising intracellular glutamine seen with acute liver injury<sup>[18]</sup>.

DTI is a technique that is able to reveal and quantify the direction of water mobility in tissues, which in white matter is normally anisotropic because of axonal fibers running in parallel. The two commonly used DTI metrics are fractional anisotropy (FA) and mean diffusivity (MD). FA reflects the degree of anisotropy due to the hindrance of water molecules mobility caused by various physical barriers. MD is a measure of tissue water diffusivity and is dependent upon interactions between water molecules and the structural components at cellular and subcellular level<sup>[19]</sup>.

To the best of our knowledge, this is the first study evaluating the effect of mannitol on brain water content using DTI and PMRS in controls as well as in patients with ALF and ACLF. We hypothesize that the effect of bolus infusion of mannitol in reducing brain water content will be reflected by changes measured by conventional MRI, *in-vivo* PMRS and DTI. Since the peak effect of a single bolus in mobilizing fluid from tissues to the intravascular compartment according to the osmotic gradient is observed at about 45 min after infusion<sup>[14]</sup>, it was decided to evaluate the effect of intravenous bolus of mannitol during the baseline MRI scan (pre-mannitol study) and after the completion of mannitol administration (post-mannitol study). The parameters compared between controls and patients, before and after mannitol infusion were (1) relative metabolite alterations in the right parietal region using *in-vivo* PMRS, (2) brain water content using DTI metrics, and (3) changes in the brain parenchyma volume as well as cerebrospinal fluid (CSF) volume. Changes were further correlated with the clinical outcome.

## MATERIALS AND METHODS

### **Patients**

In this study, we have included 5 ALF patients (3 males, 2 females; range, 14–46 years), and 5 ACLF patients (4 males, 1 female; range, 24–48 years). The patients with diagnosis of ALF and ACLF were admitted to the Gastroenterology intensive care ward and those who were clinically stable underwent imaging protocol. ALF was diagnosed in the presence of jaundice and encephalopathy with jaundice-to-encephalopathy interval being < 4 wk, and in the absence of clinical and radiological evidence of cirrhosis<sup>[20]</sup>. ACLF was diagnosed when there was acute hepatitis defined by abrupt (<4 wk) rise in serum bilirubin to  $\geq 10$  mg/dL and ALT to  $\geq 5$  times of normal ( $\geq 200$  IU/L) on a patient with clinical, biochemical or ultrasonographic evidence of chronic liver disease (ascites, nodular and irregular liver, patent portal vein and portosystemic collaterals). Upper gastrointestinal endoscopy was done in the patients who recovered from encephalopathy to look for portal hypertension (esophageal varices  $\geq$  grade II) as evidence of chronic liver disease. The

etiology, baseline clinical profile and biochemical profile of ALF has been shown in Tables 1 and 2, respectively. All the patients had acute viral hepatitis; none of them had drug induced hepatitis. The etiology of acute and chronic liver disease, baseline clinical profile and biochemical profile in ACLF patients has been shown in Tables 3 and 4, respectively. None of these patients had history of prior neurological illness. Patients with history of significant alcohol intake over the previous six months were excluded since de-compensation could have been related to recent alcohol intake. Patients with ultrasonographic evidence of a mass lesion in the liver (hepatocellular carcinoma), portal vein thrombosis or biliary obstruction, or suspected sepsis at presentation were excluded, since the liver decompensation could have been related to these factors. Serum specimens were obtained from the study subjects and stored at -70°C until analysis. Etiological tests for cause of both acute hepatitis and chronic liver disease were done in patients with ALF and ACLF. These included IgM anti-hepatitis E virus, IgM anti-Hepatitis A virus (HAV), HBsAg, IgM anti-HAV, anti-HCV, antinuclear antibodies, anti smooth muscle antibodies, anti LKM, anti-mitochondrial antibodies, serum ferritin, and Wilson's disease work-up.

### **Healthy controls**

Five healthy controls (3 males, 2 females; range, 18-50 years) were also included in this study, who had no history of neurological or psychiatric illness, alcohol or drug abuse, and head injury or liver disease.

### **Management**

Close monitoring and meticulous optimization of all metabolic derangements identified were done in all patients. Oxygenation was continuously monitored in each patient using pulse oximetry. Blood glucose level was monitored 6-hourly using a glucometer. Vital parameters, neurologic status and signs of raised ICP were checked 4-hourly. Raised ICP was diagnosed in presence of decerebrate posturing alone or, when two out of four of the following criteria were met, i.e. hypertension (supine blood pressure > 150/90 mmHg), bradycardia (pulse rate < 10/min for the expected pulse rate for the given body temperature), pupillary changes and neurogenic hyperventilation (hyperventilation in absence of metabolic or respiratory cause)<sup>[21]</sup>. ICP recordings were not done in any of these patients. However, the diagnosis of raised ICP was based on the clinical signs, imaging features of cytotoxic and interstitial edema on DTI. Sedation or muscle paralyzing agents were not used. We did not treat seizures prophylactically nor looked for subclinical seizures as prophylactic therapy for seizures as well as monitoring by EEG is not recommended in the management of ALF<sup>[22,23]</sup>. Arterial ammonia was measured in heparinized plasma by enzymatic method (RANDOX lab Ltd, UK) immediately before or within 6 h of imaging. Prior to infusion of mannitol infusion any metabolic derangement identified was corrected and all patients had been receiving standard anti-coma measures as well

as other supportive measures such as head end elevation, oxygen supplementation, dextrose infusion to maintain normoglycemia. We did not hyperventilate our patients because this is not an established method for decreasing raised ICP, and our second aim was to see the effect of mannitol so we tried to avoid all other methods of decreasing ICP mentioned in literature<sup>[23,24]</sup>.

An intravenous bolus of 20% mannitol solution (1 g/kg body weight) was given in controls as well as patients with ALF and ACLF after a baseline MRI scan (pre-mannitol study) for 10 min. After 30 min of mannitol injection, repeat MRI (post-mannitol study) for the same position was acquired. In post-mannitol study, both conventional T2-weighted and T1-weighted spin-echo (SE) imaging took a total time of 2.14 min and 1.34 min respectively, *in vivo* PMRS was done in 3.45 min and DTI data was acquired after 9.36 min and therefore the effect of mannitol was seen between 30-46 min (including time). The head was strapped to prevent any artifacts related to motion. The study protocol was approved by the institutional Ethics Committee and written informed consent was obtained from each subject or the nearest kin after explaining the nature of investigation to be carried out.

### **MRI protocol**

Imaging was performed on a 1.5 tesla MRI scanner (Signa Lx Echo speed plus, General Electric Healthcare Technologies, Milwaukee, WI) equipped with an actively-shielded whole body magnetic field gradient set (allowing up to 33 mT/m) equipped with a quadrature birdcage receive and transmit radio frequency head coil. The routine imaging studies included the following: fast spin echo (FSE) T2-weighted images with repetition time (TR)/echo time (TE)/number of excitations (NEX) = 6000 ms/85 ms/4, and T1-weighted SE images with TR/TE/NEX = 1000 ms/14 ms/2. A total of 36 contiguous 3 mm thick axial sections were acquired with a 240 mm × 240 mm field of view (FOV) and image matrix of 256 × 256.

### **In vivo proton MR spectroscopy**

The controls, ALF and ACLF patients underwent *in vivo* PMRS during the pre-mannitol study and post-mannitol study after the completion of intravenous mannitol administration to determine the changes in the brain metabolites. Spectra were obtained by using a water suppressed localized single voxel SE sequence with TR/TE = 3000 ms/35 ms. A voxel of 2 cm × 2 cm × 2 cm was located mainly in the right parietal region of the brain<sup>[25]</sup> in all the cases, containing part of white matter and gray matter (putamen and caudate nucleus) (Figure 1A). After global shimming, voxel shimming was performed, and a full width at half maximum of 4-6 Hz was achieved in all the cases. For evaluation and quantification of all individual spectra, the LC-Model software package (Version 6.0; Stephen Provencher, Ontario, Canada) was used for processing the MRS data. The process of determining peak intensities of the different metabolites is described in detail elsewhere<sup>[26]</sup>.

The metabolite ratios of N-acetylaspartate (NAA), choline (Cho), glutamine (Gln), glutamine/glutamate (Glx), and myoinositol (mI) were calculated with respect to creatine (Cr).

### **DTI protocol**

DTI data were acquired using a single-shot echo-planar dual SE sequence with ramp sampling<sup>[27]</sup>. The diffusion-weighted acquisition parameters were: b-factor = 0 s/mm<sup>2</sup>, 1000 s/mm<sup>2</sup>, slice thickness = 3 mm with no gap, number of slices = 34-38, FOV = 240 mm × 240 mm, TR = 8 s, TE = 100 ms and NEX = 8. The acquisition matrix was 128 × 80 and the homodyne algorithm was used to construct the  $\kappa$ -space data to 128 × 128 and zero-filled to generate an image matrix of 256 × 256. The diffusion tensor encoding used was the balanced rotationally invariant<sup>[28]</sup> dodecahedral scheme with 10 uniformly distributed directions over the unit hemisphere.

### **DTI data processing and analysis**

The magnitude averaged data were transferred to a workstation for further analysis. In general, the DTI data analysis involves three major steps: pre-processing, processing, and post-processing.

### **Data pre-processing**

The data were distortion corrected for shear, scale, rotation, and translation using the Automated Image and Registration package<sup>[29]</sup>. The removal of scalp to isolate the brain in the collected raw images was done, in all the cases, by an automated stripping procedure<sup>[30]</sup>. Subsequent DTI processing did not require any filtering, as justified by the absence of unprocessed voxels.

### **Data processing**

The distortion corrected data were then interpolated to attain isotropic voxels and decoded to obtain the tensor field for each voxel. The tensor field data were then diagonalized using the analytical diagonalization method<sup>[31]</sup> to obtain the eigenvalues ( $\lambda_1$ ,  $\lambda_2$  and  $\lambda_3$ ) and the three orthonormal eigenvectors ( $e_1$ ,  $e_2$  and  $e_3$ ). The orthogonality of the computed eigenvectors and the correctness of the eigenvalues were checked using random sampling at a number of voxels. The correctness observed was up to an order of 10<sup>-17</sup>, indicating that no iterative refinement of the computed eigenvalues/vectors was needed. The tensor field data was then used to compute the DTI metrics such as mean diffusivity (Equation 1) and fractional anisotropy (Equation 2) for each voxel.

$$MD = (\lambda_1 + \lambda_2 + \lambda_3)/3 \quad \text{Equation 1}$$

$$FA(\lambda_1, \lambda_2, \lambda_3) = \text{Sqrt}\{[(\lambda_1 - \lambda_2)^2 (\lambda_2 - \lambda_3)^2 (\lambda_1 - \lambda_3)^2]/2(\lambda_1^2 + \lambda_2^2 + \lambda_3^2)\} \quad \text{Equation 2}$$

### **Data post-processing and quantification**

JAVA based software was used to calculate various DTI derived metrics (MD and FA)<sup>[32]</sup>. To show homogenous distribution of metabolites within the brain, we selected major white matter and deep gray matter regions for region-of-interest(s) (ROI's) analysis, because it

has been reported in the previous studies that the changes are widespread in both the gray and the white matter in patients with hepatic encephalopathy<sup>[33]</sup>. For quantitative analysis, the DTI derived FA and MD maps were displayed and overlaid on images with different contrasts to facilitate the ROI's placement. Elliptical and/or rectangular ROI's varying from 2 × 2 and 6 × 6 pixels were placed on right and left anterior (ALIC) and posterior (PLIC) limb of internal capsule, right and left caudate nuclei (CN), right and left putamen (P), right and left thalamus (TH), right and left periventricular white matter of frontal (FWM) and occipital (OWM) lobes, right and left cingulum and corpus callosum (CC) at the level of third ventricle for DTI metrics quantification in these controls as well as patients (Figure 1E). Rectangular ROI's were also placed at the level of frontal cortex, parietal cortex and occipital cortex to quantify the various DTI metrics.

The total brain volume changes (brain parenchyma as well as CSF volume) before and after the intravenous infusion of mannitol was also measured in all subjects on the T2-weighted images using the in-house JAVA based software.

### **Statistical analysis**

Before statistical analysis, left and right measurements for all regions were pooled together. Mann-Whitney rank sum test was performed between the pre-mannitol study and post-mannitol study to see the statistical significant difference in the metabolite ratios (with respect to Cr), DTI metrics (FA and MD), brain parenchyma volume as well as CSF volume for controls ( $n = 5$ ), ALF ( $n = 5$ ) and ACLF ( $n = 5$ ) patients. A P value of less than or equal to 0.05 was considered to be statistically significant. All the statistical analyses were performed using the statistical package for social sciences (SPSS, V12, Inc, Chicago, USA).

## **RESULTS**

### **Imaging findings**

All patients in ALF and ACLF groups had grade 3 or grade 4 hepatic encephalopathy when they were subjected to MRI study after excluding all the metabolic factors which might contribute to altered mental state. All of these patients had imaging features of cytotoxic and interstitial edema on DTI suggestive of raised ICP. These patients were then treated with mannitol infusion and repeat MRI for the same position was acquired as shown in Tables 5-7, respectively. We compared the clinical signs and MR changes in both group of patients as well as controls pre and post mannitol infusion. None of the patients with ALF and ACLF showed significant clinical improvement in terms of the grade of encephalopathy and appearance of defined clinical signs of cerebral edema and MR findings.

### **In vivo MR spectroscopy**

The mean metabolites ratios calculated for the controls, ALF patients and ACLF patients are shown in Table 5. In all these subjects, no statistical significant difference

was observed in the ratios of NAA/Cr, Cho/Cr, Gln/Cr, Glx/Cr, and mI/Cr between the pre-mannitol study (Figure 1B) and post-mannitol study (Figure 2B).

#### Changes in DTI metrics

The mean MD and FA values extracted from ROI's in controls, ALF patients and ACLF patients are summarized in Tables 6 and 7, respectively. None of the DTI metrics showed any significant difference between the pre-mannitol study (Figure 1C and D) and post-mannitol study (Figure 2C and D) in controls as well as ALF and ACLF patients.

#### Changes in total brain volume

In all subjects, no significant change was found in both brain parenchyma volume as well as CSF volume before mannitol administration and at 45 min after the completion of mannitol infusion (Table 8).

#### DISCUSSION

In case of patients with abnormal liver function or liver failure, detoxification of ammonia into glutamine by glutamine synthetase occurs in the brain astrocytes<sup>[34,35]</sup>. It has been reported that the facilitated transport system

operates to maintain the normal level of the nitrogen-rich osmolytes<sup>[36]</sup>. This process is energy dependent and requires normal metabolic conditions to operate. However, in case of patients with liver failure such a favorable milieu is not present. This suggests the increased concentration of nitrogen-rich compounds in brain of patients with liver failure, as also reported in previous studies<sup>[37,38]</sup>. It has been reported that the increased concentration of glutamine in these patients is associated with increased brain water content resulting in cerebral edema<sup>[39,40]</sup>. The use of hypertonic solutions for pulling out water initially from extracellular space and eventually from the intracellular compartment, along with clinical improvements in these patients, has been reported<sup>[41]</sup>.

In the present study, no significant change in the relative concentration of various metabolites in controls, ALF and ACLF patients after mannitol administration was observed, and this finding was associated with no change in the brain water content as well as in the clinical condition of patients. It has been reported that decreased myoinositol concentration is associated with compensatory response to the osmotic gradient induced by the high level of glutamine<sup>[17]</sup>. In case of controls and ALF patients, no significant decrease in mI/Cr

ratio after mannitol infusion suggests that the osmotic gradient due to mannitol might not be able to shift the myoinositol osmolyte across the BBB to compensate the intracellular osmolarity caused by accumulation of astrocytic glutamine. In case of ACLF patients, the slight increase in Gln/Cr, Glx/Cr and mI/Cr was seen after the infusion of mannitol; however, it did not reach the level of statistical significance. This further confirms that the osmotic gradient due to mannitol is not able to influence the efflux of organic osmolytes across the BBB. The lack of significant change in PMRS findings may be due to the fact that this was an acute study in which the pre- and post-mannitol studies were spaced 45 min apart. It is well known that the proxy changes of cerebral edema picked up by PMRS (i.e. depletion of choline, myoinositol, N-acetyl aspartate) are due to osmolyte shifts that occur over a prolonged timeframe and not in minutes<sup>[42,43]</sup>.

We did not find any significant change in the DTI metrics (FA and MD) in controls as well as in patients with ALF and ACLF at 45 min after the completion of mannitol administration. In controls, insignificant change in either FA or MD values in normal brain tissues (white matter and gray matter) suggest that mannitol has no effect on the microstructural integrity and brain water

content. This finding is in line with the previous study, which showed no change in the brain water content in normal white matter and cortex of patients with cerebral tumors<sup>[14]</sup>. The possible explanation could be due to the high hydraulic resistance of the capillaries in the normal brain tissues, and therefore mannitol might not be able to withdraw water osmotically from normal brain tissues<sup>[14]</sup>. Cascino *et al* have shown that the increased brain density of both edematous peritumoral white matter and normal gray and white matter on CT is related to the mannitol induced reduction in brain water content in patients with cerebral tumors<sup>[13]</sup>. They found that the maximum changes occurred after 36 min of mannitol infusion<sup>[13]</sup>. Bell *et al* showed that mannitol significantly reduced longitudinal relaxation time (T1) of oedematous peritumoral white matter and tumor tissue but did not have any significant effect on the normal white matter or cortex<sup>[14]</sup>. The maximum decrease in brain water content was found after 30 min of mannitol infusion, which was associated with the reduction in T1 values<sup>[14]</sup>.

The effect of mannitol in patients with liver failure depends on the nature of cerebral edema. It has been reported that the nature of cerebral edema in case of ALF is predominantly cytotoxic along with some interstitial component<sup>[44]</sup>. However, the nature of cerebral edema in ACLF has yet to be described. The result from unpublished data suggests the predominant interstitial component of edema in ACLF<sup>[45]</sup>. In a

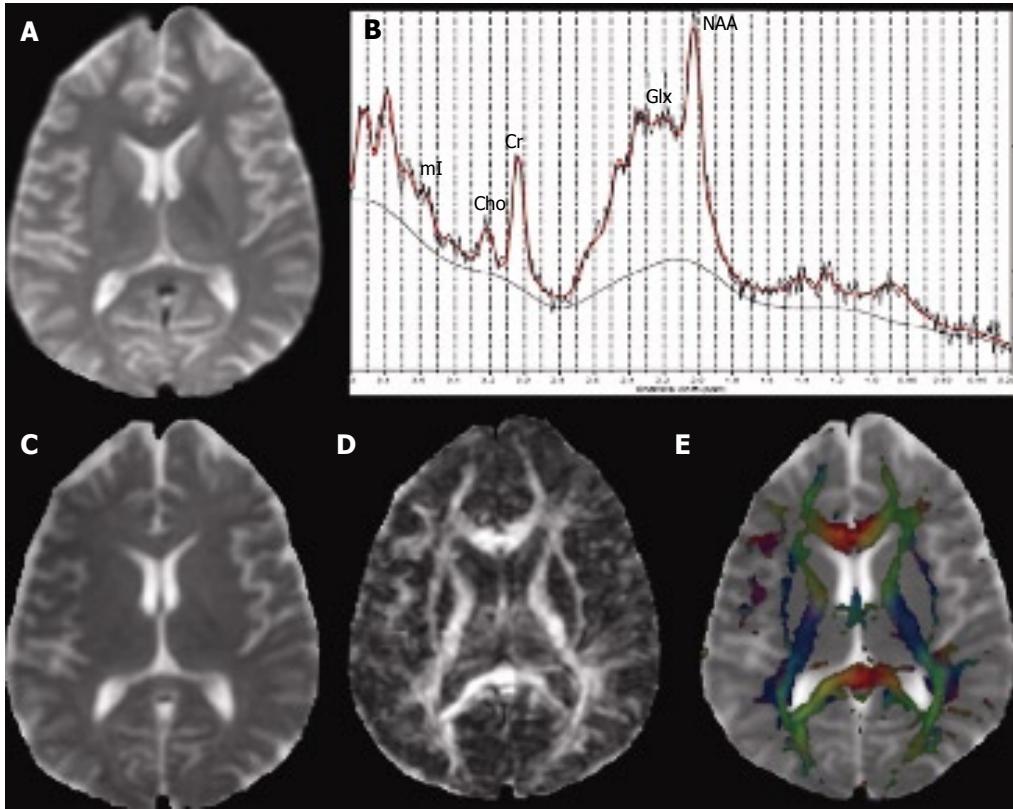

previous study, the reduction in brain water content has been reported after mannitol administration in ALF patients by the observed decrease in ICP, as well as reversal of the clinical signs and concluded that the operative edema is of the cytotoxic type that resolved after mannitol treatment<sup>[10]</sup>. However, in the current study no change in the FA and MD values in patients with ALF and ACLF suggests any effect of mannitol on the brain water content along with the microstructural integrity. The BBB is known to be disrupted in both conditions of ALF and ACLF resulting in the interstitial component of cerebral edema. The tight endothelial junctions of the BBB open in both these conditions; however, the extent to which these endothelial junctions of BBB open is different. Hartwell *et al* also have reported no significant change in the water content of the edematous white matter after mannitol infusion in cats. This finding was explained based on the changes in the BBB that extended beyond the region of central necrosis induced by the cold lesion, which may have resulted in the disturbance of osmotic gradient<sup>[12]</sup>. In our study, no change in the brain water content as depicted by no change in the MD values in ALF and ACLF patients after mannitol infusion can be explained on the basis of the disruption of BBB due to the presence of interstitial component of cerebral edema. This may affect the mannitol induced osmotic gradient across the BBB and result in no withdrawal of water from the edematous brain tissue to the intravascular space.

**Figure 1** Conventional magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) were performed at three days after the onset of encephalopathy in a 29-year-old man with acute liver failure (ALF) before the mannitol administration. **A:** Axial T2-weighted imaging at the level of third ventricle does not show any visible abnormality; **B:** Localized proton spectrum from  $2\text{ cm} \times 2\text{ cm} \times 2\text{ cm}$  voxel placed on right parietal region (**A**) shows the metabolite ratios with respect to Cr (NAA/Cr = 1.35, Cho/Cr = 0.34, Gln/Cr = 2.57, Glx/Cr = 4.12, mI/Cr = 0.45); **C:** Mean diffusivity (MD) map, [anterior limb of internal capsule (ALIC) = 0.68, posterior limb of internal capsule (PLIC) = 0.65, caudate nuclei (CN) = 0.67, putamen (P) = 0.60, thalamus (TH) = 0.66, frontal white matter (FWM) = 0.66, occipital white matter (OWM) = 0.67, corpus callosum (CC) = 0.60, cingulum = 0.70, frontal cortex = 0.63, parietal cortex = 0.70, occipital cortex = 0.63]; **D:** Fractional anisotropy (FA) map, (ALIC = 0.32, PLIC = 0.34, CN = 0.09, putamen = 0.08, thalamus = 0.11, FWM = 0.33, OWM = 0.38, CC = 0.53, cingulum = 0.45, frontal cortex = 0.16, parietal cortex = 0.10, occipital cortex = 0.12). The cut off value for the color-coded FA for display is kept at 0.2 (**E**) above which the color-coded regions reflect the white matter only [red (right-left), green (anterior-posterior), and blue (superior-inferior)]. Cho: Choline; Cr: Creatine; Gln: Glutamine; Glx: Glutamine/glutamate; mI: Myoinositol; NAA: N-acetylaspartate.

Our above results are further supported by no significant change in the brain parenchyma volume and CSF volume in controls and patients with ALF and ACLF. In our study, we have explained the action of mannitol only on the basis of the osmotic gradient across the BBB, which is known to affect the brain volume of the normal tissue<sup>[11]</sup>. The cerebral blood flow is an important hemodynamic parameter that is shown to be reduced after mannitol administration<sup>[46,47]</sup>. Although in our study we do rule out the possibility of an osmotic gradient across the BBB, other vascular factors such as changes in cerebral blood flow, blood viscosity and oxygen delivery at the tissue level might be responsible for the effects of mannitol<sup>[12]</sup>. However, in our patients we did not quantify the cerebral blood flow and ICP. The use of ICP monitoring in ALF is a subject of ongoing debate. ICP monitoring is used variably across the world, with some centers not considering it useful and other using it regularly. In our study and, in fact, in most of the centers in our country direct ICP measurement is not used. The clinical signs used in our study are the reliable clinical signs of raised ICP, provided that other causes like brain hemorrhage or intracranial space occupying lesion which may cause raised ICP are excluded. However, these clinical signs are

not uniformly present in all cases, but if at all present these signs are suggestive of raised ICP. In our study, all the patients had these clinical signs. In a landmark study, Canalese *et al* measured cerebral edema by the presence of defined clinical signs as well as continuous monitoring of ICP in two different groups in their study<sup>[10]</sup>. Among the patients who received mannitol, cerebral edema was considered to have developed in 17 patients, in nine on evidence from continuous intracranial monitoring and in eight on the basis of clinical signs<sup>[10]</sup>. In those patients who died, ICP was monitored with either clinical signs of cerebral edema or direct measurement; when brain autopsy was done, a close correlation was found between the evidence of cerebral edema in life and findings at the autopsy of brain, whereas there was no evidence of correlation in the four other patients whose ICP was not raised and who had no clinical features of cerebral edema<sup>[10]</sup>. Acharya *et al* in their study of clinical profile of ALF patients and predictors of mortality from tropical country had also used similar clinical signs to monitor cerebral edema<sup>[21]</sup>. The AASLD guidelines for management of ALF mentioned ICP monitoring either by direct measurement or by obvious clinical signs<sup>[23]</sup>. Stravitz *et al* reported that there are insufficient data to recommend ICP monitor placement in all patients with

**Figure 2** Repeat MRI and DTI were performed after 30 min of mannitol infusion on the same ALF patient as in Figure 1 to look for any mannitol effect on imaging. In post-mannitol study, the effect of mannitol was quantified between 30–46 min. **A:** Axial T2-weighted image; **B:** Localized proton spectrum from the same region as in Figure 1A shows NAA/Cr = 1.83, Cho/Cr = 0.29, Gln/Cr = 2.60, Glx/Cr = 4.57, mI/Cr = 0.32; **C:** Mean diffusivity (MD) map, [anterior limb of internal capsule (ALIC) = 0.67, posterior limb of internal capsule (PLIC) = 0.70, caudate nuclei (CN) = 0.70, putamen (P) = 0.63, thalamus (TH) = 0.62, frontal white matter (FWM) = 0.66, occipital white matter (OWM) = 0.60, corpus callosum (CC) = 0.70, cingulum = 0.72, frontal cortex = 0.69, parietal cortex = 0.66, occipital cortex = 0.62]; **D:** Fractional anisotropy (FA) map, (ALIC = 0.32, PLIC = 0.34, CN = 0.08, putamen = 0.06, thalamus = 0.13, FWM = 0.30, OWM = 0.43, CC = 0.46, cingulum = 0.40, frontal cortex = 0.10, parietal cortex = 0.12, occipital cortex = 0.08) at the level of third ventricle. **E:** There is no significant change in the MD and FA values, and metabolite ratios mentioned here compared to what is mentioned in Figure 1. Cho: Choline; Cr: Creatine; Gln: Glutamine; Glx: Glutamine/glutamate; mI: Myoinositol; NAA: N-acetylaspartate.

ALF; however, according to these authors all patients who are candidate for orthotopic liver transplantation (OLT) should undergo ICP monitoring<sup>[20]</sup>. In our study, all the patients were managed conservatively and none had finances for OLT. Nevertheless, it is true without ICP monitoring we can not quantify ICP, and this is one of limitations of our study since we did not measure ICP. However, the monitoring of response can be done by improvement of clinical signs or reduction of ICP, and obviously reduction in ICP would have been the best way to see the amount of response. There is no relationship of dosing of mannitol according to the severity of ICP. AASLD guidelines suggested the main role of ICP monitoring to detect early rise in intracranial pressure even before the development of clinical signs, and ICP should be maintained below 20–25 mmHg if possible. So once clinical features of raised ICP appear, it means intracranial pressure has significantly raised<sup>[23]</sup>.

The absence of changes in the clinical status of these patients further supports that there is likely no significant effect of mannitol on their clinical management in this time window. However, the effect of mannitol over days is more difficult to assess due to other co-variates used for its management that might also contribute for the survival of some of these patients.

The osmotic effect of mannitol in the reduction of brain water content does not have any significant immediate effect on the clinical status in ALF and ACLF patients. The effect of other vascular factors that may alter the ICP indirectly will be the subject for future study to assess the mannitol effect using other noninvasive techniques such as perfusion imaging.

This is a first pilot study to see the direct effect of mannitol in ALF and ACLF patients. The conclusion of our study is that mannitol does not have an early effect (single dose effect seen in 45 min). However, we cannot conclude by saying that mannitol does not have any role in the management of ALF and ACLF patients, as previous studies<sup>[10]</sup> have shown that average response to mannitol therapy comes after 3 doses. Therefore, from our study, we cannot comment upon the delayed effect of mannitol with multiple doses. We plan to study the delayed effect of mannitol with more than one dose of mannitol in future.

## COMMENTS

### Background

Cerebral edema plays a major role in the outcome of both acute liver failure (ALF) and acute-on-chronic liver failure (ACLF). Bolus intravenous infusion of

mannitol has been widely used to treat episodes of raised intracranial pressure (ICP) in these conditions. However, there are no data available regarding the effect of mannitol infusions on brain water content in ALF and ACLF, using sensitive imaging techniques.

### Research frontiers

This is a pilot study to see the acute effect of mannitol in ALF and ACLF patients. The conclusion of our study is that mannitol does not have an early effect (single dose effect seen in 45 min). However, we cannot conclude by saying that mannitol does not have any role in the management of ALF and ACLF patients, as previous studies have shown that average response to mannitol therapy comes after three doses of mannitol. Therefore, from our study, we cannot comment upon the late effect of mannitol with multiple doses. The osmotic effect of mannitol in the reduction of brain water content does not have any significant immediate effect on the clinical status in ALF and ACLF patients. The effect of other vascular factors that may alter the ICP indirectly will be the subject for future study to assess the mannitol effect using other noninvasive techniques such as perfusion imaging.

### Innovations and breakthroughs

This is the first study evaluating the effect of mannitol on brain water content using diffusion tensor imaging (DTI) and proton magnetic resonance spectroscopy (PMRS) in controls as well as in patients with ALF and ACLF. We hypothesize that the effect of bolus infusion of mannitol in reducing brain water content will be reflected by changes measured by conventional magnetic resonance effect (MRI), *in vivo* PMRS and DTI. Since the peak effect of a single bolus in mobilizing fluid from tissues to the intravascular compartment according to the osmotic gradient is observed at about 45 min after infusion, it was decided to evaluate the effect of intravenous bolus of mannitol during the baseline MRI scan (pre-mannitol study) and after the completion of mannitol administration (post-mannitol study).

### Applications

Conventional MRI, DTI and PMRS can be used as a diagnostic modality to demonstrate the raised ICP in ALF and ACLF patients noninvasively. The purpose of this paper is to establish whether mannitol has any role in the reduction of brain water content, alteration in metabolite ratios or any change in the clinical status of ALF and ACLF patients during or within 45 min of mannitol infusion, and to know about the exact duration and dose of mannitol to show response after therapy.

### Peer review

This is the first study evaluating the effect of mannitol on brain water content using DTI and PMRS in controls as well as in patients with ALF and ACLF. The osmotic effect of mannitol in the reduction of brain water content does not have any significant immediate effect on the clinical status in ALF and ACLF patients. The effect of other vascular factors that may alter the ICP indirectly will be the subject for future study to assess the mannitol effect using other noninvasive techniques such as perfusion imaging.

adenoma and the highest levels found in high-grade adenoma. GST-pi was located mainly in undifferentiated epithelial cells. GST-pi positive particles were found in the cytoplasm and especially in the nucleus adjacent to the nuclear membrane of these cells.

**CONCLUSION:** The overexpression of GST-pi in mild-grade adenomas with significant subcellular changes and in the majority of high-grade dysplasia adenoma suggests that this might be related to the carcinogenetic proceeding. Immunohistochemical localization of GST-pi in combination with ultrastructural changes indicate that GST-pi might be a sensitive agent for the detection of preneoplastic transformations in adenoma.

## Abstract

**AIM:** To investigate the distribution of the placental form of glutathione-S-transferase (GST) in colon polyps in order to evaluate the role of GST-pi in these tissues.

**METHODS:** Sixteen polyp tissues removed at colonoscopy were examined. Tissues were investigated histologically and ultrastructurally. GST-pi expression was also analysed immunohistochemically, using peroxidase anti-peroxidase (PAP) method and immunogold labelling method, for light and electron microscope respectively.

**RESULTS:** All polyp tissues examined were adenoma of low, mild and high- grade dysplasia as shown in the histopathological reports. Nevertheless, the examination of the above specimens with electron microscope revealed that 3 of 9 adenoma of mild dysplasia had ultrastructural features similar to high-grade dysplasia adenoma. GST-pi was variably expressed in adenoma, with the lowest relative levels occurring in low-grade

## INTRODUCTION

Glutathione S-transferases (GST) are a family of enzymes that play an important role in the prevention of cancer by detoxifying numerous potentially carcinogenic compounds<sup>[1,2]</sup>. In this respect high tissue levels of GST's are protective against cancer. In preneoplastic cells as in neoplastic cells, specific molecular forms of GST are known to be expressed and have been known to participate in their resistance to drugs. GSTs are present in most epithelial tissues of the human gastrointestinal tract, as it is an important site of contact with compounds from food, drugs or medication<sup>[3,4]</sup>. The cytoplasmic GSTs have been grouped into four main classes, each with a different tissue-specific expression<sup>[5]</sup>. Significant amounts of the class pi GST were expressed in the majority of human

tumors and human tumor cell lines<sup>[6]</sup>. Recent studies have shown increased levels of human placental glutathione S-transferase (GST-pi) in different tumors of gastrointestinal tract as well as in precancerous lesions<sup>[5,7,8]</sup>. GST-pi was significantly increased in proliferative hepatic nodules induced by chemical carcinogen and in well-differentiated carcinoma<sup>[9]</sup>. Studies have shown that GST-pi is expressed highly in neoplasms and could be regarded as a tumor marker<sup>[10-12]</sup>.

There are immunohistochemical studies about colorectal carcinoma, suggesting that GST-pi is located in cancer cells<sup>[13,14]</sup>.

As the description of the immunohistochemical and the immunoelectron microscopic localization of GST-pi in human polyps is not available, we performed a combined study to examine the distribution of GST-pi in these tissues.

## MATERIALS AND METHODS

### Materials

In this study, 16 polyp tissues were removed at colonoscopy from the Department of Gastroenterology of the Regional Anticancer-Oncologic Hospital of Athens "Agios Savvas". Paraffin-sections were obtained from all tissues and examined by pathologists. When histological grading was performed, all polyp tissues were adenoma of different stage of dysplasia (3 of low-grade, 9 of mild-grade and 4 of high-grade).

### Methods

**Specimen preparation for light microscopy:** Samples for light immunohistochemical study were immediately placed in ice-cold saline in the endoscopic room. In the laboratory, the tissue was washed free of blood with ice-cold saline, frozen in liquid nitrogen and kept at -80°C until further use. The specimens were cut in frozen sections (6 µm).

**Electron microscopy:** Shortly after colonoscopy, tissues for electron microscopy were fixed in 2.5% glutaraldehyde in 0.1 mol/L sodium phosphate buffer (pH 7.3) for 1 h at room temperature, and postfixed with 1% osmium tetroxide for 1 h at room temperature. All samples were then dehydrated *via* graded alcohol (25%, 30%, 50%, 70%, 90%, and 100%) and propylene oxide and embedded in Araldite resin. Semi-thin sections (1 µm) were cut, stained with toluidine blue, and examined under light microscope. Silver sections (500 Å) were collected on uncoated copper grids for ultrastructural observation and on uncoated nickel grids for immunolabeling. These sections were further stained with uranyl acetate and lead citrate and examined with a C-100 Phillips Electron Microscope.

**Peroxidase anti-peroxidase (PAP) method for light microscopy:** Sections on gelatin coated slides were treated in 0.3% H<sub>2</sub>O<sub>2</sub>. Following incubation for 30 min in a blocker solution containing 1/30 normal goat serum in phosphate buffered saline (PBS), sections

were immunostained with antiserum to glutathione-S-transferase-pi (Dako Company). Then PAP was applied and diluted in bovine serum albumin (BSA) and PBS 1/400 for 30 min. Finally, the sections were incubated for 5 min in a solution containing diaminobenzidine (DAB), H<sub>2</sub>O<sub>2</sub> and PBS.

Following that, the slides were rinsed twice with tap water and counterstained in hematoxyline for 2 min. They then were visualized using an optical microscope and were photographed using a Nikon Coolpix 3100.

### Immunogold labeling for electron microscopy:

All steps except for incubation with antibodies were carried out at room temperature. Ultra-thin sections in silver uncoated grids were treated in 8% H<sub>2</sub>O<sub>2</sub> for 8 min and etched with saturated aqueous sodium metaperiodate for 30 min. After incubating for 30 min. in a blocker solution containing 5% normal goat serum in PBS, sections were immunostained with antiserum to glutathione S-transferase-pi. The rabbit monoclonal anti S-transferase pi antiserum (Dako Company) was used at a dilution of 1:20 to 1:40. The incubations were carried out at 4°C, overnight. Following several washings in BSA, immunoreactivity was visualized by incubating the sections in 20 nm colloidal gold-labeled goat anti-rabbit IgG (British BioCell International, Cardiff, UK). The specificity of the immunolabeling was assessed by incubation of the sections with non-immune serum. When we performed the appropriate negative controls, we followed the same procedure described above except for incubation in the absence of primary antibody after the treatment with non-immunoreactive goat serum. After counterstaining with uranyl acetate and lead citrate, the sections were viewed under the Philips C100 Electron Microscope.

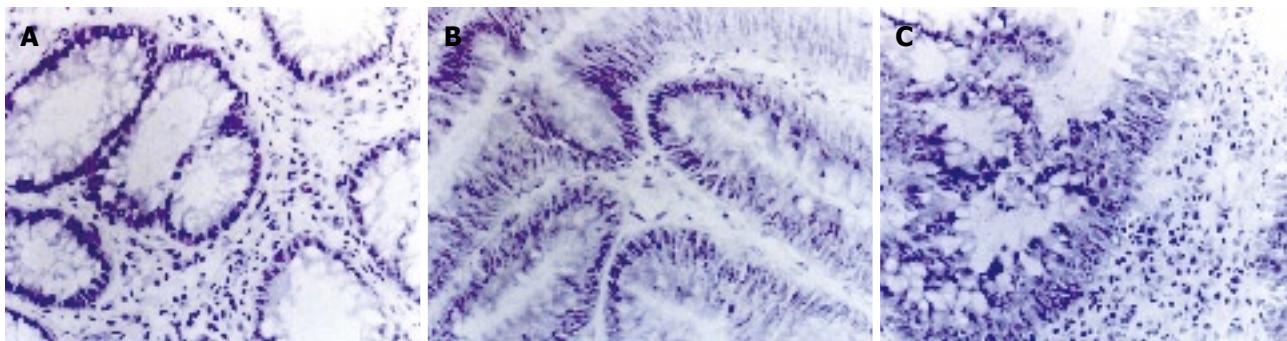

## RESULTS

### Light microscopy

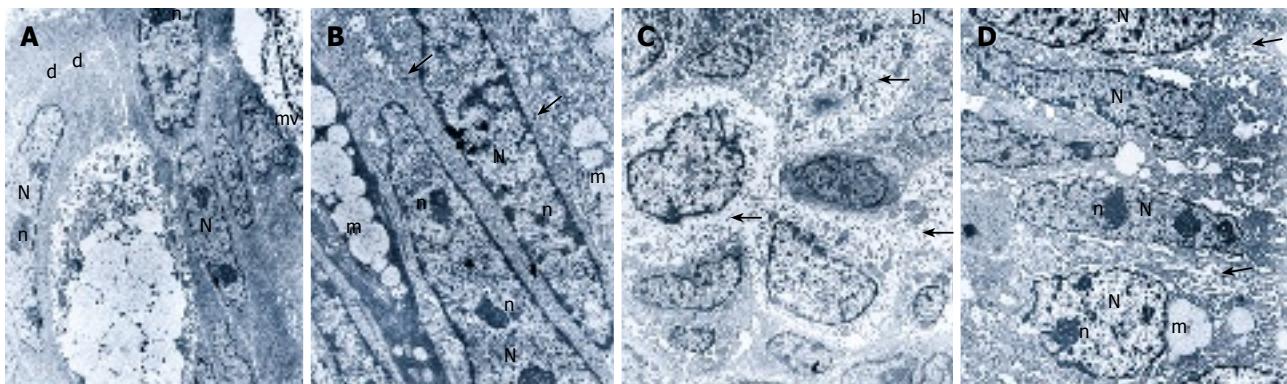

Histological examination of the tissues demonstrated that all were colorectal adenomas of low-grade dysplasia to high-grade dysplasia. Morphologically, adenomas showed abnormalities in epithelial cells that agree with the histopathological reports. Low-grade dysplasia adenoma is characterized by tall epithelial cells with elongated and hyperchromatic nuclei (Figure 1A). In mild-grade dysplasia adenoma, crypt architecture tends to be distorted. Nuclei are crowded, hyperchromatic and may be stratified near the base of the crypts without reaching the lumen (Figure 1B). High-grade dysplasia adenoma is characterized by a true nuclear stratification and a back-to-back pattern, and nuclei extend all the way to the lumen (Figure 1C).

### Electron microscopy

All cases were examined under the electron microscope. At least four specimens from each case were examined and the most representative block was used for electron microscopic examination. The relative number of each cell type in the low, mild and high-grade dysplasia varied. Low-grade dysplasia tissues closely mimicked those of normal colorectal mucosa but goblet cells

**Figure 1** Sections of human colorectal adenoma (HE,  $\times 150$ ). **A:** Low-grade dysplasia; **B:** Mild-grade dysplasia; **C:** High-grade dysplasia.

**Figure 2** Transmission electron micrograph, routine double staining with uranyl acetate and lead citrate. Nucleus (N), nucleoli (n), mucus granules (m), microvilli (mv). **A:** From a low-grade dysplasia adenoma ( $\times 5900$ ), desmosomes (d); **B:** From a mild-grade dysplasia adenoma, desmosomes (arrows); **C:** From a mild-grade dysplasia tissue ( $\times 11700$ ), free polyribosomes (arrows), basal lamina (bl); **D:** From a high-grade dysplasia adenoma ( $\times 5900$ ), intracellular junctions (arrows).

were fewer and nuclei were elongated. The luminal surface of epithelial cells exhibited microvilli with core rootlets and glycocalyxal bodies (Figure 2A). Mild-grade dysplasia tissues contained not only fewer but also incompletely differentiated goblet cells. In mild-grade dysplasia, we observed an increased nuclear cytoplasm ratio. The nuclei were large, elongated with peripheral (around the nuclear membranes) aggregation of heterochromatin, and nucleoli were increased in number. There were no significant changes in intercellular relationships. The junctions, especially desmosomes, were well developed (Figure 2B). In 3 out of 9 tissues histologically characterized as mild-grade dysplasia, we observed more significant subcellular changes. Almost every cell was undifferentiated with an abundance of free polyribosomes. Intercellular junctions appeared poorly differentiated. Nevertheless, the basal lamina was reduplicated (Figure 2C). In high-grade dysplasia tissues, intercellular junctions were slightly opened and in many cases we could not confirm cell borders. Epithelial cells and especially goblet cells were undifferentiated. The most significant ultrastructural change occurred in the nucleus. Nuclei were elongated or round with prominent nucleoli. Nucleoli were also increased in number and were marginated near the nucleus periphery (Figure 2D).

#### Immunohistochemistry for light microscopy

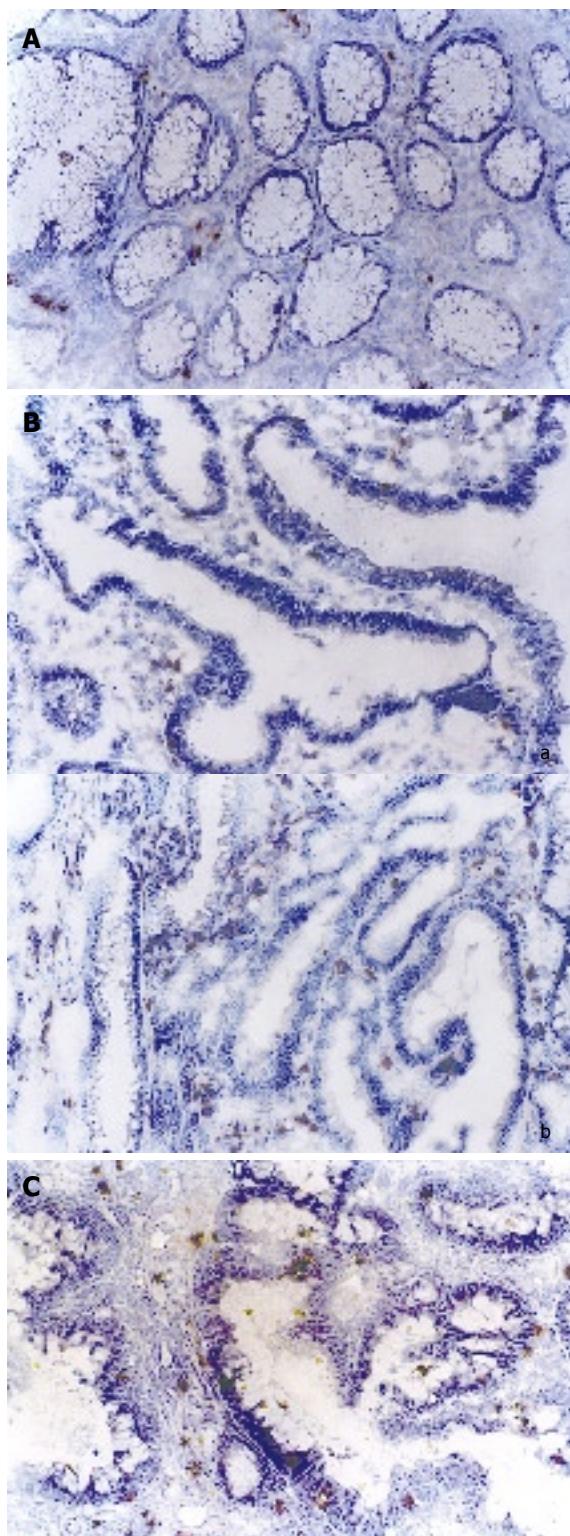

The examined colorectal adenoma tissues exhibited positive immunoreaction to glutathione S-transferase-

<sup>1</sup>Mild-grade dysplasia adenoma tissues with more significant ultrastructural changes.

pi with different density, which is expressed as weak, moderate and strong (Table 1). Low-grade dysplasia adenoma showed mainly a weak immunoreactivity to GST-pi (Figure 3A). Five out of nine adenoma of mild-grade dysplasia immunoreacted moderately and three out of nine showed a strong immunoreaction (Figure 3B), respectively. Three out of four adenoma of high-grade

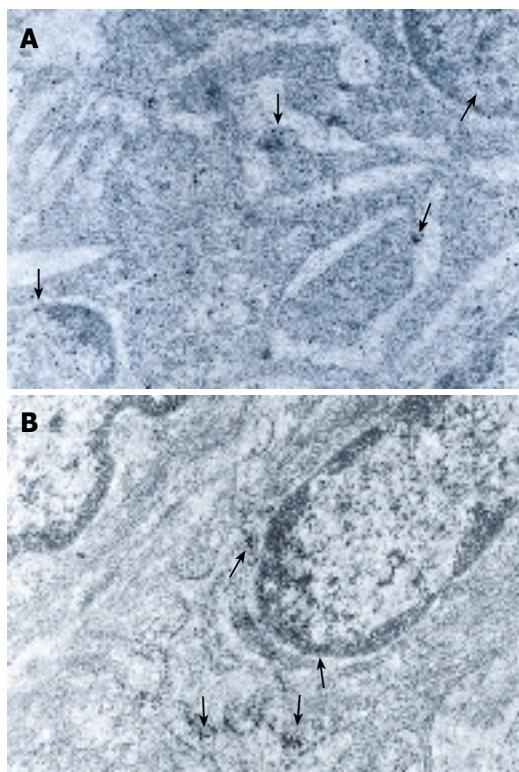

**Figure 3** GST-pi positive cells (HE,  $\times 100$ ). **A:** In low-grade dysplasia colorectal adenoma; **B:** In mild-grade dysplasia colorectal adenoma, moderate immunoreactivity (**a**) and strong immunoreactivity (**b**); **C:** In high-grade dysplasia colorectal adenoma.

dysplasia showed a strong immunoreactivity to GST-pi (Figure 3C). In all the above specimens, GST-pi was positive in epithelial cells and lamina propria cells.

#### Electron Immunocytochemistry

In low and mild-grade dysplasia tissues, GST-pi was

**Figure 4** **A:** Electron micrograph from a mild-grade dysplasia adenoma showing GST-pi positive particles located in ribosomes and nucleus (arrows,  $\times 42000$ ); **B:** Ultrathin section from a high-grade dysplasia adenoma showing GST-pi positive particles located in cytoplasmic membranes and nuclear membrane (with uranylacetate and lead citrate arrows,  $\times 57000$ ).

located in the cytoplasm, mainly ribosomes, and nucleus adjacent to nuclear membrane, and the intensity of the immunostaining was moderate (Figure 4A). In histologically and ultrastructurally high-grade dysplasia cases, GST-pi was located mainly in undifferentiated epithelial cells. GST-pi positive particles were found in membranes of the cytoplasm and especially the nucleus adjacent to the nuclear membrane of these cells. The positive particles accumulated in lumps and the intensity of the immunostaining was strong (Figure 4B).

#### DISCUSSION

Investigations revealed that GST-pi was widely distributed in the human gastrointestinal tract<sup>[15-17]</sup>. GST-pi may be over expressed in an early phase of malignant transformation in premalignant and malignant cells<sup>[18,19]</sup>. Nevertheless, the description of the immunohistochemical and immunoelectron microscopic localization of GST-pi in human polyps is not available. In this respect, we performed a combined study to explore the distribution of GST-pi in these tissues.

We combined the power of morphologic evaluation that is obtained through the use of light and electron microscopy with the detection of GST-pi in tissue and in subcellular structures of colorectal polyp tissues. We believe it was necessary for the correct assessment of changes associated with premalignant transformation in these tissues.

Our study revealed that the immunoreaction of GST-pi was in specific cell-types in adenoma tissues. The location of GST-pi was mainly in epithelial cells of the crypts. Immunoreaction was also found in lamina propria cells, where the positive staining was located in lymphocytes and phagocytes. Endocrine cells were negative. Electron microscope immunohistochemistry revealed that between different cell types the highest intensity stain was in the columnar epithelial cells.

Other investigators have shown cell-type specific expression of the isoenzyme in the human gastrointestinal tract<sup>[15,20]</sup> in normal<sup>[16]</sup> and cancerous tissues<sup>[5]</sup>. This expression of GST pi has been associated with the progression of cancer after exposure to carcinogens<sup>[21]</sup>. In other studies, GST-pi is regarded as a marker in evaluating the effect of tumorectomy or in predicting the drug resistance of tumor cells<sup>[22-24]</sup>.

Our investigation revealed that the immunoreaction varied from weak to strong, according to the degree of adenoma and the ultrastructural changes. The different density of GST-pi immunoreaction was weak in low-grade dysplasia to strong in high-grade dysplasia. There was an exception in this rule. We observed significant ultrastructural changes in some cases histologically characterized as mild-grade dysplasia. These cases, as high-grade dysplasia cases, revealed a contrast with the pattern of progressive differentiation seen in low-grade dysplasia tissues. We found immature undifferentiated cells showing a fast growing population, with many free polyribosomes and enlarged nucleus and nucleoli increased in size and number, showing increased protein synthetic activity. These cases also exhibited strong GST-pi immunoreactivity similar to those of high-grade dysplasia.

In our study, immunostaining was also observed in specific cellular structures. We found that GST-pi was located in the cytoplasm and especially in the nucleus adjacent to the nuclear membrane of colorectal dysplasia cells. This nuclear staining of GST-pi as found here also has been investigated in other studies. It has been reported previously that GST-pi was located in healthy and diseased stomach<sup>[25]</sup>, esophagus<sup>[19,26]</sup> and uterine cervix<sup>[27]</sup>. It has been postulated that nuclear GSTs are involved in RNA processing<sup>[28]</sup>. GST-pi also may induce apoptosis in premalignant cases and may play a pivotal role in early colon carcinogenesis. Other studies revealed lower percentages of apoptotic cells in premalignant cases than in healthy epithelium<sup>[29]</sup>.

Glutathione-pi analog has been synthesized recently. Clinical trials have shown that GST-pi inhibitor induces the apoptosis in the precancerous lesions. It is expected to be promising in future carcinogenesis preventive medicine<sup>[30,31]</sup>.

The combination of immunohistochemical and ultrastructural analysis of GST-pi in polyp tissues and the variation of the isoenzyme expression in adenoma of different degree of dysplasia ultimately may lead to a better understanding of its role in carcinogenesis. These findings also may contribute to a better treatment of colorectal polyps in the future.

## ACKNOWLEDGMENTS

## COMMENTS

### Background

Placental Glutathione S-transferase (GST-pi) is an enzyme that plays an important role in the removal of toxic, probably carcinogenic, agents from the cell. GST-pi is extremely increased in colon adenocarcinoma in comparison to normal samples. The authors performed a combined study to explore the distribution of GST-pi in colon polyps, as they had no data for these tissues. They used the power of morphologic evaluation that is obtained through the use of light and electron microscopy with the detection of GST-pi in tissue and in subcellular structures of colorectal polyp tissues.

### Research frontiers

Clinical outcome of colon polyps is under consideration. Human placental GST-pi concentrations are increased in colon tumors even in premature stages, as well as in precancerous lesions. GST-pi protects cancer cells from cytostatic compounds and thereby apoptosis. The increased GST-pi levels contribute to the relatively high resistance to anti-cancer drugs, such as mitomycin C.

### Innovations and breakthroughs

Investigations revealed that GST-pi was widely distributed in the human gastrointestinal tract. GST-pi may be over-expressed in an early phase of malignant transformation in premalignant and malignant cells. Nevertheless, the description of the immunohistochemical and the immunolectron microscopical localization of GST-pi in human polyps was not available.

### Applications

The combination of immunohistochemical and ultrastructural analysis of GST-pi in polyp tissues and the variation of the isoenzyme expression in adenoma of different degree of dysplasia ultimately may lead to a better understanding of its role in carcinogenesis. These findings also may contribute to a better treatment of colorectal polyps in the future, as Glutathione-pi analog has been synthesized recently. Clinical trials have shown that GST-pi inhibitor induces the apoptosis in the precancerous lesions. It is expected to become promising in future carcinogenesis preventive factors.

### Peer review

This is an interesting study. Authors give valuable data for colon polyps. Immunohistochemical localization of GST-pi in combination with ultrastructural changes indicates that GST-pi might be a sensitive agent for the detection of preneoplastic transformations in colon adenoma tissues.

Endoscopic treatment of biliary complications after liver transplantation. *World J Gastroenterol* 2008; 14(26): 4185-4189 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4185.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4185>

## Abstract

**AIM:** To evaluate the efficacy of endoscopic treatment in patients who undergo OLTx or LRLTx and develop biliary complications.

**METHODS:** This is a prospective, observational study of patients who developed biliary complications, after OLTx and LRLTx, with duct-to-duct anastomosis performed between June 2003 and June 2007. Endoscopic Retrograde Cholangiopancreatography (ERCP) was considered unsuccessful when there was evidence of continuous bile leakage despite endoscopic stent placement, or persistence of stenosis after 1 year, despite multiple dilatation and stent placement. When the ERCP failed, a percutaneous trans-hepatic approach (PTC) or surgery was adopted.

**RESULTS:** From June 2003 to June 2007, 261 adult patients were transplanted in our institute, 68 from living donors and 193 from cadaveric donors. In the OLTx group the rate of complications was 37.3%, while in the LRLTx group was 64.7%. The rate of ERCP failure was 19.4% in the OLTx group and 38.6% in LRLTx group. In OLTx group, 1 patient was re-transplanted and 8 patients died. In the LRLTx group, 2 patients underwent OLTx and 8 patients died. The follow-up was  $23.3 \pm 13.13$  mo and  $21.02 \pm 14.10$  mo, respectively.

## INTRODUCTION

Biliary complications are the most frequent problem after liver transplantation. The available data show that the rate of biliary complications in transplant recipients ranges between 8% and 20%. This rate of complications is higher for living-related liver transplantation (LRLTx) vs orthotopic liver transplantation (OLTx)<sup>[1,2]</sup>. Biliary complications may include: anastomotic stricture, biliary leaks, stones or debris and Oddi dysfunction. Often patients develop more than one complication<sup>[3]</sup>. Whether the rate of biliary complications is lower in patients with the duct-to-duct anastomosis than with choledocojejunum anastomosis is unknown. However, the duct-to-duct anastomosis is usually preferred because it can easily be reached with an endoscopic procedure, which the published data has proven to be very effective<sup>[1]</sup>. Early diagnosis is crucial, as the treatment may improve graft function and help to avoid repeated surgery. Patients often show unspecific symptoms, such as fever or anorexia, even without pain<sup>[3]</sup>. More often patients are asymptomatic but have high liver functions test (LFT) values and/or bilirubin levels. Abdominal ultrasonography often shows no biliary dilatation, while

liver biopsy (used in many centers) does not appear to be conclusive in this type of patient<sup>[4]</sup>. Interpreting the histologic findings of bile duct damage and bile flow impairment can be confusing. Typical findings of extra-hepatic bile duct obstruction include portal edema, proliferation of ducts and ductules, neutrophilic cholangitis, and hepatocanicular cholestasis. However, concomitant histologic findings of cellular rejection from associated biliary stasis or infection can confuse the primary diagnosis and lead to a misdiagnosis of rejection<sup>[4]</sup>. When comparing histologic features from patients with and without biliary strictures, Campbell *et al*<sup>[5]</sup> found that cholangitis was the only biopsy feature significantly associated with a documented stricture. Therefore, a low threshold to obtain an early cholangiogram should exist. Magnetic Resonance Cholangiopancreatography (MRCP) has shown a 93% diagnostic accuracy, with sensitivity and specificity over 90% and a PPV equal to 86%<sup>[6]</sup>. Endoscopic Retrograde Cholangiopancreatography (ERCP) remains the gold standard when suspicion of biliary complications is high, and allows a direct approach to interventional procedures<sup>[3]</sup>. Some studies have already been published on the endoscopic treatment of biliary complications, and show a success rate of approximately 70%-80% of cases<sup>[6-10]</sup>.

The aim of this study was to evaluate the efficacy of endoscopic treatment in patients who undergo OLTx or LRLTx and develop biliary complications.

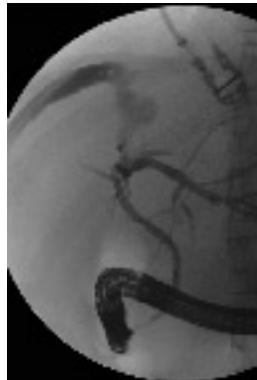

## MATERIALS AND METHODS

This is a prospective, observational study of patients who developed biliary complications after cadaveric and living-related liver transplants (OLTx and LRLTx) with duct-to-duct anastomosis between June 2003 and June 2007.

To overcome the gap between the number of donations and number of patients listed for OLTx, our institute decided to accept "extended criteria donors" (ECD). An ECD was defined as: age > 60 years; macrovesicular steatosis > 30%; prolonged intensive care unit stay (> 7 d); hemodynamic risk factors, including under this term the following conditions: prolonged hypotension (systolic blood pressure < 60 mmHg for more than 2 h); use of dopamine > 10 mcg/kg per min for more than 6 h to sustain blood pressure; need for 2 inotropic drugs to sustain donor blood pressure for more than 6 h; cold ischemic time > 12 h; and hypernatraemia (Na peak > 160 Meq/L) before aortic cross clamp.

With regard to the diagnosis of biliary complications, abdominal ultrasonography with Doppler was routinely performed in order to rule out vascular alterations, but indication for ERCP was based on increased LFT values and MRCP for the OLTx group. In the LRLTx group all patients had a T-tube insertion during the transplant, so the diagnosis of biliary complications was made on T-tube cholangiogram.

Separate databases were created for patients who

**Figure 1** Endoscopic retrograde cholangiography shows biliary fistula at the anastomosis.

**Figure 2** **A:** Endoscopic retrograde cholangiography shows anastomotic stenosis; **B:** Pneumatic dilatation on anastomotic stricture.

**Figure 3** Endoscopic retrograde cholangiography shows lack of contrast flow through the papilla, and dilatation of the choledochus.

underwent OLTx and LRLTx. For each patient, the following data were recorded: demographic information and clinical data, type of biliary complication, time of onset, type of endoscopic treatment, number of procedures received, recovery-time, need for other treatment, surgery or re-OLTx, and final outcome.

All biliary complications were initially treated with standard ERCP, performing the conventional procedure: sphincterotomy plus stent placement for biliary leak (Figure 1) and progressive pneumatic dilatation, and double stent placement for stricture (Figure 2). Sphincterotomy alone for Oddi dysfunction, diagnosed as a lack of biliary and contrast flow through the papilla and dilatation of the choledochus (manometry of Oddi is not available at our Institute, Figure 3); and finally, stone removal with Fogarty balloon or Dormia for stones. For cases requiring more than one

**Table 1** Biliary complications

	<b>OLTx (72/193)</b>	<b>LRLTx (44/68)</b>
Stenosis	55	20
Leak	5	12
Stenosis + leak	4	6
Oddi dysfunction	6	5
Stenosis + stones	1	1
Biliary sludge	1	0
Time of onset (mo)	5.1 (SD, 7.1)	3.7 (SD, 3.97)

procedure, ERCPs were repeated every 3 mo. ERCP was considered unsuccessful when biliary damage was not resolved despite an adequate endoscopic treatment: more precisely, when there was evidence of continuous bile leakage despite endoscopic stent placement, and/or persistence of stenosis, after 1 year, despite multiple dilatation and stent placement. When the endoscopic treatment failed, a percutaneous transhepatic approach (PTC) or surgery, with Roux-en-Y choledochojejunostomy, was adopted.

## RESULTS

### **Patients**

From June 2003 to June 2007, 261 adult patients were transplanted in our institute, 68 from living donors and 193 from cadaveric donors (2 were re-transplants after LRLTx failure). In the OLTx group with duct-to-duct anastomosis, 72/193 (37.3%) had biliary complications, while the rate in the LRLTx group was 44/68 (64.7%, Table 1). The follow-up was  $22.18 \pm 13.6$  mo.

### **OLTx group**

The highest rate of complications, 78.6%, was observed during the first 6 mo after transplantation. Biliary leaks occurred in 9 (12% of all complications) patients: 5 with leak alone and 4 with an associated anastomotic stricture. All biliary leaks occurred at the anastomosis, and were diagnosed within 3 mo of transplant. Of the 5 patients with leaks alone, 2 recovered well after endoscopy (within 3 mo), 2 required PTC, and 1 is still in follow-up. Of the 4 patients with leaks and stenosis, 1 recovered after 3 ERCPs (6 mo), 1 needed percutaneous stent placement, and 2 are in follow-up.

Anastomotic stenosis occurred in 60 patients (80% of all complications): 4 of them with biliary leak and 1 with associated biliary stones. In 45/60 patients (75%) the diagnosis was done within 6 mo. Of the 55 patients with stenosis alone, 27 recovered well with endoscopic treatment within 1 year, while 2 recovered after 18 mo (success rate, 52.7%). Seventeen patients are still in follow-up. Eleven patients required further treatment: 10 required PTC (2 required subsequent surgery), while 1 patient was treated directly with surgical anastomosis reconstruction. The patient with biliary stenosis and stones recovered after a single ERCP with dilatation and stone removal. The patients with biliary stenosis and leak are described above.

One patient presented biliary sludge at 1 mo after

**Table 2** Results and final outcome

	<b>OLTx (n = 72)</b>	<b>LRLTx (n = 44)</b>
Number of procedures	3.2 (SD, 2.4)	3.5 (SD, 2.9)
Success rate (%)	80.56	61.37
Mean follow-up (mo)	23.34 (SD, 13.13)	21.02 (SD, 14.10)
PTC	13	15
Surgery	3	6
RE-OLTx	1	2
Death	8	8

transplant, which was solved with an ERCP session with sphincterotomy and stone removal.

Six patients had Oddi dysfunction after an average of 4 mo post-transplant. These patients were treated with sphincterotomy and recovered after one procedure. Three patients with high levels of cholestatic index and MRI positive for anastomosis stricture showed a normal cholangiography, so no therapy was undertaken.

Finally, in the OLTx group, we observed 14 ERCP failures (19.4%): 13 patients needed PTC with internal-external stent placement (2 of them required surgery), and 1 underwent surgical biliary anastomosis reconstruction. The mean follow-up was 23.3 mo (4–52 mo). During the follow-up, 1 patient was re-transplanted due to graft failure. Eight patients died during follow-up (Table 2).

### **LRLTx group**

The highest rate of complications (79%) was observed in the LRLTx group during the first 6 mo after transplant. Biliary leaks occurred in 18 patients (40.9% of all complications). In 6 patients the leak was associated with anastomotic stricture. All leakages were observed at anastomosis, and all were diagnosed within 2 mo of transplantation. With regard to the 12 patients with leak alone, 3 recovered with ERCP after 1 mo, 3 mo and 4 mo, respectively, (average of 2.3 procedures). Of the 8 patients who did not recover despite the endoscopic treatment, 7 were treated with PTC (3 required subsequent surgery), and one was directly treated surgically due a large leak. The last patient treated by ERCP is still in follow-up. Of the 6 patients with leak and anastomosis stenosis, 4 are still in follow-up, 1 recovered with percutaneous approach and 1 surgically. None of the patients in this subgroup recovered after ERCP.

Anastomotic stenosis occurred in 27 patients: 1 patient had associated stones. Six patients had associated leak (discussed above). Anastomotic strictures occurred in 61.3% of patients with biliary complications. Of the 20 patients with anastomotic stricture, 9 recovered with the endoscopic treatment alone after a mean of 3.4 procedures (45% success rate); 5 patients are still in follow-up; and 6 required a percutaneous approach. The patient with stenosis and stones did not recover despite 7 ERCPs, and was treated successfully with a percutaneous approach. Five patients had Oddi dysfunction and recovered after 1 ERCP with sphincterotomy.

Finally, in the LRLTx group we observed 17 patients in whom the ERCP failed (38.6%): 15 were treated with

PTC (4 requiring subsequent surgical treatment), and 2 were sent directly to surgery after ERCP failure. The follow-up was  $21.02 \pm 14.10$  mo, with a maximum of 59 mo and a minimum of 3 mo. During the follow-up, 2 patients underwent OLTx due to graft failure. Eight patients died (Table 2).

## DISCUSSION

This report shows the results and follow-up of a large cohort of patients who developed biliary complications after liver transplantation (from both cadaveric and living donors) and were treated with ERCP. As previously reported, even in our transplant recipient population, biliary complications are very frequent. Moreover, complications occur more frequently in the LRLTx than in the OLTx recipients. The high rate observed in our OLTx group may be explained by the broad use of extended donor criteria (EDC) at our institute: 46.1% (89/193) of OLTx recipients received a marginal allograft. In the sub-group of patients receiving marginal livers the rate of biliary complications was higher (41.6%) than in non-marginal graft recipients (33.6%), though this difference was not statistically significant.

The extensive use of LFT and MRI for diagnosis of biliary disease results in a correct indication for ERCP: no false negative and 3 false positive (with normal cholangiography at ERCP) were observed. Most of the complications (about 80%) occurred within 6 mo of transplant (early complications); the most frequent was the anastomotic stricture, even if biliary leaks accounted for approximately 40% of all complications in the LRLTx group.

In this series, biliary complications were initially treated with a standard ERCP, using the conventional procedures: sphincterotomy with stent placement for biliary leak, and with progressive pneumatic dilatation, and double stents placement for stricture; sphincterotomy alone for Oddi dysfunction and stone removal with Fogarty balloon for stones. In the cases for which more than one session was required, the ERCPs were repeated every 3 mo (as maximum). The evidence of continuous bile leakage despite the endoscopic stent placement, or the persistence of stenosis after 1 year despite multiple dilatation and stent placement, was considered criteria for switching to another type of treatment: PTC as first choice, or surgery with biliary anastomosis reconstruction if the PTC approach failed or in the event of a very large leak. This approach led to a higher success rate in the OLTx group than in the LRLTx group: the ERCP was successful in 80.56% of the OLTx recipients, vs 61.37% for the LRLTx group. If we analyze the complications separately, the success rate for the treatment of anastomotic stenosis was the same in the both groups, but the success rate for the leak treatment was lower in the LRLTx group. The mean follow-up was long enough to allow us to view these data as reliable ( $22.18 \pm 13.6$  mo).

In conclusion, our data confirmed that, although ERCP is a quite effective mode of managing post-

transplant bile duct complications, a significant number of patients need other types of approach. Therefore, different techniques should be considered in order to improve the results. For instance, large, fully-covered metallic stents could improve the results for biliary leakage, and, in patients with stenosis, reduce the number of dilatation sessions. Partially covered metal stents have been employed in an effort to reduce stricture recurrence and to maintain duct patency; these stents are effective in the initial treatment of stricture but long term success is limited due to problems with stent patency<sup>[11]</sup>. The use of fully covered metal stents (removable) for leaks and strictures has not been tested yet, so further prospective studies are necessary in order to establish whether these new devices could improve the current results.

## COMMENTS

### Background

Biliary complications are the most frequent problem after liver transplantation. This rate of complications is higher for living-related liver transplantation (LRLTx) vs orthotopic liver transplantation (OLTx). Early diagnosis is crucial, as the treatment may improve graft function and help to avoid repeated surgery. Some studies have already been published on the endoscopic treatment of biliary complications and show a success rate of approximately 70%-80% of cases. But no standardized treatments in a long follow up were tested.

### Research frontiers

Although our data confirmed that Endoscopic Retrograde Cholangiopancreatography (ERCP) is a quite effective mode of managing post-transplant bile duct complications in a long follow up, a significant number of patients need other types of approach. Therefore, different techniques should be considered in order to improve the results. Partially covered metal stents have been employed in an effort to reduce stricture recurrence in benign stenosis and to maintain duct patency, but these stents are effective only in the initial treatment of strictures and the long term success is limited due to problems with stent patency. For instance, large, fully-covered metallic stents (removable) could improve the results for biliary leakage, and in patients with stenosis, reduce the number of dilatation sessions. The use of fully covered metal stents for leaks and strictures has not been tested yet, so in our opinion further prospective studies are required in order to establish whether these new devices, could improve the current results.

### Innovations and breakthroughs

This is a large prospective study on transplanted patients (both from cadaveric and live donors), in which the endoscopic treatments and the criteria of endoscopic therapy failure were well defined and standardized. The mean follow-up is long enough to allow us to view these data as reliable.

### Applications

Management of patients who underwent liver transplant from cadaveric and living donors, with duct-to-duct biliary anastomosis, who develop biliary complications.

### Peer review

This paper shows the long term results of a large cohort of patients treated with a well standardized endoscopic therapy; it clearly defines the criteria of endoscopic treatment failure with the appropriate timing to shift for other techniques. The long follow up allows the readers to consider the consistency of the results.

### Abstract

**AIM:** To analyze pituitary hormone and melatonin circadian rhythms, and to correlate hormonal alterations with clinical performance, hepatic disease severity and diagnostic tests used for the detection of hepatic encephalopathy in cirrhosis.

**METHODS:** Twenty-six patients with cirrhosis were enrolled in the study. Thirteen patients hospitalized for systemic diseases not affecting the liver were included as controls. Liver disease severity was assessed by the Child-Pugh score. All patients underwent detailed neurological assessment, electroencephalogram (EEG), brain magnetic resonance imaging (MRI), assays of pituitary hormone, cortisol and melatonin, and complete blood chemistry evaluation.

**RESULTS:** Pituitary hormone and melatonin circadian patterns were altered in cirrhosis patients without clinical encephalopathy. Circadian hormone alterations were different in cirrhosis patients compared with controls. Although cortisol secretion was not altered in any patient with cirrhosis, the basal cortisol levels were low

and correlated with EEG and brain MRI abnormalities. Melatonin was the only hormone associated with the severity of liver insufficiency.

**CONCLUSION:** Abnormal pituitary hormone and melatonin circadian patterns are present in cirrhosis before the development of hepatic encephalopathy. These abnormalities may be early indicators of impending hepatic encephalopathy. Factors affecting the human biologic clock at the early stages of liver insufficiency require further study.

### INTRODUCTION

Hepatic encephalopathy, a major complication of cirrhosis, is a clinical syndrome characterized by mental status changes in patients with severe hepatic insufficiency. By contrast, the term "Minimal Hepatic Encephalopathy", also known as subclinical hepatic encephalopathy (SHE) describes disturbances of several biological functions, including sleep and activities of daily living, in the absence of clinical neurologic symptoms<sup>[1-3]</sup>. Hormonal disorders and circadian rhythm abnormalities are often associated with liver disease<sup>[4]</sup>, and the severity of these disorders is related to liver disease severity and duration. The role of melatonin is critical, as diurnal melatonin rhythm disrupts

tion may significantly contribute to circadian function alterations<sup>[5]</sup>.

The main goal of the present study was to evaluate the circadian hormone secretion profile in cirrhosis patients without hepatic encephalopathy. Specifically, the study was designed to analyze the circadian rhythm of pituitary hormone, serum cortisol and melatonin, and correlate the hormone levels and 24-h hormone secretion abnormalities with brain magnetic resonance imaging (MRI) and electroencephalogram (EEG), which are used for the diagnosis of encephalopathy. In addition, the study also assessed the correlation between circadian hormone rhythm and the severity of hepatic disease as measured by the Child-Pugh score.

## MATERIALS AND METHODS

### Study design

This was an observational study conducted at the University Hospital of Patras, Greece, in the years 2005-2006.

### Patient recruitment

Twenty-six patients with cirrhosis were enrolled in the study. In addition, 13 patients hospitalized for various chronic diseases without liver or central nervous system (CNS) involvement were included as controls. We chose not to have a healthy control group, because hormone patterns in healthy people have been described in detail. Inclusion criteria were: age 35-75 years, abstinence from alcohol for at least 6 mo, cirrhosis confirmed by liver biopsy, and regular follow-up in our Liver Outpatient Clinic. Exclusion criteria were signs or symptoms of encephalopathy, any CNS or endocrine disease, use of medications with CNS effects, and illegal substance abuse.

Mean age was  $64.6 \pm 9.5$  years in cirrhosis patients and  $67.8 \pm 10.8$  years in controls. There were no significant differences between men and women. The etiology of disease in the two study groups is shown in Table 1.

The study was approved by the Institution Ethics Committee, and a written informed consent was obtained from all patients.

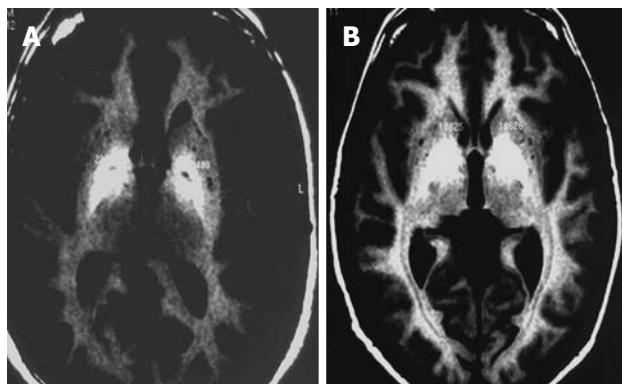

All study participants underwent comprehensive biochemical and clinical evaluation. The severity of cirrhosis was assessed by the Child-Pugh classification: 22 patients were Child-Pugh A (16 with score 5, and 6 with score 6), and 4 patients were Child-Pugh B (1 with score 7, 2 with score 8 and 1 with score 9). There was no patient with Child-Pugh class C.

### Hormone assays

Blood samples for cortisol, melatonin, prolactin and TSH levels were drawn at 09.00, 14.00 and 21.00 h in an attempt to make inferences about circadian hormone secretion patterns. Prolactin, TSH and cortisol levels were measured by the electrochemiluminescence technique (Elecys 2010 ROCHE, Roche Diagnostics GmbH D-68298 Manheim), while melatonin levels were determined using a radio-immunoassay method (Biosource, rue de l'Industrie-B-1400 Nivelles, Catalog Nr. KIPLO800).

**Table 1 Diagnostic data on patients with cirrhosis and control patients**

Cirrhosis etiology	Patient number	Controls	
		Admission diagnosis	Patient number
Alcohol	13	COPD	5
HBV infection	9	Cancer (no liver or CNS metastasis)	4
HCV infection	1	Ulcerative colitis	3
Alcohol + HBV	1	Crohn's disease	1
Alcohol + HCV	1		
Unknown	1		

**Figure 1** T1 MRI of basal ganglia in cirrhosis: mild (grade 1) signal increase (A) and severe (grade 2) signal increase (B).

### Brain MRI

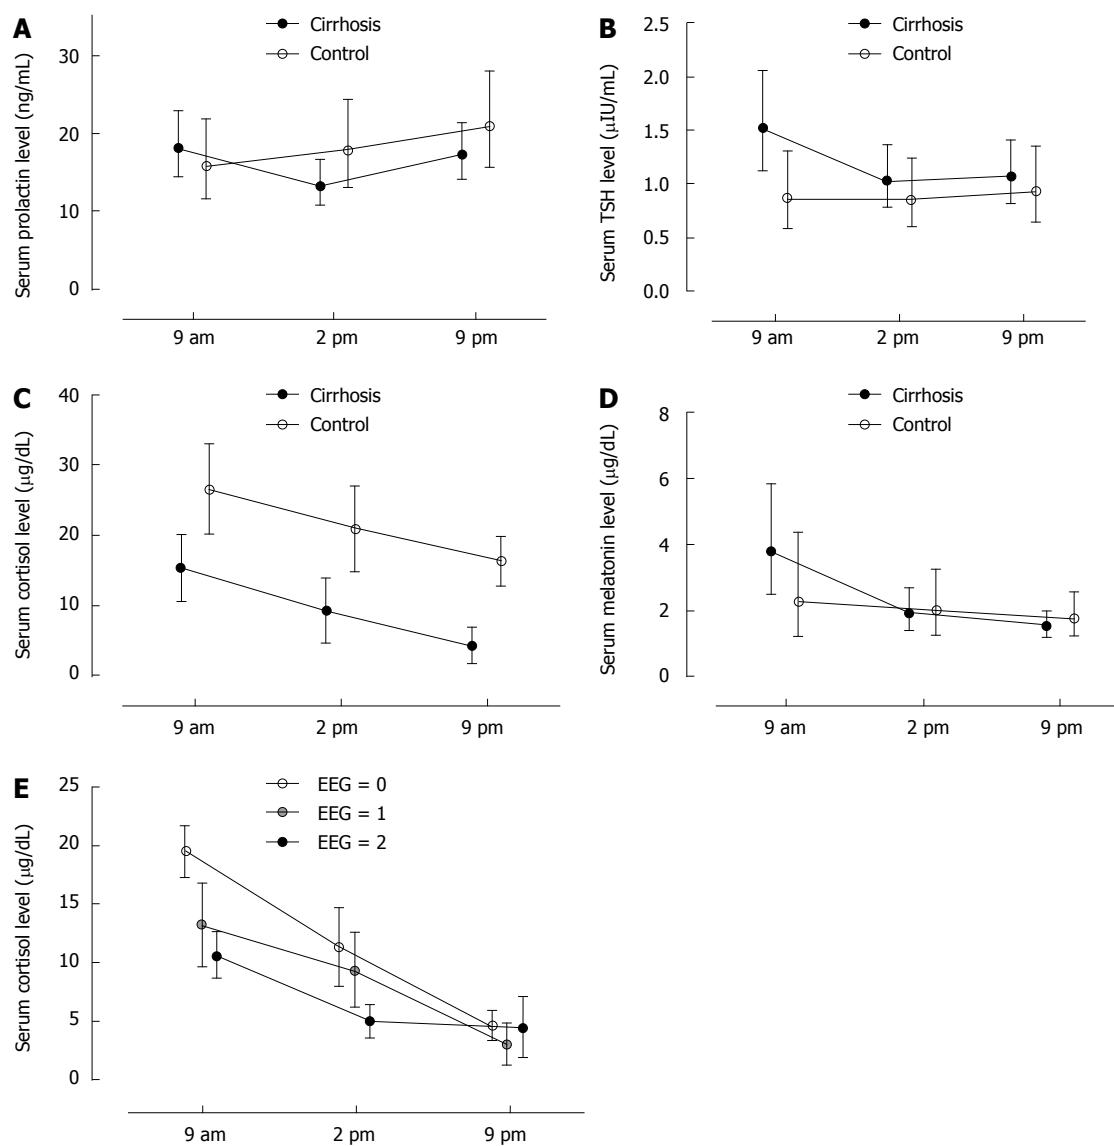

Brain MRI was performed without contrast with a 1 Tesla Gyroscan Intera MRI scanner using a head coil. Transverse and coronal sections were obtained with T1 sequences. Basal ganglia MRI signal was evaluated and compared with adjacent brain white matter MRI signal. The regions of interest (ROI) in the globus pallidus were defined bilaterally in axial and coronal images, whereby each ROI included a predetermined number of pixels. Quantitative image analysis was done by calculating the mean signal intensity for each ROI. MRI signal was classified as Grade 0 = no alterations, Grade 1 = mild alterations (Figure 1A) or Grade 2 = severe alterations (Figure 1B).

### Neurologic assessment

All patients underwent comprehensive clinical neurologic examination with emphasis on cortical function assessment. An awake 16-channel digital EEG was obtained with a standard 10-20 scalp electrode system. Abnormal EEG findings were classified as specific (epileptiform or paroxysmal) or nonspecific (theta and delta waves in various combinations) disturbances. Nonspecific disturbances were further classified as mild, moderate or severe.

### Statistical analysis

All statistical analysis was done with SPSS (Chicago, Illinois, USA) version 12 for Windows. Continuous data are presented as mean  $\pm$  SD. The Student's *t*-test was used to compare means and the Fischer's exact test to compare

**Figure 2** A: Prolactin levels in cirrhosis patients and controls; B: TSH levels in cirrhosis patients and controls; C: Cortisol levels in cirrhosis patients and controls; D: Melatonin levels in cirrhosis patients and controls; E: Cortisol and severity of EEG abnormalities.

proportions. Correlations between continuous variables were evaluated with Pearson's correlation coefficient. Hormone assay results were analyzed with repeated measures ANOVA on the log of measured values. The Student-Neumann-Keuls test was used for post-hoc multiple comparisons.  $P < 0.05$  was considered statistically significant for all tests.

## RESULTS

### Physical exam

All cirrhosis patients had normal muscle tone, normal tendon reflexes and no flapping tremors. Ascites was present in 2 patients, splenomegaly in 14 and endoscopically documented esophageal varices in 8 patients. Neurological evaluation did not reveal any abnormalities in the control subjects.

### Liver function tests and hormone assays

Baseline liver function tests showed minimal hepatic insufficiency without evidence of active liver disease (Table 2).

Hormone concentrations at 09.00 h, 14.00 h and

**Table 2 Baseline biochemical data (mean  $\pm$  SD)**

Parameter	Cirrhosis	Control	P
Bilirubin (mg/dL)	$1.44 \pm 0.95$	$0.89 \pm 0.24$	< 0.01
Albumin (g/dL)	$4.0 \pm 0.5$	$3.7 \pm 0.9$	
Globulin (g/dL)	$3.9 \pm 0.7$	$3.8 \pm 0.5$	
PT (s)	$14.4 \pm 1.8$	$11.4 \pm 0.8$	< 0.001
SGOT (U/L)	$49 \pm 31$	$42 \pm 34$	

21.00 h are presented in Figure 2A-D.

Prolactin levels did not show significant variations during the day in the controls. By contrast, prolactin levels were significantly ( $P < 0.05$ ) lower at 14.00 compared to 09.00 and 21.00 h in the cirrhosis group.

Morning TSH levels were significantly higher ( $P < 0.05$ ) in cirrhosis patients compared to controls. Within the cirrhosis group, TSH levels were significantly higher ( $P < 0.001$ ) at 9.00 h compared to 14.00 h and 21.00 h.

Cortisol levels were significantly lower ( $P < 0.001$ ) at all times in cirrhosis patients compared to controls. However, the circadian cortisol secretion pattern was not altered compared to the pattern described in healthy

**Table 3** MRI abnormalities and child scores n (%)

Child score	A5 (n = 16)	A6 (n = 6)	B7 (n = 1)	B8 (n = 2)	B9 (n = 1)	C (n = 0)
Severity of brain MRI abnormalities	0	8 (50)	-	-	-	-
	1	5 (31.20)	5 (83)	1 (100)	1 (50)	-
	2	3 (18.80)	1 (17)	-	1 (50)	1 (100)

MRI abnormality Grading: 0 = no abnormalities, 1 = mild abnormalities, 2 = severe abnormalities.

individuals. Both the study groups (cirrhosis patients and controls) demonstrated a significant ( $P < 0.05$ ) trend of decreasing cortisol levels from morning to night.

Melatonin levels were higher at 9.00 h compared to 14.00 h ( $P < 0.05$ ) and 21.00 h ( $P < 0.01$ ) in cirrhosis patients, whereas there was no such pattern in controls. The main difference between cirrhosis patients and controls was higher morning melatonin levels in patients with cirrhosis.

### Brain MRI

Brain MRI was abnormal in 18 of 26 cirrhosis patients, with high bilateral symmetrical signal intensity on T-1 images in the globus pallidus, the putamen, or both. The mean basal ganglia signal intensity was  $1093.4 \pm 171.8$  units on T-1 images. We did not find any brain MRI abnormalities in controls. The MRI abnormalities and Child Scores are presented in Table 3.

### EEG

EEG was performed in 22 of 26 cirrhosis patients and demonstrated nonspecific disturbances in 11 (50%) patients. Disturbances consisted of theta or delta waves, and were graded as mild (7 patients), moderate (3 patients), or severe (1 patient). We did not find epileptiform discharges in any patient. Cirrhosis patients with abnormal EEG had significantly ( $P < 0.05$ ) higher mean basal ganglia MRI signal intensity ( $1151.1 \pm 177.8$  units) compared to those with normal EEG ( $1014 \pm 135.3$  units).

### Hormone profile and MRI

We did not find any correlation between melatonin, TSH and prolactin levels with MRI abnormalities. However, serum cortisol levels showed significant ( $P < 0.005$ ) association with brain MRI abnormalities; the 9.00 ( $P < 0.04$ ) and 14.00 h ( $P < 0.01$ ) cortisol levels correlated with the severity of MRI disturbances.

### Hormone profile and cirrhosis severity

We did not find any association between prolactin or TSH levels and cirrhosis severity as measured by the Child-Pugh score. However, there was an association between cortisol and melatonin levels in patients with Child-Pugh score of 5 (16 patients) compared with those with score  $> 5$  (10 patients). Specifically, patients with Child score  $> 5$  manifested impaired circadian cortisol variation ( $P < 0.05$ ) and significantly lower morning cortisol levels ( $P < 0.01$ ) compared to those with Child score of 5 (Figure 2E).

The evening melatonin levels were significantly ( $P$

$< 0.04$ ) lower in cirrhosis patients with Child-Pugh score  $> 5$  (Group 2) compared to those with Child-Pugh score of 5 (Group 1).

### Hormone profile and EEG

We did not observe any association between prolactin, TSH, or melatonin levels and the severity of EEG disturbances (quantified as 0 = no EEG abnormalities, 1 = mild EEG abnormalities, 2 = severe EEG abnormalities). However, cortisol levels were higher in cirrhosis patients without EEG abnormalities compared to those with mild ( $P < 0.05$ ) EEG disturbances, and were even higher compared to those with severe ( $P < 0.01$ ) EEG abnormalities. The observed association between cortisol and EEG abnormalities was more pronounced in the morning ( $P < 0.001$ ).

## DISCUSSION

The presence of characteristic brain MRI and EEG disturbances, and hormone abnormalities in cirrhosis patients without hepatic encephalopathy is the main finding of the present study.

Hepatic encephalopathy is a syndrome characterized by abnormal mental status in patients with severe liver disease<sup>[6-8]</sup>. SHE is a milder condition associated with cirrhosis and/or porto-systemic shunts. The diagnosis of SHE is clinically relevant because it may precede the development of overt hepatic encephalopathy. Moreover, the psychomotor deficits in SHE may impair cognitive function and activities of daily living<sup>[2,3]</sup>. SHE diagnosis is based on psychometric tests, EEG and brain MRI. However, since there is no "gold standard" for diagnosing SHE<sup>[1-3,9]</sup>, the prevalence of this condition in cirrhosis has been reported variously as 30% to 84%, possibly due to different diagnostic criteria used in the various studies.

Cirrhosis patients without clinical encephalopathy often demonstrate high basal ganglia MRI T-1 signal intensity, likely due to manganese deposition in the brain<sup>[10-12]</sup>.

EEG is useful in the diagnosis of SHE, as slow (2-5 Hz) high-amplitude frontal lobe waves are characteristic of early hepatic encephalopathy. Although EEG abnormalities are not encephalopathy-specific, abnormal theta and delta wave activity correlates with disease severity<sup>[13]</sup>.

Several biological rhythm abnormalities, including impaired arterial pressure diurnal variation, nocturnal portal pressure rise, melatonin secretion and sleep pattern alterations occur in cirrhosis. The various mechanisms proposed to explain these circadian abnormalities include the following: (a) effect of neurotoxins on the

suprachiasmatic hypothalamic nucleus (SCN), which is the "human biologic clock"<sup>[14,15]</sup>, and (b) elevated morning melatonin levels due to impaired liver melatonin metabolism, causing a circadian clock phase-shift<sup>[16,17]</sup>.

Liver diseases are associated with several hormone disorders, including decreased serum levels of T3, cortisol, testosterone, FSH and insulin, and elevated prolactin concentrations<sup>[18-22]</sup>. In addition, a characteristic high daytime melatonin pattern<sup>[5]</sup> has been described; this may contribute to the sleep-wake cycle disturbances and hormone disorders, as SCN is located in the hypothalamus, which regulates pituitary hormones<sup>[5,23-26]</sup>.

Melatonin may act as an internal circadian body rhythm "synchronizer", and plasma melatonin profile may be a circadian pacemaker marker. Therefore, melatonin rhythm disruption observed in cirrhosis may reflect circadian alterations with significant clinical implications: high daytime melatonin levels can cause an endogenous clock phase-shift and may therefore partly explain the sleep disturbances observed in cirrhosis<sup>[5,27-29]</sup>. Additional factors, unrelated to melatonin but involved in liver failure, such as false neurotransmitters, cerebral amines and cerebral arteriovenous shunts may also contribute to hormonal circadian abnormalities in the early stages of hepatic encephalopathy. Our findings suggest that diurnal melatonin abnormalities correlate with the severity of liver disease in cirrhosis and may be identifiable early, before the development of clinical hepatic encephalopathy.

Prolactin secretion follows a pulsatile pattern, with a characteristic nocturnal rise, but cirrhosis is associated with elevated 24-h prolactin levels and loss of circadian prolactin rhythm<sup>[30-32]</sup>. However, our cirrhosis patients had significant prolactin circadian rhythm disturbances without baseline elevation. The differences between our findings and previous studies<sup>[30,31]</sup> may be explained by patient selection, as we excluded patients with clinical encephalopathy.

A diurnal TSH secretion pattern, with the highest concentrations in late evening and the first hours of nocturnal sleep is well documented in normal subjects. Circadian TSH level variations may be modulated, in part, by a dopaminergic mechanism, which plays a major role in TSH rhythmicity in liver disease<sup>[33-35]</sup>. In our study TSH circadian abnormality was identified in the absence of clinical encephalopathy.

Although impaired cortisol inactivation is well documented in cirrhosis, basal circadian cortisol secretion remains stable<sup>[36,37]</sup>. In the present study, patients with cirrhosis had low 24 h cortisol levels compared to controls.

Our data suggests that cirrhosis patients without encephalopathy have disrupted melatonin, TSH and prolactin circadian cycle, and suppressed 24-h cortisol levels, but the circadian cortisol rhythmicity is unaffected. More importantly, the melatonin abnormalities (lower night levels) are more pronounced in advanced liver failure (Child score > 5). As these findings were not seen in controls, the hormone abnormalities identified in cirrhosis could be specific for liver disease.

We did not find any correlation between melatonin, TSH or prolactin levels with the severity of brain MRI

or EEG abnormalities, but the lack of association may be a type-II error due to the small number of patients. Cortisol levels correlated with brain MRI abnormalities, EEG abnormalities and severity of liver disease (Child score > 5). Melatonin and cortisol abnormalities correlated with severity of liver disease, while TSH and prolactin levels did not. As we could not find any similar findings in the literature, we believe these observations deserve further investigation.

Our cirrhotic patients with SHE had abnormal circadian pituitary hormone secretion and diurnal melatonin cycle. The abnormal hormonal pattern in SHE is different compared to patients with systemic diseases not affecting the liver and healthy individuals. The presence of these abnormalities in cirrhosis without clinical encephalopathy raises the possibility that these patterns may represent indicators of early hepatic encephalopathy.

We believe that originality is the main strength of our study, as there are no published reports on pituitary hormone abnormalities in relation to the severity of hepatic encephalopathy. The main limitations include the study design (observational, no randomization, no power analysis, small patient number), and the attempt to make inferences about circadian patterns from three measurements per day. An additional (fourth) measurement if obtained the following morning could have provided additional insight into the time course of the observed hormone changes. Since the number of statistical comparisons largely exceeded the number of cases and groups, positive findings should be interpreted with caution, because of the possibility of type I error. The inclusion of a healthy control group would have improved the study, and should perhaps be considered in future studies on this subject.

In conclusion, circadian hormone disturbances occur early in cirrhosis and are associated with disease severity. These observations raise the interesting hypothesis that alterations in circadian hormone secretion may be an early sign of impending clinical encephalopathy. This hypothesis has significant clinical implications and therefore, we believe, deserves further investigation.

## COMMENTS

### Background

Hepatic encephalopathy is a neuropsychiatric disorder associated with clinical manifestations ranging from slightly altered mental status to coma. The severity of symptom depends on the severity of liver disease, and the presence of metabolic or infectious complications. The term "Minimal Hepatic Encephalopathy" includes biological disturbances such as that of sleep and daily activities, in the absence of neurologic symptoms. Abnormalities of psychometric tests, electroencephalogram (EEG) and brain magnetic resonance imaging (MRI) may support the diagnosis of Minimal Hepatic Encephalopathy. Hormonal disorders and circadian rhythm abnormalities are often associated with liver disease, and the severity of these disorders is related to the severity and duration of the liver disease. The role of melatonin, a marker of intrinsic circadian pacemaker is critical, since diurnal melatonin rhythm disruption may reflect circadian function alterations leading to disturbances in the daily activities.

### Research frontiers

Circadian pituitary hormone alterations, brain MRI and EEG abnormalities have been described in cirrhosis. However, there is limited data on the relationship of these abnormalities with the severity of cirrhosis and hepatic encephalopathy. This field deserves further study.

### Innovations and breakthroughs

This present study is the first attempt to evaluate circadian hormone abnormalities in relation to EEG, brain MRI, subclinical hepatic encephalopathy (SHE) and the severity of cirrhosis. The main finding is the presence of characteristic brain MRI, EEG and hormone secretion abnormalities in cirrhosis patients with SHE.

### Applications

Our data suggests that melatonin and pituitary hormone circadian rhythm abnormalities are present early in the course of cirrhosis and are associated with the severity of liver disease in patients without clinical encephalopathy. These findings raise the interesting hypothesis that circadian hormone abnormalities may be an early sign of the development of hepatic encephalopathy.

### Terminology

Circadian rhythm means a predictable physiologic fluctuation in a 24 h period; SHE is a clinical entity consisting of mild neuropsychological abnormalities affecting the activities of daily living in cirrhosis patients without clinical encephalopathy.

### Peer review

This is a non-randomized observational study with novel and interesting findings, demonstrating that abnormal pituitary hormone and melatonin circadian patterns are present in cirrhosis patients without hepatic encephalopathy. The manuscript is well written.

### Abstract

**AIM:** To test this hypothesis of barrett esophagus (BE) classified into two types and to further determine if there was any correlation between the shape of endoscopically suspected esophageal metaplasia (ESEM), prevalence of reflux esophagitis (RE) and heartburn.

**METHODS:** A total of 6504 Japanese who underwent endoscopy for their annual stomach check-up were enrolled in this study. BE was detected without histological confirmation that is ESEM. We originally classified cases of ESEM into 3 types based on its shape: Tongue-like (T type), Dome-like (D type) and Wave-like (W type) ESEM. The respective subjects were prospectively asked to complete questionnaires concerning the symptoms of heartburn, dysphagia, and abdominal pain for a one-month period.

**RESULTS:** ESEM was observed in 10.3% of 6504 subjects (ESEM  $< 1$  cm, 9.4%; 1 cm  $\leq$  ESEM  $<$  3 cm, 1.7%; ESEM  $\geq$  3 cm, 0.5%). The frequency of ESEM

### INTRODUCTION

Barrett's esophagus (BE) is considered to be a significant complication of gastroesophageal reflux disease (GERD) due to its association with adenocarcinoma<sup>[1]</sup>. For many years, BE was considered as an acquired disorder that developed as a result of GERD<sup>[2]</sup>. Patients with BE tended to have higher esophageal acid exposure compared with normal subjects, patients with non-erosive reflux disease, or those with erosive esophagitis<sup>[3]</sup>. The age of onset, duration of symptoms, and complications of GERD have been also demonstrated to be markers for increased risk of BE<sup>[4]</sup>. Interestingly, similar clinical risk factors were identified for esophageal

adenocarcinoma<sup>[5]</sup>.

According to Montreal definitions, the term endoscopically suspected esophageal metaplasia (ESEM) describes endoscopic findings consistent with BE that await histological evaluation<sup>[6]</sup>. The epidemiology of ESEM in Japan has been investigated<sup>[7,8]</sup>. It has been reported that the prevalence of long-segment ESEM was estimated to be 0.2%-0.4%<sup>[7]</sup>, which is consistent with reports from several other studies<sup>[8]</sup>. However, there appears to be considerable variation in reports of prevalence of short segment ESEM. The estimated range of short segment ESEM has been reported, varying from 6.0%-20.6%<sup>[7,8]</sup>. It is difficult to compare previous reports on the prevalence of ESEM because of the diverse methodologies used and the different methods of sample selection. However, because of considerable differences in the reported prevalence of short segment ESEM, we hypothesize that short segment ESEM may not always be associated with reflux esophagitis (RE). In fact, there are paradoxical reports in which no association between RE and BE has been reported<sup>[9]</sup>. Although ESEM is generally a complication of GERD, some cases of ESEM, especially the short segment type, have an obscure connection with GERD<sup>[10,11]</sup>. Therefore, ESEM may be best described as having two types: ESEM non-short segment type, which is closely associated with GERD, and ESEM short segment type, which may not be associated with GERD.

The aim of the present study was to determine whether there was a correlation between the shape and localization of ESEM and the prevalence of GERD. We also tested the hypothesis that ESEM might result from replacement of erosions in RE, thus we compared the circumferential involvement by erosions in RE and ESEM.

## MATERIALS AND METHODS

### **Patients**

A total of 160 983 Japanese patients (male/female, 60 774/100 209; mean age,  $61.9 \pm 11.1$ ), who underwent a stomach exam at the Miyagi Cancer Society between January and December 2003, were enrolled in this study. In order to check for gastric cancer, X-ray examinations were performed on all enrolled subjects. In addition, we evaluated disease classifications based on X-ray examinations. There were 15 616 subjects in whom further endoscopic testing was necessary because they were suspected of having gastric cancer. From this group, a total of 6504 subjects (male/female, 3197/3307; mean age  $62.7 \pm 10.7$ ) who underwent further endoscopic testing at the above center between January and December 2003 were enrolled in this study.

### **Endoscopic findings**

At the Miyagi Cancer Society, when endoscopically

examining and photographing the esophageal mucosa, the gastroesophageal junction (GEJ) is always prospectively photographed, and the ventral side of the esophagus is positioned at 12 o'clock, in the top upper part of the photograph. The Miyagi Cancer Society operates a digital filing system for endoscopic images (ScopeReader DCR. Rise Co., Ltd). All digital endoscopic images were independently and retrospectively reviewed by two endoscopists to investigate the presence and localization of RE and ESEM. If there was any inconsistency in the assessment of the digital endoscopic images, a final diagnosis was decided upon by a joint review of the digital endoscopic images. Furthermore, if less than 60% of the esophageal mucosa could be seen in any photograph, that patient was excluded from the analysis. A total of 134 cases were excluded from the analysis because of difficulty in assessment.

### **ESEM**

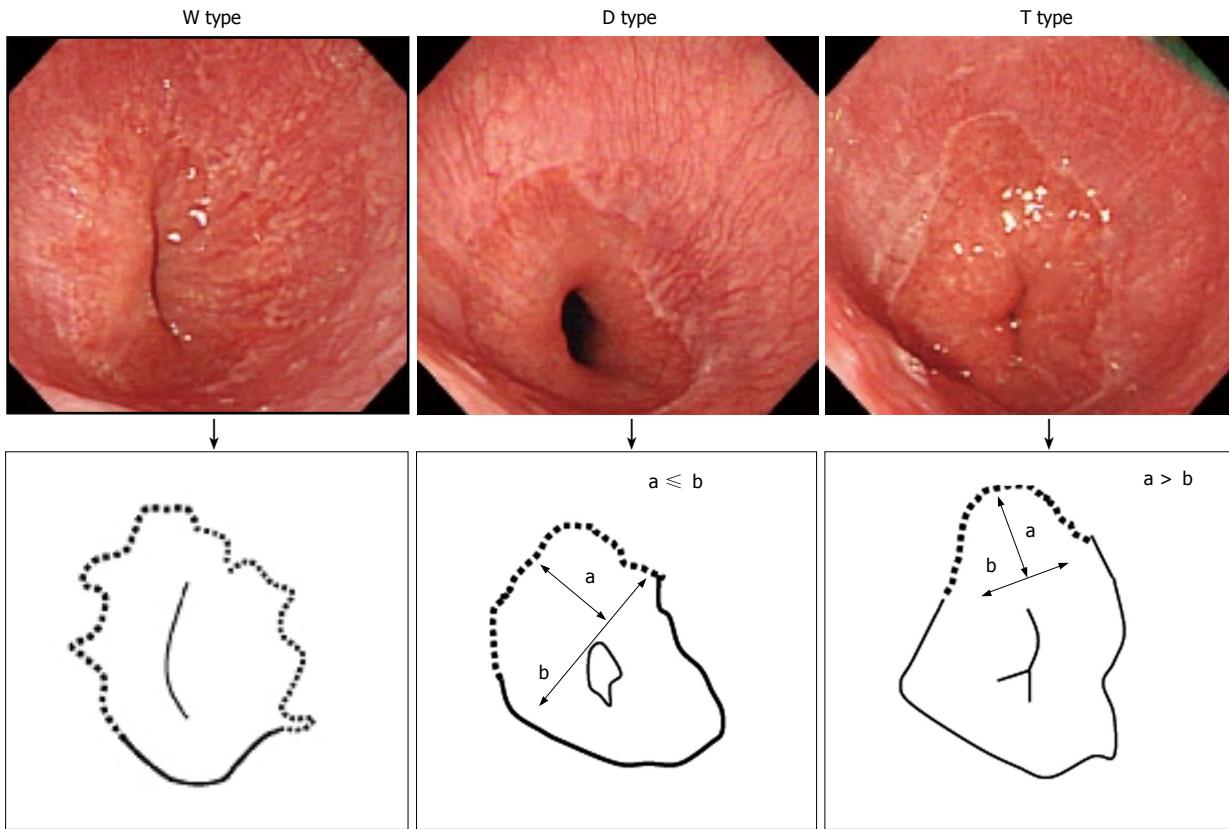

Although endoscopy with biopsy is the only validated technique to diagnose BE<sup>[6]</sup>, it has clear limitations as a screening tool due to cost, risk, and complexity. We therefore chose to assess ESEM in study patients. Diagnosed ESEM was defined as any length of columnar epithelium that extended continuously from the gastric lumen to the esophagus, and the GEJ was defined as the end of the palisade vessel of the lower esophagus<sup>[12]</sup>. If palisade vessels were not visible, the proximal margin of the gastric fold was used for detection of the GEJ. Furthermore, we also defined ESEM based on length and the following grading system was used.

### **Length of ESEM**

ESEM < 1: Defined as segments of columnar epithelium from the GEJ measuring <1 cm in length; 1 ≤ ESEM < 3: Defined as segments of columnar epithelium from the GEJ measuring 1 ≤ ESEM < 3 cm in length; ESEM ≥ 3: Defined as segments of columnar epithelium from the GEJ (measuring at the uppermost extent of red columnar epithelium) ≥ 3 cm in length, whether the columnar lining was circumferential or not.

### **Shape of ESEM**

We originally classified ESEM into 3 types based on shape. As shown in Figure 1, we classified the shape of ESEM as the following: (1) W type, in which the ESEM was defined by a columnar epithelium that extended continuously from the gastric lumen to the esophagus, in which the uppermost extent of the visible red columnar epithelium could be observed as a wave-like formation. The broken line in Figure 1 shows this type of ESEM; (2) D type, in which the length of basal part of the ESEM (b) was longer than the length of the major part of the ESEM (a) (i.e. a < b). The columnar epithelium of the ESEM is observed as a dome-like shape. The broken line in Figure 1 shows this type of ESEM; (3) T type,

**Figure 1** The shape of ESEM. We originally divided ESEM into 3 types based on its shape. The W type, in which the ESEM was defined by a columnar epithelium which extended continuously from the gastric lumen to the esophagus, in which the uppermost extent of the visible red columnar epithelium could be observed as a wave-like formation (W). The broken line in the illustration shows the ESEM. The D type, in which the length of basal part of the ESEM (b) was longer than the length of the major part of the ESEM (a; i.e.  $a < b$ ). The columnar epithelium of the ESEM is observed as a dome-like shape (D). The broken line in the illustration shows the ESEM. The T type in which the length of the major axis of the ESEM (a) is longer than the basal part of ESEM (b; i.e.  $a \geq b$ ). The columnar epithelium of the ESEM is observed as a tongue-like shape (T).

in which the length of the major axis of the ESEM (a) is longer than the basal part of ESEM (b) (i.e.  $a \geq b$ ). The columnar epithelium of the ESEM is observed as a tongue-like shape.

### Reflux esophagitis

RE is divided endoscopically into four grades, A to D, according to the severity of the mucosal breaks as defined by the Los Angeles (LA) classification<sup>[13]</sup>. A mucosal break was defined as "an area of slough or an area of erythema, with a discrete lined demarcation from the adjacent or normal looking mucosa"<sup>[13]</sup>.

### Localization of RE and ESEM

We also investigated the location in which mucosal breaks or ESEM occurred in the lower esophageal wall. The circumferential localization of mucosal breaks and the ESEM (according to shape) in the lower esophageal wall were determined according to the numbers on a clock face, with 12 o'clock always situated at the top of the photograph. When multiple mucosal breaks or ESEM were present, for example, grade A and B esophagitis or T type ESEM, the circumferential positions of all the mucosal breaks or ESEM were recorded. In cases of grade C esophagitis or W type ESEM, the transverse extent of the mucosal breaks or

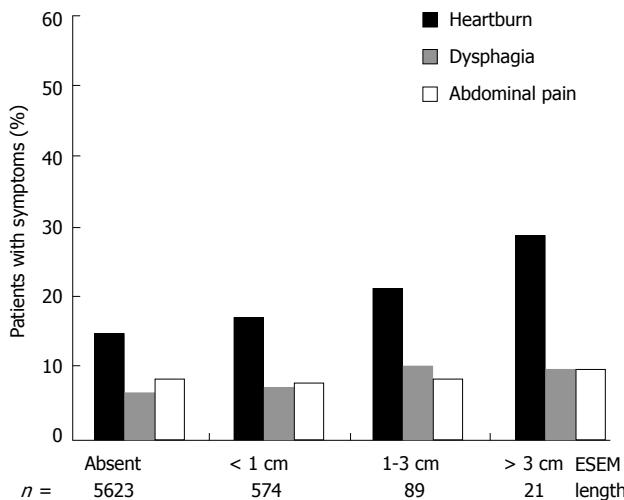

**Table 1** Questionnaire used in this study

Please circle the appropriate responses for each of the following symptoms during a 1-mo period	
Do you suffer from the symptom of dysphagia?	
1: yes	2: no
(a: usually; b: sometimes)	
(c: throat; d: chest; e: stomach)	
Do you suffer from the symptom of heartburn?	
1: yes	2: no
(a: usually; b: sometimes)	
Do you suffer from the symptom of abdominal pain?	
1: yes	2: no
(a: usually; b: sometimes)	
(f: before eating; g: after eating; h: no relation)	

the ESEM was assessed, and all the directions in which lesions existed were counted.

### Questionnaire

Table 1 showed the questionnaire used in this study. The subjects in each group were prospectively asked to complete the questionnaire concerning symptoms of heartburn, dysphagia, and abdominal pain within a one month period. The subjects were requested to simply answer "yes" or "no" to the symptoms, and if they answered "yes", they were further questioned

**Figure 2** Correlation between ESEM length grading and each clinical symptom. The prevalence of heartburn significantly increased in direct proportion to endoscopic ESEM length grading ( $P < 0.05$ ). No significance was observed between the length of ESEM and symptoms of dysphagia and abdominal pain.

on the frequency of symptoms ("usually" or "sometimes"). In addition, concerning the symptom of dysphagia, subjects were asked where the symptom of dysphagia occurred (throat, chest, or stomach). Regarding abdominal pain, its relationship with meals, if any, was elicited. This questionnaire was designed as a self-reporting instrument to measure symptoms experienced over one month previous to returning the completed questionnaire.

### Statistical analyses

The Mann-Whitney  $U$  test for nonparametric data was used for statistical analysis to compare results among the groups with different ESEM lengths and clinical symptoms. The Kruskal-Wallis rank test was used for statistical analysis to compare the results among the groups with different ESEM shapes. Values were additionally expressed as frequencies. Categorical variables were compared using the  $\chi^2$  test. A  $P$  value of less than 0.05 was considered significant.

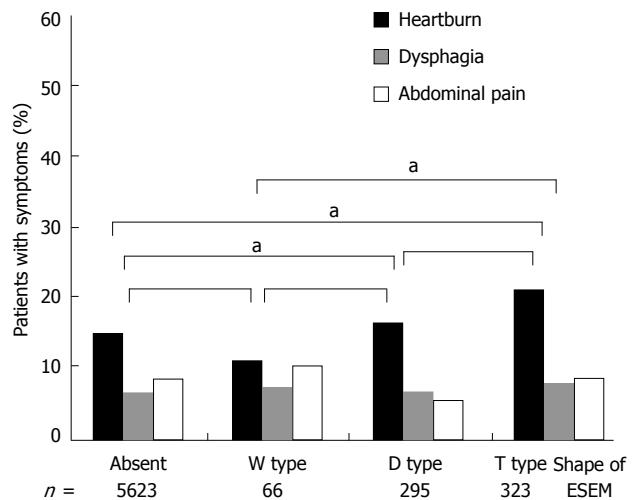

### The study protocol

The study protocol was approved by the ethical committee of the Tohoku University Graduate School of Medicine.

## RESULTS

### Study population

The mean age of the sample population was  $62.7 \pm 10.2$  years. All subjects responded to the questionnaire on heartburn, dysphagia and abdominal pain. Because the majority of subjects (99%) gave the frequency of the respective symptoms as "sometimes", the frequency of symptoms was omitted from our analysis. Among the 6504 subjects, 63 who had undergone some degree of stomach resection and 134 in whom judgment

**Figure 3** Correlation between the ESEM shape and each clinical symptom. The prevalence of heartburn significantly increased in the T type ESEM than the W type ESEM and ESEM-free patients ( $\chi^2$  test;  ${}^aP < 0.05$ ).

was difficult based on the digital photographic data were excluded from the final study analysis. Of the 6307 subjects in the final analysis, the mean age of the sample population was also  $62.7 \pm 10.2$  years. Females accounted for 50.8% of the interviewed subjects ( $n = 3206$ ).

### The prevalence of ESEM

ESEM was observed in 10.3% of subjects (ESEM  $< 1$  cm, 9.4%;  $1\text{ cm} \leqslant \text{ESEM} < 3$  cm, 1.7%; ESEM  $\geqslant 3$  cm, 0.5%). The frequency of ESEM was significantly higher in males compared with female subjects ( $\chi^2$  test).

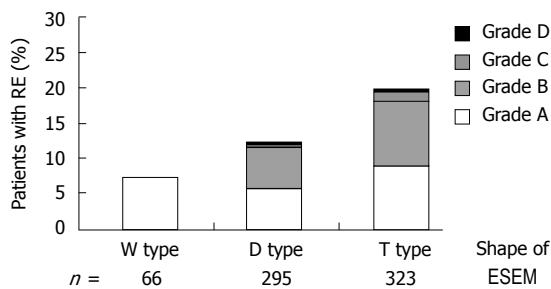

### Correlation between ESEM and clinical symptoms

Figure 2 shows the correlation between ESEM length grading and each clinical symptom. The prevalence of heartburn significantly increased concomitantly with the endoscopic ESEM length grading (Mann-Whitney  $U$  test). No significance was observed between the length of the ESEM and the prevalence of dysphagia and abdominal pain (Mann-Whitney  $U$  test).

Figure 3 shows the correlation between ESEM shape and each clinical symptom. The prevalence of heartburn was significantly higher in T type ESEM than W type ESEM and those subjects who did not have ESEM ( $\chi^2$  test). The subjects with T type ESEM tended to suffer from a high prevalence of heartburn compared to the subjects with D type ESEM, but without statistical significance ( $\chi^2$  test). No significance was observed between the shape of the ESEM and the prevalence of dysphagia and abdominal pain ( $\chi^2$  test).

### Correlation between ESEM and the prevalence of RE

Figure 4 shows the correlation between the shape of the ESEM and the prevalence of RE. The prevalence of RE was significantly higher in subjects with T type ESEM than those with the other shapes (Kruskal-Wallis rank test).

**Figure 4** Correlation between the shape of ESEM and the prevalence of RE. The prevalence of RE is significantly higher among those suffering from the T type ESEM (Kruskal-Wallis rank test,  $P < 0.05$ ).

### Localization of ESEM

Figure 5 shows the localization of ESEM. In subjects with T type ESEM, the ESEM was located mainly at the 12 o'clock and 1 o'clock wall (right anterior) of the lower esophagus, whereas in subjects with the D and W types, the ESEM was mainly located at the 9 o'clock to 12 o'clock wall (left anterior) of the lower esophagus. The circumferential location of the ESEM significantly differed among the different types of ESEM ( $\chi^2$  test).

### The prevalence of RE

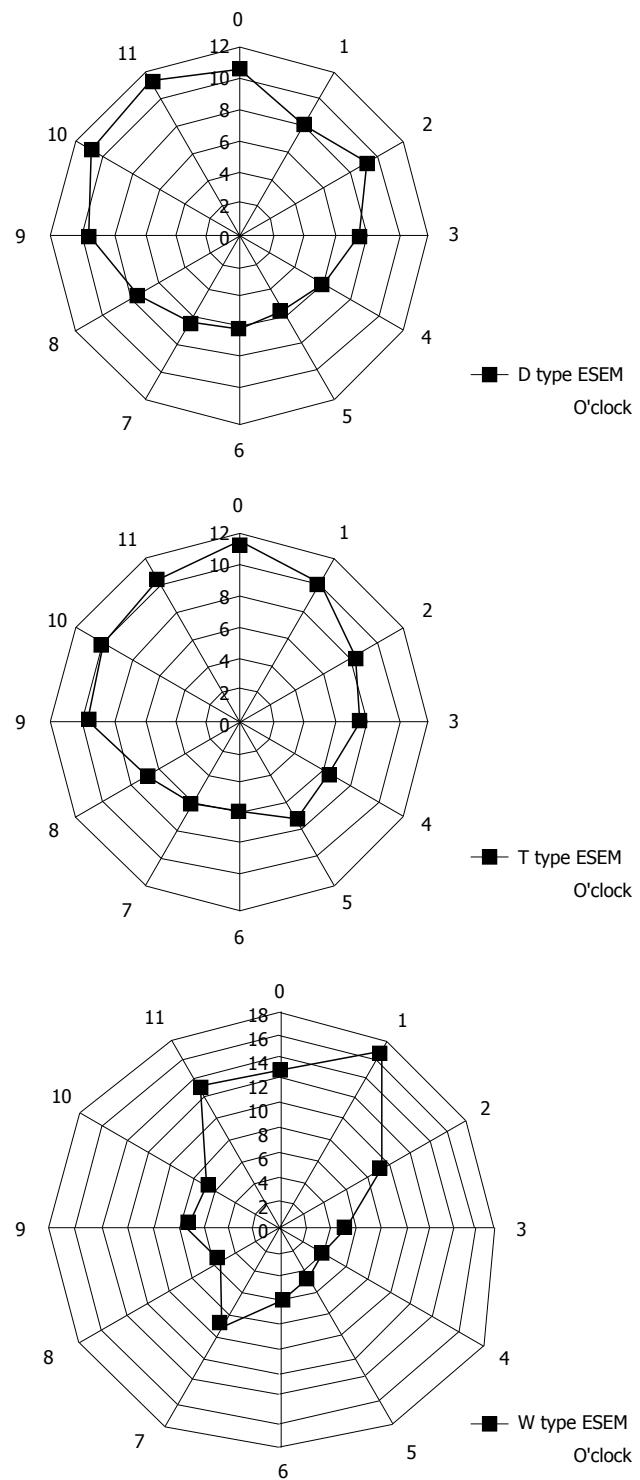

The endoscopic results revealed that 6.3% (grade A 3.7%, grade B 2.3%, grade C 0.2%, grade D 0.1%) of the subjects had RE according to the LA classification. The prevalence of RE was significantly higher in males (7.7%) than in females (6.3%,  $\chi^2$  test).

### Localization of RE

Figure 6 shows the localization of mucosal breaks in the lower esophageal wall. Subjects with grade A and B esophagitis had longitudinal mucosal breaks mainly at the 12 o'clock and 1 o'clock wall of the lower esophagus, whereas subjects with grade C and D esophagitis had transverse mucosal breaks mainly at the 4 o'clock to 6 o'clock wall of the lower esophagus (Figure 6). The circumferential locations of esophageal mucosal breaks significantly differed among different grades of esophagitis.

## DISCUSSION

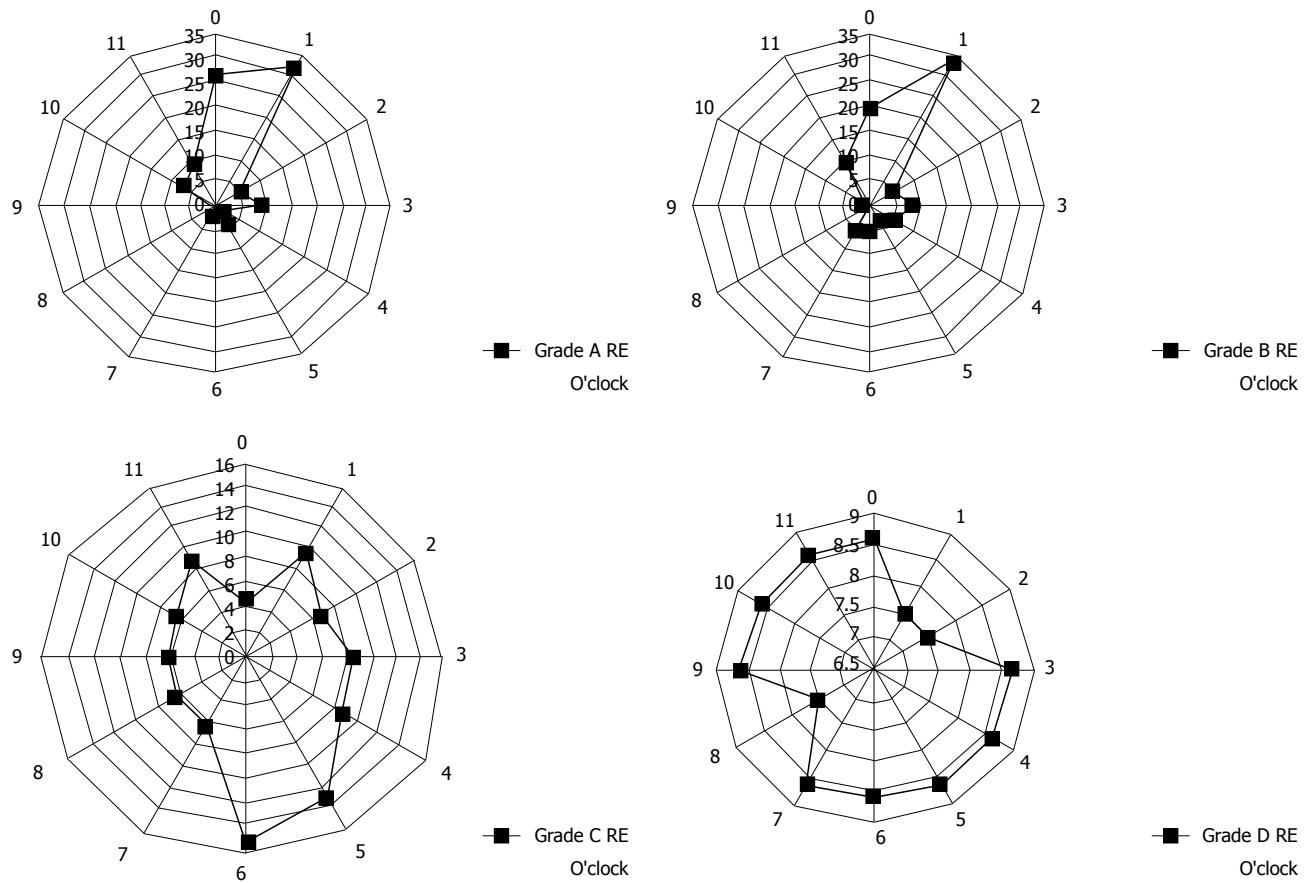

BE has been generally accepted as a complication of chronic and severe GERD<sup>[2-4]</sup>. It is currently accepted that BE places individuals at risk for the development of esophageal adenocarcinoma, which is the most rapidly increasing cancer in the United States<sup>[14]</sup>. Because the prevalence of RE in Japan is increasing to become near that of Western countries<sup>[15,16]</sup>, there might be a tendency for an increased number of esophageal adenocarcinomas in the Japanese population in the future. The fact that clinical risk factors with BE were also identified for esophageal adenocarcinoma attracted our attention<sup>[17]</sup>. The more frequent, more severe, and longer lasting the symptoms of acid reflux are, the greater the risk is for the development of

**Figure 5** The circumferential location of ESEM in subjects with the W, D, and T types of ESEM. Data are shown in terms of clock face orientation. The numbers represent the percentage of lesions on each side of the esophageal wall relative to the total number of lesions. The T-type ESEM is located mainly at the 12 and 1 o'clock wall (right anterior) of the lower esophagus, whereas the D and W types of ESEM are mainly located at the 9 to 12 o'clock wall (left anterior) of the lower esophagus. The circumferential distribution of ESEM differed significantly among subjects with different types of ESEM ( $\chi^2$  test:  $P < 0.05$ , T vs D, D vs W and W vs T).

adenocarcinoma of the esophagus<sup>[5]</sup>.

Although no one can doubt the importance of strong and chronic acid reflux in the development of BE, there is, however, doubt that all patients with BE

**Figure 6** The circumferential location of esophageal mucosal breaks in subjects with grade A-D RE. Data are shown in terms of clock face orientation. The numbers represent the percentage of lesions on each side of the esophageal wall relative to the total number of lesions. Patients with grade A and B esophagitis had longitudinal mucosal breaks mainly at the 12 o'clock and 1 o'clock wall of the lower esophagus, whereas patients with grade C and D esophagitis had transverse mucosal breaks mainly at the 4 o'clock to 6 o'clock wall of the lower esophagus. The circumferential distribution of esophageal mucosal breaks differed significantly among subjects with different grades of RE ( $\chi^2$  test:  $P < 0.05$ , A vs B, A vs C, A vs D, B vs C, B vs D and C vs D).

will show characteristic GERD symptoms. Ronkainen *et al* reported that BE may not develop as a late consequence of RE<sup>[9]</sup>. It is reported that obesity and smoking and drinking habits are also risk factors for developing BE<sup>[9,18-21]</sup>. A familial aggregation study of BE has been reported<sup>[22]</sup>. Several studies on BE have been carried out in Japan<sup>[7,8]</sup>. Kawano *et al* reported that there is a weak association between short segment BE and RE.

In summary, controversy exists regarding the potential of BE to develop as a late consequence of RE<sup>[10,11]</sup>. Paradoxical reports lead us to the idea that there are at least two types of short segment BE: one type that is closely associated with GERD and one that is not associated with GERD. We decided to investigate the relationship between ESEM endoscopic findings and clinical symptoms. We hypothesized that ESEM could be distinguished into two morphologically different types, one of which is closely associated with GERD and the other not associated with GERD.

We elucidated a significant correlation between the ESEM shape and each clinical symptom. The prevalence of heartburn was significantly higher in T type ESEM than in W type ESEM and ESEM-free subjects. Furthermore, subjects with T type ESEM tended to be

more symptomatic than the subjects with D type ESEM, and the prevalence of RE was highest in T type ESEM subjects. We found that T type ESEM was closely associated with GERD, whereas W type ESEM had a weak or no association with GERD.

We also hypothesized that T type ESEM might originate as a direct result of columnar replacement of areas damaged by RE. If this was correct, the localization of RE and localization of the T type ESEM should be in accord. Thus, we investigated the relationship between the localization of RE and ESEM and demonstrated that the localization of T type ESEM was also mainly at the 12 o'clock and 1 o'clock wall of the lower esophagus, which was similar in the case with grade A and B RE. This fact may support the proposition that RE plays an important part in the development of T type ESEM.

The reason why the circumferential location of esophageal mucosal breaks differs among different grades of esophagitis has not yet been fully investigated, but several speculative proposals have been put forward by Katsume *et al* and Winans<sup>[23,24]</sup>. Winans investigated the circumferential pressure of the lower esophageal sphincter, and confirmed that a significantly higher localized pressure existed in the orifices directed towards

the left posterior quadrant of the esophagus in normal subjects without hiatal hernia. Differing degrees of pressure due to the circumferential asymmetry of the lower esophageal sphincter could be a major cause of the differences in the localization of RE. With these dynamic causes in grade A and B RE, the mucosal breaks mainly exist at the 12 o'clock and 1 o'clock wall of the lower esophagus mucosal breaks. We may surmise that the mild type of RE, which is the most prevalent form of RE in Japan, may lead to the development of T type ESEM.

Two studies<sup>[25,26]</sup> in particular have attracted our attention. It has been reported that the localization of dysplasia in BE and cardiac cancer is dominant at the 12 o'clock and 3 o'clock wall of the lower esophagus<sup>[25,26]</sup>. However, we did not detect any corroborative findings in histological examinations in this study, thus more epidemiological studies will be required to examine this issue further.

The present study has a potential limitation. We collected data from subjects who had undergone further endoscopic testing among subjects who were suspected of having gastric cancer (cancer s/o) based on an X ray examination. Subjects who were suspected of having gastric cancer might have had a high degree of atrophic gastritis that resulted in low acid output, whereby the prevalence of GERD might be relatively low compared to the general Japanese population.

In conclusion, the prevalence of heartburn and RE was significantly higher in the T type of ESEM. The localization of ESEM was similar to the localization of mild RE, which is the most prevalent form of RE in Japan. We therefore propose that T type ESEM may arise as a result of RE.

## COMMENTS

### Background

Although Barrett esophagus (BE) is generally in place as a complication of Gastroesophageal reflux disease (GERD), some cases of BE, especially the short segment type, have an obscure connection with GERD.

### Research frontiers

We hypothesized that endoscopically suspected esophageal metaplasia (ESEM) could be distinguished into two morphologically different types, one of which is closely associated with GERD, and the other not associated with GERD.

### Innovations and breakthroughs

The controversy still exists regarding the potential of BE to develop as a late consequence of RE. These paradoxical reports lead us to the hypothesis that there are at least two type of short segment BE, namely one type that is closely associated with GERD, and one that is not associated with GERD.

### Applications

The prevalence of heartburn was significantly higher in the Tongue like (T-type) ESEM than in the Wave-like (W type) ESEM, and the prevalence of RE was highest in T type ESEM subjects. We found that the T type ESEM was closely associated with GERD, whereas the W type ESE had a weak or no association with GERD.

### Peer review

This is a good study that explores the possibility that Barrett's esophagus is not a homogeneous entity, but its shape and location may suggest a correlation with reflux symptoms and GERD. The authors have done a systematic job and have based their conclusions on sound reasoning.

Prevalence and clinical significance of SEN virus infection in patients with non A-E hepatitis and volunteer blood donors in Shanghai. *World J Gastroenterol* 2008; 14(26): 4204-4208 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4204.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4204>

## Abstract

**AIM:** To explore the prevalence of SEN virus (SENV) in patients with non A-E hepatitis and volunteer blood donors in Shanghai.

**METHODS:** According to the published gene sequences, primers from the conserved region were designed. Then, the prevalence of SEN virus in 30 samples from healthy voluntary blood donors and 30 samples from patients with non A-E hepatitis were detected by nested-PCR of SENV-D/H. Some PCR products were cloned and sequenced.

**RESULTS:** The specificity of genotype-specific PCR was confirmed by sequencing, the SENV DNA was detected in 53.3% of the patients with non A-E hepatitis and 10% of the blood donors. The prevalence of SENV-D/H viremia was significantly higher in patients with non A-E hepatitis than in blood donors ( $P = 0.0002$ ). SENV-H subtype and SENV-D subtype were found in 2 and 1 samples, respectively from blood donors. SENV-H subtype, SENV D subtype, mixed SENV-D and SENV-H subtype were found in 8, 6 and 2 samples, respectively, from patients with non A-E hepatitis.

**CONCLUSION:** The gene type of SENV in patients with non A-E hepatitis and blood donors in Shanghai is D or H subtype, and transfusion is not the only transmitting form of SENV.

## INTRODUCTION

A DNA virus-designated SEN virus (SENV), which was discovered in the serum of a human immunodeficiency virus type 1 (HIV-1)-infected patient, has been described recently<sup>[1]</sup>. It is assumed to be transmitted parenterally and to cause posttransfusion hepatitis in humans. SENV is described as a small single-stranded, non-enveloped circular DNA virus containing a genome of approximately 3800 nucleotides, possibly belonging to the circoviridae family. To date, eight distinct strains of SENV (A-H) have been identified<sup>[2]</sup>. There are 15%-50% sequence diversities among them. Phylogenetically, SENV is distantly related to TTV with which it shares a similar structural organization but only about 40%-60% sequence homologies<sup>[3]</sup>. According to previous studies, the prevalence of these eight different strains of SENV (A-H) is different in each infected group. The prevalence of SENV-D or SENV-H strains was 2.25% and 92.31% in different groups including healthy blood donors, patients with acute or chronic non A-E hepatitis, respectively, suggesting that SENV-D or SENV-H is significantly associated with the pathogenesis of non A-E hepatitis<sup>[3]</sup>.

To date, the prevalence of SENV in patients with various forms of liver disease has been reported in many countries and several districts of China, but the results are not consistent to a certain extent, and the role

of SENV infection in patients with non A-E hepatitis or other viral hepatitis, and the transmitting form of SENV are not very clear<sup>[4-7]</sup>. The purpose of this study was to investigate the prevalence and molecular biology characteristic of SENV in patients with non A-E hepatitis and volunteer blood donors in Shanghai, and the possible clinical significance of SENV infection in patients with non A-E hepatitis.

## MATERIALS AND METHODS

### **Patients**

A total of 30 serum samples from volunteer blood donors and 30 serum samples from patients with non A-E hepatitis from January 2005 to June 2007 in sixth people's Hospital affiliated to Shanghai Jiaotong University were studied. These cases included 42 men and 18 women, with a mean age of  $37.2 \pm 7.1$  years (range, 19-65 years). All the serum samples were negative for both HBsAg and anti-HCV. The patients with non A-E hepatitis were defined as negative control for known serologic markers, including IgM anti-HAV, IgM antibody to hepatitis B core antigen (anti-HBc), hepatitis B surface antigen (HBsAg), HBV DNA, and antibodies to HCV, HDV and HEV. The patients had no history of HAV, HDV, HEV, EBV, CMV infection, or of adiposis hepatica and hepatic lesions induced by drugs, alcohol, cholestatic and autoimmunity, or of transfusion.

### **Detection of SENV DNA**

The primers were designed according to the sequences submitted to GenBank with computer analysis to determine the outer primer by inner primer. All primers were synthesized by Shanghai Sangon Biological Engineering Technology & Services Co. Ltd. The sequences of primers are as follows (W = A or T, Y = C or T, M = A or C). SENV common primers: P1, 5'-TW CYCMAACGACCAGCTAGACCT-3'; P2, 5'-GTTTG TGGTAGCAGAACCGGA-3'. SENV-D primers: P3, 5'-CTAAGCAGCCCTAACACTCATCCAG-3'; P4, 5'-GCAGTTGACCGCAAAGTTACAAGAG-3'. SENV-H primers: P5, 5'-TTTGGCTGCACCTCTGGTT-3'; P6, 5'-AGAAATGATGGGTGAGTGTAGGG-3'.

All blood samples were separated by centrifugation. The sera were stored at -80°C until SENV DNA analysis. Viral DNA was extracted from 200 μL serum with the QIAamp DNA blood mini kit (Qiagen) and resuspended in 100 μL elution buffer according to the manufacturer's instructions.

PCR mixture of 50 μL contained 0.5 μL (50 pmol/L) sense primer SENV-P2, 0.5 μL (50 pmol/L) antisense primer P1, 250 μmol/L of each dNTP, 6 μL DNA sample, and 2.5 U Taq DNA polymerase (TaKaRa). The reactions consisted of preheating at 94°C for 4 min, 35 cycles of denaturation at 94°C for 40 s, annealing at 55°C for 50 s, extension at 72°C for 50 s, and a final at 72°C for 10 min.

The second PCR step was carried out with 50 μL PCR reaction mixture containing 10 μL of the first-

step amplification product. The same PCR buffer was used for the first PCR step, 0.5 μL (50 pmol/L) sense primer P4 and antisense primer P3 for SENV-D, 0.5 μL (50 pmol/L) sense primer P6 and antisense primer P5 for SENV-H, 250 μmol/L of each dNTP, and 2.5 U Taq DNA polymerase. PCR consisted of preheating at 94°C for 30 s, annealing at 55°C for 50 s, extension at 72°C for 50 s, and a final incubation at 72°C for 10 min.

### **Determination of SENV genotypes**

PCR amplified products were separated in 10 μL reaction mixture by electrophoresis on a 1.5% agarose gel, stained with ethidium bromide, and visualized using an ultraviolet transilluminator. Amplicons containing poly A tails and producing visible bands on agarose gel were excised from the gel and ligated to the pMD18-T vector (TaKaRa). DNA extracted from transformed *Escherichia Coli* was sequenced in Shanghai Sangon Biological Engineering Technology & Services Co, Ltd. The sequences excluding primer sequences were aligned with Cluster W to A-H SENV genotypes. The genotypes of SENV were determined by the phylogenetic trees.

### **Statistical analysis**

Descriptive statistical data such as means and proportions were calculated. Frequency was compared between groups using the chi-square test or Fisher's exact test, and group means were compared using Student's *t* test. Stepwise logistic regression method was used to analyze the data. *P* < 0.05 was considered statistically significant.

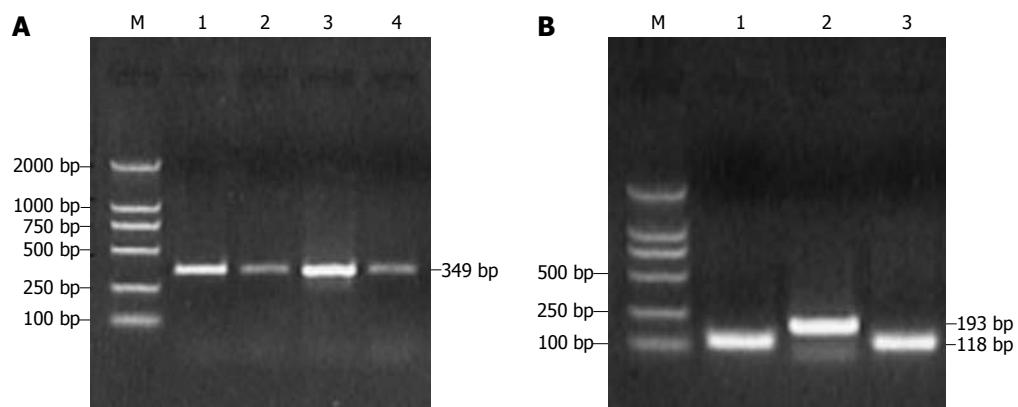

## RESULTS

### **Prevalence of SENV-D/H DNA in patients with non A-E hepatitis and blood donors**

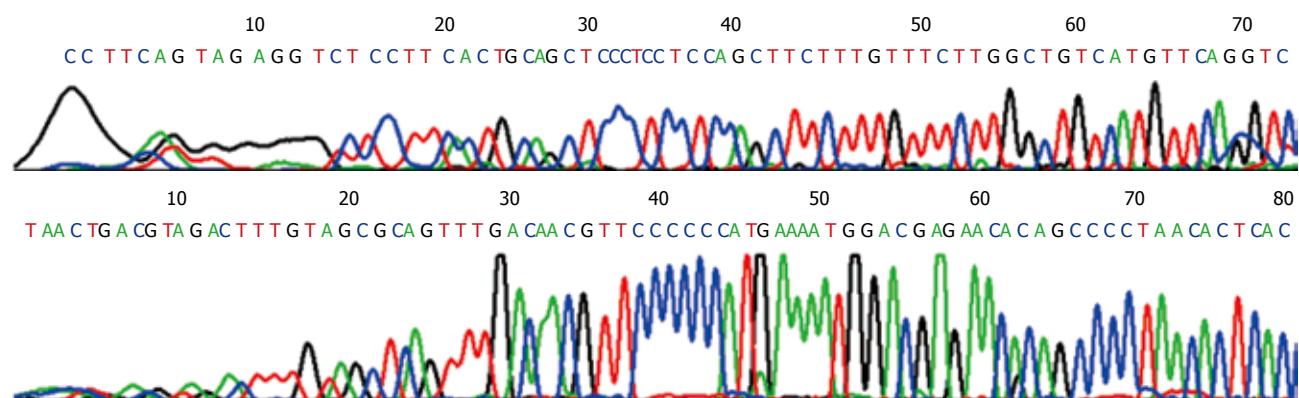

The nPCR results showed that 3 (10%) of the 30 volunteer blood donors and 16 (53.3%) of 30 patients with non A-E hepatitis were positive for SENV. Of 3 volunteer blood donors, 1 was positive for SENV-D and 2 were positive for SENV-H. Of the 16 patients with non A-E hepatitis, 6 were positive for SENV-D, 8 were positive for SENV-H, 2 were positive for both SENV-D and SENV-H DNA (SENV-D/H co-infection). The overall prevalence of SENV-D/H was 30%. After electrophoresis on 1.5% agarose gel stained with ethidium bromide on DNA product, the expected 349 bp, 118 bp and 193 bp bands were visualized on an UV transilluminator for SENV and SENV-D/-H, respectively (Figure 1). The positive rate of SENV infection was significantly higher in patients with non A-E hepatitis than in volunteer blood donors (*P* = 0.0002).

### **Sequencing PCR products and homology analysis**

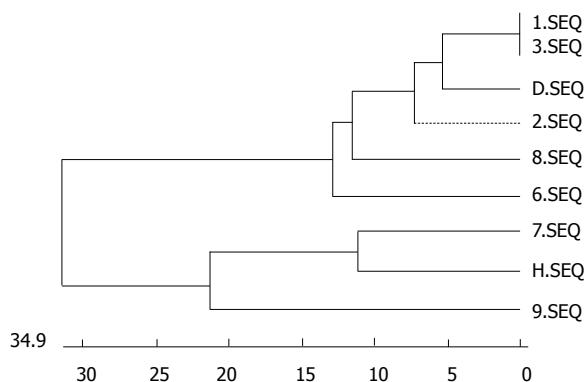

Randomly selected PCR products of P3 and P4 (118 bp) or P5 and P6 (193 bp) were sequenced. When the sequences of PCR positive products were compared with those of SENV by homology analysis, the

**Figure 1** Detection of SENV DNA (A) and SENV-D/H DNA (B). M: Marker DL2000; lane1-4: Primers and PCR products.

**Figure 2** Sequences of P3-P6 products.

**Figure 3** Phylogenetic tree of certain sequences of PCR products from patients with non A-E hepatitis and SENV-D and SENV-H subtype genes from GenBank.

homology was 98% between P3 and P4 amplification sequences of SENV-D, likewise, the homology was 98% between P5 and P6 amplification sequences of SENV-H. Some sequences of PCR positive products are shown in Figure 2. The phylogenetic tree for certain sequences of PCR products from patients with non A-E hepatitis and SENV-D/ H subtype genes from the GenBank (<http://www.ncbi.nlm.nih.gov/BLAST/>) are shown in Figure 3.

#### Distribution of SENV in blood donors and patients with non A-E hepatitis

SENV infection in different regions of China has been reported elsewhere<sup>[8-13]</sup>. The detected population was

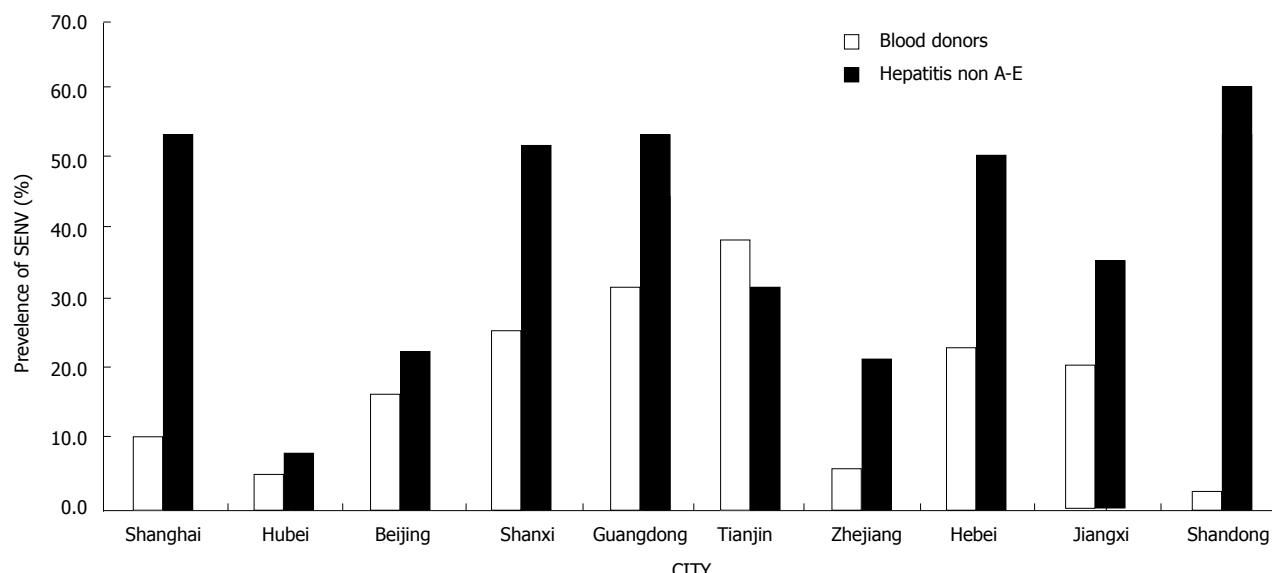

concentrated in areas of high CLD infection and the prevalence of SENV was different in these regions of China (Figure 4).

#### DISCUSSION

Hepatitis viruses can be divided into five types: A-E and cause 80%-90% hepatitis cases. Some viruses such as TTV are correlated with non A-E hepatitis<sup>[14-16]</sup>. However, no pathogenicity of TTV has been found in different populations<sup>[17-20]</sup>.

SENV has been recently identified as a candidate agent of non A-E hepatitis virus<sup>[21]</sup>. However, the exact role of this virus in the pathogenesis of chronic liver diseases, including chronic hepatitis and cirrhosis, and the development of hepatocellular carcinoma (HCC) remains to be verified<sup>[22]</sup>. The prevalence of transfusion-associated non A-E hepatitis is high and the SENV-D and SENV-H strains are significantly associated with transfusion-associated non A-E hepatitis.

Pirovano *et al*<sup>[23]</sup> found that aminotransferase level is transitly elevated in infants with positive SENV. Umemura *et al*<sup>[24]</sup> showed that SENV-D/H infection is related with posttransfusion hepatitis and special RNA molecule of SENV in which non A-E hepatic tissue probably is an intermedium of SENV replication. Recent data indicate that SENV DNA can be found in hepatic tissue from acute non A-E hepatitis patients and SENV perhaps causes hepatic lesions induced by *in situ* PCR. In addition, the detectable SENV DNA rate

**Figure 4** Prevalence of SENV in different provinces of China.

is 21% in patients with chronic hepatitis C<sup>[25-27]</sup>. In this study, the detectable SENV DNA rate was 10% (3/30) in 30 volunteer blood donors and 53.3% (16/30) in 30 patients with non A-E hepatitis.

In the present study, SENV infection was found in blood donors and patients with non A-E hepatitis in Shanghai. We found that approximately 3.2%-38.9% of blood donors and 9.3%-59.6% of non A-E hepatitis had positive SENV (Figure 4) and the positive SENV DNA rate was significantly different in different areas, suggesting that we must continue the detection of SENV DNA prevalence in other provinces. Interestingly, the prevalence rate of SENV was higher in blood donors than in patients with non A-E hepatitis (38.9% vs 32.3%) in Tianjin.

Furthermore, SENV-H was found in 2 volunteer blood donors and SENV-D was found in 1 volunteer blood donor infected with SENV. SENV-H, SENV-D and mixed SENV-D/H were found in 8, 6, and 2 patients with hepatitis, indicating that the prevalence of SENV in Shanghai is relatively low. However, SENV infection was not associated with blood transfusion in 16 SENV positive non A-E hepatitis patients with no blood-transfusion history, indicating that blood transfusion transmission is not the only way for people to infect with SENV. Because of the limited number of serum samples in our study, we could not explain why SENV infection is related with blood transfusion or non A-E hepatitis.

In conclusion, SENV infection is higher in patients with non A-E hepatitis than in blood donors and the homology is 98%. Further study with a large number of samples is required to analyze the relationship between SENV infection and non A-E hepatitis.

## COMMENTS

### Background

SEN virus (SENV) is described as a small single-stranded, non-enveloped circular DNA virus, possibly belonging to the circoviridae family. To date, eight

distinct strains of SENV (A-H) have been identified. The prevalence of these eight different strains SENV (A-H) is different in each infected group. In the present study, the prevalence of SENV-D or SENV-H strain was 2.25% and 92.31% in blood donors and patients with acute or chronic non A-E hepatitis, suggesting that SENV-D or SENV-H is significantly associated with the pathogenesis of non A-E hepatitis.

### Research frontiers

The prevalence of SENV in patients with various forms of liver disease has been reported in many countries and several regions of China, but the results are not consistent. The role of SENV infection in patients with non A-E hepatitis or other viral hepatitis and the transmitting form of SENV are not very clear. The clinical significance of SENV infection in patients with non A-E hepatitis is also not very clear.

### Innovations and breakthroughs

SENV infection was studied in blood donors and patients with non A-E hepatitis in Shanghai. The results indicate that the prevalence of SENV in blood donors of Shanghai was relatively lower than that in other regions of China. SENV infection was not associated with blood transfusion in SENV positive patients with non A-E hepatitis with no blood-transfusion history, suggesting that blood transfusion transmission is not the only way to spread SENV.

### Applications

The SENV infection rate is higher in non A-E hepatitis than in blood donors in Shanghai. Because of the limited number of serum samples in our study, we could not explain why SENV infection is associated with blood transfusion or non A-E hepatitis. Further study with a large number of samples is required to analyze the relationship between SENV infection and non A-E hepatitis.

### Peer review

This paper describes the prevalence of SEN virus in blood donors and hepatitis patients. The study is well designed and provides important information about the prevalence of SENV in hepatitis patients.

## Abstract

**AIM:** To study the expression of human insulin gene in gastrointestinal tracts of diabetic rats.

**METHODS:** pCMV.Ins, an expression plasmid of the human insulin gene, wrapped with chitosan nanoparticles, was transfected to the diabetic rats through lavage and colocephaly, respectively. Fasting blood glucose and plasma insulin levels were measured for 7 d. Reverse transcription polymerase chain reaction (RT-PCR) analysis and Western blot analysis were performed to confirm the expression of human insulin gene.

**RESULTS:** Compared with the control group, the fasting blood glucose levels in the lavage and colocephaly groups were decreased significantly in 4 d ( $5.63 \pm 0.48$  mmol/L and  $5.07 \pm 0.37$  mmol/L vs  $22.12 \pm 1.31$  mmol/L, respectively,  $P < 0.01$ ), while the plasma insulin levels were much higher ( $32.26 \pm 1.81$   $\mu$ IU/mL and  $32.79 \pm 1.84$   $\mu$ IU/mL vs  $14.23 \pm 1.38$   $\mu$ IU/mL, respectively,  $P < 0.01$ ). The human insulin gene mRNA and human insulin were only detected in the lavage and colocephaly groups.

**CONCLUSION:** Human insulin gene wrapped with chitosan nanoparticles can be successfully transfected to rats through gastrointestinal tract, indicating that chitosan is a promising non-viral vector.

## INTRODUCTION

Type 1 diabetes mellitus is the result of insulin deficiency caused by the autoimmune destruction of insulin-producing pancreatic  $\beta$  cells. Hyperglycemia would cause a lot of long-term clinical problems, including renal failure, retinopathy, neuropathy and heart disease<sup>[1]</sup>. Although intensive exogenous insulin therapy can delay or prevent the onset of chronic complications, it is rather cumbersome and sometimes would cause hypoglycemia, which could be life-threatening. However, the development of gene therapy has also generated a greater hope and excitement for a possible “cure” of diabetes since insulin gene was first cloned and expressed in cultured cells in the late 1970s<sup>[2]</sup>. Many attempts have been made, including islet transplantation<sup>[3-5]</sup>, whole pancreas transplantation<sup>[6,7]</sup>, regeneration of  $\beta$  cells<sup>[8-10]</sup> and insulin gene therapy<sup>[11-13]</sup>.

In general, whole organ transplants have more sustained and durable function. Advances in islet transplantation procedures now mean that patients with the disease can be cured by transplantation of primary human islets of Langerhans. The major drawbacks of these strategies are the insufficient availability of donor islets, invasive procedure and high cost. Due to the limited available number of donor islet cells, researchers are looking for different

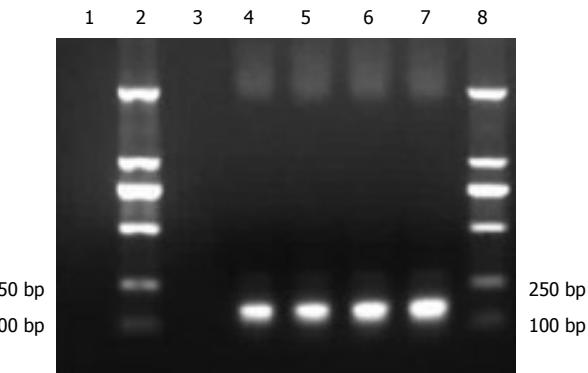

sources of pancreatic islet progenitor or stem cells. Stem cells with an extensive proliferative ability may provide a valuable source of islet progenitor cells. Several studies have demonstrated that progenitor/stem cells can be expanded *in vitro* to generate a large number of islet progenitor cells<sup>[14-16]</sup>. However, efficient and direct differentiation of these cells to an endocrine pancreatic lineage is difficult to achieve. Insulin gene therapy including any approach involving the introduction of a foreign gene into any cell type in the body can produce insulin<sup>[17]</sup>. The gene(s) introduced could be the insulin gene itself, perhaps under control of a tissue specific promoter, allowing for expression in a selected non-β-cell type, or in a gene encoding for a factor that activates the insulin gene, thereby allowing for ectopic insulin production. In insulin gene therapy, one of the key issues is the selection of carriers. Conventional viral vectors can introduce exogenous genes into cells precisely and effectively, but they can easily cause immune reactions because of the existence of antiviral immune system. More and more researchers are interested in non-viral vectors.

In this study, we constructed an expression plasmid pCMV.Ins expressing human insulin gene. Then, we wrapped the pCMV.Ins with chitosan nanoparticles, a non-viral vector, and transfected to diabetic rats through gastrointestinal tract to explore the gene therapy for type 1 diabetes mellitus. At present, there is no report on transfection of human insulin gene to gastrointestinal tract and application of chitosan as a vector in gene therapy for type 1 diabetes mellitus.

## MATERIALS AND METHODS

### Materials

The cDNA sequences of human insulin gene were cut from the PBAT16, hInsG1.M2 (presented by Doctor Michael German, Department of Hormone Research Institute, University of San Francisco, USA.) using *Bgl*II / *Not*I enzyme inserted into the expression vector of pCMV.eGFP in the cohesive end. Then the pCMV.Ins was transformed into *E.coli*. The top10F strains (Invitrogen) were screened. Plasmids isolated with a large-scale alkaline lysis procedure were purified, 0.1 g chitosan was dissolved in 100 mL acetic acid, and the pH was adjusted to 5.5 with sodium hydrate. The solution was stored at 4°C after determined with a micropore film, the aperture of which was 0.22 μm. Before it was used, the chitosan solution was diluted with ddH<sub>2</sub>O until the concentration reached 0.02%. One hundred μL DNA solution at a concentration of 200 μg/mL was added into 100 μL sodium sulfate solution at a concentration of 25 mmol/L. After the chitosan and DNA solutions were heated to 55°C in an aqueous bath for 15 min, respectively, they were mixed immediately and put into convolution for 1 min. The volume of reaction system should not excess 500 μL<sup>[18]</sup>. Experiments were carried out in 45

**Figure 1** PCR of recombinant plasmid pCMV.Ins. Lane 1: PCMV.eGFP, lanes 2 and 8: Molecular marker, lane 3: Negative control, lane 4: Recombinant plasmid pCMV.Ins, lanes 5-7: Bacterial suspension.

male Wistar rats (weighing 180-190 g) at the age of 8 wk. After an overnight fasting, the rats were given a single intraperitoneal injection of 60 mg/kg streptozotocin (STZ, Upjohn, Kalamazoo, MI, USA) in a 0.01 mol/L citrate buffer. Forty rats with their fasting blood glucose level > 16.7 mmol/L were used in the study. The rats were randomly divided into 4 groups. Chitosan-DNA nanoparticles were transfected to the diabetic rats through lavage and colocephaly, respectively. The two control groups were treated with naked chitosan and normal saline respectively. The rats had free access to diets and water.

### Identification of plasmid

pCMV.Ins was identified by PCR. The sequences of primers used for human insulin specifically are 5'-ATCACTGTCCTCTGCCA-3' (forward) and 5'-GGGTGTGTAGAAGAAAGCC-3' (reverse). The PCR products were analyzed by a 1.5% agarose gel electrophoresis, and the expected amplification length was 173 bp. The DNA sequencing of pCMV.Ins plasmid was performed in the Shanghai Sangon Sequencing Center.

### Measurement of fasting blood glucose and plasma insulin levels

The fasting blood glucose and plasma insulin levels were measured in all groups. The glucose levels in blood samples obtained from tail veins were measured with the one touch meter and test strips (Lifescan Inc, USA) every morning. The plasma human insulin was detected with a commercial human insulin radioimmunoassay (RIA) kit (Institute of Atomic Energy, China).

### Reverse transcription polymerase chain reaction (RT-PCR) analysis

RT-PCR was performed to verify the expression of human insulin gene in gastrointestinal tract. Half of the rats in each group were killed on the 4th d after they transfected with chitosan-DNA nanoparticles. Immediately upon death, stomachs, intestines and rectums of the treated and control animals were flash-frozen in liquid nitrogen, and stored at -70°C. Total RNA

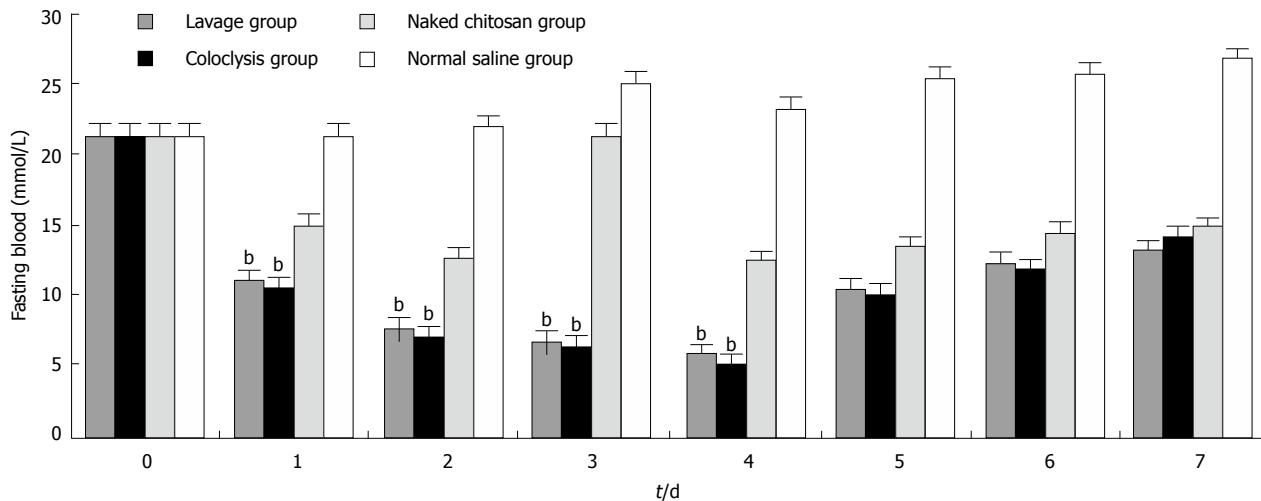

Figure 2 Fasting blood glucose levels in each group after the normal saline treatment. <sup>b</sup> $P < 0.01$  vs naked chitosan group and normal saline group ( $n = 10$ ).

(5 µg), obtained using Trizol (Gibco BRL, Gaithersburg, MD, USA) according to the manufacturer's instructions, was subjected to reverse transcription by using an oligo-dT21 primer, recombinant RNasin, and AMV reverse transcriptase (all Promega, Madison, WI, USA). AMV RT was inactivated at 95°C, and PCR was performed by using a gene amp PCR system 9600 thermal cycler (Perkin Elmer, Norwalk, CT, USA), and Taq DNA polymerase (Perkin Elmer). The cDNA-mixture was allowed to react for 19 (*GAPDH*), or 22 (insulin) cycles. The sequences of primers used for human insulin are 5'-ACCATGGCCCTGTGGATGCGC-3' (forward), and 5'-CTAGTTGCA GTAGTTCTC-CAG-3' (reverse). The sequences of primers for *GAPDH* are 5'-ACCACAGTCCATGCCATCAC-3' (forward) and 5'-TCCACCACCTGTTG CTGTA-3' (reverse). Insulin primers were designed to amplify human insulin specifically. Primers for *GAPDH* were used in control reactions. The RT-PCR products were analyzed by a 1.5% agarose gel electrophoresis, and the expected amplification lengths were 336 bp and 451 bp, respectively.

#### Western blot analysis

Four days after the transfection, stomachs and intestines were harvested and resuspended in a lysis buffer containing 1% nonidet P-40, 50 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 200 U/mL aprotinin, 1 mmol/L phenylmethanesulfonyl fluoride. The tissue lysates (50 mg of protein) were separated by 12% polyacrylamide gel electrophoresis and blotted onto poly-vinylidene difluoride membranes. Immunoblotting was performed with the antibody against human insulin (Sigma-Aldrich Corp, St Louis, MO, USA), and the molecular weight of human insulin was known as 56 kDa.

#### Statistical analysis

Data were expressed as mean  $\pm$  SD. The concentrations of blood glucose and plasma insulin were evaluated by

one-way ANOVA (SPSS for Windows 11.5).  $P < 0.05$  was considered statistically significant.

## RESULTS

#### Identification of recombinant plasmid pCMV.Ins

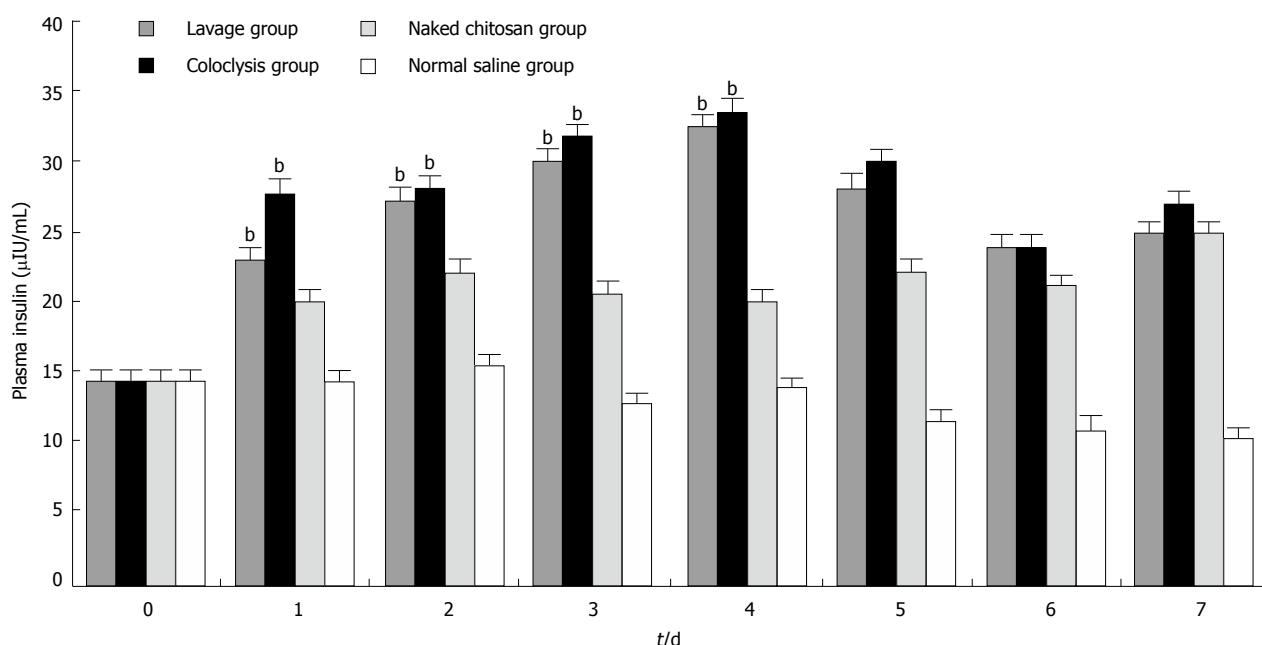

The PCR products of recombinant plasmid pCMV.Ins and bacterial suspension were amplified. One specific band was obtained in lanes 4-7, respectively, corresponding to the expected size of 173 bp. No fragments in lanes 1 and 3 were amplified from pCMV.eGFP and negative control (Figure 1), suggesting that the human insulin gene was successfully inserted into recombinant plasmid pCMV.Ins. The sequencing results also revealed that the recombinant pCMV.Ins plasmid was successfully constructed. The number of sequencing reports was LE142.

#### Change in fasting blood glucose

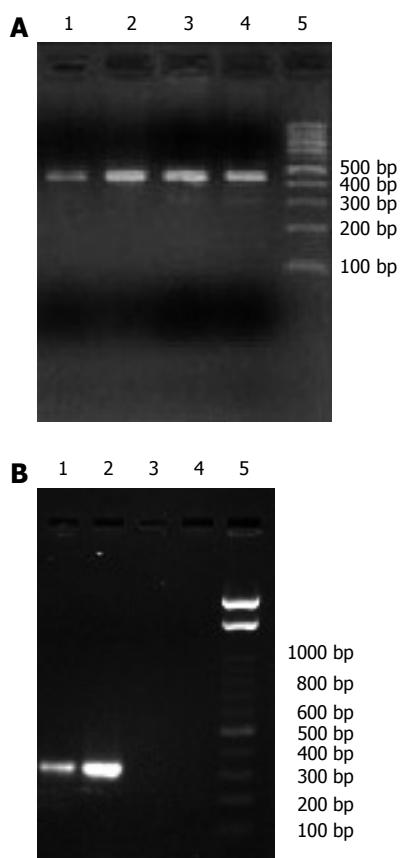

The fasting blood glucose level was decreased in lavage and coloclysis groups from  $22.12 \pm 1.31$  mmol/L to  $5.63 \pm 0.48$  mmol/L and  $5.07 \pm 0.37$  mmol/L, respectively, after transfected ( $n = 10$  each group). The levels of fasting blood glucose were significantly lower in the lavage group and coloclysis group transfected with chitosan-DNA nanoparticles ( $P < 0.01$ ) after the normal saline treatment from the 1st to 4th d (Figure 2). The blood glucose levels in the naked chitosan group also decreased significantly, because chitosan had the effect of decreasing blood glucose level. The blood glucose levels in the lavage and coloclysis groups were much lower than those in the naked chitosan group, and the differences were significant ( $P < 0.01$ ). There was no difference in blood glucose levels between the lavage and coloclysis groups.

#### Change in plasma insulin

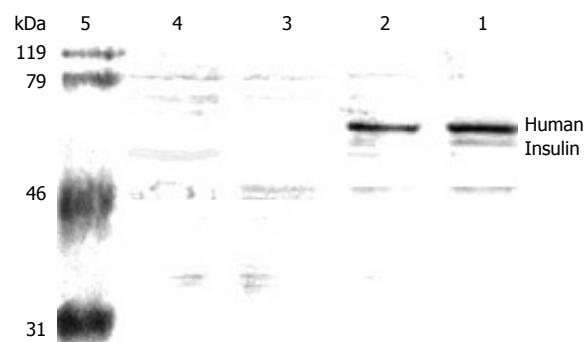

The plasma insulin in the lavage and coloclysis groups increased from  $14.23 \pm 1.38$  µIU/mL to  $32.26 \pm 1.81$  µIU/mL and  $32.7 \pm 1.84$  µIU/mL after transfection ( $n = 10$  each group). The plasma insulin levels in the

**Figure 3** Plasma insulin levels in each group after transfection. <sup>b</sup> $P < 0.01$  vs naked chitosan group and normal saline group ( $n = 10$ ).

**Figure 4** Amplification results of GAPDH (A) and human insulin gene mRNA (B) in each group. Lane 1: Lavage group, lane 2: Coloclysis group, lane 3: Naked chitosan group, lane 4: Normal saline group, lane 5: Molecular marker.

**Figure 5** Expression of human insulin in each group. Lane 1: Lavage group, lane 2: Coloclysis group, lane 3: Naked chitosan group, lane 4: Normal saline group, lane 5: Molecular marker.

#### Verification of human insulin gene expression

To analyze the expression of the human insulin gene, RT-PCR and Western blot analysis were carried out. Total RNA from the gastrointestinal tract was amplified using primers specific for GAPDH, revealing a 451 bp fragment in all groups (Figure 4A). However, human insulin specific primers produced a fragment, corresponding to the expected size of 336-bp in lanes 1 and 2, only in reactions containing RNA from the lavage and coloclysis groups, respectively (Figure 4B). No products were amplified from cDNA in the naked chitosan group (lane 3) and normal saline group (lane 4).

The molecular weight of human insulin was 56 kDa (Figure 5). One specific band was only obtained in the lavage and coloclysis groups in lanes 1 and 2, respectively. No products were obtained in the naked chitosan group (lane 3) and normal saline group (lane 4). These results suggest that the exogenous transferred pCMV.Ins plasmid but not the endogenous insulin gene expressed the mRNA and human insulin.

lavage, coloclysis and naked chitosan groups (Figure 3) were higher than those in the normal saline group from the Day 1 to the Day 4 ( $P < 0.01$ ). There were remarkable differences among the lavage, coloclysis and naked chitosan groups ( $P < 0.01$ ). The differences between the lavage and coloclysis groups did not show any statistical significance. These results were consistent with reduction in the fasting blood glucose levels.

## DISCUSSION

One factor critical to successful gene therapy is the development of efficient delivery systems. Despite the advances in gene transfer technology including viral and non-viral vectors, no ideal vector system is available at present<sup>[19]</sup>. Although viral vectors can introduce exogenous genes into cells precisely and effectively, they can easily cause immune reactions because of the existence of antiviral immune system. Due to the growing concerns over the toxicity and immunogenicity of viral DNA delivery systems, DNA delivery *via* improving viral routes has become more desirable and advantageous<sup>[20]</sup>.

A perfect vector should also be biocompatible, efficient, and modular so that it can be applied both in research and in clinical settings<sup>[21]</sup>. Taking into account this point, we selected chitosan nanoparticle, a kind of non-viral vector, in the study. We found that human insulin gene wrapped with chitosan nanoparticles could decrease the fasting blood glucose level and increase the insulin level in STZ diabetic rats. The mRNA in human insulin gene and human insulin was detectable in the gastrointestinal tract. These results demonstrate that chitosan nanoparticles can mediate the transfection of human insulin gene and that chitosan nanoparticles can be used as a good vector in gene therapy of type 1 diabetes mellitus. Köping-Höggård *et al*<sup>[22]</sup> reported that aerosol delivery formulated with chitosan oligomers can improve the distribution of pDNA polyplexes in the lungs and increase 6-fold of the efficiency of gene delivery *in vivo* over the commonly used intratracheal instillation method.

Chitosan nanoparticles are a kind of non-viral vector. Non-viral vector includes liposome<sup>[23-25]</sup>, composite<sup>[26]</sup>, microsphere, and nanoparticles, etc<sup>[27,28]</sup>, but the cytotoxicity of the bangosome limits its application *in vivo*. Owing to its loose constitution, the constancy of composites is poor. The diameter of microsphere is bigger than that of nanoparticles. Chitosan nanoparticles are a comparatively promising non-viral vector. Chitosan nanoparticles<sup>[29]</sup> have a good biocompatibility and no toxicity, and are economically available. The transfection efficiency of chitosan can be regulated by changing its molecular weight, plasmid concentration, and the chitosan/plasmid ratio. After the plasmid is embedded in chitosan, it can resist the degradation of nucleases. It also exhibits an antibacterial activity by inhibiting the bacterial metabolism.

In our study, the fasting blood glucose level was decreased during the first 4 d, due to the regeneration of gastrointestinal tract epithelial cells, which is consistent with the reported data<sup>[30]</sup>.

Further study should be performed to detect the cells intaking the plasmid. We speculate that gut K-cells may intake the expression plasmid. The gut K-cells in the epithelium mucosa of gastrointestinal tract secrete glucose-dependent insulinotropic polypeptide (GIP)<sup>[31]</sup>, an incretin hormone secreted by endocrine K-cells in response to nutrient absorption. GIP can

stimulate β cells to release insulin, and promote the regeneration of β cells<sup>[32]</sup>. GLP accounts for about 60% of the stimulation of insulin by oral glucose, but the determinants of their secretion from the small intestine are poorly understood<sup>[33]</sup>. There are many similarities between the release of GIP and the secretion of insulin. The concentration of GIP will obviously increase several minutes after glucose ingestion, and return to its basal level after 2 h. It was reported that the antagonist of GIP can remarkably degrade the secretion of insulin<sup>[34]</sup>. Furthermore, the promoter of GIP can only be activated in K-cells.

One of the key points in gene therapy for diabetes is the modification (processing) of proinsulin to insulin. Most non-β cells functioning as target cells in gene therapy for diabetes are lack of typical prohormone convertases which are essential to the processing of proinsulin, whereas K-cells can produce PC2 and PC3, which can help process the proinsulin correctly<sup>[35]</sup>. Palizban *et al* have transfected rat small intestine K-cells with pGIP/Ins plasmid by DOTAP liposome<sup>[36]</sup>. As mentioned above, K-cells might be the best target cells in gene therapy for type 1 diabetes mellitus due to their response to glucose and resistance to destruction mediated by cytokines and free radicals.

In conclusion, the human insulin gene can be transfected successfully by chitosan-DNA nanoparticles and expressed efficiently in the gastrointestinal tract of diabetic rats, and chitosan is a promising non-viral vector. If it is applied in clinic practice, it would be accepted by patients. Although much work remains to be done, the rapid progress in insulin gene therapy provides an optimistic outlook for its clinical applications in the treatment of type 1 diabetes mellitus.

## ACKNOWLEDGMENTS

The authors thank Dr. Michael German, Department of Hormone Research Institute, University of San Francisco (San Francisco, USA) for donation of pBAT16, hInsG1.M2 plasmid.

## COMMENTS

### Background

Gastrointestinal K-cells might be the best target cells in gene therapy for type 1 diabetes mellitus due to their response to glucose and the resistance to the destruction mediated by cytokines and free radicals. A perfect vector should also be biocompatible, efficient, and modular so that it can be applied both in research and in clinical settings. Chitosan is an ideal non-viral vector and has drawn wide attention.

### Research frontiers

There are considerable endocrine cells in the gastrointestinal tract. Gastrointestinal K-cells are the potential and ideal target cells in gene therapy for diabetes. Progress in gene therapy has produced promising results that translate experimental research into clinical treatment. The main barrier in gene transfer is a safe and effective gene delivery system.

### Innovations and breakthroughs

The exogenous insulin genes can be transfected by chitosan nanoparticles and expressed efficiently in the gastrointestinal tract of diabetic rats, indicating that chitosan is a promising non-viral vector. At present, there is no report on

the transfection of human insulin gene to the gastrointestinal tract and on the application of chitosan as a vector in gene therapy for type 1 diabetes mellitus.

### Applications

The superiority of human insulin gene expression in gastrointestinal tract by chitosan nanoparticles is its safety without any wound. If it can be applied in clinic practice, it would be accepted by patients. Chitosan is an ideal non-viral vector and can be widely used in gene transfer.

### Terminology

Gastrointestinal K-cells exist in the epithelium mucosa of gastrointestinal tract and can secrete glucose-dependent insulinotropic polypeptide (GIP), which can stimulate  $\beta$  cells to release insulin and promote the regeneration of  $\beta$  cells. Chitosan nanoparticles are a kind of non-viral vector and have a good biocompatibility without any toxicity, and are economically available. The transfection efficiency of chitosan can be regulated easily. After the plasmid is embedded in chitosan, it can resist the degradation of nucleases.

### Peer review

This paper reports the expression of human insulin gene in the gastrointestinal tract by chitosan nanoparticles, thus providing new technologies of gene transfer to endocrine cells in the gastrointestinal tract. This study is well designed and interesting.

### Abstract

**AIM:** To analyze the prognostic impact of lymphadenectomy extent in advanced gastric cancer located in the cardia and fundus.

**METHODS:** Two hundred and thirty-six patients with advanced gastric cancer located in the cardia and fundus who underwent D2 curative resection were analyzed retrospectively. Relationships between the numbers of lymph nodes (LNs) dissected and survival was analyzed among different clinical stage subgroups.

**RESULTS:** The 5-year overall survival rate of the entire cohort was 37.5%. Multivariate prognostic variables were total LNs dissected ( $P < 0.0001$ ; or number of negative LNs examined,  $P < 0.0001$ ), number of positive LNs ( $P < 0.0001$ ), T category ( $P < 0.0001$ ) and tumor size ( $P = 0.015$ ). The greatest survival differences were observed at cutoff values of 20 LNs resected for stage II ( $P = 0.0136$ ), 25 for stage III ( $P < 0.0001$ ), 30 for stage IV ( $P = 0.0002$ ), and 15 for all patients ( $P = 0.0024$ ). Based on the statistically assumed linearity as best fit, linear regression showed a significant survival enhancement based on increasing negative LNs for patients of stages III ( $P = 0.013$ ) and IV ( $P = 0.035$ ).

**CONCLUSION:** To improve the long-term survival of patients with advanced gastric cancer located in

### INTRODUCTION

At present, surgery is the most effective treatment for gastric cancer. As the standard procedure for advanced gastric cancer, D2 radical resection has been widely accepted and practiced<sup>[1-3]</sup>. The final results of a randomized Dutch trial<sup>[4]</sup> showed that patients with N2 disease might benefit from a D2 dissection, which required removing all the lymph nodes (LNs) of Group 1 and Group 2. According to another randomized Italian trial<sup>[5]</sup>, a D2 lymphadenectomy was also advised. Lymph node metastasis is considered one of the most important prognostic factors<sup>[6,7]</sup>, and adequate lymphadenectomy is advocated for gastric cancer. However, the number of LNs that should be removed and examined when performing a D2 lymphadenectomy has not been determined for advanced gastric cancer located in the cardia and fundus<sup>[8]</sup>. Therefore, the aim of this retrospective study was to evaluate the relative contributions of both the number of total resected LNs and the number of negative LNs to the outcome of patients with advanced gastric cancer located in the cardia and fundus, and provide further evidence for rational lymphadenectomy.

## MATERIALS AND METHODS

### Materials

Between January, 1996 and June, 2002, 236 patients diagnosed with primary gastric cancer located in the cardia and fundus was treated with curative resection at the Department of Oncology, Affiliated Union Hospital of Fujian Medical University, Fuzhou, China. The surgical procedure was defined as curative when no grossly visible tumor tissue (metastasis or LN involvement) remained after the resection and the resection margins were histologically normal. There were 197 male and 39 female patients whose ages ranged from 30 to 79 years ( $58.8 \pm 9.8$  years). All patients received a D2 or more extended dissection according to the Japanese Classification of Gastric Carcinoma (JCGC). Lymph nodes were meticulously dissected from the en bloc specimens, and the classification of the dissected LNs was determined by specialist surgeons who reviewed the excised specimens after surgery based on the Japanese Classification of Gastric Carcinoma<sup>[9]</sup>. The clinical and histopathologic data of each patient were collected and recorded in a specifically designed form. The tumors were histologically classified according to the WHO classification criteria and staged according to the 5th Edition of the TNM system<sup>[10]</sup>, as listed in Table 1. The follow-up was carried out by trained investigators through mailings, telephone calls, visiting patients or recording the patients' consultations at the outpatient service. The survival time was the time from diagnosis until the last contact, the date of death, or the date that the survival information was collected. All surviving patients were followed for more than five years. The median follow up for the entire cohort was 44 mo (range, 1-136 mo). The follow-up rate was 94.0%, with 222 cases involved.

### Methods

Patients were stratified into five groups based on the number of total LNs removed as follows: < 15 LNs (36 cases), 15-19 LNs (43 cases), 20-24 LNs (62 cases), 25-29 LNs (40 cases) and  $\geq 30$  LNs (55 cases). Meanwhile, four groups were established based on the number of negative LNs as follows: 0-9 LNs (61 cases), 10-19 LNs (93 cases), 20-29 LNs (63 cases) and  $\geq 30$  LNs (19 cases). All calculations were performed using the SPSS 11.5 statistical package. Actuarial survival was determined via the Kaplan-Meier method, with univariate comparisons between groups through the log-rank test. Cox regression was used for multivariate analysis, with a backward elimination model for all covariates. A regression model to correlate negative LN counts with survival was obtained based on Kaplan-Meier 5-year survival estimates for each LN count interval, using the LN count interval midpoints to construct the independent variable. Significance of differences was assumed at  $P$  values less than 0.05 for all analyses.

## RESULTS

### Analysis based on total and negative LNs examined

Overall, 82.2% of patients (194/236) had LN metastasis. The incidences of LN metastasis were 56% for T2, 78.8% for T3 and 93.5% for T4. A total of 5615 LNs were picked up for histological examination, with 4005 being negative. The median of total LN number was 23 (range, 7-74; mean  $23.8 \pm 8.8$ ) per patient, and the median of negative LNs was 16 (range, 0-48; mean  $16.9 \pm 9.3$ ) per patient. There were no differences between T subcategories regarding total LNs resected [median (range): T2, 22 (9-31); T3, 26 (7-47); T4, 23 (7-74); Kruskal-Wallis,  $P = 0.062$ ] or negative LN counts [median (range): T2, 12 (9-28); T3, 21 (1-45); T4, 17 (1-48); Kruskal-Wallis,  $P = 0.502$ ].

### Multivariate survival analysis

The five-year overall survival rate of the entire cohort was 37.5%. The backwards elimination model yielded the following independent prognostic variables: total LN count (or number of negative LNs examined;  $P < 0.0001$ ), number of positive LNs ( $P < 0.0001$ ), T category ( $P < 0.0001$ ) and tumor size ( $P = 0.015$ ). The covariates gender ( $P = 0.052$ ), age ( $P = 0.329$ ),

<sup>1</sup>Obtained by using number of negative LNs as the variable instead of number of total LNs.

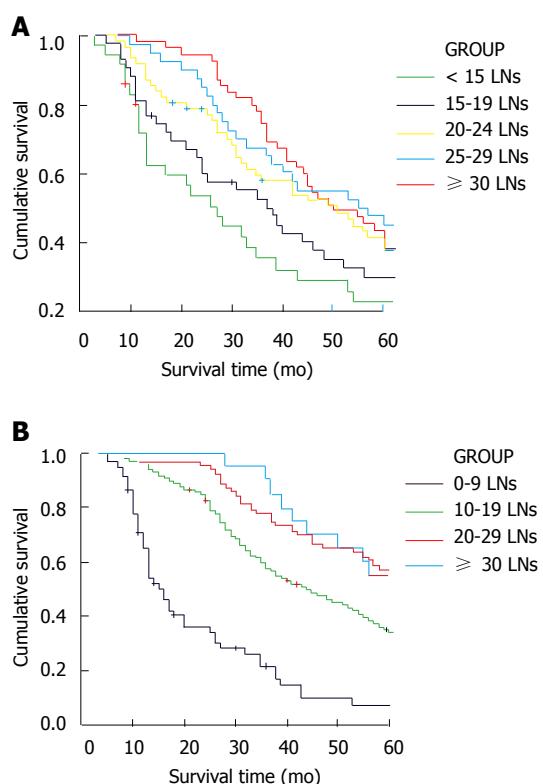

Borrmann type ( $P = 0.373$ ), histological grade ( $P = 0.132$ ), and type of gastrectomy ( $P = 0.093$ ) all failed to retain significance levels in this model. The risk ratios and 95% confidence intervals are listed in Table 2. The number of negative LNs and the total number of LNs examined behaved interchangeably and maintained a similar significance level when substituted for each other. This suggests that the number of negative LN can reflect the extent of lymphadenectomy, as can the total number of LNs.

### Impact of total LN counts by univariate survival analysis

When five-year overall survival was compared by increasing total LN count, higher LN counts were generally associated with better survival (Figure 1A). Of the entire cohort, for the T4, N2 and N3 categories, the best survival outcomes were observed with total LN counts no less than 30. For the N1 category, the best survival outcomes were observed with total LN counts between 25 and 29, as shown in Table 3. When adjusted for the T category, the survival rate of the 25-29 LNs group was higher than that of the < 15 ( $\chi^2 = 13.41$ ,  $P = 0.0002$ ), 15-19 ( $\chi^2 = 7.06$ ,  $P = 0.008$ ) and 20-24 LNs groups ( $\chi^2 = 5.69$ ,  $P = 0.017$ ). The survival rate of the ≥ 30 LNs group was higher than that of the < 15 ( $\chi^2 = 7.03$ ,  $P = 0.008$ ), and the 15-19 LNs groups ( $\chi^2 = 4.91$ ,  $P = 0.03$ ). When adjusted for the N category, the survival rate of the 25-29 LNs group was higher than that of 15-19 ( $\chi^2 = 9.67$ ,  $P = 0.002$ ) and 20-24 LNs groups ( $\chi^2 = 5.68$ ,  $P = 0.02$ ); the survival rate of the ≥ 30 LNs group was higher than that of the 15-19 ( $\chi^2 = 6.56$ ,  $P = 0.01$ ) and 20-24 LNs groups ( $\chi^2 = 4.56$ ,  $P = 0.03$ ).

### Cut point analysis of survival differences relating to total LNs dissected

In an attempt to identify the optimal total LN count cutoff, survival comparisons were made for all stage

**Figure 1** A: Five-year survival curve for all patients according to five total LN strata; B: Five-year survival curve for all patients according to four different negative LN strata.

groups at increasing total LN counts between 7 and 35. The greatest discrepancies, as measured by the chi-square test, were stage dependent, and varied from the cutoff levels of 20 (stage II), 25 (stage III), and 30 (stage IV) to the cutoff level of 15 (entire cohort), as listed in Table 4.

### Impact of negative LN counts by univariate survival analysis

The five-year survival, based on categories, showed considerable variations with increasing counts of negative LNs. An obvious trend toward better survival results for higher negative LN counts was observed (Table 5). Figure 1B shows the overall survival curve for all patients according to different negative LN strata. When adjusted for T category, the survival rate of the 20-29 LNs group was higher than that of the 10-19 LNs group ( $\chi^2 = 10.51$ ,  $P = 0.0012$ ); when adjusted for N category, the survival rate of the 20-29 LNs group was higher than that of either the 0-9 ( $\chi^2 = 14.99$ ,  $P = 0.0001$ ) or the 10-19 LNs group ( $\chi^2 = 5.23$ ,  $P = 0.02$ ); the survival rate of the 10-19 LNs group was higher than that of the 0-9 LNs group ( $\chi^2 = 19.05$ ,  $P < 0.0001$ ).

### Projected impact of negative LN counts on overall survival

Based on the statistical linearity regression, the impact of negative LN counts on overall survival was analyzed. For the stage II subgroup, the hypothetical baseline five-year survival (based on the y-intercept, i.e. no negative

LN) was 39.6%. Similarly, for the stage III subgroup, the baseline five-year survival (with an assumed zero negative LNs) was 15.4%. For the stage IV subgroup, the baseline five-year survival (also with an assumed zero negative LNs) was 2.5%. For all patients, the calculated five-year survival rate at baseline was 11.2%. For every ten extra LNs added to the negative LN count, the calculated overall survival increased by 5.77% (stage II), 6.09% (stage III), 7.65% (stage IV) or 6.24% (the entire cohort). In this setting, the regression showed a statistically significant survival improvement based on increasing negative LN number only for patients with stages III ( $P = 0.013$ ) and stages IV ( $P = 0.035$ ). The results for stage II had no statistical significance ( $P = 0.195$ ).

## DISCUSSION

Over the last few decades, an increase in the incidence of upper third gastric cancer has been reported by many investigators around the world<sup>[11-13]</sup>. It is generally accepted that the prognosis of patients with this type of carcinoma is worse than for tumors in other parts of the stomach<sup>[14,15]</sup>. The only potentially curative treatment for this disease is complete surgical resection, with an en bloc LN dissection. The D2 radical resection has been regarded as the standard surgical procedure for advanced gastric cancer<sup>[16]</sup>. Lymph node dissection during the D2 radical resection is not confined to the anatomical extent, but also to the number of LNs dissected. The current edition of the UICC staging manual recommends examining at least 15 LNs for adequate gastric cancer staging. However, is that adequate for advanced gastric cancer located in the

cardia and fundus? It was reported that patients with advanced gastric cancer located in the cardia and fundus often showed a higher frequency of perigastric LNs and higher proportion of overall LN metastasis<sup>[17]</sup>. Koufuji *et al*<sup>[18]</sup> investigated 49 cases with an upper gastric cancer invading the esophagus who underwent surgical treatment. The incidences of LN metastasis were 0% for T1, 67% for T2, 81% for T3 and 80% for T4. Ichikura *et al*<sup>[19]</sup> retrospectively analyzed 65 cases with cardiac carcinoma and found that the incidences of LN metastasis were 68% for Siewert's type II tumors, and 94% for Siewert's type III tumors. In the present study, 82.2% of patients had LN metastasis. For these patients, it is better to determine the extent of lymphadenectomy according to the extent of LN metastases preoperatively or intraoperatively. However, this is difficult to achieve as there is lack of reliable measures for clinical diagnosis preoperatively and for comprehensive LN biopsy intraoperatively<sup>[20,21]</sup>. If the LNs were not completely removed, the probability of residual tumor cells would increase, leading to poor prognosis. Therefore, some investigators advocated removing adequate LNs intraoperatively to avoid this situation<sup>[22-24]</sup>. However, it is not certain how many LNs need to be dissected in a D2 lymphadenectomy. Liu *et al*<sup>[25]</sup> showed, in 147 patients with adenocarcinoma of the stomach who had undergone gastrectomy with curative intent, that for stage III disease, removal of >15 LNs

appeared to provide a considerable survival advantage, compared with removal of < 15 LNs. Another study favoring this opinion was from Barbour *et al*<sup>[26]</sup>. They suggested that patients with Siewert type II and III adenocarcinoma of the gastroesophageal junction (GEJ) should undergo adequate lymphadenectomy to permit examination of ≥ 15 LNs, allowing accurate identification of prognostic variables. Removal of ≥ 15 LNs is associated with more accurate survival estimates for patients with advanced disease. For adenocarcinoma of the GEJ, a minimum removal of 25 LNs was recommended by Gee *et al*<sup>[27]</sup>. Our present observations showed that better long-term survival outcomes were obtained with higher numbers of LNs resected during D2 lymphadenectomy. This is consistent with the research results of Schwarz *et al*<sup>[28]</sup>. We suggest that for adequate LN resection, including total LNs and the number of negative LNs, the removal of 20 LNs for stage II, 25 LNs for stage III, 30 LNs for stage IV and 15 LNs for the entire cohort be recommended during D2 radical dissection.

Total LNs and number of negative LNs can reflect the extent of LN dissection and influence survival<sup>[29,30]</sup>. In the present study, total LN count or negative LN counts turned out to be independent protective factors, according to the symbols of regression coefficient. These two factors behaved interchangeably, and maintained a similar significance level when substituted for each other. Furthermore, an impact of total LNs or negative LNs on survival was observed. In the univariate survival analysis, higher total LN counts may translate into better outcomes. The effect was much more significant with T4 and N2, N3 disease. We thus postulate that even in locally advanced disease with adjacent organ invasion or advanced nodal involvement that is still resectable, adequate LN dissection influences survival.

The contribution of negative LN counts to the prognosis of patients is partly due to LN micrometastases. In patients without lymph metastases identified by HE staining, about 20% had LN micrometastases<sup>[31]</sup>. del Casar *et al*<sup>[32]</sup> reviewed 144 patients with primary gastric adenocarcinoma who underwent surgery and found that lymphatic and/or blood vessel tumoral invasion (LBVI) was present in 46 patients (31.9%), which was significantly associated with a poorer overall patients' survival. Therefore, curability was reported as one of the most reliable predictors of long-term survival for LN-negative gastric carcinoma patients<sup>[33]</sup>. A similar study<sup>[34]</sup> examined the impact of the number of negative LNs on survival. The study was conducted in patients with stage III colon cancer, and demonstrated that a higher number of negative nodes was associated with better survival. In our study, the impact of negative LN on survival in these stage patients also showed an obvious trend toward better survival for higher negative LN counts. For every ten extra LNs added to the negative LN count, the calculated overall survival increased by 6.09% for stage III, and 7.65% for stage IV patients, based on the linear regression. Generally, better long term survival was observed with higher total LNs

or negative LNs, showing the contribution of sufficient lymphadenectomy toward reducing residual tumor cells. For the curative-intent gastrectomy of locally advanced disease, retrieval and examination of adequate numbers of LNs is suggested for gastric cancer located in the cardia and fundus.

## COMMENTS

### Background

The incidence rates of upper third gastric cancer, mostly located in the cardia and fundus, has increased in recent years. Few studies have investigated the relative contributions of both the number of total resected lymph nodes (LNs) and the number of negative LNs to the outcome of patients with advanced gastric cancer located in the cardia and fundus.

### Research frontiers

Some researches have considered D2 radical dissection to be standard procedure for advanced gastric cancer located the cardia and fundus, which requires the removal of Group 1 and Group 2 LNs. The dissected LN count is found to have strong association with patient survival.

### Innovations and breakthroughs

The authors retrospectively reviewed 236 patients with gastric cancer in the cardia and fundus who were treated with D2 radical resection in a hospital in Fujian between 1996 and 2002 to investigate how the numbers of dissected LNs affect patients' survival outcomes.

### Applications

The authors suggest that importance should be attached to removing enough LNs so as to reduce residual tumor cells in patients with advanced gastric cancer located in the cardia and fundus.

### Peer review

This article demonstrated that in advanced gastric cancer located in the cardia and fundus, the number of lymphadenectomy with/without metastasis of gastric cancer cells influenced the prognosis of the patients. This finding has important information for gastrointestinal surgeons.

have metastasis, 29 (65.9%) and 15 (34.1%) of the lymph nodes involved were within N1 and beyond N1, respectively, in 12 patients with LNM.

**CONCLUSION:** Endoscopic mucosal resection alone may be sufficient to treat poorly differentiated intramucosal EGC ( $\leq 2.0$  cm in diameter) with no histologically-confirmed lymphatic vessel involvement. When lymphatic vessels are involved, lymph node dissection beyond limited (D1) dissection or D1+ lymph node dissection should be performed depending on the tumor location.

## Abstract

**AIM:** To identify the predictive clinicopathological factors for lymph node metastasis (LNM) in poorly differentiated early gastric cancer (EGC) and to further expand the possibility of using endoscopic mucosal resection (EMR) for the treatment of poorly differentiated EGC.

**METHODS:** Data were collected from 85 poorly-differentiated EGC patients who were surgically treated. Association between the clinicopathological factors and the presence of LNM was retrospectively analyzed by univariate and multivariate logistic regression analyses.

**RESULTS:** Univariate analysis showed that tumor size (OR = 5.814, 95% CI = 1.050 - 32.172,  $P = 0.044$ ), depth of invasion (OR = 10.763, 95% CI = 1.259 - 92.026,  $P = 0.030$ ) and lymphatic vessel involvement (OR = 61.697, 95% CI = 2.144 - 175.485,  $P = 0.007$ ) were the significant and independent risk factors for LNM. The LNM rate was 5.4%, 42.9% and 50%, respectively, in poorly differentiated EGC patients with one, two and three of the risk factors, respectively. No LNM was found in 25 patients without the three risk factors. Forty-four lymph nodes were found to

## INTRODUCTION

Endoscopic mucosal resection (EMR) is widely accepted as an alternative treatment for early gastric cancer (EGC)<sup>[1-3]</sup>. The application of EMR has been limited to differentiated EGC because of the higher risk of lymph node metastasis (LNM) in undifferentiated EGC, compared to differentiated EGC<sup>[4-6]</sup>. Therefore, gastrectomy with lymphadenectomy is considered an essential treatment for patients with undifferentiated EGC. Undifferentiated gastric cancers include poorly differentiated adenocarcinoma, signet ring cell carcinoma, and mucinous adenocarcinoma<sup>[7]</sup>. However, almost all (96.6%) surgical cases of poorly differentiated EGC confined to the mucosa

have no LNM<sup>[8]</sup>, suggesting that gastrectomy with lymphadenectomy may be an overtreatment for these cases.

We carried out this retrospectively study to determine the predictive clinicopathological factors for LNM in poorly differentiated EGC. Furthermore, we established a simple criterion for the use of EMR in the treatment of poorly differentiated EGC.

## MATERIALS AND METHODS

### **Patients**

Patients who underwent a radical operation due to EGC in Department of Oncology, First Affiliated Hospital of China Medical University (Shenyang, China) between January 1980 and December 2002, were included in this retrospective study.

The inclusion criteria were (1) possible lymph node dissection beyond limited (D1) dissection (i.e. D1 dissection + dissection of lymph nodes along the left gastric artery, D1 dissection + dissection of lymph nodes along the common hepatic artery, D1 dissection + dissection of lymph nodes along the celiac artery) or extended (D2) dissection, (2) pathological analysis of the resected specimens and lymph nodes and poorly differentiated EGC diagnosed according to the Japanese classification of gastric carcinoma (JCGC)<sup>[7]</sup>, and (3) availability of medical record of patients from the database.

During the past 23 years, operation was performed in 243 EGC patients. Of the 115 patients who were histologically diagnosed as undifferentiated EGC, 87 had poorly differentiated EGC and 28 had undifferentiated EGC. Among the 87 patients with poorly differentiated EGC, complete medical record of 2 patients was not available. Thus, 85 poorly differentiated EGC patients (60 males, 25 females, mean age of 54 years, range 19-78 years) met the inclusion criteria for further analysis.

The study protocol was approved by the Ethics Committee of China Medical University.

### **Dissection and classification of lymph nodes**

Lymph nodes were meticulously dissected from the *en bloc* specimens, and the dissected lymph nodes by a surgeon after he/she carefully reviewed the excised specimens based on the JCGC<sup>[7]</sup>. Briefly, lymph nodes were classified into two groups: group 1 as the perigastric lymph nodes and group 2 as the lymph nodes along the left gastric artery, the common hepatic artery, and the splenic artery or around the celiac axis<sup>[7]</sup>.

### **Classification of lymphadenectomy**

Accordingly, lymphadenectomy was classified as D1 (i.e. dissection of all the group 1 lymph nodes, D1 + (i.e. dissection of all the lymph nodes along the left gastric artery, lymph nodes along the common hepatic artery, or lymph nodes along the celiac artery), and

**Table 1 Distribution of metastatic lymph nodes**

Lymph node station	Tumor location in the stomach			
	Upper	Middle	Lower	Overall
Group 1 (N1)	1	3	25	29
No. 1, right paracardial nodes	1	1	0	2
No. 2, left paracardial nodes	0	0	0	0
No. 3, lesser curvature nodes	0	1	5	6
No. 4, great curvature nodes	0	1	5	6
No. 5, suprapyloric nodes	0	0	0	0
No. 6, infrapyloric nodes	0	0	15	15
Group 2 (N2)	0	3	12	15
No. 7, left gastric artery nodes	0	3	8	11
No. 8, common hepatic nodes	0	0	3	3
No. 9, celiac artery nodes	0	0	1	1

D2 (i.e. dissection of all the lymph nodes in groups 1 and 2).

### **Assessment and classification of LNM**

The resected lymph nodes were cut into sections which were stained with hematoxylin and eosin, and examined by pathologists for metastasis and lymphatic vessel involvement (LVI).

For classification of LNM, the symbol “No.” was used to indicate the lymph node station number while “N” was used to indicate the lymph node group. For example, No. 1 indicates the right paracardial lymph nodes (Table 1). No. indicates that there was no evidence of LNM. N1 indicates that metastasis was limited to lymph nodes in group 1. N2 indicates that metastasis extended to group 2 lymph nodes (Table 1).

### **Association between clinicopathological parameters and LNM**

The following clinicopathological parameters covered in the JCGC<sup>[7]</sup> were included in this study, namely the gender (male and female), age (< 60 years, ≥ 60 years), family medical history of gastric cancer, number of tumors (single or multitude), tumor location (upper, middle, or lower of the stomach), tumor size (maximum diameter ≤ 2 cm, or > 2 cm), macroscopic types including protruded (type I), superficially elevated (type II a), flat (type II b), superficially depressed (type II c), or excavated (type III), depth of invasion (mucosa, submucosa), lymphatic vessel involvement.

The associations between various clinicopathological factors and LNM was examined as described below.

### **Statistical analysis**

All data were analyzed using SPSS13.0 statistical software (Chicago, IL, United States). Differences in the clinicopathological parameters between patients with and without LNM were determined with chi-square test. Multivariate stepwise logistic regression analysis was performed subsequently in order to identify the independent risk factors for LNM. Hazard ratio and 95% confidence interval (CI) were calculated.  $P < 0.05$  was considered statistically significant.

**Table 2 Univariate analysis of potential risk characteristics for lymph node metastasis**

Factor	Lymph node metastasis n (%)	P
Sex		
Male (n = 60)	7 (11.7)	0.315
Female (n = 25)	5 (20)	
Age (yr)		
< 60 (n = 53)	9 (17.0)	0.329
≥ 60 (n = 32)	3 (9.4)	
Family medical history		
Positive (n = 6)	1 (16.7)	0.852
Negative (n = 79)	11 (13.9)	
Number of tumors

Lymphatic vessel involvement		
Positive (n = 4)	3 (75.0)	< 0.001
Negative (n = 81)	9 (11.1)	

## RESULTS

### Distribution of metastatic lymph nodes

LNM was histologically confirmed in 12 (14.1%) of the 85 patients. Forty-four metastatic lymph nodes were found in these 12 patients, of which 29 (65.9%) were classified as N1 and 15 (34.1%) as N2. LNM was located in the upper stomach of 1 patient and the observed metastatic lymph nodes belonged to N1. LNM was located in the middle stomach of 2 patients. Of the six observed metastatic lymph nodes, three (50%) belonged to N1 and three (50%) belonged to N2. Of the 37 metastatic lymph nodes observed in the lower stomach of 9 LNM patients, 25 (67.6%) belonged to N1 and 12 (32.4%) belonged to N2 (Table 1).

### Association between clinicopathological factors and LNM

The association between various clinicopathological factors and LNM was first analyzed with chi-square test (Table 2). Tumor larger than 2.0 cm in diameter ( $P = 0.007$ ), submucosal invasion ( $P = 0.009$ ), and the presence of LVI ( $P < 0.001$ ) were significantly associated with a higher incidence rate of LNM.

However, gender, age, family medical history of gastric cancer, number, location, and macroscopic type were not associated with LNM.

### Multivariate analysis of potential independent risk factors for LNM

Univariate analysis showed that tumor size (OR= 5.814,

95% CI = 1.050 - 32.172,  $P = 0.044$ ), depth of invasion (OR = 10.763, 95% CI = 1.259 - 92.026,  $P = 0.030$ ) and LVI (OR = 61.697, 95% CI = 2.144 - 175.485,  $P = 0.007$ ) were significantly associated with LNM, while multivariate analysis revealed that they were the significant and independent risk factors for LNM.

### Lymph node metastasis of poorly differentiated EGC

The LNM rate was 5.4%, 42.9% and 50%, respectively, in poorly differentiated EGC patients with one, two and three of the risk factors, respectively. No LNM was detected in 25 patients without the three risk factors.

## DISCUSSION

One of the critical factors in choosing EMR for EGC would be the precise prediction of whether the patient has LNM. To achieve this goal, several studies have attempted to identify the predictive risk factors for LNM of EGC<sup>[9-11]</sup>. Few reports, however, have focused on the applicability of endoscopic treatment for poorly differentiated EGC<sup>[12,13]</sup>.

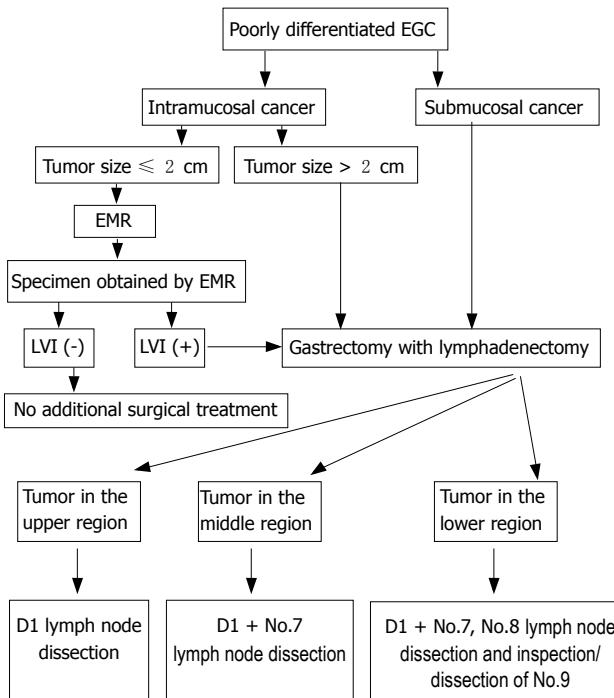

In the present study, multivariate analysis revealed that tumor larger than 2.0 cm in diameter, submucosal invasion, and the presence of LVI were the significant predictive factors for LNM in patients with poorly differentiated EGC, which is in consistent the reported findings<sup>[9-13]</sup>.

We then attempted to identify a subgroup of poorly differentiated EGC patients in whom the risk of LNM could be ruled out. As a result, no LNM was found in patients with intramucosal cancer if the tumor is less than or equal to 2.0 cm in diameter without LVI, indicating that EMR is sufficient to treat these patients.

We further examined the relationship between the three predictive factors and the LNM rate in order to establish a simple criterion for the treatment of poorly differentiated EGC. In the present study, the LNM rate was 5.4%, 42.9% and 50%, respectively, in poorly differentiated EGC patients with one, two and three of the risk factors, suggesting that gastrectomy with lymphadenectomy can be performed for these patients with the risk factors.

All the information on these predictive factors, particularly LVI, became evident after histological assessment of the entire specimen. Thus, an accurate histological examination of the endoscopically resected specimen was required to determine whether EMR alone can achieve curative effect. The new EMR technique, complete removal of a large lesion in a single fragment using an insulation-tipped diathermic knife<sup>[14-16]</sup>, is a promising procedure for this purpose.

According to the results of this study, a treatment strategy was proposed for the poorly differentiated EGC patients (Figure 1). EMR alone may be sufficient to treat poorly differentiated intramucosal EGC if it is less than or equal to 2.0 cm in diameter with no LVI. When LVI is found in specimens, an additional gastrectomy with lymphadenectomy should be

**Figure 1** Flow chart of the therapeutic strategy for patients with poorly differentiated EGC.

recommended, with the tumor location taken into consideration. For example, for patients with EGC in the upper stomach, D1 should be performed. However, for patients with EGC in the middle stomach, No.7 lymph nodes should be dissected. For patients with EGC in the lower stomach, No.7 and No.8 lymph nodes should be dissected and No.9 lymph node should be inspected carefully and dissected if LNM is suspected.

In conclusion, EMR alone may be sufficient to treat poorly differentiated intramucosal EGC if it is less than or equal to 2.0 cm in diameter with no LVI. When LVI is found in specimens, D1 or D1+ lymph node dissection should be performed depending on the tumor location.

## COMMENTS

### Background

Gastrectomy with lymphadenectomy is the standard therapy for poorly differentiated early gastric cancer (EGC) with lymph node metastasis (LNM). However, because approximately 96.6% of poorly differentiated intramucosal EGC have no LNM, gastrectomy with lymphadenectomy may be an overtreatment for such patients. We attempted to identify a subgroup of poorly differentiated EGC patients in whom the risk of LNM can be ruled out and treated with endoscopic mucosal resection, which may serve as a breakthrough management of poorly differentiated EGC.

### Research frontiers

Many clinicians and researchers are undertaking studies of the predictive factors for LNM in EGC. It is widely accepted that lymph node involvement and depth of invasion are closely correlated with LNM. However, the relationship between metastasis and diameter of tumor, histological type and macroscopic type is still controversial. Since LNM remains one of the most important predictors for survival, reduction in lymphadenectomy

will probably result in residue of metastatic lymph nodes. Unnecessarily extended resection will induce complications, thus resulting in a poor quality of life.

### Innovations and breakthroughs

Tumor size, depth of invasion, and lymphatic vessel involvement are the independent risk factors for LNM. Lymph node dissection is the treatment of choice for poorly differentiated EGC.

### Applications

Based on the predictive factors for LNM, Lymph node dissection is the treatment of choice for poorly differentiated EGC.

### Peer review

This manuscript presents a rational surgical therapy for poorly differentiated EGC with lymph node dissection and is of interest to clinicians and researchers.

## Abstract

**AIM:** To investigate the effects of aspirin (acetylsalicylic acid) on proliferation and apoptosis of colorectal cancer cell line SW480 and its mechanism.

**METHODS:** Cyclooxygenase (COX)-2 negative colorectal cancer cell line SW480 was treated with aspirin at concentrations of 2.5 mmol/L, 5.0 mmol/L, 10.0 mmol/L for different periods *in vitro*. Anti-proliferation effect of aspirin on SW480 was detected by 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cell cycle and apoptosis were observed by flow cytometry (FCM). Transmission electron microscope (TEM) was used for morphological study. Apoptosis-associated genes were detected by immunohistochemical staining and Western blotting.

**RESULTS:** Aspirin inhibited SW480 proliferation and induced apoptosis in a dose- and time-dependent manner. Treatment with different concentrations of aspirin significantly increased the proportions of cells at the G<sub>0</sub>/G<sub>1</sub> phase and decreased the proportions of cells at the S- and G<sub>2</sub>/M phases in a concentration-dependent manner. Aspirin not only induced apoptosis but also caused cell necrosis at a high concentration as well. After treatment with aspirin, SW480 cells displayed typically morphological features of apoptosis and necrosis under TEM, and increased the *Bcl-2*

## INTRODUCTION

Colorectal cancer is a common disease that remains the major cause of cancer-related mortality in developed countries. With improvement in economic status, its incidence increases in developing countries including China and severely threatens the health of human beings. Increasing evidence from human epidemiological studies, animal models, and experiments *in vitro* revealed that administration of nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin (acetylsalicylic acid) represents a treatment of choice for colon cancer<sup>[1-3]</sup>. Data indicate that use of NSAIDs, including aspirin, is inversely associated with the risk of colorectal cancer, and clinical trials in patients with familial adenomatous polyposis showed that use of NSAIDs can lead to the regression of colorectal adenomas by exerting their protective effects on the stomach and esophagus<sup>[4]</sup>. However, the molecular mechanism by which aspirin exhibits its anticancer effects is not completely clear.

The best-defined molecular target for aspirin and

other NSAIDs is cyclooxygenase (COX). COX-2, the regulated isoform of COX, plays an important role in the carcinogenesis<sup>[5]</sup> and angiogenesis<sup>[6]</sup>. A possible mechanism underlying the antitumor properties of aspirin has been ascribed to its direct inhibition of COX-2 in colorectal cancer tissue<sup>[7]</sup>. However, several lines of evidence suggest that the wide range of antiproliferative potencies of aspirin does not correlate exclusively with COX-2 inhibitory activity, because NSAIDs can induce apoptosis in colon cancer cell lines that lack detectable expression of COX-2 protein<sup>[8,9]</sup>. Until now, most researchers recruit COX-2 positive colon cancer cell lines to study the effect of aspirin on their apoptosis and proliferation. However, few studies of the effect of aspirin on COX-2 negative colon cancer cells and few systematic analyses of aspirin-induced morphologic changes are available<sup>[10-12]</sup>. Furthermore, the results of certain studies are controversial<sup>[12,13]</sup>. The purpose of this study was to investigate the effect of aspirin on proliferation, and apoptosis of SW480 cells, a COX-2 negative human colon cancer cell line.

## MATERIALS AND METHODS

### Materials

Aspirin, 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT), penicillin/streptomycin and RNase A were from Sigma (St. Louis, MO, USA). Mouse monoclonal antibodies against Bcl-2 and Bax as well as biotin-labeled anti-mouse IgG, were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). RPMI1640 medium was purchased from Life Technologies, Inc (Grand Island, NY) and fetal bovine serum was from Gibco (GIBCO BRL). Annexin V-Cy5 apoptosis detection kit was purchased from PharMingen (San Diego, CA).

### Cell culture and culture conditions

The human colon cancer cell line SW480 was obtained from the American Type Culture Collection and cultured in RPMI 1640 medium containing 10% fetal bovine serum and 1% penicillin/streptomycin solution at 37°C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub>.

### Aspirin treatment

We dissolved aspirin in 1 mol/L Tris-HCl (pH 7.5) to a stock concentration of 1 mol/L and adjusted the pH to 7.2 with 4 mol/L HCl. Twenty-four hours before aspirin treatment, exponentially growing human colon cancer cells were seeded at a density of 10<sup>5</sup> cells/100 mm culture dish (Becton Dickinson, Franklin Lakes, NJ). The cells were washed once with phosphate buffered saline (PBS) and treated for an indicated time by adding various volumes of stock to obtain the final aspirin concentrations of 1 mmol/L, 2.5 mmol/L, 5 mmol/L, or 10 mmol/L, respectively. Control cells were treated with an equivalent volume of Tris-HCl (pH 7.2).

### Cell proliferation analysis

SW480 colon cancer cells were seeded at a density of

3 × 10<sup>4</sup> cells/well onto a 96-well plate. Twenty-four hours after seeding, the cells were exposed to different concentrations of aspirin (0 mmol/L, 2.5 mmol/L, 5 mmol/L, 10 mmol/L) and maintained in culture for 1-7 d at 37°C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub>. Individual cells were taken from suspension after exposure to trypsin/EDTA in PBS. Aliquots were counted with a haemocytometer and tested for their viability by trypan blue exclusion. Each assay was performed in triplicate.

### MTT assay

The effect of aspirin on cellular viability was also evaluated by MTT assay. SW480 cells were plated in 96-well microtiter plates at a density of 10<sup>4</sup> cells/well in a final volume of 100 μL of RPMI 1640 medium. Twenty-four hours after the initial seeding, the cells were treated with various concentrations of aspirin for 1-7 d. The untreated cells (appropriate volume of buffer solution was added) served as controls. After treatment, the cells were incubated for 3 h at 37°C with a solution of MTT at a concentration of 50 μg/100 μL, lysed for 12 h at room temperature in a buffer containing 10% SDS and 0.01 mol/L HCl as previously described<sup>[14]</sup>. For each sample, the absorbance of the reduced intracellular formazan product was read at 570 nm on a microtiter plate reader (Bio-Rad Laboratories, Hercules, CA). Each assay was performed in triplicate.

### Apoptosis determination

SW480 cells were plated at a density of 10<sup>6</sup> cells/10 cm dishes and treated with aspirin at the concentration of 0, 2.5, 5 and 10 mmol/L, respectively. After treatment, the cells were harvested by trypsinization and washed once with 10 mL of PBS. We used the Annexin V-Cy5 apoptosis detection kit according to the manufacturer's instructions to stain the apoptosis marker and cell surface phosphatidylserine. Briefly, the cells were resuspended in 200 μL of 1 × annexin binding buffer containing 10 mmol/L HEPES, 140 mmol/L NaCl, 2.5 mmol/L CaCl<sub>2</sub> (pH 7.4) and stained with 5 μL of annexin V-Cy5 (1 μmol/mL). After incubation for 15 min at room temperature, the cells were incubated with 10 μL of 7-AAD for another 15 min at 25°C in the dark. The cell suspension was gently centrifuged, into which 400 mL of 1 × annexin binding buffer was added. The cells were analyzed by flow cytometry (FCM) within 1 h of 7-AAD staining. Appropriate controls were used to subtract background counts. We used the FACScalibur flow cytometer (Becton Dickinson, San Jose, CA) for two-color analysis of apoptosis. Fluorescence compensation was adjusted to minimize overlap of the Cy5 and 7-AAD signals.

### Cell cycle analysis

The effect of aspirin treatment on cell proliferation was evaluated by measuring the distribution of cells in different phases of the cell cycle by FCM based on the measurement of the DNA content of nuclei

labeled with propidium iodide (PI). Cell suspension from either aspirin-treated or untreated cell cultures was prepared by trypsinizing the cells and washing them twice with cold PBS. The cells were resuspended at a density of  $10^6$  cells/mL in cold PBS and fixed with 75% ethanol overnight at -20°C. Ethanol-fixed cells were washed with cold PBS, resuspended in 300  $\mu$ L of PBS containing 0.15% boiled and renatured RNase A at 37°C for 30 min, and stained with 80  $\mu$ g/mL of PI for 30 min. The cells were analyzed for DNA content with the FACScalibur flow cytometer at an excitation of 488 nm with detection at 620 nm for red fluorescence. The cell cycle data were analyzed using the Multicycle Software Autofit Version 2.50 (Phoenix Flow Systems, San Diego, CA).

#### Transmission electron microscopy

For electron microscopic analysis of apoptosis, pretreated SW480 cells were fixed in 1% glutaraldehyde and 4% paraformaldehyde in PBS, postfixed in 1% osmium tetroxide in PBS, dehydrated and subsequently embedded in epoxy resin. Ultrathin sections (80 nm) were stained with uranyl and lead acetates and examined under a Hitachi H-600 electron microscope at 80 kV (Hitachi, Tokyo, Japan).

#### Immunocytochemical staining

SW480 cells were seeded at a density of  $4 \times 10^5$  cells/well onto 24-well plates and cultured for 24 h. After treatment for 48 h with ASPIRIN at final concentration of 2.5, 5.0 and 10.0 mmol/L, respectively, the untreated cells (appropriate volumes of buffer solution added) served as controls. The cells were fixed for 10 min in 100% methanol at room temperature, washed with PBS, treated with 3% hydrogen peroxide to block the endogenous peroxidase activity and incubated with 2% nonfat dry milk. After incubated for 2 h at room temperature with primary antibody, the cells were washed three times with PBS (10 min each time) and incubated with biotin-labeled anti-mouse IgG for 20 min at room temperature. After washed three times with PBS (10 min each time), the cells were stained using a streptavidin-peroxidase detection system (Novo Castra, Newcastle, UK) and viewed under a Hoffman modulation contrast microscope.

#### Measurement of Bax and Bcl-2 protein levels in cells

Bax, Bcl-2 and  $\beta$ -actin protein levels in cells were measured by Western blotting. Twenty micrograms of protein from a 20% (wt/vol) cell homogenate was separated on a 15% (wt/vol) polyacrylamide denaturing gel, and then electroblotted onto Hybond-enhanced chemiluminescence (ECL) nitrocellulose (Amersham Pharmacia Biotech Ltd). The membranes were blocked by addition of 3% (wt/vol) bovine serum albumin (BSA) into 0.1% (vol/vol) Tween-20 tris-buffered saline (TBS) at 4°C overnight. Western blots were probed with a polyclonal rabbit anti-rat Bax diluted at 1:2000 (P-19) or a monoclonal mouse anti-rat Bcl-2 diluted at 1:2000 at room temperature for 2 h. Primary Bax or Bcl-2

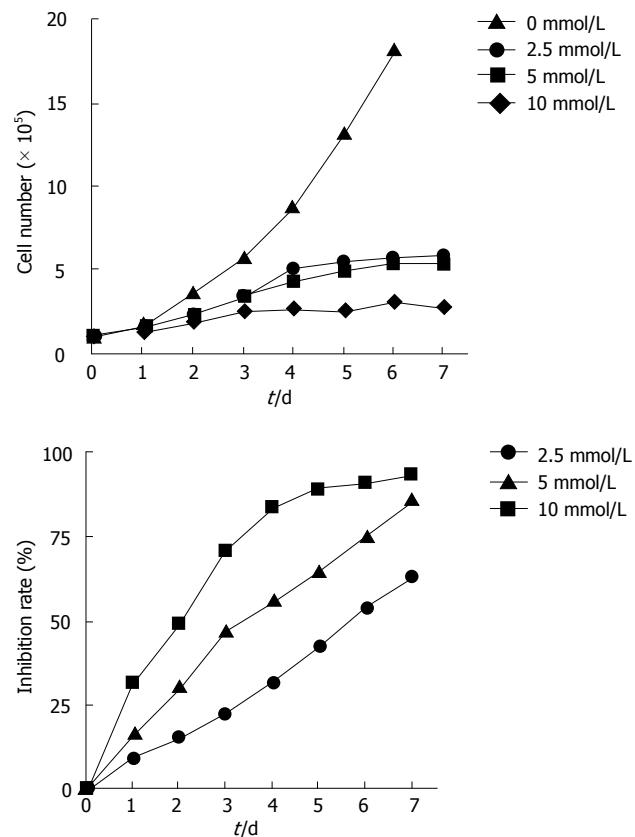

Figure 1 Effect of aspirin on proliferation of SW480 cells.

antibody binding was revealed using an anti-rabbit-HRP or an anti-mouse-HRP antibody diluted at 1:2000 or at 1:1000 for 1 h and the ECL detection system. Developed films were quantitatively analyzed using a volume densitometer and Molecular Analyst version 4 software (Bio-Rad Laboratories Ltd). The Bax to Bcl-2 ratio was determined for each sample individually by reprobing the same membrane and dividing the volume density for Bax by that for Bcl-2.

#### Statistical analyses

Data were expressed as mean  $\pm$  SE. Statistical difference was assessed by a single factor variance (ANOVA) or the Student *t* test. For each test, *P* < 0.05 was considered statistically significant.

## RESULTS

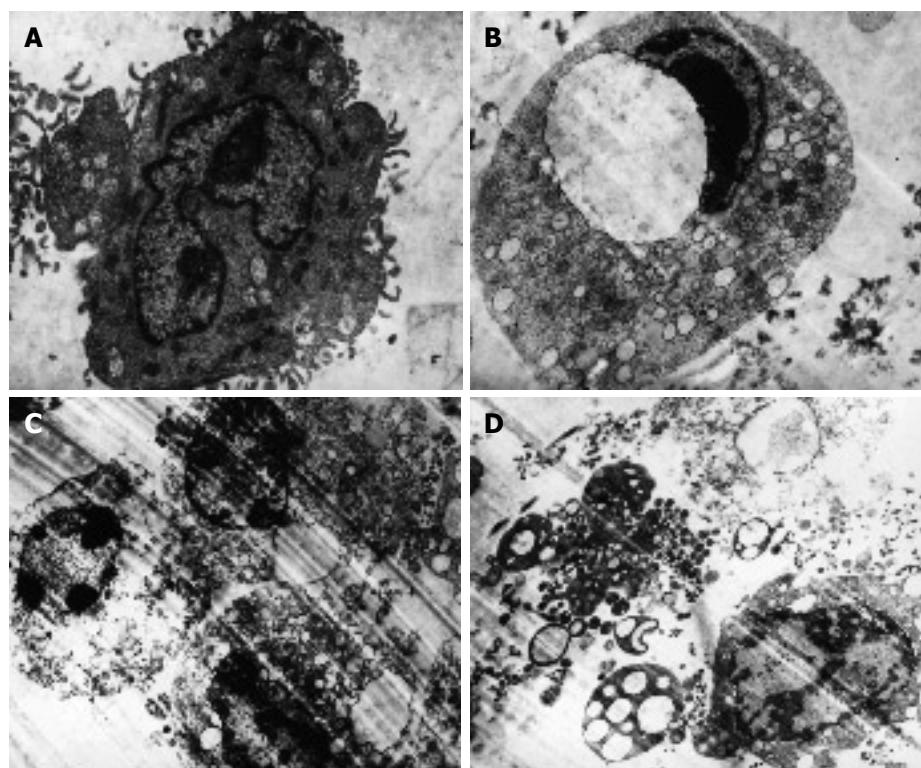

#### Aspirin inhibited the growth of SW480 cells

In the present study, SW480 cell proliferation was assessed by counting the cells after stimulation of aspirin at different concentrations for 7 d. As shown in Figure 1, the untreated cells grew in a linear manner. After aspirin treatment, the growth of SW480 cells was inhibited in a concentration-dependent manner. Moreover, aspirin modulated the growth of SW480 cells in a time-dependent manner. Being consistent with the results of cell counting, aspirin showed an anti-proliferation effect on the growth of SW480 cells in a concentration-and time-dependent manner.

**Table 1** Effect of aspirin on cell cycle distribution in SW480 cells (mean  $\pm$  SE)

Aspirin Conc (mmol/L)	Cell cycle			Proliferation index (%)	Apoptosis rate (%)
	G <sub>0</sub> /G <sub>1</sub> (%)	S (%)	G <sub>2</sub> /M (%)		
0	42.3 $\pm$ 2.49	33.0 $\pm$ 2.16	24.7 $\pm$ 0.47	57.7 $\pm$ 2.49	3.17 $\pm$ 0.37
2.5	61.0 $\pm$ 1.63 <sup>b</sup>	24.3 $\pm$ 1.25 <sup>b</sup>	14.7 $\pm$ 1.70 <sup>b</sup>	39.0 $\pm$ 1.63 <sup>b</sup>	8.92 $\pm$ 0.49 <sup>b</sup>
5	73.3 $\pm$ 3.36 <sup>b</sup>	13.7 $\pm$ 1.24 <sup>b</sup>	13.0 $\pm$ 2.42 <sup>b</sup>	26.6 $\pm$ 3.63 <sup>b</sup>	13.14 $\pm$ 1.29 <sup>b</sup>
10	80.3 $\pm$ 2.49 <sup>b</sup>	8.7 $\pm$ 0.47 <sup>b</sup>	11.0 $\pm$ 2.94 <sup>b</sup>	19.7 $\pm$ 2.49 <sup>b</sup>	37.92 $\pm$ 1.37 <sup>b</sup>

<sup>b</sup>P < 0.01 vs control group.

**Figure 2** Effect of aspirin on morphological change in normal SW480 cells (A), after treatment with aspirin at the concentration of 2.5 mmol/L (B), 5.0 mmol/L (C), and 10.0 mmol/L (D) for 72 h, respectively.

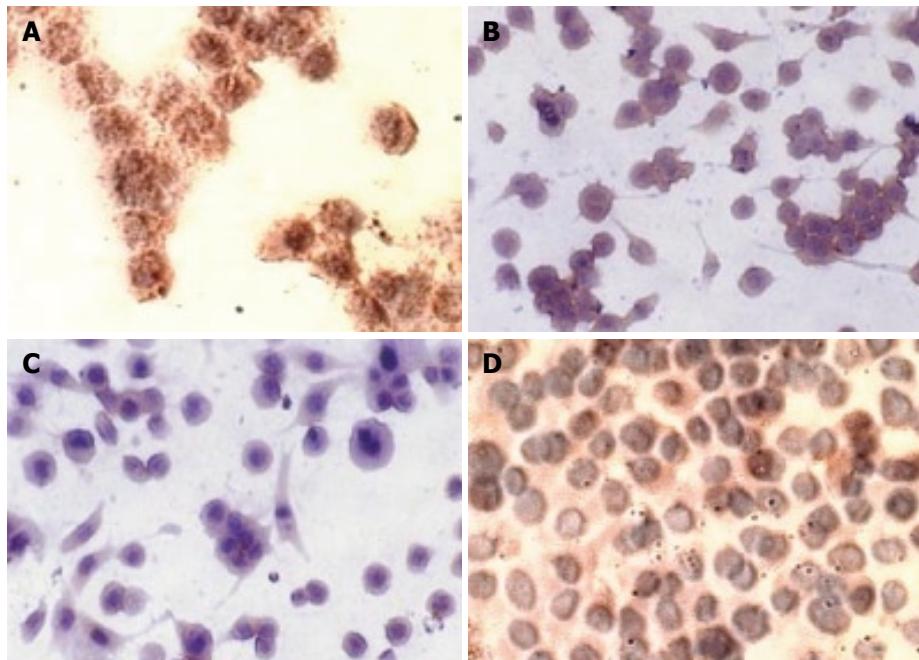

#### Aspirin arrested human colon cancer cell at the G<sub>0</sub>/G<sub>1</sub> phase and increased apoptosis of SW480 cells

To study the effect of aspirin treatment on cell proliferation at different phases of the cell cycle, we treated exponentially growing cells with aspirin at different concentrations for 72 h. Conventional DNA FCM showed that 39%-46% of the untreated SW480 cells were found at the G<sub>0</sub>/G<sub>1</sub> phase, 31%-35% at the S phase, and the remaining cells at the G<sub>2</sub>/M phase, depending on the dose of aspirin used and the percentage of cells decreased (Table 1). However, the presence of aspirin at different concentrations resulted in an accumulation of cells at the G<sub>0</sub>/G<sub>1</sub> phase. The fraction of sub-G<sub>1</sub> DNA content accounted for 3.17%, indicating that apoptosis was decayed in the untreated control cells. After treatment with aspirin at the concentrations of 2.5, 5.0 and 10.0 mmol/L, the fraction of sub-G<sub>1</sub> DNA content increased to 8.9%, 13.1% and 39.9%, respectively, indicating that aspirin could not only arrest cell cycle at the G<sub>0</sub>/G<sub>1</sub> phase, but also induce apoptosis in a concentration-dependent manner (Table 1).

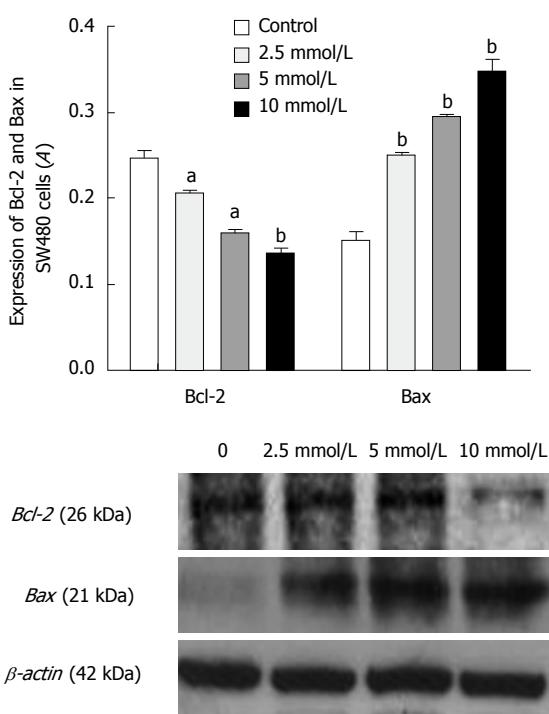

#### Effect of aspirin on morphology of SW480 cells

Electron microscopy of the aspirin-treated SW480

cells showed typical apoptosis characterized by volume reduction, chromatin condensation, nuclear fragmentation, and presence of apoptotic bodies (Figure 2) when compared to the untreated cells (Figure 2A). The severity of morphological changes increased in a dose-dependent manner. After 72 h of treatment with 2.5 mmol/L aspirin, the SW480 cells showed early changes in apoptosis with loss of microvilli, nuclear chromatin condensation that formed a crescent-like clump (Figure 2B). Intermediate and late stages of apoptosis, characterized by more extensive nuclear chromatin condensation, cytoplasmic blebbing, nuclear membrane splitting, fragmentation of nuclei, and formation of apoptotic bodies, were induced by treatment with 5 mmol/L aspirin for 72 h (Figure 2C). Aspirin induced secondary postapoptotic necrosis, defined as degeneration of subcellular organelles and rupture of the plasma membrane despite the presence of apoptotic condensation of chromatin when its concentration was increased to 10 mmol/L. Certain SW480 cells showed the features of oncotic necrosis, such as oncotic nuclear change, disrupted plasma membrane, degeneration of cytoplasmic organelles, swollen mitochondria with amorphous dense bodies (Figure 2D).

**Figure 3** Effect of aspirin on the expression of Bcl-2 in normal SW480 cells (**A, C**) and Bax after treatment with aspirin at the concentration of 5 mmol/L (**B, D**).

**Figure 4** Effect of aspirin on the expression of Bcl-2 and Bax in SW480 cells. The expression of Bcl-2 protein was down-regulated while that of Bax protein was up-regulated in a dose-depend manner. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs control group.

#### Aspirin inhibited Bcl-2 and increased Bax expression in SW480 cells

In the untreated SW480 cells, there was a strong cytoplasmic staining for Bcl-2 as detected by immunocytochemistry (Figure 3). After incubation with 5 mmol/L aspirin for 72 h, cytoplasmic Bcl-2 staining was substantially diminished (Figure 3) while immunocytochemistry staining for Bax was significantly increased after treatment with aspirin. Being consistent

with immunocytochemistry staining, the expression of Bcl-2 protein measured by Western blotting, was reduced in aspirin-treated SW480 cells while that of Bax protein was increased, suggesting that aspirin could down-regulate Bcl-2 protein expression and up-regulate Bax protein expression (Figure 4).

#### DISCUSSION

The molecular mechanism underlying the chemopreventive effects of NSAIDs is not well understood. One most widely accepted mechanism underlying the anticancer effect of NSAIDs is the reduced PG synthesis by inhibiting the COX activity. In the present study, we used a COX-2 negative colon cancer cell line SW480 as a model to exclude the pathway of COX-2. Being consistent with previous findings<sup>[10,11,15]</sup>, treatment with aspirin at different concentrations inhibited the proliferation of SW480 cells in a dose- and time-dependent, arrested the cell cycle at the G<sub>0</sub>/G<sub>1</sub> phase, decreased the cell proportions at the S- and G<sub>2</sub>/M- phases in a concentration-dependent manner. SW480 cell apoptosis induced by aspirin was confirmed by flow cytometric analyses of cellular DNA content and transmission electron microscopy (TEM). After treatment with aspirin at the concentration of 2.5–10 mmol/L for 72 h, typical morphological alterations of apoptosis were observed<sup>[16]</sup>, including cytoplasmic blebbing, nuclear membrane splitting, fragmentation of nuclei, and formation of apoptotic bodies. The mechanism underlying aspirin-induced cell cycle arrest is not known. It was reported that NSAIDs can arrest HT-29 cell cycle at the G<sub>0</sub>/G<sub>1</sub> phase by inhibiting the expression of cdc2, cdc4 and cyclin, decreasing the phosphorylation of Rb, and increasing the p21<sup>WAF-1/CIP1</sup> expression in HT-29 cells<sup>[17]</sup>. Moreover, Perugini<sup>[18]</sup> found that aspirin induces cell

cycle arrest at the  $G_1$  phase in human pancreatic cancer cells by inhibiting cyclinD1. Whether aspirin shares the same mechanism against SW480 cells still needs to be explored.

Several protein families modulating apoptosis have been described, among which the *Bcl-2* family of proteins is best characterized<sup>[19,20]</sup>. *Bcl-2* appears to function as an inhibitor of apoptosis whereas *Bax* promotes this process. It has been shown that *Bax* can form heterodimers with *Bcl-2* to inhibit the anti-apoptotic function of *Bcl-2*<sup>[21]</sup>. Our results show that aspirin could inhibit the expression of *Bcl-2* in colon cancer cells but increase *Bax* expression. The *Bcl-2/Bax* ratio is important for apoptosis and the decline of this ratio contributes to apoptosis induction. In addition, *Bax* dimers or oligomers directly form channels in mitochondrial outer membrane in apoptosis<sup>[20,21]</sup>. It is reasonable to conclude that, at least in part, aspirin promotes apoptosis of SW480 cells by down-regulating *Bcl-2* and up-regulating *Bax* expression.

In summary, aspirin inhibits the proliferation and induces apoptosis of COX-2 negative colon cancer SW480 cells by down-regulating *Bcl-2* and up-regulating *Bax* expression, which might be a potential mechanism by which aspirin plays a positive role in apoptosis of SW480 cells.

## COMMENTS

### Background

Increasing evidence from human epidemiological studies, animal models, and experiments *in vitro* reveals that administration of nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin (acetylsalicylic acid) represents a treatment of choice for colon cancer. Data indicate that use of NSAIDs, including aspirin, is inversely associated with the risk of colorectal cancer, and clinical trials in patients with familial adenomatous polyposis showed that use of NSAIDs can lead to the regression of colorectal adenomas. In addition, data derived from various animal models of chemical carcinogenesis also suggest that NSAIDs can protect the stomach and esophagus against development of cancer. However, the molecular mechanism by which aspirin exhibits its anticancer effects is not completely clear.

### Research frontiers

A possible mechanism under lying the antitumour properties of aspirin against cancer has been ascribed to its direct inhibition of cyclooxygenase (COX)-2 in colorectal cancer tissue. However, several lines of evidence suggest that the wide range of antiproliferative potencies of aspirin do not correlate exclusively with the COX-2 inhibitory activity, because some reports showed that NSAIDs can induce apoptosis in colon cancer cells that lack detectable expression of COX-2 protein. Until now, most of researchers recruited COX-2 positive colon cancer cells to study the effect of aspirin on apoptosis and proliferation of colon cancer cells. However, few studies on the effect of aspirin on COX-2 negative colon cancer cells and lack systematic analyses of aspirin-induced morphologic changes are available. Meanwhile, whether aspirin induces apoptosis of COX-2 negative colon cancer cells is controversial. The purpose of this study was to investigate the effect of aspirin on proliferation and apoptosis of SW480 cells, a COX-2 negative human colon cancer cell line.

### Innovations and breakthroughs

Aspirin could not only induce apoptosis but also necrosis of cells at high concentrations. After treatment with aspirin, SW480 cells displayed a typically morphological feature of apoptosis and necrosis under transmission electron microscope (TEM), and increased the *Bcl-2* expression, but decreased the expression of *Bax*.

### Applications

The results of this study confirmed that aspirin could inhibit the proliferation and induce apoptosis of COX-2 negative colon cancer cell line SW480 by

down-regulating the *Bcl-2* expression, and up-regulating the *Bax* expression, which might be a potential mechanism by which aspirin plays a positive role in apoptosis of this cell line. This may benefit to the exploration of new anticancer drugs in the future.

### Peer review

This paper describes the antiproliferative effect of aspirin on Cox-2 negative colon cancer cell via the activation of apoptosis, cell cycle arrest and change in the *Bax/Bcl-2* balance. The manuscript contains interesting data, and benefits to the elucidation of the pathogenesis of colon cancer.

loma without the need for intervention. In early 2006, the patient died of multi organ failure without signs of extrahepatic cholestasis or cholangitis at the age of 75, 10 years after the diagnosis of biliary papillomatosis was established. The patient exceeded the average life expectancy of patients with biliary papillomatosis by far. Thus, PDT might be a sufficient therapeutic option for recurrent papillomatosis patients with no significant side effects.

### Abstract

Papillomatosis of the bile duct is a rare disease with a high risk of malignant transformation. Therapeutic options include partial hepatectomy and liver transplantation. A previously healthy 65-years old male developed jaundice and right upper abdominal quadrant pain in 1996. A villous adenoma of the distal bile duct was diagnosed. A Whipple procedure was performed. In 2002 the patient turned symptomatic again. Another adenoma was found in the right hepatic duct resulting in a right hepatectomy. Two years later the patient again developed cholestasis. After drainage of the left hepatic duct with a percutaneous transhepatic cholangial drainage (PTCD) catheter, a recurrent biliary adenomatosis was diagnosed by cholangioscopy. As there was no surgical option left, the patient received photodynamic therapy (PDT) for the recurrent biliary papillomatosis. Three mo after he received further photodynamic therapies, the bile duct epithelium appeared normal and the patient had no signs of adenomatosis, both macroscopically and histologically. The follow-up cholangioscopy in late 2005 revealed only a small papil-

### INTRODUCTION

Biliary papillomatosis is a rare disease with less than 100 cases reported in the literature<sup>[1,2]</sup>. Biliary adenomatosis is a disease of advanced age and more common in males than in females. Similar to the adenoma-carcinoma sequence found in colon cancer, a progression to cholangiocarcinoma is presumed for biliary adenoma<sup>[3]</sup>. Therefore, patients with bile duct adenomatosis are at an increased risk of developing malignancies<sup>[1]</sup>. So far, resection of the involved liver segments and liver transplantation are the only established therapeutic options for patients with biliary papillomatosis<sup>[4,5]</sup>. Because of the advanced age and concomitant cardiovascular risk factors, many patients are neither eligible for extended liver resection nor transplantation, limiting the therapeutic options for the majority of patients with bile duct papillomatosis.

Photodynamic therapy (PDT) is a relatively new endoscopic procedure established in the local therapy for

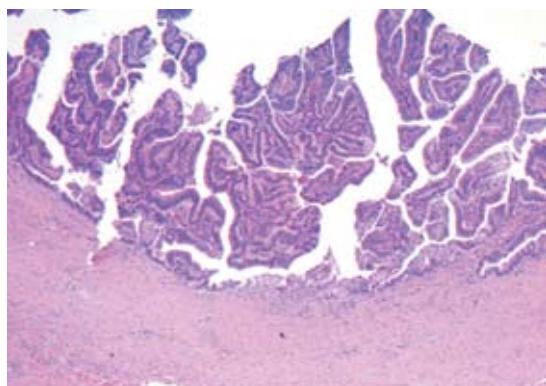

Barrett's esophagus<sup>[6]</sup>, non small-cell lung cancer<sup>[7]</sup> and newly established for the palliative treatment of malignant neoplasms of the bile duct<sup>[8-13]</sup>. After local or systemic application of a photosensitizer, the agent accumulates in neoplastic tissue while it is cleared from most other tissues within 40-60 h. Local radiation of the neoplasm with non-thermal laser activates the compound resulting in destruction of the neoplasm by a photochemical process generating oxygen radicals<sup>[11]</sup>. Effects occur with a penetration depth of 5-6 mm, depending on the physical attributes of the surrounding tissue (particle scatter, light absorption, etc.). This procedure was first reported in 1991 by Mc Coughan in the treatment of bile duct cancer<sup>[14]</sup>. In this palliative setting, PDT shows good results in terms of quality of life, relief from cholestasis and extension of lifespan<sup>[8,10]</sup>. Side effects include fever, abdominal pain, nausea, vomiting and insomnia though rare. Increased photosensitivity of the skin and eyes is observed and precautions should include avoidance of direct sunlight and bright indoor light. The skin should be covered and sunglasses should be worn when being outdoors.

## CASE REPORT

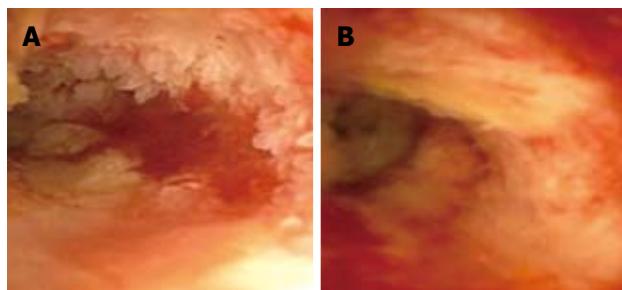

A previously healthy 65-years old male developed jaundice and right upper abdominal quadrant pain in 1996. An ERCP revealed a tumor in the common bile duct. Thus a Whipple procedure was performed. Histologically, a villous adenoma of the distal bile duct was diagnosed. The patient recovered well until he became symptomatic again in 2002. Another large adenoma was seen in a previously performed cholangioscopy of the right hepatectomy and hepatico-jejunostomy. The histological examination again revealed a villous adenoma with mild inflammation of the adjacent proximal parts of the bile duct and the surrounding liver tissue (Figure 1).

Two years later, the patient developed cholestasis again. After drainage of the left hepatic duct with a percutaneous transhepatic cholangial drainage (PTCD) catheter, a recurrent biliary adenomatosis was diagnosed via cholangioscopy. Following the Whipple-procedure, hemihepatectomy and hepatico-jejunostomy in the past, another surgical procedure was found to be of little benefit for the 72-years old patient. Thus we decided to perform a therapeutic trial of photodynamic therapy (PDT). Forty-eight hours after injection of 2 mg/kg of photosensitizer Photofrin II®, we performed laser irradiation (633 nm) of the bile duct via videocholangioscopy (Olympus) with 400 W/cm. A Yamakawa catheter was placed for drainage of the biliary tract. The patient was instructed to protect against sunlight for the following 6 wk and discharged. No side effects of the PDT procedure were seen. He recovered well and was regularly readmitted 6 mo later for a follow-up cholangioscopy.

This time, the biliary papillomatosis appeared less extensive and the Yamakawa-drain was exchanged. Another PDT procedure was performed using the same protocol as in the first attempt. In June 2005, the patient was regularly readmitted for another follow-up. This

**Figure 1** HE staining for samples collected at the right-sided hemihepatectomy and hepatico-jejunostomy of the left hepatic duct ( $\times 40$ ) showing a villous adenoma with mild inflammation of the adjacent proximal parts of the bile duct and the surrounding liver tissue but no invasive growth.

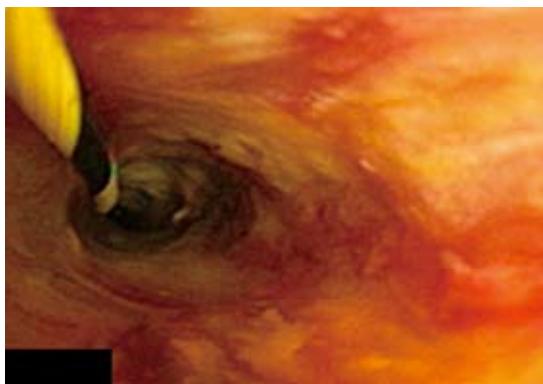

**Figure 2** Recurrent papillomatosis before the third course of photodynamic therapy without signs of a functional stenosis of the bile duct (A) and one month after the second course of PDT (B).

time a mild recurrent papillomatosis was diagnosed and another PDT procedure was performed (Figure 2). Three months later, we repeated photodynamic therapy with only remnants of the papillomatosis seen cholangioscopically. By that time histology revealed a papillary adenoma with focal high-grade dysplasia. The patient remained asymptomatic for months. Three months after the third treatment, the bile duct epithelium appeared normal and the patient had no signs of adenomata or dysplasia, both macroscopically and histologically. Another follow-up cholangioscopy in late 2005 revealed only a small adenoma without the need for intervention (Figure 3).

In early 2006, the patient presented with signs of end-stage liver disease accompanying portal hypertension, ascites, spontaneous bacterial peritonitis and caput medusae. The underlying liver disease was most likely secondary biliary cirrhosis, caused by chronic cholestasis in the past. In March 2006, he was admitted to hospital with severe pneumonia and decompensated liver cirrhosis. A few weeks later, the patient died of multi organ failure. By that time, he had no clinical or sonographical signs of extrahepatic cholestasis or cholangitis.

## DISCUSSION

We report the first successful photodynamic therapy for biliary adenomatosis without any serious side effects.

**Figure 3** Cholangioscopy showing only minor adenomatosis 3 mo after the third course of PDT.

Photodynamic therapy is an established intervention in the treatment of Barret's esophagus<sup>[6]</sup>, lung cancer<sup>[7]</sup> and bile duct cancer<sup>[8]</sup>. It was reported that photodynamic therapy can improve the quality of life and the survival of such patients<sup>[8,10,15,16]</sup>.

Our patient survived ten years after the diagnosis of biliary papillomatosis was established, exceeding the average survival time of biliary adenomatosis patients ranging from 28<sup>[1]</sup> to 32 mo<sup>[2]</sup>. Yeung *et al*<sup>[2]</sup> reviewed 78 cases of biliary papillomatosis and postulated a median survival of 28 mo after radical resection irrespective of the histological signs of dysplasia, while the median survival time was only 11 mo when no radical resection was performed. Only few cases having a survival time of more than 4 years after the diagnosis of biliary papillomatosis have been reported. In the patient presented here, the first biliary adenoma was diagnosed in 1996 and recurred in 2002, resulting in hemihepatectomy. After initiation of the PDT, the patient survived another four years with a good quality of life until admission for decompensated liver cirrhosis, a few weeks before he died. From the first manifestation of the disease he even survived 10 years.

Depending on the location and extension of the disease so far, the Whipple procedure and hemihepatectomy are the therapies of choice for biliary papillomatosis resulting in an average survival time of approximately 17 mo<sup>[2,17]</sup>. Extensive preoperative diagnosis is required to determine the resectability and the extent of the disease by ERCP, CT, cholangioscopy and intraoperative ultrasound studies<sup>[18]</sup>. In cases of diffuse hepatic manifestations, liver transplantation should be considered<sup>[4]</sup>. Bile duct papillomatosis is a disease of the elderly (mean age at time of diagnosis: 63 years), thus many patients would not be eligible for transplantation limiting the therapeutic options.

Apart from other local palliative procedures (i.e. stenting, drainage), few cases of local ablation have been reported<sup>[19,20]</sup>, most of them in the palliative setting with advanced disease plus cholangiocarcinoma were treated with a conventional laser. Data on the long term survival of these patients are lacking so far. However, PDT ablation seems to be more specific targeting dysplastic tissue

with less harm to the surrounding tissue<sup>[11]</sup>. Thus, using PDT in this particular setting might improve the quality of life and prolong life expectation of this group of patients without exposing them to risky procedures. The use of PDT in this setting has not been reported in the literature so far.

Side effects of PDT include fever, abdominal pain, nausea, vomiting and insomnia though rare. Increased photosensitivity of the skin and eyes is observed and precautions should include avoidance of direct sunlight and bright indoor light<sup>[11]</sup>. In this case only minor adverse effects are reported including mild inflammatory reaction two days after the PDT and mild skin reaction. The quality of life was significantly improved with relief from cholestasis and cholangitis for months and the patient exceeded the survival rate of most other cases reported in literature<sup>[2]</sup>.

In conclusion, PDT might be a therapeutic option for patients with recurrent biliary papillomatosis after resection as well as for those who are not eligible for surgery. Further studies are needed to prove the role of PDT in the treatment of biliary papillomatosis.

### Abstract

Chronic hepatitis C virus (HCV) infection is associated with multifarious extra-hepatic manifestations; the most described and discussed being mixed cryoglobulinemia which is strongly related to B-cell lymphoproliferative disorders (LPDs). We present a case of chronic HCV infection and mixed cryoglobulinemia, with minimal liver involvement. The case is a 53-year-old patient who was diagnosed as having bone marrow hypoplasia at the age of three. She received several blood transfusions to normalize her haemoglobin. At the age of 31, she was diagnosed with rheumatoid arthritis on account of her diffuse joint pain and inflammation, elevated rheumatoid factor (RF) and Raynaud's phenomenon. Twenty years later, monoclonal gammopathy of IgG Lambda (one year later, changed to IgM Kappa) was detected during a routine examination. A bone marrow biopsy showed hypoplasia, Kappa positive B-lymphocytes and low-grade malignant lymphoma cells. PCR of the bone marrow aspirate was not contributory. No treatment was initiated owing to her

poor bone marrow function and she is under regular follow-up.

### INTRODUCTION

Natural history of chronic hepatitis C virus (HCV) infection is still evolving. Several factors contribute to the long term consequences. Although the exact mechanism is not known, the ability of virus to modulate the immune system plays a significant role in the long term consequences. It has been observed that the extra-hepatic manifestations which appear during the chronic course do not alter HCV infection clinically. In this context we present a case of chronic HCV infection in a patient with bone marrow failure.

### CASE REPORT

The patient was a 53-year-old woman. In 2004, she was found positive by a screening in a public program to track HCV infected individuals. She presented to our institution immediately and HCV genotype 1b was detected on further evaluation. The liver function test, fibrotest and ultrasound transient elastography (fibroscan) indicated liver in non-fibrosis stage (F0-F1). Retrospection into her medical history revealed a slow evolution of chronic HCV infection, paradoxically mixed cryoglobulinemia was the first diagnosis. At 3 years of age, the patient was diagnosed as having cytopenia involving leukocyte

and erythrocyte lineages secondary to Chloramphenicol toxicity. To normalize her very low hemoglobin, she received several blood transfusions at unspecified intervals. However, an early or late transfusion reaction was never reported. At age 19, she developed severe bone marrow hypoplasia and anaemia and was treated with Prednisone for 5 years until her bone marrow recovered. Twelve years later, she presented with pain, redness and swelling of inter-phalangeal joints of hand. The symptoms were characteristically bilateral and progressively involved other joints, such as wrists, shoulders, knees and hips. Simultaneously she developed Raynaud's phenomenon and blood examination showed an elevated rheumatoid factor (RF). Although the symptoms were not very typical, a diagnosis of rheumatoid arthritis was established based on her clinical spectrum. Radiography of the joints taken during the course of the disease showed neither destructive and erosive features nor obvious deformities. In 2001, a blood test showed monoclonal gammopathy of IgG Lambda isotype. In the following year, aggravating cytopenia and change in isotype of monoclonal immunoglobulin to IgM Kappa were noted. A bone marrow biopsy showed hypoplasia and infiltration with Kappa positive small B lymphocytes, with mature chromatin and a high cytoplasmic-nuclear ratio. Dispersed between the B lymphocytes were low-grade malignant lymphoma cells, however, in view of her hypoplastic bone marrow, no treatment was initiated. Persistent joint symptoms, Raynaud's phenomenon and steadily increasing values of RF (from 146 IU/mL in 1998 to 7400 IU/mL in 2004) led to the detection of mixed cryoglobulinemias (MC) in 2003. Anti-cyclic citrullinated peptide (CCP) and anti-keratin antibodies were negative, suggesting the arthritis is a manifestation of cryoglobulinemia. With time she developed paraesthesia of upper and lower limbs. Nevertheless, neither sensory nor motor neuropathy was detected objectively. The common manifestation of MC, i.e. vasculitis and skin involvement was never seen in our patient. Her persisting anaemia was treated with blood transfusion and a subsequently elevated serum ferritin with Desferrioxamine.

## DISCUSSION

Chronic HCV infection is associated with a variety of extra-hepatic manifestations, the prototype being MC with a prevalence rate of 19%-50%<sup>[1]</sup>. MC is associated with lymphoproliferative disorder (LPD) of small B lymphocytes in the bone marrow or the liver<sup>[2]</sup>. Two distinct mechanisms of LPD development have been suggested, the first being specific binding of HCV E2 protein with CD81 on the B-cell which promotes consistent polyclonal response to the viral antigens and favor the development of LPD, and the second being HCV induced mutations in Ig genes and oncogenes such as *Bcl-2* rearrangement (t14; 18 translocation). However, Zignego *et al* suggested a multi-step process of pathogenesis involving both mechanisms. Persistent stimulation of B-cells followed by mistakes in Ig gene rearrangement and t (14; 18) translocation which favors the survival of abnormal B-cells<sup>[2,3]</sup>. It is estimated

that 8-10% of type II MC evolves into lymphoma (Bcell non-Hodgkins lymphoma)<sup>[2]</sup>.

Based on the type of Ig, MC is classified into three types, of which, type II MC (polyclonal IgG and Monoclonal IgM) and type III (polyclonal IgG and IgM) are commonly seen in chronic HCV infection. The Ig participates in the formation of circulating immune complexes and exerts RF like activity, usually by IgM component which frequently displays WA cross-reactive idiotype. RF is positive in 50%-80% of the patients with MC and clinically present as polyarthritis involving large joints in contrast to rheumatoid arthritis involving smaller joints<sup>[1,3]</sup>.

MC is a systemic vasculitis and circulating immune complexes are deposited in small and medium sized vessels<sup>[3]</sup>. Nevertheless, low levels of cryoglobulins can remain undetected for a long duration due to the absence of specific symptoms<sup>[2,3]</sup>. Clinical manifestations are observed in 10%-30% of the patients and the most common symptoms are weakness, arthralgias and purpura (Meltzer and Franklin triad)<sup>[2]</sup>. Apart from the triad, bilaterally symmetrical and distal neuropathy (mostly sensory) is the most frequent clinical feature of MC. Patients have variable degrees of paraesthesia and multiple mononeuritis and mononeuropathies are diagnosed infrequently<sup>[2,3]</sup>. Renal involvement is recognized in 20% of the patients with MC and is considered as one of the worst prognostic indices. Patients present with haematuria, proteinuria, edema and renal failure of variable grade. Precipitation of cryoglobulins in the capillary loops gives a histological picture similar to idiopathic membranoproliferative glomerulonephritis<sup>[2]</sup>. However, progression of renal pathology is slow and less than 15% of the affected patients develop renal failure requiring dialysis<sup>[3]</sup>. Additionally, the large spectrum of extra-hepatic manifestations also include thyroid disorders, anti-thyroid antibodies, porphyria cutanea tarda, lichen planus, diabetes mellitus, sicca syndrome, cardiomyopathy, amyloidosis, alveolitis, lung fibrosis, etc<sup>[1-3]</sup>.

There are no definite criteria for the diagnosis of MC, therefore clinical features and laboratory results such as elevated RF, reduced C4 values and presence of cryoglobulins might provide the clue<sup>[1,2]</sup>. Even in the absence of symptoms it is prudent to monitor the patients with positive HCV RNA at regular intervals for the development of MC. The mainstay treatment for HCV infection is Interferon-alpha. Several studies have proven the linear relation between clinico-immunological and virological response to anti-HCV treatment with pegylated interferon alpha (IFN- $\alpha$ ) and Ribavirin. Virological relapse on discontinuing treatment is also associated with expansion of B-cell clones bearing t (14; 18) translocation. IFN- $\alpha$  exhibits antiproliferative and immunomodulatory effects. It effectively inhibits viral replication and B-cell clonal expansion which is considered as the pathogenetic basis of MC. Interestingly, long-term analysis of treated patients with sustained virological response have developed expansion of B-cell clone with translocation, suggesting persistent lymphatic infection<sup>[2]</sup>.

The ultimate prognosis in chronic HCV infection is

determined by the development of liver cirrhosis and MC is considered as a negative prognostic indicator in this context by many authors<sup>[2-4]</sup>. In a recent publication on the natural history of chronic HCV by Vigano *et al*, 343 patients were followed up for 10 years<sup>[5]</sup>. They found that cryoglobulins did not affect the clinical course of HCV infection and had little impact on the development of extrahepatic complications. Additionally, they also cited that MC had no influence on the development of liver decompensation or hepatocellular carcinoma in chronic HCV infection. However, they could not prospectively assess any association between MC and development of cirrhosis<sup>[5]</sup>. Several factors such as male gender, older age at infection, excessive alcohol consumption and secondary hemochromatosis (due to blood transfusion) enhance the fibrotic process. Furthermore, progression to cirrhosis is more rapid in patients with compromised immunity, hepatic steatosis, obesity and diabetes. Interestingly, viral factors such as viral load and genotype determine the response to treatment; however, they do not influence the fibrosis progression<sup>[6]</sup>.

The time gap between the diagnosis of rheumatoid arthritis and MC in our patient was more than twenty years. During this period, she developed progressive paraesthesia, worsening anaemia, MC and small B-cell lymphoma confined to the bone marrow. No other classical extra-hepatic manifestations were noted. Low C4 values were observed after the diagnosis of rheumatoid arthritis. It is suggested that elevated serum alanine aminotransferase (ALT) level indicates the progression of fibrosis<sup>[4]</sup> and in our patient elevated ALT values had been observed since August 2004, but the average values were always two times lower than the normal values (recent values, SGOT/AST = 41 IU/L; normal values 14-40 IU/L, and SGPT/ALT = 66 IU/L; normal values 6-40 IU/L). Patients with chronic HCV infection might demonstrate anti-LKM1 antibody as in autoimmune hepatitis type 2<sup>[4]</sup> and it was negative in our patient. The first in 2004 and recent fibroscan showed the liver in non-fibrosis stage (F0-F1). Renal manifestations and amyloidosis were excluded by a normal renal function test and normal β2 microglobulin. Her persistent anaemia was treated with regular blood transfusion after 2003 and accordingly elevated serum ferritin with Desferrioxamine. On account of her bone marrow hypoplasia anti-HCV treatment was

deferred.

We believe that our patient might have acquired the virus by blood transfusion in childhood. However, acute hepatitis C is rarely recognized in childhood and children with chronic infection are typically asymptomatic<sup>[6]</sup>. Considering this fact, it was hypothesized that children under immunosuppression (induced by chemotherapeutic agents for the treatment of leukaemia) acquiring HCV through blood transfusion might not develop an immune response that could cause chronic injury<sup>[6]</sup>. Although, this postulate was questioned due to several conflicting reports, we support it in view of the normal liver function and absent fibrosis in our patient with bone marrow hypoplasia. This could also explain the absence of other organ involvement. However, we agree that the patient should be kept under surveillance for the development of other complications.

## CONCLUSION

Chronic HCV infection might present with more serious extra-hepatic manifestations than hepatic disease itself. Patients' immunological status might influence the extent of liver injury and extra-hepatic manifestations.

### INTRODUCTION

The presence of blood into the biliary tree, as a result of hemorrhage through the biliary tract, has first been reported by Francis Glisson<sup>[1-3]</sup>. The term hemobilia, however, which is used to describe this phenomenon, was coined by Sandblom<sup>[1-3]</sup>. Hemobilia usually presents with one or more constituents of the following triad of symptoms and signs: upper quadrant pain, upper gastrointestinal bleeding and jaundice<sup>[3]</sup>. Hemobilia can occur due to trauma (both accidental and iatrogenic), gallstone disease, acalculous cholecystitis, cholangitis, ascariasis or hydatid, hepatic abscess, malignancies of the liver and pancreas and biliary tract, polyarteritis nodosa, vascular malformations of hepatic artery aneurysm or coagulopathy<sup>[3]</sup>. As far as coagulopathies are concerned, Bernard-Soulier syndrome<sup>[4]</sup>, idiopathic thrombocytopenic purpura<sup>[5]</sup>, treatment with anticoagulants<sup>[6]</sup> and hemophilia<sup>[7,8]</sup> have been implicated in the induction of hemobilia. To our knowledge, seven cases of hemobilia in patients with hemophilia have been described<sup>[7-13]</sup>, five of them following liver biopsy<sup>[9-13]</sup> and only two cases of spontaneous hemobilia<sup>[7,8]</sup>, while several cases of malignancy-associated hemobilia<sup>[14-16]</sup> have been reported. A case, however, which combines all the three conditions, has never been published. We describe a case of hemobilia as the initial manifestation of cholangiocarcinoma in a patient with hemophilia B.

### Abstract

Hemobilia is a rare manifestation of hemophilia and is usually iatrogenic following liver biopsy. There are only few reports of spontaneous hemobilia in hemophilia patients. Cholangiocarcinoma is a well-established cause of hemobilia. We describe a case of a 70-year-old male, with known haemophilia B and a past history of papillotomy, who presented with classical symptoms of hemobilia. The initial diagnostic work-up failed to demonstrate a potential cause of bleeding other than the coagulopathy. Three months later, he was readmitted to our hospital with a second episode of hemobilia. During the second work-up, a cholangiocarcinoma was diagnosed both by imaging studies and by a significant elevation of cancer antigen 19-9. Although hemobilia could be attributed to hemophilia, especially in a patient with previous papillotomy, an underlying malignancy of the biliary tree should be suspected.

### CASE REPORT

A 70-year-old male was admitted to our department during his second episode of hematemesis, melena, fever, and right upper quadrant pain. He was a known hemophilia B patient with liver cirrhosis, who was

**Figure 1** Endoscopic retrograde cholangiopancreatography showing string-like filling defects (arrows) suggestive of intraductal blood clots.

**Figure 2** MRCP image showing stricture (arrows) of the proximal segment of the common bile duct.

seropositive for hepatitis C virus and referred to our department three months ago due to a similar episode. He had a history of cholecystitis and underwent a papillotomy for choledocholithiasis and common bile duct stones two years ago. The work-up performed during his first admission revealed higher than normal serum levels of cancer antigen (CA) 19-9 (112.5 U/mL), along with ejection of a blood clot through the sphincterotomized papilla of Vater-hemobilia by side-viewing endoscopy and the presence of string-like filling defects in the biliary tree *via* endoscopic retrograde cholangiopancreatography (ERCP, Figure 1). Magnetic resonance angiography (MRA) showed no evidence of hepatic artery pseudoaneurysm or any other vascular malformation. No potential cause for hemobilia other than the underlying coagulopathy was identified since ultrasonography, magnetic resonance imaging (MRI), magnetic resonance cholangiopancreatography (MRCP) and ERCP were not suggestive of another etiology. The patient was treated at that time with factor IX concentrate, fresh frozen plasma (FFP) and blood transfusions until the prolonged activated partial thromboplastin time (APTT) and the decreased hematocrit reached their normal levels. Moreover, cholestasis resulting from intrabiliary clots was successfully managed by removing these clots with a balloon catheter during ERCP, which led to lysis of the remaining smaller clots and a significant decrease in levels of bilirubin, gamma-glutamyltransferase (gamma-GT), alanine aminotransferase (ALT), and aspartate aminotransferase (AST). As soon as the above-mentioned markers returned to normal and the patient's clinical condition improved, he was discharged and remained free of any bleeding or cholestasis-related manifestations for almost 3 mo. Then, he was hospitalized for a week at a peripheral hospital with low-grade fever and right upper quadrant pain. During hospitalization, he had episodes of hematemesis and melena, but the site of bleeding was not identified. The patient was then referred to our hospital.

Physical examination at admission revealed that his temperature was 37.4°C, blood pressure was 160/70 mmHg and heart rate was 55 beats per minute.

Right upper quadrant tenderness, jaundice and melena were also present. Laboratory findings included 7.2 g/dL hemoglobin,  $2.65 \times 10^6/\mu\text{L}$  erythrocytes,  $227 \times 10^3/\mu\text{L}$  platelets,  $6.1 \times 10^3/\mu\text{L}$  leucocytes with 55.6% polymorphs, 6.9 mg/dL total serum bilirubin, 4.03 mg/dL direct bilirubin, 199 IU/L AST, 53 IU/L ALT, 633 IU/L gamma-GT, 1466 IU/L alkaline phosphatase (ALP), 36.2 s APTT. Moreover, the determination of serum tumor markers revealed significantly elevated levels of CA 19-9 (3456 U/mL). Abdominal ultrasonography showed echogenic non-shadowing debris in the common bile duct and dilation of the intrahepatic bile ducts in the right liver lobe. Side-viewing endoscopy revealed blood in the lumen of the second part of the duodenum and a prominent blood clot at the papilla of Vater. Finally, MRCP revealed dilation of the intrahepatic bile ducts and identified the cause of hemobilia: a cholangiocarcinoma involving a 3 cm-long proximal segment of the common bile duct (Figure 2). These findings were confirmed by ERCP. The intrabiliary blood clots were removed using a balloon catheter and a 10 cm-long (10 Fr) stent was placed to stop the bleeding and decrease the level of bilirubin, gamma-GT and ALP. Factor IX concentrates, erythrocyte concentrates and FFP were also transfused until APTT, hemoglobin and erythrocyte count levels returned to normal. In addition, he was also treated with antibiotics. The patient was doing well, no recurrence of bleeding or cholangitis was recorded and he was discharged. Two weeks later, almost 6 wk before a scheduled stent was replaced, he presented with high-grade fever, jaundice and upper quadrant pain. The patient was septic at admittance. Despite full antibiotic coverage, he died of septic shock soon.

## DISCUSSION

Hemophilia is a rare cause of non-iatrogenic hemobilia. To our knowledge, only two cases of spontaneous hemobilia in hemophiliacs have been described so far<sup>[7,8]</sup>. Malignancies, on the other hand, are a more common cause of hemobilia, compared to hemophilia. Malignant tumors, however, do not account for more than 10% of total hemobilia incidents<sup>[3]</sup>. Hemophilia and malignancy, two potential causes for hemobilia, were both present in our patient. Hemorrhagic diathesis induced by

hemophilia B, increased the susceptibility to bleeding originating from a tumor-infiltrated ductal system. What seems to be of some importance is the fact that hemobilia was proved to be an early manifestation of the underlying cholangiocarcinoma, and that ultrasonography, ERCP and MR techniques (MRI, MRCP, MRA) failed to identify it. A mild elevation of CA 19-9 was also recorded during the patient's first admission. It was reported that use of this tumor marker in the diagnosis of cholangiocarcinoma shows a sensitivity of 53%, when a CA19-9 value  $> 100$  U/mL is used<sup>[17]</sup>, and is considered to be misleading when such patients have gallstone disease and/or cholangitis<sup>[18]</sup>. In our case, the elevation of CA19-9 was initially attributed to chronic ascending cholangitis following papillotomy which in turn could affect the arterial wall, thus leading to the formation of hepatic artery pseudoaneurysm, a known cause of hemobilia<sup>[19]</sup>.

Although cholangiocarcinoma was not detected during the initial work-up, hemobilia was successfully recorded during both work-ups. The combination of upper quadrant pain, upper gastrointestinal bleeding (hematemesis, melena) and jaundice as well as the evidence provided by the abdominal ultrasonography were all indicative of hemobilia. It was not, however, until side-viewing endoscopy and ERCP were performed, hemobilia was diagnosed.

In view of the classical triad of hemobilia, all the three constituents are present in up to 22% of patients<sup>[3]</sup>. Side-viewing endoscopy performed independently or as a part of ERCP can reveal active bleeding<sup>[6,20]</sup> or blood clots at the papilla of Vater (as in this case). Moreover, cholangiography may show string-like, as reported here, or spherical filling defects<sup>[3]</sup>. Angiography also plays a significant role in the confirmation and management of hemobilia and in the identification of vascular malformations as a potential cause of bleeding<sup>[3]</sup>. Ultrasonography, on the other hand, offers circumstantial evidence of bile duct dilation along with the presence of echogenic, non-shadowing, non-mobile formations of blood clots that evolve less reflective masses<sup>[3]</sup>. Computed tomography<sup>[21]</sup> and radioisotope studies<sup>[3]</sup> can also be used.

As far as the management of hemobilia is concerned, different approaches have been applied, depending on the etiology and the underlying diseases. It was reported that decompression of the biliary tree encourages resolution of jaundice and contributes to the arrest of hemobilia<sup>[3,8]</sup>. As shown in a study performed by Sandblom, bile enzymes can perform lysis of fibrin, but a free flow of bile is needed so that this lytic activity can occur<sup>[22]</sup>. Embolization techniques, such as transarterial embolization<sup>[23]</sup> or even surgery<sup>[3]</sup>, have also been applied in the management of hemobilia. In our case, decompression of the biliary tree (by means of a balloon catheter and stenting during ERCP) along with correction of the patient's bleeding diathesis was adequate for both resolution of jaundice and control of bleeding.

In summary, underlying malignancy should be

suspected in cases of non-traumatic, non-iatrogenic hemobilia irrespective of any coincident coagulopathies, such as hemophilia. Hemobilia should not be easily attributed to hemophilia, even when the first work-up fails to identify a potential cause other than coagulopathy. ERCP may serve as a diagnostic tool for both hemobilia and underlying malignancy as well as a therapeutic technique for the management of obstructive jaundice and, in part, of bleeding. The correction of bleeding diathesis by treatment with factor IX, FFP and erythrocyte concentrates is mandatory for the arrest of hemobilia.

## Abstract

Although interferon (IFN) based therapy for recurrent hepatitis C virus (HCV) infection after liver transplantation has been widely accepted, it induces various adverse effects such as thrombocytopenia, resulting in its interruption. Recently, concomitant splenectomy at the time of living donor liver transplantation (LDLT) has been tried to overcome this problem, but this procedure leads to several complications such as excessive intraoperative bleeding and serious infection. A 60-year-old female received LDLT using a left lobe graft from her second son for liver failure caused by hepatitis C-related cirrhosis. Six months after LDLT, she was diagnosed as recurrent HCV infection by liver biopsy. IFN monotherapy was started from 7 mo after LDLT and her platelet count decreased to less than 50 000/ $\mu$ L, which thus made it necessary to discontinue the treatment. We decided to attempt laparoscopic splenectomy (LS) under general anesthesia. Since intra-abdominal findings did not show any adhesion formations around the spleen, LS could be successfully performed. After LS, since her platelet count immediately increased to 225 000/ $\mu$ L 14 d after operation, IFN therapy was restarted and we could convert the combination therapy of IFN and ribavirin, resulting in no detectable viral marker. In

## INTRODUCTION

Recurrence of hepatitis C virus (HCV) infection is a serious problem of HCV positive patients receiving liver transplantation, because it has been universally documented as the leading cause of allograft destruction<sup>[1,2]</sup>. Although interferon (IFN) based therapy in combination with ribavirin for recurrent HCV infection has been widely accepted after liver transplantation, it induces various adverse effects related to bone marrow suppression such as thrombocytopenia and leukopenia, resulting in its interruption. Until recently, no approved treatment for thrombocytopenia in patients with HCV infection is available except for splenectomy or partial splenic embolization (PSE). However, it was most recently reported that the efficacy of eltrombopag, an orally active thrombopoietin-receptor agonist, for

thrombocytopenia in patients with cirrhosis is associated with hepatitis C<sup>[3]</sup>. At present, this drug is not available in our country, and thus splenectomy is the treatment of choice to overcome this problem. Kishi *et al*<sup>[4]</sup> performed splenectomy concurrently with liver transplantation for all HCV-positive liver transplant patients. However, the indication for concomitant splenectomy still remains controversial.

As for splenectomy, laparoscopic splenectomy (LS) is employed as the minimal invasive surgery for various diseases including a normal-size spleen in idiopathic thrombocytopenic purpura (ITP) as well as a huge-size spleen in hypersplenism due to liver cirrhosis<sup>[5]</sup>. It is believed that LS is relatively contra-indicated for patients with previous abdominal surgery, especially with upper abdominal surgery<sup>[6]</sup>. However, it was reported that the incidence of adhesion after organ transplantation is very low<sup>[7,8]</sup>. Wasserberg *et al*<sup>[9]</sup> revealed that post-surgical adhesion formation is significantly reduced in rats receiving tacrolimus immunosuppression after intestinal transplantation.

We therefore performed LS in a female patient with recurrent HCV infection after living-donor liver transplantation (LDLT), which did not lead to any complications. She developed severe thrombocytopenia after antiviral therapy using IFN. This is the first case of LS after LDLT.

## CASE REPORT

A 60-year-old female received LDLT with an ABO identical left lobe graft from her second son for liver failure due to hepatitis C-related cirrhosis at our institution. She was discharged without any postoperative complications. Six months after LDLT, however, her liver function was elevated and she was diagnosed as recurrent HCV infection by liver biopsy. IFN (alpha 2b) monotherapy (3 mega units, 3 times a week) was started 7 mo after LDLT and the levels of liver enzyme and HCV-RNA were notably improved. After 11 mo, however, her platelet count decreased to 32 000/ $\mu$ L, and thus INF treatment was discontinued. After interruption, her liver enzyme and HCV-RNA levels were remarkably elevated again 13 mo after LDLT. IFN therapy was started again when her platelet count was 70 000/ $\mu$ L and discontinued when her platelet count decreased to 39 000/ $\mu$ L (Figure 1).

She was then admitted to our institution to receive splenectomy for thrombocytopenia 15 mo after LDLT. At admission, her laboratory test showed elevated levels of liver and biliary enzymes (157 IU/L AST, 184 IU/L ALT, 201 IU/L  $\gamma$ -GTP, 3.5 mg/L T-Bil, 2.7 mg/L D-Bil) and viral load of HCV-RNA was 5.4 LogIU/mL (genotype 1b). An abdominal enhanced CT demonstrated the enlarged spleen of 140 mm in maximum diameter and collateral vessels derived from the splenic vein (Figure 2A-B).

We decided to perform LS even after LDLT, because the trial of LS was acceptable since LS is potentially

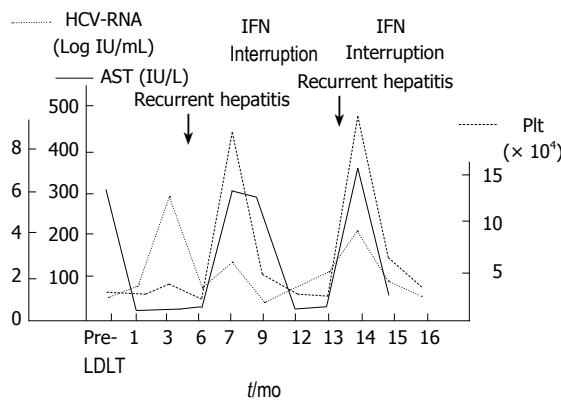

Figure 1 Changes in serum levels of AST, HCV-RNA and platelet after LDLT.

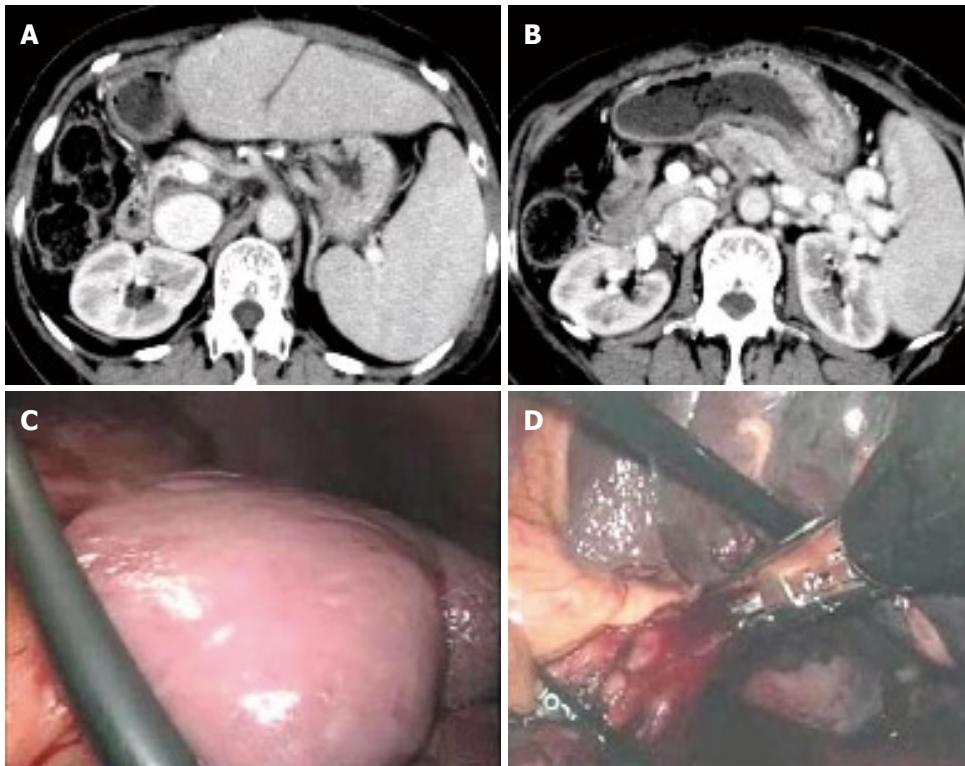

successful because the operation field of LDLT is mainly the right upper abdomen and the mobilization of spleen from the retroperitoneum under laparoscopic approach as much as possible makes a skin incision smaller even if LS is converted to open surgery. In addition, as LS after LDLT is not widely recognized and also has significant short term and long term considerable risks such as infectious complications, we gave the patient sufficient information about splenectomy.

The patient was placed at a right semidecubitus position under general anesthesia. The pneumoperitoneum was introduced with the open Hasson's technique at the left lateral to the umbilicus and intra-abdominal findings did not show any adhesion to abdominal wall and around the spleen (Figure 2C). Thus, we started dissection of the splenocolic ligament and parietal peritoneum using the vessel sealing system (Ligasure AtlasTM) from the lower pole to the upper pole through the lateral side of spleen. After enough mobilization of the spleen, we stapled the splenic hilum with linear staplers (Figure 2D) and delivered the crushed spleen from the extended wound. The operation time was 2 h and 32 min and the amount of bleeding was 72 g. The weight of spleen was 260 g.

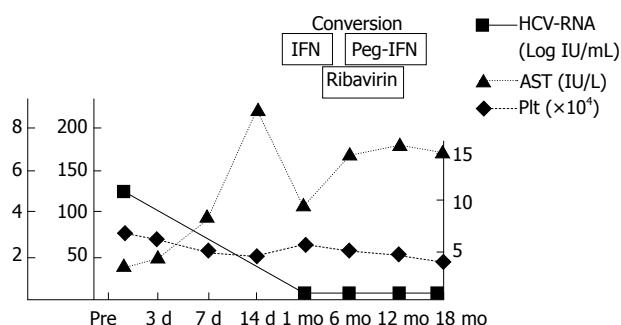

After splenectomy, her platelet count immediately increased and we could restart IFN monotherapy from postoperative day (POD) 7. Furthermore, since her platelet count increased to 225 000/ $\mu$ L on POD 14, we could convert IFN monotherapy to combination therapy of IFN (convert to peg-IFN 1 mo after operation) and ribavirin, resulting in no detectable viral marker 18 mo after LS and achievement of sustained viral response (Figure 3).

## DISCUSSION

Since Delaitre<sup>[10]</sup> performed the first laparoscopic splenectomy (LS) in the last decade, it has gained more and more respect because of its minimal invasion. Similarly to other laparoscopic procedures, it is characterized by shorter hospital stay, lower perioperative complication rate, better cosmetic result and earlier return to full working activity, which are the most important advantages over the open approach.

**Figure 2** Abdominal enhanced CT showing splenomegaly with 140 mm in maximum diameter (**A**) and development of collateral veins around the splenic vein (**B**), no peritoneal adhesion to abdominal wall and around the spleen (**C**), and splenic hilum stapled with linear staplers (**D**).

**Figure 3** Changes in serum levels of AST, HCV-RNA and platelet count after operation.

In recent years, extension of its indications has been noted and this operation has been employed for diseases with normal size spleen such as ITP and huge size spleen such as hypersplenism related to liver cirrhosis. Furthermore, patients with thrombocytopenia caused by IFN therapy for recurrent HCV infection are good candidates for LS in order to overcome this problem<sup>[5,11]</sup>. Kent *et al*<sup>[5]</sup> reported that patients undergoing LS for thrombocytopenia associated with IFN therapy can improve their thrombocytopenia and their platelet count remains above 100 000/ $\mu$ L during subsequent pegylated-IFN therapy. However, no reports are available on successful LS after LDLT for the improvement of thrombocytopenia, as a result of PubMed search using laparoscopic splenectomy and liver transplantation as the key words.

It was reported that concomitant splenectomy with LDLT is necessary to prevent the progression of thrombocytopenia caused by postoperative antiviral therapy<sup>[4,12]</sup>. On the other hand, it is well known that

concomitant splenectomy with LDLT induces several severe complications, such as postoperative portal vein thrombosis, re-bleeding, increasing intraoperative bleeding, and severe infection<sup>[13,14]</sup>. Therefore, indications for concomitant splenectomy should be decided carefully. Although we perform splenectomy concurrently with LDLT to modulate portal venous pressure, especially when the portal venous pressure is over 20 mmHg after reflowing<sup>[15]</sup>, we do not perform concomitant splenectomy for introduction of IFN therapy routinely at present.

Sohara *et al*<sup>[11]</sup> have reported the efficacy of PSE on overcoming IFN-related thrombocytopenia after liver transplantation. But in our hospital, LS is regarded as the first-line treatment for thrombocytopenia in patients with cirrhosis associated with hepatitis C, because PSE induces various severe complications, such as abscess of spleen, persistent fever, severe abdominal pain and the efficacy of PSE lasts for only one year and it is necessary to perform several times of PSE for good results<sup>[16-18]</sup>.

Although LS has been accepted as a minimum invasive method, abdominal surgery used to be a relative contraindication to LS because of some complications related to peritoneal adhesions including other organ injury<sup>[6]</sup>. DeRoover<sup>[19]</sup> reported the first case of LS after orthotopic liver transplantation and described mild peritoneal adhesion found at intra-operation. In addition, various laparoscopic surgeries including incisional hernia repair, proctocolectomy and Roux-en-Y gastric bypass after liver transplantation have been successfully performed in recent years<sup>[20-22]</sup> with a very low incidence of adhesion<sup>[7-9]</sup>. We successfully performed LS after LDLT.

In conclusion, LS can be performed safely even after

LDLT, and LS after LDLT is a feasible and less invasive modality for thrombocytopenia caused by antiviral therapy.

## INTRODUCTION

Arteriovenous fistula (AVF) in the portal circulation is rare and usually involves the hepatic, splenic, or superior mesenteric vessels<sup>[1]</sup>. Inferior mesenteric AVF is uncommon, and only isolated cases have been reported<sup>[2,3]</sup>. Though inferior mesenteric AVF may be congenital<sup>[4-6]</sup>, it results more often from penetrating traumas, such as a gunshot or knife wound, or may be a complication of arterial catheterization or abdominal surgery with bowel resection<sup>[2,3,7-9]</sup>. Inferior mesenteric AVF usually presents with abdominal pain, mass, or features of established portal hypertension<sup>[2,3]</sup>. Colonic ischemia is a less common and more serious manifestation of AVF<sup>[2]</sup>.

Portal vein stenosis is a relatively rare vascular complication affecting 1%-2% of patients who have undergone orthotopic liver transplantation<sup>[10,11]</sup>. Clinical symptoms of portal vein stenosis are usually less pronounced. Patients carrying this diagnosis may develop portal hypertension with ascites and esophageal varices, but portal vein stenosis is potentially devastating, leading to graft failure<sup>[10,11]</sup>.

We report a case of ischemic colitis secondary to an inferior mesenteric AVF in a patient who underwent a previous liver transplantation, subsequently developed portal vein stenosis, and then presented with acute lower gastrointestinal bleeding.

## CASE REPORT

A 46-year-old man was admitted to our hospital for abdominal pain and hematochezia. Two years previously, he underwent cadaveric, orthotopic, whole liver transplantation due to hepatitis B-associated decompensated hepatic cirrhosis. Forty-two days

## Abstract

Arteriovenous fistula (AVF) involving the inferior mesenteric vessels is rare, and the affected patients usually present with abdominal pain, mass, or features of established portal hypertension. Colonic ischemia is a less common and more serious manifestation of AVF. We report a case of ischemic colitis secondary to inferior mesenteric AVF in a patient who underwent a previous liver transplantation, subsequently developed portal vein stenosis, and then presented with acute lower gastrointestinal bleeding. He underwent percutaneous transhepatic placement of a portal vein stent and left colectomy.

**Key words:** Ischemic colitis; Inferior mesenteric; Arteriovenous fistula; Portal vein stenosis

**Figure 1** Colonoscopy revealing diffuse colonic ulceration, exudate, and hemorrhage in the sigmoid and descending colon.

after liver transplantation, the patient developed cytomegalovirus colitis which was treated with intravenous ganciclovir, 5 mg/kg, twice per day for 4 wk. Follow-up colonoscopy showed healing of ulcers, and serology showed negative cytomegalovirus antigenemia. The patient had no history of abdominal trauma or abdominal surgery other than liver transplantation.

At the first clinical examination, the lower abdomen was distended and painful, but bowel sounds were decreased. Hematologic, biochemical and liver function tests showed  $10.2 \times 10^3 / \text{mm}^3$  white blood cells,  $29.5 \times 10^3 / \text{mm}^3$  red blood cells, 9.7 g/dL hemoglobin,  $167 \times 10^3 / \text{mm}^3$  platelet count, 75.3 mg/L C-reactive protein (range  $\leq 5$ ), 32 mg/dL blood urea nitrogen, 0.68 mg/dL serum creatinine, 45 U/L alanine aminotransferase, 15 U/L aspartate aminotransferase, 1.24 mg/dL total bilirubin, and 3.2 g/dL serum albumin. Colonoscopy showed diffuse ulceration, exudate, and hemorrhage in the sigmoid and descending colon, associated with narrowing of the lumen (Figure 1). Histopathologic evaluation of biopsy specimens from the colon revealed mucosal and submucosal hemorrhage and edema, with partial necrosis and ulceration of the mucosa. Blood and tissue analysis for cytomegalovirus and *Clostridium difficile* was negative. Stool cultures and samples were also negative for bacteria and parasites. A clinical diagnosis of ischemic colitis was made. Contrast-enhanced computed tomography (CT) showed severe stenosis at the anastomosis of the donor portal vein and the native portal vein (Figure 2A), and a 30 mm  $\times$  18 mm enhancing vascular structure in the left lower abdominal cavity connecting to the inferior mesenteric vein associated with venous stasis in the mesenteric vein (Figure 2B). Diffuse thickening of the wall of the sigmoid colon without mucosal enhancement was also seen. We reviewed a previous CT scan performed before liver transplantation and found a 10 mm  $\times$  8 mm enhancing vascular structure at the same location, indicating that the structure was increased in size over the two years following transplantation (Figure 2C). Angiography of the inferior mesenteric artery showed both the artery and its partner vein emerging from the lesion, along with very early

**Figure 2** Contrast-enhanced CT of the abdomen showing portal vein stenosis (white arrows) (A), an approximately 30 mm  $\times$  18 mm contrast-enhancing vascular mass (black arrows) (B), and an approximately 10 mm  $\times$  8 mm enhancing vascular structure before transplantation (black arrows) (C).

opacification of the markedly dilated inferior mesenteric vein (Figure 3). Based on this, the mass-like vascular lesion was diagnosed as an AVF. Angiography also showed an additional small inferior mesenteric AVF with venous dilatation and decreased perfusion of the sigmoid colon. We felt that portal hypertension secondary to portal vein stenosis developed after liver transplantation, which contributed to enlargement of the inferior mesenteric AVF and venous congestion, and then resulted in decreased perfusion of the sigmoid colon and ischemic colitis. Therefore, we decided to attempt a percutaneous angioplasty for the portal vein stenosis and surgical repair of the inferior mesenteric AVF associated with severe ischemic change in the sigmoid colon.

The patient underwent a percutaneous transhepatic portography for portal vein stenosis. Portogram revealed an almost complete obstruction at the extrahepatic

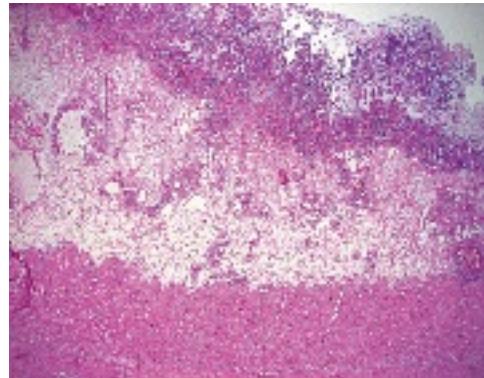

**Figure 3** Angiography of the inferior mesenteric artery showing an AVF (arrow) with early opacification of a dilated vein.

**Figure 4** Transhepatic portal venography showing portal vein stenosis (white arrow) with stasis in the mesenteric vein (A) and good patency of the portal vein following deployment of the metal stent (black arrows) (B).

anastomosis of the portal vein and a marked delay of venous drainage of the mesenteric vein (Figure 4A). A 14 mm × 4 cm self-expandable bare metallic stent was deployed in the stenotic portal vein area, and a 10 mm × 4 cm balloon was dilated for residual stenosis. Portogram performed after stent deployment revealed good patency of the portal vein and no continuous contrast filling in the mesenteric vein (Figure 4B).

Two days after percutaneous angioplasty, the patient underwent a laparotomy for colon ischemia. After the mesocolon was ligated and divided, the sigmoid and descending colon with fistulae were resected. Pathological examination of the resected specimens demonstrated extensive necrosis of mucosa, diffuse inflammatory infiltrations extending into submucosa, and focally hyalinized thick-wall vessels, which were compatible with the symptoms of ischemic colitis (Figure 5). The patient's

**Figure 5** Histopathologic examination of the resected sigmoid showing diffuse ischemic necrosis inflammatory infiltrations (HE  $\times 20$ ).

postoperative course was uneventful, and an abdominal CT scan 6-mo later showed a mildly dilated inferior mesenteric vein without aneurysmal dilatation. The portal vein stent patency was good, with homogeneous enhancement of the liver.

## DISCUSSION

Inferior mesenteric AVF is a rare splanchnic AVF. Only 11 cases have been reported in the literature<sup>[3]</sup>. Our patient had no history of abdominal trauma or abdominal surgery other than liver transplantation. An abdominal CT scan performed before liver transplantation demonstrated a small inferior mesenteric AVF, suggesting that the fistula is congenital in origin and increases in size after transplantation, resulting in the patient's presentation.

The common clinical symptoms and signs of inferior mesenteric AVF include abdominal pain, mass, or bruit, or a combination of these symptoms<sup>[2,3]</sup>. More serious manifestations of mesenteric AVF are associated with portal hypertension, which is present in about 50% of patients with splanchnic AVF<sup>[1]</sup>. Okada *et al*<sup>[3]</sup> reported that 7 of 11 patients with inferior mesenteric AVF had either signs or symptoms of portal hypertension (mainly ascites, esophageal varices, or splenomegaly) or elevated portal venous pressure. Portal hypertension in an inferior mesenteric AVF is called "forward" or "hyperkinetic" portal hypertension and may result from both increased blood flow into the portal system and from compensatory increase in hepatic vascular resistance<sup>[2,3,12]</sup>. Inferior mesenteric AVF may also be a factor predisposing to non-occlusive ischemic colitis<sup>[2]</sup>. An AVF is usually associated with decreased arterial blood flow to the tissue beyond it and increased venous pressure distal to it<sup>[2,12]</sup>.

Portal venous stenosis in patients who have undergone orthotopic liver transplantation may be caused by disparity in the diameters of recipient and donor portal veins (particularly in pediatric transplants). Cryopreserved grafts, excessively long vessel stumps or thrombotic occlusion of the veno-venous bypass, or portosystemic shunt surgery can be used prior

to transplantation<sup>[10,11,13]</sup>. The majority of those patients who are found to have portal vein stenosis are otherwise asymptomatic and detected on routine screening ultrasound<sup>[10]</sup>. Contrast-enhanced CT scan and magnetic resonance imaging can clearly show portal vein stenosis. When patients are symptomatic, they also present with typical signs of portal hypertension, including ascites, esophageal varices, and splenomegaly with or without thrombocytopenia.

The present patient reported no usual symptoms of ischemic colitis, such as hematochezia, melena, or abdominal pain before liver transplantation. However, he suffered from esophageal variceal hemorrhages and ascites, which were thought to be caused by advanced hepatic cirrhosis and portal hypertension. Two years after transplantation, he presented with abdominal pain and hematochezia. Colonoscopy and histopathologic evaluation of biopsy specimens revealed ischemic colitis in the sigmoid and descending colon, and radiologic evaluation showed an inferior mesenteric AVF and portal vein stenosis, suggesting that the portal vein stenosis induced portal hypertension is associated with hepatofugal flow. High arterial flow due to inferior mesenteric AVF and venous stasis in the fistula due to hepatofugal flow, may have contributed to the pseudoaneurysmal dilatation of the inferior mesenteric vein in our patient, leading to augmentation of the preexisting inferior mesenteric AVF and induced the development of ischemic colitis due to steal phenomenon.

Percutaneous transhepatic balloon angioplasty or placement of metal stent has been widely accepted as a safe and effective procedure for portal vein stenosis following liver transplantation<sup>[13]</sup>. Our patient underwent percutaneous transhepatic deployment of a metal stent with balloon angioplasty. The stent patency was good, the stenosis was disappeared after treatment.

The choice of therapy for inferior mesenteric AVF is surgical correction with or without associated bowel resection<sup>[3]</sup>. Some studies reported that percutaneous endovascular embolization of the feeding artery may be useful in selected cases, particularly in critically ill patients<sup>[2,4,7]</sup>. In our case, the combination of clinical state, CT and endoscopic images and the presence of the large AVF all prompted a surgical repair.

Inferior mesenteric AVF is rare, but may be associated with portal hypertension and non-occlusive ischemic colitis. To our knowledge, this is the first report of inferior mesenteric AVF-induced ischemic colitis

complicated by portal vein stenosis developed after liver transplantation.

### Abstract

We present the case of a 57-year-old man who underwent esophagectomy for esophageal carcinoma found at barium meal and gastroscopic examination. He was diagnosed as esophageal basaloid squamous carcinoma (BSC) and gastric stromal tumor, which were associated with focal proliferation of melanocytes/pigmentophages and hair follicles in esophageal mucosa. Melanocytic hyperplasia (melanocytosis) has previously been recognized as an occasional reactive lesion, which can accompany esophageal inflammation and invasive squamous carcinoma. The present case is unusual because of its hyperplasia of not only melanocytes but also hair follicles. To our knowledge, this is the first report of esophageal blue nevus and hair follicle coexisting with BSC.

Coexistence of esophageal blue nevus, hair follicles and basaloid squamous carcinoma: A case report. *World J Gastroenterol* 2008; 14(26): 4253-4256 Available from: URL: <http://www.wjgnet.com/1007-9327/14/4253.asp> DOI: <http://dx.doi.org/10.3748/wjg.14.4253>

### INTRODUCTION

Scattered melanocytes at the epithelio-stromal junction of esophageal mucosa are an incidental finding. This phenomenon was first described in 1963 by De la Pava, who found melanocytes in 4% of his autopsy material from the esophagus<sup>[1]</sup>. Subsequent studies showed that the incidence of esophageal melanocytes ranges 2.5%-8%<sup>[2,3]</sup>.

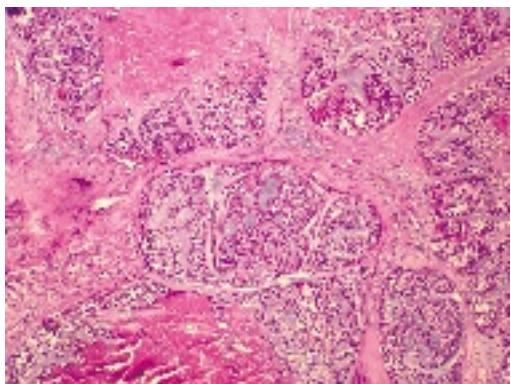

The increased number of esophageal melanocytes along the epithelio-stromal junction is considered benign and has been described in association with chronic esophagitis, squamous epithelial hyperplasia and infiltrating squamous carcinoma of the esophageal mucosa<sup>[2]</sup>.

In the present report, we describe a very unusual proliferation form of melanocytes and hair follicles in esophageal mucosa, which is associated with basaloid squamous carcinoma (BSC) of esophagus and gastric stromal tumor. To our knowledge, esophageal blue nevus coexisting with hair follicles is first described.

### CASE REPORT

#### Clinical history

A 57-year-old man complained of feeling an aggravating obstruction when taking food for 3-mo, which was more severe and affected his normal diet when taking solid food. He had no vomiting, abdominal pain or melena. Physical examination revealed no obvious anemia. The lung and heart sounds were normal, the abdomen was soft and flat with no hepatomegaly or splenomegaly or palpable abdominal mass. Rectal examination found no abnormalities and no enlargement of the superficial lymph nodes. He had an over 30-year history of gastroesophageal reflux disease, and an over 10-year history of chronic gastritis with occasional duodenal ulcer. To cure these diseases, he took soda tablets/powder and other drugs in the past 6-7 years. The patient smoked more than twenty cigarettes and drank 100-150 mL alcohol per day. His family medical history and physical examination were negative. At the lower third esophagus, barium meal examination indicated an esophageal carcinoma, gastroscopic examination showed a 1 cm × 1 cm smooth protrusion and a 0.5 cm × 0.5 cm mucosa erosion on its top, identified by subsequent biopsy as a low-differentiation carcinoma. The

**Figure 1** Arrangement of basaloid cells in the form of anastomosing trabeculae and microcystic structures. The microcystic spaces contained basophilic mucoid matrix, mimicking an adenoid cystic carcinoma. The cells at the edges of basaloid islands tended to show peripheral nuclear palisading. Comedo necrosis was observed in the center of basaloid lobules (HE,  $\times 40$ ).

patient underwent a lower third esophagectomy with gastric tube reconstructed.

### Materials and methods

The surgical specimen including the dissected lymph nodes was fixed in a 4% buffered formalin solution. All the samples taken from the esophagus and stomach were embedded in paraffin for routine histology. All sections were stained with hematoxylin and eosin (HE).

Immunohistochemistry was performed on selected paraffin sections using a standard avidin-biotin complex method with diaminobenzidine as chromogen. Monoclonal antibodies against CD117, CD34, SMA, S100 protein (S-100), were used.

### Pathologic findings

The surgical specimen consisted of the lower-third esophageal tissue and the proximal tissue of the stomach including two tumid lymph nodes around the esophagus and one lymph node from the lesser gastric curvature. Another specimen was resected from the subserosa of gastric anterior wall.

Gross examination revealed that the esophageal mucosa was regular and smooth. A 2.5 cm  $\times$  1.5 cm tumor was found 1 cm away from the lower margin and 4 cm near the upper margin. The tumor was found to be gray-white with weak mucus shine, and easy to be separated from muscularis. No visible pigmentation was found in esophageal mucosa. The specimen from the gastric part including the squamo-columnar junction appeared normal.

Microscopy revealed that the tumor occupied the area from lamina propria to submucosa and crossed the muscularis mucosa in the lower third of esophagus. Histologically, the basaloid cells were arranged mainly in the form of solid, smooth-contoured lobules, or in the form of solid sheets, anastomosing trabeculae, or microcystic structures. Eosinophilic hyaline materials were found in the intertrabecular spaces and stroma of the tumor. The microcystic spaces contained basophilic mucoid matrix. The basaloid cells were round or oval in

shape with scant amphophilic cytoplasm, but sometimes they were abundant and clear. The nuclei showed either dark hyperchromatin or vacuolated nucleoplasm with 1 to 3 small distinct nucleoli. The number of mitoses was 15 under 10 high-power fields. The cells at the edges of basaloid islands tended to show peripheral nuclear palisading. Comedo necrosis was found within the basaloid lobules (Figure 1), mimicking adenoid cystic carcinoma and basaloid carcinoma without association with dysplasia, carcinoma *in situ*, squamous cell carcinoma, or focal squamous cell differentiation. It did not invade the muscularis. No malignant cells were observed in the two resection margins. All lymph nodes were free of malignant cells.

The mucosa of the upper resection margin exhibited a population of melanocytes/pigmentophages. The melanocytes were focally distributed in keratinocytes of the basal esophageal mucosa layer. Heavily pigmented, spindled or dendritic melanocytes/pigmentophages were located predominately in the superficial lamina propria, which were parallel to the covering epithelium and vertical to the long esophagus axis. The spindle and dendritic cells displayed no cytologic atypia and mitoses, in which the small nuclei were covered by the pigment. The pigmented cells occupied about 1 mm, and the thickness was no more than 1 mm. We did not find pigmented cells any more when we recut the specimen embedded in paraffin (Figure 2A). Moreover, there was single or cluster of hair follicles and horn cysts in the mucosa with melanocytes (Figure 2A-E). Similarly, below the esophageal carcinoma, melanocytes were focally distributed in keratinocytes of the basal esophageal mucosa layer, but not in hair follicles or horn cysts (Figure 2F).

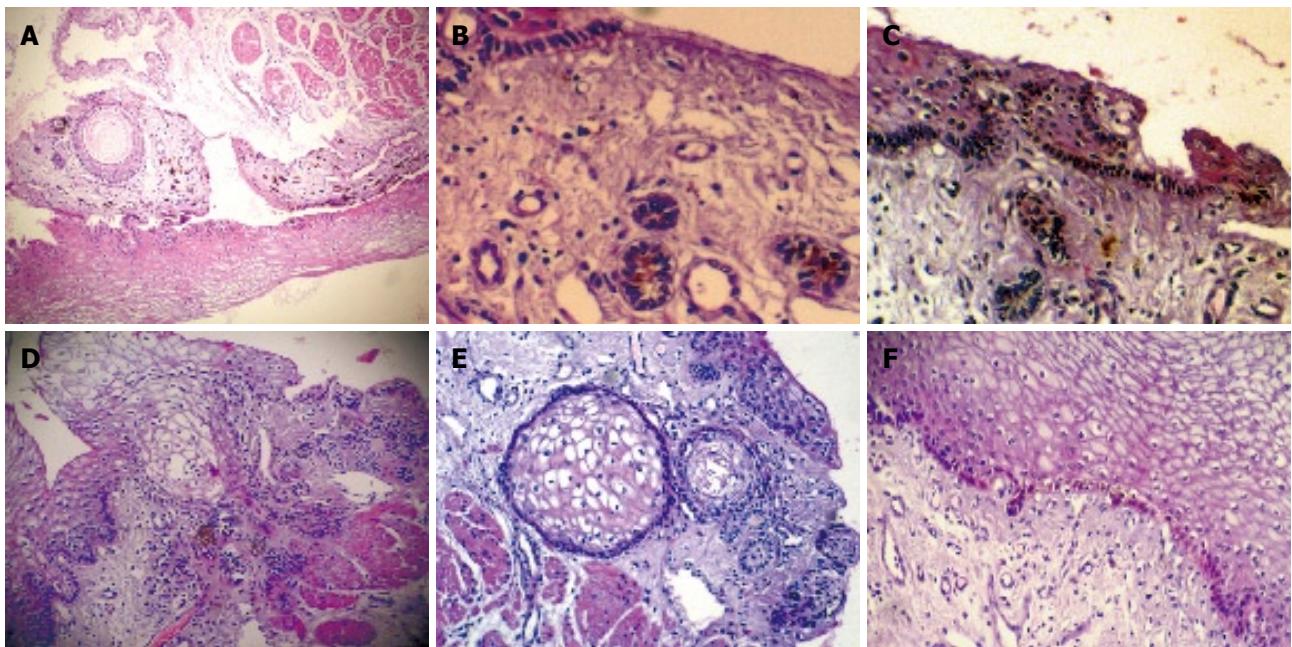

The gastric tumor consisted of basophilic spindle-cells, which were arranged in short fascicles but could be aligned in a strikingly Schwannian pattern with prominent nuclear palisading but no mitotic activity and necrosis (Figure 3A). Immunohistochemistry showed that these cells exhibited a strong immunoreactivity on CD117 (Figure 3B) and CD34 (Figure 3C). No specific reaction to the antibodies SMA (Figure 3D) and S-100 (Figure 3E) was observed.

Based on morphology and marker pattern, a diagnosis of esophageal BSC and low malignant potential gastric stromal tumor was made with blue nevus and hair follicle proliferation.

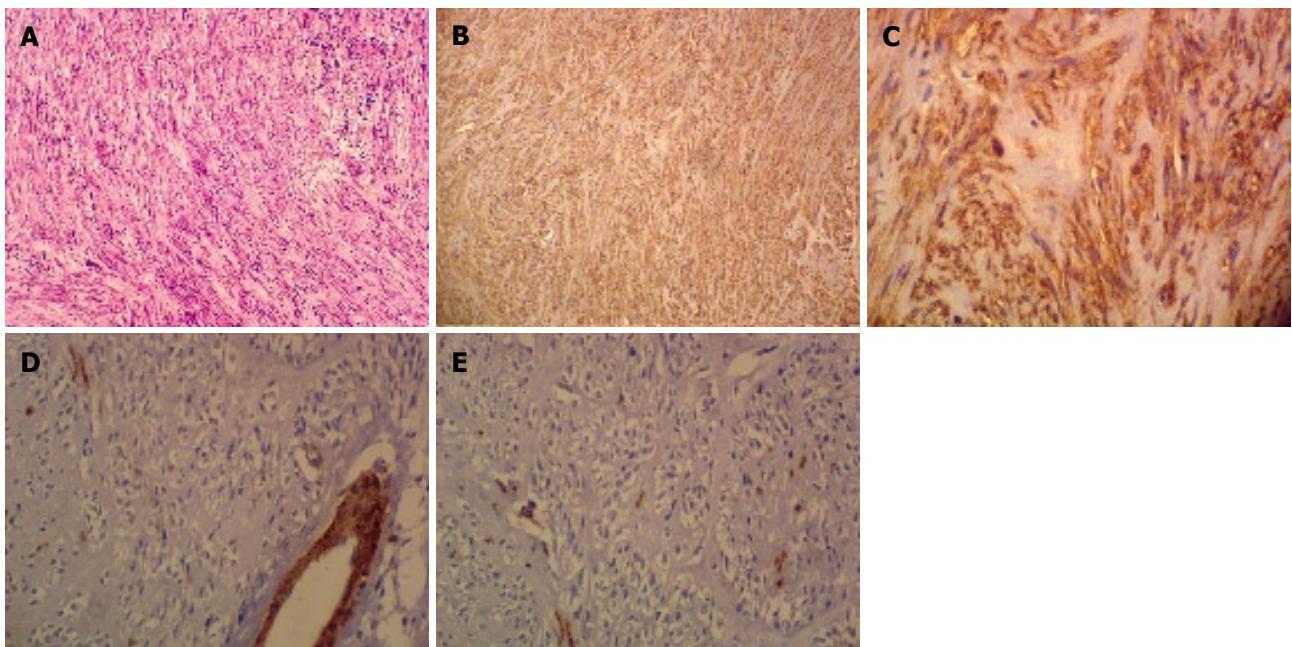

## DISCUSSION

During early embryogenesis, melanocytes migrate from the neural crest to the epidermis, hair follicles, oral cavity, nasopharynx, uvea, leptomeninges and inner ear. In the normal human esophagus, scattered melanocytes may occur at the epithelial-stromal junction. In 1963, Dela Pava first described pre-existing esophageal melanocytes found in 4 out of 100 autopsies and found that they are not related to esophageal disorders<sup>[1]</sup>.

In the normal esophagus, the number of intramucosal melanocytes is low and their presence can

**Figure 2** Focal distribution of melanocytes in keratinocytes of the basal esophageal mucosa layer, heavily pigmented, spindled or dendritic melanocytes/pigmentophages locate predominately in the superficial lamina propria. Moreover, there are several hair follicles and a horn cyst in the mucosa, with melanocytes in the hair follicle (HE,  $\times 40$ ) (A), and distribution of melanocytes in keratinocytes of the basal esophageal mucosa layer and hair follicles in the mucosal lamina propria with melanocytes (B,C) (B: HE,  $\times 200$ ; C: HE,  $\times 40$ ), cluster of hair follicles and horn cysts in the mucosa (D,E) (HE,  $\times 40$ ), and focal distribution of melanocytes in keratinocytes of the basal esophageal mucosa layer below the BSC (HE,  $\times 40$ ) (F).

**Figure 3** Gastric tumor consisting of basophilic spindle-cells arranged in short fascicles and aligned in a strikingly Schwannian pattern with prominent nuclear palisading but no mitotic activity and necrosis (HE,  $\times 40$ ) (A), and immunohistochemistry showing strong immunoreactivity of basophilic spindle-cells on CD117 ( $\times 40$ ) and CD34 (C) ( $\times 400$ ) but no specific reaction to the antibodies SMA (D) ( $\times 200$ ) and S-100 (E) ( $\times 200$ ).

easily be overlooked, but many pathologic conditions can increase the number of melanocytes at the epithelial-stromal junction<sup>[4]</sup>, suggesting that proliferation of melanocytes is based on pre-existing melanocytes in the interface between epithelium and underlying stroma. However, the proliferation of melanocytes might also arise from the scattered stromal neuroectodermal cells or from pluripotent epithelial stem cells<sup>[2]</sup>. The

proliferation of melanocytes is rarely observed with an estimated incidence of about 0.07%-0.15% in patients undergoing endoscopy<sup>[3]</sup>. Results of a recent study<sup>[2]</sup> and our case, however, indicate that melanocytes are much more frequently seen in association with reactive changes in the squamous epithelium, such as chronic esophagitis. Moreover, melanocytes seem to be more frequently found in carcinoma specimens than in

unselected autopsy material, which supports the notion that melanocytes may develop due to the long-standing inflammatory irritation of the mucosa. Our patient had a 30-year history of reflux, soda, smoking and alcohol which might indicate that esophageal BSC and proliferation of melanocytes are a general tissue reaction pattern in response to acid, basic and noxious stimuli. Hair follicles in the esophagus have not been reported up to now and may be due to the tissue reaction to the stimuli too, suggesting that melanocytes and hair follicles might develop from pluripotent epithelial stem cells. Up to now, no report is available on the association between esophageal BSC and hair follicles. Melanocytic nevi are uncommonly seen in esophageal mucosa. To our knowledge, only two cases of blue nevus in the esophagus are reported<sup>[5]</sup>. The blue nevus may be derived from the aboriginal melanocytes or pluripotent epithelial stem cells, and may be transformed into melanoma. What physiological and/or pathologic potential the hair follicles and blue nevus have in the esophageal mucosa needs to be further investigated.

The present case is very unusual because not only melanocytes and hair follicles proliferate in esophagus but also are associated with esophageal BSC and gastric stromal tumor. The epidemiology and etiology remain uncertain, although esophageal melanocytes are mostly located in the middle and lower thirds of the esophagus<sup>[6-9]</sup>. The intrinsic pathogenesis underlying

these pathological changes in the gastrointestinal tract remains largely a mystery.

### TO THE EDITOR

We have previously described a case of huge biliary cystadenoma in a middle aged woman and presented an extensive review of this uncommon entity<sup>[1]</sup>. We report, from the same institution, a case of synchronous, multiple, huge biliary mucinous cystadenomas with unique features.

A 70-year old woman presented in our institution with a 1-year history of low back pain. Abdominal ultrasonography revealed the presence of multiple hepatic cysts (the largest one measuring 16 cm in diameter) and cholelithiasis. Subsequent abdominal computer tomography (CT) scan showed multiple hepatic cysts in the right lobe of the liver and a smaller cyst in the left lobe (Figure 1). The cysts were unilocular, smooth, without septa but with homogeneous content. The cysts were well defined, had no irregular thickness, mural nodules or papillary projections. The radiological findings were consistent with simple liver cysts. Laboratory examination showed an elevation of CA 125 to 94.50 U/mL (reference value: ≤ 35 U/mL) and CA 15.3 to 45.10 U/mL (reference value: ≤ 35 U/mL), while carcinoembryonic antigen (CEA), α-fetoprotein (AFP) and CA19.9 were within the normal values.

The liver function tests and serum bilirubin levels were also within the normal range. The patient underwent a wide laparoscopic fenestration of the cysts and laparoscopic cholecystectomy, under general anaesthesia. Intraoperatively, three cysts were identified (Figure 2). Laparoscopic Lin fenestration<sup>[2]</sup> was performed following the decompression of the cysts with aspiration of their mucinous content. The cysts were unroofed and haemostasis was obtained with UltraCision harmonic scalpel. The frozen section examination was unrevealing. Finally, a typical laparoscopic cholecystectomy was performed. The postoperative period was uneventful. The patient was discharged on the second postoperative day.

Pathologic evaluation of the paraffin-fixed material revealed that the cyst wall was comprised of a single layer of cuboidal-to-columnar epithelium, a moderately

### Abstract

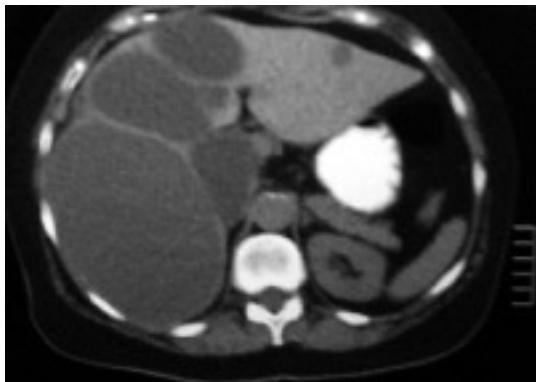

Biliary cystadenomas of the liver are rare, cystic neoplasms of the biliary ductal system usually occur in middle aged women. We report a case of synchronous multiple huge biliary mucinous cystadenomas with unique features. This is, according to our knowledge, the first report in the literature about three synchronously occurring hepatobiliary cystadenomas. Cystadenomas have a strong tendency to recur, particularly following incomplete excision, and a potential of malignant transformation. A therapeutic re-evaluation may be necessary when the diagnosis of hepatobiliary cystadenoma is made after the operation and an open liver resection should be considered.

**Figure 1** CT scan demonstrating multiple unilocular liver cysts. The cysts are well delineated, smooth with uniform content, consistent with simple liver cysts.

**Figure 3** The cysts are lined with cuboidal to columnar non ciliated mucin secreting cells. A moderate cellular stroma and an outer collagenous layer comprise the rest of the cyst wall (HE,  $\times 40$ ).

**Figure 2** Laparoscopic view of the cysts and gallbladder.

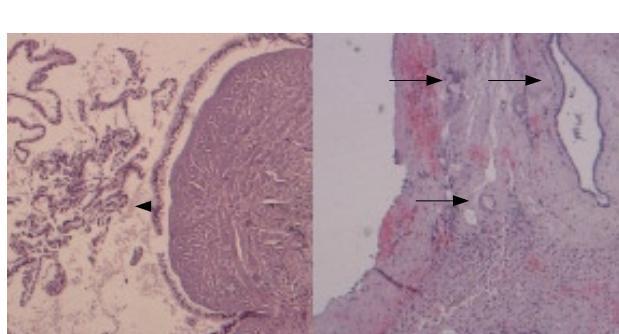

cellular stroma and an outer dense layer of collagenous connective tissue (Figure 3). These findings were consistent with cystadenoma without evidence of malignancy.

The pathologic examination of the specimen from the largest cyst, measuring 17 cm in diameter, showed papillary projections, internal smaller cysts, calcifications and hyaline degeneration of the stroma (Figure 4). These findings were not found in the smaller cysts and might represent the natural course of the cystadenoma. The absence of cellular atypia and intestinal metaplasia indicated the benign nature of this tumour.

The patient was informed about the possibility of malignant degeneration of the lesions and declined a further surgical intervention. No evidence of recurrence was found after a 6-mo follow-up period.

This is, according to our knowledge, the first report in the literature about three synchronously occurring hepatobiliary cystadenomas.

Hepatobiliary cystadenoma is an unusual cystic lesion, occurring more commonly in middle age women in the fifth decade of life and its size varies from 2 to 25 cm<sup>[3,4]</sup>. The exact etiology of biliary cystadenoma is unknown. The tumor is thought to result from the development of ectopic rests of primitive foregut sequestered within the liver or from the obstruction of the congenitally aberrant bile duct<sup>[5]</sup>. Malignant transformation is known to occur from hepatobiliary cystadenoma to cystadenocarcinoma<sup>[3]</sup>.

**Figure 4** The wall of the largest cyst showing papillary projections of the lining epithelium (arrowhead), presence of microscopic cysts with the same epithelial lining (arrows), calcifications and hyaline degeneration of the stroma (HE,  $\times 40$ ).

The diagnosis of liver cyst can be easily made by ultrasonography, CT and magnetic resonance imaging (MRI). Hepatobiliary cystadenoma can be differentiated from simple cysts due to internal echogenic content or other ultrasonographic features<sup>[6]</sup>. However, in our patient, the differentiation of the cystadenomas from simple cysts was not possible by either ultrasound or even CT scan.

Radical excision of the tumor is the first choice of treatment. Operative removal is essentially important considering the high rate of recurrence (90%) if excision is not complete, and the possibility of a malignant transformation. Frozen sections are used to direct the surgical treatment but they can miss the diagnosis of hepatobiliary cystadenoma during a fenestration as was the case in our patient<sup>[7]</sup>. Thomas *et al*<sup>[8]</sup> reported that tumor recurrence occurs in two thirds of the patients, who have only local or pericystic excision. In contrast, only 10% of the patients, who have hepatic lobectomy, hemihepatectomy or radical excision of cystadenoma with a rim of normal tissue with a diameter of 2 cm, require further surgery for recurrence. Therefore, the detection of hepatobiliary cystadenoma after a laparoscopic surgical approach implies many challenging therapeutic dilemmas<sup>[8,9]</sup>.

In conclusion, differential diagnosis of cystic lesions of the liver should always include hepatobiliary cystadenoma. There are no major reports addressing the diagnosis, treatment and follow-up outcome of laparoscopic surgery

for hepatobiliary cystadenoma. A therapeutic evaluation may be necessary when the diagnosis of hepatobiliary cystadenoma is made after the operation and an open liver resection should be considered.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London, The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

*WJG* publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidemiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialties, and thus eventually improving the clinical practice and healthcare for patients.

ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

#### Published by

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

#### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjnet.com>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjnet.com](mailto:submission@wjnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

**Author contributions:** The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

#### Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: <http://www.wjnet.com/wjg/help/11.doc>.

#### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

#### Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

### DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (<http://www.crossref.org/SimpleTextQuery/>) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L;  $\text{CO}_2$  volume fraction, 50 mL/L  $\text{CO}_2$ , not 5%  $\text{CO}_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of

Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *KhoI*, *KpnI*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Telephone: +86-10-59080039

Fax: +86-10-85381893

## Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/9.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/10.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

### Abstract

Interactions between BabA and Lewis b ( $Le^b$ ) related antigens are the best characterized adhesin-receptor interactions in *Helicobacter pylori* (*H pylori*). Several mechanisms for the regulation of BabA expression are predicted, including at both transcriptional and translational levels. The formation of chimeric proteins (*babA/B* or *babB/A* chimeras) seems to play an especially important role in translational regulation. Chimeric BabB/A protein had the potential to bind  $Le^b$ ; however, protein production was subject to phase variation through slipped strand mispairing. The *babA* gene was cloned initially from strain CCUG17875, which contains a silent *babA1* gene and an expressed *babA2* gene. The sequence of these two genes differs only by the presence of a 10 bp deletion in the signal peptide sequence of *babA1* that eliminates its translational initiation codon. However, the *babA1* type deletion was found only in strain CCUG17875. A few studies evaluated BabA status by immunoblot and confirmed that BabA-positive status in Western strains was closely associated with severe clinical outcomes. BabA-positive status also was associated with the presence of other virulence factors (e.g. *cagA*-positive status and *vacA* s1 genotype). A small class of strains produced low levels of the BabA protein and lacked  $Le^b$  binding activity. These were more likely to be associated with increased mucosal inflammation and severe clinical outcomes than BabA-positive strains that exhibited  $Le^b$  binding activity. The underlying mechanism is unclear, and further studies will be necessary to investigate how the complex BabA-receptor network is functionally

coordinated during the interaction of *H pylori* with the gastric mucosa.

### INTRODUCTION

The adherence of *Helicobacter pylori* (*H pylori*) to the gastric mucosa is widely assumed to play an important role in the initial colonization and long-term persistence in the human gastric mucosa. Analysis of the three completed *H pylori* genomes (strains 26695, J99, and HPAG1) has confirmed the presence of five major outer membrane protein (OMPs) families, which comprise approximately 4% of the *H pylori* genome. Among the families, members of the large Hop (*Helicobacter* outer membrane protein) family were the first characterized OMPs in *H pylori*. Several OMPs in the Hop family have been reported to act as adhesion molecules including the blood group antigen binding adhesin (BabA), sialic acid binding adhesin (SabA), adherence-associated lipoprotein (AlpA and AlpB), outer membrane inflammatory protein (OipA), and HopZ. Lewis b antigen ( $Le^b$ ) and related fucosylated ABO blood group antigens are recognized by BabA<sup>[1]</sup>, whereas sialyl-Lewis x and sialyl-Lewis a antigens ( $sLe^x$  and  $sLe^a$ ) are recognized by SabA<sup>[2]</sup>. The corresponding receptors for AlpAB, OipA, and HopZ remain unknown. To date, BabA- $Le^b$  is the best-characterized adhesin-receptor interaction in *H pylori*. In this review, I summarize recent data giving new insight into BabA and its role in pathogenesis.

### IDENTIFICATION OF BABA

It is well known that  $Le^b$  is the dominant antigen in the

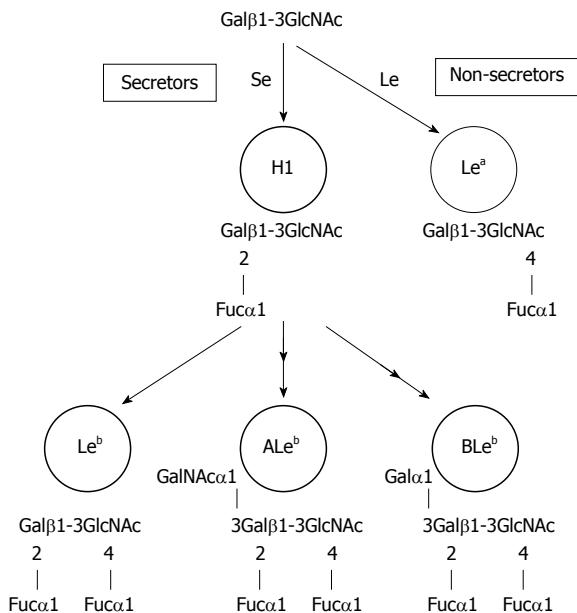

gastric mucosa of secretor-positive individuals<sup>[3]</sup>, and the negative secretor status is associated with a Lewis a ( $\text{Le}^a$ )-dominant phenotype in the gastric mucosa (Figure 1). In 1993, two studies showed that *H pylori* can bind to fucosylated glycoconjugates containing  $\text{Le}^b$  structures on the surface of gastric epithelial cells within human biopsy specimens<sup>[4,5]</sup>. Studies using transgenic mice expressing the human  $\text{Le}^b$  epitope in gastric epithelial cells indicated that  $\text{Le}^b$  functions as a receptor for an *H pylori*-specific adhesin and mediates its attachment to the gastric pit and surface mucous cells<sup>[6]</sup>. Further studies using the same transgenic mice showed that *H pylori* was adherent to the surface of gastric epithelial cells, resulting in severe chronic gastric inflammation and atrophy; whereas *H pylori* was localized in the mucous layer in non-transgenic control mice<sup>[7]</sup>.

In 1998, Ilver *et al* analyzed the blood group antigen-binding activity by measuring binding of *H pylori* to  $^{125}\text{I}$ -labeled fucosylated blood group antigens<sup>[1]</sup>. Among 100 *H pylori* isolates examined, 66% bound the  $\text{Le}^b$  antigen; whereas 95% of the isolates did not bind the related  $\text{Le}^a$ , H-2,  $\text{Le}^x$ , or  $\text{Le}^y$  antigens. The 78 K adhesin recognizing the  $\text{Le}^b$  antigen was detected on the bacterial cell outer membrane and was isolated by a combined ligand identification and purification technique and designated as blood group antigen-binding adhesin (BabA)<sup>[1]</sup>. Additional analyses revealed two sets of clones that encode two proteins with almost identical NH<sub>2</sub>-terminal domains and completely identical COOH-terminal domains, but with divergent central domains. The corresponding genes were designated *babA* and *babB*; BabA but not BabB had  $\text{Le}^b$  antigen-binding activity. Therefore, the central domain in *babA* is believed to determine the specificity of receptor binding<sup>[1, 8-12]</sup>; however, the motifs of the *babA* gene that are involved in binding are still unknown.

## FUNCTION OF BABA

BabA originally was defined as an adhesin binding to the  $\text{Le}^b$  antigen. The H-1 antigen is the carbohydrate structure that defines the blood group O phenotype in the ABO blood group system.  $\text{Le}^b$ , which is difucosylated, is formed by the addition of a branched fucose (Fuc) residue to H-1. The antigens that define blood group A and B phenotypes and corresponding antigens in the Lewis blood group system are formed by terminal N-acetylgalactosamine (GalNAc) or galactose (Gal) substitutions of H-1 and  $\text{Le}^b$  [A-1 and A-Lewis b ( $\text{ALe}^b$ ), and B-1 and B-Lewis b ( $\text{BLLe}^b$ ) antigens, respectively; Figure 1].

Recently, Aspholm-Hurtig *et al* investigated the ability of BabA to bind  $\text{Le}^b$ ,  $\text{ALe}^b$  and  $\text{BLLe}^b$ <sup>[8]</sup>. Among 265  $\text{Le}^b$ -binding *H pylori* strains from various geographic regions, more than 95% of *H pylori* strains are “generalists” (able to bind  $\text{ALe}^b$  and  $\text{BLLe}^b$  in addition to  $\text{Le}^b$ ); whereas a small subset of strains bind exclusively to  $\text{ALe}^b$ , and are called “specialist” strains. The authors proposed that the middle region of BabA was responsible for determining the different binding patterns; however, the

**Figure 1** Biosynthetic pathways of Lewis antigens starting from type 1 lacto series core chains. Starting from type 1 core chains, an  $\alpha 1,2$ -fucosyltransferase (Se) transfers fucose (Fuc) to the terminal galactose (Gal), resulting in the H-1 antigen (H1). H-1 antigen is a target for GalNAc- or Gal-transferases (in blood group A or B individuals) or remains unmodified (in blood group O individuals). These intermediates are modified for the fucosylation step by an  $\alpha 1,3/4$ -fucosyltransferase (Le), resulting in the difucosylated histo-blood group antigens  $\text{ALe}^b$ ,  $\text{ALe}^b$  and  $\text{Le}^b$ . Non-secretors are unable to produce an active Se product, and are only targets for the Le gene product  $\text{Le}^a$ .

specific motifs could not be identified<sup>[8]</sup>. Interestingly, “specialist” strains originated predominantly from South American individuals (where 60% of strains were classified as “specialist”), who are known to express almost entirely the blood group O phenotype. South American isolates in their study were from Peruvian and Venezuelan Amazon Amerindian populations and also from a Colombian mestizo (mixed Amerindian-European ancestry) population; probably most of these strains came mainly from European strains<sup>[13,14]</sup>. These data suggest that most specialist *babA* alleles may have arisen by mutation and/or recombination within the last 500 years. Therefore, the authors propose that such rapid evolution of BabA in response to host mucosal glycosylation patterns would enable the pathogen to adapt to their individual hosts while avoiding host immune responses, and contributes importantly to the extraordinary chronicity of human *H pylori* infection worldwide.

The mucins secreted by gastric mucous cells form a mucous gel layer covering the gastric mucosa. This gel layer is considered the first line of gastric mucosal defense against luminal noxious agents<sup>[15-17]</sup>, and damage to the mucous gel is thought to precede gastric mucosal injury. The gastric surface mucous cells and gland mucous cells express the secretory mucins MUC5AC and MUC6/MUC5B, respectively<sup>[18,19]</sup>. The majority of *H pylori* reside in the gastric mucus overlying the epithelium. It is reported that *H pylori* could be co-localized with MUC5AC gastric mucin, but not with MUC6-producing cells in the glandular areas, suggesting

that adhesion is predominantly toward MUC5AC-specific ligands in gastric mucosa<sup>[20]</sup>. Subsequently, this binding phenotype could be correlated with the expression of an active BabA protein in *H pylori* and the presentation of the Le<sup>b</sup> antigen in the gastric mucin MUC5AC<sup>[21,22]</sup>. However, since BabA-positive strains also attached to Le<sup>b</sup>-negative MUC5AC of non-secretors, the involvement of additional epitopes and/or adhesins also must be involved<sup>[21]</sup>. In addition, binding of *H pylori* to MUC5B had been described<sup>[23]</sup> and a recent study confirmed that the binding was predominantly mediated by BabA and to a lesser degree by SabA adhesin<sup>[24]</sup>.

## LOCATION OF THE *BABA* GENE IN THE *H PYLORI* GENOME

*H pylori* 26695, J99 and HPG1 each possess one *babA* allele (HP1243/JHP0833/HPG1\_0876) and one *babB* allele (HP0896/JHP1164/HPG1\_0320)<sup>[25-27]</sup>. Interestingly, the genomic locations of *babA* and *babB* genes are completely different among three strains (Figure 2). In strain J99, *babA* (JHP0833) is downstream of *hypD* (JHP0835) with a J99-specific gene (JHP0834) intervening, and *babB* (JHP1164) is downstream of *s18* (JHP1165). In strain 26695, the locations of *babA* (HP1243) and *babB* (HP0317) are reversed. The chromosomal locations downstream of *hypD* and *s18* are referred to as locus A and locus B, respectively. In strain 26695, one gene encoding OMPs homologous to *babA* and *babB* (HP0317: denoted *babC*) with unknown function have been identified<sup>[27-29]</sup>. The location is referred to as locus C; interestingly, in strain HPG1, the *babB* gene is located at locus C and *babC* gene at locus B. The *bab* genes initially were cloned from the strain CCUG17875, and this strain has two *babA* genes and one *babB* gene<sup>[1]</sup>. Gene inactivation experiments identified that only one gene (denoted *babA2*) had Le<sup>b</sup> antigen-binding activity; whereas another gene (*babA1*) did not; *babA1* was located at locus B; however the locus of *babA2* was not determined<sup>[1]</sup>.

The location of *babA* and *babB* in various clinical isolates of *H pylori* recently has been reported<sup>[29,30]</sup>. Hennig *et al*<sup>[30]</sup> analyzed a panel of 35 *H pylori* isolates and found that 24 (69%) contained *babA* sequences. In contrast, the *babB* gene was identified in 34 strains (97%). The *babA* gene was located at locus A for 19 strains (54%), at locus B for four strains (11%), and at locus C for three strains (9%). Four strains contain two copies of the *babA* gene, and the *babA* sequences found at two loci were identical in three strains and almost identical in one strain (i.e. three substitutions near the 5' ends of the genes in one strain), indicating that the multiple copies of *babA* presumably resulted from gene conversion (intragenomic nonreciprocal recombination) events. Importantly, two strains possessed the *babA* gene; however, the locus could not be identified, suggesting that there are additional unidentified chromosomal loci for *babA*, although *babA* may be found in one of three chromosomal loci in most cases.

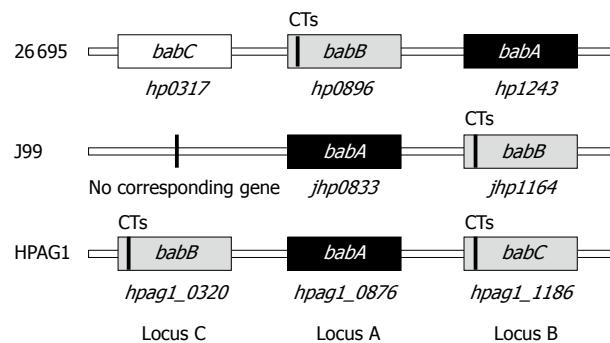

Figure 2 Genomic location of the *babA*, *babB*, and *babC* genes in strains J99, 26695, and HPG1. CT: CT dinucleotide repeats.

Colbeck *et al*<sup>[29]</sup> analyzed a panel of 44 *H pylori* strains and found that 32 (73%) contained *babA* sequences. In contrast, the *babB* gene was identified in 41 (95%) isolates. The *babA* gene was located at locus A for 25 strains (57%) and at locus B for 18 strains (41%); locus C was not evaluated. Interestingly, although chromosomal DNA from low-passage-number, single-colony isolates was used, there was a mixed genotype in 30% (13/44) of the isolates, where the population of cells contained both *babA* and *babB* at the same locus. As a result, 11 strains were found to contain two copies of the *babA* gene including eight with mixed *babA* and *babB* at locus B.

Overall, from two detailed studies I conclude that the *babA* gene prefers to be located at locus A, some strains do not possess the *babA* gene, some strains possess multiple copies of the *babA* gene, and most strains possess the *babB* gene. The presence of *babB* might confer a stronger selective advantage than the presence of *babA*.

## REGULATION OF BABA

### Chimera formation between *babA* and *babB*

Several different mechanisms for regulation of BabA expression are predicted, including at the transcriptional and translational levels. As for translational regulation, the formation of chimeric proteins seems to play an important role. Chimera formation between *babA* and *babB* initially was reported by Pride and Blaser<sup>[11]</sup> who found that in two of 42 (5%) clinical isolates studied, the 5' regions of *babB* were replaced with the first 56 bp of *babA* (*babA/B* chimera). In addition, these authors showed that gene conversions frequently ( $10^{-3}$ ) occur in *H pylori*, and the events are *recA*-dependent and DNase-resistant, indicating that they likely result from intragenomic recombination. *babA/B* chimeras also have been reported experimentally during *H pylori* infection in Rhesus monkeys<sup>[10]</sup>.

In addition to *babA/B* chimeras, *babB/A* chimeras have been observed<sup>[9]</sup>. A *babA2* mutant from strain CCUG17875, defective in Le<sup>b</sup>-binding, regained its activity by homologous recombination of a silent *babA1* gene into the *babB* locus, resulting in a chimeric *babB/A* gene. A silent wild-type *babA1* gene still was present.

The frequency of the *babA* mutant with Le<sup>b</sup>-binding was approximately 10<sup>-5</sup>. Detailed analyses of the chimeric *babB/babA* gene showed that the first 47 bp were *babB*-specific, the following 66 bp were shared between both *babA* and *babB*, and the remaining sequence was *babA*-specific. The second crossover event likely occurred within a region where the sequences of the *babA1* and the *babB* locus were identical. The chimeric BabB/A protein has the potential to bind Le<sup>b</sup>; however, protein production was subject to phase variation through slipped-strand mispairing based on the number of Cysteine-Threonine (CT) dinucleotide repeats in the 5' region of the *babB* gene (switch "on" = functional and switch "off" = non-functional).

Initially, only five genes encoding the OMPs in *H pylori* (*oipA*, *sabA*, *sabB*, *babB* and *hopZ*) were reported to undergo phase variations in the 5' region such that not all strains produce functional proteins<sup>[25,27]</sup>. However, recent studies confirmed that phase variation is a method of regulating BabA production in some strains<sup>[10,29,30]</sup>. CT repeats were observed in 13 of 43 (30%) strains<sup>[29]</sup> and 4 of 22 (18%) strains<sup>[30]</sup>. Importantly, detailed analyses of the *babA* gene with CT repeats showed that the signal peptides are closely related to signal peptides of paralogous BabB proteins, whereas sequences further downstream were typical BabA sequences<sup>[30]</sup>. Taken together, these data suggest that the *babA* gene with the CT repeat might be the result of the translocation of *babA* into *babB* thereby generating a chimeric *babB/babA* gene. Interestingly, the *babC* gene in strain HPAG1 possessed CT repeats in the 5' coding region, whereas the *babC* gene in strain 26695 did not. These data suggest that *babB/C* chimera also might have occurred in some strains.

As described above, Colbeck *et al* found that there were cases with mixed *babA* and *babB* genes, especially at locus B<sup>[29]</sup>. The frequency of *babA* translocated at the *babB* locus was between 10<sup>-3</sup> and 10<sup>-4</sup>, which is in agreement with the frequency in strain CCUG17875<sup>[9]</sup>. Detailed investigation of 10 strains showed that the recombination event was identified from approximately 50 to 200 bp downstream of the ATG in five strains (all recombination occurred at locus B) and upstream of the ATG in the other five strains<sup>[29]</sup>. In the former case, the resulting gene forms the *babB/A* chimera, whereas complete recombination occurred in the latter case.

Overall, frequent translocation between *babA* and *babB* genes appears to be the main mechanism of regulating BabA expression. Therefore, *H pylori* uses both antigenic variation and phase variation to regulate *babA* expression.

#### **Genomic mutations in the coding region of the *babA* gene**

The *babA* gene initially was cloned from strain CCUG17875, which contains a silent *babA1* gene and an expressed *babA2* gene<sup>[1]</sup>. The sequence of these two genes differed only by the presence of a 10 bp deletion in the signal peptide sequence of *babA1* that eliminates its translational initiation codon. However, my group re-

cently found that all 80 strains from a panel of Western and East Asian isolates contained an intact ATG start codon in the *babA* gene<sup>[31]</sup>, and another group also reported the absence of the *babA1* type deletion<sup>[11,12,29,30,32]</sup>. Overall, the absence of a translation initiation codon, as described for *babA1* from CCUG17875, should be rare. Point mutations leading to stop codon, deletion and insertion in other parts of the *babA* gene also are not common; Hennig *et al* found one of 24 *babA*-positive strains (4%) contained a frameshift mutation that prevented expression of a full-length BabA protein (amino acid position at 55)<sup>[30]</sup>.

#### **Transcriptional regulation of BabA**

Transcriptional regulation of BabA also has been reported. Backstrom *et al* found that only *babA2*, but not *babA1* was transcribed in strain CCUG17875<sup>[9]</sup>. Their analyses showed that *babA* transcription seemed to be regulated by the number of adenine [poly(A)] nucleotides within the -10 to -35 region of the *babA* promoter. The -10 and -35 region of the *babA2* sequences are highly homologous to the consensus for *E.coli*  $\sigma^{70}$  promoter sequences. This region was stable when the number of adenines was 10 (*babA2*) but would become non-functional when the number was 14 (*babA1*). The authors hypothesized that the poly(A) sequences between the -10 and the -35 sites could be prone to slippage mutations that allow changes in the level of transcription of downstream genes. However, other studies could not confirm that the -10 to -35 spacing played an important role in regulating *babA* expression<sup>[30,31]</sup>. Further studies will be necessary to fully interrogate the roles of transcriptional regulation of BabA.

Overall, there are several predicted mechanisms that may control BabA expression in some strains; however, there are many cases that remain unexplained. *H pylori* strains that do not produce BabA can be divided into five types, as shown in Table 1.

#### **RELATIONSHIP BETWEEN BABA AND LE<sup>B</sup> BINDING ACTIVITY**

My group recently examined BabA protein and Le<sup>b</sup> binding activity for 80 strains (40 from Japan and 40 from Colombia)<sup>[31]</sup>. BabA protein was measured by immunoblot analyses using anti-BabA antiserum (AK277), and Le<sup>b</sup> binding activity was measured by binding of *H pylori* to <sup>125</sup>I-labeled fucosylated blood group antigens. *H pylori* strains were divided into two major groups: BabA-positive (76 strains) or BabA-negative (four strains). Semi-quantitative analyses of the BabA-positive strains allowed the BabA-positive strains to be classified into two distinct groups: those with high levels of BabA expression (68 strains) or those with low levels of BabA expression (eight strains). All of the 68 strains that exhibited Le<sup>b</sup> binding activity produced high levels of BabA. The low and non-producer strains did not exhibit Le<sup>b</sup> binding activity. Based on this finding, my group classified the strains into three distinct groups

**Table 1** Five major types of *H pylori* strains that do not produce BabA

<i>babA</i> gene	Status
Negative	Include <i>babA/B</i> chimeras
Present	Regulated by slipped strand repairing and the status is "off" (probably equal to <i>babB/A</i> chimeras)
Present	Lack a translation initiation codon (single case of <i>babA1</i> in strain CCUG17875)
Present	Have a frameshift mutation(s) causing non-productive translation
Present	Without apparent mutations and without a hypothesis for the lack of expression

based on their expression levels of BabA: (1) BabA-high producers (BabA-H), which produce BabA protein at high enough levels to mediate Le<sup>b</sup> binding, (2) BabA-low producers (BabA-L), which produce a small amount of BabA but not enough to mediate Le<sup>b</sup> binding, and (3) BabA-negative strains, which do not produce any BabA protein.

## BABA, LE<sup>b</sup> BINDING ACTIVITY AND CLINICAL OUTCOMES

There currently are only a few studies that correlate the importance of BabA with clinical outcomes using immunoblot analyses<sup>[31,33,34]</sup>. My group recently performed large scale studies of 520 geographically diverse patients presenting with different clinical symptoms to evaluate BabA status by immunoblot analysis<sup>[31]</sup>. A total of 250 isolates from Western countries (150 strains from Colombia, 100 from the U.S.) and 270 isolates from East Asia (150 from Korea and 120 from Japan) were studied. All strains from East Asia expressed BabA protein. Twenty-four (9.8%) of Western strains were BabA-negative and were associated with milder gastric injury and lower *H pylori* density than BabA-positive status. BabA-negative status was inversely correlated with *cagA* status or *vacA* s1 genotype (i.e. only one (4.2%) and none (0%) of these BabA-negative strains were *cagA*- or *vacA* s1-positive, respectively). This is in agreement with previous studies that the *cagA* status was related to the presence of Le<sup>b</sup> binding activity<sup>[11]</sup> and the presence of the *babA* gene<sup>[30]</sup>.

Importantly, a small class of strains were BabA-positive but produced low levels of the BabA protein and lacked Le<sup>b</sup> binding activity (BabA-L)<sup>[31]</sup>. Although these strains were functionally BabA-negative and were typically CagA-positive, they were more likely to be associated with duodenal ulcer, gastric cancer, and increased mucosal inflammation and atrophy than BabA-positive strains that exhibited *in vitro* Le<sup>b</sup> binding activity (BabA-H strains) and BabA-negative strains. This finding suggests that either *in vitro* Le<sup>b</sup> binding activity does not accurately reflect the severity of mucosal damage or that the clinical outcome or *in vitro* binding activity does not accurately reflect *in vivo* conditions. The underlying reason why strains with BabA-L status were more highly correlated with severe diseases than strains with BabA-H status is unknown, and it remains unclear whether expressing low levels of BabA have a direct role in the pathogenesis of gastroduodenal diseases. It is possible that BabA expression is influenced by the

intragastric environment and that the phenotype of the BabA-L strains is an epiphenomenon rather than a cause of disease. It is possible that strong Le<sup>b</sup> binding activity is associated with an inappropriate immune response resulting in severely inflamed mucosa. If so, the ability to change the BabA status from a high producer to low producer (i.e. Le<sup>b</sup> binding to Le<sup>b</sup> non-binding) would be advantageous for the organism, and a low producer might reflect an adaptation of *H pylori* that enhances survival in inflamed gastric mucosa. It also is possible that BabA expression down-regulates the proinflammatory effects of other putative virulence factors, such as the *cag* PAI and OipA.

## DETECTION OF FUNCTIONAL BABA GENE

Most previous studies evaluating BabA (*babA*) status have used PCR techniques based on detection of the 10 bp deletion to distinguish between the *babA2* and *babA1* genes (Table 2)<sup>[35-53]</sup>. However, as described above, strains carrying the prototypical silent *babA1* gene are very rare, and in addition, the BabA protein levels often do not match the presence of the *babA* (*babA2*) gene<sup>[31]</sup>. Current terminology for *babA1* and *babA2* in the literature is confusing, and many researchers mistakenly understand that *H pylori* strains that do not produce BabA are either *babA* gene-negative or *babA1*-positive (= *babA* gene lacking a translation initiation codon). However, only one case with *babA1* has been reported, and BabA non-producing strains also usually possess non-functional silent *babA* gene sequences (i.e. 2, 4, and 5 in Table 2). Unfortunately, current PCR methods regard non-functional *babA* status as *babA2*-positive. In addition, a recent study confirmed that the PCR method used to detect *babA2* with only one primer pair previously designed yielded many false-negative results, probably due to sequence variation among strains<sup>[31]</sup>.

Only a few studies have used a forward primer that is within the promoter region of the *babA* gene, a region that is identical to the sequence of *babA2* but different from that of *babA1* in strain CCUG17875<sup>[32,54,55]</sup>; however, recent analyses showed that the primers could also detect *babB* gene<sup>[31]</sup>. Overall, the information gained from currently used PCR-based methods must be interpreted with caution. In addition, I propose that researchers should not use current PCR-based methods in future studies.

Nonetheless, approximately half of the studies have suggested a correlation between *babA2*-positive *H pylori* in Western countries and increased risk of

developing significant clinical outcomes<sup>[38,44-46,52]</sup> and are in agreement with protein data as described above<sup>[31,33,34]</sup>. The prevalence of clinical isolates with a non-functional *babA2* gene without production of BabA protein may be low and negligible in some studies.

## CONCLUSION

Several different mechanisms for regulation of BabA expression are predicted, including at both the transcriptional and translational levels. The formation of chimeric proteins seems to play an especially important role in translational regulation. The chimeric BabB/A protein has the potential to bind Le<sup>b</sup>; however, the production was subject to phase variation through slipped-strand mispairing. Currently used PCR-based methods to evaluate BabA status do not take this mechanism of regulation into account, and information gained from currently used PCR-based methods must be interpreted with caution. I strongly recommend that researchers should not use PCR-based methods in their future studies. Recent studies evaluating BabA status by immunoblot confirmed that BabA-positive status in Western strains was closely associated with severe gastric injury, high *H pylori* density, and severe clinical outcomes. A small class of strains produced low levels of the BabA protein and lacked Le<sup>b</sup> binding activity. Surprisingly, they were more likely to be associated with increased mucosal inflammation, atrophy, and severe clinical outcomes than BabA-positive strains that exhibit Le<sup>b</sup> binding activity.

The underlying reason is unclear, and further studies will be necessary to investigate how the complex BabA-receptor network is functionally coordinated during the interaction of *H pylori* with the gastric mucosa.

### Abstract

The recent advancements in stem cell (SC) biology have led to the concept of regenerative medicine, which is based on the potential of SC for therapies aimed to facilitate the repair of degenerating or injured tissues. Nonetheless, prior to large scale clinical applications, critical aspects need to be further addressed, including the long-term safety, tolerability, and efficacy of SC-based treatments. Most problematic among the risks of SC-based therapies, in addition to the possible rejection or loss of function of the infused cells, is their potential neoplastic transformation. Indeed, SCs may be used to cure devastating diseases, but their specific properties of self-renewal and clonogenicity may render them prone to generate cancers. In this respect, 'Stemness' might be seen as a two-edged sword, its bright side being represented by normal SCs, its dark side by cancer SCs. A better understanding of SC biology will help fulfill the promise of regenerative medicine aimed at curing human pathologies and fighting cancer from its roots.

### A LESSON FROM THE PAST: STEM CELLS AND TUMORS

The recorded history of human cancer begins with an Egyptian papyrus, dating between 3000 and 2000 B.C., which describes breast tumors in humans. The nomenclature 'cancer' was first proposed by Hippocrates. The term derives from the Greek words carcinos and carcinoma, both literally meaning crab. Galen offered a possible explanation for this name based on similitude with either the morphology of cancer or with its tenacious and parasitic behavior. According to legend, Celsus attempted to classify pathologic masses into three categories: secundum naturam, associated with pregnancy; propter naturam, the tumefaction which develops following traumas and leads to tissue repair; and contra natura, synonymous with cancer<sup>[1,2]</sup>. After two millennia, this classification has found renewed perspective based on recent advancements in cell biology, with particular emphasis on the concepts of stemness and SCs.

In multicellular organisms, tissues are organized in a hierarchical manner, with SCs residing at the apex of the developmental pathway. SCs are defined as undifferentiated cells capable of self-renewal and differentiation into diverse mature progenies<sup>[3,4]</sup>. Therefore, SCs play a central role in tissue genesis, regeneration and homeostasis by providing new elements to increase tissue mass during pre- and post-natal growth, and replacing cell loss due to senescence or damage<sup>[5,6]</sup>. SCs are thought to alternate symmetric and asymmetric divisions, hence maintaining the property of self-renewal<sup>[7]</sup>. SCs possess a hierarchy of potentialities: from the totipotency of the zygote and its immediate progeny, to the pluripotency of embryonic SCs (ESCs), and the multi/unipotency of adult SCs (ASCs)<sup>[5,8,9]</sup>. ESCs are pluripotent cells derived from the inner cell mass of the blastocyst. ESCs can generate

any differentiated phenotype of the three primary germ layers by a process called determination<sup>[9,10]</sup>. At the end of embryogenesis, each tissue contains a heterogeneous population of cells at different stages of maturation, including relatively undifferentiated, self-renewing cells, termed adult SCs (ASCs). ASCs have a limited differentiation potential and are responsible for turnover and repair within the tissue of origin. ASCs have been identified in several organs, such as bone marrow (BM), gastrointestinal epithelium, skin, brain, muscle, and liver<sup>[8,11,12]</sup>. SCs colocalize with supporting cells in a physiologically limited and specialized niche, that varies in nature and location depending upon the tissue type<sup>[13,14]</sup>. The reciprocal interactions between SCs and their niche influence SC behavior: a complex network of developing signals regulates the balance between quiescence and the dividing state, leading ASCs toward self-renewal or differentiation<sup>[15,16]</sup>. According to the hierarchical model, long-term SCs (true SCs, extremely rare, with high differentiation potential and proliferative capacity) can give rise to short-term SCs (transit-amplifying or committed progenitors), which in turn are able to differentiate into mature elements providing tissue-specific functions<sup>[5,17]</sup>. Despite the paradigm of unidirectional cell determination, recent studies have shown that ASCs are endowed with an unexpected plasticity, as circulating adult progenitor cells can differentiate into mature cells of other tissue types<sup>[10,14,18]</sup>. A particularly high degree of plasticity is shown by bone marrow SCs (BM-SCs), which *in vivo* and *in vitro* studies have proved to be able to differentiate into a wide range of non-hematopoietic phenotypes<sup>[19-22]</sup>. It has also been demonstrated that BM-SCs normally circulate in the peripheral blood, and that the number of circulating SCs committed toward neuronal and hepatic differentiation increases following treatment with mobilizing agents<sup>[23]</sup>. This phenomenon has led to speculation about the existence of BM-derived pluripotent SCs, which could migrate from the peripheral blood into various tissues and contribute to normal turnover and repair following injury<sup>[5,15,24]</sup>.

## REGENERATIVE MEDICINE BASED ON STEM CELLS

The recent advancements in SC biology have led to the concept of regenerative medicine, which is based on SC potential for therapies aimed to facilitate the repair of degenerating or injured tissues<sup>[6]</sup>. SC-based therapies could be used to cure degenerative disorders associated with the loss of ASC functions, such as hematologic, cardiovascular, muscular and neurological diseases, gastrointestinal pathologies and chronic hepatopathies. SCs can be obtained from various sources, including embryos, fetal tissues, umbilical cord blood and adult organs. Once isolated, these cells may be forced to expand and differentiate into functional progenies suitable for cell replacement and tissue engineering<sup>[24]</sup>. ESCs, which have been isolated from humans and mice, can be maintained in an undifferentiated state indefinitely, though

they seem to develop genetic abnormalities over long periods in culture<sup>[15,25]</sup>. ESCs and their derivatives might constitute an easily available source to obtain a large number of transplantable cells for regenerative treatments. Nevertheless, the possibility of immune rejection and teratoma/teratocarcinoma formation in the recipients represent major obstacles to the success and safety of ESC clinical applications<sup>[26]</sup>. A promising alternative source for SC-based treatments may be represented by cells established from fetal organs and placental tissues, which do not seem to form teratomas/teratocarcinomas in humans. In particular, several studies have indicated that umbilical cord blood SCs (CBSCs) are an easily accessible source of multipotent SCs, which may be readily available for transplantation, or for further expansion and manipulation prior to cellular therapies<sup>[8]</sup>. The plasticity and accessibility of CBSCs has provided the rationale for creation of CBSC unit banks, where these cells can be collected and stored for future use<sup>[24]</sup>. Finally, the manipulation and/or stimulation of ASCs seems to be the most promising tool for SC-based treatments, as it could improve the endogenous regenerative potential without risk of rejection and overcome the ethical and political issues related to embryonic and fetal SCs<sup>[6,8,24]</sup>.

Focusing on ASC-based therapies in Gastroenterology, first attempts to translate regenerative medicine from theory to clinical practice have been made for various diseases, including celiac disease and inflammatory bowel disorders (IBD). In particular, following autologous BM transplantation, in a selected group of refractory celiac patients, significant histological improvement associated with impressive clinical progresses has been recorded<sup>[27,28]</sup>. Crohn's disease (CD) and ulcerative colitis (UC) are characterized by a status of chronic inflammation, mainly as a result of local immunological imbalance<sup>[29]</sup>. Several studies have suggested that either allogeneic or autologous BM-SC transplants may be effective in inducing CD and UC remission<sup>[30]</sup>. Various authors report their experience with IBD patients who underwent BM-SC transplantation for haematological malignancies and maintained a complete remission of their intestinal disease following transplantation<sup>[30]</sup>. The specific pathways and molecular mechanisms underlying the beneficial effects of HSC transplantation in IBD are still largely undefined. The immune system ablation followed by allogeneic transplantation of BM-SCs might provide a reset of the host immune system imbalance. Moreover, BM cells might contribute to tissue repair by facilitating neoangiogenesis and might also differentiate into epithelial cells and myofibroblasts<sup>[30,31]</sup>. The potential of BM-derived SCs in the treatment of IBD is currently being analyzed in clinical trials<sup>[30]</sup>. SCs might be used to cure other gastrointestinal pathologies, such as gastric ulcers, gastrointestinal motility disorders, and diabetes mellitus (DM)<sup>[32,33]</sup>. Regarding the latter, a major challenge in the treatment of DM is to provide patients with an insulin source that regulates glucose levels on a mandatory minute-to-minute basis<sup>[34,35]</sup>. In recent decades, new therapeutic strategies for the treatment of DM type I have been proposed, such as growth factor

administration, islet cell transplantation and also SC infusion to replace the dysfunctional beta-cells<sup>[35]</sup>. Different adult sources of extra-pancreatic SCs have been investigated, including CBSCs, whose efficacy for the treatment of DM has been shown in diabetic mice<sup>[36-39]</sup>. Another candidate for DM regenerative therapy is represented by BM-SCs. Numerous reports have showed that the infusion of BM-SCs can restore chemically-induced DM in mice<sup>[40,41]</sup>. Along with extra-pancreatic SC-based therapies, other researchers have focused their interest on endogenous pancreatic SCs (PSCs). The quest for an organ-bound PSC has received growing attention by the scientific community, because PSCs hold several advantages over extra-pancreatic sources, combining the ability for prolonged proliferation with an already established pancreatic commitment<sup>[35,42]</sup>. Finally, recent reports have demonstrated that extra-pancreatic, organ-bound SCs, such as liver SCs<sup>[43-46]</sup>, human adipose tissue-derived mesenchymal SCs<sup>[47]</sup> and gastrointestinal SCs<sup>[48]</sup> can differentiate into islet cells. Unfortunately, there are still no functional studies that show biphasic insulin release upon glucose challenge by these cells.

In Hepatology, the most appealing application for SC-based therapies consists in the treatment of end-stage hepatic diseases. Chronic liver pathologies affect almost a fifth of the general population, often requiring an orthotopic liver transplantation (OLT)<sup>[49]</sup>. Given the donor organ shortage, various alternatives to OLT have been evaluated, including cell-based therapies which are currently under investigation all over the world. Cell-therapies in hepatology have numerous advantages when compared to OLT: the cells can be expanded *in vitro*, genetically manipulated, cryopreserved, obtained from the same patient and infused without major surgery. Possible cell-based treatments consist of hepatocyte transplantation and the development of bio-artificial liver systems (BALs). BALs have been mainly applied as supportive devices in patients excluded from or waiting for OLT and hepatocyte transplantation has limited overall success, related to the large amount of cells required to achieve acceptable function<sup>[50,51]</sup>. Therefore, SC-based therapies are emerging as new alternatives to OLT for end-stage liver pathologies. The most promising source for SC-based therapies is currently represented by BM-SCs and/or by mobilizing/proliferating agents, such as granulocyte-colony stimulating factor (G-CSF), which is able to both enhance the BM-SC mobilization into the peripheral blood and facilitate the endogenous liver SC activation<sup>[52,53]</sup>. BM-SCs seem to be physiologically involved in the processes of liver repair in humans<sup>[54,55]</sup>. The possible therapeutic potential of these cells has been investigated by intraportal autologous transplantation of BM-SC, which achieved some clinical improvement<sup>[56,57]</sup>. However, some authors reported negative results regarding BM-SC-therapies for end-stage liver disorders<sup>[58]</sup>. Other clinical approaches have been based upon the administration of G-CSF alone or in combination with the reinfusion of the mobilized BM-SCs. The feasibility, safety, and pattern of BM-SC mobilization following G-CSF treatment in patients affected by cir-

rhosis has been evaluated in a few clinical trials<sup>[59-64]</sup>.

Overall, the use of ASCs for the treatment of gastrointestinal and hepatic disorders holds several advantages, such as easy accessibility, unlimited supply (given the possibility to expand the collected cells *in vitro*) and no risks of rejection or need for immunosuppressive therapies when autologous cells are employed. Nonetheless, some conceptual issues still limit the diffusion of such treatments into clinical practice. Firstly, on the basis of preclinical data, BM cells seem to facilitate gastrointestinal and hepatic regeneration mainly by a microenvironment modulation, which is likely to be transitory. In such a case, multiple treatments would presumably be required to achieve significant and lasting clinical results. Moreover, it has been observed that in some models of apparent transdifferentiation, SCs may actually be fusing with cells in the host tissue. Fusion phenomena between BM-SCs and other cells (Purkinje cells, cardiomyocytes and hepatocytes) have been shown both *in vitro* and *in vivo*<sup>[15,24]</sup>. The implications of this discovery are notable: fusion and transdifferentiation are not synonymous, since transdifferentiation requires that a specific SC program be activated on the basis of extracellular signals, whereas in the case of fusion, the plasticity is triggered by endogenous factors upon mixing of the cytoplasm and joining of the nuclei. It must also be noted that the fused cells are aneuploid and potentially unstable<sup>[15]</sup>. Consequently, the possibility of cell fusion and the risk of malignant transformation of the transplanted cells, especially those pre-expanded *in vitro* before reinfusion, cannot be excluded and impose a need for careful evaluation and longer follow-up periods for assessing the safety and efficacy of these SC-based treatments<sup>[24]</sup>.

## STEM CELL ORIGIN OF CANCER AND CANCER STEM CELLS

In the nineteenth century, Virchow and Cohnheim proposed that some tumors, such as teratocarcinomas, exhibiting features of a whole range of different organs and therefore mimicking fetal development, could originate from embryonic rests<sup>[10,65-67]</sup>. Over 150 years later, the hypothesis of a SC origin of cancer lends itself to a modern-day interpretation of this theory: in a given tissue, somatic tumors could originate from the malignant transformation of a SC or its progeny during the determination process, a phenomenon called maturation arrest<sup>[10]</sup>. It is well accepted that carcinogenesis is a multi-step process, involving accumulation of genetic mutations leading to the transformation of normal cells into tumorigenic cells. Every proliferating cell within a tissue may be targeted by carcinogenic stimuli and undergo the process of transformation. Because of the specific characteristics of SCs, mutations within the SC compartment may result in cancer transformation<sup>[15]</sup>. Similarly, tumors might also arise from mutated progenitor cells which have regained the property of self-renewal, thereby dedifferentiating towards a SC phenotype<sup>[68-72]</sup>. Presumably, fewer mutagenic changes are required to transform a SC, in which the machinery to specify and

regulate self-renewal is already active, as compared to more committed progenitor cells, in which self-renewal must be activated ectopically<sup>[70]</sup>. Another potential source of tumorigenic cells may be represented by circulating pluripotent cells, originating from the BM and able to migrate into non-hematopoietic sites. The existence of such a population of SCs, whose properties are reminiscent of ESCs, has been suggested in humans and experimental animal models<sup>[73]</sup>. Once recruited, these cells may behave as normal SCs, and, therefore may accumulate mutations over time and initiate malignancies. Indeed, a recent report described a mouse model of gastric cancer induced by *H Pylori* infection, in which BM-derived cells were able to contribute to cancer development<sup>[74]</sup>. The hypothesis of a SC origin of tumors imposes caution when proposing SC-based therapies to treat human diseases. It is well known that ESCs may give rise to tumors, while cancers derived from ASC-therapies have never been reported. Nonetheless, the long-term safety of ASC infusion has not been adequately tested: preclinical studies and clinical trials with longer follow-up periods should be recommended prior to large-scale clinical applications of such cell-based therapies.

Along with the possible role of SCs in the cellular origin of tumors, mounting evidence suggests that cancer might be considered as a SC disease. Over the past 30 years, several studies have demonstrated that most cancers possess a hierarchic organization: the great majority of cancer cells cannot sustain the tumor mass, nor establish secondary lesions elsewhere in the body. Only a minority of cancer cells appear to be tumor-initiating and possess the metastatic phenotype. These cells have the property of self-renewal, can differentiate into any cell within the tumor population, and can migrate, establishing metastases. Given the similarities between normal SCs and tumor-initiating cells, the latter have been termed cancer SCs (CSCs)<sup>[75]</sup>. Studies on acute myelogenous leukemia (AML) firstly showed that only a small subset of cancer cells was capable of extensive proliferation both *in vitro* and *in vivo*. Two models have been proposed to explain this phenomenon: the stochastic theory and the cancer SC theory<sup>[76]</sup>. In the first model, processes of self-renewal versus differentiation occur randomly, so that every cancer cell has an equal probability of retaining self-renewal capacity. Conversely, the cancer SC theory postulates a hierarchical organization of functionally distinct cell subpopulations, at the apex of which resides a small population of tumor-initiating cells, responsible for cancer growth and progression. Such a hierarchical organization was first documented in hematological malignancies by Dick *et al*, who showed that only AML-initiating cells could induce AML when transplanted into SCID mice<sup>[77,78]</sup>. These results represented both the first direct demonstration of the existence of CSCs, and a proof of principle extendible to solid tumors. Currently, distinct populations of CSCs have been identified within the hematopoietic system<sup>[77,79]</sup>, breast<sup>[80]</sup>, brain<sup>[81]</sup>, prostate<sup>[82,83]</sup>, lung<sup>[84]</sup>, skin, bone, kidney, ovary, head and neck cancers, and also gastrointestinal and liver tumors<sup>[85-90]</sup>.

Tumor-initiating cells mimic SC properties to sustain

the growth and spread of the tumor, while eluding the intrinsic and extrinsic controls that regulate homeostasis within SC populations. The unique properties of CSCs explain the failure of traditional chemotherapeutic strategies aimed at reduction of tumor mass by targeting proliferating cells: CSCs are usually quiescent and thus refractory to these treatments. The cancer SC hypothesis offers new insights for the development of therapeutic strategies in oncology, which will require a deep understanding of CSC molecular profile and biological behaviour<sup>[15,65]</sup>. Potential targets for CSC-based therapies in oncology might be found by comparing SC and CSC properties. i.e. it is well known that CSCs share molecular pathways involved in the maintenance of stemness (such as Wnt, Sonic Hedgehog, and Notch signalling) with SCs and that they are responsive to similar motomorphogens involved in both SC migration and cancer metastasis. The development of drugs antagonizing these signals may be helpful in inhibiting CSC proliferation and mobilization, therefore blocking cancer growth and metastasis<sup>[15,65]</sup>. Moreover, SCs and CSCs are able to secrete cytokines and angiopoietic factors which are critical for sustaining tumors, and that can be specifically targeted by anti-angiogenetic therapies<sup>[24]</sup>. However, an ideal CSC-based therapy would require targeting of CSCs, while sparing normal SCs. Indeed, despite similarities in terms of immunophenotype with their normal counterparts, some cell-surface markers and metabolic pathways must differ in CSCs compared with SCs, implying a biological uniqueness of CSCs. As a consequence, the identification of specific CSC-markers and pathways appears to be fundamental in order to develop novel therapeutic strategies in oncology. The quest for a surface marker which will enable isolation and further characterization of tumor-initiating cells within human cancers has already begun. Several studies have suggested that the CSC fraction within various tumors might be identified by the expression of CD133, a trans-membrane glycoprotein<sup>[91]</sup>. CD133 is expressed by progenitor cells belonging to neuronal, hematopoietic, epithelial and endothelial lineages and its expression has been reported in several tumor tissues, including melanomas, kidney, ovarian, colon and liver cancers<sup>[85-91]</sup>. In our opinion, CD133 might be useful to enrich the CSC fraction within some tumors, but it cannot be considered as a specific cancer SC-antigen. Indeed, CD133 is expressed by various normal SCs and also progenitor cells; moreover, upon a careful examination of the published studies, it seems that only a minority of CD133+ cancer cells is tumor-initiating<sup>[85-91]</sup>.

## STEMNESS AS A TWO-EDGED SWORD

A regenerative medicine based on SCs is no longer a future perspective, since SC research is already supporting an escalating industry, engaged in testing treatments for every sort of disease. Nonetheless, critical aspects need to be further addressed, including the long-term safety, tolerability, and efficacy of SC-based treatments, as well as their carcinogenic potential. Indeed, SCs represent the key to tissue genesis, regeneration and homeosta-

sis. However, for their specific characteristics, SCs may also represent a unique target for tumorigenic stimuli<sup>[16]</sup>. Stemness might be seen as a two-edged sword, its bright side being represented by normal SCs, its dark side by CSCs. This scenario leads to a reinterpretation of the previously mentioned Celsus' tumor classification, where ESCs represent the source of tumors secundum naturam; normal ASCs restore homeostasis following injuries, being responsible for tumors propter naturam; CSCs mimic normal ASCs in respect to self-renewal potential, but elude homeostatic regulation, resulting in tumors contra natura.

The CSC hypothesis imposes caution when proposing SC-based therapies, because infused SCs may degenerate into CSCs and give rise to neoplasms. This possibility should impose further preclinical studies prior to large-scale clinical applications of SC-based therapies. However, the CSC hypothesis also offers new insights for anti-cancer treatments, based upon the similarities and differences between SCs and CSCs. As a consequence, normal SC and CSC research must proceed side-by-side, because the identification of unique CSC targets requires a deep understanding of normal SC molecular profile and properties. The promise of regenerative medicine based on SCs imposes a better knowledge of SC and CSC biology, to help prevent and cure human pathologies and fight cancers from their roots.

## INTRODUCTION

Inflammatory bowel disease (IBD) comprises two forms, Ulcerative Colitis (UC) and Crohn's disease (CD). Currently, the pathogenesis of UC and CD is not completely understood, although the chronic relapsing inflammation is thought to be result from a dysregulated, aberrant immune response to intestinal flora in a context of genetic predisposition. In IBD, this loss of immune tolerance toward the enteric flora it is mediated by different molecules.

Cytokines are key signals in the intestinal immune system, and are known to participate in the disruption of the so-called normal state of controlled inflammation (physiological inflammation of the gut)<sup>[1]</sup>. Cytokines are small peptide proteins produced mainly by immune cells that facilitate communication between cells, stimulate the proliferation of antigen specific effector cells, and mediate the local and systemic inflammation in an autocrine, paracrine, and endocrine pathways<sup>[2]</sup>. In IBD, the innate immune response plays a critical role. Activated dendritic cells (DC) and macrophages secrete several cytokines that actively regulate the inflammatory response in UC and CD. Once secreted by these antigen presenting cells (APC), these cytokines trigger and differentiate many T cells activating the adaptive immune response. IBD has also a T cell dysregulation where clearance of overreactive and autoreactive cells is disturbed, in addition to an imbalance of Treg/Th1, Th2 and newly described Th17 cells populations in the activated state. The lack of appropriate regulation from T cells, or an over-production of effector T cells, participates in the development and exacerbation of IBD<sup>[3]</sup>.

Altogether, APCs, Th1, Th2, T regulatory cells and

## Abstract

Inflammatory bowel disease (IBD), which includes Crohn's disease (CD) and ulcerative colitis (UC), represents a group of chronic disorders characterized by inflammation of the gastrointestinal tract, typically with a relapsing and remitting clinical course. Mucosal macrophages play an important role in the mucosal immune system, and an increase in the number of newly recruited monocytes and activated macrophages has been noted in the inflamed gut of patients with IBD. Activated macrophages are thought to be major contributors to the production of inflammatory cytokines in the gut, and imbalance of cytokines is contributing to the pathogenesis of IBD. The intestinal inflammation in IBD is controlled by a complex interplay of innate and adaptive immune mechanisms. Cytokines play a key role in IBD that determine T cell differentiation of Th1, Th2, T regulatory and newly described Th17 cells. Cytokines levels in time and space orchestrate the development, recurrence and exacerbation of the inflammatory process in IBD. Therefore, several cytokine therapies have been developed and tested for the treatment of IBD patients.

**Key words:** Cytokines; Inflammatory bowel disease; Crohn's disease; Ulcerative colitis; Inflammation

**Peer reviewers:** Atsushi Mizoguchi, Assistant Professor,

**Table 1** Role of cytokines and cell lines involved in their production in patients with IBD

Cytokine	UC	CD	Cells involved in the production
TNF- $\alpha$	Up-regulated	Up-regulated	Macrophages
TL1 $\alpha$	Unknown	Up-regulated	Th1
IL-1 $\beta$	IL-1ra/IL-1 ratio	IL-1ra/IL-1 ratio	Macrophages
IL-6	Up-regulated	Up-regulated	Macrophages, DC, Th17 and others
IL-18	Not	Yes, not in all patients	Macrophages
TGF- $\beta$	Not clear, maybe defective signalling	Not clear, maybe defective signalling	Th0, Th3, Treg
IL-10	Not clear	Yes, up-regulated	Tr1 and Breg
IL-4	Not clear	Not clear	Th2, NK
IL-12	Up-regulated	Up-regulated	Macrophages, DC
IL-23	Yes	Yes	Macrophages, DC
IL-27	Not clear	Up-regulated	APCs
IL-17	Up-regulated	Up-regulated	Th17
IL-13	Up-regulated	Not	Th1, NK
IL-5	Up-regulated	Not	Th2, NK

**Figure 1** Cytokines imbalance between effector and T regulatory cells in IBD.

most recently characterized Th17 and their cytokine products play a complex role in IBD<sup>[4]</sup>. These cellular interactions are modulated by both traditionally studied cytokines (such as TNF- $\alpha$ , INF- $\gamma$ , IL-1, IL-6, IL-4, IL-5, IL10, TGF- $\beta$ ) and others recently characterized (like IL-13, IL-12, IL-18, IL-23), considered to be either pro or anti-inflammatory, as shown in Table 1<sup>[5]</sup>. Although many common responses in IBD are mediated by cytokines, such as the regulation of the production of inflammatory mediators, reactive oxygen metabolites, nitric oxide, leukotriens, platelet-activating factor, and prostaglandins, activation of the nuclear factor  $\kappa$ B (NF- $\kappa$ B) and inhibition of apoptosis, how cytokines determine the nature of the immune response in IBD may be quite different among IBD forms<sup>[6]</sup>. CD is associated with a Th1 T cell mediated response, characterized by enhanced production of IFN- $\gamma$  and TNF- $\alpha$ . IL-12 and IL-23 govern the Th1 differentiation which in combination with IL-15, IL-18 and IL-21 will induce the stabilization of polarized Th1. On the other hand, in UC, the local immune response is less polarized, but it is characterized by CD1 reactive natural killer T cell production of IL-13 and Th2 cytokine production, as shown in Figure 1<sup>[7]</sup>.

## CLASSICAL PRO-INFLAMMATORY CYTOKINES

Lymphocytes and APCs orchestrate a lot of the inflammation in IBD, mainly the production of TNF- $\alpha$ , a 17-kD pleiotropic cytokine produced by innate immune cells as macrophages, monocytes, and also by differentiated T cells. TNF- $\alpha$  exerts its pro-inflammatory effects through increased production of IL-1 $\beta$  and IL-6, expression of adhesion molecules, proliferation of fibroblasts and procoagulant factors, as well as initiation of cytotoxic, apoptotic, acute-phase responses, and inhibition of apoptosis<sup>[8,9]</sup>. TNF- $\alpha$  expression in human macrophages was discovered in the colonic tissue and macrophages in both patients with CD and UC<sup>[10]</sup> and serum levels of TNF- $\alpha$  correlate with clinical and laboratory indices of intestinal disease activity<sup>[11]</sup>. Clinical studies have reported a dramatic improvement in CD patients treated with anti-TNF- $\alpha$  therapy such as infliximab, adalimumab and certolizumab pegol<sup>[12]</sup>. Reductions in the number of IFN- $\gamma$  producing, lamina propria mononuclear cells (LPMC) in colonic biopsies results from anti-TNF- $\alpha$  treated patients<sup>[13]</sup>.

The signalling of TNF- $\alpha$  starts with serum soluble TNF receptor I and II (sTNF-R I, II) levels correlate with disease activity in IBD patients. More specifically, sTNF-RI is up-regulated in the serum of IBD patients compared to healthy controls and could be used as a marker for disease activity<sup>[14]</sup>. sTNF-RII levels are significantly more elevated in serum from active CD patients as compared to UC and could be used as an additional parameter to discriminate both diseases<sup>[12]</sup>. Recently TNF receptor type 1-dependent activation of innate responses was shown to reduce intestinal damage-associated mortality<sup>[15]</sup>.

Related to the TNF- $\alpha$ , the TNF-like factor (TL1A) seems to stimulate IFN- $\gamma$  secretion by binding to the death receptor 3 (DR3). A higher percentage of cells express the TL1A receptor DR3 in mucosal biopsies taken in CD and UC, and increased synthesis of IFN- $\gamma$  has been observed to correlate with severity of disease in IBD patients<sup>[16]</sup>. This molecule links TNF related apoptosis in inflammatory intestinal epithelial lesions,

tumour-necrosis-factor related apoptosis inducing ligand (TRAIL) messenger RNA and protein were markedly up-regulated in IEC and lamina propria lymphocytes in animal model. Interferon-gamma and TNF-alpha potently induced TRAIL in IEC and TRAIL is highly up-regulated in IEC in inflammatory ileum and colon<sup>[19]</sup>.

In addition to TNF- $\alpha$ , IL-1 seems to be important in the pathogenesis of IBD because of its immunological up-regulatory and pro-inflammatory activities. The IL-1 system consists of IL-1 $\alpha$  and IL-1 $\beta$ , both of which are produced by various cell types through the initiation of cyclooxygenase type 2, phospholipase A, and inducible nitric oxide synthase (iNOS)<sup>[17]</sup>. The IL-1 system can be also highly regulated by IL-1 receptor antagonist (IL-1Ra), as supported by the findings of high plasma and tissue levels of IL-1Ra in patients with IBD, indicating that IL-1Ra may be part of the host mechanism for downregulation of inflammation<sup>[18]</sup>. The IL-1Ra/IL-1 ratio decreases with increasing IBD activity, while remaining constant in uninvolving CD and inflammatory control specimens: this may contribute to the pathogenesis of chronic gut inflammation<sup>[19]</sup>. Increased levels of IL-1 in IBD may be result of stimulation of colonic macrophages that can activate interleukin (IL)-1 converting enzyme (ICE) and hence release mature IL-1 $\beta$  into the colonic mucosa<sup>[20]</sup>.

In contrast to other cytokines, IL-6 is a pleiotropic cytokine that exerts its proinflammatory effects largely by means of its soluble IL-6 receptor (sIL-6R). The combination of soluble IL-6 receptor (sIL-6R) and IL-6 stimulates cells that only express gp130 and not IL-6R, a process known as trans-signalling. IL-6 signalling through signal transducer and activator of transcription-3 (STAT3) has been extensively studied<sup>[21]</sup>. This system plays a central role in several immunologic reactions during the development of IBD, and circulating levels of IL-6 and sIL-6R correlate with many clinical features of CD and UC<sup>[22-24]</sup>. Blockade of IL-6 trans-signalling causes T-cell apoptosis, indicating that the IL-6-sIL-6R system mediates the resistance of T cells to apoptosis in CD<sup>[24]</sup>. Yamamoto *et al* (Kallen KJ<sup>[25]</sup>) introduced the anti-IL-6 receptor monoclonal antibody to a murine colitis model and found that the treatment with this antibody reduced IFN- $\gamma$ , TNF- $\alpha$ , and IL-1 $\beta$  mRNA, and suppressed expression of several intracellular adhesion molecules in the colonic vascular endothelium. The anti-IL-6 receptor monoclonal antibody also abrogates murine colitis by effectively blocking the recruitment of leukocytes and increasing T-cell apoptosis<sup>[26]</sup>. Peripheral immune cells as well as colon epithelial and lamina propria cells with an active form of IL-6/STAT3 system may be responsible of the high correlation with the degree of mucosal inflammation<sup>[27]</sup>. The signaling of IL-6/STAT3 in the activation of mucosal T cells has been suggested as a major therapeutic target for the future<sup>[28]</sup>. STAT-3 itself induces the anti-apoptotic factors Bcl-2 and Bcl-xL, thus resulting in T-cell resistance against apoptosis. This circle of T-cell accumulation, mediated by apoptosis resistance, finally leading to chronic

inflammation, can be blocked by anti-IL-6 receptor antibodies<sup>[29]</sup>.

## IL-18

IL-18 is produced by intestinal epithelial cells and was originally identified as an IFN- $\gamma$  inducing factor, shares similarities with the IL-1 family in terms of its structure, processing, receptor, signal transduction pathway, and pro-inflammatory properties<sup>[30]</sup>. Recent studies have shown that the balance between this pleiotropic pro-inflammatory cytokine and its natural inhibitor, IL-18-binding protein (IL-18BP), may contribute to the pathogenesis of IBD<sup>[31]</sup>. A local increase of IL-18 expression has been demonstrated in chronic lesions of CD compared with uninvolving areas or normal controls<sup>[32]</sup>, and an increase in IL-18 was also shown to be accompanied by marked increases in IL-18 receptor-positive immune cells as well as intense transcription of IL-18 induced by cytokines, such as IFN- $\gamma$ , IL-1 $\beta$ , and TNF- $\alpha$ <sup>[33]</sup>. In a recent study has been reported that IL-18 up-regulation may be found only in a minority of patients with CD<sup>[34]</sup>. Furthermore, in the presence of IL-18, T cells from the inflamed CD tissue have been shown to produce less IL-10 than control tissue<sup>[35]</sup>. Although recombinant IL-18 alone induces significant proliferative responses in freshly isolated mucosal lymphocytes from CD patients<sup>[36,37]</sup>, a synergy between IL-12 and IL-18 in activated macrophages may be a regulatory mechanism driving lamina propria lymphocytes toward a Th1 response in IBD<sup>[38]</sup>. It has been reported that cytokine IL-12 may act in synergy with IL-18 to promote the induction of IFN- $\gamma$ , leading to severe gut inflammation in mice<sup>[39]</sup>. The development of Th1 CD4+ T cells in the intestinal mucosa is driven by IL-12, produced from activated macrophages, and IL-18, produced from activated macrophages and colonic epithelial cells. The synergistic effect is mainly caused by mechanisms involving the up-regulation of the IL-18 receptor by IL-12<sup>[40]</sup>.

## ANTI-INFLAMMATORY AND IMMUNOMODULATORY CYTOKINES

### IL-10

IL-10 is an anti-inflammatory cytokine that inhibits both antigen presentation and subsequent release of pro-inflammatory cytokines, thereby attenuating mucosal inflammation. The pivotal role played by IL-10 within the mucosal immune system has been extensively studied in the chronic ileo-colitis that develops in gene-targeted IL-10 knockout mice and by its therapeutic efficacy in several animal models of colitis<sup>[41]</sup>. An inactivation of IL-10 in mice results in an increased production of IL-12 and IFN- $\gamma$ <sup>[42,43]</sup>. Inflamed tissues and granulomas of CD show low IL-10<sup>[44]</sup>. Melgar *et al*<sup>[45]</sup> reported a highly significant increase in IL-10 mRNA levels in T lymphocytes and in IL-10-positive cells in the colons of UC patients. Recently produc-

tion of IL-10 by regulatory T cells has been implicated as important issue in IBD<sup>[46]</sup>. Other regulatory cells that may participate in UC through the production of IL-10 are a regulatory B cells subtype called Bregs<sup>[47]</sup>. The importance of IL-10 production by B cells has been evidenced in IBD models and in humans<sup>[48,49]</sup>, Mizoguchi *et al* showed that Bregs can be responsible for the suppression and/or recovery from acquired immune mediated inflammations by mechanisms that include IL-10 and TGF-β1 in IBD<sup>[47]</sup>.

### **IL-4 and TGF-β**

Overall, anti-inflammatory cytokines whose roles are less well characterized in IBD include IL-4 and TGF-β. IL-4 is a stimulatory molecule for B and T cells, and has known immunosuppressive effects in the intestine<sup>[50]</sup>. T-cell receptor alpha chain-deficient mice (TCR -/-) treated with anti-IL-4 monoclonal antibody showed a decrease in Th2-type mRNA cytokine production and an increase in expression of IFN-γ, suggesting that IL-4 plays a major role in inducing Th2-type CD4+ cells in the gut to shift towards a Th1 response<sup>[51]</sup>. Also another study showed that development of colitis in the TCR -/- mice depends on IL-4 rather than IFN-γ<sup>[52]</sup>. A study reported that the administration of IL-4 led to a significant reduction of the vascular endothelial growth factor (VEGF) production by peripheral blood mononuclear cells in active CD and UC patients<sup>[53]</sup>.

Similarly, TGF-β is an inhibitory cytokine recognized as a key regulator of immunological homeostasis and inflammatory responses. Reduced TGF-β activity is considered to be responsible for the development of autoimmune disorders in several pathologic conditions including IBD<sup>[54]</sup>. Defective transforming growth factor TGF-β1 signaling due to high levels of Smad7 is a feature of IBD<sup>[55]</sup>. UC patients have exhibited increased production of TGF-β1 by LPMC as compared with both CD patients and controls, highlighting that although TGF-β acts on the systemic immune system to promote a potent immunosuppressive effect, locally TGF-β may demonstrate pro-inflammatory properties<sup>[56]</sup>. Evidence suggests that TGF-β can act in concert with epidermal, insulin-like, fibroblast growth factors, as well as VEGF to protect host tissue from luminal challenges and facilitate repair of mucosal injury in IBD<sup>[57,58]</sup>. As future therapy, the inhibition of Smad7 may reestablish TGF-β1 function and the suppression of colitis as proven in experimental models of colitis<sup>[59]</sup>.

### **IL-12 and related cytokines**

IL-12 and IL-23 belong to the IL-12 family of pro-inflammatory heterodimeric cytokines and comprises IL-12p40/IL-12p35 and IL-12p40/IL-23p19 subunits<sup>[60]</sup>. They are mainly produced by activated APCs and accessory cells such as DC and phagocytes<sup>[61]</sup>. The receptors for these cytokines are also heterodimeric IL-12 binds an IL-12Rβ-IL-12Rβ2 heterodimer, whereas IL-23 binds an IL-12Rβ1-IL-23R heterodimer<sup>[60]</sup>. The receptors for both IL-12 and IL-23 are mainly expressed on T cells,

NK cells, and NKT cells. However, low levels of the receptor for IL-23 are also expressed on monocytes, macrophages, and DCs<sup>[61]</sup>. Both cytokines activate TYK2 and JAK2 as well as STAT1, STAT3, STAT4, and STAT5<sup>[60]</sup>. Although IL-12 activates STAT4 most efficiently, IL-23 preferentially activates STAT3<sup>[60]</sup>. Despite the similarities in receptor subunit and signaling, recent studies have shown that IL-12 and IL-23 drive divergent immunological pathways.

The expression of IL-12 is up-regulated in both active UC and CD biopsies and it correlates with activity index score<sup>[62]</sup>. Levels of IL12p40 and IL12Rβ2 are higher in early rather than in late CD suggesting that IL12-mediated modulation is strongly dependent on the stage of disease<sup>[63]</sup>. In particular, to drive adaptive immune responses, DCs (that sense the nature of the micro-organisms in the intestine) are key producers of IL-12 in IBD<sup>[64]</sup>.

In animal models, IL-23 showed to be essential for manifestation of chronic intestinal inflammation, whereas IL-12 is not. A critical target of IL-23 is a unique subset of tissue-homing memory T cells, which are specifically activated by IL-23 to produce the pro-inflammatory mediators IL-17 and IL-6<sup>[65]</sup>.

Recently, another IL-12-related cytokine, IL-27, was described. IL-27 consists of EBI3, an IL-12p40-related protein, and p28, a newly discovered IL-12p35-related polypeptide. Mucosal expression of IL-23p19 and IL-27p28 transcripts correlate with the inflammatory activity in IBD both CD and UC. Particularly, IL-27p28 transcripts and EBI3 transcripts were significantly elevated only in active CD<sup>[66]</sup>.

### **IL-17 and Th17 cells**

Recently, a new T cell subset named “Th17”, characterized by the production of IL-17, was identified as an important player in inflammatory responses<sup>[67]</sup>. Sequencing the human genome resulted in the discovery of an additional five members of the IL-17 family that were consecutively named IL-17B to IL-17F. IL-17A is exclusively produced by Th17 cells<sup>[68]</sup>. The production of IL-17 relies on STAT3 activation triggered by IL-23<sup>[69]</sup>. IL-17 in general induces the recruitment of immune cells to peripheral tissues, a response that requires NF-κB activation after IL-17 receptor engagement<sup>[70,71]</sup>. IL-17 also leads to the induction of many pro-inflammatory factors, including TNF-α, IL-6, and IL-1β, suggesting an important role for IL-17 in localizing and amplifying inflammation<sup>[72-74]</sup>. Furthermore, TNF-α and IL-6, which are both produced by Th17 cells, not only support Th17 cell development but also synergize with IL-17 to enhance the production of pro-inflammatory mediators<sup>[74]</sup>. Regulatory T cells CD4+CD25-Foxp3- could be a source of Th17 cells<sup>[75]</sup>. In human cells, IL-1, IL-6, and IL-23 promote human CD4+ to Th17 differentiation, but TGF-β1 is not needed like in mouse<sup>[76]</sup>. IL-17 as well as Th17 cells have both been found to be elevated in serum and intestinal tissue of IBD patients. IL-17 was not detected in inactive patients tissue as well as other colitis<sup>[77]</sup>.

### **IL-13 and T cell response in UC**

UC is characterized by a Th2 immune response in which IL-13, which is produced by specialized cells such as NK T-cells, was identified as an important effector cytokine<sup>[78]</sup>. In UC, IL-13 may impair epithelial barrier function by affecting epithelial apoptosis, tight junctions, and restitution velocity<sup>[79]</sup>. Both discoveries were made by determining the cytokine profile of LPMC isolated from tissue recovered from colonic resection from UC and CD patients. It was found that LPMC from UC patients secreted high amounts of Th2 cytokines IL-13 and IL-5<sup>[78,79]</sup>. This research group found that the IL-13 and IL-5 LPMC cells bear NK specific markers CD161 and recognize CD1d, indicating that they are NK T-cells<sup>[78]</sup>. These NK T-cells are considered "non-classical". The NK T-cells isolated from UC patients exhibited cytotoxicity towards an epithelial cell line (HT-29)<sup>[78]</sup>. This cell population possibly could be the cells causing epithelial cell cytotoxicity in UC described in the 1980s<sup>[80]</sup>. IL-13 signalling through the IL-13 $\alpha$ 2 receptor (IL-13R $\alpha$ ) in general is involved in induction of TGF- $\beta$ 1 production and fibrosis<sup>[81]</sup>. The signalling through IL-13R $\alpha$  was important in the fibrosis caused by TGF- $\beta$ 1 in an animal model<sup>[82]</sup>. However, the extent to which this leads to the ultimate cascade of inflammation in UC remains to be determined.

### **NOVEL CYTOKINES INVOLVED IN IBD**

Other cytokines like IL-21 and IL-22, which have been implicated in the pathophysiology of inflammatory and autoimmune diseases such as asthma, arthritis and lupus, play also an important role in IBD. IL-21 is a T cell derived cytokine member of the common gamma-chain-dependent cytokine family, which in general acts on intestinal epithelium helping to maintain the ongoing Th1 inflammation by inducing the production of IFN- $\gamma$ <sup>[83,84]</sup>. IL-21 also has been shown to enhance the expansion of NK cells<sup>[85]</sup>. IL-21 is expressed by immune T and B cells and non-immune cells like fibroblasts, where it activates the metalloproteinase 1 production, and signalling through its receptor IL-21R it activates STAT-3 in T cells<sup>[86]</sup>. IL-21, like IL-6 and IL-23 is also involved in Th17 cell differentiation<sup>[87]</sup> and it is over-expressed in both CD and UC, with higher levels being found in CD<sup>[88]</sup>.

IL-22 was originally described as an IL-9-induced gene and was named as IL-10-related T cell-derived inducible factor (IL-TIF)<sup>[89]</sup>. This cytokine shows 22% amino acid identity with IL-10 and belongs to a family of cytokines with limited homology to IL-10. IL-22 binds at the cell surface to a receptor complex composed of two chains belonging to the class II cytokine receptor family (CRF2): IL-22R1 and IL-10R2<sup>[90,91]</sup>. In the intestinal cells, particularly innate immune cells, the binding of IL-22 to its respective R1 chain induces a conformational change that enables IL-10R2 to interact with the newly formed ligand-receptor complexes. This in turn, activates a signal transduction cascade that re-

sults in rapid activation of several transcription factors, including STAT1/3 proteins<sup>[91]</sup>. The principal sources of IL-22 are natural killer and activated T and B cells. Th17 has proven a very important role in this matter<sup>[92]</sup>. IL-22 has proinflammatory functions in IEC and is upregulated in CD both in tissue and in serum<sup>[93,94]</sup>. Surprisingly, in a murine model of UC, Sugimoto *et al* demonstrated a novel protective role for IL-22, in which IL-22 attenuates in the intestine inflammation by inducing mucin membrane bound production by goblet cells<sup>[93,94]</sup>. Another recent paper showed that IL23R genotypes affect IL-22 serum concentrations, linking for the first time genetic CD susceptibility to Th17 cell function<sup>[94]</sup>.

### **POTENTIAL BIOLOGICAL THERAPIES DIRECTED TO CYTOKINES**

Controlling the expression, production and activity of IL-23 as well as IL-17 is an approach that would allow the development of a novel treatment strategy with more anti-inflammatory efficacy and potentially with less suppressive effects on host defenses<sup>[95]</sup>. There are different biologic therapies directed to several cytokines tested in patients with IBD: fontolizumab (anti-interferon  $\gamma$ ) is a humanized monoclonal antibody to interferon gamma. A small phase 2 study of fontolizumab at subcutaneous doses of 10 mg/kg in patients with moderate to severe CD demonstrated efficacy and safety<sup>[96]</sup>. A randomized clinical trial of 79 patients with CD receiving 1 mg or 3 mg of anti-IL-12 monoclonal antibody *versus* placebo demonstrated a response in 75% of CD patients compared with 25% in the placebo group<sup>[97]</sup>. Other antibodies have been generated against to T-cell subsets blockade including CD3+ cells (visilizumab) and CD25+ cells (daclizumab and basiliximab) for UC. Pilot studies have shown promising results in steroid-resistant UC patients<sup>[98]</sup>. IL-6 participates in a variety of critical functions, including T cell growth and differentiation, as well as B-cell proliferation. In a pilot study, where patients with active CD were treated with an antibody directed against the IL-6 receptor (Atlixumab), 80% responded at the full dose compared with 31% in the placebo group<sup>[99]</sup>. IL-11 is produced by cells of mesenchymal origin. A placebo controlled trial of subcutaneous IL-11 in patients with active CD did not demonstrate clear efficacy<sup>[100]</sup>.

### **CONCLUSION**

Cytokines are important in the pathogenesis of IBD and their manipulation has successfully reduced disease severity and maintained remission. Following the discovery of novel cytokines and the role they may play in gut mucosal immunity, as well as the emergence of new concepts and changing paradigms in IBD pathogenesis, the roles of several cytokines have been elucidated and tested in both preclinical animal models and clinical trials of patients with IBD. Complementary to this, proof of

concept for new cytokine targets is rapidly developing, with the possibility of future cytokine-based therapies that may offer greater specificity and decreased toxicity for the treatment of IBD. In addition, further applications of cytokine-based therapies in human clinical trials and preclinical animal studies are ongoing.

## GENERAL CONCEPT TO APPLY ENDOSCOPIC SUBMUCOSAL DISSECTION FOR GASTROINTESTINAL NEOPLASMS

Endoscopic submucosal dissection (ESD) is a new endoluminal therapeutic technique involving the use of cutting devices to permit a larger resection of the tissue over the muscularis propria in three steps: injecting fluid into the submucosa to elevate the lesion from the muscularis propria, precutting the surrounding mucosa of the lesion, and dissecting the connective tissue of the submucosa beneath the lesion. The major advantages of the technique in comparison with polypectomy and endoscopic mucosal resection (EMR) are these: the resected size and shape can be controlled; *en bloc* resection is possible even for a large lesion; and the lesions with ulcerative findings are also resectable<sup>[1,2]</sup>. Retrospective analyses of the comparison between ESD and EMR for the stomach epithelial neoplasms showed that ESD increased *en bloc* and histologically complete resection rates compared with EMR but was associated with longer average operation times and a higher incidence of intraoperative bleeding and perforation<sup>[3,4]</sup>.

Two aspects are considered to determine the application of ESD for each lesion by each operator (Figure 1). The first is a little likelihood of lymph node metastasis and the second is the technical resectability. The former has been determined by the large numbers of surgically resected cases in each organ before establishment of ESD and the latter may be determined by the applied technique, the expertise of the operators, the location of the lesions or their characteristics. In terms of technical resectability, *en bloc* resection is more desirable than piecemeal resection for accurate assessment of the appropriateness of the therapy, because the depth of invasion and lymphovascular infiltration of cancer cells (that are considerable risk factors for nodal metastasis) are not accurately assessed by piecemeal resection. Almost all possible node-negative epithelial neoplasms can be resected *en bloc* by

## Abstract

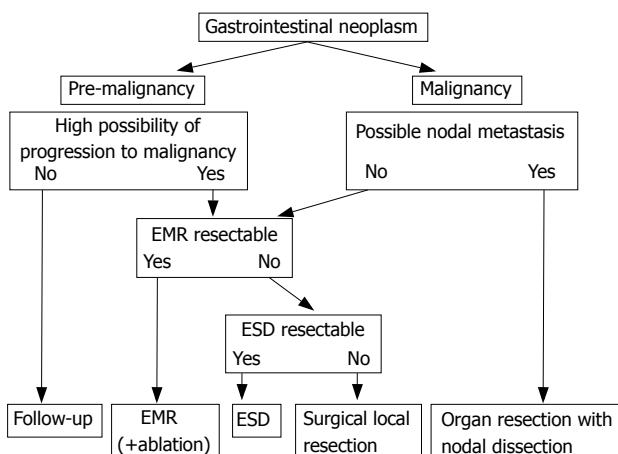

Endoscopic submucosal dissection (ESD) is a new endoluminal therapeutic technique involving the use of cutting devices to permit a larger resection of the tissue over the muscularis propria. The major advantages of the technique in comparison with polypectomy and endoscopic mucosal resection are controllable resection size and shape and *en bloc* resection of a large lesion or a lesion with ulcerative findings. This technique is applied for the endoscopic treatment of epithelial neoplasms in the gastrointestinal tract from the pharynx to the rectum. Furthermore, some carcinoids and submucosal tumors in the gastrointestinal tract are treated by ESD. To determine the indication, two aspects should be considered. The first is a little likelihood of lymph node metastasis and the second is the technical resectability. In this review, practical guidelines of ESD for the gastrointestinal neoplasms are discussed based on the evidence found in the literature.

**Figure 1** Algorism for endoscopic submucosal dissection of gastrointestinal neoplasms.

ESD, when they are treated by very experienced hands. This does not mean that all endoscopic resection should be performed as ESD. Polypectomy or endoscopic mucosal resection (EMR) are beneficial for patients with pedunculated neoplasms or small neoplasms because of the little invasiveness<sup>[5]</sup>. If the lesions are apparently pre-malignant neoplasms, piecemeal resection by using EMR may be permissible with the best balance of risks and benefits. Surgical organ resection with lymphadenectomy should be applied to those neoplasms with high probability of positive lymph nodes or failure in complete removal by ESD. Recurrent lesions can be also indicated for ESD, if they fulfill the criteria of no nodal metastasis, but indication should be carefully determined considering the risks of accompanying complications.
