INTRODUCTION

Irritable bowel syndrome (IBS) is defined according to Rome Ⅲ criteria as recurrent abdominal pain or discomfort for at least 3 d per month during the previous 3 mo associated with two or more of the following symptoms: improvement with defecation, onset associated with a change in the frequency of stools and/or onset associated with a change in form or appearance of stools[1,2]. There are four types of IBS: constipation-predominant IBS, diarrhea-predominant IBS, mixed IBS and unclassified IBS. Within one year, 75% of patients change subtypes. Population-based studies show prevalence of IBS to be 10%-20% and an incidence level of IBS at 1%-2% per year[3].

The precise etiology of IBS is still unknown, but there is evidence in the last decade regarding the contribution of genetic, infectious, psychosocial and dietary factors.

Although to date there has been little support found for the role of different genes in the development of IBS, growing evidence suggests that genetic factors may contribute to the etiology and clinical manifestations of IBS.

The evaluation of genetic influence is based on familial aggregation, twin studies, and genetic epidemiological studies focusing on gene polymorphisms.

FAMILIAL AGGREGATION

Although the family clustering of IBS has been noticed in medical practice for several years, Whorwell undertook

pioneering work regarding familial aggregation of IBS. He found that 33% of patients with IBS reported a family history of IBS compared with only 2% of the control group[4].

A family cluster study of 643 subjects from Olmsted County, USA, showed a significant association between having a first-degree relative with bowel problems and presenting with IBS [odds ratio, 2.3; 95% confidence interval (CI), 1.3-3.9]. Those who reported having a spouse with bowel problems were no more likely to present with IBS. The authors also concluded that familial associations may represent exposure to a similar environment as well as the influence of genetic factors[5].

A recent study that directly surveyed relatives showed a prevalence of IBS of 17% in patients' relatives *vs* 7% in spouses' relatives [odds ratio adjusted for age and sex 2.7 (95% CI, 1.2-6.3)]. When also adjusted for somatization score, the odds ratio was 2.5 (95% CI, 0.9-6.7). The authors concluded that IBS presents a familial aggregation due to genetic or intrafamilial environmental factors, but this may be partially explained by familial aggregation of somatization[6].

Some limitations of these studies were that only abdominal symptoms in first-degree relatives were assessed and that the IBS diagnosis was not confirmed by a specialist.

Some studies have shown that specific types of gastrointestinal illness behavior may be learned through modeling[7], thus biasing the data on genetic transmission.

A Japanese study showed that both patients with IBS and IBS nonconsulters were more likely than controls to present positive family history (33.9% *vs* 12.6%, $P < 0.001$, for patients; 26.1% *vs* 12.6%, $P < 0.01$, for nonconsulters). The parental history was associated with a significantly higher impact on clinical manifestations, including indigestion, diarrhea, constipation, anxiety. The authors concluded that a parental history of bowel problems represents a significant risk factor for development of IBS in Japan, as reported in USA. Patients with a family history present with more psychological distress than other patients[8].

TWINS STUDIES

The contribution of genetic factors to the development of IBS was assessed in several major twin studies.

The Australian study, conducted on 343 twin pairs, by Morris-Yates, in 1998, showed a higher concordance rate for IBS in monozygotic twins than in dizygotic twins (33.3% *vs* 13.3%). This study, revealing that 56.9% (95% CI, 40.6%-75.9%) of the variance is attributed to additive genetic factors, shows a substantial involvement of the genetic component in IBS[9].

The American study conducted by Levy and published in 2001, studied the concordance rate of IBS among 6060 twin pairs. The concordance rate in monozygotic twins was twice as high as that in dizygotic twins (17.2% *vs* 8.4%, $P = 0.03$). However, the number of dizygotic twins with IBS who have mothers with IBS was greater than the number of dizygotic twins with IBS who have co-twins with IBS (15.2% *vs* 6.7%, $P < 0.001$); data also showed that having a mother or a father with IBS are both independent predictors of irritable bowel status ($P < 0.001$) and both are stronger predictors than having a twin with IBS. Data about the other twin accounted for little additional predictive power. The study concluded that heredity contributes to development of IBS, but social learning has also an important influence[10].

In contrast with these studies, a British study published in 2005, which included 1870 twin pairs, showed an IBS prevalence of 17% in monozygotic twins and 16% in dizygotic twins. There was no significant difference regarding the concordance rates between monozygotic and dizygotic twins (28% *vs* 27%). Logistic regression analysis revealed that decreasing age and increasing psychosomatic score were independent factors associated with IBS. Somatization was shown to be moderately heritable. The study concluded that genetic factors are of little or no contribution to the development of IBS[11].

A Norwegian study published in 2006 showed a concordance for IBS significantly greater in monozygotic (22.4%) than in dizygotic (9.1%) twins ($P = 0.011$). The heritability of IBS was found to be 48.4% among females. Birth weight below 1500 g (adjusted odds ratio 2.4 (95% CI, 1.1-5.3)) influenced significantly the development of IBS, which occurred 7.7 years earlier in the low weight group than in higher weight groups[12].

Another recent twin study performed on 986 twin pairs and published in 2007 showed a polychoric correlation for monozygotic twins and IBS (0.47) larger than that for dizygotic twins (0.17). Genetic variance was 22%, but adjusting for anxiety and depression removed the statistical significance for IBS. The study concluded that genetic factors are involved in IBS, possibly mediated by the hereditability of anxiety and depression[13].

GENE POLYMORPHISMS

No single pathophysiologic mechanism explains entirely the clinical manifestations of IBS. Current evidence suggests that altered brain-gut axis is the key mechanism associated with disordered motility, visceral hypersensitivity and autonomic dysfunction[3,14]. Regulation of these connections occurs *via* numerous neurotransmitters such as CCK, VIP, substance P, serotonin (5-hydroxytryptamine, 5-HT). Recent studies have also shown the involvement of the corticotropin-releasing hormone (CRH) in stress-related pathophysiology of IBS and possibly in inflammation of the intestinal mucosa[15].

Genetic factors may influence all these mechanisms, affecting both central and peripheral levels of the brain-gut interrelations[16].

Some authors have shown that substances and genes involved in the brain-gut axis may represent the key factor solving IBS[14].

Gene polymorphisms involve the serotonergic, adrenergic and opioidergic systems, and genes encoding proteins with immunomodulatory and/or neuromodulatory features[17,18].

Serotonin polymorphisms

At the gastrointestinal level, 5-HT acts as a paracrine signalling molecule and as a transmitter released by serotonergic interneurons. Serotonin activates at least five types of receptors, influencing intestinal peristalsis, secretion and signalling in the brain-gut axis. Based on the differences in structure and function, seven types of 5-HT receptors have been described[18]. In patients with IBS, stimulation of 5-HT type 3 receptors may lead to cramps, urgency, diarrhea and colonic contractions. The serotonin removal from the sites of action is mediated by a specific protein, the serotonin reuptake transporter (SERT). Increased 5-HT release in the bowel may induce diarrhea, nausea, and vomiting[19].

A high level of 5-HT may result from exaggerated synthesis, excessive release, or inadequate uptake and inactivation. Modifications in the serotonin transporter, responsible for removing 5-HT from the interstitial space and terminating its action, may also contribute to gastrointestinal motility troubles[19].

Whereas no specific gene has been identified in association with IBS, recent studies have demonstrated the importance of polymorphisms in the promoter region of the serotonin reuptake transporter gene for motility disorders[19].

The *SERT* gene encoding the SERT protein is located on the chromosome 17q11.2-q1. A functional polymorphism, an insertion or deletion of 44 base pairs in the 5-HT-transporter-gene-linked polymorphic region (5-HTTLPR), was first reported in 1996 by Heils[20].

An association between 5-HTTLPR polymorphism and diarrhea in women with IBS has been reported[19]; however, insufficient numbers of constipation-predominant IBS patients represented a limitation of this study. Homozygous or heterozygous patients for the 5-HTTLPR deletion (the short allele) have decreased transcription of *SLC6A4*, reduced expression of the sodium-dependent serotonin transporter and, therefore, reduced reuptake of serotonin. Homozygous patients for the 5-HTTLPR insertion polymorphism (the long allele) present wth significantly slower colonic transit than heterozygous patients, whereas no difference regarding the colonic transit time is found between homozygous or heterozygous patients for the 5-HTTLPR deletion polymorphism[17,19].

The 5-HTTLPR polymorphism was also studied in various behavioral traits and psychiatric disorders; a recent study has shown that IBS patients homozygous for the short allele of 5-HTTLPR or carrying a STin2.9VNTR allele (polymorphism located in intron 2 of *SERT* gene) are significantly more likely to present a history of depression[20].

Another study has revealed that 5-HTTLPR long allele may be one pathway that activates negative emotion in females and has a contrary action in males[21].

A recent Chinese study has investigated the relationship between polymorphisms of the serotonin reuptake transporter and the IBS subtypes, and its influence on the efficacy of tegaserod treatment. This study suggests that individuals with the long allele genotype are vulnerable to develop IBS with constipation and respond poorly to tegaserod treatment[22]. Another study has shown that alosetron, a 5-HT type 3 receptor antagonist, relieves IBS-related pain and normalizes bowel function in women with diarrhea-predominant IBS. This study also suggests that this drug is more effective in homozygous patients than in heterozygous patients for 5-HTTLPR insertion. However, the small number of patients enrolled in this study does not permit a firm conclusion[23,24].

Interaction of serotonergic and adrenergic receptors

Adrenergic agents act upon the sensory and motor function of the human gastrointestinal tract, *via* α_2 adrenergic receptors (adrenoceptors). Three human α_2 adrenoceptors have been identified: the α_{2A}, α_{2B} and α_{2C} subtypes.

There is evidence that polymorphisms in the genes encoding these receptors may decrease the synaptic autoinhibitory feedback and increase presynaptic release of norepinephrine. Norepinephrine transporter modulates the synaptic level of norepinephrine. There is evidence of an interaction between serotonin and norepinephrine in the modulation of gastrointestinal function[25]. Associations have been observed between polymorphisms in *SLC6A4* or genes that encode α_{2A} and α_{2C} adrenoceptors and IBS phenotypes. A polymorphism in *ADRA2C*, the gene encoding the α_{2C} adrenoceptor, is associated with an increased likelihood of constipation in patients with gastrointestinal functional disorders ($P = 0.05$), and also with an increased likelihood of severe and frequent somatic symptoms. Polymorphisms in the genes encoding the α_{2A} adrenoceptor and the α_{2C} adrenoceptor are significantly associated with a high somatic symptom score[26].

In patients with functional dyspepsia, modified alpha-adrenoreceptor function and depression are common; features that are linked to a G-protein beta 3 (GNB3) subunit gene polymorphism (C825T), as shown in a study published in 2004. G-protein beta 3 subunit 825 *CC* genotype was significantly associated with unexplained (functional) dyspepsia; the odds ratio adjusted for age and sex for upper abdominal symptoms was 2.2 (95% CI, 1.4-3.3)[27].

Cholecystokinin

Cholecystokinin (CCK) is released by endocrine I cells within the duodenal and jejunal mucosa in response to the products of protein and fat digestion.

Patients with IBS have high fasting and postprandial plasma levels of CCK. The effects of CCK are mediated *via* CCK-A receptor and CCK-B receptor (also known as CCK1-R and CCK2-R) located in the peripheral and central nervous system. Therapeutical blockade of CCK-A receptors may stimulate gut motility and may

reduce colonic transit time in patients with constipation-predominant IBS[28].

A polymorphism in *CCKAR* gene (779T>C) in IBS patients with constipation is associated with slower gastric emptying. This suggests that, compared with the 779T variant, the 779C substitution results in an increased response to endogenous CCK, retarding the gastric emptying. Future confirmatory studies are needed, due to the small sample size in this study[29].

Cytokines

Although the definition of IBS states that no active inflammation causes symptoms, transient mucosal inflammation is considered to be an important factor for the manifestation of IBS.

Cytokines are involved in the regulation of the immune and inflammatory reaction with proinflammatory effects, such as tumor necrosis factor (TNF) and interferon, and with anti-inflammatory effects, such as interleukin 10 (IL-10) and transforming growth factor (TGF) β1.

A genetic predisposition to produce high or low amounts of a particular cytokine may modify the susceptibility to a certain disease, or affect its clinical manifestation. Some studies have shown no significant association between TGF β genotypes and IBS patients.

By contrast, a low prevalence of the high-producer genotype of IL-10 in patients with IBS has been noticed, suggesting the association between the predisposition to produce low amounts of this cytokine and IBS, or a possible protective role of high levels of IL-10. A genetic predisposition to produce low levels of anti-inflammatory cytokines may signify a compromised control of the inflammatory response[17,30].

Another study has shown that high-producer TNF-α genotype is more prevalent in IBS patients than in healthy subjects. Homozygous high-producer genotypes were rare in both groups; the heterozygous genotype was found in 41% of IBS patients *vs* only 26% of healthy controls. By contrast, no significant difference regarding the IL-10 genotypes prevalence was found in IBS patients and control group. The authors concluded that high producer TNF-α and low producer IL-10 genotypes were significantly more prevalent in IBS patients than control group (9% *vs* 3%, $P = 0.035$) and in diarrhea (20%) compared to other IBS subtypes (< 4%, $P = 0.026$)[30]. Another study showed a significantly low prevalence of the high-producer IL-10 genotype in IBS patients compared with controls (21% *vs* 32%)[31]. This difference might be related to variation in genotype frequencies according to ethnicity: the high-producer IL-10 genotype is significantly higher in the Irish population (34%) than in Africans (9.5%). A limitation of the study consisted of the assessment of only one anti-inflammatory cytokine polymorphism[17].

Post-infectious IBS

A recent study evaluated the involvement of genetic factors in post-infectious IBS; the authors capitalized on the opportunity to study these correlations after the contamination of the municipal water in a small rural town in Canada. They identified four candidates associated with post-infectious IBS: two located in Toll-like receptor 9 (the coding SNP rs352139 and the promoter SNP rs5743836), one involving the promoter SNP of E-cadherin (rs16260) and the other involving a promoter SNP of IL-6 (rs1800795). The authors concluded that after corrections for multiple comparisons, none of these associations is significant and stressed the importance of the further population studies for validations of the gene candidates in post-infectious IBS[32].

Psychological distress

Association between psychological distress and IBS may be due to common genetic factors, but this remains debatable.

The association between major depressive disorder and IBS (with a 13%-45% co-occurrence) may involve genetic and environmental common pathophysiological mechanisms[33]. A recent study has shown the lack of specificity regarding this association; chronic widespread pain related to fibromyalgia and chronic fatigue are also associated with IBS. The authors concluded that genetic and family environmental factors do not explain the association between IBS and major depressive disorder[33,34].

Another recent study has investigated the genetic compo-nent in the co-occurrence of IBS with psychological factors; the authors have shown that independent risk factors for IBS are: female gender, somatization, neuroticism, phobia; no environmental factors are significantly involved. Depression and neuroticism do not co-occur with IBS through common genetic factors, whereas somatization associated with IBS share common genetic components[35]. The authors concluded that identifying the genes involved in somatization may represent a key in understanding IBS etiology[35].

CONCLUSION

IBS is a multifactorial functional disorder, resulting from a complex interaction of genes, environment and psychosocial factors. Recent studies have shown that genes may play an important role in IBS. Thus, the environmental factors can trigger the clinical manifestations of IBS when acting on a certain genetic background.

Genetic factors may be directly linked to gastro-intestinal sensory and motor functions or cause initiation of the modifications underlying the symptoms in the presence of exogenous factors.

Further studies are necessary to develop the facts known so far about the genetic determination of the clinical features and therapeutical response in IBS.

Abstract

Economic analysis of chronic diseases is required for proper allocation of resources and understanding cost-effectiveness studies of new therapies. Studies on health care cost of ulcerative colitis (UC) and Crohn's disease (CD) are reviewed here. These studies were carried out in various countries with disparate health care systems. In the United States, data were often modeled or retrieved from large insurance schemes. Surgery and in-patient hospitalization accounted for over half the outlay on UC and CD. Fistulous disease in CD and parenteral nutrition were very costly. In Canada, overall charges were lower than in the United States, but there too, surgical costs were relatively high. In European studies, economic data were abstracted directly from patients' files. One pan-European study examined the outlay on UC and CD in a community-based prospective inception cohort followed for 10 years. Overall costs in Europe were lower than in the United States. Surgery, hospitalization, year of follow-up, disease phenotype in CD and ASCA-positivity impacted significantly on costs. In all studies, the cost data were right skewed, aminosalicylates were expensive drugs, and biological agents the most expensive; moreover indirect costs were not calculated. Infliximab raised costs considerably in CD, but there were no long-term follow-up studies, so that the cost-benefit of biological agents remains unknown. In conclusion, costs of managing UC and CD vary by country, surgery, genotype and several other factors. The most important question for further research is whether the biological therapies are cost-effective in the long-term.

INTRODUCTION

The science of medical economics, as a branch of welfare economics, is concerned with providing quality health care to patients while streamlining costs. In the current age of escalating health care charges and growing constraints on national health budgets, formal economic analysis of chronic diseases is essential for the proper allocation of resources and the design of cost-effectiveness studies of novel therapeutic agents and diagnostic modalities that are invariably more expensive than existing methods. The fundamental requirements of good economic studies are given in Table 1. Inflammatory bowel disease (IBD) comprises ulcerative colitis (UC), Crohn's disease (CD), and indeterminate colitis (IC). These are idiopathic chronic inflammatory conditions that affect the intestines in particular, with a high rate of extraintestinal manifestations[1]. CD and UC present predominantly in young adults, whose concerns relate to their higher education, careers and establishing their families. These persons then find themselves having to cope with illnesses that have life-time morbidity. Life-long medical treatment is required, and often surgery. CD has been shown to have an increased mortality even in its early course[2], but this was not found for UC[3]. Patients spend variable time periods in transition states, which depend on the severity of disease, type of

pharmacotherapy given, need for surgery, and apparently also geographical origin[4,5]. Additionally, there is the risk of intestinal and extraintestinal malignancies, and extraintestinal manifestations in the joints and other systems. There is evidence for a rising incidence of these maladies in many countries, including in Asia and Africa, where cases were scarce until recently[6]. For all the foregoing reasons, the direct health care costs of UC and CD are expected to place a considerable and increasing burden on national health care resources. In addition, there is the large burden of indirect health costs engendered by decreased work productivity and disability[7,8]. This is quite difficult to estimate and no suitable method exists.

There have been a number of studies published on the health care costs of UC and CD and these are reviewed in this article. IC will not be discussed in detail because it is rarer and has been seldom the subject of economic analysis. A MEDLINE search was conducted using the terms ulcerative colitis, Crohn's disease, indeterminate colitis, inflammatory bowel disease, infliximab (and other biological agents), health care cost, economics, charges, cost-benefit, cost-utility, cost-effectiveness, and Markov model, to find pertinent original research articles published after 1990, excluding letters, commentaries and reviews. The studies selected for inclusion will be reviewed by country. Of note, there have been few actual investigations (as opposed to speculative models) attending to the issue of the cost-utility of modern biological agents that are becoming so widely used in CD, and now more recently, in UC. Furthermore, there are new expensive technologies for the investigation of patients with CD and UC. These matters have considerable economic importance.

Table 1 Requirements of good cost-of-disease studies

Requirements
Economic analysis is carried out from the societal perspective
The cohort is community-based
The study provides knowledge of
Total direct cost of a disease
Inclusion of diagnostic costs and treatments until diagnosis
Inpatient and outpatient costs
Resources that drive costs
The analysis
Accounts for the skew of cost data
Provides for time-based discounted downstream costs
The result
Is applicable to patient cohorts from other countries
Provides a basis for cost–utility analysis

COST STUDIES

United States

In the 1990s, the initial cost studies in IBD were carried out in the United States. Hay *et al*[9,10] produced the first reports. They described an economic evaluation of UC and CD using a medical decision algorithm costing methodology, based on examination of 1988-1989 claims data from a major United States commercial medical insurer. They calculated a mean annual direct cost per patient with CD as $6561 (1990 US dollars), and for UC $1488. Surgery accounted for the majority of these sums. The distribution of annual medical expenses was right-skewed. The top 2% of CD patients accounted for 28.9% of total charges and 34.3% of the total amount paid; for UC, the corresponding estimates were 36.2% and 39.0%. Surgery and inpatient costs accounted for some 56% of costs; outpatient care 3.0%-7.1%; initial diagnostic workup 1.5%-7.8%, and medications 10%.

Feagan *et al*[11] used a commercial claims database serving employees of about 50 large companies in the US, to determine the payer costs of CD. Charge claims from 607 patients were analyzed and the results expressed in 1995 US values. The mean annual cost of medical care per patient was determined to be $12417 (95% CI, $10226-$14607). In a sub-set of 117 hospitalized CD patients, the mean annual cost per patient was $37135 (95% CI, $28227-$46043). Pharmacy charges amounted to about 4% of this outlay. The cost data were again right-skewed, with 25% of patients accounting for 80% of total costs. Thus, in 607 CD patients, the median annual cost was $3668 (95% CI, $1417-$12107), and in the sub-set of hospitalized patients the median annual cost per patient was $21671 (95% CI, $11738-$35535). The major determinants of cost, in descending order of magnitude, were inpatient hospitalization, outpatient services, physician office visits and prescription medications. Twenty-seven of the CD patients had a fistula, and these individuals encountered 2.5-fold higher mean total medical care costs, $31370 per patient per year, of which amount, inpatient services contributed 71%.

Silverstein *et al*[4] performed a Markov model analysis of the costs of health care; the utilization/time profile in this study was based largely on assumed conditions. They examined direct health care costs in a population-based inception CD cohort (174 patients, time period 1970-1993), who were residing in Olmsted County, southeastern Minnesota. Clinical information was abstracted retrospectively and sometimes from original medical records, and data on direct medical charges (the payer's perspective) were obtained from a county database. Medical expenses of matched non-CD subjects were subtracted from the health care expenses of the CD patients to derive charges that were then attributed solely to their CD illness. Results were given in 1995 US prices. The estimated life-time direct cost of health care in the CD cohort (with a 5% annual discount rate applied) was $125404. Taking the projected follow-up period of the disease to be 42.6 years (mean age at diagnosis 32.1 years plus assumed 42.6 years of life after diagnosis in a representative patient), the mean cost of health care can be calculated to be $2944 per patient per year of disease. In appreciation of the skew of health care cost data, calculations using median values can be performed instead. The predicted median life-time cost of health care was $39906. Again, using the authors' assumed median follow-up period of 46.4 years (28.1 median age at diagnosis plus 46.4 projected life years),

the median cost can be calculated at $860 per patient per year of disease. Alternately, using the figure of 10 years median follow-up time of the cohort, as stated by the authors, the cost of disease becomes $3991 per patient per follow-up year (or roughly $12 504 mean cost per patient per disease year). Surgery and aminosalicylate therapy accounted for 44% and 30% of the total cost, respectively. The mean cost of surgery was $9109 per patient per month, compared with medical costs up to $1000 per patient per month for cases in remission or with mild disease, or up to $1500 per patient per month for those on steroids and immunosuppression. Charges for physician services constituted the largest component of services for non-surgical patients. CD patients in remission after medical or surgical treatment had health care expenses that were substantially higher than those of the matched controls.

Cohen *et al*[12] looked at the cost of hospitalization in CD patients hospitalized in Chicago. There were 147 patients with 175 hospitalizations, mostly surgical, in a 1-year period ending in June 1997. Duration of hospitalization was: overall, 8.7 d; medical, 7.5 d; and surgical, 9.6 d. The mean overall hospitalization charges, excluding physicians' fees, totaled $12 528, with medical and surgical admissions being $10 020 and $14 409, respectively. The mean charges including physicians' fees amounted to: overall, $35 378; medical, $20 744; and surgical, $46 354. High-cost items were surgery and total parenteral nutrition.

Canada

Bernstein *et al*[13] investigated the direct hospital costs from the payer perspective for a cohort of 187 CD and 115 UC patients at a tertiary care hospital in Manitoba, in 1994-1995. Charts were reviewed to validate that the admissions were for CD or UC only. There were 275 hospital admissions entered in the analysis. Resources used were documented and priced (Canadian $, 1994-1995) according to the hospital billing database. Cases were classified as medical or surgical admissions. Data are shown here for the costs that were related to CD or UC and not non-digestive disease admissions. The mean cost of hospital admission per medical case was C$2571 (95% CI, C$1801-C$3340) for CD and C$2186 (95% CI, C$1449-C$2922) for UC. The mean cost per hospitalized surgical case was higher, with C$3427 (95% CI, C$2728-C$4126) for CD and C$4635 (95% CI, C$3549-C$5726) for UC. Using the median values per hospitalized patient, the medical cost was C$1664 for CD and C$1262 for UC; the surgical cost was C$2546 for CD and C$3341 for UC. Surgery accounted for 50% of all hospital admissions, 58% of all hospital days, and 61% of all costs. Patients with multiple admissions were more costly than those with only a single admission. Patients receiving total parenteral nutrition demonstrated escalated costs. IC was more costly for surgical hospitalization (mean C$6898) than CD or UC.

Europe

Cost studies were reported from Europe in the present decade. Bassi *et al*[14] reported retrospectively the inpatient and outpatient costs, from the payer perspective (UK National Health service), of patients with CD (160 prevalent cases, 12 incident cases), UC (253, 31) and IC (20, three) at a university hospital in north-west England, over a 6-mo period, ending in December 2000. Charges for hospitalization, surgery, outpatient services, investigations and medications were documented. IC was included with UC in the paper. Values were expressed in 2000-2001 values. Costs are re-calculated here to represent a period of a calendar year. The cost for treating CD was £3416 per patient per year, and for UC, £3021 per patient per year. Fourteen percent of the patients were hospitalized during the study period. Inpatient and surgery costs accounted for over half of the costs for CD and UC. Patients not requiring hospitalization had less than 10% of the costs of patients who were admitted. The outlay on oral 5-aminosalicylates exceeded that of all other medications. Cost data were highly skewed: the 10% most costly patients in CD and UC accounted for 59% and 62% of total costs. Variables driving up the cost of disease care were a diagnosis of CD, hospitalization, and severity of illness, but not age, sex or disease extent.

Ebinger *et al*[15] assessed retrospectively the cost of outpatient care in CD (390 patients) and UC (158 patients) in a German university hospital in Ulm from 1997 to 2000, using the payer perspective and the current hospital fee schedule. The mean annual cost for outpatient care was €3171 in all 548 patients, with drugs accounting for 85% of this outlay. The mean cost for one outpatient visit was €162, of which diagnostic procedures accounted for 82% of charges. Costs were higher in patients with disease duration of less than one year. Variables driving the cost of care were frequent visits to outpatient clinics, complications and corticosteroid therapy. Costs were no different between patients with CD or UC.

Odes *et al*[16] carried out a cost analysis in a community-based inception cohort with 10 years of follow up. There were 425 CD patients and 896 UC patients from eight European countries and Israel (the European Collaborative Study Group of Inflammatory Bowel Disease (EC-IBD) inception cohort, established 1991-1993) followed through to 2004. Extensive measures were taken to assure the highest rate of case ascertainment. All patients met the exacting diagnostic criteria of Lennard-Jones[1]. Data on consumption of resources were obtained retrospectively from electronic patient questionnaires (in nine languages) and electronic physician-per-patient follow-up questionnaires. The mean annual expenditure (2004 monetary values) on total health care (outpatient care, diagnostics, hospitalization, surgery, medication) in IBD was €1871 (SD €4884) per patient per year over the decade of follow up. The mean outlay on total health care for CD (€2548 per patient-year) was appreciably higher than that for UC (€1524 per patient-year). Mean costs varied considerably between countries, being highest in Denmark at €3705 per patient-year and lowest in Norway at €888 per patient-

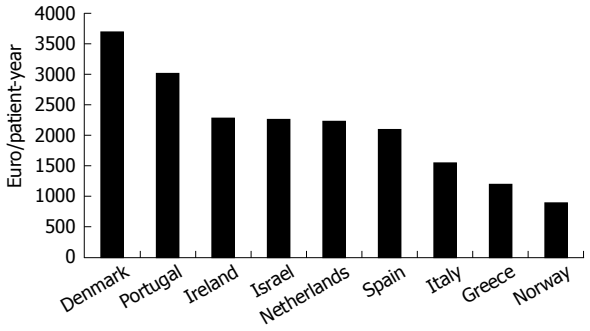

Figure 1 Mean annual cost of health care for IBD patients in the EC-IBD countries with 10-year follow-up. Data provided by EC-IBD.

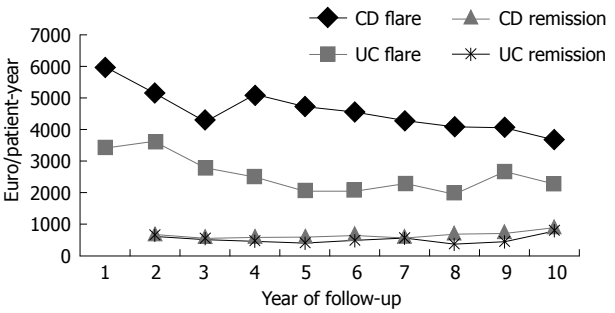

Figure 2 Mean annual expenditure in CD and UC in remission and with flares in the EC-IBD countries during 10 year follow-up. Data provided by EC-IBD.

year (Figure 1). Median costs were lower than mean costs, which confirmed the right skew of the mean cost data. The most expensive resources were hospitalization, which accounted for 63% of the cost in CD and 45% in UC. Total and hospitalization costs were much higher in the first year after diagnosis than in the follow-up period. The significant variables driving the cost of care were country, year of follow-up [year 1: odds ratio (OR) = 3] and diagnosis (CD: OR 1.5); sex and age had no incremental effect on cost. Patients with flares were more expensive than those without during the entire follow-up period (Figure 2). 5-Aminosalicylate was the most expensive drug category; this was the result of a high price and long duration of use. There were too few patients receiving infliximab in this study to greatly affect cost. The extent of disease was found to affect the cost significantly in UC but not CD patients; the cost in CD varied significantly according to the Vienna classification phenotypes. Of importance in this context is the finding that the extent of UC is known to be changeable over time in about half of patients, with extension as well as regression being noted[17].

Juan *et al*[18] reported a cost study on CD in Spain in 2003. It was based on questionnaires to gastroenterologists to obtain disease-related information, and phone interviews to patients to obtain drug utilization data. The annual cost per patient was estimated at between €2104 to €6808 for direct medical costs, and €4704 for indirect costs. Hospitalization and loss of productivity were the items driving these respective costs.

INFLIXIMAB AND COST

Infliximab entered widely into the management of CD over the last decade or so, and since 2006 for UC as well. Recently, other biological therapies have entered the market. Infliximab is an antibody to tumor necrosis factor α which has revolutionized therapy in over 50% of patients who receive this treatment, and who were non-responders to standard medical therapies[19]. There is a developing trend to introduce infliximab earlier into the therapeutic regimen, in the hope that prolonged unresponsive illness, steroid side-effects and surgery may be avoided, and health-related quality of life improved. The use of maintenance therapy with biological agents is gaining acceptance, as it reduces hospitalization and surgery[20]. However, these are expensive agents, and assessment of their impact on short- and long-term health care costs is required. Such studies lead to disease activity scores and outcomes of biological treatments as reported in clinical trials. Not all reports fulfill these criteria. Modeling can only approximate real patient documentation but does provide a useful indicator of costs. To date, there have been few reports published in this area.

Arseneau *et al*[21] were the first to determine the cost-utility of treatment with infliximab in CD with perianal fistulae. Using a Markov model, and with a given cost of a three-course infusion of infliximab of $6420 (2000 prices), the cost of achieving one quality-adjusted life-year exceeded US $350 000. This result was highly dependent on the cost of the medication. Since 2001, the cost of infliximab has decreased somewhat, and several of the disease-course assumptions have changed. A more recent retrospective audit by Jewel *et al*[22], based on 205 patients who received infliximab in seven hospitals in the UK, showed that the mean total health care costs in the 6 mo before the initial infliximab infusion (£2883 per patient) exceeded the mean costs in the 6 mo following the infusion (£2744 per patient), by an average of £139 per patient (a saving of 5%), which suggests that this biological agent is potentially cost-effective. There was a 76% reduction in the number of hospitalization days and 79% of patients reduced or stopped taking corticosteroids. Lindsay *et al*[23] used this study as a basis for determining the cost-effectiveness of scheduled maintenance treatment with infliximab for moderate/severe luminal and fistulizing CD in hypothetical patients in a commercially funded study. Markov models were constructed to simulate the progression of adult CD patients, using transition states estimated from published clinical trials of infliximab, particularly the ACCENT trial. The respective incremental costs per quality-adjusted life year gained were £26 128 and £29 752 in severe luminal and fistulizing CD at a 5-year time horizon. The body weight of patients had the most important impact on the incremental cost-effectiveness ratio, since dosing of infliximab is weight-based. A 10% increase in body weight raises the cost per quality-adjusted life year by some £7000. The reduction in surgery predicted in this

study was similar to that documented by Saro *et al*[24] and the time of follow up was similar. Dose-escalation in patients losing their response to infliximab was very expensive[25].

Jaisson-Hot *et al*[26] carried out a life-time cost-utility analysis with an analytic Markov decision model in non-fistulizing resistant CD patients treated with infliximab (episodic re-infusions for relapse, or scheduled maintenance therapy), compared with conventional surgery and medical treatment. The perspective was that of the third-party payer system. Utility measurement using Standard Gamble was employed to adjust the survival time for each transition state of disease. The incremental cost-utility ratio per quality-adjusted life years saved varied from €63 701 (episodic re-infusions) to over €762 245 (scheduled infusions). The analysis suggested that infliximab could be cost-effective only in the case of treatment for flares of disease.

Saro *et al*[24] reported the impact of infliximab on health care costs in CD patients in northern Spain. There were 34 patients in the study with a mean disease duration of 13.6 years. The mean follow-up time was 9.8 years before and 4.3 years after the first infliximab treatment. About 53% of the patients had penetrating and/or perianal disease, and 41% had extraintestinal manifestations. Following the introduction of infliximab (which was always given as 5 mg/kg body weight) to the treatment regimen, mean hospitalization costs were reduced from €2783 to €679 per patient-year, and the mean surgical cost dropped from €139 to €79 per patient-year. However, the cost of infliximab treatment amounted to a mean €7996 per patient-year. Therefore, the total annual cost of health care increased considerably, from a mean €4464 per patient-year before to a mean €10 594 per patient-year after the introduction of infliximab. This study contradicts that of Jewell *et al*[22]. It must be stressed that all the foregoing studies did not account for the innate fluctuations of disease activity and the so-called placebo-response of the disease, so that future studies need to take these factors into consideration in the interpretation of outcomes and costs after therapeutic interventions.

GENOTYPES AND PHENOTYPES DRIVING COSTS

It would be very useful to identify patients whose genotypes and phenotypes predicted higher health care costs, since aggressive treatment might reduce morbidity as well as cost. Alternatively, genotypes and phenotypes with a better prognosis would be a reassuring finding. It was reported recently that the expenditure on patients with CD was greatly influenced by the disease phenotypes. In a cohort of 418 patients with CD and 10 years of follow-up, the total cost of health care for the Montreal classification[27] behavior phenotypes was €1690 for non-stricturing/non-penetrating, €2081 for stricturing, €3133 for penetrating, and €3356 for penetrating-with-perianal-fistula ($P < 0.001$); all values given as means per phenotype-patient-year[28]. Taking these phenotypes in the same order, the cost of surgical hospitalization was €215, €751, €1293 and €1275 per patient-phenotype-year ($P < 0.001$). Surgical hospitalization costs differed significantly by the location phenotypes: ileum, €558, €209, €492 and €542, expressed as means per patient-phenotype-year ($P < 0.001$). Younger age at diagnosis predicted greater surgical expenses. Estimates of the proportion of CD patients with the various phenotypes of disease vary in different reports[28]. Notably, there is a change in phenotype with length of follow-up, with structuring and penetrating disease becoming more frequent[29]. Unlike behavior, location of disease was shown to be relatively stable over time[29]. Additionally, smoking appears to influence disease location in CD, with current smokers having a lower rate of colonic disease, fewer strictures and fistulae, and a lower rate of surgery[30]. CD patients with stricturing and penetrating disease were more likely to be positive for anti-*Saccharomyces cerevisiae* antibody[31]. CD patients with the NOD2/CARD15 mutation Gly908Arg or positive serology to ASCA had higher health care costs, in particular for surgery, and prolonged hospitalization[32]. However, the mutants Leu1007fsinsC and Arg702Trp had little effect on disease course in that study. ASCA-positive patients were significantly younger at diagnosis than ASCA-negative patients, and Gly908Arg-positive patients showed a trend towards younger age at diagnosis of CD. In another study, NOD2/CARD15 variants in CD patients aged under 16 years were strongly associated with jejunal and ileal involvement, stricturing disease and early recourse to surgery[33]. ASCA is an established serological marker for CD. Moreover, ASCA is frequently detected in CD patients with NOD2/CARD15 allele mutations[34]. NOD2/CARD15 variants constitute a risk factor for ileal site of disease, development of intestinal strictures and fistulae, occurrence of more severe disease, and an increased requirement for surgery[35]. It is possible that measurements of Gly908Arg and ASCA at onset can be used to foretell increased health care costs in CD patients.

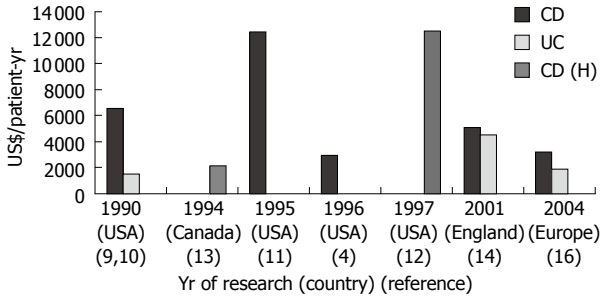

Figure 3 Mean annual total direct cost of health care in selected countries, discounted[36] to year 2004, and expressed as US$ (currency conversions from http://www.oanda.com/convert/fxhistory, accessed 10 May 2008). H: Hospital costs only.

CONCLUSION

CD and UC are serious diseases with considerable health care costs. The studies reviewed above however

displayed considerable disparity of outcomes (Figure 3). These differences clearly cannot be resolved by simply applying a discount rate (currently reckoned to be 2.5%-3.0%[36]) to the costs derived at different time periods. Some of these discrepancies can be attributed to variations of methodology, selection of cohorts, locality, and whether the health care system is private or public. In these studies, the costs were computed from the payer (third party) perspective or from economic data abstracted directly from patients' files, according to the nature of the research. Differences of medical practice would seem to play a role as well. There are also wide differences in the health care price structure within and between countries[9,16]. This could explain some of the differences in health care expenditure between the various European countries that participated in the EC-IBD study. In all the studies, the charges for hospitalization, surgery and biological therapy comprised a large percentage of costs. Despite the trend to do as much care as possible on an outpatient basis, it appears that the rate of hospitalization is increasing[37]. The benefits of keeping patients in remission include a significant drop in the rate of medical as well as surgical hospitalization[38], and therefore a reduction in cost. A new issue in recent years is the welcome development of biological therapies for CD and UC; these drugs have profoundly improved the treatment of these diseases, but with a large price tag. Available economic modeling exercises and the study from Spain imply that infliximab has a relatively high incremental cost per quality-adjusted life year compared with standard care, but this requires further investigation, preferably with real patient data. Comparison of the costs of biological agents with established treatments in trials is complicated by the need to assess the downstream effects of an intervention. In those situations, modeling is a quicker method to obtain cost data, but has its limitations. More data of health cost in CD and UC are certainly required.

Abstract

AIM: To distinguish anastomotic from parenchymal leakage at duct-to-mucosa reconstruction of the pancreatic remnant.

METHODS: We reviewed the charts of 68 pancreaticoduodenectomies performed between 5/2000 and 12/2005 with end-to-side duct-to-mucosa pancreatojejunostomy (PJ). The results of pancreatography, as well as peripancreatic drain volumes, and amylase levels were analyzed.

RESULTS: Of 68 pancreatojejunostomies, 48 had no leak by pancreatography and had low-drain amylase (normal); eight had no pancreatographic leak but had elevated drain amylase (parenchymal leak); and 12 had pancreatographic leak and elevated drain amylase (anastomotic leak). Although drain volumes in the parenchymal leak group were significantly elevated at postoperative day (POD) 4, no difference was found at POD 7. Drain amylase level was not significantly different at POD 4. In contrast, at POD 7, the anastomotic-leak group had significantly elevated drain amylase level compared with normal and parenchymal-leak groups (14158 ± 24083 IU/L *vs* 89 ± 139 IU/L and 1707 ± 1515 IU/L, respectively, $P = 0.012$).

CONCLUSION: For pancreatic remnant reconstruction after pancreaticoduodenectomy, a combination of pancreatogram and peripancreatic drain amylase levels can be used to distinguish between parenchymal and anastomotic leakage at pancreatic remnant reconstruction.

INTRODUCTION

Pancreaticoduodenectomy remains the surgical resection of choice for cancer of the head of the pancreas. Surgical techniques for reconstructing the pancreatic remnant after pancreaticoduodenectomy include end-to-end pancreatojejunostomy (PJ) with invagination, end-to-side PJ with[1,2] or without pancreas invagination[3], pancreatic duct invagination[4], pancreaticocutaneous fistula[5], and external drainage of the pancreatic duct without pancreaticoenteric reconstruction[6]. However, pancreatic leakage remains a significant complication, occurring in 0%-37% of cases[1,7,8]. An unrecognized leak at the PJ anastomosis can result in lethal complications, in particular, intra-abdominal abscess and hemorrhage[9-12].

Pancreatic leaks have traditionally been defined by amylase levels measured in the peripancreatic fluid obtained by placing a drain immediately around the PJ anastomosis[13]. However, pancreatic juice can originate either from the main pancreatic duct or from the cut surface of the pancreatic parenchyma. Thus, an elevated level of amylase in the fluid obtained from the peripancreatic drain suggesting pancreatic leakage does not indicate whether the leak is at the duct-to-mucosa anastomosis (an anastomotic leak) or from the resection parenchyma surface (a parenchymal leak). The existence

of parenchymal leakage was previously shown to be from an accessory small duct in the parenchyma, separate from the duct-to-mucosa anastomosis[14]. However, it is difficult to distinguish between an anastomotic and a parenchymal pancreatic leak at end-to-side duct-to-mucosa PJ reconstruction. The aim of this study was to assess the PJ following pancreaticoduodenectomy to characterize the nature of PJ leaks.

In the cases studied, the pancreatic remnant following pancreaticoduodenectomy was reconstructed with end-to-side duct-to-mucosa PJ, as described previously[15]. The PJ anastomosis was critically evaluated postoperatively with pancreatography *via* an externalized pancreatic stent placed at the time of surgery. We found that duct-to-mucosa anastomotic leakage could be distinguished from parenchymal leakage at the PJ reconstruction after pancreaticoduodenectomy by using the combined radiographic findings on pancreatography and amylase levels in the peripancreatic drain fluid.

MATERIALS AND METHODS

Medical records of patients who underwent abdominal exploration for pancreatic mass between May 2000 and December 2005 were reviewed. The review of patient records was approved by the Institutional Review Board at the Mayo Clinic in Jacksonville, Florida. Classical pancreaticoduodenectomy was performed as previously described[3]. The pancreas was divided left of the portal vein[14]. The pancreatic remnant was reconstructed with end-to-side duct-to-mucosa PJ using 6-0 PDS sutures as previously described[15]. The anterior and posterior parenchyma-to-serosa layers were completed with interrupted 3-0 silks. End-to-side choledochojejunostomy and antecolic gastrojejunostomy were performed.

Across the PJ anastomosis, a stent was placed through the jejunal limb as shown in Figure 1, similar to previous reports[11,16-18]. The exit site of the stent at the jejunal serosa was secured with a Witzel's tunnel using 3-0 silks and a 5-0 Vicryl™ suture. A stent was similarly placed across the biliary reconstruction. This stenting technique was adopted from the same technique used routinely in liver transplantation at our center since 1998. A 6-mm round Blake drain was placed beneath the PJ reconstruction and brought through the left abdominal wall. A nasogastric tube was positioned just above the gastrojejunal anastomosis. The biliary and pancreatic stents were brought through the right abdominal wall.

On postoperative day (POD) 4, a pancreatogram and a cholangiogram were performed by interventional radiologists, who gently injected 1 to 3 mL of water-soluble contrast through the respective externalized pancreatic and biliary stents. The biliary and pancreatic anastomoses were evaluated by fluoroscopy. Serum and drain amylase levels were measured. Drain amylase level was considered significant when it was at least 3 times the upper normal level of serum amylase[13]. After several days of oral food intake, normal pancreatogram results, and low or normal drain amylase level, the drain was removed and the patient was discharged. The patient returned to the outpatient clinic on POD 28, and a repeat pancreatogram and cholangiogram were performed. If there was no evidence of leakage at either anastomosis, the stents were removed.

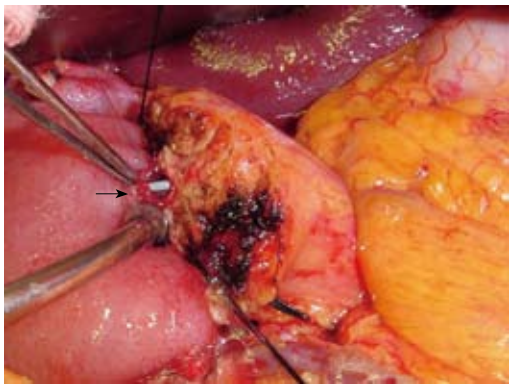

Figure 1 PJ reconstruction of pancreatic remnant after pancreaticoduodenectomy. Posterior layer with interrupted 3-0 silk sutures approximating pancreatic parenchyma to jejunal serosa. Arrow shows ongoing duct-to-mucosa anastomosis with stent inside lumen. Once the duct-to-mucosa anastomosis is completed, anterior of parenchyma to jejunal serosa approximation is done.

When a leak was identified at the PJ anastomosis, the peripancreatic drain was maintained until the leak resolved. Patients were started on a fat-free diet and subcutaneous octreotide (Novartis, USA). A pancreatogram was repeated weekly until the PJ leak resolved. Once the leak was resolved, as confirmed by repeat pancreatography, the stents and drain were removed and a regular diet was begun. Surgical re-exploration was performed when peripancreatic abscess was not amenable to percutaneous drainage, and/or when a widely disrupted PJ anastomosis was visualized on pancreatogram.

RESULTS

From May 2000 to December 2005, of the 105 cases of surgical exploration for pancreatic mass, there were seven palliative bypasses due to unresectable metastatic disease. Seventeen cases had distal pancreatectomy, two transduodenal ampullectomy, 11 pancreaticoduodenectomy with total pancreatectomy, and 66 classical pancreaticoduodenectomy. The demographic data are summarized in Table 1.

Of the 66 patients who had pancreaticoduodenectomy, two required revision of the PJ anastomosis. One patient had afferent loop obstruction and necrosis due to radiation-induced stricture 2 years after the pancreaticoduodenectomy. The afferent loop was revised with a new end-to-side duct-to-mucosa PJ anastomosis and biliojejunostomy. The other patient developed a large peripancreatic abscess and PJ anastomotic leak that did not resolve with conservative management. After re-exploration, the PJ was reconstructed. Since these revisions required complete reconstruction of the pancreatic remnant, the two revised PJ anastomoses were considered independent anastomoses. The outcomes in these 68 PJ anastomoses formed the basis of this study.

Table 1 Clinical parameters of the three groups of patients who had duct-to-mucosa PJ reconstruction after resection of the pancreatic head

	Normal	Parenchymal leak	Anastomotic leak
n	48	8	12
Age (yr[1])	67.5 (29-81)	56.0 (51-79)	65.5 (51-82)
Diagnosis			
Ductal adenocarcinoma	28	1	4
Duodenal adenomas	3	0	1
Neuroendocrine	2	2	1
FAP	0	1	0
Cystadenoma	2	0	1
Benign stricture	2	0	0
Chronic pancreatitis	4	1	1
IPMN	0	2	3
Others	7	1	1
RBC transfused (U[1])	2 (0-39)	2 (0-18)	2.5 (0-88)
OR time (h[1])	5.94 (4.18-11.04)	5.55 (3.40-14.55)	5.04 (4.93-10.65)
Biliary leak	1	0	0
Gastric leak	2	0	0
Intraabdominal abscess	0	0	1

The normal group had no evidence of any pancreatic leakage. Parenchymal leak indicates no extravasation at the duct-to-mucosa anastomosis in the presence of elevated amylase levels in the peripancreatic drain. Anastomotic leak indicates active contrast extravasation at the PJ reconstruction during pancreatography in the postoperative period after pancreaticoduodenectomy. FAP: Familial adenomatous polyposis; IPMN: Intraductal papillary mucinous neoplasm. Other diagnoses included pseudoinflammatory tumor, hereditary pancreatitis, metastatic renal cell carcinoma, solid pseudopapillary tumor, cystic lymphangioma, microcystic adenoma, recurrent duodenal perforation s/p liver transplant; GIST: Gastric efferent stricture with GJ efferent stricture. [1]Age, RBC transfused, and OR time are expressed as median (range).

Table 2 Outcome patterns of PJ anastomosis after pancreaticoduodenectomy based on pancreatography findings and amylase levels in peripancreatic drain fluid

	Normal	Anastomotic leakage	Parenchymal leakage
Pancreatography	No extravasation	Extravasation present	Normal
Peripancreatic drain	Normal	Elevated	Elevated
Occurrence, *n* (%)	48 (72.7)	8 (12.1)	12 (18.2)

Evaluating duct-to-mucosa anastomosis of PJ reconstruction via pancreatography

The integrity of the PJ anastomosis was visualized by fluoroscopy. Of the 68 PJ anastomoses, eight pancreatic anastomotic stents migrated out of the pancreatic remnant. Of those eight, three had successful reflux of the injected contrast into the pancreatic ductal system, demonstrating no leak. In the remaining five, there was no reflux of contrast into the pancreatic ductal system, nor was extravasation seen at the PJ anastomosis. Of the 60 cases with successful pancreatograms, 48 showed no PJ extravasation, i.e., no anastomotic leak, and 12 showed the presence of an anastomotic leak.

A typical pancreatogram and cholangiogram are shown in Figure 2, demonstrating intact PJ and choledochojejunostomy anastomoses. Three patients had mild abdominal discomfort during the pancreatogram injections without increased serum amylase levels. The discomfort resolved spontaneously within a few hours, and there were no other complications directly associated with the pancreatic stents and pancreatograms. Although not shown, in all cases serum amylase levels did not change the day before or the day after the pancreatograms. Serum amylase levels were normal by POD 4.

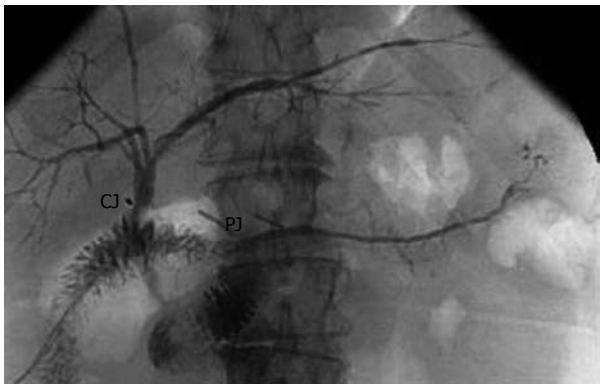

Figure 2 Typical normal pancreatogram and cholangiogram. CJ indicates bilioenteric anastomosis, and PJ indicates PJ reconstruction.

Characteristics of three different outcomes of the PJ anastomosis

As shown in Table 2, we noted three outcomes at the PJ anastomosis after pancreaticoduodenectomy.

Normal: This pattern was associated with a normal pancreatogram, demonstrating an intact PJ anastomosis and low amylase levels from the drain. Forty-eight cases had this normal pattern, including both PJ revisions. The eight cases in which the pancreatic stent dislodged into the lumen of the jejunum had normal drain amylase levels and were included in this normal group. As shown in Figure 3, the peripancreatic PJ drain amylase levels and volumes in the normal group were lower than those in patients with a pancreatic leakage.

Parenchymal leak: This pattern was recognized when there was a normal PJ anastomosis without contrast extravasation on pancreatograms but with persistently high amylase levels in the peripancreatic drains. Eight patients had this pattern. On POD 4 and 7, drain amylase levels in the parenchymal leak group were elevated at 1885 ± 1129 IU/L *vs* 428 ± 1063 IU/L ($P = 0.062$) and 1707 ± 151 IU/L *vs* 89 ± 139 IU/L ($P = 0.012$), respectively. The drain amylase levels became normal between POD 18 and POD 101 after parenchymal pancreatic leak. Most parenchymal leaks resolved by POD 48. In one patient, a repeat study showed the presence of a parenchymal side-branch duct that appeared to be responsible for the high amylase levels detected in the drain (Figure 4). Tessel fibrin sealant was injected, and the drain was removed. Follow-up study showed no fluid collection at the immediate

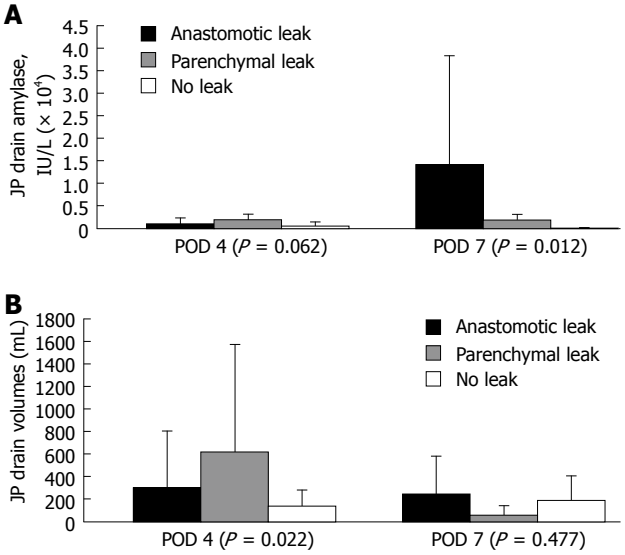

Figure 3 Fluids collected from the peripancreatic drain are analyzed for amylase content and volumes at postoperative day (POD) 4 and 7. A: Amylase levels are not different among the 3 groups at POD 4 (P = 0.062); however, at POD 7, the anastomotic leak group has the significantly highest level, then the parenchymal leak group as compared to the normal group (P = 0.012). B: Volume of peripancreatic drain of the parenchymal leak group was significantly increased above the anastomotic leak and normal group at POD 4 (P = 0.022); on the other hand, there was no difference among the three groups at POD 7 (P = 0.477).

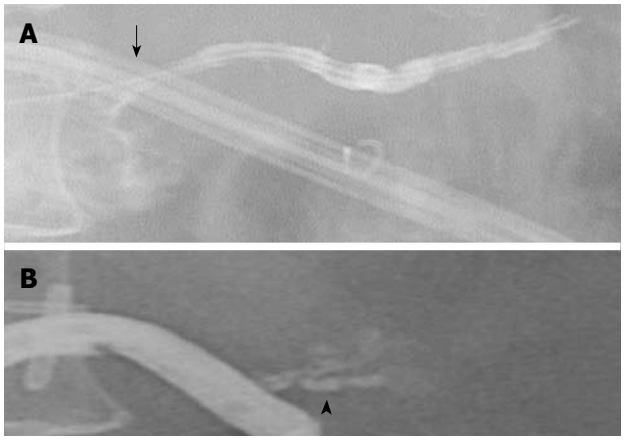

Figure 4 Parenchymal leaks due to a side branch in the pancreatic remnant surface. A: Normal pancreatogram shows intact PJ anastomosis (arrow); B: Sinogram shows a side-branch duct of the pancreas remnant (arrowhead).

or surrounding areas of the pancreatic anastomosis, suggesting complete resolution of the pancreatic leakage.

Anastomotic leak: This pattern was defined by the presence of contrast extravasation at the duct-to-mucosa PJ anastomosis on pancreatogram. These pancreatographic findings were similar to those in a previous report[11]. There were 12 anastomotic leaks. Eleven of the 12 PJ leaks were diagnosed on POD 7 *via* pancreatogram. The highest drain amylase level was 90 000 IU/L. Most elevated drain amylase levels occurred between POD 5 and POD 9, when the anastomotic leaks were also documented radiographically. In fact,

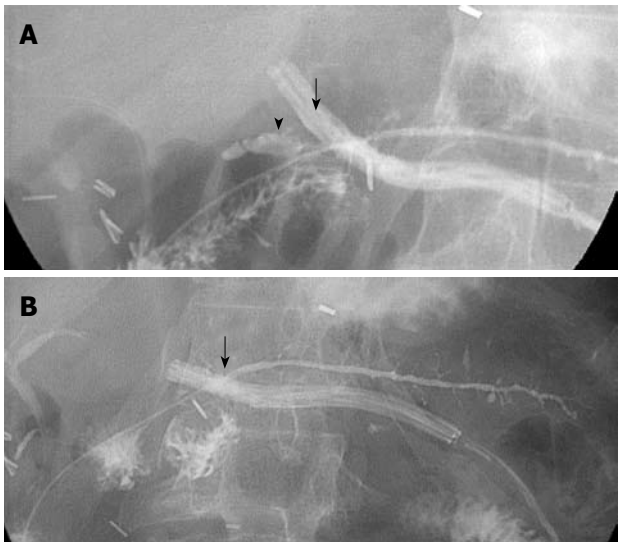

Figure 5 Anastomotic leak is visualized at the initial diagnosis and its resolution is confirmed. A: Contrast extravasation into the surrounding (arrowhead) from the PJ anastomotic (arrow); B: Complete resolution of PJ anastomotic leak (arrow).

the drain amylase levels in this group were significantly elevated at 14158 ± 24083 IU/L *vs* 1707 ± 1515 IU/L and 89 ± 139 IU/L for the parenchymal leak and normal groups at POD 7, respectively (Figure 3A). There was no significant difference among the three groups at POD 4.

The volumes of the peripancreatic drains did not correlate with the leaks seen on pancreatography or the drain amylase levels. As shown in Figure 3B, the volumes of the peripancreatic drains in the anastomotic group were not different from the other two groups at POD 7, although the parenchymal leak group had significantly higher drain volumes at POD 4.

The results of serial pancreatograms provide insight into the natural progression of anastomotic leaks at an end-to-side duct-to-mucosa anastomosis after pancreaticoduodenectomy. Figure 5 shows an example of an anastomotic leak at the duct-to-mucosa PJ reconstruction. The first pancreatogram, done on POD 4, did not show a leak. With a high level of drain amylase on POD 7, repeat pancreatogram showed a significant leak at the duct-to-mucosa anastomosis with extravasation into the surrounding space (Figure 5A). Subsequent pancreatograms showed gradual and complete resolution of the PJ leak (Figure 5B).

Of the 12 pancreatic anastomotic leaks, eight showed radiographic evidence of resolution in conjunction with drain amylase levels tapering toward normal levels by POD 42. In two cases, the anastomotic leak resolved by POD 123 and 189. None of the pancreatic anastomotic leaks resolved without therapeutic intervention, such as replacement of the peripancreatic drains if the primary drains were displaced and/or replacement of pancreatic anastomotic stents if they became dislodged from the lumen of the pancreatic remnant. One patient had a small leak at the PJ anastomosis on pancreatogram on POD 4. The drain amylase level was 1184 IU/L on POD 2. No subsequent amylase levels were obtained.

This patient had portal vein thrombosis, intracranial infarction, and multiorgan failure, and died on POD 31. Autopsy did not show a pancreatic leak. The pancreatic leak had resolved and was not the cause of death.

Among the 12 patients with pancreatic anastomotic leaks, only one required surgical re-exploration due to refractory abscess. On the day of surgical re-exploration at POD 37, the drain amylase level was 1919 IU/L. Yet, the pancreatogram showed a large leak at the PJ anastomosis. During re-exploration, the PJ anastomosis was found to be almost completely disrupted. A new end-to-side duct-to-mucosa PJ anastomosis was performed. No PJ anastomotic leak recurred.

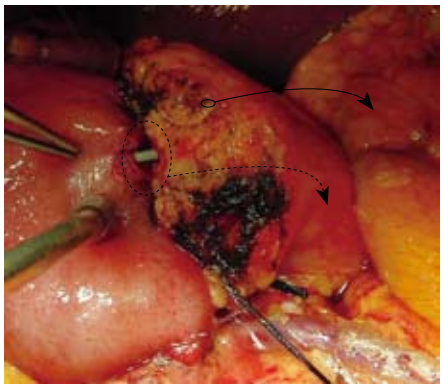

Figure 6 At completed PJ anastomosis, pancreatic leakage can occur either at anastomosis (dotted circle and arrow) or at a small peripheral duct opening or tear in the parenchyma (black circle and arrow).

DISCUSSION

Pancreatic leakage results in major morbidity and mortality after pancreaticoduodenectomy. In this study, we critically examined the integrity of the duct-to-mucosa PJ anastomosis. By analyzing both pancreatography findings and drain amylase levels, we found a way to distinguish parenchymal from anastomotic leakage at the PJ anastomosis. Of the 20 pancreatic leaks at the PJ anastomosis, eight (40%) originated from the parenchymal or small side branch duct, and 12 (60%) originated from the duct-to-mucosa anastomosis. These findings suggest that in duct-to-mucosa PJ anastomosis, parenchymal leakage is almost as common as anastomotic leakage.

In parenchymal pancreatic leakage, pancreatography consistently showed no extravasation at the pancreatic anastomosis. Nevertheless, drain amylase levels were elevated. In one of the eight cases, a small side-branch ductal leak was found along the parenchymal surface of the pancreatic remnant. Although only one case, it represented a potential and likely source of pancreatic leakage in the absence of true anastomotic leakage. It also appears that these parenchymal non-anastomotic leaks tend to resolve spontaneously. These findings are consistent with a previous report demonstrating that most pancreatic leaks do not require surgical exploration[19]. In another case, a 1.5-mm side branch in the cut surface of the pancreatic remnant was observed intraoperatively. This side branch duct was approximate 1 cm from the main pancreatic duct and was only 1 cm in length. Fibrin sealant was injected, and the PJ anastomosis was completed in routine fashion. Postoperatively, there was no evidence of pancreatic leakage.

In the cases studied, pancreatic anastomotic leakage was confirmed by the presence of contrast extravasation at the duct-to-mucosa anastomosis on pancreatogram. The levels of drain amylase continued to increase until the leak started to resolve. In contrast to parenchymal leaks, anastomotic leaks tend not to resolve spontaneously. Appropriate intervention, either replacement of the indwelling anastomotic stent or surgical exploration for large anastomotic disruption, is required. In this series, after re-establishing the dislodged pancreatic stents by interventional radiology, the two anastomotic leaks resolved at 123 and 189 d, compared with 14 wk (or 98 d) in a previous report[20]. Eight of the 12 PJ anastomotic leaks resolved within 10 wk in this series, with a range of 15 to 76 d. The patients whose PJ leak took the longest to heal had a dislodged pancreatic anastomotic stent. Once the percutaneous stent was successfully replaced, the PJ leak healed within 3 wk. These findings support the concept that mucosa-to-ductal epithelial healing is probably promoted by stent placement across the PJ anastomosis[21]. In addition, the externalized stent allows for continuous external drainage of luminal pancreatic juice and promotes healing of the PJ anastomosis. However, our results do not directly suggest that a pancreatic stent is required. Pancreatic stents are not commonly used, therefore, PJ anastomoses might heal without a stent. Rather, the use of pancreatic stents in this study may provide a means to understand the exact source and nature of pancreatic leaks after pancreaticoduodenectomy.

We have found that most pancreatic leaks can be managed conservatively, which is consistent with the findings of others[16,19,20]. The indications for surgical re-exploration are intra-abdominal refractory abscess or hemorrhage. In this series, no hemorrhage occurred. However, hemorrhage secondary to a pancreatic leak remains a lethal complication. Accurate diagnosis of a pancreatic anastomotic leak is thus essential. In our series, only one of the 12 anastomotic leaks needed surgical correction.

Other studies have indicated different factors related to increased risk of a pancreatic leak after pancreatectomy, such as soft pancreatic texture and small duct size[4,11,22]. It seems probable that pancreatic leaks may result from parenchymal tears by sutures, resulting in a leak *via* a parenchymal side-branch duct. However, without objective evidence, such as a pancreatogram, it would be impossible to define the exact nature of the leak.

Although they did not demonstrate their findings radiographically, Matsusue and colleagues suggested a similar distinction for peripancreatic sepsis as the result of parenchymal or non-anastomotic seepage of pancreatic juice versus a pancreatic fistula from

pancreatic anastomotic failure[19]. Our findings for parenchymal leakage correspond to their description of peripancreatic sepsis, and our anastomotic leak corresponds to their pancreatic fistula. Furthermore, without radiographic evidence, a pancreatic leak can be classified by using the volume and amylase level of the fluid in the peripancreatic drain and the requirement for therapeutic intervention[13]. However, the most important difference lies within our capability to directly visualize radiographically the pancreatic anastomosis. Together, the results from drain amylase levels and the pancreatogram can clearly distinguish a true anastomotic leak from a parenchymal non-anastomotic leak as illustrated in Figure 6. These findings are limited, however, by the small number of parenchymal leaks (n = 8). Larger numbers in future prospective studies will be required to further understand the exact nature of pancreatic leaks at PJ reconstruction after pancreaticoduodenectomy.

One can argue for the need for pancreatic and biliary stenting. From our experience with liver transplantation, biliary stenting is not uniformly used. This is because the placement of the biliary tube is usually performed *via* a T-tube through a surgically created opening in the common bile duct, which leads to persistent biliary leakage after removal of the biliary T-tube. In contrast, since the beginning of the liver transplantation program at our center in 1998, we insert the biliary tube *via* the donor cystic duct and secure it with a rubber band. For bilioenteric anastomosis, the biliary tube is inserted through the jejunal limb and secured with a Witzel's tunnel. The biliary tube and the pancreatic stent are each kept in place with a 5-O Vicryl™ suture, which will dissolve by 4 wk, allowing for safe removal of the biliary tube at 28 d. When this method is used, biliary stenting and pancreatic stenting have been safe. No complications have occurred as a result of a stent.

Although it was not a stated aim of this study, we have found that the technique of placing an externalized PJ anastomotic stent at the time of pancreaticoduodenectomy is helpful for postoperative management. Such stenting allows access to the pancreatic ductal system for assessing anastomotic integrity by pancreatography and control of drainage, should a leak be found. None of our patients with leaks had significant hemorrhage, peripancreatic inflammation, or completion pancreatectomy[10]. In addition, the presence of this stent allows ongoing assessment of the anastomosis and facilitates decisions about timing of drain removal and progression of diet. For these reasons, we continue to use this technique in our practice.

In conclusion, duct-to-mucosa anastomotic leakage can be distinguished from parenchymal (non-anastomotic) leakage after duct-to-mucosa PJ. Both parenchymal and anastomotic pancreatic leaks contribute almost equally to pancreatic leaks after pancreaticoduodenectomy. Knowledge of the exact nature of the leak is important for optimal treatment and management of this complication.

COMMENTS

Background

Pancreatic leakage after pancreaticoduodenectomy is a significant source of morbidity and mortality, with anastomotic leaks being more refractory than parenchymal leaks. It is important to be able to distinguish one from the other so that appropriate treatment can be given.

Research frontiers

Pancreatic surgeons need new ways to monitor pancreatic leakage after pancreaticoduodenectomy to know whether conservative treatment is sufficient or more aggressive treatment should be undertaken.

Innovations and breakthroughs

By analyzing pancreatographic findings, drainage volumes, and amylase levels, author found patterns among cases of pancreatic leakage that enable us to distinguish parenchymal leakage from anastomotic leakage. Specifically, in parenchymal pancreatic leakage, pancreatography showed no extravasation at the pancreatic anastomosis, yet drain amylase levels were elevated, whereas in anastomic pancreatic leakage, contrast extravasation is present and the levels of drain amylase increased until the leak started to resolve. In contrast to parenchymal leaks, anastomotic leaks tend not to resolve spontaneously.

Applications

This retrospective study identified distinguishing characteristics of parenchymal *versus* anastomotic leakage. These distinctions should be confirmed prospectively and can be used clinically to provide better treatment after pancreatic surgery.

Terminology

Pancreaticoduodenectomy is a procedure that is used to treat tumors located in the head of the pancreas. Parenchymal leakage refers to leakage that occurs from the resection surface of the pancreas remnant, and anastomotic leakage refers to a specific leakage that occurs due to a failure of the reconstructed duct-to-mucosa anastomosis between the pancreas remnant and the intestine.

Peer review

The author evaluated the incidence of anastomotic versus parenchymal leakage following duct-to-mucosa pancreatic reconstruction in pancreaticoduodenectomy. This is a well-written paper. The findings provided great inspiration about how to consider and manage pancreatic leakage after pancreaticoduodenectomy.

Abstract

AIM: To investigate the innate immune reactivity of tumor necrosis factor-alpha (TNF-α), Toll-like receptor 4 (TLR4), and CD14 in the liver of non-alcoholic steatohepatitis (NASH) model rats.

METHODS: Male F344 rats were fed a choline-deficient L-amino-acid-defined (CDAA) diet. The rats were killed after 4 or 8 wk of the diet, and their livers were removed for immunohistochemical investigation and RNA extraction. The liver specimens were immunostained for TNF-α, TLR4, and CD14. The gene expressions of *TNF-α*, *TLR4*, and *CD14* were determined by reverse-transcriptase polymerase chain reaction (RT-PCR). Kupffer cells were isolated from the liver by Percoll gradient centrifugation, and were then cultured to measure TNF-α production.

RESULTS: The serum and liver levels of TNF-α in the CDAA-fed rats increased significantly as compared with the control group, as did the immunohistochemical values and gene expressions of TNF-α, TLR4, and CD14 with the progression of steatohepatitis. TNF-α production from the isolated Kupffer cells of the CDAA-fed rats was elevated by lipopolysaccharide stimulation.

CONCLUSION: The expressions of TNF-α, TLR4, and CD14 increased in the NASH model, suggesting that TLR4 and CD14-mediated endotoxin liver damage may also occur in NASH.

INTRODUCTION

Some patients who are not regular drinkers of alcohol have hepatic histological features that mimic alcoholic hepatitis and can progress to liver cirrhosis[1]. This condition has been named non-alcoholic steatohepatitis (NASH) and is thought to begin with excessive fat accumulation in the liver (first hit), followed by aggravating factors such as oxidative stress, inflammatory cytokines, and endotoxins (second hit)[2].

Kupffer cells, the resident macrophages in the liver, are localized in the non-parenchymal tissue and involved in the organ's innate immunity. Activation of Kupffer cells induces progression of NASH *via* tumor necrosis factor-alpha (TNF-α)[3]. The recent discovery of Toll-like receptor 4 (TLR4), a functional receptor on the surface of macrophages and various other types of cells that transmit Et signals, has led to recognition of molecules, including CD14, that bind to lipopolysaccharides (LPSs) as the mainstay of the mechanism that initiates signal transduction leading to LPS recognition and cellular activation[4].

NASH is characterized by hepatic steatosis, inflammation, and fibrosis, with increased risk of developing cirrhosis and hepatocellular carcinoma (HCC)[5]. It is

known that the choline-deficient L-amino-acid-defined (CDAA) fed rat model shows fatty accumulation and fibrosis, and after 16 wk the liver shows cirrhotic changes and nodules appear like HCC[6]. This model is sometimes used as a hepatocarcinogenesis model. In this study, we used a CDAA diet to produce one of the experimental animal models of NASH[7], to investigate the innate immune reactivity of the liver in NASH.

MATERIALS AND METHODS

Animal model

Male F344 rats (6-wk-old, weighing 180-200 g) were purchased from Japan SLC (Hamamatsu, Japan), and fed a CDAA diet for up to 8 wk to induce NASH. At 1, 4, and 8 wk, the control rats (fed a standard rat chow), and the CDAA-fed rats were killed and bled from the inferior vena cava (IVC). Liver tissues were excised after perfusion with PBS into the portal vein. All procedures were approved by our institutional animal care committee and conducted in accordance with Nara Medical University Guidelines for the Care and Use of Laboratory Animals.

Serum alanine aminotransferase (ALT)

Serum samples from the control and CDAA-fed rats were used to measure the serum ALT levels. The serum ALT levels were determined using a 7170 Clinical Analyzer (Hitachi High-Technologies, Tokyo, Japan).

Serum TNF-α

Serum samples (50 μL) from the control and CDAA-fed rats were used to measure the TNF-α concentration by enzyme-linked immunosorbent assay (ELISA) kit (BioSource International, Camarillo, CA, USA).

Liver TNF-α

Liver tissues were frozen in liquid nitrogen, powdered, and 30 mg were homogenized in 1 mL of lysis buffer. The supernatant (50 μL) was used to measure the TNF-α levels by ELISA kit (BioSource International).

Histology

The liver tissues were fixed in 40 g/L formalin, embedded in paraffin, and 5-μm thick sections were cut from the paraffin blocks for staining with hematoxylin-eosin (HE) and Azan stains. Histological grading and staging were performed using a modified scoring system based on the classification of either Matteoni *et al*[8] or Brunt *et al*[9] proposed NAFLD types 1-4 based on long-term outcome studies, while Brunt *et al*[9] proposed a system of grading and staging for NASH that follows methods of separate assessment for necroinflammatory lesions (grading) and fibrosis (staging) accepted in other forms of non-biliary chronic liver diseases.

Immunohistochemistry

The TNF-α immunohistochemical staining was performed on the paraffin sections using an anti-rat TNF-α/TNFSF1A antibody (R&D Systems, Minneapolis, MN, USA), and the TLR4 and CD14 immunohistochemical staining was performed on frozen sections using an anti-rat TLR4 antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA), and an anti-rat CD14 antibody (Santa Cruz Biotechnology Inc.), respectively. After that, a Vectastain ABC Elite Kit (Vector Laboratories, Burlingame, CA, USA), and DAB peroxidase substrate solution (Vector Laboratories Inc.), with counterstaining by Hematoxylin Mayer were used. The stained areas were analyzed by NIH image software (Version 1.61, U.S. National Institute of Health, Bethesda, MD, USA).

Kupffer cell isolation and culture

Kupffer cells were isolated from the control and CDAA-fed rat livers according to a previously described procedure[10,11]. In brief, the liver was perfused through the portal vein with 100 mL of PBS containing 0.5 mmol/L EGTA (Research Organics, Cleveland, OH, USA) solution. The perfusion was carried out at 37℃ at a flow rate of 10 mL/min. Subsequent perfusion with Hanks' balanced salt solution containing 0.5 g/L collagenase type Ⅳ (Wako, Osaka, Japan) (collagenase solution) was carried out at 37℃ at a flow rate of 10 mL/min for 20 min. Then, the liver was excised and minced in the collagenase solution.

The liver slurry was filtered through gauze mesh, then washed with collagenase solution. Next, Percoll (Sigma-Aldrich Corp, St. Louis, MO, USA) was used for density gradient centrifugation of cells. Kupffer cells were collected from the layer between 1.04 and 1.06. They were then cultured in RPMI 1640 supplemented with 10% fetal bovine serum and SAG (50 μg/mL streptomycin, 50 μg/mL ampicillin, 0.3 g/L L-glutamine). The viability of the cultured Kupffer cells was determined by trypan blue exclusion. Kupffer cells were seeded at a density of 5×10^5 cells/mL on a 12-well plate with RPMI 1640. For LPS-stimulated group, Kupffer cells were then exposed to 1 μg/mL of LPS (Sigma-Aldrich Corp.) and incubated for 4.5 h at 37℃ in a 50 mL/L CO_2-humidified air atmosphere. The cells untreated with LPS were used as control. The supernatant was analyzed by ELISA kit (BioSource International) to measure the TNF-α concentration.

Reverse transcriptase-PCR (RT-PCR) analysis

The total RNA was extracted from the powdered frozen liver samples using an RNeasy mini kit (Qiagen, Valencia, CA, USA) according to the manufacturer's protocol. Briefly, 2 μg of the RNA sample were used for cDNA synthesis using Moloney Murine Leukemia Virus (M-MLV), Reverse Transcriptase RNaseH Minus (Toyobo, Osaka, Japan), and RNase Inhibitor (Toyobo) to investigate the expressions of *TNF-α* mRNA, *TLR4* mRNA, and *CD14* mRNA. PCR procedure was performed as follows: the samples were heated at 94℃, subjected to 30 cycles of 45 s at 94℃ for denaturing, 45 s at 60℃ for annealing,

Table 1 Primers for the target genes used in RT-PCR

Target gene	Primer
TNF-α	5′-TACTGAACTTCGGGGTGATTGGTCC-3′ (F)

and 2 min at 72℃ for extension. Following RT-PCR, 10-μL samples of the amplified products were resolved by electrophoresis on 15 g/L agarose gel, and stained with ethidium bromide. Each PCR product was analyzed by NIH image software. The specific primers for *TNF-α*, *TLR4*, *CD14*, and *β-actin* used are described in Table 1.

Statistical analysis

All results are expressed as mean ± SD. The analysis was carried out using Statview software (version 5.0, SAS Institute, Cary, NC, USA). Statistical differences between groups were evaluated using the paired *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Serum ALT

The mean serum ALT level in the control rats was 41.7 ± 7.4 IU/L, as compared with 524.6 ± 101.7 IU/L, 267.9 ± 47.5 IU/L, and 251.4 ± 81.6 IU/L in the 1-, 4-, and 8-wk CDAA-fed rats, respectively. All CDAA-fed groups showed a statistically significant elevation in the serum ALT level as compared with the control group ($P < 0.01$).

Serum TNF-α

As compared with the control rats (5.2 ± 4.4 pg/mL), the serum TNF-α level in the 4-wk CDAA-fed rats was elevated (55.9 ± 1.7 pg/mL, $P < 0.01$), and that in the 8-wk CDAA-fed rats (48.2 ± 5.3 pg/mL, $P < 0.01$) was elevated (Figure 1A).

Liver TNF-α

The liver TNF-α was 15.8 ± 3.6 pg/μg protein in the control rats, 30.3 ± 5.4 pg/μg protein in the 4-wk CDAA-fed rats, and 29.6 ± 4.4 pg/μg protein in the 8-wk CDAA-fed rats. The CDAA-fed groups showed a statistically significant elevation in the liver TNF-α level as compared with the control group ($P < 0.05$) (Figure 1B).

Histological findings

Histologically, the livers of the 1-wk CDAA-fed rats showed inflammation and fat deposits, but no fibrosis, and were classified as Matteoni's type 2. The livers of the 4-wk CDAA-fed rats showed more inflammation, fat deposits, and fibrosis, equivalent to Matteoni's type 3 and grade 2/stage 2 of Brunt's NASH classification. The histological findings in the livers of the 8-wk CDAA-fed rats were equivalent to Matteoni's type 4 and Brunt's grade 2/stage 3 (Figure 2).

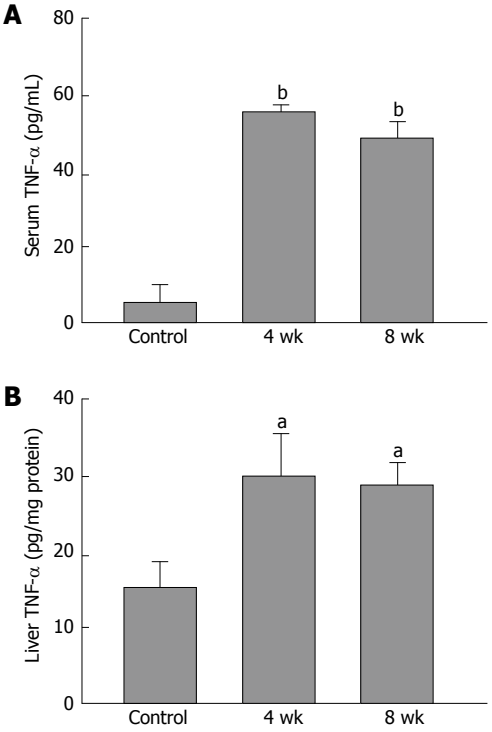

Figure 1 Serum TNF-α levels and liver TNF-α (ELISA method) compared with the control group ($n = 5$). A: Serum TNF-α levels were significantly elevated in the livers of the 4- and 8-wk CDAA-fed rats; B: Liver TNF-α was significantly elevated in the livers of the 4- and 8-wk CDAA-fed rats. [a]$P < 0.05$ *vs* the control; [b]$P < 0.01$ *vs* the control.

Immunohistochemical findings

The TNF-α immunoreactivities in the tissue samples from the livers of the 4- and 8-wk CDAA-fed rats were increased as compared with those in the control rats. The TLR4 and CD14 immunohistochemical findings in the 4- and 8-wk CDAA-fed rats were also increased as compared with those in the control rats. Moreover, the immunopositive areas in those animals were localized either in the periphery of fatty spots or non-parenchymal cells. The semiquantitative analysis of TNF-α, TLR4, and CD14 staining revealed significantly increased immunoreactivity in the livers of the 4-wk (14600 ± 5700, 26400 ± 2300, 17400 ± 6000, respectively) and 8-wk (10600 ± 1800, 21600 ± 4700, 21300 ± 3900, respectively) CDAA-fed rats as compared with the control rats (1560 ± 1080, 3160 ± 1000, 4290 ± 1110, respectively) ($P < 0.01$) (Figure 3).

Kupffer cell isolation and culture

The viability of the cultured Kupffer cells was over 98% as determined by trypan blue exclusion. The basic TNF-α production of the Kupffer cells isolated from 4- (26.4 ± 2.3 pg/mL) and 8-wk CDAA-fed rats (26.6 ± 1.4 pg/mL) was equal to that of the control rats (23.4 ± 1.8 pg/mL). After LPS stimulation, the TNF-α

production in the control rats (48.9 ± 7.5 pg/mL) was significantly higher than the basic control levels, and that in the 4-wk (85.8 ± 16.8 pg/mL) and 8-wk (73.8 ± 8.4 pg/mL) CDAA-fed rats was significantly higher than in the control rats ($P < 0.01$) (Figure 4).

RT-PCR analysis

The expression of both *TNF-α* mRNA and *TLR4* mRNA was significantly increased in the livers of the 4- and 8-wk CDAA-fed rats as compared with those in the control group ($P < 0.01$). The expression of *CD14*

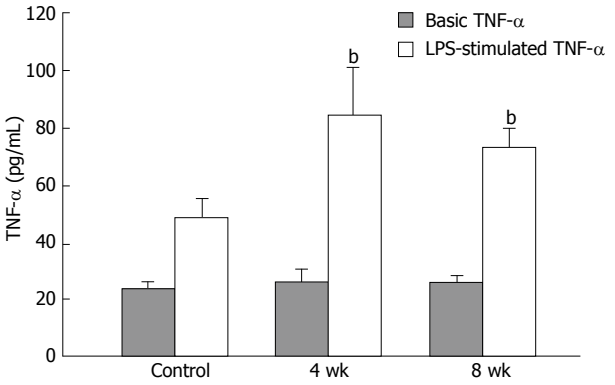

Figure 4 TNF-α production of Kupffer cells *in vitro*. The basic TNF-α production of Kupffer cells isolated from 4- and 8-wk CDAA-fed rats was equal to that of the control rats. After LPS stimulation, the TNF-α production of the control rats was significantly higher than the basic control levels, and that of the 4- and 8-wk CDAA-fed rats was significantly higher than that of the control rats. $^{b}P < 0.01$ *vs* the control.

mRNA was increased in the livers of the 8-wk CDAA-fed rats as compared with that in the control group ($P < 0.05$) (Figure 5).

DISCUSSION

Kupffer cells secrete inflammatory cytokines[12] and reactive oxide[13], which affect the hepatocytes, stellate cells, endothelial cells, *etc*[14]. In alcoholic hepatitis, inflammatory cytokines, such as TNF-α, induce the liver injury[15]. After chronic ethanol feeding, Kupffer cells exhibit enhanced sensitivity to LPS-stimulated TNF-α production[16]. Increased serum levels of TNF-α have been noticed in patients with NASH[17]. The mechanism of the latter may be secretion from adipocytes, as a result of obesity, or secretion from Kupffer cells activated by endogenous endotoxin originating from enteric bacteria. The activated Kupffer cells induce increases in the levels of cytokines, such as TNF-α or reactive oxide, which may be involved in the progression of NASH. Rats fed a high-fat diet become obese and show insulin resistance. In addition, the activities of both nuclear factor kappa enhancer binding protein (NF-κB) and the inhibitor of NF-κB kinase beta (IKKβ) significantly increase in the liver, and the expression of inflammatory cytokines such as TNF-α becomes excessive[18]. Our results showed that the livers of CDAA-fed rats developed inflammation in the early stage, and this was sustained by chronic feeding of the diet. After 4 wk or more, the livers of the CDAA-fed rats developed progressive steatohepatitis. In the present study, we confirmed by ELISA, immunohistochemistry, and RT-PCR that both the serum level of TNF-α and the liver TNF-α expression were increased, suggesting involvement of TNF-α in the development and progression of NASH similar to that in alcoholic hepatitis. Moreover, the TNF-α production of the isolated Kupffer cells was equal in the NASH model. Kupffer cells from the control rats were sensitive to LPS stimulation. Furthermore, those from NASH were more sensitive to LPS stimulation, suggesting that the continuous inflammation leads to up-regulation of the LPS-

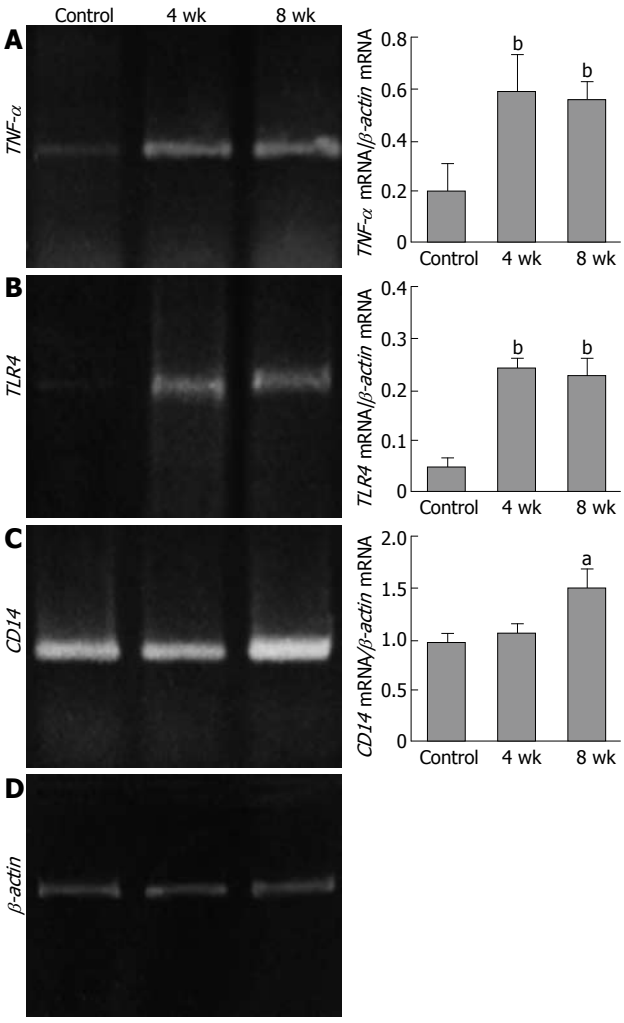

Figure 5 RT-PCR and semiquantification ($n = 5$). A: *TNF-α* mRNA; B: *TLR4* mRNA; C: *CD14* mRNA; D: *β-actin* mRNA. $^{a}P < 0.05$ *vs* the control, $^{b}P < 0.01$ *vs* the control.

stimulated TNF-α production by the activated Kupffer cells.

To date, 13 TLRs have been described in mice and 11 in humans. Recently, TLR4 has been highlighted as an important membrane protein[19,20] and is now established as the receptor for LPS. CD14 binds LPS and subsequently presents it to TLR4 and MD-2, which activate the intracellular signaling pathway *via* myeloid differentiation factor 88 (MyD 88), resulting in NF-κB activation[21]. Experiments using TLR4 knockout (KO) mice or CD14 KO mice have revealed a reduced reaction to LPS and a reduced expression of TNF-α[22,23], indicating that LPS signaling induces TNF-α production *via* TLR4 or CD14. The intake of alcohol facilitates the permeability of endotoxin from the gut to the portal vein, and the increased concentration of endotoxin in the portal vein leads to Kupffer cell activation *via* TLR4, with consequent increases in the liver expression of TNF-α, progression of inflammation, and fibrosis of the liver[24]. In the experimental chronic liver injury model, the expression of TLR4 in isolated Kupffer cells increases with progression of liver injury[25], suggesting a correlation between inflammation and expression of

TLR4. The present study showed increased expression of mRNA levels and immunohistochemical values of TNF-α, TLR4, and CD14 in the livers of rats with NASH induced by CDAA diet, suggesting that TLR4-mediated endotoxin liver damage may also occur in NASH. Rivera *et al*[26] also demonstrated enhanced TLR4 expression together with steatohepatitis in the liver of mice fed a methionine choline-deficient (MCD) diet. They further reported that the liver injury was attenuated in the TLR4 mutant mice and in Kupffer cell-depleted mice, and pointed out the importance of TLR4 signaling and Kupffer cells in the pathogenesis of steatohepatitis. Although these models lack obesity and insulin resistance, two major characteristics of NASH in humans, the possible relation of Kupffer cells with inflammation, steatosis, and fibrosis may resemble the human NASH. We also demonstrated decreased Kupffer cell phagocytic activity in this model[27]. The possible Kupffer cell dysfunction characterized by decreased phagocytic activity and increased cytokine production should be investigated in future studies.

Although the pathogenic mechanism of NASH is still unclear, its histopathology is similar to that of alcoholic hepatitis. Enhanced activation of the TLR4 dependent signaling pathways was also observed after chronic ethanol feeding[28]. There is a possibility that TLR4-dependent innate immunity induced by intestinal bacterial endotoxin may work as a common pathway in these two types of steatohepatitis. Further studies are needed to confirm this hypothesis.

In conclusion, our study focused on the innate immune reactivity of livers in the rat model of NASH, and we found overexpressions of TNF-α, TLR4, and CD14 in association with liver fibrosis and inflammation. These results suggest that TLR4 and CD14-mediated endotoxin liver damage may also occur in NASH.

COMMENTS

Background

Recently, non-alcoholic steatohepatitis (NASH) has become a common disease in Japan. The two-hit theory has been widely accepted to explain the progression from simple steatosis to NASH. Moreover, NASH is known as a disease progressing to liver cirrhosis or hepatocellular carcinoma (HCC). The mechanism of NASH progression has not been clarified yet. Authors investigated the engagement of Toll-like receptor 4 (TLR4) or CD14 in the rat NASH model.

Research frontiers

This is the first report showing the innate immune response in the rat NASH model. Authors found overexpression of tumor necrosis factor-alpha (TNF-α), TLR4, and CD14 in association with liver fibrosis and inflammation. These results suggest that TLR4 and CD14-mediated endotoxin liver damage may occur in NASH.

Innovations and breakthroughs

The present study demonstrated the overexpression of TNF-α, TLR4, and CD14 in the rat NASH model. This result suggests that the involvement of endotoxin-induced TLR4 activation led to the NASH progression.

Applications

The present study is an experimental research using the rat NASH model, which was made by feeding a choline-deficient L-amino-acid-defined diet to rats, to examine their innate immunity. For understanding NASH progression, further evaluation of the cytokine production from the Kupffer cells and the expressions of TLR4 and CD14 from the isolated Kupffer cells should be employed in the subsequent experiments.

Terminology

TLR4 is a transmembrane receptor for lipopolysaccharides (LPS) on the surface of macrophages. LPS stimulation activates TLR4 by binding with CD14, resulting in pro-inflammatory cytokine production, like TNF-α.

Peer review

Authors described the importance of innate immune responses to the pathogenesis of rat model of NASH. The findings are important.

Abstract

AIM: To investigate alternative or subordinate pathways involved in colorectal tumorigenesis and tumor growth, possibly determining at-risk populations and predicting responses to treatment.

METHODS: Using microarray gene-expression analysis, we analyzed patterns of gene expression relative to canonical molecular changes and clinicopathological features in 84 sporadic colorectal cancer patients, standardized by tumor location. Subsets of differentially expressed genes were confirmed by real-time reverse-transcript polymerase chain reaction (RT-PCR).

RESULTS: The largest number of genes identified as being differentially expressed was by tumor location, and the next largest number by lymphovascular or neural invasion of tumor cells and by mismatch repair (MMR) defects. Amongst biological processes, the immune response was significantly implicated in entire molecular changes observed during colorectal tumorigenesis ($P < 0.001$). Amongst 47 differentially expressed genes, seven (*PISD*, *NIBP*, *BAI2*, *STOML1*, *MRPL21*, *MRPL16*, and *MKKS*) were newly found to correlate with tumorigenesis and tumor growth. Most location-associated molecular changes had distinct effects on gene expression, but the effects of the latter were sometimes contradictory.

CONCLUSION: We show that several differentially expressed genes were associated with canonical molecular changes in sporadic colorectal cancers, possibly constituting alternative or subordinate pathways of tumorigenesis. As tumor location was the dominant factor influencing differential gene expression, location-specific analysis may identify location-associated pathways and enhance the accuracy of class prediction.

INTRODUCTION

Analysis of genetic alterations in hereditary colorectal cancers have identified several molecular changes, including those involving APC-Wnt signaling, mismatch repair (MMR) defects, RAF cascades, and p53 alterations[1-3]. The pattern of molecular changes observed in hereditary colon cancers suggested a stepwise model for colorectal tumorigenesis. About 80% of colorectal cancers, however, are sporadic, and the pattern of genetic alterations observed in hereditary tumors has been consistently observed in only a small number of sporadic tumors[1]. These findings suggest the existence of alternative or subordinate and crossover pathways of colorectal tumorigenesis.

The APC protein is thought to contribute to all processes governing tumor tissues, including proliferation, migration, apoptosis, and differentiation[4]. Loss of APC

function leads to intracellular β-catenin stabilization, the key component of canonical Wnt signaling, and constitutive signaling of β-catenin within the nucleus[5,6]. The current model of colon tumorigenesis suggests that MMR defects cause tumors primarily through two mechanisms, mutations in tumor suppressor gene pathways and inappropriate apoptosis[7]. Sporadic colorectal cancers with MMR defects, including almost all those with BRAF mutations, are thought to arise through the CpG island methylator phenotype (CIMP) associated with methylation of MLH1[3]. These alterations initiate cellular processes directed towards either proliferation or differentiation, depending on signal intensity and duration[8]. Alternatively, RAS mutations may be early events in the adenoma-carcinoma sequence, and *RAF* alterations may be related to the progression and development of de novo colorectal cancer[9].

The p53 pathway is ubiquitously lost in human cancers, either by *p53* mutations, observed in 60% of tumors, or by loss of cell signaling upstream and downstream of p53 in the 40% of cancers expressing wild-type p53[10]. Following disruption of $p21^{WAF1}$, p53 expression is enhanced because of p53 stabilization, which correlates with the increased expression of the tumor suppressor $p14^{ARF}$, an inhibitor of the ubiquitin ligase activity of MDM2[11]. Apart from these molecular changes, however, little is known about crossover pathways between APC-Wnt signaling and MMR or RAF alterations. *APC* and *RAS* mutations have been shown to be synergistic in promoting β-catenin nuclear translocation, thus enhancing canonical Wnt signal transduction[12]. Moreover, APC was shown to regulate cellular proliferation and transformation induced by the activation of both RAS and β-catenin signaling[13].

To identify alternative or subordinate pathways involved in colorectal tumorigenesis and tumor growth, we assessed gene expression patterns, relative to canonical molecular changes and clinicopathological features in patients with colorectal tumors. Individual steps and pathways were sorted into various biological processes. We also performed location-specific analysis to determine whether this exercise might improve the accuracy of class prediction. Our results may also be used to determine at-risk populations and to predict responses to treatment.

MATERIALS AND METHODS

Patients and tissue samples

We prospectively enrolled 84 consecutive patients with sporadic colorectal cancer scheduled to undergo curative resection between 2006 and 2007 at the Asan Medical Center (Seoul, Korea) (Table 1). Tumors were standardized by location, and samples of tumor and normal colonic mucosa, taken at least 5 cm from the tumor borders, were obtained at the time of surgery. The tissue samples were snap-frozen in liquid nitrogen. Total RNA was extracted using RNeasy RNA extraction kits (Qiagen, Valencia, CA, USA), according to the manufacturer's instructions, and DNA was extracted from lymphocytes and tumors using standard methods. Cancer staging was determined by imaging studies and operative findings with histological diagnosis according to the American Joint Committee on Cancer (6th ed., 2001). Our sample size was determined for competent cluster analysis using an efficient annealing algorithm with error rates of < 10%. All patients provided written informed consent, and the study protocol was approved by the Institutional Review Board for Human Genetic and Genomic Research, in accordance with the Declaration of Helsinki.

Clinicopathological features and molecular changes in colorectal tumorigenesis

Methods of representative molecular changes in tumor tissues, including *APC* mutations, Wnt-activated alterations, MMR defects, RAF-mediated changes, and p53 alterations have been described using different samples[14]. Briefly, *APC* mutations were assessed throughout all exons and introns, whereas Wnt-activated alterations were assessed by immune staining for β-catenin, Axin2, GSK3β, and E-cadherin. The search for MMR alterations included microsatellite instability (MSI) assays using the Bethesda panel, assays of methylation status at the 5'-promoter site and the 3'-small site of *hMLH1*, and immune staining for hMLH1 and hMSH2. We assessed RAF-mediated alterations by determining *BRAF* codon 600 mutations, mutations in *KRAS* exons 12 and 13, and immune staining for MEK. Alterations in *p53* were assessed by immune staining for altered p53. Crossover was defined when a tumor carried both APC/Wnt-activated changes and MMR defects or RAF-mediated alterations.

cDNA microarray and data analyses

The 21k cDNA microarray chips were prepared using Korean Unigene Information (KUGI) cDNA clones (http://kugi.kribb.re.kr/) and Incyte Human 10k cDNA clones. The PCR products of each clone were spotted on type-7 glass slides using an Array Spotter Generation Ⅲ (Amersham Pharmacia, Piscataway, NJ, USA). Aliquots of tumor and non-tumor RNAs (20 mg respectively) were used as templates for the synthesis of cDNA, labeled with Cy5 or Cy3, respectively, using SuperScript Ⅱ reverse transcriptase (Invitrogen, Carlsbad, CA, USA) for 2 h at 42℃. The two labeled cDNAs were mixed, filtered through Microcon YM-30 filters (Millipore, Bedford, MA, USA) to exclude unincorporated dNTPs, and hybridized to the microarray slides at 50℃ overnight using a 3DNA Array 50 kit (Genisphere Inc., Hatfield, PA, USA). After hybridization, each microarray was washed twice with 2 × SSC with 0.2% (w/v) SDS at room temperature for 5 min, and finally with 95% (v/v) ethanol at room temperature for 1 min. The slides were scanned using a ScanArray 5000 Scanner (Axon Instruments, Union City, CA, USA), and scanned images were analyzed using the GenePix Pro 4.0 program (Axon Instruments). The raw data were normalized using the print-tip Lowess method available in the OLIN package

of the Bioconductor project (http://www.bioconductor.org)[15]. Missing values were imputed using the k-nearest neighbor method (available at the GEPAS web service: http://gepas.bioinfo.cipf.es/cgi-bin/preprocess/). The raw data have been deposited in the Gene Expression Omnibus (GEO, http://www.ncbi.nlm.nih.gov/projects/geo/) under the accession number GSE10982.

Quantitative reverse-transcript polymerase chain reaction (RT-PCR)

Total cellular RNA (5 μg) was reverse transcribed into cDNA using SuperScript Ⅱ (Invitrogen). Real-time (RT)-PCR was performed using the Exicycler Quantitative Thermal Block (Bioneer, Daejeon, Korea). The RT-PCR reaction product (100 ng) was amplified in a 15 μL reaction volume with 2 × SYBR Premix EX *Taq* (Takara, Shiga, Japan). Primers were designed using the Primer3 program (http://frodo.wi.mit.edu/cgi-bin/primer3/primer3_www.cgi). Following an initial denaturation at 95℃ for 1 min, the amplification protocol consisted of 45 cycles of denaturation at 95℃ for 30 s, annealing at 60℃ for 30 s, and extension at 72℃ for 30 s, followed by a final extension step of 72℃ for 10 min. The β-actin protein was used as an internal control. Relative quantification of each mRNA was analyzed by the comparative threshold cycle (TC) method.

Parametric analysis of gene set enrichment (PAGE)

We applied the PAGE method to identify significant changes in expression of gene sets[16]. Diverse categories of gene sets included molecular changes associated with colorectal tumorigenesis, namely cell cycle and apoptosis pathways, receptor protein tyrosine kinase signaling, Wnt/cadherin signaling, DNA MMR, and TGF-β signaling pathway. They were prepared from Affymetrix annotation files (http://www.affymetrix.com/netaffy) and annotation files were downloaded from the Source web service (http://genome-www5.stanford.edu/cgi-bin/source/sourceBatchSearch). Gene sets identified by gene ontology (GO) protocols included those involved in various biological processes, genes responsible for cellular components and molecular functions, genes defined by chromosomal locations, genes related by InterPro domains, and genes involved in distinct metabolic pathways. Pathway information was obtained from the BioCarta (http://www.biocarta.com) and KEGG (http://www.genome.ad.jp/kegg/) databases. Publications on differentially expressed genes were accessed to understand gene effects on biological functions and tumorigenesis, using PubMed (http://www.ncbi.nlm.nih.gov/sites/entrez).

Statistical analysis

The associations of molecular changes and clinicopathologic features with tumor location were examined by cross-table analysis using Fisher's exact or Pearson's χ^2 tests with their significance level at 5%. The statistical significance of between-group comparisons was analyzed using Student's *t*-test and *Q*-values were calculated from corresponding *P*-values to control the false discovery rate (FDR) that may occur when testing multiple hypotheses[17]. Differential gene expression between tumors and normal epithelia were deemed to be significant at $P < 0.01$ for initial screening and $P < 0.001$ for individual gene candidates. Class prediction was examined using the BRB-Array Tools package (version 3.6) available at http://linus.nci.nih.gov/BRB-ArrayTools.html. All computations were performed using R statistical programming language (http://cran.r-project.org/) and the Bioconductor packages.

RESULTS

Differentially expressed genes relative to molecular changes and clinicopathological features

Assays for genes differentially expressed relative to molecular changes and clinicopathological features (Tables 2 and 3) showed that tumor location was associated with the highest numbers of differentially expressed genes. When we compared the right colon with the left colon and rectum taken together, we found that 1628 genes were differentially expressed, and when we compared the right colon with the left colon and rectum considered separately, we found that 1263 genes were differentially expressed. The next greatest extent of differential gene expression was seen when lymphovascular or neural invasion (LVI) of tumor cells occurred, and an analysis by defects in MMR yielded the next largest differentially expressed gene set. The differentially expressed genes significantly associated with canonical tumorigenesis and tumor progression are

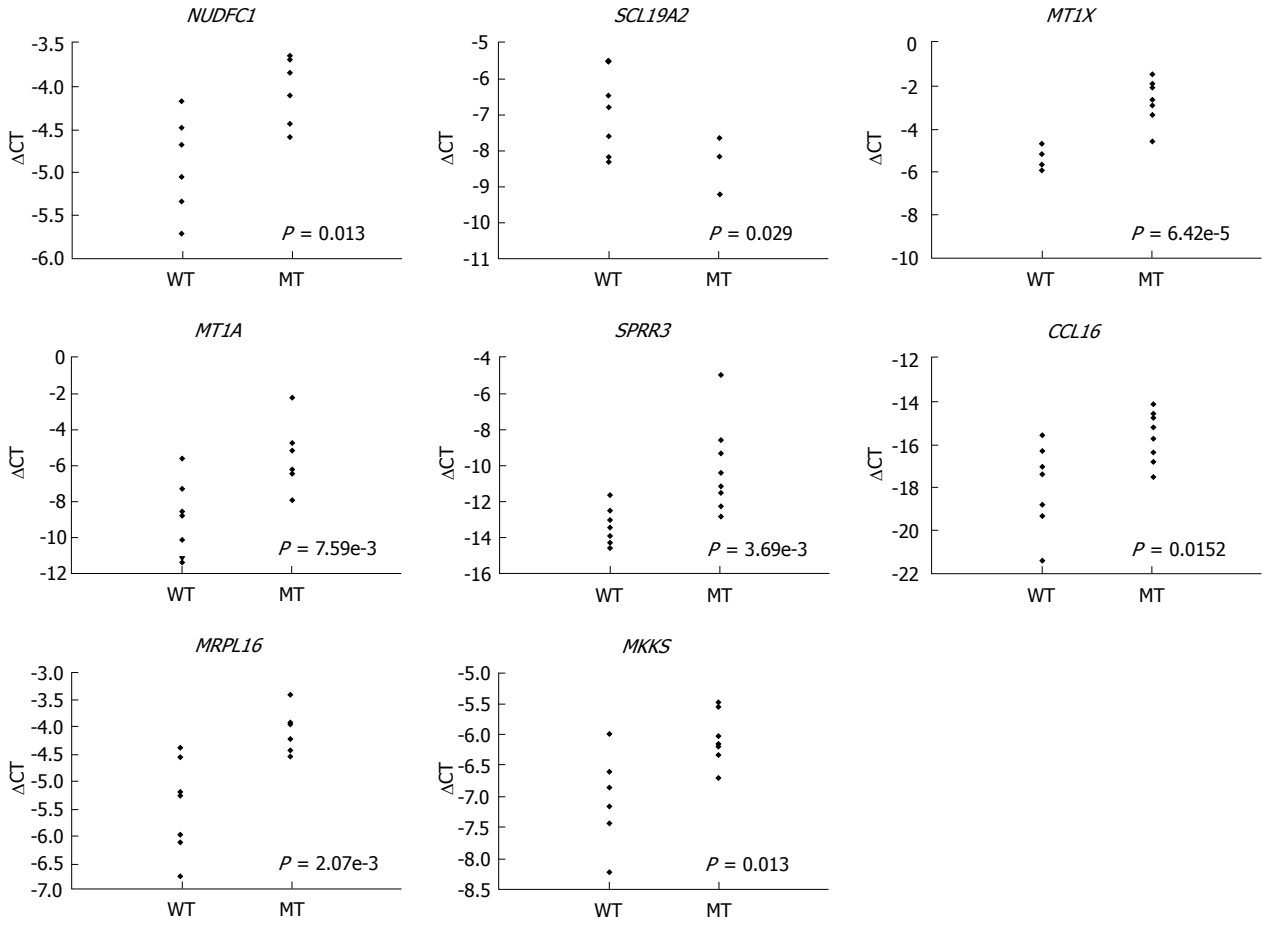

Figure 1 Quantitative RT-PCR of selected genes associated with molecular changes and clinicopathological features from microarray gene expression data. These were *NUDFC1* and *SCL19A2* (with *APC* mutations), *MT1X* and *MT1A* (with MMR defects), *SPRR3* (with crossover), *CCL16* (with lymphovascular or neural invasion), and *MRPL16* and *MKKS* (with synchronous adenoma). Genes differentially expressed between two groups were selected and their expression patterns measured using RT-PCR. WT: Without molecular or clinicopathological changes; MT: Molecular or clinicopathological changes. *P*-values from unpaired *t*-tests are shown.

collectively shown in Table 3. The differential expression of several candidate and novel genes was confirmed by real time RT-PCR (Figure 1).

Gene sets associated with APC and Wnt pathways

APC mutations are related to expression of constituents of the extracellular matrix (ECM) and to formation of the axonemal dynein complex, whereas Wnt-associated alterations are associated with the immune response, ECM formation, and filopodium expression. In addition, changes in pyruvate and arginine/proline metabolism have been associated with *APC* mutations; whereas alterations in G-protein receptor binding, the activities of various chemokines, phosphatase binding efficiency, and glycolysis/gluconeogenesis rates are associated with mutations in *Wnt*. We found that upregulation of three genes (*CDH7*, *DYRK1A*, *PISD*) and downregulation of one (*SLC19A2*) were associated with APC mutations, whereas upregulation of two genes (*PRAF2*, *CD99L2*) and downregulation of one (*FOXF1*) were associated with Wnt-activated changes ($P < 0.001$).

Gene set alterations associated with the MMR and RAF pathways

Biologically, MMR defects affect the immune response (including antigen processing), chromosome functions, and cytoskeleton structure, whereas RAF-mediated alterations are related to thyroid hormone generation and cytoplasmic effects. Cadmium and copper ion binding, MHC class Ⅱ receptor activity, and fatty acid metabolism have been associated with MMR defects, and protein dimerization activity with RAF-mediated alterations. We found that four upregulated genes (*MT1X*, *MT1A*, *SST*, *TDG*) and three downregulated genes (*HMGB1*, *SUGT1*, *VTI1B*) were associated with MMR defects, and that two were upregulated (*PPP1R13L*, *CAST*) and one was downregulated (*RAB22A*) in association with RAF-mediated alterations ($P < 0.001$).

Gene set alterations associated with p53 and crossover pathways

Alterations in p53 have been associated with the immune response (including antigen processing), ECM structure, and sensory perception, whereas crossover was related to cell cycle stage and protein localization. MHC class I receptor activity, oxidoreductase activity, and glycolysis were associated with p53 alterations, and protein kinase binding and renyltransferase activity were associated with crossover. No upregulated but three downregulated genes (*HLA-F*, *XRCC3*, *CCDC24*)

Table 2 Number of differentially expressed genes in terms of molecular changes and clinicopathological features

Parameters	No. of patients (missing)	No. of differentially expressed genes (P < 0.01), total (up/down)
Molecular changes[1], -/+		
APC mutations	55/27 (2)	83 (41/42)
Wnt-activated	45/38 (1)	82 (37/45)

LVN invasion, -/+	57/27	279 (147/132)

[1]Wnt-activated: explored by β-catenin assay, AXIN2 measurement, and GSK-3β immune staining; MMR defect: analyzed by MSI assay, MLH1 5'-promoter measurement or 3'-methylation, and MLH1 or MSH2 immune staining; RAF-mediated alterations: assayed by detection of mutations in *BRAF* V600E and *KRAS* exons 12 and 13, and MEK immune staining; Crossover: When a tumor carried both APC/Wnt-mediated alterations and MMR defects or RAF-mediated alterations. [2]R: Caecum-splenic flexure of transverse colon; L: Splenic flexure of transverse colon-sigmoid colon; P: Rectum. [3]According to the American Joint Committee on Cancer (6th ed., 2001). WD, MD, PD, and muc, well-, moderately-, poorly-differentiated, and mucinous; MMR: Mismatch repair.

were associated with p53 alterations, whereas four upregulated genes (*NID2*, *EGLN3*, *NIBP*, *SPRR3*) and three downregulated genes (*ITIH1*, *CFH*, *ABI3BP*), were associated with crossover ($P < 0.001$).

Tumor location-specific analysis shows distinct patterns of gene expression

As colon tumor location had a very marked effect on differential gene expression, genes differentially expressed as a result of particular molecular changes and clinicopathological features may be concealed by tumor location. Interestingly, the number of genes differentially expressed as a result of tumor location increased slightly in association with several clinicopathological variables, although the sample size was much smaller (about one-third, data not shown) than those of other tumor sets. More importantly, most molecular changes had distinct location-associated effects on gene expression, but these were sometimes accompanied by contradictory effects. For example, p53 alterations inhibited the expression of antigen presentation-related genes only in right colon cancers, but had no effect in left colon or rectal cancers (Figure 2). After separation into classes showing various molecular and clinicopathological characteristics, the accuracy of binary outcome prediction was estimated using seven different machine learning algorithms available at BRBArrayTools. As expected, the best prediction accuracy (85%-94%) was achieved by tumor location (Table 4), followed by MMR defects (76%-83%). Most of the other molecular and clinicopathological variables had prediction accuracies < 75%. The prediction accuracies for each variable were

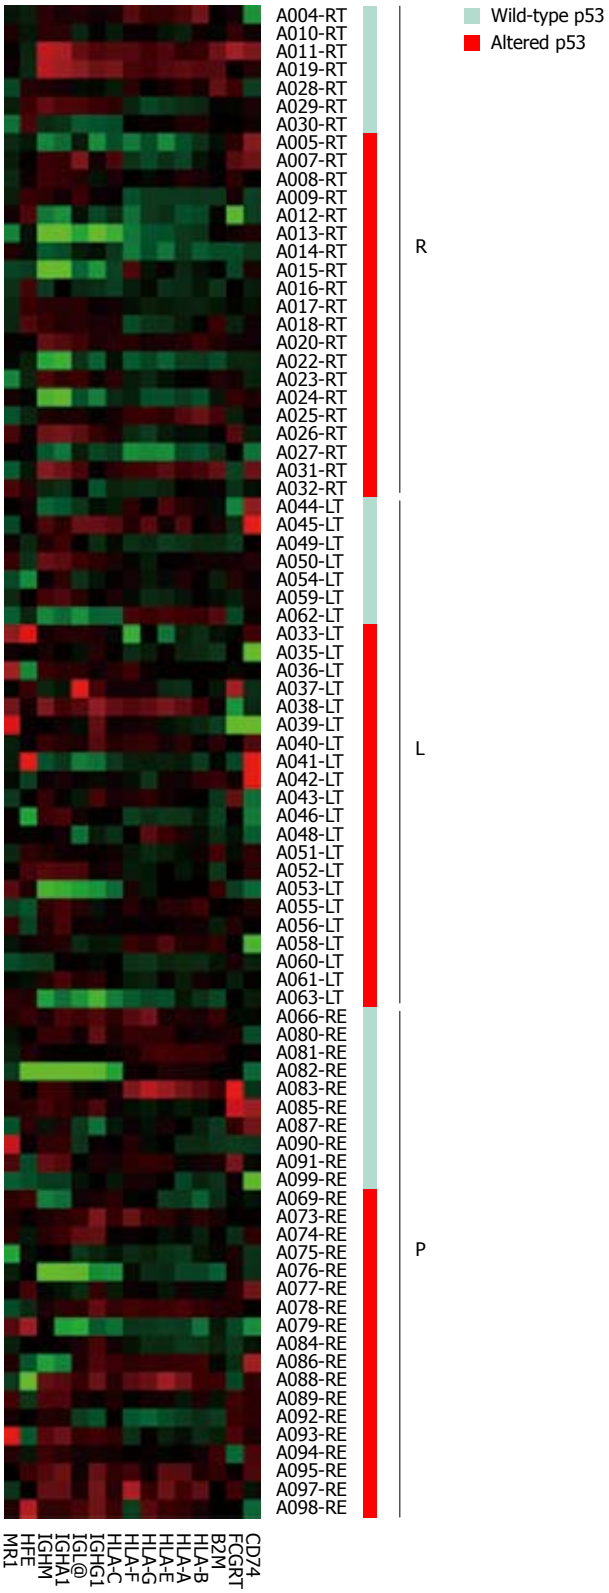

Figure 2 Pattern of expression of genes in the "antigen presentation, endogenous antigen" gene set as distinguished by tumor location and p53 status. Protein p53 alterations in the ascending colon coordinately decreased the expression of genes in the gene set whereas p53 alterations in the descending colon or rectum had no effect on gene expression. R: Cecum-splenic flexure of transverse colon; L: Splenic flexure of transverse colon-sigmoid colon; P: Rectum.

[1]Differential gene expression in tumor tissues compared to normal epithelia was examined in terms of molecular changes and clinicopathological features, as was considered to be significant when $P < 0.001$; [2]When a tumor carried both APC/Wnt-mediated alterations and MMR defects or RAF-mediated alterations; [3]According to the American Joint Committee on Cancer (6th ed., 2001).

also examined after restricting the analysis by the three tumor locations mentioned above. As expected, location-specific analysis generally increased the prediction accuracy significantly (Figure 3), especially in the case of variables associated with synchronous adenoma, tumor stage, RAF-mediated changes, and Wnt-activated alterations. Accuracy, however, decreased when variables associated with *APC* mutations, p53 alterations, and crossover, were analyzed.

Clinicopathological features correlated with genomic alterations

Biologically, we found that tumor stage was related to antigen presentation, cell adhesion and migration, bone mineralization, and epithelial cell differentiation, and that lymphovascular or neural invasion was related to cell adhesion, immune response, and sensory perception. We also found that serine-type enzyme activities, high-density lipoprotein binding, pancreatic RNase activity, and glycolysis/gluconeogenesis were related to tumor stage, and that various structural molecules, hormones, serine-type enzyme activities, phosphate transport, the metabolism of the ECM and related molecules, and high density lipoprotein binding were related to lymphovascular or neural invasion. Synchronous adenoma was related to protein biosynthesis, ribosomal

Table 4 Class prediction accuracies (%) relative to molecular changes and clinicopathological features

[1]Number of classifier genes. CCP: Compound covariate predictor; DLDA: Diagonal linear discriminant analysis; 1-NN: One nearest-neighbor; 3-NN: Three nearest-neighbor; NC: Nearest centroid; SVM: Support vector machine; BCCP: Bayesian compound covariate predictor; LVN: Lymphovascular or neural.

proteins, and MHC class I receptor activity. We found that five genes (*PNPT1*, *BAI2*, *VEGFC*, *RPS6K6A*, *FGF5*) were upregulated and three (*ADCY1*, *ATAD3B*, *CAP1*) were downregulated in association with tumor stages; that two genes (*CCL16*, *NOTCH3*) and four genes (*MMP12*, *RAP1GDS1*, *STOML1*, *DHPS*) were up- or down-regulated, respectively, in association with lymphovascular or neural invasion, and that five genes (*PARP2*, *MRPL21*, *MRPL16*, *MKKS*, *LHX2*) were upregulated but no gene was downregulated in association with synchronous adenoma ($P < 0.001$).

DISCUSSION

Distinctive molecular changes, such as *APC* mutations and MMR defects, are respectively associated with two types of hereditary colorectal cancers, familial adenomatous polyposis and hereditary non-polyposis colorectal cancer. Although these hereditary tumors constitute fewer than 5%-8% of all colorectal cancers, the molecular changes identified in hereditary tumors are important in sporadic colorectal cancers[14,18,19]. The tumor suppressor APC is the major regulator of canonical Wnt signaling; these two proteins form a multi-protein complex encompassing kinases such as GSK-3β, CK1, and Axins, to prevent colorectal tumorigenesis[5]. Mutations in the oncogenes *RAF* and *RAS* are closely associated with MMR defects, and may act as alternative tumor-initiating steps that synergize with DNA methylation and occur within the context of serrated polyps[19,20]. The p53 protein, which normally induces G1 cell cycle arrest to facilitate DNA repair during replication, cannot induce cell cycle arrest when mutated in later stages of the adenoma-carcinoma sequence, thus leading to cell proliferation[21].

In our study, ECM interactions and the immune response were down- and up-regulated in tumors with *APC* mutations and Wnt-activated alterations, respectively. Gene set analysis earlier showed that the structural motif of osteopontin mediated critical cell-matrix and cell-cell signaling whose transcriptional regulation involves multiple pathways including Wnt/β-catenin/APC/GSK-3β/Tcf-4[22]. Expression of the E-cadherin β-catenin was observed in dendritic cells and loss of E-cadherin adhesion triggered a functionally distinct pathway of maturation linked more closely to the maintenance of tolerance than to the initiation of immunity[23]. In $Apc^{Min/+}$ mice, in which *APC* mutations are upregulated, dietary arginine increased colon tumorigenesis[24]. Amongst the eight genes we identified that were associated with *APC* mutations and Wnt activation, we found that one, *PISD*, was a novel gene upregulated in tumor cells with these alterations. Phosphatidylserine decarboxylation may provide a functionally important source of phosphatidylethanolamine in mitochondria[25].

We found that MMR defects correlated positively with an enhanced immune response and metal ion binding, whereas RAF alterations correlated with activation of cellular processes and thyroid hormone generation. Many tumor-infiltrating lymphocytes are present in MSI+ tumors, along with activated CD8+ cytotoxic T cells[26,27]. Furthermore, tumor-specific peptides generated by MSI may be involved in anti-tumor immune responses and may be useful in the diagnosis and treatment of patients with MSI+ colorectal cancers[27]. The deleterious effects of Cd2+ reported to date include generation of reactive oxygen species, inhibition of DNA repair, depletion of glutathione, and alteration of apoptosis[28]. In contrast, RAS/RAF/MEK/ERK-transduced signals can initiate cellular processes directed towards either proliferation or differentiation, depending on signal intensity and duration[29]. *RAF* mutations are associated with advanced clinical stages and early recurrence in patients with papillary thyroid cancer[30]. Amongst the genes up-regulated by MMR defects are the metallothionein genes, including *MT1X* and *MT1A*, which are expressed differentially in various tissues, during several developmental stages, and in response to metals, steroids, and stress[30]. Several of these genes, including *MT1X*, were overexpressed in MSI+ colorectal and gastric cancers[31].

We found that alterations in p53 downregulated immune responses and ascorbic acid binding. Anti-p53 IgG has been detected in the sera of subjects with various types of cancer, indicating induction of anti-p53 CD4+ Th cells[32]. Ascorbic acid can block the effects of TNF-α on endothelial cell proliferation and apoptosis

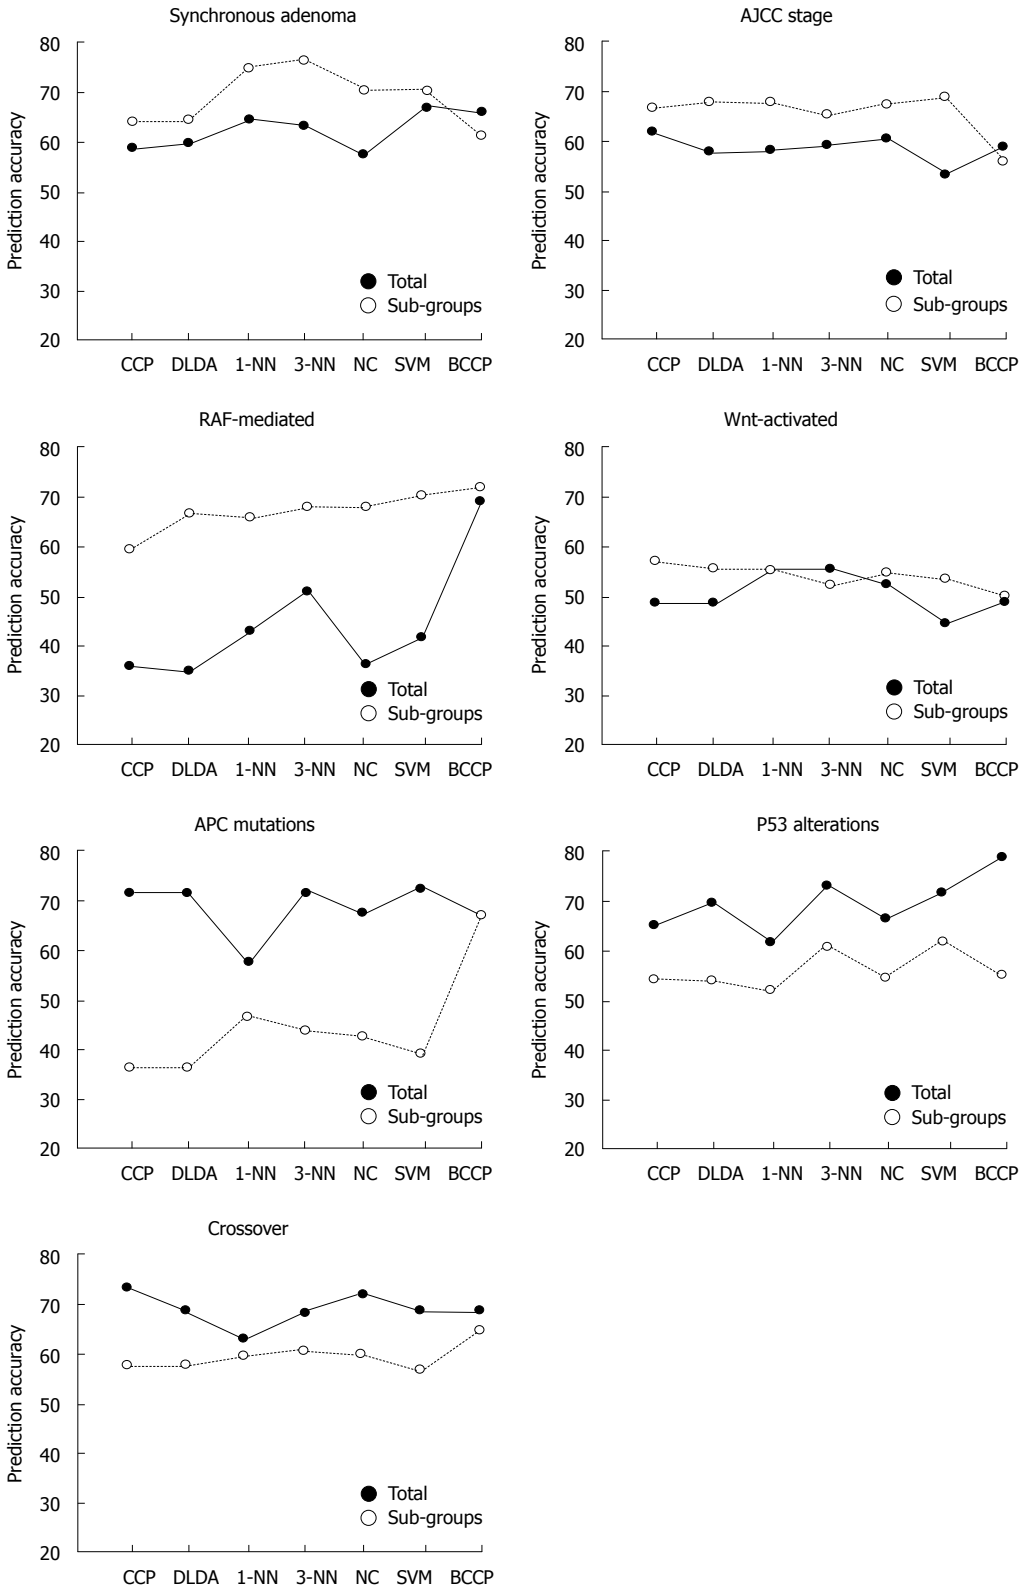

Figure 3 Accuracy of class prediction increases with tumor location-specific analysis. Samples were divided into three subgroups corresponding to three tumor locations (right colon, left colon, and rectum). Class prediction was performed using either all samples or samples within each subgroup. For tumor location-specific analysis, the results of class prediction (true or false) from each of the three locations were combined to calculate the overall prediction accuracy. Ten genetic or clinicopathological parameters were analyzed.

by inhibiting TNF-α-induced p53 expression and Rb hypophosphorylation, as well as by promoting collagen IV production[33]. We also observed that the crossover pathway between APC/Wnt-activated and MMR defects or RAF-mediated alterations, which has rarely been observed in human colorectal cancers, was associated with cell cycle and protein localization. Recently, mice carrying compound *Apc* and *Ras* mutations were characterized as having a striking increase in intestinal tumor multiplicity and progression, compared with *Apc*-only mutant animals[12]. Amongst the seven genes we identified as associated with the crossover pathway, one, *NIBP*, was a novel gene upregulated in tumor cells with these alterations. NIBP has been reported to enhance the cytokine-induced NF-κB signaling pathway by interacting with NIK and IKKβ[34], which may activate the TNF-induced invasive activity of tumor cells.

Embryologically, the right and left colon has different

origins, the midgut and hindgut, respectively, and is supplied by different circulation and innervation[35]. We found that tumor location was the dominant factor for differential gene expression in colorectal cancers. Thus, location-specific analysis may more precisely discriminate between alterations in gene expression caused by canonical molecular changes. The dependence of gene expression differences on tumor location has been reported previously[36-39]. The dominant expression pattern has been shown to be consistent with different embryonic origins and a second pattern reveals a gradual change from the caecum to the rectum[39]. We found that the prediction accuracy by tumor location-specific analysis was increased using analyses by synchronous adenoma, tumor stage, and RAF-mediated and Wnt-activated alterations, but decreased by analyses using *APC* mutations and p53 alterations. These findings suggest that *APC* mutations and p53 alterations may affect tumorigenesis as initiators and terminators, respectively, along the entire colon. In the absence of *APC* mutations and p53 alterations, however, synchronous adenoma, tumor stage, RAF-mediated changes, and Wnt-activated alterations may determine tumorigenesis at different locations. In addition, we found that several biological processes were affected differently by tumor location, often in opposite senses. One of the most significantly altered biological processes was the immune response. We observed that genes involved in the immune response were coordinately downregulated in left colon cancers with p53 alterations but not in right colon or rectal cancers. The same trend was observed with *APC* mutations, but the opposite trend was observed with MMR defects. Location-specific analysis also allowed the prediction of gene class by expression profiling in 6 of 10 parameters in our analysis, and in agreement with previous findings[38]. Gene expression profiling has been used to predict metastasis or recurrence in patients with stage Ⅱ colon cancer, thus enhancing the selection of chemosensitive patients for adjuvant chemotherapy[40,41]. Our finding that distinct molecular pathways of tumorigenesis occur in right and left colon cancers suggests that prediction of responsiveness to adjuvant therapy will benefit from location stratification.

In our study, both tumor stage and lymphovascular or neural invasion were associated with antigen presentation, ECM metabolism, and cellular and extracellular processes that determine tumor initiation and progression. Amongst the 14 differentially expressed genes associated with these biological functions, one encodes CCL16, a chemoattractant for monocytes and lymphocytes that can increase tumor rejection, antigen presentation by macrophages, T cell cytotoxicity, and the angiogenic activity of vascular endothelial cells[42]. *BAI2* and *STOML1* are novel genes, upregulated in advanced cancers and downregulated in lymphovascular and neural tumor invasion, respectively. Human BAI2, probably a G-protein-coupled receptor in the brain, participates in the early stages of neovascularization of the cerebral cortex after ischemia[43]. The stomatin homolog (UNC-24) of *C. elegans*, a protein similar to the human stomatin homolog STOML1 (SLP-1), is required for normal locomotor response to volatile anesthetics and contains a region of sequence homologous to the nonspecific lipid transfer protein[44].

As the traditional adenoma-carcinoma sequence, which is instigated in adenomas (or aberrant crypt foci) by the APC-Wnt signaling pathway, accounts for more than two-thirds of all colorectal cancers[3], we examined the molecular association of tumorigenesis in patients with synchronous adenoma. We found that three novel genes, *MRPL21*, *MRPL16*, and *MKKS*, were upregulated in tumors with synchronous adenoma. A mitochondrial ribosomal protein, MRPL21, arrests the cell cycle by increasing p21WAF1/CIP1 and p27Kip1 levels under growth inhibitory conditions[45]. The *MRPL16* gene originated *via* duplication of a pre-existing mitochondrial ribosomal protein gene as well as by recruitment of some DNA sequence from outside of the mitoribosomal genome[46]. McKusick-Kaufman syndrome (MKKS) is a human developmental anomaly syndrome featuring hydrometrocolpos, postaxial polydactyly, and congenital heart disease[47]. In protein biosynthesis, MKKS is similar in function to type Ⅱ chaperonins, which are responsible for folding a wide range of proteins[48].

In conclusion, we found that the differential expression of 47 genes was associated with canonical molecular changes and clinicopathological characteristics of sporadic colorectal cancers, possibly constituting alternative or subordinate pathways of tumorigenesis and tumor growth. Currently, the seven novel genes of our study that correlate with tumorigenesis and tumor growth, are functionally assessed to be possible candidates as diagnostic or therapeutic targets for colorectal cancers. Amongst these biological processes, the immune response was uniformly involved in all molecular changes, that is, APC/Wnt-activated alterations, changes arising from MMR defects, RAF-mediated changes, and p53-caused alterations. As tumor location was the dominant factor for differential gene expression in colorectal cancers, location-specific analysis may precisely discriminate particular gene expression profiles and enhance the accuracy of tumor class prediction.

COMMENTS

Background

Although various molecular changes have been identified in colorectal cancers, a clear pattern is detected in only 6.6% of these tumors, indicating the need to identify alternative or subordinate pathways involved in colorectal tumorigenesis and tumor growth.

Research frontiers

To identify alternative or subordinate pathways involved in colorectal tumorigenesis and tumor growth, this study assessed gene expression patterns, relative to canonical molecular changes and clinicopathological features, in patients with colorectal tumors. Individual steps and pathways were sorted into various biological processes.

Innovations and breakthroughs

The largest number of genes identified as differentially expressed was by tumor location, and the next largest number by lymphovascular or neural invasion of tumor cells and by mismatch repair (MMR) defects. Amongst biological

processes, the immune response was significantly implicated in entire molecular changes observed during colorectal tumorigenesis ($P < 0.001$). Amongst 47 differentially expressed genes, seven (*PISD*, *NIBP*, *BAI2*, *STOML1*, *MRPL21*, *MRPL16*, and *MKKS*) were newly found to correlate with tumorigenesis and tumor growth. Most location-associated molecular changes had distinct effects on gene expression, but the effects of the latter were sometimes contradictory.

Applications

This study found that the differential expression of 47 genes was associated with canonical molecular changes and clinicopathological characteristics of sporadic colorectal cancers, possibly constituting alternative or subordinate pathways of tumorigenesis and tumor growth. The seven novel genes of this study correlate with tumorigenesis and tumor growth and can functionally be assessed as possible candidates for diagnostic or therapeutic targets of colorectal cancers.

Terminology

The cDNA microarray becomes a fundamental tool to gain direct molecular insight into tumorigenesis. Additionally, as phenotypic diversities of cancer occur from genetic alterations, genomic expression profiling might have been recognized as the first step to find useful therapeutic targets.

Peer review

This paper describes alternative or subordinate pathways involved in colorectal tumorigenesis and tumor growth, constituting an individual geno-pathogenesis map for colorectal cancer. As the study strengthened tumor location as a dominant factor for differential gene expression in colorectal cancers, location-specific analysis precisely discriminate particular gene expression profiles, possibly providing individual responses to respective regimen. It's an interesting paper.

Abstract

AIM: To investigate the effect of activation of canonical Wnt signaling pathway on the proliferation and differentiation of hepatic oval cells *in vitro*.

METHODS: WB-F344 cells were treated with recombinant Wnt3a (20, 40, 80, 160, 200 ng/mL) in serum-free medium for 24 h. Cell proliferation was measured by Brdu incorporation analysis; untreated WB-F344 cells were taken as controls. After treatment with Wnt3a (160 ng/mL) for 24 h, subcellular localization and protein expression of β-catenin in WB-F344 cells treated and untreated with Wnt3a were examined by immunofluorescence staining and Western blot analysis. *CyclinD1* mRNA expression was determined by semi-quantitative reverse-transcript polymerase chain reaction (RT-PCR). The mRNA levels of some phenotypic markers (*AFP*, *CK-19*, *ALB*) and two hepatic nuclear factors (*HNF-4*, *HNF-6*) were measured by RT-PCR. Expressions of CK-19 and AFP protein were detected by Western blot analysis.

RESULTS: Wnt3a promoted proliferation of WB-F344 cells. Stimulation of WB-F344 cells with recombinant Wnt3a resulted in accumulation of the transcriptional activator β-catenin, together with its translocation into the nuclei, and up-regulated typical Wnt target gene *CyclinD1*. After 3 d of Wnt3a treatment in the absence of serum, WB-F344 cells retained their bipotential to express several specific phenotypic markers of hepatocytes and cholangiocytes, such as AFP and CK-19, following activation of the canonical Wnt signaling pathway.

CONCLUSION: The canonical Wnt signaling pathway promotes proliferation and self-renewal of rat hepatic oval cells.

INTRODUCTION

The liver is an organ with a remarkable regenerative capacity, provided by preexisting hepatocytes and cholangiocytes under normal conditions[1]. However, viral infection, alcohol, some drugs and self-immunity may cause liver inflammation and fibrosis. When the regenerative ability of hepatocytes to divide and replace the damaged tissue is compromised, oval cells are activated, and then may give rise to both hepatocytes and biliary epithelial cells[2,3]. Oval cell activation and proliferation serve as a source of cell replenishment and tissue repair as they differentiate into functional mature hepatocytes, thus aiding in the process of liver regeneration[4,5]. Therefore, oval cells are also designated as facultative hepatic stem cells because they proliferate only in response to chronic regenerative stimuli and have bipotential differentiation capabilities for both hepatocytes and cholangiocytes[6,7]. Although oval cells are usually found in normal human fetal livers, they are also observed in numerous hepatic pathologies[8,9]. Oval cell activation in malignancies such as hepatocellular carcinoma (HCC) and cholangiocarcinoma is of special relevance in light of the theories supporting the existence of cancer stem cells, which may serve as a tumor source, or as a mechanism

of cancer recurrence or metastasis[10,11]. However, little is known about the signaling mechanisms involved in oval cell proliferation and differentiation.

The canonical Wnt signaling pathway is highly conserved throughout animal development, during which it exerts pleiotropic effects on cell proliferation, differentiation, and polarity or migration[12]. The Wnt signaling pathway, identified recently, critically regulates various postnatal stem cell compartments, including the hematopoietic, skin, and enteric systems. In this respect, it has been demonstrated that hematopoietic stem cells maintain an undifferentiated self-renewing state through constitutive activation of the canonical Wnt signaling pathway with Wnt3a, a prominent member of the Wnt family[13,14]. In the liver, there is accumulating evidence that Wnt/β-catenin signaling plays a central role in various aspects of hepatic biology, including liver development, regeneration, growth, and oncogenesis. During liver development, β-catenin critically regulates hepatic progenitor cell proliferation, and over-expression or inhibition of β-catenin either increases or decreases the overall liver size, respectively[15-19]. Studies of pathological specimens and rodent models of liver diseases have demonstrated aberrations in the Wnt/β-catenin signaling pathway in conditions ranging from hepatitis to HCC[20]. However, no studies have definitively addressed the role of canonical Wnt signaling in proliferation and differentiation of hepatic oval cells. Therefore, we hypothesize that Wnt signaling can regulate the proliferation and differentiation of oval cells.

WB-F344, a rat hepatic stem-like epithelial cell line, isolated from the liver of an adult male Fischer-344 rat, can express a phenotypic repertory of both hepatocytes and bile duct epithelial cells compared with those of normal hepatocytes, biliary epithelial (ductular) and "oval" cells isolated from liver treated with chemical carcinogens. The phenotypic properties of cultured liver epithelial cell line most resemble those of the "oval" cells. Thus, it is considered to be an *in vitro* model of bipotent oval cells as it shares their phenotype[21,22]. After transplantation into livers of adult syngeneic German-strain Fischer-344 rats that are deficient in bile canalicular enzyme dipeptidyl peptidase Ⅳ (DPP-Ⅳ), WB-F344 cells integrate into hepatic plates and differentiate into mature hepatocytes[23]. Moreover, when treated with sodium butyrate and cultured on Matrigel, WB-F344 cells can differentiate along the biliary phenotype *in vitro*[24]. In the present study, we provided direct evidence for the activation of canonical Wnt signal transduction in WB-F344 cells in response to Wnt ligands, and showed that activation of canonical Wnt signaling regulates the proliferation and bipotential of WB-F344 cells. A better understanding of its role in hepatic stem cell proliferation and differentiation can lead to the successful manipulation of liver biology for therapeutic purposes.

MATERIALS AND METHODS

Cell line culture

The rat hepatic oval cell line (WB-F344) was obtained from Academy of Military Medical Sciences. The cells were cultured in Dulbecco's modified Eagle's medium/F12 (Invitrogen, Carlsbad, CA), supplemented with 10% fetal bovine serum (Gibco BRL, USA), 10 mL of 200 mmol/L L-glutamine and 0.5 mL of penicillin-streptomycin mixture. All cultures were maintained at 37℃ in 50 mL/L CO_2.

Proliferation test (Brdu incorporation assays)

Cell proliferation was detected by Brdu incorporation assays. A total of 6000 WB-F344 cells were seeded into 96-well culture plates. Cells were brought to 90% confluence and then fasted overnight in serum-free media before addition of Brdu to a final concentration of 10 μmol/L. Two hours later, the cells were stimulated with escalating doses of Wnt3a (R&D, Systems, Inc) (20, 40, 80, 160, and 200 ng/mL) for 24 h, washed free of BrdU and harvested. The cells were fixed with 4% paraformaldehyde for 30 min, blocked with 1% BSA in phosphate-buffered saline containing 0.2% Triton X-100 for 30 min, incubated with a HRP-Brdu antibody (1:200) for 2 h at 37℃, and washed. A TMB substrate solution was added to the wells and color developed in proportion to the amount of Brdu bound. The stop solution changed the color from blue to yellow, and intensity of the color was measured at 450 nm with a spectrophotometer.

Immunofluorescence staining

For subcellular localization of β-catenin by immunocytochemistry, WB-F344 cells were plated onto chamber slides resulting in 90% confluence, and then fasted overnight in serum-free media before the addition of 160 ng/mL Wnt3a (R&D, Systems, Inc). The cells were fixed with 4% paraformaldehyde for 30 min at 37℃. Permeabilization of the cells was achieved after incubation for 30 min at 37℃ with PBS containing 0.2% Triton X-100. To minimize nonspecific binding of the antibody, blocking was carried out with a buffer containing 1% bovine serum albumin for 1 h. β-catenin antibody (R&D, Systems, Inc) was applied at a 1:25 dilution for 90 min at 37℃. As a negative control, PBS was used instead of the primary antibody to exclude the unspecific binding of the secondary antibody. No fluorescent labeling was observed in the negative control. After repeated washing with PBS, the cells were incubated with a goat-anti-mouse antibody labeled with fluorescein isothiocyanate (1:10) for an additional 30 min. Finally, cell nuclei were counterstained with Hoechst 33258. Images were obtained using a confocal laser scanning microscope.

RNA isolation and reverse-transcription polymerase chain reaction (RT-PCR)

WB-F344 cells were brought to 90% confluence and then fasted overnight in serum-free media. After stimulation with or without Wnt3a, cells were cultivated for 1 and 3 d, respectively. Total RNA was extracted from WB-F344 cells treated with Wnt3a with Trizol according to the manufacture's instructions. RNA (1 μg) was reverse

transcribed. For semi-quantitative PCR, the number of cycles corresponded to the mid-logarithmic phase. Primers were designed using GenBank sequences (Table 1). PCR amplification was performed using PCR Master Mix (Taqman) according to the manufacturer's instructions. PCR products were analyzed by electrophoresis on a 2% agarose gel.

Western blot analysis

After stimulation with Wnt3a, cells were cultivated for 1 and 3 d, respectively. Trypsinized protein was isolated using a lysis buffer (50 mmol/L Na_2HPO_4, 50 mmol/L NaH_2PO_4, 0.2 mol/L NaCl, 5 mmol/L EDTA, 1% Triton X-100, pH 6.0). After incubation on ice for 30 min, samples were centrifuged at 13000 r/min for 20 min at 4℃. Then, a 2 × dithiothreitol (DTT) loading buffer containing 0.4 mol/L Tris (pH 6.8), 4% SDS, 20% glycerol, and 10% DTT was added to the sample supernatants, and incubated for 5 min at 95℃. Following electrophoretic separation by 10% SDS-polyacrylamide gel electrophoresis, proteins were electroblotted onto nitrocellulose membranes. The membranes were blocked in a NET buffer (150 mmol/L NaCl; 5 mmol/L EDTA, pH 8.0; 50 mmol/L Tris/HCl, pH 7.5; 0.05% Triton X-100) containing 2.5% gelatin (Merck) for 1 h at room temperature. Polyclonal antibodies against β-catenin (R&D, Systems, Inc), cytokeratin-19 (CK-19) (Santa Cruz Biotechnology Inc), AFP (Santa Cruz Biotechnology Inc) were used at a dilution of 1:25 (β-catenin), 1:200 (AFP, CK-19) and 1:400 (β-actin), respectively, and incubated for 1 h at room temperature. Thereafter, the membranes were washed in a NET buffer, and further incubated with a peroxidase-conjugated antibody at a dilution of 1:20000. Antibody binding was visualized by DAB. The bands were semi-quantitatively evaluated by densitometric analysis. Protein expression levels of β-catenin were thereby normalized to those of the housekeeping gene β-actin.

Differentiation assay

WB-F344 cells grown in a Wnt3a-containing medium in the absence of serum were cultured with or without Wnt3a for 3 d. The medium was changed every day. After 3 d of coculture, total Mrna and protein were extracted and analyzed for expression of CK-19, ALB, AFP by RT-PCR and Western blot analysis.

Statistical analysis

All results were expressed as mean ± SD. Measurement data were analyzed using one-way analysis of variances (ANOVA, SPSS 11.5). $P < 0.05$ was considered statistically significant.

RESULTS

Activation of the Wnt pathway, accumulation of β-catenin, its translocation into nuclei, and transcriptional activation of Wnt target genes

To investigate whether treatment of WB-F344 cells with recombinant Wnt3a (160 ng/mL) influences β-catenin in WB-F344 cells at the protein level, we monitored the expression of β-catenin by semi-quantitative Western blot analysis. Accumulation of β-catenin protein (1.2-fold) was observed 1 d after addition of 160 ng/mL Wnt3a (Figure 1A). To confirm the data obtained by Western blot analysis and prove whether Wnt3a stimulation has any influence on the subcellular localization of β-catenin, immunocytochemistry was performed. Clear nuclear staining for β-catenin was observed after treatment with 160 ng/mL Wnt3a for 1 d, suggesting that Wnt3a stimulation is responsible for the accumulation of β-catenin and its translocation from cytoplasm into nuclei (Figure 1B). To evaluate whether Wnt3a-mediated accumulation of β-catenin would result in the activation of typical Wnt target genes, the mRNA expression levels of *CyclinD1* was semi-quantified by RT-PCR 1 d after Wnt3a stimulation (160 ng/mL). A significant induction in CyclinD1 was observed (Figure 2). These findings indicate that activation of the Wnt pathway in WB-F344 cells can result in accumulation of β-catenin, its translocation into nuclei, and enhanced expression of Wnt target genes.

Effect of Wnt3a on WB-F344 cell proliferation

To determine whether WB-F344 cells respond to Wnt ligand stimulation with activation of the canonical

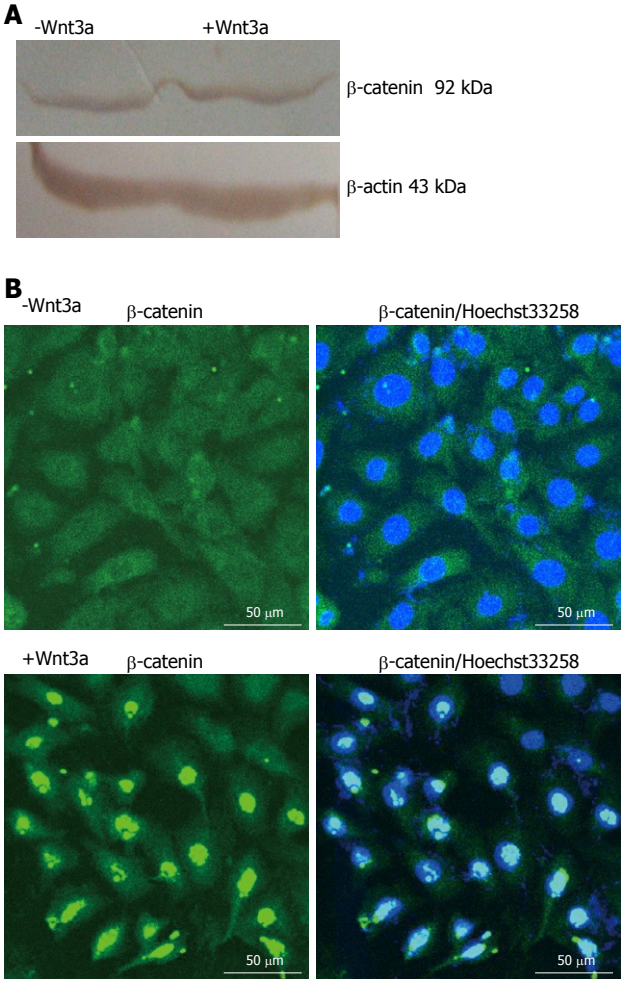

Figure 1 Effects of Wnt3a on β-catenin expression, its subcellular localization, and induction of typical Wnt target genes. A: Stimulation of WB-F344 cells with 160 ng/mL Wnt3a for 1 d revealing a slight increase in β-catenin protein level as shown by Western blot analysis and densitometric analysis; B: Immunocytochemistry analysis of β-catenin exhibiting perinuclear staining for β-catenin in unstimulated WB-F344 cells (upper panels), whereas addition of 160 ng/mL Wnt3a for 1 d (lower panels) showing clear nuclear staining for β-catenin. Immunofluorescence was performed using a polyclonal antibody against β-catenin (left panels). In addition, nuclei of WB-F344 cells were stained with Hoechst33258 (right panels). Scale bars: 50 μm.

Wnt pathway, WB-F344cells in culture were stimulated by purified Wnt3a protein. Brdu incorporation assays were performed to determine whether Wnt stimulates the proliferation of WB-F344 cells. After serum starvation, Wnt3a stimulation of WB-F344 cells resulted in significantly more uptake of Brdu compared with controls in the absence of serum. The proliferation of WB-F344 cells increased after the addition of Wnt3a, and reached its peak at 160 ng/mL Wnt3a (Figure 3). To evaluate whether the expression of Wnt target gene CyclinD1 is directly correlated with the proliferation of WB-F344 cells, the mRNA expression level of *CyclinD1* was determined by semi-quantitative RT-PCR 1 d after Wnt3a stimulation (160 ng/mL). A significant up-regulation of CyclinD1 expression was observed, suggesting that CyclinD1 has a major impact on the proliferation of WB-F344cells. These findings indicate that proliferation of WB-F344 cells is stimulated by

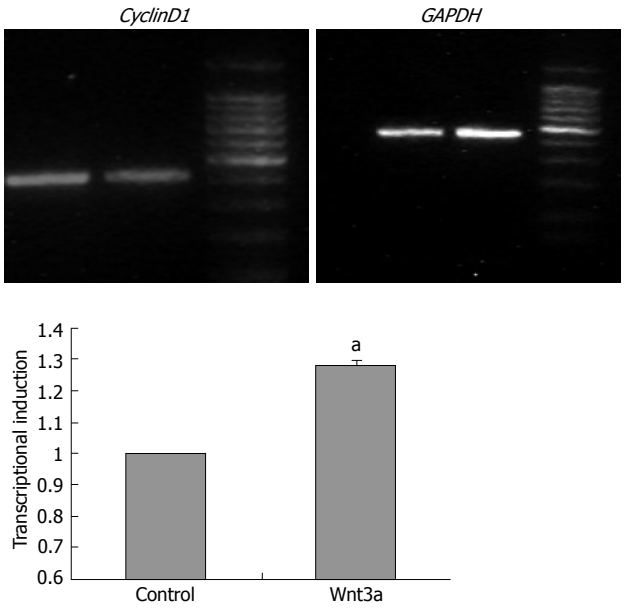

Figure 2 The mRNA expression levels of the known Wnt target genes *CyclinD1* was semi-quantified at day 1 during stimulation with Wnt3a (160 ng/mL) and normalized to the expression levels in untreated WB-F344 cells (set as 100%). The mRNA expression level of *CyclinD1*, one of the known Wnt target genes in WB-F344 cells after stimulation by Wnt3a (160 ng/mL) for 1 d was semi-quantified by RT-PCR and the results was normalized to the expression levels in untreated WB-F344 cells (set as 1). *CyclinD1* was upregulated under stimulating conditions on day 1. For quantification, *CyclinD1* mRNA was scanned by densitometric analysis and normalized to GAPDH. Data are presented as mean ± SD of triplicate experiments. $^{a}P < 0.05$ in comparison with un-treated cells.

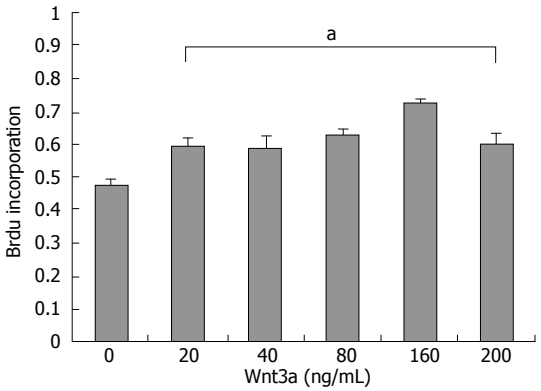

Figure 3 Proliferation of WB-F344 cells upon treatment with Wnt3a measured by Brdu incorporation assay. The proliferation of WB-F344 cells was significantly enhanced by stimulation with recombinant Wnt3a for 1 d Data are presented as mean ± SD. $^{a}P < 0.05$ *vs* untreated WB-F344 cells.

the canonical Wnt signaling pathway, which may be the mechanism underlying the up-regulated CyclinD1 expression.

Activation of the canonical Wnt signaling pathway promoted self-renewal of WB-F344 cells

Although Wnt3a can activate the canonical Wnt signaling pathway, it remains unclear whether activation of the canonical Wnt signaling pathway results in differentiation of WB-F344 cells. If Wnt3a can promote cell differentiation, WB-F344 cells treated with Wnt3a

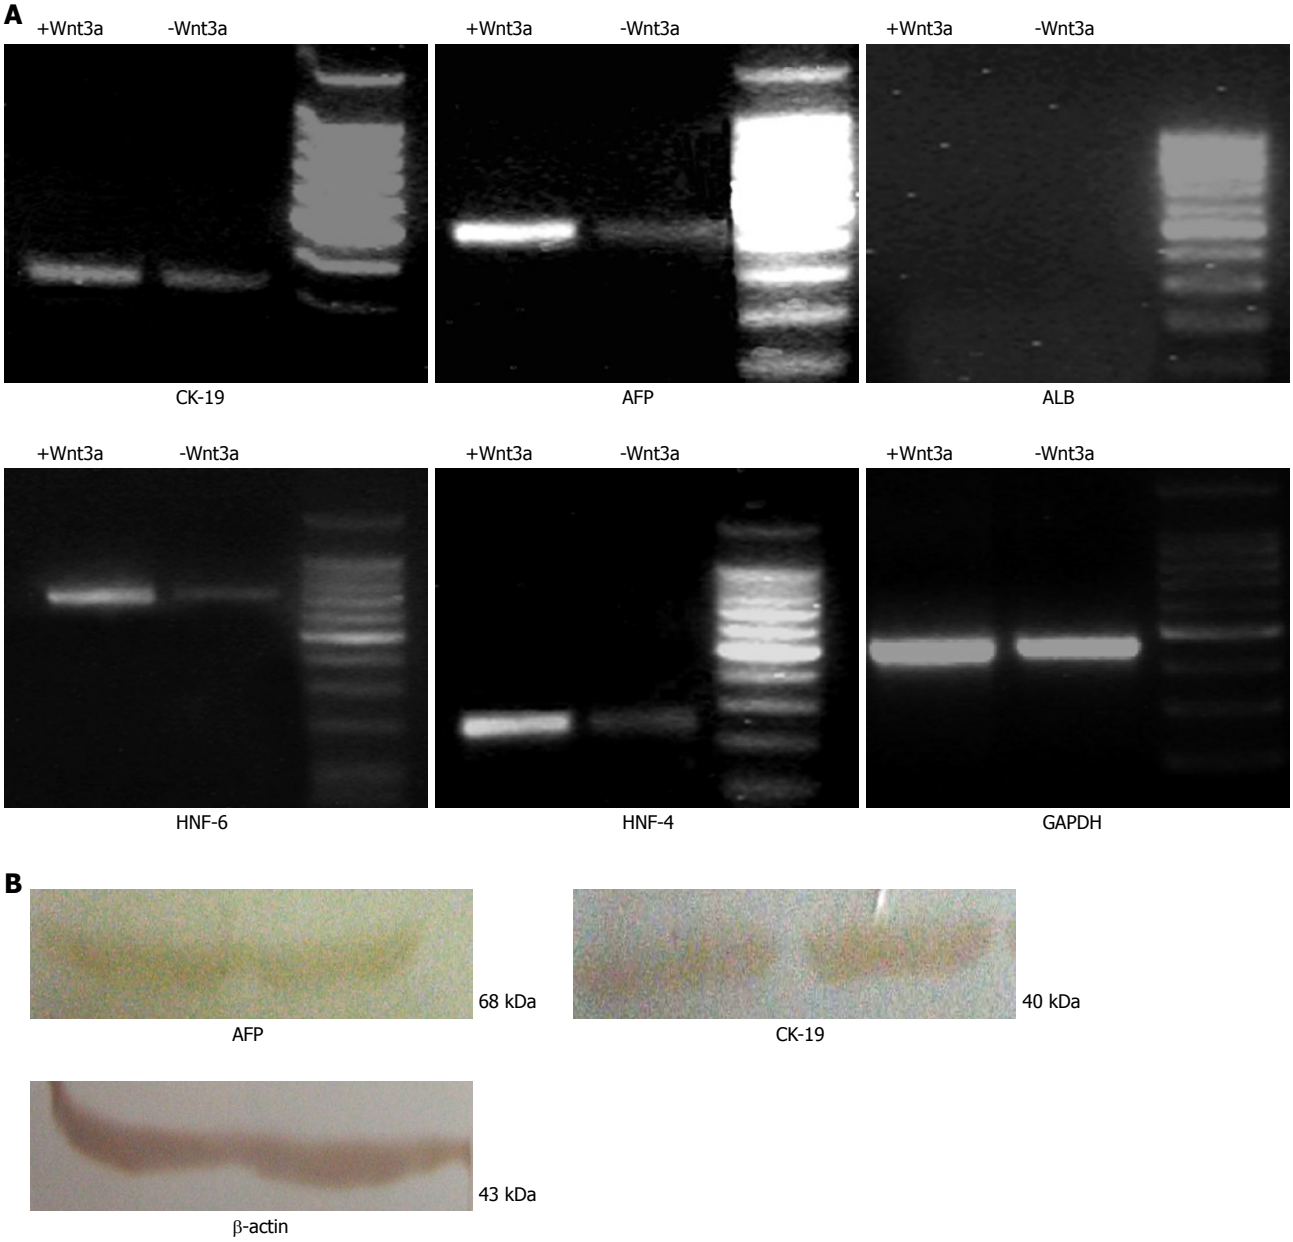

Figure 4 RT-PCR and Western blot analysis of differentiated WB-F344 cells treated or untreated with Wnt3a. A: Wnt3a-treated WB-F344 cells expressing two phenotypic markers (CK-19 and AFP) and two hepatic nuclear factors (HNF4α and HNF-6) at mRNA level with untreated WB-F344 cells as controls; B: Wnt3a-treated cells expressing two phenotypic markers (CK-19 and AFP) at protein level.

should express specific markers after activation of the canonical Wnt signaling pathway. To test this hypothesis, WB-F344 cells were cultured in the presence or absence of Wnt3a-containing medium for 3 d under serum-free conditions. RT-PCR and Western blot were performed for the expression of markers in WB-F344 cells treated or untreated with Wnt3a. Two cell–specific markers, AFP and CK-19 and two hepatocyte nuclear factors, HNF-4α, HNF-6 were expressed in both Wnt3a-treated and untreated WB-F344 cells. In respect of these markers, Wnt3a-treated WB-F344 cells did not show any marked deviation compared with untreated WB-F344 cells (Figure 4). The transcription factors, known to play a key role in differentiation of hepatocytes and cholangiocytes, were expressed in both Wnt3a-treated and untreated WB-F344 cells. These findings suggest that self-renewal of WB-F344 cells is stimulated by the canonical Wnt signal transduction.

DISCUSSION

Oval cell activation occurs in the majority of chronic liver diseases and increases with the severity of the disease. In moderate and severe degrees of inflammation, intermediate hepatocytes occur, having a phenotype intermediate between progenitor cells/ductular cells and mature hepatocytes. The number of these intermediate hepatocytes gradually increases with higher degrees of inflammation and necrosis in necrotizing hepatitis or with more advanced stages of (non) alcoholic steatohepatitis[25-27]. However, little is known about the signaling pathways involved in controlling hepatic oval

cell proliferation and differentiation. The present study demonstrated that Wnt/β-catenin signaling plays an important role in the proliferation and renewal of oval cells *in vitro*.

Although multiple Wnts are now known to play a role in the proliferation and renewal of stem cells via the canonical or non-canonical pathway, Wnt-1 and -3 have a similar mode of action leading to β-catenin accumulation[28,29]. Taking advantage of this redundancy and availability of biologically active Wnt3a, we tested the impact of Wnt enrichment on WB-F344 cells, at beginning of cultures. Thus, this study directly addressed the effect of Wnt3a on the proliferation and differentiation of WB-F344 cells.

We performed this study in serum-free conditions to minimize other confounding factors. Our initial results demonstrate that Wnt proteins, showing high transforming activity in WB-F344 cells, could activate the canonical Wnt signaling pathway. To activate the canonical Wnt signaling pathway, WB-F344 cells were stimulated with recombinant Wnt3a (160 ng/mL) for 24 h. β-catenin, upon treatment with Wnt3a, translocated into the nuclei of WB-F344 cells where it promotes TCF/LEF-dependent transcription, with a slightly increased accumulation of β-catenin at protein level, suggesting that degradation of β-catenin diminished by the destructive complex is the underlying mechanism[30]. Nuclear accumulation of this protein indicates that activity of the Wnt signal pathway is increased[31]. Furthermore, Wnt3a-mediated nuclear translocation of β-catenin results in the up-regulation of CyclinD1, suggesting that the canonical Wnt target gene, originally identified in colon carcinoma cells[32], can be induced in WB-F344 cells. Accumulated β-catenin is translocated into the nuclei of WB-F344 cells where it binds to the transcription factors, T cell factor (Tcf)/lymphoid enhancer factor (Lef), thereby stimulates expression of target genes[33]. Therefore, activation of the Wnt signaling pathway in WB-F344 cells results in accumulation of β-catenin, its translocation into nuclei, and enhanced expression of Wnt target genes.

We also investigated the effect of recombinant Wnt3a on proliferation of WB-F344 cells in serum-free environment, showing that recombinant Wnt3a could stimulate the proliferation of WB-F344 cells. This observation is consistent with the reported findings that β-catenin plays a central role in regulating the proliferation and regeneration of hepatocytes[34-36]. To investigate whether the expression of CyclinD1 is directly correlated with the proliferation of WB-F344 cells, mRNA expression in *CyclinD1*, which plays a fundamental role in cell cycle at the G1-S phase transition, was semi-quantified by RT-PCR 1 d after Wnt3a stimulation (160 ng/mL). A significant mRNA expression was induced in *CyclinD1*. This effect was even more pronounced under Wnt stimulatory conditions. Moreover, it was reported that proliferation of WB-F344 cells is severely impaired in the absence of β-catenin, secondary to the decreased expression of downstream targets such as CyclinD1, which are critical in proliferation[37]. It has also been shown that WB-F344 cells proliferate in postnatal liver development, *ex vivo* embryonic liver development, and in facultative liver stem and oval cells[38-41]. These findings further support the idea that the Wnt signaling pathway is largely involved in controlling the proliferation of WB-F344 cells.

Oval cells are known to be tumorigenic[42]. The Wnt/β-catenin signaling pathway plays an important role in the pathogenesis of hepatic adenoma and its progression to HCC[43] and also in self-renewal of stem cells in several tissue types[44]. β-catenin is a mediator of cancer stem cells[43] and plays an important role in early liver development at the stage of ongoing hepatic progenitor proliferation[39,45]. In the present study, the hepatobiliary phenotype was confirmed by RT-PCR and Western blot analysis. Wnt3a-treated and untreated WB-F344 cells cells were positive for AFP and CK-19 but negative for ALB, one of the final maturation phase markers, indicating that they were immature cells. The bipotential phenotype of WB-F344 cells was observed in oval cells, presumed precursors of hepatocytes and biliary cells. HNF4α and HNF6 are known to play a key role in differentiation of hepatocytes and cholangiocytes[46-50]. Our results also demonstrate that WB-F344 cells treated or untreated with Wnt3a expressed HNF4α and HNF6. Studies in knockout mice showed that hepatocyte nuclear factor HNF4α regulates transcription of genes essential for hepatocytic cell lineage[51,52], whereas HNF6 is involved in the development of gallbladder and bile ducts[53,54]. HNF4α and HNF6 are expressed in fetal hepatoblasts and show different expression patterns in adult liver. HNF4α is exclusively expressed in fetal and adult hepatocytes. No HNF4α expression has been observed in fetal ductal plate or in bile duct epithelium or in normal adult liver. HNF6 is also expressed in fetal and adult hepatocytes and in fetal BEC. HNF6 is completely lost from the BEC with mature biliary phenotype[55]. It was reported more recently that the Wnt/β-catenin signaling pathway plays a critical role in oval cell activation[40]. HNF4α and HNF6 are expressed in oval cells of the liver activated by 2-AAF/PH[56]. Our results show that activation of the Wnt/β-catenin signaling pathway could promote self-renewal of WB-F344 cells, indicating that some molecules involved in the canonical Wnt pathway may be therapeutic targets. β-catenin targeting might be of essence in preneoplastic and early or late HCC as a chemopreventive or chemotherapeutic measure.

In conclusion, the canonical Wnt signaling pathway plays a key role in regulating the proliferation and self-renewal of hepatic oval cells. The detailed mechanism of Wnt3a underlying the differentiation of WB-F344 cells and whether β-catenin can directly control the expression of HNF4α and HNF6 need further study.

COMMENTS

Background

Oval cell activation occurs in the majority of chronic liver diseases and increases with the severity of the disease. However, little is known about the signaling pathways involved in controlling hepatic oval cell proliferation

and differentiation. The canonical Wnt signaling pathway is highly conserved throughout animal development during which it exerts pleiotropic effects on cell proliferation, differentiation, and polarity or migration. In the present study, the authors aimed to investigate the effect of activation of canonical Wnt signaling pathway on the proliferation and differentiation of heaptic oval cells *in vitro*.

Research frontiers

There is accumulating evidence that Wnt/β-catenin signaling in the liver plays a central role in various aspects of hepatic biology, including liver development, regeneration, growth, and oncogenesis. Studies of pathological specimens and rodent models of liver diseases have demonstrated aberrations in the Wnt/β-catenin signaling pathway in conditions ranging from hepatitis to hepatocellular carcinoma (HCC). However, no studies have definitively addressed the role of canonical Wnt signaling in proliferation and differentiation of hepatic oval cells.

Innovations and breakthroughs

This is the first study addressing the role of canonical Wnt signaling in proliferation and differentiation of hepatic oval cells. The canonical Wnt signaling pathway plays a key role in regulating the proliferation and self-renewal of hepatic oval cells.

Applications

Oval cells are known to be tumorigenic. The Wnt/β-catenin signaling pathway plays an important role in the pathogenesis of hepatic adenoma and its progression to HCC, and also in self-renewal of stem cells in several tissue types. β-catenin is a mediator of cancer stem cells. Activation of the Wnt/β-catenin signaling pathway could promote self-renewal of oval cells, indicating that some molecules involved in the canonical Wnt pathway may be therapeutic targets. β-catenin targeting might be of essence in preneoplastic and early or late HCC as a chemopreventive or chemotherapeutic measure.

Terminology

The Wnt signaling pathway, identified recently, critically regulates various postnatal stem cell compartments, including the hematopoietic, skin, and enteric systems. In this respect, it has been demonstrated that hematopoietic stem cells maintain an undifferentiated self-renewing state through constitutive activation of the canonical Wnt signaling pathway with Wnt3a, a prominent member of the Wnt family.

Peer review

In this study, the authors demonstrated the role of canonical Wnt signaling in proliferation and differentiation of hepatic oval cells. This work adds significant information that activation of the Wnt/β-catenin signaling pathway could promote proliferation and self-renewal of oval cells, indicating that some molecules involved in the canonical Wnt pathway may be therapeutic targets.

Abstract

AIM: To explore the influence of portal vein hemodynamic changes after portal venous arterialization (PVA) on peribiliary vascular plexus (PVP) morphological structure and hepatic pathology, and to establish a theoretical basis for the clinical application of PVA.

METHODS: Sprague-Dawley rats were randomly divided into control and PVA groups. After PVA, hemodynamic changes of the portal vein and morphological structure of hepatohilar PVP were observed using Doppler ultrasound, liver function tests, ink perfusion transparency management and three-dimensional reconstruction of computer microvisualization, and pathological examination was performed on tissue from the bile duct wall and the liver.

RESULTS: After PVA, the cross-sectional area and blood flow of the portal vein were increased, and the increase became more significant over time, in a certain range. If the measure to limit the flow in PVA was not adopted, the high blood flow would lead to dilatation of intrahepatic portal vein and its branches, increase in collagen and fiber degeneration in tunica intima. Except glutamic pyruvic transaminase (GPT), other liver function tests were normal.

CONCLUSION: Blood with a certain flow and oxygen content is important for filling the PVP and meeting the oxygen requirement of the bile duct wall. After PVA, It is the anatomic basis to maintain normal morphology of hepatohilar bile duct wall that the blood with high oxygen content and high flow in arterialized portal vein may fill PVP by collateral vessel reflux. A adequate measure to limit blood flow is necessary in PVA.

INTRODUCTION

In the clinical practice of enlarged radical operation and liver transplantation, revascularization of the liver is often needed. For this reason, portal venous arterialization (PVA) has been extensively studied and carried out in clinical practice[1-5]. PVA has been used in more than 10 cases during liver transplantation and some transplant centers have achieved good outcomes[6,7]. Blood flow and oxygen content in the peribiliary vascular plexus (PVP) play an important role in ensuring the normal physiological function of bile-duct epithelial cells[8]. After PVA, the influence of portal vein hemodynamic changes on hepatohilar PVP is important for the incidence of bile duct complications and is directly associated with clinical application of PVA.

Therefore, the purpose of our study was to explore the influence of portal vein hemodynamic changes after PVA on PVP morphological structure, and liver function and pathology, and to establish a theoretical basis for the clinical application of PVA.

MATERIALS AND METHODS

All study methods were approved by the ethics committee of Xiamen First Hospital.

Materials

Healthy, adult, male, clean Sprague-Dawley rats weighing 250-300 g were provided from the Laboratory Animal Center, General Hospital of PLA, Beijing. All rats were maintained under specific pathogen-free conditions. The CK40 inverted phase contrast microscope and BX51TF system microscope were provided by Olympus. Perfusion ink was from China.

Establishment of PVA model

Rats were randomly divided into control and PVA groups (each group with 17 rats). Rats were fasted 12 h prior to operation, then anesthetized with 3% chloral hydrate (1 mL/100 g). Models were made under BX51TF system microscope. In the control group, after opening the abdomen, the porta hepatis was isolated, and then the abdomen was closed. In the PVA group, after opening the abdomen, the inferior vena cava, portal vein and common hepatic artery were isolated, and then double ligations were performed with 0 silk thread on the common hepatic artery and it was cut in the middle, the proximal broken end with silk thread and small round pin for further use. The portal vein and the celiac artery were blocked with vascular clamps, the stump of the common hepatic artery was connected to the portal vein, and then the celiac artery clamp was removed, and tremors from the portal vein were felt (Figure 1A). The portal vein clamp was removed and the blood flow was temporarily restored (cross-clamp for 5-7 min). Subsequently, the side-to-side anastomosis (cross-clamp for 10-12 min) of the portal vein and the inferior vena cava was performed, with the portal vein diameter the same as the anastomotic stoma diameter (Figure 1B). The anastomotic stoma was confirmed to be unobstructed. Finally, ligation was performed between the anastomotic stoma of the hepatic artery and the portal vein, and the right gastric vein branch of the portal vein. Therefore, only arterial blood flowed into the intrahepatic portal vein. All rats in the PVA and control groups were observed for 6 mo.

Hemodynamic changes of arterialized portal vein

Color Doppler ultrasound was used to monitor the cross-sectional area and blood flow of the portal vein at the mid-point of the main portal vein in seven rats from the two groups, at 1 and 6 mo after PVA, which was carried out in the Department of Ultrasound, PLA General Hospital. The included angle between the ultrasound probe and the main portal vein was < 60° and the frequency of the probe was 5-13 MHz.

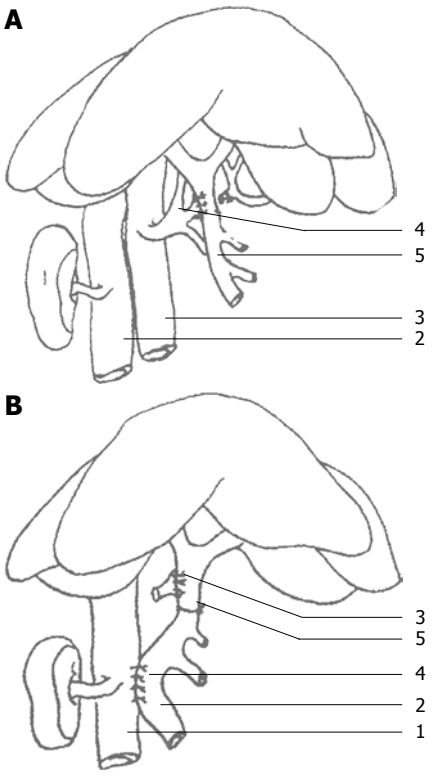

Figure 1 Animal PVA model establishment. A: Side-to-side anastomotic stoma of the hepatic artery and the portal vein. (1) kidney; (2) inferior vena cava; (3) abdominal aorta; (4) hepatic artery; (5) portal vein. B: Side-to-side anastomotic stoma of the portal vein and the venae cavae. (1) inferior vena cava; (2) portal vein; (3) arteriovenous anastomotic stoma; (4) anastomotic stoma of the portal vein and the venae cavae; (5) ligation of the portal vein.

Liver functions in rats 6 mo after PVA

Two milliliters of blood were taken from the abdominal aorta in randomly selected 8 rats from the two groups respectively for determining liver functions. Then ink perfusion was performed in the 8 rats respectively (as follow).

Capillary morphology in hepatohilar bile duct wall after PVA

Ink perfusion: Six months after PVA, the portal vein and abdominal aorta were intubated in 10 rats (remained 2 rats and 8 rats above) in the control group, and only the abdominal aorta was intubated in 10 rats (remained 2 rats and 8 rats above) from the PVA group. In the 20 rats, the thoracic aorta was ligated, then a cut was made on the vena cava of the midriff, 1% heparin physiological saline was infused till clear efflux from thoracic cavity. Ink had not been equably and slowly infused under pressure of 16.0 kPa into the abdominal aorta until ink exuded from inferior vena cava of thoracic cavity, The perfusion state of the bile duct wall capillaries was closely observed with a dissecting microscope. The liver and extrahepatic bile ducts were removed, and fixed with 10% formaldehyde solution over 72 h.

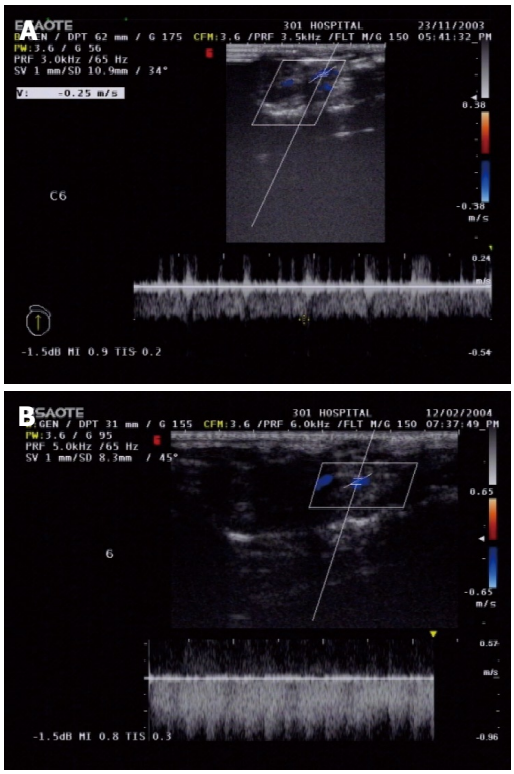

Figure 2 Frequency spectrums in the portal vein. A: Venous frequency spectrums in the portal vein of control group; B: Arterial frequency spectrums in the portal vein 6 mo after PVA.

Tissue dehydration, transparency and embedding: Five hepatohilar bile ducts from both groups were washed with lotic water, dehydrated in graded alcohol, and placed in dimethylbenzene for transparence over 24 h. The distribution of the hepatohilar bile duct wall capillaries was observed using an inverted phase contrast microscope. Another five hepatohilar bile ducts from the two groups were dehydrated in graded alcohol, placed in dimethylbenzene for transparence, embedded in paraffin, and continuously sectioned at a thickness of 20 μm. After adhering on, sections were slightly raised and heated until the paraffin disappeared, then they were incubated at 60℃ for 24 h in a thermostat. The sections were again put in dimethylbenzene for transparence over 24 h, during which the transparence liquid was changed three times. After transparence, the sections were mounted in gum, and pictures were collected with Motic 0.65 times light microscope for three-dimensional reconstruction of computer microvisualization.

Three-dimensional reconstruction of computer microvisualization: Firstly, primitive three dimensional data field was constructed by registering the sequence of two-dimensional section images according to feature points of ink perfusion blood vessel on bile duct thick sections, then the wave filter of the primitive three dimensional data was performed with median filter to inhibit noises and to enhance image characteristics, improving the ratio of signal to noise. Lastly the isosurfaces of cube voxel were extracted from three dimensional data field with Marching Cubes algorithm to construct the three-dimensional structure of sequence sections. Three-dimensional reconstruction was completed with PIV 2.53 GHz, 512M RAM microcomputer and algorithm was finished with language C++. The resolution of each section was 686 × 548 × 8 bits.

Pathological changes in hepatohilar bile duct and liver 6 mo after PVA using hematoxylin and eosin (HE) and Masson staining

The rats that underwent ultrasonography were killed 6 mo after PVA. Samples of hepatohilar bile ducts and liver were removed, fixed with 10% neutral formalin for 48-72 h, embedded in paraffin, continuously sectioned at a thickness of 5 μm, and stained with HE and Masson stain.

The steps for Masson staining were as follows. Samples were fixed with neutral formalin, sectioned, deparaffinized in water, stained with Masson composite staining solution for 5 min, washed with 0.2% acetic acid solution, washed with 5% phosphotungstic acid for 5-10 min, washed twice with 0.2% acetic acid solution, stained with bright green staining solution for 5 min, washed twice with 0.2% acetic acid solution, dehydrated in absolute alcohol, put in xylene for transparency, and mounted with neutral gum. Collagen fibers were bluish green in color and red blood cells were orange.

Statistical treatment

Data were expressed as mean ± SD. The *t* test was used for comparison between the two groups. Statistical analysis was performed with Stata software.

RESULTS

General status of experimental animals

In all rats, normal diet was restored, and fur was shiny. Body weight showed an increasing trend 3 d after operation, and then returned to normal 1 mo after PVA. There was no significant difference in body weight between the two groups at 6 mo after PVA.

Hemodynamic changes of the portal vein after PVA

Spectral changes of the portal vein and the status of vascular anastomosis 6 mo after PVA: In the portal vein, the continuous venous frequency spectrum was changed into a pulsatory arterial frequency spectrum 6 mo after PVA (Figure 2). Six months after PVA, the status of the vascular anastomosis of the portal vein with hepatic artery and vena cava is shown in Figure 3. The hepatic artery and the portal vein were obviously enlarged 6 mo after PVA.

Cross-sectional area of the portal vein in the two groups after operation: Compared with the control group, the cross-sectional area of the portal vein in the PVA group was significantly increased ($P < 0.01$) (Table 1).

Volume of blood flow of the portal vein in the two groups after operation: Compared with the control group, the volume of blood flow in the portal vein 6 mo after PVA was obviously increased ($P < 0.01$) (Table 1).

Table 1 Comparison of cross section area and volume of blood flow of the portal vein between the two groups (mean ± SD, n = 7)

Group	1 mo	6 mo
Cross section area of the portal vein (mm^2)		
Control group	0.0317 ± 0.0098	0.0333 ± 0.0103
PVA group	0.0433 ± 0.0242	0.0657 ± 0.0151[1,2]
Volume of blood flow of the portal vein (mL/min)		
Control group	37.6 ± 11.36	37.72 ± 9.09
PVA group	74.70 ± 42.76	132.01 ± 78.72[3]

[1]Compared with control $P < 0.01$; [2]Compared with cross section area of the portal vein one month after PVA $P < 0.05$; [3]Compared with control group $P < 0.01$.

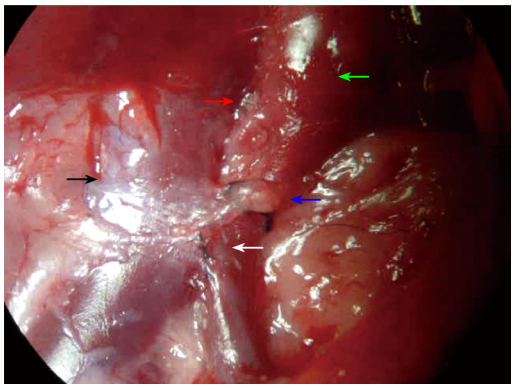

Figure 3 The status of the vascular anastomosis of the portal vein with hepatic artery and vena cava. The red arrow indicates the anastomotic site of the hepatic artery and portal vein. The white arrow indicates the side-to-side anastomotic stoma of the portal vein and the venae cavae. The green arrow indicates thickening of the portal vein. The black arrow indicates the venae cavae. The blue arrow indicates a thread blocking the portal vein.

Liver functions in rats 6 mo after PVA

Total bilirubin (TBIL), direct bilirubin (DBIL) and total bile acid (TBA) in the PVA group were greater than those in the control group, but there was no significant difference between the two groups ($P > 0.05$). Serum albumin (ALB) and alkaline phosphatase (AKP) in the PVA group were lower than those in the control group, but there was no significant significance between the two groups ($P > 0.05$). Glutamic pyruvic transaminase (GPT) in the PVA group was significantly greater than that in control group ($P < 0.01$) (Table 2).

Morphological changes of hepatohilar capillaries after PVA

Ink perfusion sections showed that, compared with the control group, the capillaries of the outside layer of the PVP were obviously thickened and dilated, and capillary density of the inside layer was increased, and capillary diameter of the inside layer was enlarged in the PVA group (Figure 4). Ink perfusion gross transparent specimens clearly showed the capillary structure in the forked site of the hepatohilar bile duct in the two groups. Capillaries in the forked site of the bile duct were obviously thickened in the PVA group (Figure 5). Three-dimensional reconstruction clearly showed the

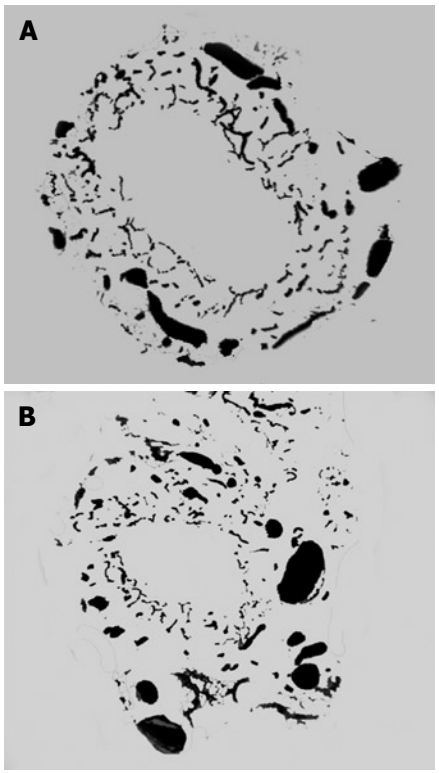

Figure 4 PVP plane structure of hepatohilar bile duct. A: Control group (20 μm, x 100); B: PVA group (20 μm, x 100).

PVP stereochemical structure of the hepatohilar bile ducts in the two groups. Peripheral vessels of the PVP were obviously thickened in the PVA group (Figure 6).

Histopathological changes in the hepatohilar bile duct wall

Figure 7A and B shows that, in both groups, the epithelial cell morphology of the bile ducts was normal, the thickness of bile duct was not increased, and there was no inflammatory cell infiltration.

Masson staining of the liver

In the PVA group, Figure 7C-F shows the dilated portal vein and its branches, thickened blood vessel wall, increased collagen fiber and fiber degeneration in the tunica intima. Hepatic lobule structure was intact. Pseudolobule formation was not present. Hepatic sinusoids were widened. The morphology of the hepatic cells was not obviously abnormal.

DISCUSSION

Since the incidence of hepatic encephalopathy is increased because of the decrease in hepatic blood perfusion after portosystemic shunting in portal hypertension, Cohn & Herrod[9] and Fisher *et al*[10] originally thought that portal vein blood was replaced with arterial blood in hepatic perfusion. Subsequently, many researchers have carried out a large number of animal experiments and confirmed that when the portal vein is perfused with arterial blood at an appropriate

Table 2 Liver Functions in the two groups (mean ± SD, *n* = 8)

flow and pressure, animals are able to maintain normal liver blood flow and levels of blood ammonia and blood colalin, to ensure normal liver detoxification and cell morphology. Since 1960, PVA has attracted extensive attention because of its various clinical applications[11-13], especially in the enlarged radical operation for hepatohilar cancer that invades the hepatic artery and liver transplantation. PVA has been used in reconstructing hepatic vascular access because of the presence of thrombosis of the portal and other veins, or the anatomical variation of the portal and mesenteric veins[14,15]. Morphological changes in PVP after PVA have attracted the attention of many workers. Hepatohilar bile ducts have become a concern because of their unique anatomical factors, including less collateral circulation and easily-damaged blood supply. The purpose of this study was to explore the influence of PVA on the morphology of hepatohilar bile ducts and PVP, epithelial cells of bile ducts, and to provide a theoretical basis for the clinical application of PVA.

Within 6 mo after PVA, rats were well and did not have jaundice. Their body weights showed an increasing trend. If the measure to limit blood flow was not taken within 1 mo after PVA, the cross-sectional area and blood flow of the portal vein were increased, and the increasing trend became more significant over time in a certain range. Hemodynamic changes after PVA will have an influence on hepatic structure. In our study, Masson staining 6 mo after PVA showed that, when measures to limit blood flow were not adopted, high blood flow in the portal vein led to dilation of the intrahepatic portal vein and its branches, increased collagen fibers in the tunica intima, widening of the hepatic sinusoids, and collagen fiber hyperplasia in the sinusoidal walls. However, the structure of hepatic lobule was not obviously disordered and pseudolobule formation was not present. Liver function tests showed that compared with the control group, except for GPT (significant increase $P < 0.01$), ALB in the PVA group was slightly lower, and bile acid and BIL were slightly increased, but there was no significant difference between the two groups. This demonstrated that PVA had no significant influence on ALB synthesis, bile acid and BIL metabolism and bile salt enterohepatic circulation. The increase in GPT may have been associated with high blood flow after PVA.

E: Masson staining of the liver 6 mo after PVA in PVA group (x 40); F: Masson staining of the liver 6 mo after PVA in PVA group (x 400).

The PVP is common in mammals and its structure differs with various parts. It has been reported that the PVP of the large bile ducts consists of three layers of capillaries. The capillaries of the inside layer are arranged in an orderly manner and are open to capillaries beneath the epithelial lining. The middle and outside layer consist of a few capillaries, venules and arterioles in the bile duct wall or in peribiliary tissue[16]. It has been reported that different diseases will lead to different pathological features of the bile ducts, and PVP morphology will also show different pathological changes[17]. Blood flow and oxygen content in the PVP play important roles in ensuring normal physiological function of bile duct epithelial cells.

Ink perfusion thick sections and transparent specimens indicated that after PVA, capillaries of the outside layer of the PVP were obviously thickened, the number of blood vessels in the outside layer was not reduced, and capillary morphology in the hepatohilar bile duct walls was not disordered. This demonstrates that after the PVP loses its arterial blood supply, the blood in the arterialized portal vein can meet fully the requirement of the PVP, by portal vein collateral branch reflux, which may be the theoretical basis for clinical application of PVA. A semi-quantitative study of the PVP with normal portal pressure and portal hypertension has been performed by Terada *et al*[18] using immunohistochemistry. Results indicated that intrahepatic peribiliary vascular density was obviously increased in congenital portal hypertension and other forms of portal hypertension, because of extrahepatic portal vein thrombus and portal vein cancer embolus, but was only slightly increased in hepatic cirrhosis. PVP density is associated with portal vein pressure. It may be that the blood of the portal vein flows back into the PVP by internal routes, or flows directly into the PVP via arteries, which leads to PVP hyperplasia. This further indicates there are collateral vessels between the portal vein and PVP.

The three-dimensional reconstruction of computer microvisualization realistically illustrated PVP three-dimensional structure. Peribiliary capillaries after PVA were obviously thickened, which may have been caused by the increases in blood flow and blood flow rate of

the arterialized portal vein. MoticBuaa3DVol three-dimensional reconstruction software used in this study established a foundation for further research on capillary structure of hepatohilar bile ducts.

To maintain normal physical activities of bile duct tissue, adequate blood flow and a certain degree of blood oxygen content are required. Early study has shown that, since it possesses low blood flow and low oxygen content, the blood in the portal vein cannot completely fill the PVP, and local tissue is in a state of chronic hypoxia. Chronic inflammatory hyperplasia will occur in the hepatohilar bile duct administered by portal vein blood[19]. After PVA, blood flow and blood oxygen content were able to meet the requirements of the local tissues of the bile duct wall, and no ischemic lesion occurred in the bile ducts. HE staining results of this experiment disclosed that after PVA, there was no pathological change in bile duct tissue, which further verified this inference. At the same time, there were no significant differences in BIL and ALP between the two groups, which further confirmed the HE staining results.

In short, blood with a certain flow and oxygen content has important significance for filling the PVP and meeting the oxygen requirement of the bile duct wall. After PVA, it is the anatomic basis to maintain normal morphology of hepatohilar bile duct wall that the blood with high oxygen content and high flow in arterialized portal vein may fill PVP by collateral vessel reflux. The high blood flow in the portal vein after PVA is the main reason for the obvious dilation of the intrahepatic portal vein and collagen fibroplasia. Therefore, certain measures to limit blood flow in PVA are necessary.

COMMENTS

Background

During the enlarged radical operation for hepatohilar cancer that invades the hepatic artery and liver transplantation, the presence of portal vein and internal organ vein thrombosis or the congenital absence of the portal and mesenteric veins often require liver revascularization. For this reason, many researchers have carried out a large number of experiments and have applied portal venous arterialization (PVA) in clinical practice. Blood flow and oxygen content in the peribiliary vascular plexus (PVP) play an important role in ensuring normal physiological functions of bile duct epithelial cells. After PVA, the influence of portal vein hemodynamic changes on hepatohilar PVP has an important effect on the incidence of bile duct complications, and is directly associated with the clinical application of PVA. Therefore, to establish a theoretical basis for clinical application of PVA, we explored the influence of portal vein hemodynamic changes after PVA on PVP morphological structure and hepatic pathological structure.

Research frontiers

Liver revascularization is important in enlarged radical operation and liver transplantation. PVA is applied in clinical practice to resolve this problem, but some complications occur after PVA. In order to make clinical application of PVA better and reduce incidence of complications, it is necessary to study some subjects related to PVA.

Innovations and breakthroughs

In this study, we observed hemodynamic changes in the portal vein, morphological structure of hepatohilar PVP, and bile duct and liver pathology after PVA. We found that after PVA, the cross-sectional area and blood flow of the portal vein were increased and this trend became more significant over time in a certain range. If measures to limit the flow in PVA are not adopted, the high blood flow will lead to dilatation of the intrahepatic portal vein and its branches, and increased collagen and fiber degeneration in the tunica intima. Therefore, it is necessary to limit blood flow in PVA.

Applications

Measures to limit blood flow are likely to reduce the incidence of complications after PVA.

Terminology

PVA: portal venous arterialization; PVP: peribiliary vascular plexus.

Peer review

The paper addresses an important issue in hepatobiliary and liver transplantation practice, particularly in the cases of diffuse mesenteroportal venous thrombosis. In the current study, the authors used a model with a portacaval shunt in conjunction with complete arterialization of the portal inflow of the liver. The results are interesting.

Abstract

AIM: To study the prevalence and risk factors associated with triple infection with human immunodeficiency virus (HIV)/hepatitis B virus (HBV)/hepatitis C virus (HCV) in an urban clinic population.

METHODS: Retrospective chart review of 5639 patients followed at St. Luke's-Roosevelt Hospital HIV Clinic (Center for Comprehensive Care) in New York City, USA from January 1999 to May 2007. The following demographic characteristics were analyzed: age, sex, race and HIV risk factors. A multiple logistic regression analysis was performed to evaluate the influence of demographic factors on acquisition of these viruses.

RESULTS: HIV/HBV, HIV/HCV and HIV/HBV/HCV infections were detected in 252/5639 (4.47%), 1411/5639 (25.02%) and 89/5639 (1.58%) patients, respectively. HIV/HBV co-infections were associated with male gender (OR 1.711; $P = 0.005$), black race (OR 2.091; $P < 0.001$), men having sex with men (MSM) (OR 1.747; $P = 0.001$), intravenous drug use (IDU) (OR 0.114; $P < 0.001$), IDU and heterosexual activity (OR 0.247; $P = 0.018$), or unknown (OR 1.984; $P = 0.004$). HIV/HCV co-infections were associated with male gender (OR 1.241; $P = 0.011$), black race (OR 0.788; $P = 0.036$), MSM (OR 0.565; $P < 0.001$), IDU (OR 8.956; $P < 0.001$), IDU and heterosexual activity (OR 9.106; $P < 0.001$), IDU and MSM (OR 9.179; $P < 0.001$), or transfusion (OR 3.224; $P < 0.001$). HIV/HBV/HCV co-infections were associated with male gender (OR 2.156; $P = 0.015$), IDU (OR 6.345; $P < 0.001$), IDU and heterosexual activity (OR 9.731; $P < 0.001$), IDU and MSM (OR 9.228; $P < 0.001$), or unknown (OR 4.219; $P = 0.007$).

CONCLUSION: Our study demonstrates that co-infection with HBV/HCV/HIV is significantly associated with IDU. These results highlight the need to intensify education and optimal models of integrated care, particularly for populations with IDU, to reduce the risk of viral transmission.

Co-infection of hepatitis B and hepatitis C virus in human immunodeficiency virus-infected patients in New York City, United States. *World J Gastroenterol* 2008; 14(43): 6689-6693 Available from: URL: http://www.wjgnet.com/1007-9327/14/6689.asp DOI: http://dx.doi.org/10.3748/wjg.14.6689

INTRODUCTION

Co-infection with hepatitis B virus (HBV) or hepatitis C virus (HCV) in patients infected with human immunodeficiency virus (HIV) is common and well-recognized worldwide, as they are blood-borne pathogens that share similar routes of transmission, such as intravenous drug use (IDU), sexual contact, percutaneous exposure, or from mother to child during pregnancy or birth[1]. The Joint United Nations Programme on HIV/

AIDS (UNAIDS) and the World Health Organization estimate that 1.2 million people live with HIV in the United States of America (US)[2]. Among HIV-infected patients studied from Western Europe and the US, chronic HBV infection has been found in 6%-14%, while chronic HCV has been found in approximately 33%[3,4]. Co-infections of HBV or HCV with HIV have been associated with increased risk of antiretroviral-therapy-related hepatotoxicity and increased risk of progression to liver disease, which is a major cause of morbidity and mortality in HIV-infected patients[5-8]. It is well known that in the US and Europe, HIV/HBV co-infection is linked most often to sexual intercourse [both heterosexual and men who have sex with men (MSM)], followed by IDU, while HIV/HCV co-infection has predominantly been associated with a non-sexual parenteral route of transmission of blood or blood products, particularly IDU[9-13]. Although the rate of HBV and/or HCV co-infection in HIV patients varies according to geographic region and various risk groups, there is limited data on the prevalence and risk factors associated with triple infections with HIV/HBV/HCV in an urban clinic population. Therefore, we investigated the co-infection patterns of HBV and HCV among HIV-infected patients coming to a HIV clinic located in New York City, to determine the prevalence and risk factors associated with triple infections with HIV/HBV/HCV.

MATERIALS AND METHODS

Study population

We conducted a retrospective chart review of 5639 patients followed in two HIV/AIDS clinics that comprise the Center for Comprehensive Care at St. Luke's–Roosevelt Hospital in New York City. The study period was from January 1999 to May 2007. All patients were HIV-infected and were analyzed for hepatitis B surface antigen (HBsAg) and HCV antibody, along with demographic characteristics and risk factors for HIV acquisition.

Virological assays

HIV infection was defined by positivity on an enzyme-linked immunosorbent assay (ELISA) (HIVABTM HIV-1/HIV-2 (rDNA) EIA, Abbott Laboratories, Abbott Park, IL, USA) and confirmatory Western Blot test (HIV 1/HIV 2 WESTERN BLOT/IMMUNOBLOT, Quest Diagnostics, USA) with viral detection of HIV RNA by polymerase chain reaction (PCR) (Roche HIV-1 Amplicor Monitor , version 1.5, Roche Diagnostics, Basel, Switzerland).

HCV serology was performed using an ELISA (VITROS^{R} Immunodiagnostics, Ortho-Clinical Diagnostics, USA). Positive HCV serology results were confirmed by PCR test [VERSANT^{R} HCV RNA 3.0 Assay (bDNA); Siemens Healthcare Diagnostics, USA]. HBV serology was performed using ELISA (VITROS^{R} Immunodiagnostics, Ortho-Clinical Diagnostics).

HIV/HBV, HIV/HCV, and HIV/HBV/HCV co-infections were defined as positive HIV and HBV serology, positive HIV and HCV serology, and positive HIV and HBV and HCV serology results, respectively.

Statistical analysis

The tables describe the distribution of co-infections among HIV-infected patients according to several characteristics. The χ^2 test was performed in order to investigate the association between the presence of HIV/HBV/HCV co-infections and demographic variables. The Fisher exact test was used where applicable. In order to identify factors associated with HIV/HBV, HIV/HCV and HIV/HBV/HCV co-infections, three multiple logistic regression analyses were performed to determine odd ratio (OR) and 95% confidence interval (CI). The level of statistical significance was fixed at $P = 0.05$. The statistical analysis was performed using the statistical software SPSS 15.0 for Windows (SPSS, Chicago, IL, USA).

RESULTS

Epidemiological characteristics

Of the 5639 HIV-infected patients investigated, 1752 (31.07%) were co-infected with hepatitis viruses [252/5639 (4.47%) HIV/HBV, 1411/5639 (25.02%) HIV/HCV, and 89/5639 (1.58%) HIV/HBV/HCV]. The main epidemiological demographic characteristics are presented in Table 1.

HIV and HBV co-infection

Of the 252 HIV/HBV co-infected patients, the majority was male (203/252, 80.6%). Mean age was 44.2 years old. Black race was dominant (169/252, 67.1%). Risk factors for acquisition of HIV included: heterosexual contact (35.7%), MSM (46.4%) and IDU (2.4%). The results of the multiple regression analyses are presented in Table 2. HIV/HBV co-infections were associated with male gender (OR 1.711; 95% CI 1.179-2.482; $P = 0.005$), Black race (OR 2.091; 95% CI 1.404-3.114; $P < 0.001$), MSM (OR 1.747; 95% CI 1.247-2.448; $P = 0.001$), IDU (OR 0.114; 95% CI 0.049-0.262; $P < 0.001$), IDU and heterosexual activity (OR 0.247; 95% CI 0.077-0.789; $P = 0.018$), or unknown (OR 1.984; 95% CI 1.249-3.153; $P = 0.004$).

HIV and HCV co-infection

The majority of patients were male (1005/1411, 71.2%). Mean age was 50.4 years old. Hispanic and black ethnic group constituted the majority (553/1411 39.2%, 630/1411 44.6%, respectively). Concerning the risk factors of acquiring HIV, 702 patients (49.8%) reported IDU and 148 patients (10.5%) reported MSM.

Table 2 illustrates the factors associated with HIV/HCV co-infection, which show that co-infections were significantly associated with male gender (OR 1.241; 95% CI 1.052-1.464; $P = 0.011$), Black race (OR 0.788; 95% CI 0.631-0.984; $P = 0.036$), MSM (OR 0.565; 95% CI 0.446-0.715; $P < 0.001$), IDU (OR 8.956; 95% CI 7.502-10.693; $P < 0.001$), IDU and heterosexual activity

(OR 9.106; 95% CI 6.905-12.007; $P < 0.001$), IDU and MSM (OR 9.179; 95% CI 5.767-14.609; $P < 0.001$), transfusion (OR 3.224; 95% CI 1.866-5.572; $P < 0.001$).

HIV and HBV/HCV co-infection

The prevalence of triple co-infection was found to be 1.58% (89/5639). Mean age was 47.8 years old and the majority was male (75/89, 84.3%). Hispanic and black ethnic group constituted the majority (34/89 38.2%, 39/89 43.8%). Regarding the risk factors of HIV acquisition, 38 patients (42.7%) reported IDU and 17 (19.1%) reported MSM.

The multiple regression analysis showed that factors associated with triple infections with HIV/HBV/HCV, were male gender (OR 2.156; 95% CI 1.159-4.011; $P = 0.015$), IDU (OR 6.345; 95% CI 3.015-13.351; $P < 0.001$), IDU and heterosexual activity (OR 9.731; 95% CI 4.082-23.196; $P < 0.001$), IDU and MSM (OR 9.228; 95% CI 2.897-29.391; $P < 0.001$), or unknown (OR 4.219; 95% CI 1.478-12.044; $P = 0.007$).

DISCUSSION

Our clinics serve a large number of diverse HIV-infected populations in New York City. Most of our patients are men, black and Hispanic, which reflects the national epidemic of HIV infection[2]. In our study period of 8.5 years and the review of 5639 HIV-infected patients, as Figure 1 shows, the prevalence of HIV/HCV co-infection was remarkably high, at 25.02%. Co-infection with HBV was not uncommon, at 4.47%, and triple co-infected patients with HIV/HBV/HCV were not rare either, at 1.58%.

The results of the present study are consistent with previous studies conducted in urban HIV/HBV or HCV co-infected populations in the US and Western Europe[14,15].

In our study, HIV/HBV co-infection was more likely associated with male gender, black race and MSM, but less likely associated with IDU, and IDU plus heterosexual activity, than with heterosexual reference. These results are consistent with previous studies, demonstrating that HIV/HBV co-infection is highly linked to sexual intercourse, including MSM.

In our study, HIV/HCV co-infection was significantly associated with male gender, IDU, IDU plus heterosexual activity, IDU plus MSM, and transfusion, but less likely associated with black race and MSM than heterosexual reference. These results are in agreement with previous reports that HCV is not efficiently transmitted by perinatal or sexual exposure, which are major modes of transmission for HBV and HIV. HCV is predominantly found in persons who have had percutaneous exposure to blood products and IDU in particular[16]. Even though we did not analyze patients for unsafe sexual practices, recent evidence shows increased incidence of HCV infection in MSM population who do not use condoms, especially young individuals, and in the heterosexual population who report multiple sexual partners[17]. 10.5% and 20.2% of our HIV/HCV co-infected patients are MSM and heterosexual, respectively. Not counting for other possible risk factors, sexual acquisition of HCV is likely very important in HIV-infected MSM and heterosexual individuals with multiple partners.

The prevalence of triple infection with HIV/HBV/HCV in our cohort was 1.58% and significantly associated with male gender, IDU, IDU plus heterosexual activity, and IDU plus MSM. Our results demonstrate that IDU is the most important factor associated with triple infections with HIV/HBV/HCV in urban HIV-infected populations. Therefore, the study results highlight the need for special attention to populations with IDU for screening viral co-infections with HIV and HBV/HCV.

Interestingly, among intravenous drug users, we found that the prevalence of IDU in heterosexuals was significantly higher than that of MSM with a history of IDU in HIV/HBV/HCV and HIV/HCV co-infected patients (14.6% *vs* 5.6% $P < 0.001$, 11.7% *vs* 4% $P < 0.001$), which is consistent with previous studies conducted in the US[18,19]. This could be explained by fewer high-risk IDU practices, such as needle sharing, among MSM in our cohort, although IDU behavior was not assessed in our study. As Figure 2 illustrates, overall IDU-related prevalence in our cohort was 26.49%, 32.14%, 24.31% in white, Hispanic and black ethnic groups, respectively. Our findings contrast with recent data, in which blacks were more likely to inject than whites, while Hispanics and whites had similar injecting rates[20]. This indicates another example of considerable variations in disparities of IDU in ethnic groups in large urban US cities.

The HIV/AIDS epidemic in the US affects ethnic and racial groups disproportionally. This was clearly depicted in our study. Co-infection with hepatotropic viruses shows similar trends. Physicians who care for patients with HIV/AIDS should be vigilant to frequently screen for these infections and vaccinate for hepatitis A and B when appropriate. Also, our study demonstrates that co-infection with all three viruses, HIV/HBV/HCV, is significantly associated with IDU. These results highlight the need to intensify risk reduction education, such as needle exchange programs, safe sex programs, and optimal models of integrated care, particularly for populations with IDU, to reduce the risk of viral transmission of HIV and hepatotropic viruses.

We are grateful to J Park and T Robinson from the Center for Comprehensive Care at St. Luke's-Roosevelt Hospital in New York City for assistance with data collection.

COMMENTS

Background

Co-infection with hepatitis B virus (HBV) and hepatitis C virus (HCV) in human immunodeficiency virus (HIV)-infected patients has been recognized worldwide. HIV and hepatitis co-infections have considerable impact, and result in increased morbidity and mortality in these co-infected patients. However, there are limited data on prevalence and risk factors associated with triple co-infections with HIV/HBV/HCV in an urban clinic population.

Research frontiers

To investigate epidemiological characteristics of triple co-infected patients with HIV/HBV/HCV.

Innovations and breakthroughs

In this study, the prevalence of triple co-infected patients was 1.58% and it was significantly associated with male gender and intravenous drug use (IDU). The prevalence of HIV and HCV co-infected patients was 25.02%, and it was associated with male gender and IDU. Whereas, the prevalence of HIV and HBV co-infected patients was 4.47% and was associated with male gender, black race, and MSM, but not likely associated with IDU than heterosexual reference.

Applications

This study demonstrates that triple co-infections with HIV/HBV/HCV are significantly associated with IDU. Therefore, education and integrated care, particularly for populations with IDU, would help reduce the risk of viral infections.

Peer review

This is an interesting paper. The authors demonstrated that co-infection with all three viruses, HBV/HCV/HIV, is significantly associated with IDU. These results highlight the need to intensify education and optimal models of integrated care, particularly for populations with IDU, to reduce the risk of viral transmission.

Abstract

AIM: To study the sensitivity, specificity and cost effectiveness of barium meal follow through with pneumocolon (BMFTP) used as a screening modality for patients with chronic abdominal pain of luminal origin in developing countries.

METHODS: Fifty patients attending the Gastroenterology Unit, SMS Hospital, whose clinical evaluation revealed chronic abdominal pain of bowel origin were included in the study. After routine testing, BMFT, BMFTP, contrast enhanced computed tomography (CECT) of the abdomen, barium enema and colonoscopy were performed. The sensitivity, specificity and cost effectiveness of these imaging modalities in the detection of small and/or large bowel lesions were compared.

RESULTS: Out of fifty patients, structural pathology was found in ten. Nine out of these ten patients had small bowel involvement while seven had colonic involvement alone or in combination with small bowel involvement. The sensitivity of BMFTP was 100% compared to 88.89% with BMFT when detecting small bowel involvement (BMFTP detected one additional patient with ileocecal involvement). The sensitivity and specificity of BMFTP for the detection of colonic pathology were 85.71% and 95.35% (41/43), respectively. Screening a patient with chronic abdominal pain (bowel origin) using a combination of BMFT and barium enema cost significantly more than BMFTP while their sensitivity was almost comparable.

CONCLUSION: BMFTP should be included in the investigative workup of patients with chronic abdominal pain of luminal origin, where either multiple sites (small and large intestine) of involvement are suspected or the site is unclear on clinical grounds. BMFTP is an economical, quick and comfortable procedure which obviates the need for colonoscopy in the majority of patients.

INTRODUCTION

Abdominal pain lasting more than 6 mo duration is defined as chronic abdominal pain. Some of these patients have colicky pain or have other associated features in the form of abdominal distension, constipation or vomiting which suggests bowel involvement. The majority of these patients turn out to have functional disorders such as irritable bowel syndrome, functional dyspepsia and functional abdominal pain syndrome. Of these patients, only a few will definitely have organic lesions.

The evaluation of chronic abdominal pain of luminal etiology is a challenging problem for primary care physicians and gastroenterologists. The exact localization of lesions in either the small or large bowel remains difficult in many subjects. In tropical countries, where most of the population is of low socioeconomic status, an imag-

ing modality which screens small and large bowel lesions simultaneously at a reasonable cost and with good sensitivity and specificity is needed. Small bowel evaluation by barium meal follow through (BMFT) and colonic evaluation by double contrast barium enema (DCBE) are the standard norms[1].

The technique of pneumocolon has been used previously to evaluate the terminal ileum and caecum[2-5]. Performing pneumocolon along with BMFT at the same time evaluates both the small as well as the large bowel and is more economical than the combination of BMFT and barium enema. However, its potential in identifying colonic lesions is still controversial[6,7]. We evaluated BMFT with pneumocolon (BMFTP) as a single test for the assessment of chronic abdominal pain of bowel origin, screening both the small and large bowel simultaneously.

MATERIALS AND METHODS

One hundred and fifty consecutive patients with chronic abdominal pain attending the Gastroenterology Unit of SMS Medical College and Hospital, Jaipur were evaluated. A detailed history and thorough physical examination were carried out. Fifty patients in whom clinical evaluation suggested the involvement of the small bowel, large bowel or both were enrolled in the study (Figure 1A). Complete blood count, ESR, chest X-ray, liver function tests, renal function tests, serum amylase and complete examination of stools were performed. BMFT, DCBE, BMFTP and colonoscopy were carried out as per standard protocol. Contrast enhanced computed tomography (CECT) of the whole abdomen was also done. Subjects underwent overnight fasting and were asked to drink 100 mL of oral contrast dissolved in one liter of water around one and a half hours before the procedure. When subjects were taken for CECT, around 1 mL/kg of non-ionic contrast was given intravenously on the CT table. CT cuts were subsequently taken. We compared the sensitivity of these tests in detecting lesions as well as their cost effectiveness.

BMFTP was carried out in a similar way to BMFT. Microbar (Eskay fine chemicals) containing barium sulphate (92%) was used. 175 mg of Microbar powder was stirred in 150 mL of water to make a homogeneous solution. Patients were prepared with laxatives 1 d before the procedure. Preliminary plain abdominal films were taken prior to the procedure to rule out significant obstruction and perforation and to evaluate the patient's bowel preparation status. Preliminary films of the gastroesophageal junction, stomach and duodenum under IITV control were taken in the prone, supine and oblique positions to rule out diaphragmatic hernia, stomach and duodenum lesions and to assess the position of the duodeno-jejunal flexure. The patient then lay on his right side so that a continuous single column of barium was delivered into the small intestine. Prone postero-anterior (PA) films of the abdomen were taken every 20 min during the first hour and subsequently every 30 min to 45 min until the barium reached the colon[8]. A light dry meal was allowed after the barium had reached the ileum to speed up the examination if transit time was slow. Spot films of the ileocecal junction were also taken if required. Spot films with compression were taken of suspected abnormal bowel loops and strictures if required. When the barium was seen to cross the splenic flexure and the small bowel was almost devoid of barium on fluoroscopy, sufficient air was insufflated rectally using a sphygmomanometer cuff to achieve adequate distention of the colon.

About 300 mL to 450 mL of air was insufflated. Standard antero-posterior (AP), PA and oblique views of the colon were taken to observe the proximal and distal large intestine.

Table 1 Comparison of sensitivity and specificity in detecting colonic abnormalities using various imaging modalities and colonoscopy (%)

Imaging	Sensitivity	Specificity
Barium enema	7/7 (100)	42/43 (97.67)
BMFT with pneumocolon	6/7 (85.71)	41/43 (95.35)
CT abdomen	3/7 (42.87)	41/43 (95.35)
Colonoscopy	7/7 (100)	43/43 (100)

BMFT: Barium meal follow through.

RESULTS

One hundred and fifty patients presented with chronic abdominal pain, of which fifty patients (28 males, 22 females) had bowel symptoms. The mean age of these 50 patients was 35 years (range 25-55 years). Structural pathology was found in only 10 patients (Figure 1A). Caecal deformity along with distal ileal narrowing was seen in 2 patients, multiple ileal strictures in 3 patients, ileal stricture and stricture of the descending colon in 1 patient, multiple small bowel strictures with loss of haustration in most of the large bowel in 1 patient, jejunal and transverse colonic stricture in 2 patients (Figure 2) and stricture of the sigmoid colon in 1 patient. Nine of these ten patients had small bowel involvement while seven had colonic involvement.

BMFT detected 8 of 9 patients (sensitivity = 88.89%) who had small bowel involvement while BMFTP detected one additional patient with ileocecal involvement which was missed on BMFT (sensitivity = 100%).

In 7 patients where colonic pathology was found, BMFTP detected lesions in six patients while DCBE detected lesions in all seven patients. BMFTP gave false-positive results in 2 patients while DCBE was false-positive in one patient. Colonoscopy was normal in these false-positive cases. The sensitivity of BMFTP in the detection of colonic pathology was 85.71% (6/7) and was 100% (7/7) for DCBE. The specificity of BMFTP was 95.35% (41/43) and was 97.67% (42/43) for DCBE (Table 1).

CT scanning of the abdomen revealed small bowel involvement in only four of the nine patients (sensitivity

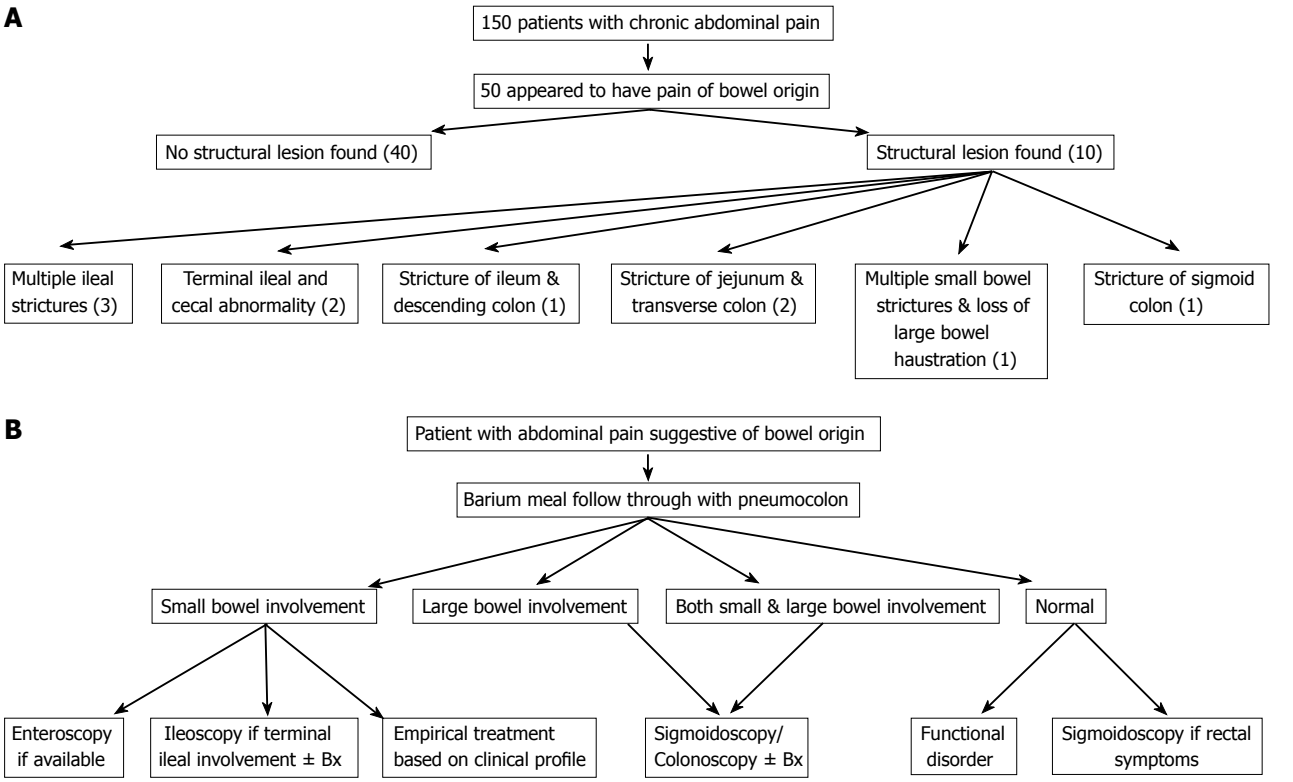

Figure 1 Study design. A: Study design revealing the various structural lesions observed in subjects; B: Step-up approach for investigating patients with chronic abdominal pain suggestive of bowel origin.

Figure 2 BMFTP. A: Showing multiple small bowel strictures; B: Adding pneumocolon to barium meal follow through revealed transverse colonic stricture in the same patient.

= 44.45%) and colonic lesions in three of seven patients (sensitivity = 42.87%), although CT revealed additional findings including abdominal lymph nodes (4 patients) and a small amount of free fluid in the abdomen (2 patients).

Colonoscopy performed in all fifty patients revealed colonic lesions in seven patients and terminal ileal involvement in two patients. Biopsies taken from various lesions revealed tuberculosis in four patients, two patients had features of Crohn's disease and one had colonic malignancy.

Screening a patient with abdominal pain suggestive of bowel origin using a combination of BMFT and DCBE cost three thousand rupees (71.43 $) while BMFTP cost eighteen hundred rupees (42.86 $) and the sensitivities were almost comparable. Screening with BMFTP instead of BMFT and DCBE obviates the need for colonoscopy in around 80% of patients.

DISCUSSION

This study revealed that screening patients with abdominal pain of luminal origin using BMFTP alone was cheaper compared to the combination of BMFT with DCBE and was almost as sensitive and specific. BMFTP obviates the need for colonoscopy in a number of patients as it also screens patients with colonic involvement.

BMFTP was better than BMFT alone in identifying terminal ileal and cecal lesions[9-12]. In a study by Marshall *et al*[13], BMFTP was found to be as accurate as ileoscopy in diagnosing terminal ileal disease. Minordi *et al*[14] showed that combining pneumocolon with BMFT improved the identification of terminal ileal and cecal lesions. Taves *et al*[7] reported two cases of cecal carcinoma which were initially described as Crohn's disease on the basis of BMFT, but were later diagnosed as malignant by the addition of pneumocolon and further confirmed by colonoscopy and pathology. In this study, we also found that the two patients who had terminal ileum and cecal involvement were both identified by BMFTP while one was missed on BMFT alone.

Adding pneumocolon to BMFT helped in the detection of colonic lesions[15-17]. Previous studies have revealed that BMFTP was better at detecting proximal colonic lesions compared to distal lesions. Chou *et al*[6]

showed that a routine overhead radiograph following the use of the pneumocolon technique was a useful adjunct to small bowel meal examination as it could yield unsuspected and clinically significant colonic findings. Colonic abnormalities such as ascending colonic cancer, acute or chronic colitis, diverticulosis, cecal polyps and ileosigmoid fistula were diagnosed using this pneumocolon technique in their study of 151 patients. Various studies which have combined contrast CT of the abdomen with pneumocolon have been used to evaluate various colonic lesions[18-22]. Some of these studies have shown CT pneumocolon to be a reliable alternative to barium enema where colonoscopy is incomplete, with the added advantage of extra luminal screening, and examination of the proximal bowel[23-25].

In this study, we were able to detect 6 of 7 colonic lesions by adding pneumocolon to BMFT. One of the patients who had sigmoid colonic stricture was missed using this imaging method and was detected by subsequent colonoscopy. Although there is little data available on the role of BMFTP in the detection of colonic lesions, most of the colonic lesions observed in this study were detected by BMFTP.

The findings from this study showed that in a patient with abdominal pain which clinically appeared to be arising from the bowel, that by performing BMFTP, both the small and large bowel were screened at the same time, and that the technique showed an efficacy comparable to that of BMFT combined with DCBE. The BMFTP technique was found to be simple and easy and obtained excellent double contrast visualization of the distal ileum and colon. The rectal and sigmoid areas were difficult to interpret on BMFTP. These patients usually have clinical symptoms suggestive of distal colonic or rectal involvement and they can be investigated with the added procedure of sigmoidoscopy.

In addition, BMFTP obviated the need for colonoscopy in the majority of patients as most of these patients were ultimately found to have functional disorders. Colonoscopy should only be performed in those patients who have positive findings on BMFTP, thereby decreasing the cost significantly. Colonoscopy is an invasive technique with significant procedure-associated discomfort.

Common luminal diseases of the gut such as tuberculosis and Crohn's disease involve more than one site in the bowel. Imaging requires the screening of both the small and large bowel for these diseases and effects therapeutic decisions. BMFTP helped in the investigation of these diseases by screening the whole lumen at one time. This study revealed that many patients who had strictures at multiple sites were successfully detected by BMFTP.

Based on our findings, we proposed a step-up approach for investigating patients with chronic abdominal pain of bowel origin (Figure 1B). Patients presenting with chronic abdominal pain of luminal nature in whom involvement of both the small and large bowel is suspected or where differentiation between the two is not possible, BMFTP should be performed after all baseline investigations. If BMFTP reveals only small bowel involvement, then depending on whether the terminal ileum is involved, patients should undergo ileo-colonoscopy with biopsy or enteroscopy. When terminal ileum is not involved and enteroscopy is unavailable, then patients should undergo empirical treatment based on their clinical profile. On the other hand, if BMFTP shows associated or isolated large bowel involvement, colonoscopy with biopsy of the lesion should be performed. By following this algorithm, one can investigate these patients in a cost effective manner which carries great significance for poor developing nations.

CONCLUSION

In tropical countries where the majority of the population is of low socio-economic status, BMFTP should be included in the investigative workup of patients with chronic abdominal pain of luminal origin, where either multiple sites (small and large intestine) of involvement are suspected or the site is unclear on clinical grounds. BMFTP is an economical, quick and comfortable procedure and obviates the need for colonoscopy in the majority of patients.

COMMENTS

Background

Few studies have tried to evaluate barium meal follow through (BMFT) with pneumocolon as a screening modality in subjects with chronic abdominal pain of luminal origin in developing countries where an inexpensive and cost effective screening tool is needed. Only a few studies have compared BMFT with pneumocolon *vs* plain BMFT for imaging ileocecal areas and the results of these studies have been varied.

Research frontiers

Evaluating small and large bowel simultaneously with a cost effective screening modality in developing countries is needed, as costly invasive modalities like double balloon enteroscopy and colonoscopy can be used only in selected subjects.

Innovations and breakthroughs

This is the first study to evaluate BMFT with pneumocolon as a screening tool for the evaluation of chronic abdominal pain of bowel origin. Adding pneumocolon to BMFT not only helped in detecting ileocecal lesions but also helped to detect colonic lesions with a sensitivity of 88.89% and a specificity of 95.35%.

Applications

This study showed that including BMFTP in the investigative workup of patients with chronic abdominal pain of luminal origin, where either multiple sites (small and large intestine) of involvement are suspected or the site is unclear on clinical grounds, helps in screening both the small and large bowel simultaneously and effectively without adding much to the total cost. This can be of great value in tropical countries where most of the population is of poor socioeconomic status.

Peer review

This study from India demonstrates the effectiveness and cost-effectiveness of BMFTP compared to other methods in screening patients with chronic abdominal pain. It's an interesting paper.

Abstract

AIM: To evaluate the differences that exist between peripheral and mesenteric serum levels of carcinoembryonic antigen (CEA) and cytokeratins in patients with colorectal adenocarcinoma.

METHODS: One hundred and thirty-eight patients with colorectal adenocarcinoma who underwent surgery at Hospital São Paulo (Discipline of Surgical Gastroenterology of UNIFESP-EPM) between December 1993 and March 2000 were retrospectively analyzed. Differences between CEA and cytokeratin (TPA-M) levels in peripheral blood (P) and in mesenteric blood (M) were studied. Associations were investigated between peripheral and mesenteric levels and the staging and histopathological variables (degree of cell differentiation, macroscopic appearance, tumor dimensions and presence of lymphatic and venous invasion).

RESULTS: Differences were observed in the numerical values of the marker levels: CEA (M) (39.10 mg/L ± 121.19 mg/L) *vs* CEA (P) (38.5 mg/L ± 122.55 mg/L), $P < 0.05$; TPA-M (M) (325.06 U/L ± 527.29 U/L) *vs* TPA-M (P) (279.48 U/L ± 455.81 U/L), $P < 0.01$. The mesenteric CEA levels were higher in more advanced tumors ($P < 0.01$), in vegetating lesions (34.44 mg/L ± 93.07 mg/L) ($P < 0.01$) and with venous invasion (48.41 mg/L ± 129.86 mg/L) ($P < 0.05$). Peripheral CEA was higher with more advanced staging ($P < 0.01$) and in lesions with venous invasion (53.23 mg/L ± 158.57 mg/L) ($P < 0.05$). The patients demonstrated increased mesenteric and peripheral TPA-M levels with more advanced tumors ($P < 0.01$ and $P < 0.01$) and in non-ulcerated lesions [530.45 U/L ± 997.46 U/L ($P < 0.05$) and 457.95 U/L ± 811.36 U/L ($P < 0.01$)].

CONCLUSION: The mesenteric levels of the tumor markers CEA and cytokeratins were higher than the peripheral levels in these colorectal adenocarcinoma patients. Higher levels of these biologic tumor markers are associated with an advanced state of cancerous dissemination.

INTRODUCTION

The estimates of cancer incidence in Brazil for the year 2006, published by INCA, indicate that colorectal cancer is the fifth most common malignant tumor type among men (11 390 new cases) and the fourth among women (13 970 new cases). The greatest incidence of cases occurs in the age group between 50 and 70 years old, but the possibility of developing this disease is already increasing after the age of 40 years is reached[1-3].

In 2004, in a study carried out in the 25 member countries of the European Union, 2 886 800 new cases of cancer and 1 711 000 deaths were recorded. The most common type was lung cancer (13.3%) followed

by colorectal cancer (13.2%) and breast cancer (13%). Lung cancer was also the greatest cause of death (341 800 cases) followed by colorectal cancer (203 700 cases)[4].

When colorectal cancer is detected in its initial stage, it may even be curable. However, the overall survival of patients with colorectal cancer does not exceed 40%. The mean five-year survival for patients with early diagnosis (stage Ⅰ) is approximately 70%, while it is 6% for advanced cases of the disease (stage Ⅳ)[1,2].

Tumor markers are substances produced by the neoplasia than can be identified in the neoplastic tissue itself and in patients' biological fluids. Many studies have been conducted to evaluate serum tumor markers at different stages of diagnosis and follow-up of colorectal carcinoma cases. Carcinoembryonic antigen (CEA) is distinguished as the most important marker[1,2,5-9].

CEA was first identified in 1965, and is a high-molecular-weight glycoprotein that is found in the cytoplasmic membrane of digestive system cells in the fetal phase and in neoplastic cells[10]. Cytokeratins form part of the microtubules of the cellular cytoskeleton, and they are released into the bloodstream during processes in which there is intense cell proliferation or apoptosis[11].

There is controversy regarding whether or not there are differences in the serum levels of the markers according to the location of the blood sample collection: from peripheral veins or from blood flowing directly out of the lesions. If there were a difference between the mesenteric and peripheral serum levels of such markers, the former might more accurately reflect the real levels produced by the tumors than would the latter. Some authors have found a significant difference between the mesenteric and peripheral levels of CEA, while others have not reproduced these results. Some studies have also demonstrated relationships between high marker levels in mesenteric serum and the histopathological variables of colorectal tumors[12-16].

The objective of the present investigation was to analyze the mesenteric and peripheral levels of CEA and cytokeratins in patients with colorectal adenocarcinoma and observe their correlation with the staging and certain histopathological variables.

MATERIALS AND METHODS

The patients were volunteers and were treated in accordance with a protocol approved by the Research Ethics Committee of the institution. In this study, 138 patients with colorectal adenocarcinoma were retrospectively analyzed. These patients were attended to and surgically treated by the Coloproctology Group, Discipline of Surgical Gastroenterology, Department of Surgery, Federal University of São Paulo-Escola Paulista de Medicina (UNIFESP-EPM). The operations were performed at Hospital São Paulo between December 1993 and March 2000. Surgical resection was performed on 124 patients, while the tumors were considered irresectable in 14 patients.

Patients who had had some other benign or malignant neoplasia at some previous time, and those for whom it was not possible to collect the data needed for the proposed analysis, were not included in the study.

With regard to the ethnic group to which the patients belonged, 68.1% were white, 22.5% brown, 6.5% yellow and 2.8% black. With regard to gender, 57.2% were female. The patients' ages ranged from 19 to 87 years, with a mean of 61.7 years.

The variables analyzed in the present investigation were: staging of the colorectal neoplasia by means of the TNM classification, degree of cell differentiation, diameter of the neoplasia, presence or absence of venous invasion and presence or absence of lymphatic invasion.

According to the TNM classification, 34 patients were in stage Ⅰ, 21 in Ⅱ, 34 in Ⅲ and 49 in Ⅳ. With regard to the degree of cell differentiation, there were 55 patients with well-differentiated tumors, 66 with moderately-differentiated tumors and three with poorly-differentiated tumors. Regarding the diameter of the neoplasia, 16 patients had tumors of $\leqslant$ 3.9 cm; 76 of 4.0-7.9 cm and 32 $\geqslant$ 8.0 cm. The presence of venous invasion was identified in the lesions of 23 patients, while lymphatic invasion was identified in 41 patients.

The collection of peripheral venous blood was done by means of direct puncture in the arm that was free of endovenous hydration, while anesthesia was being induced. Samples of 10 mL of blood were collected in dry tubes. These were centrifuged to obtain the serum from the sample, and this was stored at -20℃.

The mesenteric blood for assaying the marker levels was collected by dissection, sectioning and catheterization of the inferior mesenteric vein, when the tumor was located in the left colon or the rectum. For tumors in the right colon, collection was *via* the wide tributary vein of the superior mesenteric vein, and for tumors in the transverse colon, collection was *via* the middle colic vein. The corresponding vein was dissected and repaired with 00 cotton thread; the vein was sectioned obliquely and the catheter was introduced towards the tumor, with the collection of 10 mL of blood. This procedure was carried out before any manipulation of the tumor. The blood was centrifuged, with separation of the serum and storage in the same way as done for the peripheral blood samples.

The method utilized for assaying the CEA levels was DELFIA®. The CEA levels were considered to be normal when they were less than the limit of 5.0 mg/L.

For assaying the cytokeratin (TPA-M) levels, the LIA-mat® TPA-M Prolifigen® method was utilized, (AB Sangtec Medical®), which utilizes a reference value of 72 U/L as the cutoff point between normal and abnormal values, and this point was taken for the present investigation. The apparatus utilized for carrying out the serum assays was the Lumat LB 9501® luminometer, (EG&G Berthold).

Statistical analysis

For the statistical analysis of the data obtained in this study, *t* test and the marginal homogeneity test were

utilized. To study the correlations using the TNM variable, the Bonferroni multiple comparisons method was utilized.

In the tests utilized, the level of statistical significance for rejection of the nullity hypothesis was set at 0.05% or 5% ($\alpha \leqslant 0.05$), thereby indicating the results that were considered significant.

RESULTS

Analysis of the mesenteric and peripheral levels of the markers

Two statistical analysis methods were performed (one numerical and the other categorical), and each of the markers was analyzed in relation to its peripheral and mesenteric concentrations. With regard to the numerical descriptive measurements of the CEA levels, the mean for CEA (M) was 39.10 mg/L ± 121.19 mg/L and the mean for CEA (P) was 38.5 mg/L ± 122.55 mg/L, with a statistically significant difference ($P < 0.05$). Comparison between the proportions of positive rates of mesenteric and peripheral CEA was done by means of the marginal homogeneity test. No statistical difference was found from this.

With regard to the numerical descriptive measurements of the TPA-M levels, the mean for TPA-M (M) was 325.06 U/L ± 527.29 U/L and the mean for TPA-M (P) was 279.48 U/L ± 455.81 U/L ($P < 0.01$). To compare the evaluations of mesenteric and peripheral TPA-M, the marginal homogeneity test was utilized, from which it was found that rate of positive results was greater for mesenteric TPA-M ($P < 0.05$).

Associations

For both markers and for both mesenteric and peripheral blood, the levels were related to advanced stage of the neoplasia, and especially to stage Ⅳ of TNM. In addition to this association, CEA (M) and CEA (P) presented correlations with venous invasion, and CEA (M) alone correlated with vegetating lesions. Both the mesenteric and peripheral levels of TPA-M were high in non-ulcerated lesions (Table 1).

DISCUSSION

Many studies have been conducted on tumor markers, seeking greater understanding of all the possible ways of using them in diagnoses, staging, prognoses and

detection of neoplastic recurrences[1,5-7,14,17]. Even the location for sample collection has been analyzed, seeking the site that would best translate the serum levels of tumor markers and identify groups of patients with more limited prognoses (with or without liver micrometastases), and also to identify the patients who would most benefit from adjuvant therapy, for example[8,17-20].

Studies have analyzed samples from different markers collected from different points: peripheral veins or the main drainage vein from the neoplasia. The levels of these markers have been found to be higher when sampled closer to the tumors, and thus the peripheral levels do not provide a true reflection of the production of these markers.

The production of markers by diseased cells, the release of these markers and their passage through adjacent tissue, their entry into lymphatic vessels and the bloodstream, the formation of immunocomplexes, metabolism of these markers, their excretion from the liver and absorption by the colorectal wall, are factors that would influence the peripheral levels of these markers[12,13].

The way in which markers arrive in the peripheral blood has still not been clearly established. It could be *via* the portal vein system, the lymphatic system, or both. Previous studies have suggested that CEA arrives in the peripheral blood *via* the portal system[12,13]. These studies have shown that there is a strong association between the mesenteric and peripheral CEA levels and the extent of venous invasion and degree of penetration of this invasion into the colorectal wall. They have also shown that there is a significant increase in the portal levels of CEA soon after the manipulations carried out during the surgical resection of the neoplasia.

In the case of colorectal adenocarcinoma, CEA has become prominent in demonstrating usefulness for following up patients who have undergone surgery with curative intent, with increases in its levels in the event of probable tumor recurrence or development of liver metastases[7,17-19,21].

Cytokeratins have shown greater sensitivity than that of CEA in the initial diagnosis, staging, establishment of prognoses and detection of recurrence in colorectal adenocarcinoma cases[1,2,5].

The studies performed by Tabuchi *et al*[12,13] in Japan have established that there is a statistically significant difference between the mesenteric and peripheral CEA levels, and thus the authors postulate that this marker reaches the peripheral blood *via* the portal system. Positive rates were correlated with certain histopathological variables, such as venous invasion and Dukes classification. These studies have also demonstrated that patients with high mesenteric CEA levels are potentially at risk of developing liver metastases and that such levels have a negative impact on patient survival.

The mesenteric-peripheral CEA gradient has also been utilized, together with the mesenteric levels, for assessing the impact on postoperative survival among patients with colorectal cancer. A study published in Japan in 1990 demonstrated that patients with a mesenteric-peripheral CEA gradient greater than 10 ng/mL would have a worse prognosis[18].

Another study of interest showed that the mesenteric levels and the mesenteric-peripheral gradient were more effective than the utilization of the peripheral levels alone for predicting liver metastases. A study published in Japan in 1998 compared patients with advanced colorectal cancer divided into two groups: with and without liver metastases. The mean mesenteric CEA level and mesenteric-peripheral gradient were greater than the peripheral level in the group with postoperative liver metastases. This suggests that mesenteric assaying of this marker would be more effective for predicting this event[22].

Subsequent studies conducted by other authors have not shown significant differences between the peripheral and mesenteric CEA levels[14-16]. This may be related to the small size of the samples analyzed in these studies.

In the present investigation, the sample was composed of 138 patients who were analyzed retrospectively. All of them underwent peripheral and mesenteric assaying of the CEA and cytokeratin (TPA-M) levels, which were evaluated in relation to seven histopathological variables. Statistically significant differences were found between the peripheral and mesenteric CEA and cytokeratin levels when numerical analysis was performed. When only the positive frequency of the markers was investigated, there was only a difference for cytokeratins. This may signify that the main drainage route for the markers is the portal system.

Both of these markers had high levels in TNM stage IV, both for mesenteric and for peripheral blood. Thus, the markers had significantly higher levels when the neoplastic disease was no longer limited to the colon. This corroborates the findings of Fernandes *et al*[1] (2005), which showed higher marker levels in cases of patients with extra-colonic disease, perhaps signifying the presence of liver or occult lymph node micrometastases[17].

The mesenteric and peripheral CEA levels were higher in the presence of venous invasion, and this reproduces the results from previous studies. This may corroborate the hypothesis that drainage *via* the portal vein system is the fundamental principle for the distribution of this marker[12-16].

In the present study, the cytokeratin levels were also higher in the presence of non-ulcerated lesions. No studies presenting an association between peripheral and mesenteric CEA and cytokeratin levels and the macroscopic characteristics of the lesion were found in a search of the medical literature. In the present investigation, there were associations between mesenteric CEA and vegetating lesions and between mesenteric and peripheral cytokeratins and non-ulcerated lesions. It is believed that subsequent studies will be necessary, in order to analyze and compare ulcerated, vegetating and infiltrative lesions in relation

to survival and the peripheral and mesenteric levels of biological tumor marker, so as to obtain greater depth for the conclusions.

In summary, the present results allow it to be concluded that, for the patients analyzed, there was a significant difference between the CEA and cytokeratin tumor marker levels, with higher levels in the samples collected from the portal vein system than in those obtained from the peripheral blood. The levels increased in accordance with the progression of neoplastic dissemination. High mesenteric and peripheral CEA levels were associated with venous invasion. There were higher assayed cytokeratin levels in patients with non-ulcerated colorectal adenocarcinoma lesions.

Abstract

AIM: To evaluate endoscopic and histopathologic aspects of acute gastric injury due to ingestion of high-dose acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) with respect to some risk factors and patient characteristics.

METHODS: The study group consists of 50 patients admitted to emergency department with high dose analgesic ingestion (group Ⅰ) with suicidal intent. Thirty patients with or without mild complaints of dyspepsia (group Ⅱ) were selected as the control group. The study group was stratified according to the use of type and number of analgesics. Endoscopic findings were evaluated according to the Lanza score (LS), expressing the severity of the gastroduodenal damage and biopsies according to a scoring system based on histopathologic findings of acute erosive gastritis.

RESULTS: Gastroduodenal damage was significantly more severe in group Ⅰ compared to group Ⅱ ($P < 0.01$). The LS was similar in both groups Ⅰa and Ⅰb. However LS was significantly higher in patients who had ingested multiple NSAIDs (group Ⅰc) compared to other patients ($P < 0.01$). The LS was correlated to age ($P < 0.01$) and total amount of drug ingested ($P < 0.05$) in group Ⅰ; but it was not correlated with *Helicobacter pylori (H pylori)* infection or duration of exposure ($P > 0.05$). The biopsy score (BS) was higher in group Ⅰ than group Ⅱ ($P < 0.01$), and higher in group Ⅰb than group Ⅰa ($P < 0.05$).

CONCLUSION: The histopathologic damage was more severe among NSAID ingesting patients compared to those ingesting only acetaminophen and there is no significant difference in the endoscopic findings between the groups. There is no significant difference in the LS between the groups. This lack of significance is remarkable in terms of the gastric effects of high-dose acetaminophen.

INTRODUCTION

Analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are extensively used pharmaceutical agents. NSAIDs are well known and widely used for their anti-inflammatory, analgesic and antipyretic properties. Incidence of gastrointestinal side effects associated with NSAIDs is relatively high

and common. Gastrointestinal side effects of NSAIDs are related to various factors such as individual risk factors, the dose and the duration of use. NSAID use presents with a 2.5- to 5-fold increase in the risk of gastrointestinal tract (GI) complications[1]. These complications vary from abdominal discomfort to serious complications like ulceration, bleeding, perforation or obstruction[2]. Risk for adverse gastrointestinal events related to NSAID use are related to the age of the patient (> 60 years), presence of previous complicated/uncomplicated ulcer, use of multiple NSAIDs, dose of NSAIDs, type of drug, the presence of *H pylori* infection, concomitant use of corticosteroids and serious comorbid diseases[1,3]. Besides these, duration of the NSAID use, smoking and alcohol consumption have also been reported to increase the risk of NSAID complications, and the incidence of adverse events decrease with long-term use due to adaptation mechanisms[4,5].

The reports about NSAID use and related adverse events have so far involved therapeutic doses of NSAIDs. Therefore acute effects of short-term, especially high-dose NSAID and acetaminophen use have not been reported. This study was designed to investigate acute gastric injury and histological changes among patients who ingested high dose NSAID with suicidal intent. We evaluated the association of single high dose analgesic use with previous gastric complaints, smoking, food intake, drug dose, duration of exposure, co-existence of *H pylori*, and body position during intake (standing/supine) on the distribution of gastric lesions.

MATERIALS AND METHODS

Study group

This is a prospective, randomized and controlled study. Fifty Patients admitted to the emergency unit after ingestion of high-dose analgesics with suicidal intent (group Ⅰ) were included in the study. The control group consisted of 30 patients with or without mild dyspeptic complaints (group Ⅱ). The patients in the study group were grouped according to the type of analgesic use: Of the 50 patients, 18 ingested only acetaminophen (group Ⅰa), 32 have ingested only NSAIDs (group Ⅰb) and in a subgroup of the NSAID ingesting group 10 ingested multiple types of NSAID simultaneously (group Ⅰc). Exclusion criteria were: antacids, acid suppressants (H_2-blocker, PPI), NSAIDs and steroid use with or without alcohol consumption, established gastric condition and treatment for gastric symptoms, systemic disease and homodynamic disorders and cognitive problems. The control group consisted of patients presenting with or without mild gastric complaints who had not been previously diagnosed with a gastric or any other disease, no history of alcohol use, and who had not used acid suppressants or NSAIDs within the last month. Exclusion of chronic or intermittent NSAIDs users enabled us to compare the endoscopic and histological assessed acute gastric damage with an almost healthy group. The study protocol was approved by the local ethics committee.

Table 1 Maximum recommended daily dose according to drug type[6]

Drug	Dose (mg)
Acetaminophen	4000
Aspirin	4000
Etodolac	1200
Flurbiprofen	300
Ibuprofen	2400
Naproxen sodium	1375

Table 2 Endoscopic grading scale: LS[7,8]

Grade	Scale
0	No visible lesions
1	Redness and hyperemia in the mucosa
2	One or two erosions or hemorrhaging lesions
3	3-10 erosions or hemorrhaging lesions
4	> 10 erosions or hemorrhaging lesions or an ulcer

Note: Erosions are defined as flat, white-based mucosal breaks of any size; Ulcers are defined as mucosal breaks of at least 3 mm or more.

Study design

Demographic characteristics, smoking habits and history of gastric complaints during the last month were compared. The dose and type of drug used with suicidal intent was identified by examination of drug pack physically and information were obtained from the household. Information about time of the ingestion, type and amount of the drug, the occurrence of vomiting after intake, food intake and body position following the ingestion (standing/supine) and gastric lavage after the ingestion were recorded. The amount of ingested drug was standardized based on the pharmacological maximum recommended daily dose and scored in multiples (Table 1)[6].

Within 24 h following drug ingestion, gastroduodenoscopy was performed on the study and control groups. Endoscopic gastric findings were recorded by video endoscopy, and evaluated by a second endoscopy specialist according to the Lanza score (LS) (Table 2)[7,8]. Biopsies were obtained from the antrum for *H pylori* testing from all patients and from lesions if present. Biopsy specimens were stained with hematoxylin-eosin and with modified Giemsa for *H pylori*. In order to evaluate and quantify the histopathologic findings we have made a list of microscopic findings of NSAID-related acute erosive/hemorrhagic gastritis[9,10]. These findings were stratified into a three-scaled scoring algorithm according to the severity of the lesions which we present in Table 3 as biopsy score (BS).

Statistical analysis

Besides descriptive statistical methods (mean, standard deviation, frequency), the Mann-Whitney *U* test, χ^2 test, and Spearman's Rank Correlation Test were used in the

Table 3 Three-scaled histomorphologic scoring algorithm developed by us indicating the severity of the lesions according to microscopic findings of NSAID-related acute erosive/hemorrhagic gastritis

Score	Microscopic findings
1	Superficial epithelium is intact, edema at superficial lamina propria, dilated and congested capillary structures, extravasated erythrocyte and tiny fibrin clots
2	Multiple focal scattered erosions + 1
3	Disappearance of superficial epithelium, presence of proteinose materials on the surface of epithelium, diffuse hemorrhages within lamina propria, transmural ischemic necrosis + 2

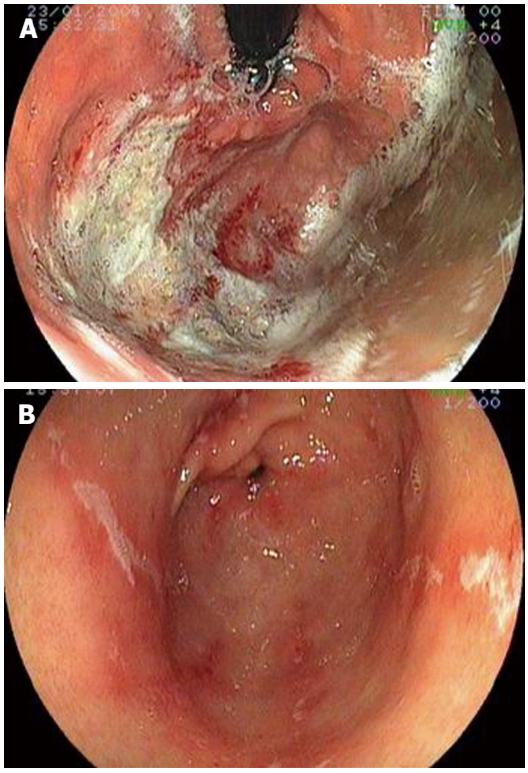

Figure 1 Images of lesions according to the posture after the ingestion. A: Patients in the supine position following ingestion of NSAID; B: Patients in the upright position following ingestion.

assessment of study results. Results were evaluated with a 95% confidence interval (CI) and a significance level of $P < 0.05$.

RESULTS

Patients in group Ⅰ [23.3 ± 7.5 years (range: 14-50)] were younger than those in group Ⅱ [32.3 ± 7.6 years (range: 19-48)] ($P = 0.001$). There was no difference between the two groups in terms of smoking ($P = 0.39$) and *H pylori* positivity ($P = 0.385$) (Table 4). Patients in group Ⅰ a had ingested 1-5 times the maximum daily dose of acetaminophen, while those in group Ⅰ b had ingested 1.2-13.6 times the maximum daily dose of NSAIDs.

Clinical findings

There was no significant difference between group Ⅰ and group Ⅱ with respect to gastric symptoms within the last month. Of the group Ⅰ patients, 12% had nausea, 6% had mild heartburn, 4% had epigastric pain and 4% had hemathinized gastric fluid in nasogastric lavages during the emergency department examination. There was no difference in LS and BS among group Ⅰ patients with or without gastric symptoms during last month.

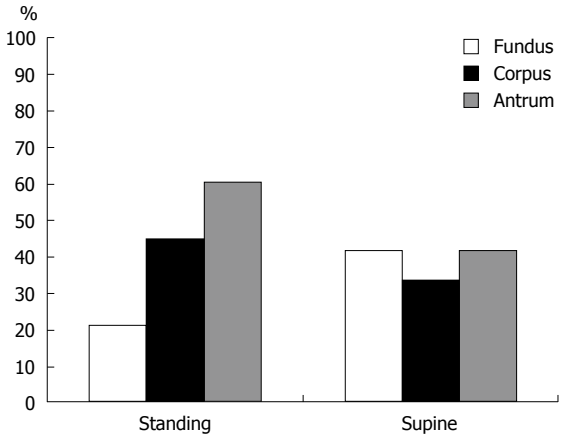

Figure 2 Distribution of the localization of endoscopic lesions in patients in the standing and supine positions following ingestion.

Endoscopic findings

There was no difference between fundus, corpus, and antrum involvement of endoscopic lesions according to body position after drug intake ($P > 0.05$). Although there was no statistically significant difference in the distribution of gastric lesions in the fundus, corpus, or antrum according to body position after ingestion, the allocation of gastric lesions in the fundus were 21.1% in the standing and 41.7% in the supine positions, lesions in the antrum were 60.5% in the upright and 41.7% in the supine positions. Images of lesions according to the posture after the ingestion are demonstrated in Figure 1. Although there was no statistical significance, anatomical distribution of gastric lesions differed according to the body position after the ingestion (Figure 2).

LS

The LS of group Ⅰ (2.3 ± 1.2) was higher than in group Ⅱ (0.77 ± 0.6) ($P < 0.01$). The LS was positively correlated with age in group Ⅰ ($r = 0.39$, $P < 0.01$), with a significant correlation at the 39.1% level. LS increased with age (Figure 3). Conversely, LS was not correlated with smoking habits, food intake, *H pylori* positivity and duration of exposure to the drugs ($P > 0.05$). Interestingly, the difference between the LS of patients who ingested only NSAIDs (group Ⅰ b) was higher but not significant compared to those who ingested only acetaminophen (group Ⅰ a) ($P = 0.08$). The LS of patients who ingested multiple types of NSAIDs was significantly higher than those who took a single type of NSAID ($P < 0.01$). There was a positive correlation between the total amount of ingested drugs and LS ($r = 0.35$, $P < 0.05$) which means that LS increased with increasing drug dose.

Table 4 Comparison of LS and BS in relation to various patient characteristics

		LS (median)	BS (median)
Group	Patients	2.30 ± 1.18 (2)	2.26 ± 0.83 (2.5)

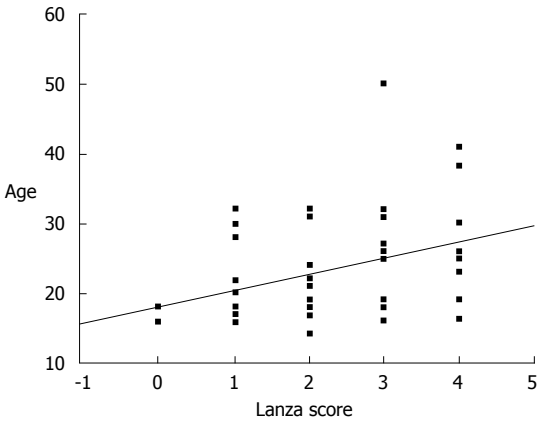

Figure 3 Correlation between age and LS.

BS

The BS of patients in group Ⅰ (2.3 ± 0.8) was significantly higher than in patients of group Ⅱ (1.47 ± 0.73) ($P < 0.01$). There was no correlation between BS and age, smoking habits, food intake, *H pylori* positivity or duration of drug exposure among group Ⅰ ($P > 0.05$). The BS of group Ⅰb patients (2.58 ± 0.70) was higher than in patients in group Ⅰa (1.94 ± 0.87) ($P < 0.05$). The BS of patients who ingested only NSAIDs was higher than in those who ingested only acetaminophen ($P < 0.05$). The BS of patients who took multi-agent NSAIDs and of those who took single-agent NSAIDs were similar ($P > 0.05$). There was no significant correlation between the total amount of ingested drug and BS ($P > 0.05$).

DISCUSSION

Besides personal risk factors, the type and the dose of NSAIDs, duration of exposure to the drug and concomitant use of other drugs play an important role on NSAID-related GI side effects[11]. In our study, we observed a positive correlation between endoscopically observed gastric injury and age, although none of our patients were in the age group (> 60 years) established as an individual risk factor. The gastric effects of NSAIDs vary according to their acute or chronic use. Short-term studies have reported that gastroduodenal mucosal injury is dose-dependent. Acute injury on the gastric superficial epithelium occurs within minutes, whereas subepithelial hemorrhage and erosions occur within hours[12,13]. Asymptomatic endoscopically observed lesions are submucosal hemorrhage, erosions, and ulceration. Intramucosal hemorrhage, petechia, and mucosal erosions have been observed endoscopically with short-term usage. Superficial ulceration typically appears within 1 wk[11]. Following single-dose (650-1300 mg) aspirin intake, gastric lesions occur with a 100% certainty[12]. This gastric mucosal injury has been reported to develop rapidly, within 24 h of ASA intake, erosions have been observed within the first 24 h, and maximal damage appeared within 3 to 7 d[8,14,15]. In our endoscopic evaluation within the first 24 h, hemorrhagic foci, erosions and marked gastric ulceration were observed. There were acute findings in the histomorphological evaluation such as congestion of the superficial lamina propria, edema, extravasated erythrocyte and fibrin aggregates within two patients whose LS was 0.

The gastric effects of long-term NSAID use are diverse. Gastric and duodenal mucosal erosions and gastroduodenal ulcers, hemorrhage, perforation and even fatality due to complications of ulceration can occur[12,16]. In long-term NSAID users, gastric injury is more likely to be more severe and has a higher possibility to be localized in the antrum than the corpus[13,17]. Lesions situated in the antrum might penetrate into the submucosa and tend to be wider in size (> 6 mm)[13,18]. Ulcers are most commonly localized in the stomach and are diffused, multiple and painless[4]. Many patients who show mucosal damage in the form of ulceration have no or mild symptoms, while many cases without visible mucosal damage present with indigestion, abdominal pain, distension and flatulence[8,16,19]. Sudden-onset GI hemorrhage or silent perforation has also been reported following ingestion of NSAIDs[8]. In our study of acute high dose use, physical examination and symptom inquiry did not reveal apparent differences and clinical presentation and endoscopic findings were not correlated as in the chronic NSAID users. None of the patients were admitted for gastric symptoms, they were rather admitted for the long term toxicity concerns. One patient with marked ulcerations had mild epigastric pain. Abdominal palpation was normal for two patients who had extensive superficial ulcerations and hemathinized fluid in nasogastric lavage.

Various studies have reported an increase in the risk of gastrointestinal toxicity with short-term NSAIDs use, and demonstrated that the first month of treatment presents the largest risk, while the risk thereafter decreases with chronic use[4]. A meta-analysis of 16 studies by Gabriel *et al* reported an 8-fold increase in the NSAID-related gastrointestinal risk within the first 1 mo, a 3.3-fold increase within 1-3 mo and 1.9-fold increase for longer than 3 mo of use[5]. LS was 4 in 20% of our cases, which present an example for risk of high-dose NSAIDs in the short-term use. This high percentage may be interpreted as the added ulceration effect of acute local toxic damage without a period of adaptation, thus these patients had multiple and large superficial ulcerations and marked hemorrhagic foci.

Endoscopic evaluations demonstrated that superficial lesions develop acutely, within minutes, and that topical factors prevail in the development of lesions. Acute lesions involve only the mucosa, are small in size, and are more prevalent in the fundus than in the antrum[13,18]. NSAID-related ulceration is most often localized in the greater curvature of the antrum. In adults, in the normal upright position, this region is susceptible to external factors, indicating that this type of ulceration (sump-ulcer) is related to the direct ingestion of corrosive substances[13]. A study on this subject reported more histological damage in the antrum than in the corpus[15]. In an endoscopic evaluation in 6 healthy dogs following administration of carprofen (4 mg/kg) and deracoxib (4 mg/kg), involvement of the fundus, antrum and lesser curvature was reported to deteriorate on the second day of treatment and heal on the fifth day[20]. Since early topical consequences are in the forefront in our cases, gastric lesion involvement in the fundus was observed in 41.7% of the patients who were in the supine position following drug intake, and in the antrum in 60.5% of the patients who remained standing, albeit without statistical significance. Considering that local damage is greater than systemic effects, this may account for the lack of significance of high-dose drug use with more intense topical exposure and localization.

Subsequent doses have been determined to increase the frequency, but not the severity of lesions[14,20]. The damage was greatest on the third day of continuous use, and endoscopic damage was lesser on the seventh day than the first day. Adaptation occurred at around the third day, and was found to be associated with increasing healing processes[14]. Endoscopic gastric damage is primarily dose-related and occurs even in anti-inflammatory doses of NSAIDs. In a study with 1 064 healthy volunteers, 6.7% of the subjects developed ulcerations after a 7-d course of anti-inflammatory dose[19]. Adaptation and resolution occur more slowly with high doses and more rapidly with low doses, and discontinuation accelerates the healing process[15]. We have preferred not to have a chronic NSAID user control group, so that we could demonstrate gastric damage in acute NSAID use.

Bergmann *et al*[21] administered single-dose ketoprofen (25 mg), ibuprofen (200 mg) or aspirin (500 mg) to 12 healthy subjects with empty stomach and found that lesions were similar with ketoprofen and ibuprofen using the LS and they were less local toxic compared to aspirin. Previous publications support the finding of the local damaging effect of short-term, single-dose use of NSAIDs[15]. In our study, the total amount of drug taken was found to be correlated with LS. We found a correlation between the total amount of drug taken and the severity of endoscopic findings. Also, multiple types of NSAID users had more endoscopic gastric damage than acetaminophen only or single NSAID users.

In a study that investigated damage on the gastric mucosa 10 and 60 min after the direct administration of 2 g acetaminophen in 100 mL saline solution, 10 min after administration cellular damage was seen in 3%-5% in the study group and 1%-7% in the control group. Microscopic evaluation showed focal cellular disruption and erythrocyte infiltration. Electron microscopy revealed minimal loss in the cellular apex, but no erosion. The corresponding findings with aspirin are quite different. A 2 g dose of acetaminophen caused minimal mucosal damage[22]. After a 7d continuous treatment on 7 healthy volunteers, aspirin and acetaminophen (1.95 g/d or 2.6 g/d) plus aspirin (1.95 g *vs* 3.9 g) on a full stomach caused escalating mucosal damage with increasing doses in the group that received aspirin. However, the addition of acetaminophen to the aspirin regimen did not cause any deterioration of gastric damage. All doses were received on a full stomach[23]. In the study group, food intake before ingestion of analgesics had no effect on LS or BS. Patients who took acetaminophen had ingested single doses of 4000 to 20 000 mg, and their endoscopic evaluations revealed LS of 0 to 4. The LS of

two patients who took 10 000 mg acetaminophen was 0 and 4, respectively. The unsteadiness of the BS might be due to the non-uniformity of gastric histomorphologic findings. In this study, the determination of endoscopic damage among patients who ingested higher doses of acetaminophen compared to previous studies[22,23] indicate that high-dose acetaminophen use may cause damage, however the damage and dose relationship suggests that factors other than dose also play a role.

Chemical gastropathy may present with separate or concurrent nonspecific histopathologic lesions of various degrees and proportions, and no correlation between histological findings and clinical symptoms, particularly the risk of bleeding, has been documented in gastropathy[24]. Following aspirin ingestion, the inconsistency of biopsy results during histological evaluations may reflect sampling errors, or aspirin-related changes may be unpredictable. None of the biopsies taken from normal-appearing mucosal tissue following aspirin intake yielded normal results. Visible damage may somewhat intensify after the second and third doses, but the extent of damage does not increase after a couple of doses, and may even start to diminish. Although mucosal appearance normalizes, gastric microhemorrhages do not cease to occur during aspirin use[15]. Histomorphological evaluation is significant in such cases[9]. In this study, BS was not correlated with the total amount of drug taken or the use of multiple NSAIDs. However, histological gastric damage was more extensive in patients who ingested NSAIDs compared to those who ingested acetaminophen only. There were no marked histomorphologic differences between biopsy evaluations of acetaminophen and NSAID patients. Nonetheless, the biopsies of all patients who took only acetaminophen revealed acute gastric damage, and six patients with a BS over 3 had ingested 6000 mg (n = 1) or 10 000 mg (n = 5) acetaminophen. The BS and LS of acetaminophen only patients did not correlate to the acetaminophen dose increments (Figure 4). Even the patient with a LS of 0 had findings of erosive gastritis in the histomorphologic evaluation. Also, all patients had more bleeding during endoscopic biopsy procedures compared to routine procedure or chronic NSAID users.

H pylori infection and NSAID-related gastric mucosal damage occur through different pathways and separate mechanisms[16]. Foveolar hyperplasia, edema and vascular ectasia are more extensive in NSAID-related gastritis compared with *H pylori* gastritis[13,17]. Gastric damage related to aspirin use was found to be more limited in patients with *H pylori* eradication, thus indicating that *H pylori* may enhance NSAID-induced gastric damage[25]. It was also reported that ulcer bleeding was more prevalent in patients with *H pylori* infections[26]. Conversely, certain studies have reported that positivity or negativity of *H pylori* in NSAID users made no significant difference[27,28]. In our study, *H pylori* positivity was not related to significant changes in LS or BS in patients who had taken acetaminophen and NSAIDs.

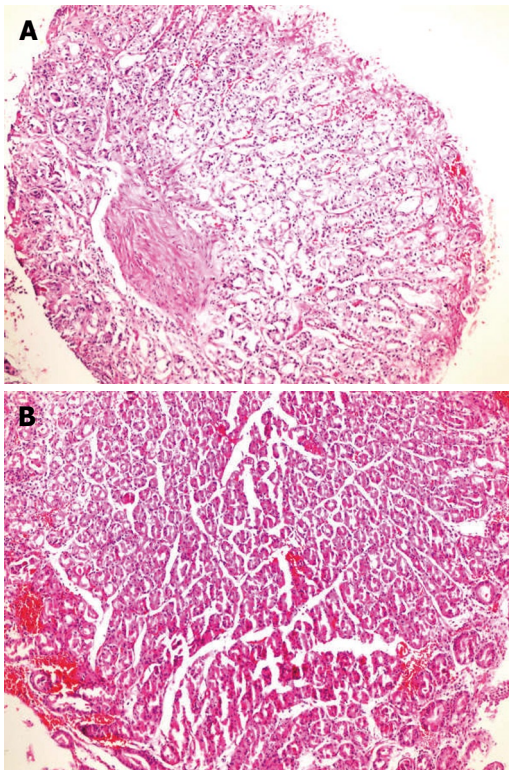

Figure 4 HE stain images, x 100. A: Acetaminophen only (10 000 mg) patient with LS = 4 and BS = 2. Erosion within superficial epithelium, fibrin clots on superficial lamina propria, widespread congested vessel structures and marked edema; B: Acetaminophen only (6000 mg) patient with LS = 3 and BS = 2. Focal erosion within superficial epithelium, extravasated erythrocyte clusters and congested veins.

CONCLUSION

Acute gastric damage of varying degrees occurs in subjects who ingest high doses of NSAIDs and acetaminophen with suicidal intent. The degree of endoscopic acute lesions in high-dose analgesic use also increases with age, total drug dose, concurrent use of multiple types of NSAIDs. We found the BS of patients who ingested only high-dose NSAIDs to be higher than in those who took acetaminophen, while there was no significant difference between gastric lesions. The lack of statistical significance between the LSs of patients who ingested NSAIDs and those who took only acetaminophen is remarkable in terms of the gastric effects of high-dose acetaminophen. It may be concluded that, contrary to current convictions, high-dose acetaminophen may also cause endoscopic acute gastric damage. Body position following intake influences the localization of endoscopic lesions. *H pylori* positivity was not determined as a factor that may affect NSAID- and acetaminophen-related acute gastric damage endoscopically or histopathologically.

In patients in a stable condition, we recommend endoscopy within the first 24 h for the determination of gastric injury and for treatment maintenance in patients who have ingested high-dose analgesics with suicidal intent.

COMMENTS

Background

Analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, are commonly used for the relief of fever, headaches, and other minor aches and pains. The gastrointestinal side effects of NSAIDs are well documented and acetaminophen is accepted to be a safe drug for the gastrointestinal system. Acute effects of short-term, especially high-dose NSAID and acetaminophen use have not been studied adequately.

Research frontiers

Acute gastric injury due to high dose analgesic use. Gastrointestinal safety of acetaminophen. Scoring the histological severity of the gastritis.

Innovations and breakthroughs

This paper is one of the first to document the endoscopic acute gastric damage caused by acute high-dose acetaminophen.

Applications

The results of the present paper may be useful in evaluating the gastrointestinal complications of acute high dose analgesic use. Contrary to current convictions, high-dose acetaminophen, as well as NSAIDs, may also cause endoscopic acute gastric damage. Therefore physicians should be alert at evaluating the gastrointestinal complaints of acetaminophen users as well. The study suggests that clinicians might as well plan endoscopic evaluation in patients who ingested high-dose analgesics with suicidal intent.

Peer review

The importance of the research and the significance of the research contents are significant because as it is mentioned in the manuscript there is actually not much information about acute high-dose acetaminophen causing endoscopic acute gastric damage. The manuscript is very readable. Methods are appropriate and detailed description is provided for any modified or novel methods to allow other investigators to reproduce or validate.

Abstract

AIM: To evaluate seven patients with non-traumatic splenic rupture (NSR). NSR is an uncommon dramatic abdominal emergency that requires immediate diagnosis and prompt surgical treatment to ensure the patient's survival.

METHODS: Within 11 years, seven cases were evaluated for patient characteristics, anamnesis and symptoms, method of diagnosis, findings of laparotomy, and etiology of NSR.

RESULTS: There were six (86%) male and one female (14%) patient, whose mean age was 36 ± 12.8 (17-56) years. We report here four cases of *Plasmodium vivax* malaria (cases Ⅰ-Ⅳ), one case of hemodialysis (case Ⅴ), one case of spontaneous splenic rupture (case Ⅵ), and one case of hairy cell leukemia (case Ⅶ). Splenectomy was performed in all patients. All of them made an uneventful recovery and were discharged in stable condition.

CONCLUSION: NSR is a rare entity that needs a high index of suspicion for diagnosis. Using ultrasonography or computer tomography, and peritoneal aspiration of fresh blood may assist in the diagnosis of NSR. Increased awareness of NSR can enhance early diagnosis and effective treatment.

INTRODUCTION

Trauma is the most common cause of splenic rupture, while non-traumatic splenic rupture (NSR) is a rare condition. NSR has been described in the medical literature as a clinical oddity with grave consequences, if unrecognized and untreated[1]. NSR rarely occurs in a histologically proven normal spleen, and in such cases, is called a spontaneous rupture. NSR usually occurs in a diseased spleen and is called a pathologic rupture[2]. Infection, malignancy, metabolic disorders, as well as vascular and hematological diseases, of which only single case reports have been published in the literature, are the usual reasons[3-5]. Recently, some authors have reported that spontaneous splenic rupture has been seen as a factor in malaria[6,7], aortic valve replacement for bacterial endocarditis[8], normal spleen[9], factor Ⅷ deficiency, which is a rare autosomal bleeding disorder with a frequency of 1:2 000 000 in the general population[10], and autologous transplantation for primary systemic amyloidosis[11]. Especially, malaria was discussed retrospectively in all aspects by authors. It has been reported that the disease has started spreading from its hotspots to new areas, including many parts of the United States and southern Europe, including Azerbaijan and Turkey[12]. We report here seven cases with NSR, who were successfully treated by splenectomy.

MATERIALS AND METHODS

The medical records of seven patients with NSR, who

Table 1 Patient characteristics

Cause of NSR	Age/sex	TA (mmHg)	Splenic weight (g)	Diagnosis		Observation time (h)	Amount of free blood (cc)	Grade of splenic injury	Amount of blood transfusion (U)	Duration of hospitalization (d)
				Parasynthesis	Radiological imaging					
Malaria (Case Ⅰ)	56/M	80/60	950	+	USG	4	1500	Ⅲ	3	6
Malaria (Case Ⅱ)	32/M	70/40	1050	+	None	Urgent Laparotomy	1200	Ⅱ	2	11

Hairy Cell Leukemia (Case Ⅶ)	42/F	65/40	2540	+	None	Urgent Laparotomy	2500	Ⅲ	5	15

NSR: Nontraumatic splenic rupture; TA: Tension arterial; USG: Ultrasonography; CT: Computerized tomography.

were treated in the Department of General Surgery, Dicle University Hospital, between 1995 and 2006, were reviewed retrospectively. The patients did not have a minor or trivial trauma history before admission. Standard advanced trauma life support resuscitation protocols were used in all patients. All patients received preoperative antibiotics and were maintained on antibiotics for at least 24 h postoperatively. Splenic injury grade was defined in accordance with the Organ Injury Scaling Committee of the American Association of Surgery for Trauma (AAST)[13]. After splenectomy, Pneumovax and *Haemophilus influenzae* vaccines were given. Histopathological analysis of masses was performed.

Patient data were evaluated for their characteristics (Table 1), anamnesis and symptoms, method of diagnosis, findings of laparotomy, and etiology of NSR. The constant variables were expressed as mean ± SD, except where otherwise stated.

RESULTS

Cases I -IV

We determined that NSR was due to malaria in four patients. The mean age of these patients was 37.7 ± 8.48 (17-56) years, and all of them were male. Our area is endemic for malaria, and before patients presented to our hospital, they had been diagnosed as malaria by the Free Malaria Out-Patient Clinic, which treats for free patients who have been taking antimalarial therapy. Trophozoites and schizonts of *Plasmodium vivax* were identified in peripheral blood smears to confirm previous diagnoses in all patients in our institute. No patient had a history of glucose-6-phosphate dehydrogenase deficiency. The abdominal ultrasound scans of three patients showed an enlarged, ruptured spleen and intraperitoneal free blood. Gross examination revealed grayish-brown or dark grey discolored spleen with capsular tears. Microscopy revealed congestion and dilatation of sinusoids, mononuclear infiltration with focal necrosis in capillaries and splenic pulp. Mean hospitalization time of patients who had splenic rupture with malaria etiology was 6.50 ± 1.55 (4-11) d. The patient who was hospitalized for the longest period of 11 d was receiving treatment for duodenal ulcer in the gastroenterology department. He immediately became hypotensive, and had abdominal pain on the day 4 of hospitalization. We performed abdominal parasynthesis, which demonstrated free blood in the peritoneal cavity. Since he was in shock, he underwent explorative laparotomy, and splenectomy was performed. The patient had postoperative wound infection on day 5, and he was discharged on day 11 after therapy.

Case V

A 29-year-old male hemodialysis patient was admitted to our emergency department. Severe left upper abdominal pain developed 2 d prior to admission. He had a history of hypertension and urolithiasis for 6 years, and he was undergoing hemodialysis twice weekly. Abdominal ultrasonography revealed a hyperechogenic mass that was composed of spleen and perisplenic fluid, and another mass, which showed internal echogenicity. A moderate amount of free fluid was present in the pelvic abdomen (Figure 1). Gross examination showed a dark gray spleen, which weighed 220 g, with capsular tears and subcapsular hematoma on the medial side. Microscopy revealed sinus dilatation, and increased fibrous tissue and hemosiderin pigments. The postoperative course was uneventful, and the patient was discharged from hospital on day 5.

Case VI

A healthy 30-year-old man was admitted to the emergency department previously with complaints of abdominal pain. His pain began approximately 3 h before arrival, which he described as being vague periumblical pain. He had no recent illness or trauma and no medical or surgery history. Initially, pain was minimal and he had no peritoneal signs, and his abdomen was non-distended, with normal bowel sounds. He had epigastric and left upper quadrant tenderness with voluntary guarding in this region. He denied taking any drugs, and did not have any symptoms and signs such as nausea, vomiting, diarrhea, melena, hematochezia, cough,

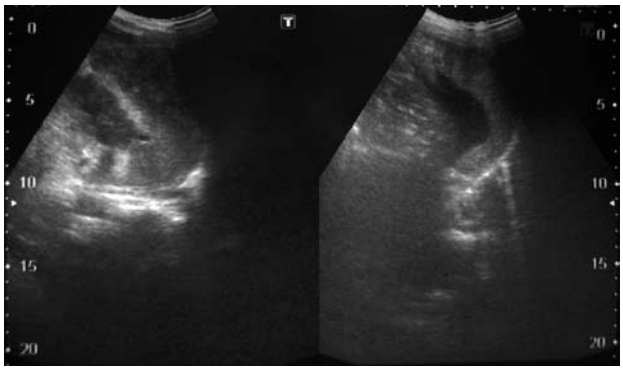

Figure 1 Abdominal ultrasonography of case Ⅴ revealed a hyperechogenic mass composed of spleen and perisplenic fluid.

Figure 2 CT of case Ⅵ revealed massive hemoperitoneum and large tears of the splenic hilus.

shortness of breath, weight loss, or fever. Heart and lung examination was normal. The genitourinary examination was normal, without hernia. Abdominal parasynthesis was performed, and free blood in the peritoneal cavity was observed. Abdominal ultrasonography showed perisplenic and left paracolic free fluid. Furthermore, computerized tomography (CT) showed massive hemoperitoneum and large tears of the splenic hilus (Figure 2). In spite of non-operative management at 18 h after arrival at the emergency department, he became hemodynamically unstable and had to be taken to the operating room for emergency surgery. Exploratory laparotomy was performed. After opening of the abdomen, 2000 mL of blood was removed immediately. The spleen was removed without complication and was sent for pathological investigation. The pathology report demonstrated the spleen to be of normal size. The rupture was found in medial side, penetrating into the parenchyma of the spleen. Paired acute-phase and convalescent sera provided no evidence of acute viral infection, and cultures from blood, sputum, stool and urine were negative. Screening for autoantibodies was negative. The patient's hospital course was uneventful, and he was discharged on postoperative day 5.

Case Ⅶ

A 42-year-old woman was admitted to our hospital with a history of weakness, easy fatigability, weight loss, and left upper abdominal pain for one month. After splenomegaly was determined, the patient was hospitalized in our department for etiological investigation. After one day of hospitalization, she developed sudden hypotension, tachycardia, and generalized abdominal pain. There was abdominal distension and peritoneal irritation upon physical examination. We performed abdominal parasynthesis, which demonstrated free blood in the peritoneal cavity. Laparotomy showed extensive hemoperitoneum and markedly enlarged spleen, with areas in which it appeared to be a tumor pushing through the splenic capsule, which was torn and bleeding excessively. Microscopic examination of the spleen revealed that splenic sinuses and cords (Figure 3A) were surrounded by hairy cells in the expanded red pulp (Figure 3B). The patient had a complication of pneumonia on postoperative day 5, which was managed successfully with antibiotic therapy; she made an uneventful recovery and was discharged in stable condition after 15 d.

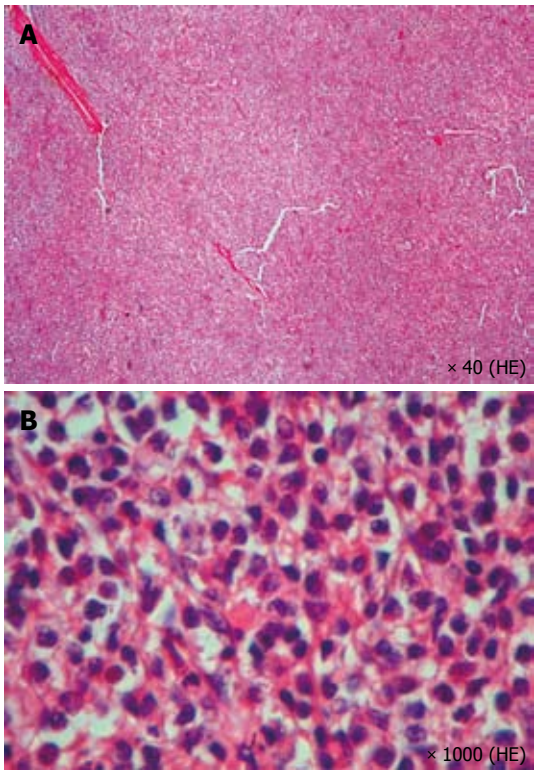

Figure 3 HE staining reveals splenic sinuses and cords of case Ⅶ (A, x 40) surrounded by hairy cells in the expanded red pulp (B, x 1000).

DISCUSSION

NSR may occur in 0.1%-0.5% of patients with no associated trauma[14]. The first cases of spontaneous splenic rupture were reported by Rokitansky[15] in 1861 and Atkinson[16] in 1874.

The actual reason for the rupture is not yet fully understood, although the size of the organ plays a significant role. However, normal-sized organs have been reported with ruptured spleen[17]. Three mechanisms have been implicated in the process. The first of these

mechanisms is increased intrasplenic tension that is caused by cellular hyperplasia and engorgement. The second is that the spleen may be compressed by the abdominal musculature during physiological activities, such as sneezing, coughing and defecation. Finally, vascular occlusion caused by reticular endothelial hyperplasia, which results in thrombosis and infarction, may be involved. This leads to interstitial and subcapsular hemorrhage and stripping of the capsule, which causes further subcapsular hemorrhage. The distended capsule finally gives way[18,19]. A Medline search for cases of NSR revealed that 454 cases were reported between 1966 and February 2007[20,21].

Malaria is the most common cause of pathologic rupture of spleen in the tropics, and life-threatening complications occur in up to an estimated 2% of cases[6,7,12,20,22]. Most cases of pathologic rupture of the spleen in malaria occur during acute infection, and usually during the primary attack[23]. Chronically enlarged spleens are less vulnerable to rupture[20]. When a palpable spleen is present, it is generally recognized within 3-4 d of the onset of symptoms. If the disease goes untreated, the spleen may grow and result in greater average spleen size, as the prevalence of malaria increases[24]. This occurrence is likely caused by rapid hyperplasia and stretching of splenic parenchyma and capsule, a high frequency of small infarctions, hemorrhage and tears, a lack of extensive connective tissue and fibrosis (as found in chronic malarial spleens); an increased risk of minor stress to the spleen (e.g. vomiting, rigors) and a lack of prior immunity[23]. Spontaneous splenic rupture is more common with *P. vivax* than *Plasmodium falciparum* malaria. In Turkey, *P. vivax* is the predominant *Plasmodium* species (99.9%)[18,25]. In all our patients, *P. vivax* was present with pathologic splenic rupture. Patients were experiencing primary attacks of malaria and were in the acute stage of the disease.

Spontaneous rupture of the spleen is extremely rare[2,26-28]. According to Orloff and Peksin[29], a small group of cases exist, in which the only justifiable conclusion is that the spleen ruptures spontaneously without known cause. They identified four criteria for the diagnosis of spontaneous splenic rupture: (1) on thorough questioning, either prior to operation or in retrospect after operation, there should be no history of trauma or unusual activity that could conceivably injure the spleen; (2) there should be no evidence of disease in other organs that are known to affect the spleen adversely and thereby could cause it to rupture; (3) there should be no evidence of perisplenic adhesions or scarring of the spleen that suggests it has been traumatized or ruptured previously; (4) without findings of hemorrhage and rupture, the spleen should be normal on both gross inspection and histological examination. Crate *et al*[30] added a fifth criterion: studies of acute-phase and convalescent sera should not show any significant rise in viral antibody titers that are suggestive of recent infection with viruses associated with splenic involvement. The patient, who was accepted with spontaneous splenic rupture, had these five criteria. The pathophysiology of spontaneous splenic rupture is obscure. It should be considered that undetected structural abnormalities in spleen may cause NSR.

Pathological rupture of the spleen is most commonly seen in the hematological malignancies[31], in which fragmentation and dissolution of the fibrous capsule of the spleen occur by infiltrating atypical lymphocytes, as seen in lymphoma or leukemia[20]. Giagounidis *et al*[32] have reported that male sex, adulthood, severe splenomegaly and cytoreductive chemotherapy are factors that are associated more often with rupture of the spleen in hematological malignancies. The most common finding was splenomegaly, which was present in 96% of patients with hairy cell leukemia[33]. One of the patients with pathological splenic rupture had hairy cell leukemia, with marked splenomegaly. In patients with hematological malignancy, pathological rupture of the spleen often happens unexpectedly, without preceding trauma[34]. Therefore, diagnosis is often difficult, and diagnosis of splenic rupture must be considered in all patients with hematologic malignancies. Acute or subacute new abdominal pain, hypotension and tachycardia, even if there is no previous history of trauma, must be treated aggressively.

Dialysis patients with chronic renal failure (CRF) show a fibrinolysis defect at the level of plasminogen activation. Reduced fibrinolysis may be responsible, along with other factors, for development of thrombosis, atherosclerosis and their complications[35]. Abnormal homeostasis is also common in CRF and is characterized by a tendency to abnormal bleeding and bruising. Prolongation of bleeding time, decreased activity of platelet factor Ⅲ, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption contribute to the clotting defects. Besides, edema of the spleen and formation of a subcapsular hematoma (secondary to uremic coagulopathy and use of heparin in those who are on hemodialysis) may occur in uremia[36]. Fluid overload is the major cause of hypertension in uremia; the normotensive state usually can be restored by aggressive ultrafiltration with dialysis. Nevertheless, because of hyper-reninemia, in spite of rigorous salt and water restriction and ultrafiltration, some patients maintain hypertension[37]. We detected hypertension in our patients. The underlying cause for the NSR may be uremic coagulopathy and hypertension.

The most common symptom is left upper quadrant abdominal pain. This pain can become generalized, with distention, tenderness and rigidity in later stages. The abdominal symptoms may be accompanied by pallor, tachycardia, hypotension and oliguria. Eventually, more than half of patients will suffer hemorrhagic shock if the condition is left untreated[27,38]. Diagnosis is based on clinical symptoms and confirmatory diagnostic tests. Some authors have reported that paracentesis is the most effective diagnostic procedure[4,39]. Abdominal ultrasound is an inexpensive and practical way to obtain a quick diagnosis of intraperitoneal fluid accumulation or hematoma, which can be performed at the patient's bedside or in the emergency unit[28]. CT signs of NSR may be useful for predicting rupture, and clearly show

grade of splenic damage severity and intraperitoneal free fluid[2]. We think that abdominal ultrasound can be a good, non-invasive technique, without risk for the patients who are hemodynamically unstable, whereas CT can be useful for patients who are hemodynamically stable. Paracentesis is not only useful in NSR, but also in patients in whom we think there is intraperitoneal hemorrhage and who are unstable. Negative results of paracentesis are not certain to show that there is no hemorrhage, but a positive result indicates the possibility of intraperitoneal hemorrhage. In fact, if paracentesis is positive, it leads us to consider the possibility of intra-abdominal hemorrhage.

The management of spontaneous or pathological splenic hemorrhage has been debated constantly. Among 136 cases of pathological splenic rupture reported in the literature, 88 underwent surgical intervention, 55 (63%) survived and 33 (37%) died. Among 43 patients who did not undergo surgery, 40 died. No information could be obtained for the five remaining cases[32]. Aggressive management with early surgical intervention and appropriate hemoderivative support is important[40]. The survival of patients following splenectomy is probably well correlated with the course of the underlying disease. The trauma literature is replete with data supporting the role of non-operative management of low-grade splenic injuries in hemodynamically stable patients[41,42]. The same principle has been applied for the management of spontaneous splenic rupture[43]. In our series, since six patients were hemodynamically unstable, after rapid fluid and blood infusions, the patients underwent splenectomy. One patient, who had SRS, and was hemodynamically stable at admission, to avoid the risks of splenectomy, was given medical therapy at first, but after 18 h, the patient became unstable; therefore, splenectomy was performed. One patient developed wound infection and another pneumonia, but all patients were discharged uneventfully.

In conclusion, NSR is a rare entity that needs a high index of suspicion for diagnosis. Absence of a history of trauma can make it difficult to reach a diagnosis, which causes delay in treatment. Using ultrasonography or CT, and peritoneal aspiration of fresh blood may assist in the diagnosis of NSR. Rapid diagnosis, aggressive resuscitation, and surgical intervention can lead to a successful outcome in patients with NSR.

COMMENTS

Background

NSR is a rare condition in emergency surgery. NSR may be seen along with different diseases, such as malaria, infections, malignancies, metabolic disorders, as well as vascular and hematological diseases. Also, spontaneous rupture of the spleen may be observed. Absence history of a trauma may not remind a rupture needs a high index of suspicion for diagnosis in spleen.

Research frontiers

The criteria for NSR were first described by Orloff *et al* in 1958 and our patients with NSR were in accordance with these criteria.

Innovations and breakthroughs

Our study emphasized that rapid diagnosis, aggressive resuscitation, and surgical intervention are important for successful outcome in patients with NSR. If the patient with intra-abdominal hemorrhage has no associated trauma, splenic rupture should be considered.

Applications

NSR may be shown in particular in endemic regions of malaria, hematological malignancies, and spontaneous and chronic renal failure.

Peer review

In this study, NSR was presented with different diseases. Diagnosis of NSR, using ultrasonography or CT, and paracentesis, is difficult. Splenectomy may lead to a successful outcome in patients with NSR.

Abstract

AIM: To determine the expression of DNA (MMR) proteins, including hMLH1 and hMSH2, in gastric epithelial cells in the patients with or without *Helicobacter pylori (H pylori)*-infected gastritis.

METHODS: Fifty *H pylori*-positive patients and 50 *H pylori*-negative patients were enrolled in the study. During endoscopy of patients with non-ulcer dyspepsia, two antral and two corpus biopsies were taken for histological examination (Giemsa stain) and for immunohistochemical staining of hMLH1 and hMSH2.

RESULTS: The percentage of epithelial cell nuclei that demonstrated positivity for hMLH1 staining was 84.14 ± 7.32% in *H pylori*-negative patients, while it was 73.34 ± 10.10% in *H pylori*-positive patients ($P < 0.0001$). No significant difference was seen between the two groups regarding the percentage of epithelial cell nuclei that demonstrated positivity for hMSH2 staining (81.16 ± 8.32% in *H pylori*-negative *versus* 78.24 ± 8.71% in *H pylori*-positive patients; $P = 0.09$).

CONCLUSION: This study indicates that *H pylori* might promote development of gastric carcinoma at least in part through its ability to affect the DNA MMR system.

INTRODUCTION

Helicobacter pylori (H pylori) infection affects about half of the world's population, and gastric carcinoma is one of the most frequent malignancies despite a decrease in incidence and mortality in recent decades[1,2]. The association of *H pylori* with gastric cancer is supported by epidemiological studies that show odds ratios for gastric cancer up to nine-fold greater in *H pylori*-infected individuals[3]. Chronic *H pylori* infection can cause chronic gastritis, which often progresses to gastric atrophy and intestinal metaplasia, which are premalignant lesions of the stomach[4]. Although many epidemiological studies that address the association of *H pylori* infection and gastric cancer have been carried out, fewer advances have been made to understand how long it takes for *H pylori* infection to induce the development of gastric cancer.

The main molecular mechanisms that underlie cancer development include the overexpression of genes, including oncogenes and growth factors or their receptors, and impaired expression of tumor suppressor genes that results from mutation or allelic losses[5,6] and deficiencies of the DNA mismatch repair (MMR) system[7,8].

Impairment of the DNA MMR system is a known mechanism of carcinogenesis and tumor progression

of both sporadic and hereditary human cancers[9,10]. The MMR deficiency leads to the accumulation of base-base mismatches, and short insertion/deletion mispairing during DNA replication, which results in widespread mutation generated as a consequence of DNA replication errors[11]. Most cells deficient in MMR display a high level of genomic instability characterized by changes in simple repetitive sequences, so-called microsatellite instability (MSI). Chronic *H pylori* infection damages the gastric barrier function[12,13] and stimulates gastric cell proliferation[14-19], which leads to mucosal repair[20], but which can also induce cellular DNA damage[18-22].

H pylori gastritis occurs more frequently in individuals with MSI-positive than MSI-negative gastric cancers, which raises the possibility that *H pylori* infection affects the DNA MMR system[23].

MATERIALS AND METHODS

Patients

We examined dyspeptic patients who were referred for endoscopic evaluation to Taleghani hospital, a tertiary hospital in Tehran, Iran. Dyspepsia was defined as persistent or recurrent abdominal pain or discomfort, centered in the upper abdomen, with a duration of at least 3 mo. Abdominal discomfort was characterized by early satiety, fullness, nausea, retching, upper abdominal bloating and anorexia[24,25]. We recruited consecutive patients with non-ulcer dyspepsia upon upper gastrointestinal (GI) endoscopy. Patients were examined using an Olympus GIF-Q30 endoscope (Olympus, Tokyo, Japan). One experienced endoscopist participated in the study, which allowed the inclusion of patients. Patients with duodenal ulcer (circumscribed break of > 5 mm depth in the mucosa, covered with exudate, present in the prepyloric, pyloric, or duodenal bulb region), gastric ulcer (with the above-described mucosal defect located at the angulus or above it), gastric polyps or cancers, bleeding complications, previous gastric resection and those who had been treated with anti-*H pylori* treatment, aspirin or other non-steroidal anti-inflammatory drugs (NSAIDs) or antibiotics 2 wk before the study were excluded.

During endoscopy, two antral and two corpus biopsies were taken and fixed in 10% buffered formalin and then embedded in paraffin for histological examination (Giemsa stain) and for immunohisto-chemical staining of hMLH1 and hMSH2. Patients were considered to be *H pylori*-positive when histological demonstration of the bacterium was positive. Fifty *H pylori*-positive and 50 *H pylori*-negative patients were enrolled. The updated Sydney system was used to evaluate pathological findings, such as gastritis severity, gastritis activity, intestinal metaplasia, gastric atrophy and dysplasia[26].

Immunohistochemical staining

Immunohistochemical staining was performed following the Envision method on the gastric biopsy specimens from *H pylori*-positive and -negative patients. Four-micrometer-thick sections were obtained from formalin-fixed paraffin-embedded tissue blocks. The tissue sections were deparaffinized in xylene and rehydrated in graded concentrations of alcohol. Endogenous peroxidase activity was blocked by treating the sections with blocking solution. For antigen retrieval, the sections were treated while boiling in citrate buffer pH 9.0 in a microwave oven. Then sections were incubated with primary antibodies against hMLH1 (BD Biosciences Pharmingen, clone G168-15, 1:100 dilution) and hMSH2 (Calbiochem, Oncogene Sciences, clone FE11, 1:100 dilution). After each step, slides were washed with TBS buffer for 3 min. Then, slides were treated with Envision (DAKO, REAL Envision) for 20 min. To visualize immunoreactivity, 3,3'-diaminobenzidine was used and samples were counterstained with hematoxylin. Intramucosal lymphocytes were used as positive controls. Samples from patients with hereditary non-polyposis colon cancer were used as a negative control. These samples have loss of nuclear staining in tumoral cells[24]. The slides were evaluated by two pathologists who were blinded regarding *H pylori* status.

A case was considered positive for expression of hMLH1 or hMSH2 in the presence of nuclear staining of epithelial cells; however, it was considered negative when there was a complete absence of nuclear staining of the epithelial cells in the presence of an unquestioned internal positive control. The staining intensity was divided into three grades. We counted more than 500 epithelial cells (including glandular neck, foveolar and surface epithelium) in each case at × 200 magnification. Quantitative I analysis was performed by measuring the total number of cells and the positive-staining epithelial cells. The percentage positivity was then calculated[24].

Statistical analysis

The χ^2 test and an unpaired Student's *t* test were used, when appropriate. $P < 0.05$ was considered statistically significant. All data were analyzed by SPSS version 13.0 (SPSS, Chicago, IL, USA).

RESULTS

Fifty *H pylori*-positive patients with a mean age of 41.78 ± 15.21 years and 50 *H pylori*-negative patients with a mean age of 46.58 ± 13.41 years were studied ($P = 0.1$). There was no significant difference in the male to female ratio between the two groups (28/22 in the *H pylori*-positive group *versus* 23/27 in the *H pylori*-negative group; $P = 0.32$). Table 1 outlines the characteristics and pathological data of both groups. As shown in Table 1, pathological findings such as gastritis severity, gastritis activity, intestinal metaplasia, gastric atrophy and dysplasia were not significantly different between the two groups.

The percentage of epithelial cell nuclei that demonstrated positivity for hMLH1 staining was 84.14 ± 7.32% in *H pylori*-negative patients; while it was 73.34 ± 10.10% in *H pylori*-positive patients ($P < 0.0001$). No

Body			
Area	77.24 ± 11.36	81.28 ± 10.58	0.07
Intensity	1.96 ± 0.57	1.96 ± 0.64	1.00
Antrum			
Area	78.76 ± 11.24	80.62 ± 10.89	0.40
Intensity	2.04 ± 0.53	1.90 ± 0.65	0.24
Overall			
Area	78.24 ± 8.71	81.16 ± 8.32	0.09
Intensity	1.99 ± 0.42	1.93 ± 0.46	0.50

significant difference was seen between the two groups regarding the percentage of epithelial cell nuclei that were positive for hMSH2 staining (81.16 ± 8.32% in *H pylori*-negative patients *versus* 78.24 ± 8.71% in *H pylori*-positive patients; $P = 0.09$). As shown in Table 2, the immunohistochemical staining in the corpus and antrum was relatively similar for hMLH1 or hMSH2.

Intensity of immmunohistochemical staining for hMLH1 did not differ significantly between the groups (1.99 ± 0.41 in *H pylori*-negative patients *versus* 1.95 ± 0.47 in *H pylori*-positive patients; P = 0.64). For hMSH2, intensity of immmunohistochemical staining was 1.93 ± 0.46 in *H pylori*-negative patients and 1.99 ± 0.42 in *H pylori*-positive patients; however, the difference was not statistically significant ($P = 0.50$).

DISCUSSION

The relationship between *H pylori* infection, gastric mucosal damage, and cell proliferation rate is a matter of debate. One hypothesis regarding how *H pylori* causes gastric carcinoma is through impairment of DNA repair in the gastric epithelium. This results in the accumulation of mutations and a genomic imbalance in the epithelium, which increases the risk of gastric carcinoma[27]. Previous studies have shown that active *H pylori* infection neither was more frequently seen in patients who had MSI-positive gastric carcinomas or intestinal metaplasia nor attach to carcinoma cells *in vivo* It is possible that during chronic gastritis, *H pylori* is physically in direct contact with gastric epithelial cells, and disturbs them at the molecular level. Studies on cytokine induction by *H pylori* support this hypothesis[28,29]. During chronic gastritis, the mucosa undergoes rapid turnover, and increased cell proliferation may permit an increased number of uncorrected mutations that may be induced by inadequate DNA MMR activity. Impairment of the DNA MMR system is a known mechanism of carcinogenesis and tumor progression in sporadic and hereditary human cancers[9,10]. In humans, MMR is mediated by at least six genes, including hMLH1, hMSH2, hMSH3, hMSH6, hPMS2 and hPMS1[30]. Germline mutations in hMSH2 and hMLH1 account for approximate 90% of all reported MMR gene mutations, whereas hPMS2 and hMSH6 account for the remainder[31]. Several studies have shown that hMLH1 and hMSH2 are the two main MMR proteins and the other MMR proteins including hPMS2, hPMS1, and hMSH6 seem to be unstable in the absence of the main MMR proteins[32,33].

Our findings indicate that decreased levels of hMLH1 proteins are seen in gastric epithelial cells in *H pylori*-positive patients. Although the level of hMSH2 proteins was lower in *H pylori*-positive patients, there was no significant difference. Results were the same as the study of Halling *et al*[34], which found that MSI-positive gastric carcinoma is usually associated with a lack of hMLH1 and rarely with a lack of hMSH2. Leung *et al*[28] have demonstrated that active *H pylori* infection is more frequently found in individuals with MSI-positive than in those with MSI-negative gastric cancer, which suggests that *H pylori* infection affects the DNA MMR system during the stepwise progression of gastric carcinogenesis. Park *et al* have studied the expression of hMLH1 and hMSH2 in patients with chronic *H pylori* infection before and after bacterial eradication. They have found that the expression of DNA MMR proteins increases in the gastric mucosa after *H pylori* eradication, which indicates that *H pylori* is associated with impairment of the DNA MMR system. Kim *et al*[27] cocultured gastric cancer cell lines with *H pylori* and then determined MutL and MutS DNA MMR protein and RNA levels. All cell lines showed decreased levels of MutL and MutS DNA MMR proteins in a dose-dependent manner[23]. Lack of an efficient DNA

MMR system can potentially have dramatic effects on the cell genome by allowing the accumulation of mutations in critical regulatory genes.

In this study, immunohistochemical staining of the corpus and antrum was similar for hMLH1 and hMSH2. This indicates that *H pylori* affects DNA MMR stems of gastric epithelium regardless of its location. In conclusion, this study indicates that the oncogenic bacterium *H pylori* might promote development of gastric carcinoma, at least in part through its effect on the DNA MMR system. Impairment of the DNA MMR system represents a novel mechanism of infection-associated cancer promotion.

COMMENTS

Background

Cancer arises from the accumulation of inherited polymorphism (i.e. SNPs) and mutation and/or sporadic somatic polymorphism (i.e. non-germline polymorphism) in cell cycle, DNA repair, and growth signaling genes. Main molecular mechanisms underlying cancer development include the overexpression of genes, including oncogenes and growth factors or their receptors, and impaired expression of tumor suppressor genes resulting from mutation or allelic losses and deficiencies of the DNA mismatch repair (MMR) system.

Research frontiers

During chronic gastritis the mucosa undergoes rapid turnover and increased cell proliferation may permit an increased number of uncorrected mutations that may be induced by inadequate DNA MMR activity. Impairment of the DNA MMR system is a known mechanism of carcinogenesis and tumor progression of both sporadic and hereditary human cancers. fewer advances have been made to understand how long it takes for *Helicobacter pylori (H pylori)* infection to induce the development of gastric cancer. The MMR deficiency leads to the accumulation of base-base mismatches, and the short insertion/deletion mispairs during DNA replication resulting in widespread mutation generated as a consequence of DNA replication errors. Most cells deficient in MMR display a high level of genomic instability characterized by changes in simple repetitive sequences so-called microsatellite instability (MSI).

Innovations and breakthroughs

Chronic *H pylori* infection damages gastric barrier function and stimulates gastric cell proliferation, which leads to mucosal repair, but which can also induce cellular DNA damage. *H pylori* gastritis occurs more frequently in individuals with MSI-positive than those with MSI-negative gastric cancers, raising the possibility that *H pylori* infection affects the DNA MMR system. The present study confirmed *H pylori* might promote development of gastric carcinoma at least in part through the ability to affect the DNA MMR system.

Applications

This study indicates that impairment of the DNA MMR system represents a novel mechanism of infection-associated cancer promotion.

Terminology

The association of *H pylori* with gastric cancer is supported by epidemiological studies showing that the odds ratios for gastric cancer is up to nine-fold greater in *H pylori*-infected individuals. Impairment of the DNA MMR system is a known mechanism of carcinogenesis and tumor progression of both sporadic and hereditary human cancers. Most cells deficient in MMR display a high level of genomic instability characterized by changes in simple repetitive sequences, so-called microsatellite instability (MSI). Chronic *H pylori* infection damages gastric barrier function[12,13] and stimulates gastric cell proliferation[14-19], which leads to mucosal repair[20], but which can also induce cellular DNA damage.

Peer review

Interesting paper but needed some amendment. This paper is adequately presented. The investigation is useful for the progress in the knowledge of this topic.

Abstract

AIM: To determine the incidence of colonoscopic perforation (CP), and evaluate clinical findings, management and outcomes of patients with CP from the World Gastroenterology Organization (WGO) Endoscopy Training Center in Thailand.

METHODS: All colonoscopies and sigmoidoscopies performed between 1999 and 2007 in the Endoscopic unit, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok were reviewed. Incidence of CP, patients' characteristics, endoscopic information, intra-operative findings, management and outcomes were analyzed.

RESULTS: A total of 17357 endoscopic procedures of the colon (13 699 colonoscopies and 3658 flexible sigmoidoscopies) were performed in Siriraj hospital over a 9-year period. Fifteen patients (0.09%) had CP: 14 from colonoscopy and 1 from sigmoidoscopy. The most common site of perforation was in the sigmoid colon (80%), followed by the transverse colon (13%). Perforations were caused by direct trauma from either the shaft or the tip of the endoscope (n = 12, 80%) and endoscopic polypectomy (n = 3, 20%). All patients with CP underwent surgical management: primary repair (27%) and bowel resection (73%). The mortality rate was 13% and postoperative complication rate was 53%.

CONCLUSION: CP is a rare but serious complication following colonoscopy and sigmoidoscopy, with high rates of morbidity and mortality. Incidence of CP was 0.09%. Surgery is still the mainstay of CP management.

INTRODUCTION

There are an increasing number of patients undergoing endoscopic examination of the colon and rectum for various purposes such as screening and surveillance of colorectal cancer. Endoscopy-related complications could result from preparation for the procedure (such as hypotension and electrolyte imbalance following mechanical bowel preparation), or they could be directly related to the endoscopic procedures (such as post-polypectomy hemorrhage and colonic perforation). Although colonoscopic perforation (CP) is a rare complication, it is associated with a high rate of morbidity and mortality[1-4]. The incidence of CP could be as low as 0.02% in diagnostic colonoscopy and could be as high as 0.6% in therapeutic colonoscopy[5,6]. The

reported morbidity following CP is about 40% and mortality might be up to 14% depending on patients' characteristics and co-morbidities[7]. Most patients with CP require open surgery; however, there is recent evidence that CP can be successfully managed by endoluminal repair[6] and laparoscopic surgery[8-11].

To the best of our knowledge, there is no published literature about CP from any World Gastroenterology Organization (WGO) Endoscopy Training Center. The aims of this study were to determine the incidence of CP following colonoscopy and flexible sigmoidoscopy, and to evaluate clinical findings, management and outcomes of patients with CP from the WGO Endoscopy Training Center in Thailand.

MATERIALS AND METHODS

All colonoscopies and sigmoidoscopies performed between 1999 and 2007 at the Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand, were reviewed. Patients with CP were identified from the prospectively collected database of the Siriraj GI Endoscopy Center or from the hospital information system. Medical records of all CP patients were reviewed. The incidence of CP, patients' characteristics, endoscopic information, intra-operative findings, management and outcomes in CP patients were analyzed. The study was approved by the Institutional Ethics Committee and informed written consent was obtained from each patient.

All data were prepared and compiled using SPSS software (version 10.0 for Windows). Pearson chi-square test or Fisher's exact test was used for comparing categorical data, whereas the Mann-Whitney *U* test was used for comparing non-categorical data. $P < 0.05$ was considered statistically significant. Values were presented as a number (percentage), or mean (range).

RESULTS

Demographic data

A total of 17357 endoscopic procedures of the colon (13699 colonoscopies and 3658 flexible sigmoidoscopies) were performed in Siriraj hospital over a 9 year period. Fifteen patients (0.09%) had CP: 14 from colonoscopy and 1 from sigmoidoscopy. The incidence of CP following colonoscopy was slightly higher than that following sigmoidoscopy (0.1% *vs* 0.03%; $P = 0.22$), with a relative risk ratio of 3.7 (95% confidence intervals = 0.5-28.4).

Patients with CP had an average age of 67 years (range 36-88) and nine patients (60%) were female. Indications for endoscopic examination in these patients were anemia or lower gastrointestinal bleeding ($n = 6$), bowel habit change ($n = 4$), large bowel mass ($n = 2$), non-specific abdominal pain ($n = 1$), refractory inflammatory bowel disease ($n = 1$), and suspected pseudomembranous colitis ($n = 1$).

Table 1 Incidence, findings and management of CP *n* (%)

Characteristics	Data
CP	15 cases
Incidence of CP	
Overall endoscopy ($n = 17357$)	0.09
Colonoscopy ($n = 13699$)	0.10
Flexible sigmoidoscopy ($n = 3658$)	0.03
Site of perforation	
Sigmoid colon	12 (80)
Transverse colon	2 (13)
Ascending colon	1 (7)
Mechanism of perforation	
Direct injury from shaft of scope	7 (47)
Direct injury from tip of scope	5 (33)
Polypectomy	3 (20)
Surgical management[1]	
Primary suture of the perforation	4 (27)
Resection with primary anastomosis	4 (27)
Resection without anastomosis	7 (47)

[1]Four patients (27%) had concomitant colorectal cancer.

Perforations

The most common site of perforation was the sigmoid colon ($n = 12$, 80%), followed by the transverse colon ($n = 2$, 13%) and the ascending colon ($n = 1$, 7%). Based on the endoscopic reports and intra-operative findings, mechanisms of perforation were determined to be direct trauma from the shaft of the endoscope in 7 patients (47%) and from the tip of the endoscope in 5 patients (33%). The others ($n = 3$, 20%) were caused by endoscopic polypectomy. All perforations were immediately recognized during endoscopy except for one electrical injury after polypectomy which caused peritonitis 24 h after the procedure. Details of the characteristics of CP are summarized in Table 1.

Management and outcomes

Non-operative management consisting of bowel rest and intravenous antibiotics was attempted in 2 patients with localized peritonitis; however, their symptoms deteriorated and an operation was eventually required. Therefore, all the patients with CP in this series underwent surgical management. Of these patients, twelve (80%) had medical co-morbidities and four (27%) had concomitant colorectal cancer. Types of operation included primary suture of the perforation in 4 patients (27%), resection and primary anastomosis in 4 patients (27%), and resection without anastomosis in 7 patients (47%).

Postoperative complications were identified in 8 patients (53%): 5 wound infections, 3 pneumonias and 1 antibiotics-associated colitis. There was no difference in age, gender, ASA status, and size of the perforation between the groups who did and did not develop postoperative complications (Table 2). There were 2 deaths (both females aged 76 and 83 years, respectively), accounting for 13% of CP patients and 0.01% of total colonic endoscopy patients. Pneumonia was the primary cause of death in both patients. The average hospital stay of CP patients was 23 d (range 3-92).

Table 2 Comparison of patients' characteristics between the groups who did and did not develop postoperative complications

	Patients with complication	Patients without complication	*P*
	(*n* = 8)	(*n* = 7)	
Age over 60	5 (63)	5 (71)	0.71
Female	6 (75)	3 (43)	0.32
ASA ⩾ 3	5 (63)	4 (57)	0.83
Perforation size ⩾ 5 cm	2 (25)	3 (43)	0.61

Values were given as a number (percentage).

DISCUSSION

The incidence of CP in our study was 0.09%, which was quite similar to that in other larger series (sample size > 30 000 cases)[12-15]. To the best of our knowledge, this is the first report of such an incidence from the WGO Endoscopy training centers. Although it remains inconclusive whether an endoscopy performed by a trainee increases risk of CP, we cannot evaluate such a potential factor because the trainee-to-endoscopist ratio for all procedures in our study was unknown. Anderson and co-workers[16] have reported that there was no significant increased risk of CP performed by training fellows. Training bodies in America, Britain and Australia have recommended a minimum of 50-100 colonoscopies should be performed by a trainee to gain endoscopic competency[17-20].

We found that colonoscopy had an almost fourfold increased incidence of CP compared with sigmoidoscopy, although this did not reach statistical significance. Many investigators have reported that the risk of CP following colonoscopy is 2-4 times higher than that following sigmoidoscopy[13,20]. Other risk factors for CP may include female gender[16], advanced age[12,21], a history of diverticular disease or previous intraabdominal surgery[12], and endoscopic interventions such as polypectomy and endoscopic mucosal resection[6].

In our study, perforation at the sigmoid colon accounted for 80% of all perforation sites. This finding was consistent with that of other studies[9,10,13]. There are three possible mechanisms responsible for CP: mechanical perforation directly from the colonoscope, perforations that occur during therapeutic procedures and, finally, barotrauma from overzealous air insufflation[22,23].

All patients with CP in the present series underwent surgical management. Clearly, the choice between conservative and surgical management depends on clinical factors[24]. Conservative management is reserved for patients in good general condition and without any sign of peritonitis. Surgical management is recommended in patients with diffuse peritonitis, with clinical deterioration under medical treatment, or with a concomitant colonic pathology such as colorectal cancer. In the published literature, less than 20% of patients with CP can be successfully treated by non-surgical approach[14,15,25].

With regard to the choices of operation for colonic perforation, we found that a quarter of CP patients underwent primary suture of the perforation while the others had bowel resection. The rate of primary repair in our study was less than that of other studies, in which the rate of non-resection procedures could be 30%-60%[7,13,15,25,26]. A possible explanation for a relatively low percentage of primary repair in our series might be that half of our patients had a large perforation caused by the shaft of the scope, and many patients were suspected of having underlying colorectal cancer which required bowel resection.

The postoperative morbidity rate was 53% and wound infection was the most common complication. We cannot identify risk factors for developing postoperative complication in CP patients. This may be due to small sample size and limitation in its power. However, some investigators have suggested that such risk factors may include delayed diagnosis, extensive peritoneal contamination, patients using anticoagulants[15], patients having severe co-morbid diseases and a large perforation[7]. The mortality rate of patients with CP in our study was fairly comparable to other reports which ranged from 0% to 14%, depending on patients' coexisting diseases, experience of the care team and hospital setting. Pneumonia was the primary cause of death in our study. Respiratory complications often occur after major abdominal surgery[27-30], particularly in advanced age patients like ours.

In conclusion, colonic perforation is a rare but serious complication following colonoscopy and sigmoidoscopy, with high rates of morbidity and mortality. In this first study into CP carried out in a WGO Endoscopy training center, we found that the incidence of CP was 0.09% and the sigmoid colon was the most common perforation site. Surgery is still the mainstay of CP management.

COMMENTS

Background

Colonoscopic perforation (CP) is a rare, but serious complication of colonoscopy. Rising use of colonoscopy could lead to a high number of endoscopic colonic perforations. Meanwhile, CP could be associated with a significant morbidity and mortality.

Research frontiers

Absent from the published literature is the incidence, management and outcomes of CP reported from World Gastroenterology Organization (WGO) Endoscopy Training Centers.

Innovations and breakthroughs

The Siriraj GI Endoscopy center (Bangkok, Thailand) is one of eight endoscopy training centers accredited by WGO. Incidence of CP in this center was 0.09%. The most common site of the perforation was the sigmoid colon. Direct trauma from either the shaft or tip of the endoscope was the most common cause of perforation. Surgical management remains a mainstay treatment of CP. The mortality rate was 13% and the postoperative complication rate was 53%.

Applications

Although the incidence of CP is very low, it is associated with high rates of morbidity and mortality. Further research might focus on identification of risk factors for CP and improvement of management in these patients.

Terminology

Incidence of CP in the WGO endoscopy training center in Thailand was 0.09%.

Peer review

This is a report of a large experience with endoscopic colonic perforations from a single institution. It is well organized. The complications and their management are clearly documented. It is a valuable contribution and should be accepted for publication.

Abstract

AIM: To introduce and evaluate the efficacy and technical aspects of endoscopic submucosal dissection (ESD) using a novel device, the Fork knife.

METHODS: From March 2004 to April 2008, ESD was performed on 265 gastric lesions using a Fork knife (Endo FS®) (group A) and on 72 gastric lesions using a Flexknife (group B) at a single tertiary referral center. We retrospectively compared the endoscopic characteristics of the tumors, pathological findings, and sizes of the resected specimens. We also compared the *en bloc* resection rate, complete resection rate, complications, and procedure time between the two groups.

RESULTS: The mean size of the resected specimens was 4.27 ± 1.26 cm in group A and 4.29 ± 1.48 cm in group B. The *en bloc* resection rate was 95.8% (254/265 lesions) in group A and 93.1% (67/72) in group B. Complete ESD without tumor cell invasion of the resected margin was obtained in 81.1% (215/265) of group A and in 73.6% (53/72) of group B. The perforation rate was 0.8% (2/265) in group A and 1.4% (1/72) in group B. The mean procedure time was 59.63 ± 56.12 min in group A and 76.65 ± 70.75 min in group B ($P < 0.05$).

CONCLUSION: The Fork knife (Endo FS®) is useful for clinical practice and has the advantage of reducing the procedure time.

INTRODUCTION

The emergence of endoscopic submucosal dissection (ESD) has allowed the achievement of histologically complete *en bloc* resection of gastric tumors regardless of size, which permits the resection of previously non-resectable tumors[1-4]. Although the fundamental incision and dissection method are the same for all ESD procedures, ESD can be classified by the type of knife that is used; for example, an IT knife (Olympus Co., Tokyo, Japan)[5-8], a Flexknife (Olympus Co.)[9], or a Hook knife (Olympus Co.)[10]. Each step of ESD, such as marking of a lesion, injection, incision and dissection, may require a different accessory or a knife, depending on the location and shape of the tumor[11]. Therefore, when performing ESD, the accessories may be frequently changed through the working channel of the endoscope[12,13], which results in a longer procedure time and a delay in controlling gastrointestinal (GI) bleeding. A two-channel endoscope can use one accessory or two accessories at the same time during a procedure[14]. However, two-channel endoscopes have a thicker diameter, which may cause additional discomfort to the

patient and impede the field of view in some situations. Consequently, the development of an instrument capable of multiple functions, such as injection, incision, dissection, coagulation, and irrigation, without the need for changing accessories is an attractive idea.

The Fork knife (Endo FS®; Kachu Technology Co., Seoul, Korea) is a device that was developed to enable an endoscopist to perform the multiple steps of ESD without the need to change accessories during the procedure. The Fork knife is capable of performing every step of ESD, including marking, injection, saline irrigation, and coagulation, and thus may enable the endoscopist to reduce the procedure time.

The aim of the present study was to introduce and evaluate the efficacy and technical aspects of ESD performed with a Fork knife, which we made ourselves in cooperation with the Kachu Technology Company.

MATERIALS AND METHODS

Fork knife

The Fork knife (Endo FS®) has two interchangeable knives, a fixed flexible snare and a forked knife, which form a single working unit, and has an inlet for material injection or saline irrigation during the procedure (Figures 1 and 2). The knives can be changed during a procedure by using two switches, the fork knob and core knob, located on the center of the body (Figure 2).

Fixed flexible snare: The first of the two knives that constitute the Fork knife is the fixed flexible snare (Figure 3A), which is operated by sliding the core knob switch forward. The blade is shaped into an elongated loop much like the Flexknife. We mainly use the fixed flexible snare for marking and making incisions around lesions. Marking around a lesion can be done using the tip of the fixed flexible snare. Additionally, the tip can be used for the incision and dissection of a lesion. Although the incision and dissection techniques are similar to those used with a Flexknife, the fixed flexible snare has the advantage of a fixed exposed body length with the snare located inside the tube, which allows the snare to be used more firmly than a Flexknife during dissection. An endoscopist does not need to be concerned about controlling the length of the body to prevent perforation in the event of a sudden movement by the patient, such as belching or coughing. The length of the blade, which can be adjusted using the switch on the center of the body, is usually set to 2.5 ± 1.0 mm in order to minimize the risk of perforation.

Forked knife: The second knife is the forked knife, which has a double-tipped blade (longer tip length, 2 mm; shorter tip length, 1.5 mm) with a forked shape (Figure 3B). The forked knife is located on the opposite side from the fixed snare knife and is operated by sliding the fork knob switch forward. It is a form of a needle knife with an M-shape that maximizes the power applied to contacted surfaces, which is advantageous for dissection and coagulation. The longer tip of the forked knife can be used as an injection needle for making a submucosal cushion, or for injecting agents such as epinephrine. The opening of the needle is located in the center of the knife, between both tips, so that the mucosa must be injected deeply and at an oblique angle for maximum injection into the submucosa. We use the forked knife mainly for submucosal dissection performed in the proximal to distal direction of the endoscope, under direct visualization of the dissection area.

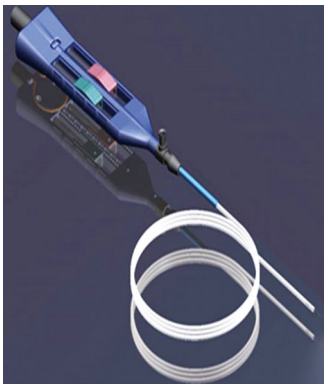

Figure 1 The Fork knife (Endo FS®).

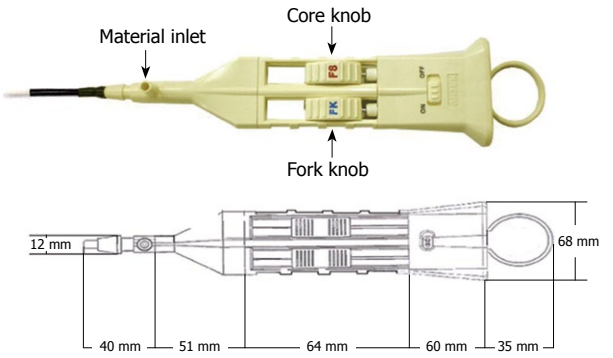

Figure 2 Working body of the Fork knife. Two switches, the fork knob and core knob, are located on the center of the body and enable the knives to be changed during the procedure. A material inlet for injection and irrigation is located forward of the body.

Multi-functions: The Fork knife has a built-in irrigation system *via* the material inlet, which allows saline irrigation while using either knife (Figure 3C). This allows the endoscopist to perform the dissection more comfortably and with prompt control of bleeding to maintain a clear endoscopic view. Additionally, by softly touching a vessel with the tip of knife and using the forced coagulation mode (40 W), an endoscopist can coagulate small vessels that may be exposed during a procedure. Thus, the use of the Forked knife permits better and faster control of any bleeding during a procedure, which reduces the time during which the endoscopic view is obscured.

Patients

From March 2004 to April 2008, we performed 715 ESDs on gastric lesions. We enrolled 337 patients with gastric lesions who underwent ESD from January 2006 to April 2008. One endoscopist, who performed ESD in

over 400 cases, performed ESD on gastric lesions during the investigation period. ESD was performed using the Fork knife from January 2006 to October 2007, and the Flexknife was used from November 2007 to April 2008. We designed this study prospectively and reviewed retrospectively all of the enrolled ESD data. A total of 265 lesions were dissected with the Fork knife (group A), and 72 lesions were dissected with the Flexknife (group B). This study was approved by the institutional review boards of our hospital.

Methods

Patients were sedated with intravenous diazepam (20-40 mg) while in the endoscopic suite, and conscious sedation was maintained with additional injections during the procedure. All patients had a performance status of < 2 on the Eastern Cooperative Oncology Group scale and fulfilled the following expanded ESD indication established by the Japanese Gastroenterologic Endoscopic Society: (1) non-ulcerated, differentiated-type mucosal carcinoma, regardless of tumor size; and (2) differentiated-type mucosal carcinoma with an ulcer scar < 30 mm[15]. The Fork knife was used for all ESD steps in group A, as shown in Figure 4.

Marking: After spraying of indigo carmine dye (Figure 4A), using the fixed flexible snare tip of the Fork knife, circumferential markings were made at 5 mm around the outline of the lesion, with 2-mm intervals between each marking dot, using a soft coagulation current of 40-50 W (ICC 200EA, ERBE Elektromedizin GmbH, Tübingen, Germany) (Figure 4B). For marking the lesion, the length of the fixed snare tip of the knife was set to approximate 1 mm, and then using the tip, the mucosa was touched lightly with electricity for 1 s.

Injection: Using the long tip of the forked knife, 2-5 mL of a saline/epinephrine solution was injected into the submucosa until the mucosa was raised. Additional injections were repeated as necessary during the procedure, without changing accessories.

Mucosal incision: After the lesion was lifted, the knife was subsequently changed to the fixed flexible snare for

incision around the lesion. The fixed flexible snare was used to make the incision along the markings, using an electrosurgical generator in ENDOCUT mode, effect 3 (output, 80 W) (Figure 4C and D). The tip of the knife was set to approximate 2 mm. Precutting was not needed.

Dissection: Followed by incision around the lesion with the fixed flexible snare, dissection was done with either the forked knife or the fixed-flexible snare, with an electrical current of 40-50 W for swift coagulation (Figure 4F-H).

Bleeding: If bleeding occurs during dissection, saline can be irrigated without delay using either blades of the knife. Usually for small vessels that are smaller than or similar to the tip of the knives, the fixed flexible snare or the forked knife is sufficient to coagulate the vessels, with an electrical current of 40 W for forced coagulation. This allows the endoscopist to prompt control of bleeding (Figure 4E). Instead of a Fork knife, a Flexknife was used for ESD in group B, according to the same steps as described for group A.

Measurements

We compared the endoscopic appearance of tumors, location of tumors, *en bloc* resection rate, complete resection rate, size of resected specimens, complications, pathological findings, and procedure time between the two groups. The resected specimens were divided into two categories, *en bloc* and piecemeal. Complete resection was identified when the lateral and vertical margins of the specimen were free from tumor involvement. The resected specimens were classified into three size categories based on the longest diameter (< 3 cm, 3 to < 5 cm, and ≥ 5 cm), and the proportion of each category was compared between the two groups. To observe the complications of bleeding and perforation, blood samples, radiological examinations, and follow-up endoscopy were performed 1 and 2 d after ESD. Control of bleeding, difficult dissection caused by fibrosis, and lesion size were the major factors that affected the procedure time. Bleeding was identified when a hemostatic treatment such as endoscopic clipping and/or electrocoagulation was required during or after the procedure. Perforation was identified by endoscopy just after the resection and/or by the presence of free air on plain abdominal radiography. Fibrosis was identified as fibrotic tissue observable during dissection; the fibrosis rate was compared with the procedure time. The procedure time was measured as the time between the marking of the first dot and the withdrawal of the endoscope. The mean procedure time was compared between the two groups.

Statistical analysis

Statistical analyses were performed using SPSS for Windows (version 12.0; SPSS Inc., Chicago, IL, USA). The data are presented as the mean ± SD or the median and range. Categorical parameters were compared using the χ^2 or Fisher's exact test, and continuous variables were compared with Student's *t*-test. $P < 0.05$ was considered significant.

Table 1 Baseline and tumor characteristics of the patients in each group

Antrum, Pylorus	115 (54.8)	21 (39.6)
Subtotal gastrectomy state	1 (0.5)	1 (1.9)

RESULTS

The mean age of group A was 62.4 ± 9.5 years and 63.3 ± 9.3 years in group B (Table 1). Gender ratios were similar between groups A and B. The number of differentiated adenocarcinomas was similarly high in both groups (36.2% in group A, 33.3% in group B), and the pathological distribution and mean size of the resected specimens were similar between the groups. Undifferentiated, signet ring cell cancer was confirmed based on resected specimens after ESD, instead of by initial biopsy before ESD. The mean longest diameter of the resected specimens was 4.27 ± 1.26 cm in group A and 4.29 ± 1.48 cm in group B.

Table 2 summarizes the depth, location, and endoscopic appearance of the tumors in the two groups. The table excludes adenomatous lesions and is limited to only those lesions confirmed to be cancerous by

pathological reports. The tumor depth distribution was similar between the two groups (83.3% of mucosal layer cancer in group A, 81.1% in group B), although group B showed a higher portion of submucosal cancers. The endoscopic appearance showed a similar pattern of distribution between the two groups. The occurrence of depressed lesions was higher in group B than in group A (35.8% *vs* 28.1%), and the occurrence of mixed lesions was lower in group B than in group A (17.1% *vs* 27.1%). With regard to tumor location, group A showed a higher proportion of antral area cancers (54.8%) than group B (39.6%), but the locations were not significantly different between the two groups.

The mean procedure time was significantly shorter in group A (59.63 ± 56.12 min), compared with group B (76.65 ± 70.75 min, $P < 0.05$) (Table 3). Other features such as fibrosis and resected specimen size, which play important roles in determining the procedure time, were similar between the groups. However, ulcerous lesions were significantly more common in group A than in group B (13.6% *vs* 6.9%, $P < 0.05$). Size of specimens was similarly distributed between the two groups.

The *en bloc* resection rate tended to be higher in group A (254, or 95.8% of cases) than in group B (67, or 93.1% of cases) (Table 4). The overall complication rate was 6.4% in group A and 2.8% in group B. Bleeding was more common in group A, but not significantly so. Perforation was observed in three cases in both group, and all cases were treated by conservative management with endoscopic clipping and fasting.

The *en bloc* resection rates were high for specimens of all size categories and were not statistically different between the two groups. *En bloc* resection was performed for 92.3% of lesions < 3 cm, 97.7% of lesions 3 to < 5 cm, and 91.9% of lesions ⩾ 5 cm in group A. In group B, *en bloc* resection was performed for 85.7% of lesions < 3 cm, 95.7% of lesions 3 to < 5 cm, and 88.9% of lesions ⩾ 5 cm. The rate for complete ESD was higher in group A than in group B (Table 5), but the difference was not significant. Overall, four cases could not be evaluated regarding the invasion of cancer in the resected margins because of cellular autolysis and coagulation artifacts.

DISCUSSION

The aim of this study was to introduce and evaluate the efficacy and technical aspects of ESD using a novel device, the multi-functional, convenient Fork knife.

ESD is an innovative technique that improves the rate of successful *en bloc* resection at an early stage of GI neoplasia[1-4]. Since Hirao *et al*[16] first introduced the ESD technique in 1988, many investigators have improved the technique and designed several devices, such as the needle-knife[16], insulated-tip (IT) knife[5-8], and Flexknife[9], that allow *en bloc* resection of widespread tumors. ESD and EMR techniques were developed mainly in Japan[16-18]. However, these techniques have now become major therapeutic modalities in Korea[19], which has a high incidence of early gastric cancer similar to that in Japan, for the treatment of early gastric cancer associated with minimal risk for lymph node metastasis[20,21]. Performing ESD is technically difficult and carries a high risk for complications such as perforation and bleeding[22-25]. The IT knife, which is commonly used for ESD, has been reported to have complication rates of 5%-22%[7,8,26]. There are no standard methods for preventing complications, and no rules exist for selecting proper devices during ESD. The proper devices for safe ESD are determined by the preference of the endoscopist and the circumstances of the dissection. Currently, ESD requires that the accessories be frequently changed through the working channel of the endoscope, according to the procedure being performed[12,13]. Using a two-channel endoscope is more convenient because two accessories can be loaded into the endoscope at the same time[14]. However, the thicker endoscopic diameter causes additional discomfort to the patient and increases the bend angle of the endoscope. The obtuse bend angle of the scope increases the difficulty of each step of ESD and complicates the response to specific conditions such as bleeding.

The Fork knife is a new device developed for ESD. It consists of two knives, a fixed flexible snare knife and a forked knife, in a single working unit. These two

knives can be interchanged easily and with minimal time during the procedure. The Fork knife has the advantage of being multi-functional, such as marking, injection, incision, irrigation, dissection, and bleeding control. The fixed flexible snare tip can be used for marking and performing incisions in the early steps of ESD, and the forked knife can be used for injections and for dissection of the submucosal layer. Both knives can also perform simple irrigation and coagulation of point bleeding from exposed vessels, without changing accessories during the procedure. This enables the endoscopist to perform ESD more conveniently and easily and thus potentially shortens the total procedure time.

The devices needed during ESD vary according to the technique used, such as a one-knife or multi-knife method. There is no principle that ESD should be performed with only one device (one-knife method). It depends on the preference of the endoscopist who performs ESD or on the technical difficulty of the target lesion. We prefer a multi-knife method and believe that it allows safer and easier ESD procedures. Also, the Fork knife enables endoscopists to perform ESD without changing accessories during the whole procedure time.

The knife tip of the Fork knife and the Flexknife are similar to that of a needle knife, and afford easier horizontal than vertical dissection. Nevertheless, a skilled endoscopist can dissect a lesion without considering the direction of the knife relative to the plane of the wall.

In the present study, most of the conditions such as tumor location, endoscopic appearance, resected specimen size, and fibrosis that can affect procedure time were similar between the two groups. However, ulcerations were significantly more common in group A than in group B. The rates of complete ESD, *en bloc* resection, and bleeding were higher in group A, but the difference was not significant. The bleeding rate in group A was 4.9%, whereas bleeding rates of 0.7% and 22% have been reported for the Flexknife[9] and IT knife[8]. The definition of bleeding in our study, i.e., all hemostatic processes that occurred during the procedure, was broader than that in the Flexknife study[9], which may account, at least in part, for the difference in the reported rates. Despite the tendency toward more frequent bleeding complications in group A, the procedure time was significantly shorter in the Fork knife than in the Flexknife group. The shorter procedure time cannot be attributed to differences in the distributions of resected specimen size, tumor location, or endoscopic appearance, as all of these factors were similar between the two groups. It is likely that the shorter procedure time in group A resulted from the faster control of bleeding with the Fork knife compared with the Flexknife.

This study was limited by the different numbers of enrolled patients in each group; group A had four times the number of subjects in group B. This may present concerns regarding statistical comparisons between the groups. Another matter to consider is that ESD using the Fork knife was performed by a single endoscopist, who developed the design. Therefore, the endoscopist may have taken exceptional care to avoid complications or to shorten the procedure time. Also, we did not take into consideration the technical improvement of the endoscopist that resulted from his accumulated experience. Nevertheless, it is our belief that the multi-functional Fork knife can potentially reduce the time required for ESD and make ESD a more acceptable procedure for experienced endoscopists. The aim of this study was not to compare resection techniques such as ESD with the Flexknife *vs* ESD with the Fork knife, but to report on our preliminary experience of using a multi-functional and convenient tool that may save time.

In conclusion, the Fork knife is a multi-functional instrument that can perform various therapeutic endoscopic procedures such as marking, injection, dissection, coagulation, and simple saline irrigation, without the need to change accessories during procedures. The major advantage of the Fork knife is that it allows endoscopists to perform ESD more easily. The Fork knife may be a very useful device for performing ESD.

COMMENTS

Background

Each step of ESD, such as lesion marking, injection, incision, and dissection, may require a different accessory or a knife, depending on the location and shape of the tumor. Therefore, when performing ESD, the accessories may need to be changed frequently through the working channel of the endoscope, prolonging the procedure and delaying the control of GI bleeding.

Research frontiers

Many investigators have improved the technique of ESD and have designed various knives that enable the endoscopist to perform ESD more easily, such as the IT knife, Hookknife, Flexknife, and triangle-tipped knife. These knives have contributed to the development of ESD techniques, and each has merits and demerits.

Innovations and breakthroughs

The authors introduced and evaluated the efficacy and technical aspects of ESD using a novel device, a convenient multi-functional Fork knife. The Fork knife consists of two knives in a single working unit: a fixed flexible snare knife and a forked knife. These two knives can be interchanged easily and have the advantage of being multifunctional; they can be used for marking, injecting, incising, irrigating, dissecting, and controlling bleeding. This enables the endoscopist to perform ESD more conveniently, thus shortening the procedure.

Applications

The Fork knife may be useful for ESD of gastric lesions, such as early gastric cancer and gastric adenoma. The feasibility and safety of the novel device is similar to that of other knives but it may actually be more convenient because of its design.

Terminology

The ESD technique was first introduced in 1988 in Japan. ESD is an innovative technique that improves the rate of successful *en bloc* resection of early-stage GI neoplasms.

Peer review

An interesting article on a timely topic, endoscopic submucosal resection of early gastric cancer. The authors compared two newer instruments and found no real difference between them. The paper is well written, the study well conceived, and I learned a lot about the new treatments of early gastric cancer.

Abstract

AIM: To evaluate the association between X-ray cross-complementing gene 1 (XRCC1) genetic polymorphism Arg399Gln and gastric cancer risk by means of meta-analysis.

METHODS: We searched PubMed and NCBI up to June 1, 2008. A total of 16 clinical trials and reports were identified, but only 8 trials qualified under our selection criteria. Statistical analysis was performed with the software program Review Manage, version 4.2.8.

RESULTS: Of the 8 case-control studies selected for this meta-analysis, a total of 1334 gastric cancer cases and 2194 controls were included. For Arg399Gln, the Gln/Gln genotype carriers did not have a decreased cancer risk compared with those individuals with the Arg/Arg genotype (OR = 0.92, 95% CI, 0.71-1.19; P = 0.51). Similarly, no associations were found in the recessive and dominant modeling (Gln/Gln *vs* Arg/Gln + Arg/Arg: OR = 0.96; 95% CI, 0.77-1.19; P = 0.70 and Gln/Gln + Arg/Gln *vs* Arg/Arg: OR = 0.90, 95% CI, 0.77-1.05; P = 0.18).

CONCLUSION: No association is found between the XRCC1 polymorphism Arg399Gln and gastric cancer risk.

Peer reviewers: Dr. Mark S Pearce, Pediatric and Lifecourse

INTRODUCTION

Gastric cancer is a leading cause of death worldwide, with nearly a million new cases diagnosed each year. It is the fourth most common cancer and the second leading cause of cancer death worldwide[1]. Multiple environmental and lifestyle factors may increase the risk of gastric cancer (GC), including tobacco use[2], a diet poor in fresh fruits and vegetables or rich in salt[3], and *Helicobacter pylori* (*H pylori*) infection[4]. However, not all of those who have been exposed to the risk factors will develop gastric cancer, suggesting the inter-individual differences in susceptibility. These differences may in part be caused by genetic variation, such as single nucleotide polymorphism (SNPs)[5] in DNA repair gene that increase susceptibility to the DNA damage resulting from carcinogens, particularly when these SNPs are located within the coding or regulating regions causing altered protein expression.

One of the important DNA repair protein is X-ray cross-complementing gene 1 (XRCC1)[6], acting as a scaffolding protein for the base excision repair (BER) and single-strand break repair (SSBR). These overlapping pathways participate in the constitutive response to endogenous mutagens and exogenous exposures, including tobacco smoke. Specifically, XRCC1-mediated pathways repair damage to DNA bases, from oxidation or covalent binding of nonbulky electrophiles, and to the deoxyribose phosphate backbone. Quick resolution of this genetic damage is imperative because repair intermediates, such as abasic sites and SSB, are generally more genotoxic and cytotoxic than the initial lesion.

Three common polymorphisms within the XRCC1 gene have been identified at codon 194, 280 and 399 (Arg194Trp, Arg280His, and Arg399Gln)[7]. These nonconservative amino acid changes may alter XRCC1 function. This change in protein biochemistry leads to the supposition that variant alleles may diminish repair kinetics, thereby influencing susceptibility to adverse health effects, including cancer.

Shen *et al*[8] first reported an association between XRCC1 codon 399 polymorphisms and gastric cancer. Since the publication of this report, many studies have appeared in the literature either supporting or negating the association. To clarify the effect of XRCC1 codon 399 polymorphisms on the risk of gastric cancer, we have undertaken a systematic review and meta-analysis.

MATERIALS AND METHODS

Literature search strategy

We searched in the Medline and Chinese National Knowledge Infrastructure (CNKI), covering all papers published up to June 1, 2008, with a combination of the following keywords: gastric cancer and XRCC1. We evaluated potentially relevant publications by examining their titles and abstracts and procured the most relevant publications for a closer examination. Besides the database search, the reference lists of the selected papers were also screened for other potential articles that may have been missed in the initial search. The search and evaluation were conducted from January to June 2008.

The following criteria were used for the literature selection for the meta-analysis: (1) The articles should be published in either English or Chinese between January 1989 and March 2008; (2) Only the case-control studies were considered; (3) The paper should clearly describe gastric cancer diagnoses and the sources of cases and controls; (4) The authors must offer the size of the sample, odds ratios (ORs) and their 95% confidence intervals (CIs) or the information that can help infer the results in the papers; (5) The definition of the exposure/risk genotypes was similar in all papers; (6) The methods of data collection and analysis should be statistically acceptable; (7) Those publications that presented data allowing such outcomes to be derived were also included.

Accordingly, the following exclusion criteria were also used: (1) The design and the definition of the exposure were obviously different from those of the selected papers; (2) Not offering the source of cases and controls and other essential information; (3) Reviews and repeated literatures were also excluded.

Data extraction

To minimize the bias and to improve the reliability, two reviewers checked all potentially relevant studies independently. Data on the following characteristics were also extracted: the first author, year of publication, journal, study population, number of genotyped cases and controls, and odds ratios and their confidence intervals.

Meta analysis

The strength of the associations between gastric cancer and the XRCC1 polymorphism was estimated by ORs and 95% CI. For the Arg399Gln polymorphism, we first estimated the risk of the variant genotype Gln/Gln and compared with the wild-type Arg/Arg homozygote, and then evaluated the risks of Gln/Gln *vs* (Arg/Gln + Arg /Arg) and (Arg/Gln + Gln/Gln) *vs* Arg/Arg, which assumed the recessive and dominant effect of the variant Gln399 allele.

We assessed the departure from the Hardy-Weinberg equilibrium for the control group in each study using the HWE program (http://linkage.rockefeller.edu/ott/linkutil.htm) for goodness of fit. The Peto Mantel-Haenszel fixed effect model or DerSimonian Laird random effect model was selected to summarize the combined *OR* dependent on the results of heterogeneity test among individual studies. And the heterogeneity was considered significant if $P < 0.05$. If there was no heterogeneity, fixed effects model was used; otherwise, a random effect model based on the DerSimonian and Laird estimator was used[9]. Inverted funnel plots were used to provide diagnosis of publication biases.

All of the statistical analyses were performed with Review Manager (version 4.2.8, The Cochrane Collaboration).

RESULTS

Literature search and meta-analysis databases

We selected 16 published papers dealing with case-control studies of the polymorphisms .We reviewed all papers in accordance with the criteria defined above, and excluded 8 papers because their study designs were different from others or they did not list data clearly enough for further analysis or repeated literatures. Hence, data were available from 8 case-control studies, including 1334 gastric cancer cases and 2194 controls (Table 1)[8,10-16]. We established a database according to the extracted information from each article. Given in Table 1 are the lists of the publication year, first author, and the number of cases and controls for each XRCC1 codon 399 genotype. Other necessary information is also listed in the forest plots in our meta-analysis. No qualified researches were acquired before 2000, which suggested that the researches between XRCC1 polymorphism and gastric cancer were started very late.

Meta analysis

The Gln/Gln genotype carriers did not have an increased cancer risk compared with those individuals with the Arg/Arg genotype (OR, 0.92; 95% CI, 0.71-1.19; $P = 0.51$). Similarly, no associations were found in the recessive and dominant modeling (Gln/Gln *vs* Arg/Gln + Arg/Arg: OR, 0.96; 95% CI, 0.77-1.19; $P = 0.70$ and Gln/Gln + Arg/Gln *vs* Arg/Arg: OR, 0.90; 95% CI, 0.77-1.05; $P = 0.18$). We did not find any associations between Arg399Gln polymorphism and gastric cancer risk in our study (Figure 1).

In all of the studies, the genotype frequencies were

HWE: Hardy-Weinberg equilibrium.

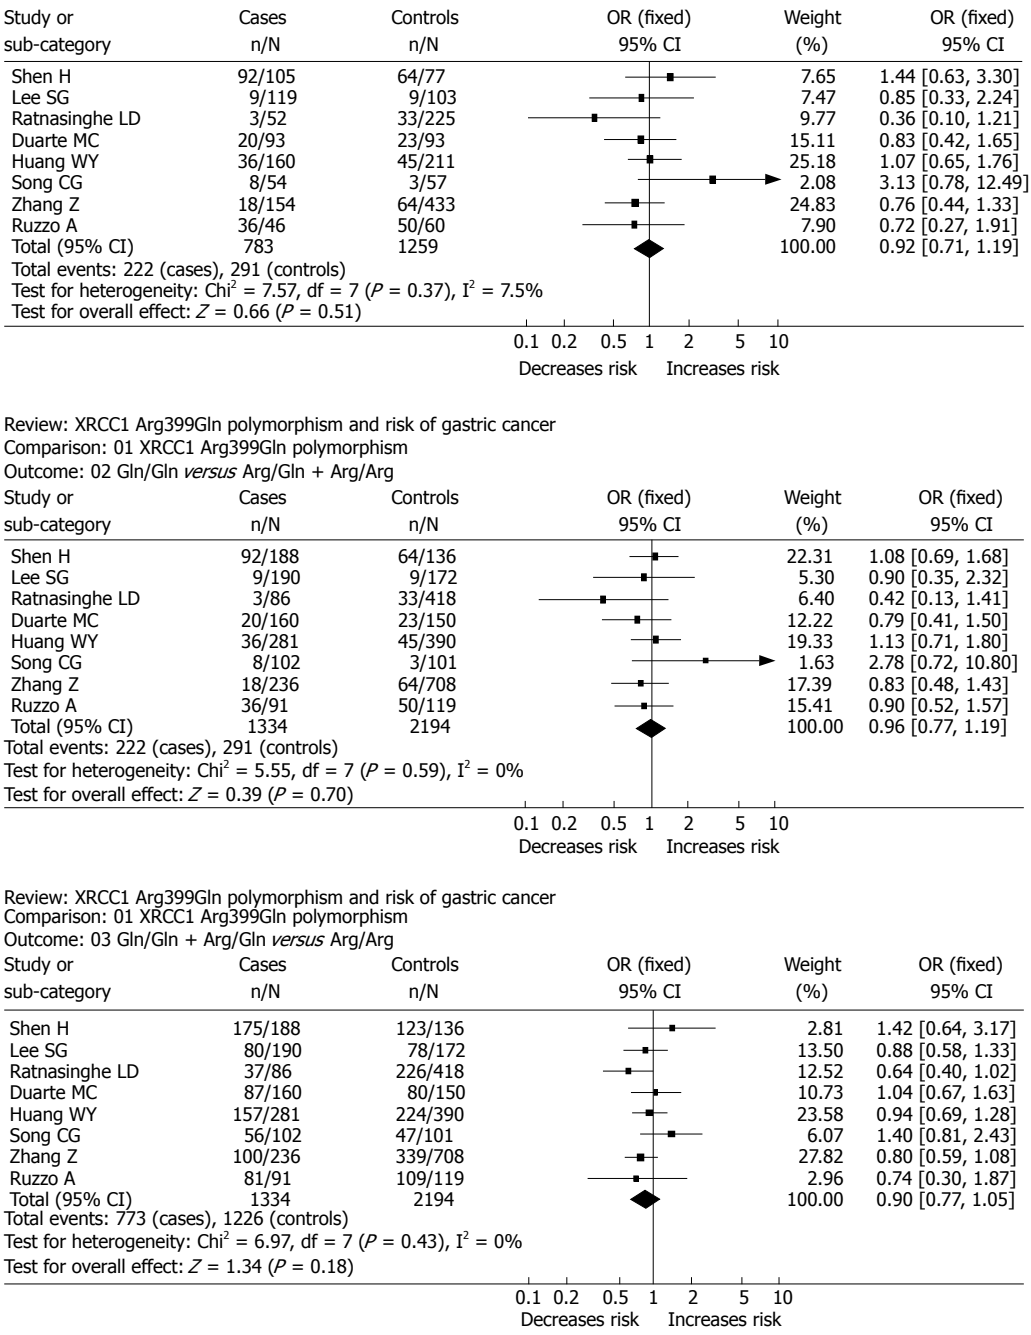

Figure 1 Forest plot of a meta-analysis of the association between XRCC1 polymorphism Arg399Gln and gastric cancer risk (fixed-effects mode).

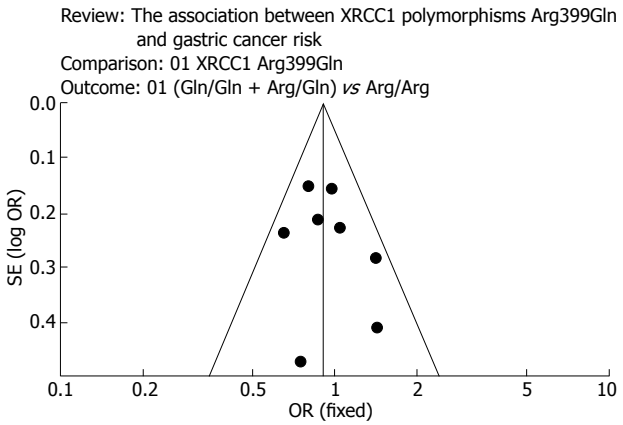

Figure 2 Funnel plot to explore publication bias. The graphical funnel plot of the 8 published studies appears to be asymmetrical.

consistent with Hardy-Weinberg equilibrium (Table 1). No significant between-study heterogeneities were present in the heterogeneity tests. In the funnel plot analysis of publication biases, the shape of the funnel plot (Figure 2) appeared to be approximately symmetrical, and the magnitude of the main ORs was in dispersion on the left side of 1. Therefore, the funnel plot analysis suggested that publication biases might not have a significant influence on the results of the XRCC1 gene.

DISCUSSION

XRCC1 protein is an important component of the BER pathway, which fixes base damage and DNA single strand breaks caused by ionizing radiation and alkylating agents. The XRCC1 protein has no known catalytic activity but serves to orchestrate BER through its role as a central scaffolding protein for DNA ligase Ⅲ, DNA polymerase β, and PARP, and also through its function in recognizing and binding to single-strand breaks[17]. The Arg399Gln polymorphism[18] is located in the region of the BRCT- I interaction domain of XRCC1 with ADPribosepolymerase, the presence of the variant 399Gln allele has been shown to be associated with measurable reduced DRC as assessed by the persistence of DNA adducts, tumor-suppressor gene P53 mutations, increased red blood cell glycophorin A, elevated levels of sister chromatid exchanges and prolonged cell-cycle delay.

To the best of our knowledge, it is the first systematic review that has investigated the association of XRCC1 codon 399 polymorphisms and gastric cancer, and no evidence has shown any associations between Arg399Gln polymorphism and gastric cancer susceptibility. One possible explanation is that human cells have five different DNA repair systems, characterized by the involvement of more than 150 proteins coded by genes, the majority of which are polymorphic. Thus, given that inter-individual variation in DNA repair capacity is in part explained by SNPs in repair genes, it is possible that the analyzed variants do not influence the basal level of damage. Nevertheless, based on our study, it is worth noting that, even if a common variant in the functional region of a definitively meaningful gene had an effect on human disease, such as cancer, it may play only a minor role in the disease causation.

Although the relationship is inconsistent in bladder cancer[19], other previous studies have found that the XRCC1 399Gln/Gln genotype is associated with an increased risk of lung cancer among Asians[20] and breast cancer in African Americans[21]. Our present and previous studies were similar in most aspects, and the reasons for this apparent difference in risk with different tumors are as yet unknown, possibly due to the overall heterogeneity in the studies that find strong positive or inverse associations. Many meta-analyses of several gene-disease associations have shown that initially promising associations often gravitate toward null over time[22].

In our study, no significant between-study heterogeneities were present in the heterogeneity tests, indicating that our present combined analyses were unbiased, and no obvious publication bias existed in our meta-analysis, since the "funnel plot" was symmetrically plotted. However, serious limitations were still inherited from the published studies. First, our assessment was based on relatively few studies, and because the papers included in our meta-analysis were limited to those published in either English or Chinese only in the periods between 1989 and 2008, it is possible that some relevant published studies and unpublished studies that are likely to have null results were not included, which may have biased the results. Therefore, although the test for publication bias was not statistically significant, possible bias, especially the outcome-reporting bias, still could not be ruled out. Second, most studies selected case subjects from Asian populations; therefore, we did not conduct a subgroup analysis according to different ethnic groups. The other studies were from Brazil, Poland and Italy, which have different patterns of lifestyle risk factors, genetic backgrounds, and gastric cancer risks. Third, we did not test for gene x environment interactions because of the issue of multiple testing and the lack of sufficient studies. Nevertheless, it is possible that these polymorphisms alter risk in subgroups of the population that have been exposed to specific environmental and lifestyle factors. Therefore, larger and well-designed studies are needed to further evaluate the association between XRCC1 polymorphism and gastric cancer risk.

In summary, our meta-analysis evaluated the relationship between genetic polymorphisms and gastric cancer risk and revealed that XRCC1 polymorphism Arg399Gln could not alter susceptibility to gastric cancer.

COMMENTS

Background

A G to A transition of the X-ray cross-complementing gene 1 (XRCC1) gene at codon 399 has been implicated as a risk factor for gastric cancer, but individual studies have been inconclusive or controversial. The aim of this meta-analysis

was to clarify the effect of XRCC1 Arg399Gln polymorphism on the risk of gastric cancer.

Research frontiers

To date, there have been many studies on the association between XRCC1 genetic polymorphism Arg399Gln and gastric cancer risk, but no meta-analyses.

Innovations and breakthroughs

XRCC1 polymorphism Arg399Gln could not alter susceptibility to gastric cancer. Further studies are needed to prove it.

Applications

It can be seen from this paper that XRCC1 polymorphism Arg399Gln could not alter susceptibility to gastric cancer. It suggests that, even if a common variant in the functional region of a definitively meaningful gene had an effect on human disease, such as cancer, it may play only a minor role in the disease causation.

Peer review

The study is nicely designed and the analytical data appear to be scientifically sound. The outcome clearly shows that XRCC1 polymorphism Arg399Gln could not alter susceptibility to gastric cancer.

Abstract

AIM: To investigate the value of clinical manifestations and ultrasound examination in the differential diagnosis of pancreatic lymphoma and pancreatic cancer.

METHODS: The clinical and ultrasonic characteristics of 12 cases of pancreatic lymphoma and 30 cases of pancreatic cancer were retrospectively analyzed.

RESULTS: Statistically significant differences were found in the course of disease, back pain, jaundice, carcino-embryonic antigen (CEA) and CA19-9 increase, palpable abdominal lump, superficial lymph node enlargement, fever and night sweats, lesion size, bile duct expansion, pancreatic duct expansion, vascular involvement, retroperitoneal (below the renal vein level) lymph node enlargement, and intrahepatic metastasis between pancreatic lymphoma and pancreatic cancer. There were no significant differences in age of onset, gender ratio, weight loss, nausea and vomiting, lesion position, the echo of the lesion, and the blood flow of the lesion.

CONCLUSION: Pancreatic lymphoma should be considered for patients with long lasting symptoms, superficial lymph node enlargement, palpable abdominal lump, fever and night sweats, relatively large lesions, and retroperitoneal (below the level of the renal vein) lymph node enlargement. A diagnosis of pancreatic cancer should be considered more likely in the patients with relatively short disease course, jaundice, back pain, CEA and CA19-9 increase, relatively small lesions, bile duct expansion, obvious pancreatic duct expansion, peripheral vascular wrapping and involvement, or intrahepatic metastases.

INTRODUCTION

Among the pancreatic tumors, there are much similarities in clinical manifestations and imaging characteristics of pancreatic cancer and pancreatic lymphoma and thus they are easy to be misdiagnosed[1-4]. However, the treatment and prognosis of pancreatic cancer and pancreatic lymphoma are quite different, and the differential diagnosis of these two diseases is therefore very important[5-7]. We retrospectively analyzed clinical and ultrasonic data of 12 cases of pancreatic lymphoma and 30 cases of pancreatic cancer to study the differentiation between the two diseases.

MATERIALS AND METHODS

Subjects

Forty-two pancreatic lesions were retrospectively analyzed. Patients with lymphoma (n = 12) and patients with pancreatic cancer (n = 30) whose diagnoses were confirmed by surgical pathology at our hospital from April 2001 to December 2007 were studied. All patients received ultrasound examinations before treatment.

Instruments and methods

Instruments: GE Logiq 7, Philips HDI-5000, HD-11 color Doppler ultrasound diagnostic instrument were used. The probe frequency was 8-12 MHz; speed range, blood flow filtering and color gain were adjusted to achieve blood flow maps with the best display status.

Ultrasound examination: Patients were placed in the supine position, the gray-scale ultrasound was used

Table 1 Clinical manifestation of pancreatic lymphoma and pancreatic cancer

	Pancreatic lymphoma	Pancreatic cancer	*P*
Age of onset (yr)	52.8 ± 3.4	53.8 ± 4.2	NS
Gender ratio (male/female)	10/2	24/6	NS
Course of disease	3 mo to 1 yr	4 wk to 3 mo	< 0.05
Weight loss	10	27	NS
Nausea and vomiting	4	12	NS
Fever and night sweats	5	1	< 0.05
Back pain	1	18	< 0.05
Jaundice	3	20	< 0.05
Palpable abdominal lump	6	0	< 0.05
Superficial lymph node enlargement	5	1	< 0.05
CEA, CA19-9 increase	0	18	< 0.05

P < 0.05, the two groups were significantly different.

to observe the size of the pancreatic lesion, lesion position, lesion echo, the main pancreatic duct, bile duct, peripancreatic vessels, and retroperitoneal lymph nodes. Then the color hemodromogram of the lesion area was displayed and divided into 3 grades: no blood flow signal, some blood flow signals, and abundant blood flow signals.

Statistical analysis

SAS V8.1 statistical software was used for data analysis. Statistical analyses were done for patient age, course of disease and lesion size using Wilcoxon's rank sum test. Fisher's exact probability and the χ^2 test were carried out for analyses of sex, back pain, jaundice, palpable abdominal lump, weight loss, nausea and vomiting, fever and night sweats, carcino-embryonic antigen (CEA) or CA19-9 increases, superficial lymph node enlargement, lesion position, lesion echo, bile duct expansion, pancreatic duct expansion, vascular invasion, retroperitoneal (below the renal vein level) lymph node enlargement, intrahepatic metastasis, and blood flow. $P < 0.05$ was taken as an indicator of a significant difference between the two groups.

RESULTS

Clinical manifestations

The clinical characteristics of pancreatic lymphoma and pancreatic cancer were compared. There was no significant difference in age of onset, gender ratio, weight loss, or nausea and vomiting between the two groups. The course of disease, back pain, jaundice, CEA and CA19-9 increase, palpable abdominal lump, superficial lymph node enlargement, fever and night sweats were significantly different between the two groups. This means that the disease course of the pancreatic lymphoma is longer, and superficial lymph node enlargement, palpable lump, and fever and night sweats occur more frequently in pancreatic lymphoma. In pancreatic cancer, back pain, jaundice, and CEA and CA19-9 increases occur more frequently (Table 1).

Table 2 Ultrasonic manifestations of pancreatic lymphoma and pancreatic cancer

	Pancreatic lymphoma	Pancreatic cancer	*P*
Lesion position			
Pancreatic head	7	19	NS
Pancreatic body & tail	3	7	NS
Diffuse	2	4	NS
Lesion echo	All 12 cases had low echo	All 30 cases had low echo	NS
Lesion size	79.6 ± 10.7 mm	34.7 ± 5.5 mm	< 0.05
Blood flow of the lesion	11 cases did not show any blood flow signals, 1 case showed some blood flow signals	None of the 30 cases showed blood flow signals	NS
Bile duct expansion	3	20	< 0.05
Pancreatic duct expansion	2	18	< 0.05
Blood vessel involvement	2	15	< 0.05
Retroperitoneal (below the renal vein) lymph node enlargement	5	1	< 0.05
Intrahepatic metastasis	0	6	< 0.05

P < 0.05, the two groups were significantly different.

Ultrasonic manifestations

The ultrasound characteristics of pancreatic lymphoma and of pancreatic cancer were compared. There were no significant differences in lesion position, lesion echo, or blood flow of the lesion between the two groups. The lesions size, bile duct expansion, pancreatic duct expansion, vascular involvement, retroperitoneal (below the renal vein) lymph node enlargement, and intrahepatic metastasis were significantly different (Table 2). In other words, the lesion size of pancreatic lymphoma is relatively larger, which is prone to causing enlargement of the lymph nodes below the renal vein level. Pancreatic cancer tends to cause bile duct and pancreatic duct expansion more frequently and is more likely to affect the blood vessels and lead to intrahepatic metastasis.

DISCUSSION

The incidence of pancreatic cancer has grown substantially in developed countries and in some developing countries. Currently, it is one of the top ten malignant tumors, and its prognosis is very poor. The 1-year survival rate is below 20% and the 5-year survival rate is only 3%[1,5,8]. Pancreatic lymphoma is a rare pancreatic tumor that accounts for only 1% of all pancreatic tumors. Its main pathological type is B-cell non-Hodgkin's lymphoma and the overwhelming majority of cases involve pancreatic infiltration by systemic lymphoma. It can also originate from the pancreas and show primary pancreatic manifestations, which are called primary pancreatic lymphoma (PPL). The average survival time of pancreatic lymphoma is 2-6.5 years, which is better than the prognosis for pancreatic cancer[9-11]. There are much similarities in the clinical and imaging examination of the two diseases so that they are easily misdiagnosed. However, the

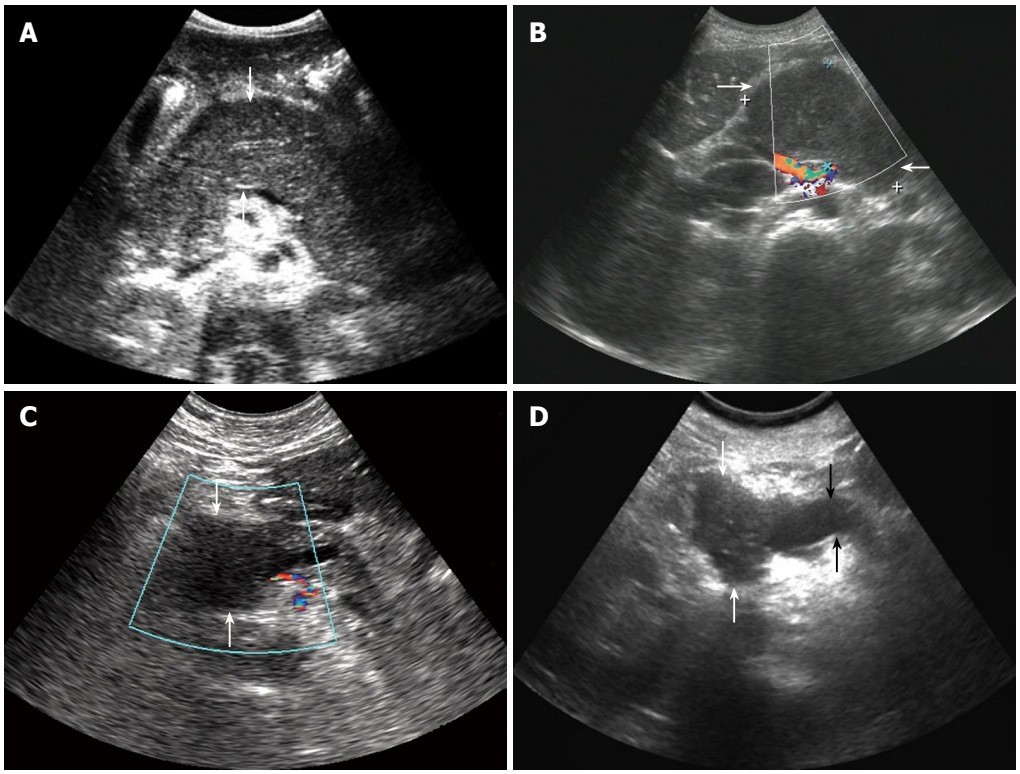

Figure 1 ultrasonic manifestation. A: Diffuse pancreatic lymphoma (arrows): the pancreas showed diffuse enlargement and the echo decreased; B: Pancreatic lymphoma (arrows): a low echo lump was seen in the pancreatic head. There were no blood flow signals; C: Pancreatic cancer (arrows): a low echo lump was seen in the pancreatic head. There were no blood flow signals; D: Pancreatic cancer: a low echo lump appeared in the pancreatic head (white arrows) and the main pancreatic duct (black arrows) was obviously expanded.

treatment and the prognosis of the two diseases are quite different. Therefore, the differential diagnosis of these two diseases is important.

Comparison of clinical characteristics of pancreatic lymphoma and pancreatic cancer

There was no significant difference in the age of onset, gender ratio, weight loss, nausea and vomiting between the two diseases. Therefore, these characteristics cannot be used for the differential diagnosis.

The course of disease of the patients with pancreatic lymphoma is usually longer than that of the patients with pancreatic cancer. As the lesion is relatively large in pancreatic lymphoma, an abdominal lump is easily palpable. In our series, an abdominal lump was palpable in 6 (50%) patients in the pancreatic lymphoma group. In addition, as the majority of the pancreatic lymphoma cases originate from systemic lymphoma, characteristics of the lymphoma such as superficial lymph node enlargement and fever and night sweats are likely to occur. Those characteristics are relatively rare in patients with pancreatic cancer. Compared with pancreatic lymphoma, jaundice and back pain are more likely to occur in patients with pancreatic cancer. This is because pancreatic cancer has perivascular and perineural growth[12-15]. It is easy for pancreatic cancer to cause jaundice by bile duct infiltration or oppression or to cause back pain by erosion of the retroperitoneal nerve, which is more obvious at night. Regarding laboratory tests, since the pancreatic cancer is a tumor with duct infiltration, most patients show increases in two tumor markers, CEA and CA19-9.Those markers will usually not increase in patients with pancreatic lymphoma[16-18].

Comparison of ultrasonic characteristics of pancreatic lymphoma and pancreatic cancer

There were no significant differences in the lesion position, lesion echo, or the blood flow of the lesion between the two diseases. Pancreatic head lesions are commonly seen in both diseases. In this study, pancreatic head lesions accounted for 58.3% of cases in the pancreatic lymphoma group and 63.3% of cases in the pancreatic cancer group. In addition, some lesions located in the body or the tails of the pancreas were diffuse (Figure 1A). All the lesions had low echo, and most lesions did not have any blood flow signals (Figure 1B and C).

The lesion sizes were significantly different between the two diseases. The lesion of the pancreatic lymphoma is usually greater than that of the pancreatic cancer. In this study, the lesion size of the pancreatic lymphoma was approximately 79.6 ± 10.7 mm, and the lesion size of the pancreatic cancer was approximately 34.7 ± 5.5 mm. Other literature reports showed similar results that the diameter of the pancreatic lymphoma lump is usually greater than 70 mm, and the diameter of the pancreatic cancer is usually less than 50 mm[19-22]. A possible reason is that the early symptoms of pancreatic lymphoma are not obvious and diagnosis is made relatively late; therefore the lesions are relatively big when they are found.

Bile duct expansion was significantly different between the two diseases. Pancreatic cancer readily infiltrates and oppresses the bile duct so that bile duct expansion occurs more frequently in pancreatic cancer than in pancreatic lymphoma. In this study, intrahepatic and extrahepatic bile duct expansion occurred in 20 (66.7%) cases of pancreatic cancer, but in only 3 (25%)

cases of pancreatic lymphoma.

Pancreatic duct expansion was statistically significant between the two diseases. In this study, 18 (60%) cases of pancreatic cancer showed pancreatic duct expansion (Figure 1D), while only 2 (16.7%) cases of pancreatic lymphoma did so. Another study showed that the pancreatic duct in pancreatic lymphoma can be discontinuous or narrow, expansion is rare, and the ratio of the expanded pancreatic duct to the anteroposterior diameter of the gland is less than 0.5. However, this ratio in pancreatic cancer (in more than 89% of cases) is often greater than 0.5[23-26].

The two diseases were significantly different regarding blood vessel involvement. The pancreatic cancer frequently wraps and erodes the blood vessels. There were 15 (50%) cases of pancreatic cancer with vascular involvement in this study; there were only 2 (16.7%) cases of pancreatic lymphoma with vascular involvement. The pancreatic lymphoma mainly pushes the surrounding blood vessels.

The two diseases were significantly different in retroperitoneal (below the renal vein level) lymph node enlargement. Peri-pancreatic and retro-peritoneal lymph node enlargement can occur in both pancreatic cancer and pancreatic lymphoma, but pancreatic lymphoma is often part of a systemic lymphoma. Therefore, there are more sites of lymph node enlargement in pancreatic lymphoma than in pancreatic cancer. It has been reported in the literature that retroperitoneal lymph node enlargement below the level of the renal vein seldom appears in pancreatic cancer[27-29]. In this study, 5 (41.7%) patients with pancreatic lymphoma showed lymph node enlargement below the level of the renal vein, but only 1 (3.3%) case of pancreatic cancer showed similar lymph node enlargement.

The two diseases were significantly different in intrahepatic metastasis. Intrahepatic metastasis occurred more easily in patients with pancreatic cancer compared with pancreatic lymphoma[30]. There were 6 (20%) cases of pancreatic cancer with intrahepatic metastasis in this study while no intrahepatic metastasis occurred in pancreatic lymphoma.

In summary, clinical and ultrasonic manifestations can aid in the differentiation between pancreatic lymphoma and pancreatic cancer. For the differential diagnosis of the two diseases, pancreatic lymphoma should be considered for patients with long lasting symptoms, superficial lymph node enlargement, palpable abdominal lump, fever and night sweats, relatively large lesions, and retroperitoneal (below the level of the renal vein) lymph node enlargement. A diagnosis of pancreatic cancer should be considered more likely for patients with relatively short disease course, jaundice, back pain, CEA and CA19-9 increase, relatively small lesions, bile duct expansion, obvious pancreatic duct expansion, peripheral vascular wrapping and involvement, or intrahepatic metastases. The diagnosis can be confirmed by biopsy or postoperative pathological results.

COMMENTS

Background

Differential diagnosis of pancreatic masses is a frequent clinical challenge. Differential diagnosis is difficult between pancreatic cancer and pancreatic lymphoma because there are a lot of similarities in clinical manifestations and imaging characteristics of pancreatic cancer and pancreatic lymphoma among pancreatic tumors. However, the treatment and prognosis of pancreatic cancer and pancreatic lymphoma are quite different, and the differential diagnosis of these two diseases is therefore, very important.

Research frontiers

Further researches are needed in order to improve the diagnosis of pancreatic cancer and pancreatic lymphoma. Availability of ultrasound examination and clinical manifestations may provide more information for the diagnosis of pancreatic cancer and pancreatic lymphoma.

Innovations and breakthroughs

Because the morbidity of pancreatic lymphoma is low, in this study, 12 cases of pancreatic lymphoma were important which could provide much favorable information for diagnosis.

Applications

Clinical and ultrasonic manifestations can aid in the differentiation between pancreatic lymphoma and pancreatic cancer.

Peer review

This is an interesting paper. The contents are important and significant because there is no much information about pancreatic lymphoma in the existing literature.

Abstract

AIM: To investigate the pathological characteristics of non-thermal damage induced by pulsed high intensity focused ultrasound (PHIFU) combined with ultrasound contrast agent (UCA), SonoVue (Bracco SpA, Milan, Italy) in rabbit liver VX2 tumor.

METHODS: Liver VX2 tumor models were established in 20 rabbits, which were divided randomly into PHIFU combined with ultrasound contrast agent group (PHIFU + UCA group) and sham group. In the PHIFU + UCA group, 0.2 mL of SonoVue was injected intravenously into the tumor, followed by ultrasound exposure of I_{SP} 5900 W/cm^2. The rabbits were sacrificed one day after ultrasound exposure. Specimens of the exposed tumor tissues were obtained and observed pathologically under light microscope and transmission electron microscope. The remaining tumor tissues were sent for 2,3,5-Triphenyltetrazolium chloride (TTC) staining.

RESULTS: Before TTC staining, tumor tissues in both the sham and the PHIFU + UCA groups resembled gray fish meat. After TTC staining, the tumor tissues were uniformly stained red, with a clear boundary between tumor tissue and normal tissue. Histological examination showed signs of tumor cell injury in PHIFU + UCA group, with cytoplasmic vacuoles of various sizes, chromatin margination and karyopyknosis. Electron microscopic examination revealed tumor cell volume reduction, karyopyknosis, chromatin margination, intercellular space widening, the presence of high electron-density apoptotic bodies and vacuoles in cytoplasm.

CONCLUSION: The non-thermal effects of PHIFU combined with UCA can be used to ablate rabbit liver VX2 tumors.

INTRODUCTION

High-intensity focused ultrasound (HIFU) is a rapidly developing non-invasive technology for tumor treatment. In recent years it has been widely used for treating a variety of solid tumors, such as liver tumor, bone tumor, and breast cancer. Mechanism for therapeutic actions of HIFU includes thermal effects and non-thermal effects with the latter dominated by cavitational effects. Thermal effects and cavitational effects work together to produce coagulative necrosis in targeted tumor and thus therapeutic purpose is achieved[1]. Glynn *et al*[2] have reported that cavitational effects of HIFU can be completed in one acoustic cycle, indicating that in the process of coagulative necrosis, cavitational effects precede thermal effects. Furthermore, cavitational effects will inhibit cell growth, increase membrane permeability, damage cellular DNA,

promote cell apoptosis and inhibit cell proliferation[3]. Therefore, efforts to reach treatment goals solely by non-thermal effects dominated by cavitational effects have become very meaningful.

Adjusting acoustic parameters of pulsed high intensity focused ultrasound (PHIFU) can control thermal effects and non-thermal effects; short duty cycle and high intensity favor the occurrence of cavitation[4]. Roberts *et al*[5] used mechanical and cavitational effects generated by pulse focused ultrasound to ablate rabbit kidney and they found that stable and predictable morphological lesions can be achieved by controlling certain parameters. Hall *et al*[6] used cavitational effects of PHIFU to ablate tissues (histotripsy), and concluded that cavitation causes orderly and predictable histologic changes. Our preliminary study results show that bovine liver can be ablated non-thermally by PHIFU using the following parameters: frequency 0.87 MHz, spatial peak intensity I_{SP} 5900 W/cm^2, pulse repetition frequency 100 Hz, and duty cycle 15%[7]. Considering blood circulation, *in vivo* tissues should be less susceptible to heating under same experimental conditions and acoustic parameters. It has been reported that ultrasound contrast agent (UCA) can enhance cavitational effects[8]. Therefore, we combined PHIFU and UCA to produce non-thermal damage in rabbit liver VX2 tumor *in vivo*, and investigated the pathological characteristics of the non-thermal damage.

MATERIALS AND METHODS

Animal model

Twenty New Zealand white rabbits of either gender, 3-4 mo old and weighing 2.0 ± 0.16 kg were used in this study. Animals were fasted 24 h before experiments; abdomen was shaved using 10% Na_2S; all rabbits were anesthetized by intramuscular injection of 0.1 mL/kg Sumianxin (Institute of Veterinary Medicine, Agriculture and Ranching University of Changchun, China). One block (bout 1 cm^3) of active tumor tissues was taken from the rabbit inoculated with VX2 tumor (VX2 squamous carcinoma cell line was offered by Funabashi Farm Company in Kyoto, Japan), washed with normal saline, and then subdivided into small tissue pieces about 1 mm^3. The 20 rabbits were fixed in prone position and routinely disinfected. A median incision was made below the Xiphoid process to expose the right lobe of liver, where a hole about 1-2 cm deep was made using ophthalmological forceps; then 2 ready tissue pieces were implanted into each hole. Bleeding points were stopped with gelatin sponge and then the abdominal wall was sutured. Skin incision was disinfected; 1 mL Suxingling was injected intramuscularly. After tumor inoculation, the rabbits were fed for 2-3 wk and then used in this study.

The experiment was approved ethically and scientifically by our university and complied with Practice for Laboratory Animals in China.

Preparation of UCA suspension

SonoVue® (Bracco Company, Italy) was used. After the plastic cap of the vial was removed, 5 mL sterile normal saline was added into the vial. The vial was shaken vigorously for about 20 s before the milky white suspension was ready.

HIFU equipment and experimental procedures

Model JC High Intensity Focused Ultrasound Tumor Therapeutic System [Chongqing Haifu (HIFU) Technology Co. Ltd., China] was used in this study and has been described in detail previously[9]. HIFU parameters used were as follows: ultrasound frequency 0.87 MHz, focal length 150 mm, I_{SP} 5900 W/cm^2, pulse repetition frequency 100 Hz, and duty cycle 15%.

Experiment started on the 15th day after VX2 tumor inoculation. The rabbit abdomen was shaved with 10% Na_2S one day before experiment. They were anaesthetized by intraperitoneal injection of 3% pentobarbital sodium solution (30 mg/kg body weight) 10 min prior to the experiment and then fixed in prone position on the treatment bed. The 20 rabbits were randomly divided into sham and PHIFU + UCA groups, with 10 rabbits in each group. In the sham group, the target tumor was localized under the assistance of B-mode ultrasonography; after the power generator was turned off, the whole target tumor was irradiated for 90 s. In the PHIFU + UCA group, after the tumor was localized using B-mode ultrasonography, 0.2 mL SonoVue was injected rapidly via ear marginal veins, followed by rapid injection of 1 mL normal saline. Fifteen seconds after the injection, the tumors were exposed to HIFU for 90 s.

Specimen

Twenty-four hours after the HIFU exposure, rabbits in both groups were killed using excessive anesthetics. The abdomen was opened to excise the liver. Multiple-spot sampling was done from the tumor center to the tumor periphery. One mm^3 tumor piece was sampled, double-fixed by glutaraldehyde and osmium acid, embedded in epoxy resin, sectioned ultra-thinly and ultra-structural changes of the targeted tissues were observed under transmission electron microscope. Another 1 mm^3 tumor piece was HE stained and observed under light microscope. The remaining tumor tissues were stained at 37℃ TTC solution for 15 min and observed grossly.

RESULTS

Gross observation

VX2 tumor model was successfully established in all the rabbits. Gross observation found that the implanted tumor was located within hepatic parenchyma, and they were spherical, elliptical or nodular shaped. The tumors resembled the appearance of gray fish meat and the cells were non-encapsulated. There was a clear demarcation between the tumor and the normal surrounding tissues. Before TTC staining, tumor tissues in PHIFU + UCA group resembled gray fish meat and they were demarcated clearly from surrounding normal liver tissues with a sharp boundary (Figure 1A). After the TTC staining the tumor

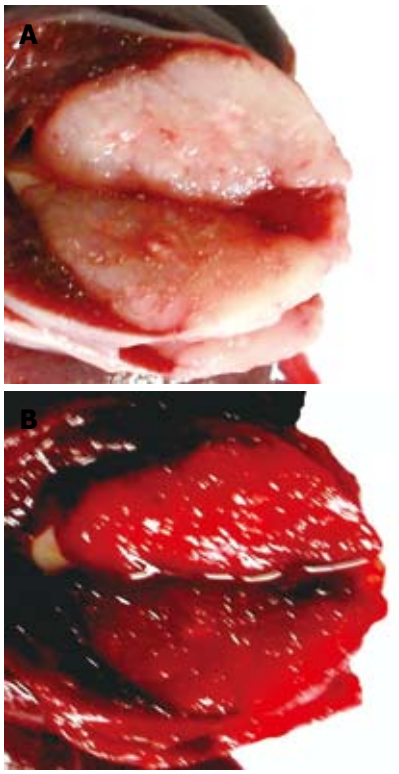

Figure 1 Gross specimen from PHIFU + UCA group before and after TTC staining. A: Before TTC staining, tumor tissues resembled gray fish meat, and the boundary between tumor and normal tissues was very clear; B: After TTC staining, tumor tissues were uniformly stained red, without unstained regions.

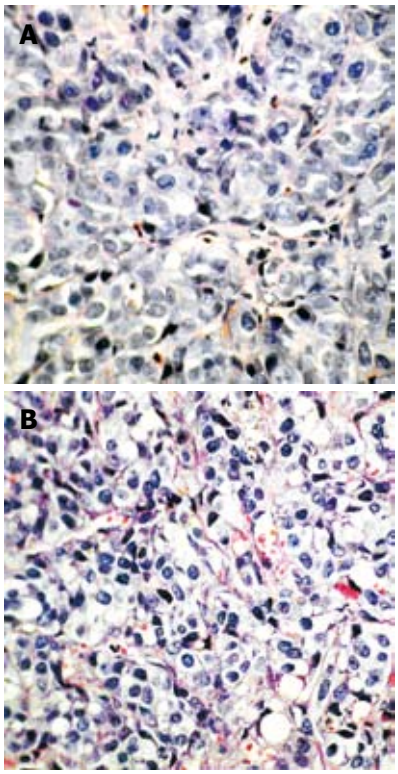

Figure 2 Light microscopic pathology of the targeted VX2 tumor rabbit liver tissues in sham group (A) and PHIFU + UCA group (B) (HE, x 400). A: In sham group, tumor cells were large, irregularly arranged and with irregular morphology. The nuclei were large and deeply H&E stained, with great karyoplasmic ratio and increased mitosis. B: In PHIFU + UCA group, tumor cytoplasm in all 10 rabbits was lightly stained, with cytoplasmic vacuoles of various sizes, chromatin margination and karyopyknosis.

tissues were uniformly stained red without any unstained regions. There was a clear demarcation between the tumor and the normal tissues (Figure 1B).

Light microscopy

Sham group: Under low power lens, VX2 tumor cells in the sham group appeared mass-flake like or an invasive cancer nest, with reduced connective tissues and an unclear demarcation between the tumor and mesenchymal cells. Under high power lens, tumor cells were large, irregularly arranged with an irregular morphology. The nuclei were large and deeply stained, with great karyoplasmic ratio and increased mitosis (Figure 2A).

PHIFU + UCA group: Tumor cytoplasm in all 10 rabbits was lightly stained, with cytoplasmic vacuoles of various sizes, chromatin margination and karyopyknosis (Figure 2B).

Electron microscopy

Sham group: Tumor cells in the sham group appeared polymorphic or spindle-shaped of various sizes and with signs of mitosis. The nuclei were large, deformed, with clear nuclear membranes and rich euchromatin. The chromatin particles were large with intranuclear pseudoinclusions and there were multiple visible nucleoli (Figure 3A).

PHIFU + UCA group: Tumor cells were reduced in size and in some tumor cells, karyopyknosis was revealed. These tumors showed chromatin margination, intercellular space widening (Figure 3B), the presence of high electron-density apoptotic bodies (Figure 3C) and various vacuoles of different sizes in the cytoplasm (Figure 3D).

DISCUSSION

In recent years, the use of microwave, radio frequency, laser and ultrasound as thermal source to ablate solid tumors has been applied in clinical use[10]. Among these treatments, image-guided high-intensity focused ultrasound (HIFU) *in situ* ablation of solid tumors is believed to be the most promising non-invasive modality. Ultrasound beams from an extracorporeal source can propagate through overlying tissues and be brought to a tight focus in the target tissue. The temperature at focus will elevate to 65℃ instantly (0.5-5 s), causing irreversible coagulative necrosis which is grossly visible and histopathologically confirmed. Coagulative necrosis is induced through a combination of thermal and cavitational effects[1]. Some researchers believe that the thermal ablation mechanism has shortcomings. Due to the individual diversity of tissue characteristics and blood perfusion, the size and morphology of thermal lesion cannot be accurately predicted. The local thermal effects may also damage the adjacent tissues and it is possible that uneven heating in the target region will cause leaping injury[11]. In order to avoid the defects of thermal effects, non-thermal effects of ultrasound may offer an alternative.

When acoustic intensity in the target tissue is higher than 1500 W/cm^2, non-thermal effects (mechanical and cavitational effects) will occur. These include forming non-thermal lesion[12], damaging DNA, promoting cell apoptosis, inhibiting cell proliferation[13] and even causing histotripsy[14]. Thermal and non-thermal effects can be effectively controlled by adjusting exposure parameters of PHIFU; short duty cycle and high intensity favor the occurrence of cavitation[4]. PHIFU parameters used in this study, ultrasound frequency 0.87 MHz, I_{SP} 5900 W/cm^2,

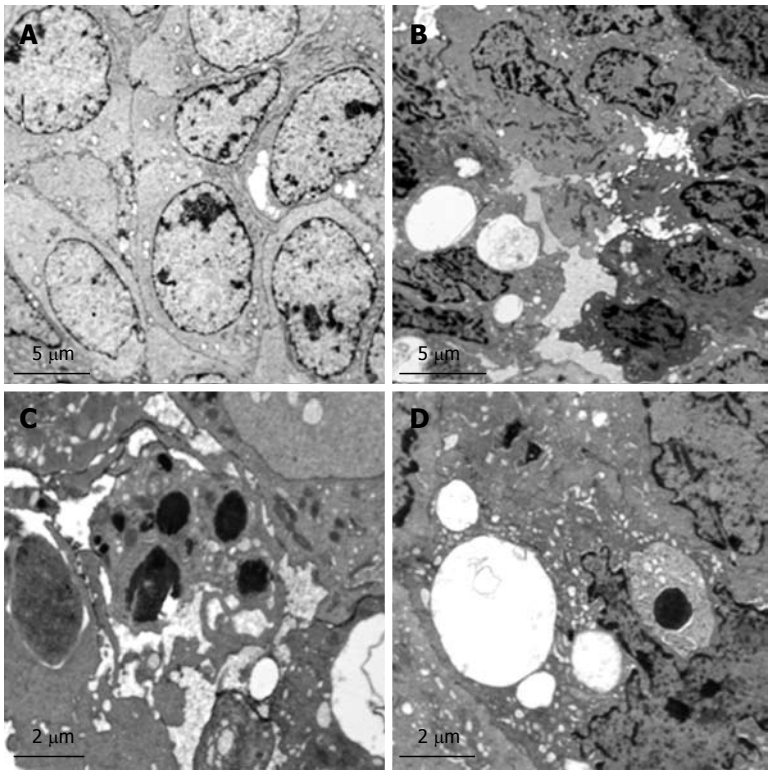

Figure 3 Ultrastructure of the targeted VX2 tumor tissues in sham group and PHIFU + UCA group under transmission electron microscope. A: Tumor cells in sham group were pleomorphic or spindle-shaped of various sizes and with mitosis; nuclei were large and deformed, with clear nuclear membranes and rich euchromatin; chromatin particles were large with intranuclear pseudo-inclusions; there were multiple visible nucleoli (sham group, lead dyeing, x 3500); B: Tumor cells reduced in size; in some tumor cells, karyopyknosis was revealed, with chromatin margination and intercellular space widening (PHIFU + UCA group, lead dyeing, x 4000); C: High electron-density apoptotic bodies were present (PHIFU + UCA group, lead dyeing, x 8000); D: Vacuoles were present in cytoplasm of tumor cells (PHIFU + UCA group, lead dyeing, x 8000).

pulse repetition frequency 100 Hz, and duty cycle 15%, have been demonstrated previously to be able to induce non-thermal damage in bovine liver[7]. These parameters are also consistent with non-thermal parameters reported elsewhere[12].

TTC staining assesses dehydrogenase activity and is a staining method for gross specimens. The main principle is that in the presence of NADH, active dehydrogenase in viable tissues will reduce colorless oxidative TTC to red reductive TTC; hence viable tissue can be stained red while necrotic tissue can not. HIFU causes instant temperature rise to above 65℃ at focus; at such a high temperature, dehydrogenase is deactivated, hence tissues within the target region cannot be stained. Based on this principle, Chang Shufang *et al*[15] applied TTC staining to observe HIFU-induced coagulative necrosis grossly. In one of our preliminary studies, the same parameters were used to form non-thermal damage *in vitro* bovine liver tissues[7]. Considering the cooling effect of blood circulation *in vivo* animals, it is inferred that temperature elevation under same exposure parameters should be lower in this study. In this study, we found that tissues in PHIFU + UCA group were stained red by TTC, indicating that focal temperature was not high enough to deactivate dehydrogenase, which further proved that temperature in the targeted tissues did not elevate to the level required for formation of thermal coagulation.

Lesions caused by non-thermal effects have characteristic pathological changes quite different from those of thermal lesions. Ashush *et al*[16] observed the following morphological changes after HIFU cavitation: cell shrinkage, vacuole formation, chromatin condensation, karyorrhexis and the formation of apoptotic bodies. Kieran *et al*[11] studied non-thermal lesion by changing ultrasound intensity and duty cycle. Their histological observation showed that within certain intensity and duty cycle, vacuoles were formed in the cells, with blanched and dense liquid inside the vacuoles. This study found that PHIFU in combination with UCA can intensify non-thermal effects of HIFU and thus achieve thermal ablation. Light microscopy displayed abundant vacuoles of various sizes in the cytoplasm and chromatin margination and karyopyknosis in some cells. Electron microscopic examination revealed presence of karyopyknosis and chromatin margination in some cells, intercellular space widening, the presence of high electron-density apoptotic bodies and many vacuoles of various sizes in the cytoplasm. These results are consistent with previous reports, indicating that by combining PHIFU with UCA, non-thermal effects can be intensified to achieve non-thermal tumor ablation. Immunohistochemical detection found that PHIFU combined with UCA can promote tumor cell apoptosis and inhibit tumor cell proliferation, which will be reported in another article.

Future studies are needed in many aspects, such as cavitation detection, temperature monitoring and other means to detect non-thermal effects; how to optimize combination between UCA and HIFU exposure parameters; means to control and monitor cavitational lesions; long-term outcomes of non-thermal tumor ablation.

COMMENTS

Background

Image-guided high-intensity focused ultrasound (HIFU) *in situ* ablation of solid tumors is believed to be a promising non-invasive modality. Ultrasound beams

from an extracorporeal source can propagate through overlying tissues and be brought to a tight focus in the target tissue. The temperature at focus will elevate to 65℃ instantly (0.5-5 s), causing irreversible coagulative necrosis. Mechanism for therapeutic actions of HIFU includes thermal effects and non-thermal effects with the latter dominated by cavitational effects. Due to the individual diversity of tissue characteristics and blood perfusion, the size and morphology of thermal lesion cannot be accurately predicted. The local thermal effects may also damage the adjacent tissues and it is possible that uneven heating in the target region will cause leaping injury. In order to avoid the defects of thermal effects, non-thermal effects of ultrasound may offer an alternative.

Research frontiers

Adjusting acoustic parameters of pulsed high intensity focused ultrasound (PHIFU) can control thermal effects and non-thermal effects; short duty cycle and high intensity favor the occurrence of cavitation. Ultrasound contrast agent (UCA) can enhance cavitation effects. Lesions caused by non-thermal effects have characteristic pathological changes quite different from those of thermal lesions. Therefore, the authors combined PHIFU and UCA to produce non-thermal damage in rabbit liver VX2 tumor *in vivo*, and investigated the pathological characteristics of the non-thermal damage.

Innovations and breakthroughs

Non-thermal damage for tumor is the modality different from thermal damage. Previous studies showed that HIFU could ablate tumors by thermal effects. Short duty cycle and high intensity of PHIFU favor the occurrence of cavitation, and ultrasound contrast agent can enhance cavitation effects. The present study used PHIFU with short duty cycle and high intensity combined with UCA to damage rabbit liver VX2 tumor by non-thermal effect. Histopathology was used to evaluate the result.

Applications

The present study showed that the non-thermal effects of PHIFU combined with UCA could be used to ablate rabbit liver VX2 tumors. And this study would help promote a new scheme of therapy for tumors.

Peer review

This is an interesting investigation, demonstrating the effect of intensity focused ultrasound combined with ultrasound contrast agent on liver metastases.

Abstract

This case report describes the unusual presentation of a patient who had findings which were initially suggestive of a type Ⅳ choledochal cyst. Her liver biopsy demonstrated biliary cirrhosis. She was treated with endoscopic retrograde cholangiopancreatography and biliary stent exchanges over one year. Her cholangiogram one year later demonstrated resolution of the biliary cystic dilation which led to her initial diagnosis, with beading and stricturing of the hepatic ducts consistent with primary sclerosing cholangitis. Liver-associated enzymes and physical findings also improved. A liver biopsy one year later demonstrated a marked improvement in hepatic fibrosis with no evidence of cirrhosis.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic progressive disorder characterized by diffuse intrahepatic and extrahepatic bile duct inflammation, stricturing, and fibrosis; progressing to cirrhosis and hepatic failure. PSC occurs more commonly in men, is frequently associated with ulcerative colitis (73%) and is a risk factor for cholangiocarcinoma[1]. We report an unusual case of PSC, which was initially diagnosed as a choledochal cyst.

CASE REPORT

A 30-year-old female presented with a 6-mo history of yellow eyes, dark urine and clay-colored stools. Two years earlier, evaluation at another facility revealed elevated liver-associated enzymes (LAEs). She was diagnosed with Caroli's disease on the basis of non-invasive imaging.

On our evaluation, scleral icterus and hepatosplenomegaly were found on physical examination. Her total bilirubin was 20.9 mg/dL (normal 0.2-1.3 mg/dL), direct bilirubin 18.0 mg/dL (0.0-0.4 mg/dL), alkaline phosphatase (ALK) 957 U/L (38-126 U/L), aspartate aminotransferase (AST) 104 U/L (14-50 U/L) and alanine aminotransferase (ALT) 56 U/L (9-52 U/L). Abdominal computed tomography (CT) scanning showed dilation of the biliary ducts involving the right and left lobes (Figure 1). The common bile duct appeared normal. Magnetic resonance cholangiopancreatography (MRCP) showed intrahepatic biliary ductal dilation including the right and left hepatic ducts consistent with choledochal cysts (Figure 2). Endoscopic retrograde cholangiopancreatography (ERCP) revealed cystic dilation of the left and right hepatic ducts and a common duct stricture (Figure 3A). The intrahepatic ducts appeared irregular and had focal areas of dilation. A 10 FR 7 cm biliary stent was placed with good drainage of bile and contrast. Cytologic specimens of the stricture were benign.

Liver biopsy demonstrated biliary-type cirrhosis with cholestasis and bile ductular proliferation. Based upon cholangiography and histological findings, we diagnosed type ⅣB choledochal cyst and biliary cirrhosis. Biliary stent exchanges were performed over the following year with gradual improvement in LAEs. ERCP performed one year after our evaluation revealed diffusely irregular intrahepatic and extrahepatic bile ducts and total resolution of the cystic dilation and common duct stricture (Figure 3B). Her bilirubin was 0.6 mg/dL, ALK 220 U/L, ALT 36 U/L, and AST 38 U/L. Liver biopsy showed only focal cholestasis, mild portal inflammation,

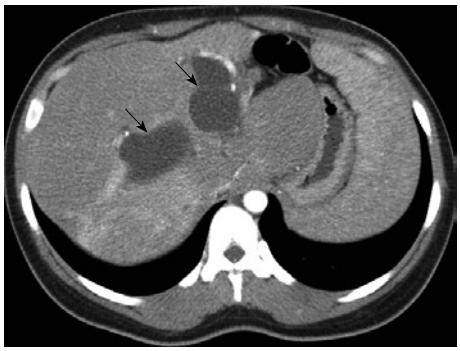

Figure 1 CT scan illustrating saccular dilations (arrows) of right and left hepatic ducts.

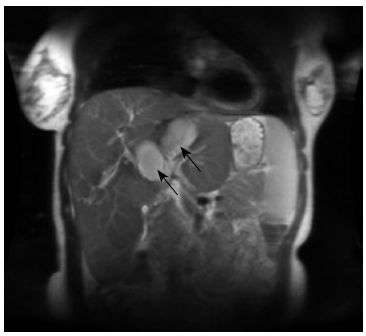

Figure 2 MRCP demonstrating saccular dilation (arrows) of the right and left hepatic ducts.

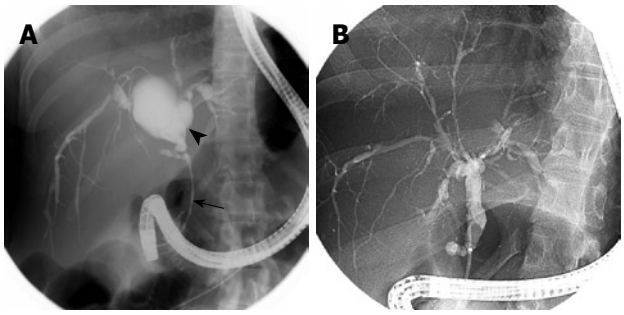

Figure 3 ERCP. A: Initial cholangiogram showing dilated extrahepatic ducts consistent with diagnosis of type IV choledochal cysts (arrowhead), and 7 cm common duct stricture (arrow); B: Final balloon occlusion cholangiogram performed one year after stenting showing resolution of the common duct stricture and cystic biliary dilation. The intrahepatic ducts are diffusely irregular.

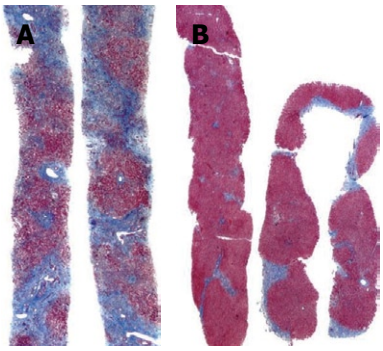

Figure 4 Liver biopsy. A: Pretreatment Trichome stain showed cirrhosis; B: Trichrome stain one year later following biliary stenting showed marked improvement in degree of fibrosis.

and irregular portal and bridging fibrosis. There was a marked improvement in the degree of fibrosis when compared to her initial liver biopsy (Figure 4), and there was no longer evidence of cirrhosis.

DISCUSSION

We present a patient with an unusual presentation of PSC, with imaging and histological findings which initially led to a diagnosis of a type ⅣB choledochal cyst and biliary cirrhosis. The diagnosis of PSC was made after her subsequent cholangiogram demonstrated pruning and stenosis of the intrahepatic ducts, with resolution of the cystic biliary dilation. PSC is a slow progressive disease, which ultimately leads to hepatic failure. Cholangiography is the gold standard for the diagnosis of PSC[2]. Orthotopic liver transplantation may be used for patients with PSC with end stage liver disease[3].

Hepatic fibrosis is triggered by recurrent liver injury, which results in the activation of perivascular stellate cells and other myofibroblasts[4]. This process may be reversible in its early stages, and there are reports of regression of liver fibrosis after biliary drainage in patients with chronic pancreatitis[5]. However, it is unusual to have significant improvement in hepatic fibrosis after years of liver injury. In our patient, pre- and post-treatment liver biopsies documented a regression in hepatic fibrosis. It is our belief that the histologic improvement in our patient can be attributed to relief of mechanical obstruction by stenting and drainage of the common bile duct. We acknowledge the possibility of liver sampling error; however, the overall improvement in her clinical picture supports a cause and effect relationship between biliary stricture therapy and regression of fibrosis.

Abstract

Gastrointestinal stromal tumors (GISTs) are rare neoplasms (1%) of the gastrointestinal tract and to our knowledge only rare cases of synchronous presentation of gastric carcinomas and GISTs are reported in the literature. A 72-year-old female with a simultaneous presentation of gastric adenocarcinoma and GIST is presented. Moreover, due to polymyalgia rheumatica the patient received corticosteroids as treatment for the last 3 years. The concomitant occurrence of these neoplasms may involve common carcinogenic factors and there could be an association with polymyalgia rheumatica either as a paraneoplastic presentation or due to its treatment with corticosteroids.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare neoplasms (1%) of the gastrointestinal tract[1]. It is believed that they originate from interstitial cells of Cajal (ICCs) or their precursors, which regulate gut motility. This hypothesis is based on observations that both GISTs and ICCs express the receptor tyrosine kinase KIT (c-KIT)[2]. Polymyalgia rheumatica is a clinical syndrome characterized by pain and stiffness in the neck, shoulders and hips, fatigue, weight loss and low-grade fever and rarely is presented as a paraneoplastic manifestation[3]. We report a case of synchronous occurrence of gastric adenocarcinoma and GIST in a 72-year-old female with polymyalgia rheumatica and provide a review of the literature. To the best of our knowledge this is the first case of a synchronous presentation of a gastric carcinoma and a GIST in a patient with polymyalgia rheumatica.

CASE REPORT

A 72-year-old woman was admitted to our department in September of 2007 because of epigastric pain lasting at least three months. Laboratory tests revealed elevation of the erythrocyte sedimentation rate (ESR) to 45 mm per hour and the presence of a microcytic, hypochromic anemia. All other studies were normal, except esophagogastroscopy which revealed a tumor in her stomach and a subtotal gastrectomy was performed. In the pathologic specimen of stomach, two different neoplasms were revealed: an adenocarcinoma and a GIST. The adenocarcinoma was a diffuse type according to Lauren classification (Figure 1). The gastrointestinal tumor of median diameter 1.8 cm was composed of spindle and epithelioid cells without atypia. Low mitotic activity (1/50 high powered field), low membranous CD117(KIT) positivity (Figure 2), median CD34 positivity, low positivity for smooth muscle actin (SMA) and scatter desmin positive cells were observed. Consequently, she received six cycles with the combination of cisplatin and fluorouracil (5-FU) and since April of 2008 has been disease free. From her past medical history it should

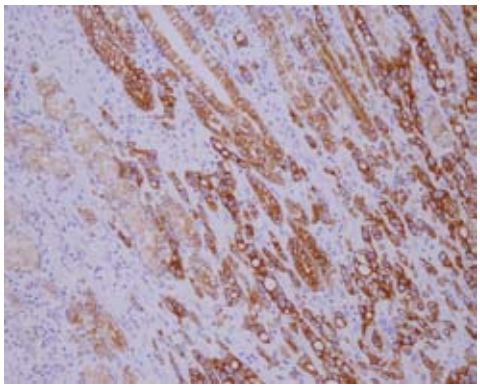

Figure 1 A diffuse type adenocarcinoma according to Lauren classification (x 20).

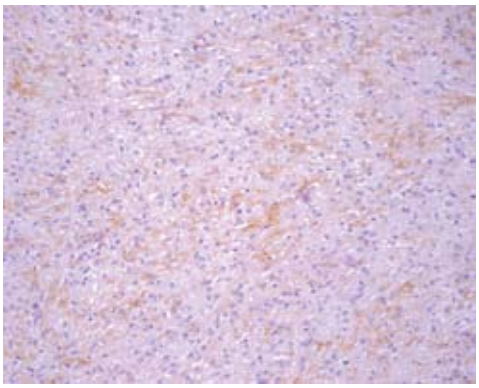

Figure 2 Spindle cells with low membranous positive CD117 immunostaining (x 20).

be noted that she has been suffering from polymyalgia rheumatica since October of 2004, and she has been receiving corticosteroids as treatment.

DISCUSSION

GISTs are rare neoplasms and the stomach (39%-60%), small bowel (30%-42%), colon-rectum (5%-10%) and esophagus (5%) are the most common locations[4]. The cell morphology is usually spindle shaped (70%), epithelioid (20%) or mixed. GISTs are immunohistochemically positive for KIT expression (90-95%) and often express BCL-2 (80%), CD34 (70%), SMA (35%), S-100 (10%) and desmin (5%)[5].

The malignancy potential of these neoplasms is highly variable and ranges from benign to malignant-aggressive tumors. Malignant proportion is about 20%-45% of all GISTs and they often lead to intra-abdominal metastases. On the contrary extra-abdominal metastases are very rare[6]. GIST size and cell proliferation rate are the most important prognostic factors. Differential diagnosis mainly includes leiomyomas and leiomyosarcomas.

They usually present as sporadic cancers but have also been reported as a familial occurrence. GISTs with extraadrenal paraganglioma and pulmonary chondroma occurred in patients with Carney's triad[7]. They are resistant to chemotherapeutic treatment, and radiotherapy and surgery is the initial treatment, while the administration of imatinib has become standard first-line therapy for patients with unresectable or metastatic GIST. Imatinib is an inhibitor of receptor tyrosine kinases including KIT, platelet-derived growth factor receptors (PDGFRs), colony stimulating factor 1 receptor (c-FMS), breakpoint cluster region and abl gene fusion protein (BCR-ABL) and specifically blocks the adenosine-5'-triphosphate (ATP) binding site[8].

Rare cases of concurrent presentation of gastric adenocarcinoma and GIST have been reported in the literature[9,10]. Some researchers claim that their presentation is based on coincidence; meanwhile, others support the hypothesis that some unknown carcinogens provoke the simultaneous proliferation and oncogenesis of epithelial and stromal cells. Cohen *et al*[11] reported that exposure to both acetylsalicylic acid and nitrosoguanidine causes synchronous development of both gastric cancer and leiomyosarcoma.

The relation between polymyalgia rheumatica and giant cell arteritis is well known[3]. There is debate as to whether there is an association with the occurrence of malignancy. Case reports present a possible association of polymyalgia rheumatica with breast cancer, colon cancer and non-Hodgkin lymphoma[12-14]. On the contrary, other researchers failed to reveal a paraneoplastic mechanism[15].

A hypothesis of a relationship between glucocorticoid and gastric cancer has also been reported[16]. Kodama *et al*[17] reported a possible linkage between glucocorticoid excess and a malignant transformation in the epithelial cells of the esophagus. It should also be noted that systemic glucocorticoid administration is associated with skin cancers and non-Hodgkin lymphoma[18].

To the best of our knowledge this is the first case of a synchronous presentation of a gastric carcinoma and a GIST in a patient with polymyalgia rheumatica. The concomitant occurrence of these neoplasms may involve common carcinogenic factors and could be associated with polymyalgia rheumatica either through a paraneoplastic mechanism or due to its treatment with corticosteroids.

Abstract

While pneumatosis cystoides intestinalis (PCI) is a rare disease entity associated with a wide variety of gastrointestinal and non-gastrointestinal disorders, PCI associated with massive intra- and retroperitoneal free air is extremely uncommon, and is difficult to diagnose differentially from perforated peritonitis. We present two cases of PCI associated with massive peritoneal free air and/or retroperitoneal air that mimicked perforated peritonitis. These cases highlight the clinical importance of PCI that mimics perforated peritonitis, which requires emergency surgery. Preoperative imaging modalities and diagnostic laparoscopy are useful to make an accurate diagnosis.

INTRODUCTION

Pneumatosis cystoides intestinalis (PCI) is a rare disease characterized by the presence of multiple gas-filled cysts in the subserosal or submucosal wall of the large and/or small intestine. Patients either stay asymptomatic or present with gastrointestinal symptoms, including nausea, vomiting, diarrhea and abdominal pain. While the exact pathogenesis of PCI is not well understood, two theories, mechanical and bacterial, have been proposed based on the known clinical associations[1]. PCI is commonly associated with chronic obstructive pulmonary disease, intestinal obstruction[2], ischemic bowel disease[3], necrotizing enterocolitis in premature infants[4], immunodeficiency such as AIDS[5], bacterial and/or viral infection[6,7] and drug therapy[8-13]. PCI may usually be found in a subserosal or submucosal location, and bowel distention and/or intraperitoneal free air can appear when the PCI is sufficiently extensive. However, PCI showing massive intraperitoneal free air and/or retroperitoneal air is extremely uncommon and only a limited number of cases have been documented[5,14]. We present two cases of PCI that mimicked perforated peritonitis, which required emergency surgery. Previously reported cases with PCI are reviewed and the significance of preoperative imaging is discussed.

CASE REPORT

Case 1 was a 58-year-old Japanese woman, who received corticosteroid therapy for rheumatoid arthritis in the department of internal medicine at our hospital. She complained of abdominal pain and distention and was referred to our department. The abdominal roentgenogram showed massive intraperitoneal free air (Figure 1A), dilatation of the intestine and circular collection of intestinal gas (Figure 1B). The abdominal computed tomography (CT) scan revealed ascites and

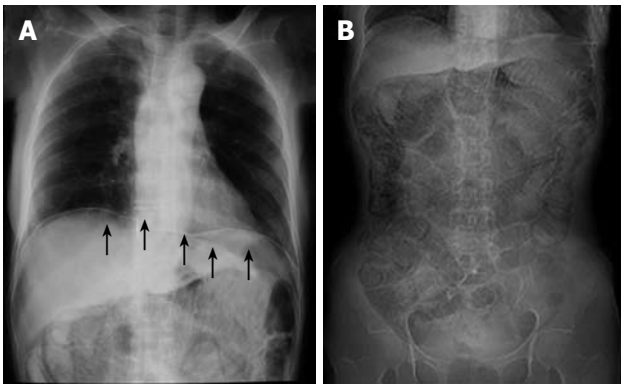

Figure 1 Abdominal roentgenogram. A: Massive intraperitoneal free air (arrows); B: dilatation of the intestine and circular collection of intestinal gas.

air collection within the bowel wall, which extended from the jejunum to the splenic flexure of the colon, which indicated that the air was present within the bowel wall (Figure 2). The laboratory data just before the operation indicated that white blood cell count was 14900/mm^3 and the serum C-reactive protein (CRP) level was 4.0 mg/dL. Although PCI was strongly suspected, the patient received corticosteroid therapy for the last 10 years, which may have masked the severe abdominal symptoms. The possibility of perforated peritonitis associated with unexplained ascites could not be eliminated, therefore emergency laparotomy was performed. At surgery, a large amount of free air exhausted when the abdomen was opened. Multiple gas-filled subserosal vesicles scattered throughout the surface of bowel wall and the mesentery were found, which were almost distributed entirely in the small intestine and the colon (data not shown). While there was a small amount of serous ascitic fluid in the abdominal cavity, the fluid was clear. Despite meticulous exploration of the abdomen, no evidence suggestive of hollow viscus perforation was found. The abdomen was irrigated with 1000 mL of saline solution. Culture of the ascitic fluid obtained at surgery was negative for any microorganism. Postoperatively, the patient received oxygen therapy for 4 d and the signs of PCI completely disappeared 5 d after surgery. The patient was discharged from the hospital 19 d after surgery. No recurrence of PCI has been found to date.

Case 2 was a 25-year-old man who had been receiving treatment for the colonic type of Crohn's disease for the last 12 years. While he had received repeated doses of infliximab 31 times from 2001 to 2005, administration was discontinued because of the appearance of colonic stenosis. He was then followed up by treatment with azathioprine and 5-aminosalicylic acid. After the patient underwent total colonofiberoscopy and barium enema, abdominal distention continued for 2 wk. The patient then complained of abdominal pain and was referred to our department in June 2006. The abdominal plain roentgenogram revealed massive intra-abdominal free air and retroperitoneal air (Figure 3). The abdominal CT scan revealed massive peritoneal free air throughout the abdomen and a small amount of ascites (Figure 4). The laboratory data just before the operation indicated that white blood cell count was 4600/mm^3 and serum CRP level was 1.8 mg/dL. To eliminate the possibility of perforated peritonitis and to confirm the diagnosis of PCI, diagnostic laparoscopy was performed. The laparoscopic findings revealed multiple glistering, translucent, gas-filled subserosal vesicles scattered throughout the surface of the bowel wall, the mesentery and omentum, which was compatible with PCI (data not shown). Although a small amount of ascitic fluid was present in the abdominal cavity, there was no finding suggestive of perforated peritonitis. Culture of the ascitic fluid obtained at surgery was negative for any microorganism. The postoperative course was uneventful and the elemental diet was started 8 d after surgery to facilitate the recovery. The patient was discharged from the hospital 19 d after diagnostic laparoscopy. The patient has remained healthy and no recurrence of PCI has been found to date.

DISCUSSION

PCI affects men more commonly than women, with a peak incidence at 30-50 years of age[15]. The sigmoid colon and its proximal side of the gastrointestinal tract has been shown to be the area that is predisposed to PCI, which is similar to diverticular disease[16]. The majority of patients are asymptomatic, therefore, the incidence of PCI may be underestimated. As a result of the high incidence of associated conditions, mortality rate of PCI in a collected series has been reported to be as high as 33%[17]. Furthermore, mortality rate of patients of PCI observed without surgery has been reported to be 18%, which suggests that emergency laparotomy is occasionally required.

The striking finding of preoperative imaging analysis in the present cases was the presence of massive intraperitoneal free air and/or retroperitoneal air that mimicked perforated diffuse peritonitis. Despite the fact that rupture of subserosal cysts of PCI results in pneumoperitoneum without peritonitis, accumulation of a large amount of intraperitoneal free air throughout the abdomen is extremely uncommon and only a limited number of cases have been documented previously[14,18,19]. Particularly, the presence of free retroperitoneal air as well as intraperitoneal air was detected in the plain abdominal roentgenogram and abdominal CT scan in case 2, which could also be signs strongly suggestive of gastrointestinal perforation. Although it is extremely rare, the presence of free retroperitoneal air caused by PCI has been reported previously[5,14]. Plain abdominal roentgenography is the most useful and easy way to ensure the diagnosis of PCI. Circular collection of gas in the bowel and mesentery is characteristic of PCI, and a review of 919 cases of PCI has shown positive abdominal roentgenography in two-thirds of patients[20]. Furthermore, recent reports have shown that abdominal CT and ultrasonography are useful methods for the

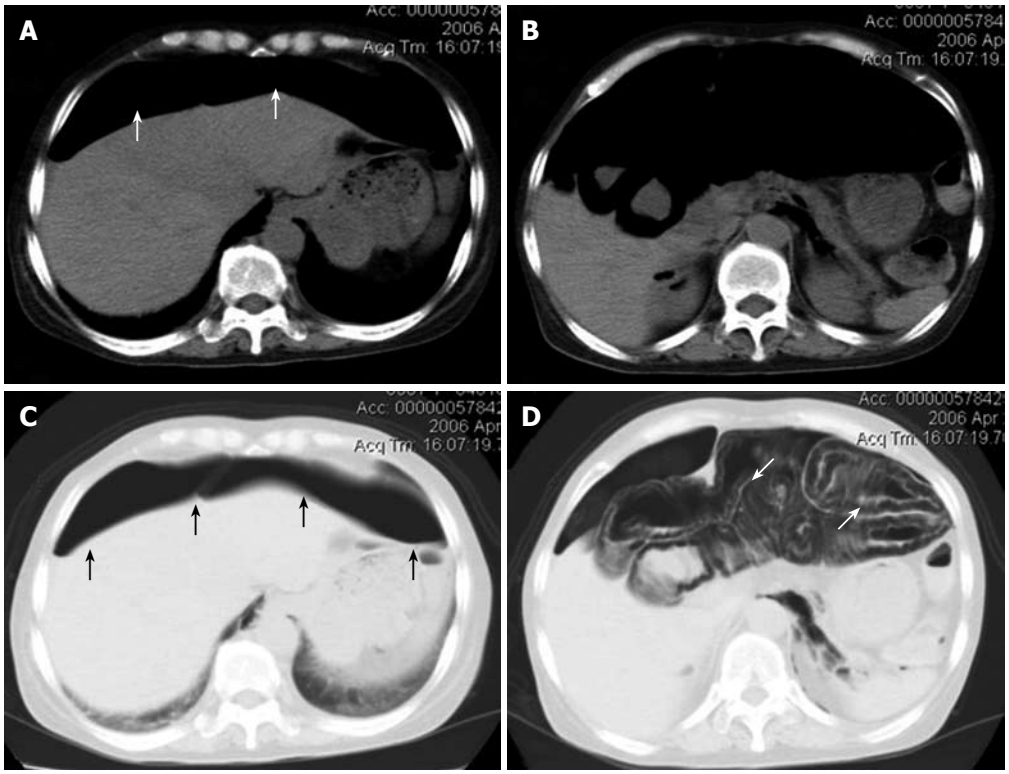

Figure 2 Abdominal CT scan images. Massive intraperitoneal free air extending throughout the abdominal cavity (white arrows, A and B), and a stranded appearance of air collection within the bowel wall detected in the lung window setting, which extended from the jejunum to the splenic flexure of the colon. This indicated that the air was present within the bowel wall (white arrows, C and D). Black arrows indicate massive intraperitoneal air (C).

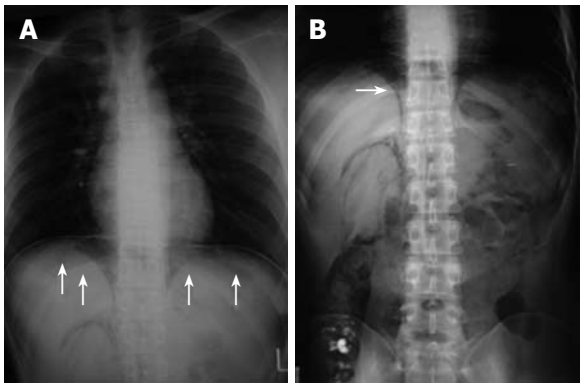

Figure 3 Roentgenogram of chest and abdomen. It revealed massive intra-abdominal free air (arrows, A) and pneunoretroperitoneum (arrow, B).

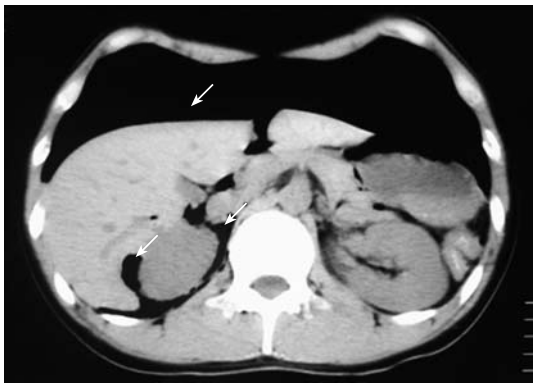

Figure 4 Abdominal CT scan, revealing massive peritoneal free air (arrows) that extended throughout the entire abdomen.

diagnosis of PCI[19,21,22]. A stranded appearance within the air collection of the bowel wall in the CT images is characteristic of PCI, which indicates that the air is present within the bowel wall[1]. In particular, lung window settings have been reported to be important in the detection of intramural air, and obviate the need for intraluminal contrast to outline the circumferential pattern of PCI[22]. This technical observation could have potential clinical significance in the evaluation of patients with suspected intestinal ischemia or gangrene, in whom the appearance of intramural air is an ominous prognostic sign. Although these CT images were useful for the diagnosis of PCI in the present cases, the possibility of gastrointestinal perforation could not be completely eliminated because of the massive intraperitoneal free air and ascites.

In the present cases, because no gastrointestinal perforation occurred, no particular surgical intervention was performed on the bowel associated with PCI. Oxygen therapy was performed in case 1 and the signs of PCI substantially disappeared 5 d after surgery. Although oxygen was first used by Forgacs *et al*[23] in 1973 for the treatment of PCI, the minimal concentration and the optimal duration of oxygen have not been established. It was initially suggested that arterial oxygen concentrations in excess of 300 mmHg were required, which could be accomplished by delivering 70%-75% humidified oxygen at 8 L/min *via* a mask. Wyatt[24] has suggested that aggressive oxygen therapy should be continued for at least 48 h after complete radiological disappearance of all cysts, and that recurrent cysts are to the result of inadequate initial treatment rather than actual recurrence. No recurrence of PCI was detected during 2 years follow-up in the present cases.

Laparoscopic examination was performed on case 2 to precisely determine the cause of massive

intraperitoneal free air, retroperitoneal air and non-infectious ascites. Although there was no gastrointestinal perforation in either of our cases, the cause of the ascites remains uncertain. Unexplained ascites associated with PCI has been reported previously[25]. The ascites disappeared as the PCI improved postoperatively in our cases, which suggests a possible link between PCI and ascites.

In summary, these cases highlight the clinical importance of PCI associated with massive intraperitoneal free air and/or retroperitoneal air that mimic perforated peritonitis, which required emergency surgery. Preoperative imaging modalities are useful to make precise diagnosis and further diagnostic laparoscopic examination is a useful adjunct to ensure the diagnosis of PCI.

Abstract

A 46-year-old Chinese woman presented with nausea, recurrent vomiting, and abdominal pain. Gastroduodenal endoscopic examination revealed an oval-shaped submucosal tumor at the prepyloric area on the posterior wall of the stomach. A degenerated gastrointestinal stromal tumor was suspected. Distal gastrectomy was performed and a histological diagnosis of heterotopic pancreas (HPs) was confirmed. The patient had an uneventful postoperative course and was discharged 7 d after operation. The patient remains healthy and symptom-free in the follow-up of 6 mo. This is a report of a case of gastric outlet obstruction resulting from pancreatic heterotopia in the gastric antrum in an adult woman.

INTRODUCTION

Heterotopic pancreas (HPs), a rare entity, is defined as the presence of pancreatic tissue outside its normal localization and without anatomic and vascular continuity with the pancreas itself. Other terms such as pancreatic rest, ectopic, aberrant, or accessory pancreas are also used [1]. It can occur anywhere in the gastrointestinal (GI) tract. The etiology of HP is unknown. In most cases, HP does not cause symptoms, but it can occasionally present as nausea, vomiting and abdominal pain. Peptic ulceration and upper GI bleeding are rare presentations, as are malignant degeneration, pancreatitis and pseudocysts[2]. HP tissue is found in persons of all ages and slightly more often in man[3]. HP has been reported as the cause of gastric outlet obstruction in infant[4] or child[5]. This is a report of a case of gastric outlet obstruction resulting from pancreatic heterotopias in the gastric antrum in an adult woman.

CASE REPORT

A 46-year-old woman was admitted to our hospital with a 5-year history of chronic epigastric pain and recurrent vomiting after meal. The patient had an unremarkable medical history. The physical examination was normal. She was afebrile with stable vital signs. The abdomen was soft and nontender with no palpable mass and normal bowel sounds. Stools tested negative for occult blood. Hematologic examination and blood chemical findings were normal as well.

Gastroscopy showed antritis and a submucosal lesion in the prepyloric posterior gastric wall (Figure 1). Proton pump inhibitors were started but did not relieve the symptoms. A computer tomography scan showed

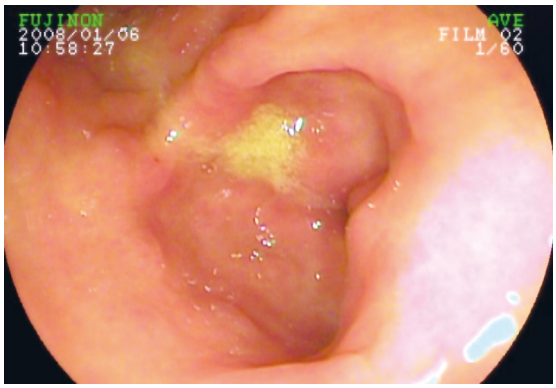

Figure 1 Submucosal lesion in the prepyloric posterior gastric wall.

Figure 2 CT scan shows thickness of posterior gastric wall, measuring 1 cm x 1.5 cm in the lower body of the stomach.

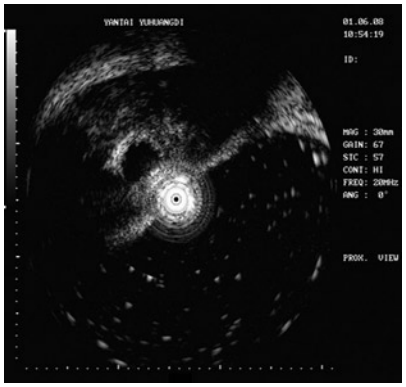

Figure 3 EUS reveals a lesion of 1.5 cm in diameter, with low and high complex echo-genicity, located within either the third or the fourth echo-layers.

thickness of posterior gastric wall, measuring 1 cm × 1.5 cm in the lower body of the stomach (Figure 2). Endoscopic ultrasonography revealed a lesion of 1.5 cm in diameter, with low and high complex echogenicity around this tissue, located within either the third or fourth echo-layers (Figure 3).

The results of biopsy were nondiagnostic, and disclosed only mild gastritis. Attempts of ploric dilation once proved unsuccessful, because the patient remained symptomatic: recurrent vomiting and epigastric pain despite helicobacter eradication and ploric dilation. A surgical exploration was proposed.

The lesion was removed with gastrectomy and gastrojejunostomy due to a presumed diagnosis of gastric outlet obstruction and submucosal tumor and because endoscopic biopsy was not diagnostic. The resected mass measured 1.5 cm × 2.0 cm × 1.0 cm with no ulceration or excessive induration. Some mucosal areas were remarkable for the presence of heterotopic pancreatic tissue with fully developed acini and ducts (Figure 4). The margins of the resection were negative, and the lymph nodes were benign.

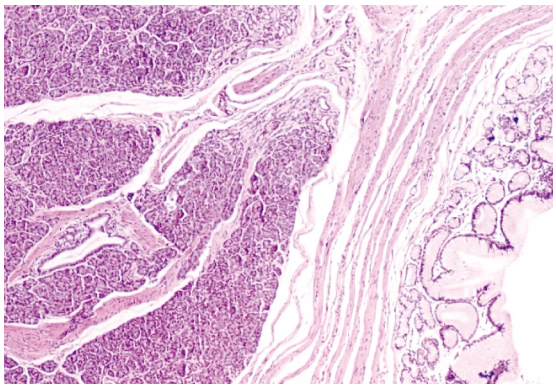

Figure 4 Heterotopic pancreatic tissue with fully developed acini and ducts. Islet is not found.

The postoperative course was uneventful. After the operation, vomiting episodes ceased, the patient gained 3 kg of body weight, and returned to full physical activity. The patient remained healthy and symptom-free in the follow-up of 6 mo.

DISCUSSION

The first case report of HP was made by Schultz in 1729. It is possible that early in fetal life, during rotation of the foregut and fusion of the dorsal and ventral parts of the pancreas, small parts are separated from it, and continue to develop in the wrong location[3]. Most often, HP is found in the stomach, duodenum and jejunum, but it may also be found anywhere in the digestive tract, intra-abdominally, in the mediastinum, and in the lung[1].

HP tissue is often found incidentally in patients operated on for other reasons or during autopsies. The condition is relatively uncommon, it has been found in 1%-2% of patients in autopsy studies and encountered in about 1 of 500 operations in the upper abdomen[6]. Macroscopically, HP consists of lobular white or yellow nodular tumors about 1-4 cm in diameter[1]. The mean size of HP was 1.52 cm in diameter (range 0.2-4 cm)[7]. A central mucosal depression, also described as volcanic of crater-like, is often recognized at endoscopy. The endoscopic appearance of gastric depends on the localization, HP may present with various symptoms. Nausea (27%) and vomiting, epigastric pain (27%) and ulceration (27%) were the most frequent clinical signs[7]. Heartburn and dyspepsia are also frequent for gastric HP, but often there are symptoms due to mechanical obstruction[1]. In the series of 34 patients with pancreatic heterotopia of Armstrong *et al*, 8 lesions were located in the stomach and 6 of those had produced symptoms[8]. There was a significant correlation between the size of the lesion and the presence of symptoms. Armstrong *et al* found that symptoms are related to the size of HP lesion. They postulated that size greater than 1.5 cm is more likely to be of clinical significance[8]. Other less

common symptoms were bleeding mimicking jejunal tumor[9], pancreatitis, and malignant transformation[10-12].

Macroscopically, the tissue often localized in the submucosa, but may also be found in the muscularis mucosa, subserously or in the serosa. In some cases, it streches through several or all of these layers[3]. Although imaging studies such as computer tomography (CT), radiographic contrast studies, and upper endoscopy are of assistance in the initial assessment of patients, the preoperative diagnosis of pancreatic heterotopia is often difficult.

Ormarsson *et al* reported that all patients examined with CT were inconclusive[1]. Cho *et al* also reported CT findings interpreted as HP in only two cases (17%)[13]. A diagnosis can occasionally be made on the basis of endoscopic biopsies. Histological examinations are inconclusive in about 50% of the cases because normal gastric mucosa covers the lesions[14]. Only in 4 out 10 patients did a biopsy lead to the correct diagnosis[1]. In most cases, however, the diagnosis is confirmed only by surgical resection.

Endoscopic ultrasonography (EUS) is widely used to evaluate submucosal lesions in the upper GI tract[15]. In a retrospective study of postresection histologic features compared with preoperative EUS findings in 10 patients with gastric HP, there was a close correlation between histology and EUS findings. EUS-guided aspiration has been reported to be helpful in diagnosis of HP[16]. If endoscopic resection is considered, EUS is also extremely useful for pre-excision assessment[17].

Most patients with HP are asymptomatic and require no treatment. The lesion is usually discovered incidentally. There was no correlation between the histological type of HP and the presence of symptoms[1,18]. Surgery is frequently needed to make a definitive diagnosis and to plan further treatment because the differential diagnosis of pancreatic rests includes leiomyoma, lymphoma, carcinoid tumors, and other malignancies[19].

If HP is discovered as an incidental finding, local excision is recommended. When HP results in symptoms, the lesion should be resected[20,21]. Increasingly, some are removed endoscopically with satisfactory postoperative results. Endoscopic excision can be considered in select cases depending on the size and location of the mass, especially for treating the benign lesions of HP.

ACKNOWLEDGMENTS

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

WJG publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidermiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialities, and thus eventually improving the clinical practice and healthcare for patients.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Adenosquamous carcinoma is rare, accounting for 3%-4% of all pancreatic carcinoma cases. These tumors are characterized by the presence of variable proportions of mucin-producing glandular elements and squamous components, the latter of which should account for at least 30% of the tumor tissue. Recently, several reports have described cases of adenosquamous carcinoma of the pancreas. However, as the number of patients who undergo resection at a single institute is limited, large studies describing the clinicopathological features, therapeutic management, and surgical outcome for adenosquamous carcinoma of the pancreas are lacking. We performed a literature review of English articles retrieved from Medline using the keywords 'pancreas' and 'adenosquamous carcinoma'. Additional articles were obtained from references within the papers identified by the Medline search. Our subsequent review of the literature revealed that optimal adjuvant chemotherapy and/or radiotherapy regimens for adenosquamous carcinoma of the pancreas have not been established, and that curative surgical resection offers the only chance for long-term survival. Unfortunately, the prognosis of the 39 patients who underwent pancreatic resection for adenosquamous carcinoma was very poor, with a 3-year overall survival rate of 14.0% and a median survival time of 6.8 mo. Since the postoperative prognosis of adenosquamous carcinoma of the pancreas is currently worse than that of pancreatic adenocarcinoma, new adjuvant chemotherapies and/or radiation techniques should be investigated as they may prove indispensible to the improvement of surgical outcomes.

INTRODUCTION

The majority of malignant tumors in the pancreas are adenocarcinomas. Adenosquamous carcinoma of the pancreas occurs less frequently with an incidence of 3%-4%[1]. These tumors are a malignant epithelial carcinoma of the pancreas and are characterized by the presence of variable proportions of both glandular and squamous components. At least 30% of the neoplasm should be comprised of the squamous component[1,2]. Recently, several reports have described cases of adenosquamous carcinoma of the pancreas[3-6]. However, as the number of patients who undergo resection at a single institute is limited, large studies describing the clinicopathological features, therapeutic management and surgical outcome for adenosquamous carcinoma of the pancreas are lacking.

To the best of our knowledge, our survey of the English literature reporting on adenosquamous carcinoma of the pancreas, which was found on Medline, revealed that only 39 intent-to-cure surgical resections had been performed and had clearly presented data (Table 1)[7-28]. The purpose of this study was to clarify the surgical outcome including survival rates after surgery, and to determine the prognostic factors of adenosquamous carcinoma of the pancreas by conducting a retrospective analysis of the 39 patients.

PATIENTS

Our survey of the literature from 1980 to the end of 2007 revealed that 45 patients underwent surgical resection for adenosquamous carcinoma of the pancreas[7-28].

Cx: Chemotherapy; RT: Radiotherapy; Rec site: Recurrence site; ND: Not described; PD: Pancreaticoduodenectomy; DP: Distal pancreatectomy; TP: Total pancreatectomy. [1]Surviving patients.

Of these, six patients were excluded due to a lack of clear data. The remaining 39 patients were analyzed in this study (Table 1) and included 25 men, 11 women, and three patients of unknown sex with a mean age of 59.0 years (range, 38-75 years). The prognosis outcome of each case was obtained from the published data. The clinicopathological data associated with the pancreatic adenosquamous carcinomas described in these case reports were evaluated, and included tumor location, type of operation, tumor size, whether chemotherapy and radiotherapy had been administered, recurrence sites, and survival times. All of the patients had undergone surgery involving an attempted curative resection. Survival rates were generated using the Kaplan-Meier method and compared using the log-rank test[29]. Values were expressed appropriately as the mean ± SD. Differences in proportions were evaluated by the Pearson chi-square test. A value of $P < 0.05$ was considered to be statistically significant.

DIAGNOSIS OF ADENOSQUAMOUS CARCINOMA OF THE PANCREAS

Table 1 lists 39 patients who had undergone surgical resection for adenosquamous carcinoma of the pancreas. Adenosquamous carcinomas have not been associated with any specific clinical syndromes[2,30]. Each of the 39 patients presented clinical symptoms such as abdominal pain, back pain, painless jaundice, anorexia, and/or body weight loss (data not shown). Accurate preoperative diagnosis of adenosquamous carcinoma of the pancreas is very difficult, because imaging studies have revealed no characteristic features that can facilitate the differentiation of this tumor type from ordinary invasive ductal carcinoma. One study reported that intense Gallium-67 citrate uptake was observed in adenosquamous carcinoma of the pancreas, indicating that Gallium-67 citrate scintigraphy might be useful in detecting these carcinomas[15]. However, more detailed

imaging data are required to improve the ability to diagnose this rare disease.

Adenosquamous carcinoma of the pancreas appears to be larger than ordinary pancreatic adenocarcinoma. The tumors in the 27 cases for which the relevant data was available had a mean size of 4.8 ± 1.8 cm (range, 2-10 cm; Table 1). Preoperative cytological or pathological diagnosis of adenosquamous carcinoma of the pancreas is reportedly rare[12,16-18,21,24,26,30]. However, the two malignant cellular components of adenosquamous carcinoma can be recognized in aspirated smears[17,18,24]. A careful search for glandular differentiation is warranted when the squamous component predominates, particularly if squamous carcinoma specimens only are obtained by biopsy or fine needle aspiration biopsy[12,16]. Adenosquamous carcinoma of the pancreas has no specific radiological findings or serum data, including tumor markers such as carcinoembryonic antigen, carbohydrate antigen 19-9, or squamous cell carcinoma antigen[12,22]. Physicians should try to remember to consider adenosquamous carcinoma of the pancreas in the differential diagnosis of ordinary pancreatic adenocarcinoma, especially if the patient has severe abdominal symptoms and/or a large tumor size[2,30]. Recently, preoperative and intraoperative cytological examinations have been diagnostically correct, however these findings did not alter treatment decisions or survival[30].

MANAGEMENT FOR RESECTABLE ADENOSQUAMOUS CARCINOMA OF THE PANCREAS

Since adenosquamous carcinomas are uncommon tumors with a poor prognosis, the outcomes associated with various therapeutic interventions are not well defined.

Table 1 lists the tumor location and operative method used in the 39 cases analyzed here. Three main operative methods were performed: pancreaticoduodenectomy (PD) including pylorus-preserving PD (PPPD) in 30 cases (76.9%); distal pancreatectomy (DP) in eight cases (20.5%); and total pancreatectomy (TP) in one case (2.6%). Tumors were located in the head alone in 28 cases (76.9%), in the head and body in two cases, and in the body and/or tail of the pancreas in nine cases (23.1%). Although adenosquamous carcinoma of the pancreas has different clinicopathological features to pancreatic adenocarcinoma, the treatment strategy of patients with adenosquamous carcinoma is dealt with in the same manner as patients with adenocarcinoma. Surgical treatment remains the only curative management option that is seriously considered for adenosquamous carcinoma of the pancreas.

To date, only eight patients have received adjuvant chemotherapy, indicating that postoperative adjuvant chemotherapy is not usually administered to patients with adenosquamous carcinoma of the pancreas (Table 1). Tanaka et al reported that the size of an unresectable adenosquamous carcinoma of the pancreas was reduced by neo-adjuvant chemotherapy consisting of a combination of interferon-α, tumor necrosis factor-α, and 5-fluorouracil[11]. However, the patient only survived 7 mo after surgery[11]. In this case, although neo-adjuvant chemotherapy might not have contributed to prolonging the patient's survival, the ability of the chemotherapy to reduce the size of the tumor from one that was unresectable to one that could be resected was confirmed. In the current study, the adjuvant chemotherapy group had a 2- or 3-year cumulative survival rate of 16.7% and a median survival period of 7 mo (Table 2). In comparison, the group who did not receive adjuvant chemotherapy had a 2-year cumulative survival rate of 9.2% and a median survival period of 5 mo ($P = 0.364$). Almost all of the patients in the adjuvant chemotherapy group were treated with a 5-fluorouracil-based regimen. Recently, adjuvant chemotherapy using new drug agents has been considered as the standard therapeutic option following resection for pancreatic adenocarcinoma, and several reports suggest that adjuvant chemotherapy with gemcitabine is responsible for a significant increase in patient survival[31-33]. Postoperative administration of gemcitabine also significantly delayed the development of recurrent disease after complete resection of pancreatic cancer compared with observation alone[34]. However, information regarding gemcitabine use in cases with adenosquamous carcinoma of the pancreas is not available as previous reports lack such data. Further investigations examining whether adjuvant chemotherapy using gemcitabine will improve surgical outcome in patients with adenosquamous carcinoma of the pancreas are therefore warranted.

There are no published prospective randomized controlled trials investigating radiotherapy treatment of pancreatic adenosquamous carcinoma following curative resection, only retrospective studies. Limitations of the present study include the errors and biases inherent in a small retrospective study design. Two retrospective studies investigating the benefit of radiotherapy following curative resection for pancreatic carcinoma showed no significant difference in the overall survival between patients who were or were not treated with radiotherapy[35,36]. In the current study, patients who had received intra- and/or postoperative radiotherapy had a 2- or 3-year cumulative survival rate of 20.0% and a median survival period of 13 mo (Table 2). By comparison, the non radiotherapy group had a 2-year cumulative survival rate of 9.0% and a median survival period of 6 mo ($P = 0.284$). There was no significant difference in survival between patients who did and did not receive radiotherapy.

PROGNOSIS AFTER PANCREATIC RESECTION

The overall 1-, 2-, and 3-year survival rates after pancreatic resection were 25.5%, 14.0%, and 14.0%, respectively (Figure 1). Table 1 shows operative mortality occurred in two patients during the early 1980s[7,8]. One patient died of myocardial infarction 2 d after undergoing PD and another died of numerous postoperative complications including electrolyte disturbance from massive abdominal fluid

Table 2 Clinical characteristics after surgical resection for adenosquamous carcinoma of the pancreas

Characteristics	No. of patients	Survival rate (%)			Median survival in months (range)	*P* value

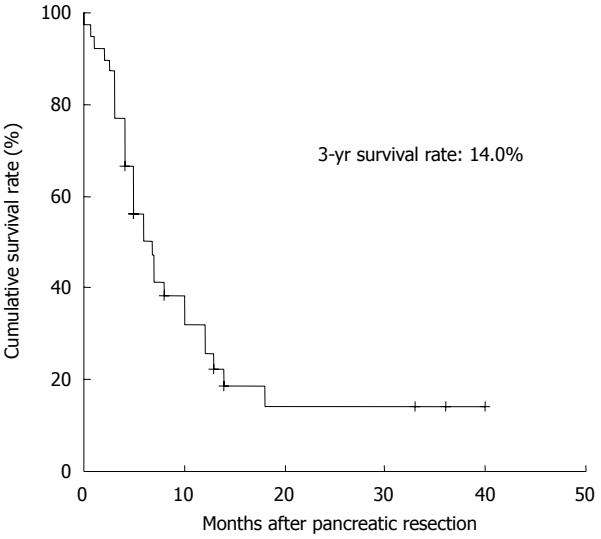

Figure 1 Survival after surgical resection for adenosquamous carcinoma of the pancreas (*n* = 39).

losses, acute renal failure and eventually congestive heart failure 20 d after undergoing PD[7,8]. Univariate analysis of the different prognostic factors predicted to contribute to patient prognosis showed that tumor location was the only unfavorable prognostic factor. Median survival of patients with a tumor located in the body and/or tail (4 mo) was significantly worse than those with tumors located in the head (8 mo) (Table 2). Prognostic differences based on tumor location may relate to tumor size, as the size of a distal pancreatic tumor (7.3 ± 1.8 cm) was significantly larger than that of a proximal pancreatic tumor (4.7 ± 1.9 cm, $P = 0.002$). Age, gender, type of operative procedure, and lymph node metastasis were not significant prognostic factors.

Recently, long-term survival after PD for pancreatic adenocarcinoma has improved, and the number of patients surviving for five or 10 years has increased[37-39]. On the other hand, the prognosis for the 39 patients with adenosquamous carcinoma in this study was poor, with a 3-year overall survival rate of only 14.0%, and includes two patients with hospital mortality. A patient surviving for five years post-resection has not been reported yet (Table 1). This suggests that adenosquamous carcinoma of the pancreas has greater malignant potential than adenocarcinoma of the pancreas. A previous report also found that squamous cell carcinomas grow at twice the speed of adenocarcinomas[31]. Therefore, once an adenocarcinoma has transformed into an adenosquamous carcinoma, the carcinoma may exhibit a higher degree of malignancy[40].

CONCLUSION

Even though curative resection for adenosquamous carcinoma of the pancreas was performed in the 39 patients, prognosis remained poor because systemic metastases in the liver and peritoneal dissemination were the major sites of recurrence (Table 1). In addition, tumor recurrence occurred during the early stages of the postoperative period in a large number of patients. Yamaue et al. reported that it might be preferable not to perform a pancreatic resection if a pancreatic tumor is diagnosed as an adenosquamous carcinoma[22]. Consensus of opinion regarding the surgical indication required for this type of tumor has not been reached yet. Elucidating

a surgical treatment strategy based on the appropriate surgical indication is essential for improving the surgical outcome of adenosquamous carcinoma of the pancreas.

The results of this current study indicate that tumor location may be an important factor in determining the appropriate surgical indication. Namely, surgical resection may be better suited for proximal pancreatic tumors than for distal tumors because the proximal location of tumors was the only significant favorable prognostic factor found in this study. Furthermore, exploration of new radiation techniques and chemotherapeutic regimens using new drug agents such as gemcitabine may be required because conventional chemotherapy and radiotherapy treatments did not contribute to survival benefit. The incorporation of novel 'molecularly targeted' agents into therapy will also be required to improve surgical outcome.

Although adenosquamous carcinoma of the pancreas has a poor prognosis even after curative resection, we must continue to endeavor to improve the surgical outcome of this tumor, because despite its rarity, it occurs worldwide. More data, including epidemiological and pathological findings, will be required to determine the appropriate surgical indication for this tumor.

Abstract

Eosinophilic gastroenteritis (EGE) in the adult is a distinctive pathologically-based disorder characterized by an eosinophil-predominant mucosal inflammatory process. Most often, the disorder is detected during endoscopic investigation for abdominal pain or diarrhea. Other causes of gastric and intestinal mucosal eosinophilia require exclusion, including parasitic infections and drug-induced causes. Occasionally, the muscle wall or serosal surface may be involved. EGE appears to be more readily recognized, in large part, due to an evolution in the imaging methods used to evaluate abdominal pain and diarrhea, in particular, endoscopic imaging and mucosal biopsies. Definition of EGE, however, may be difficult, as the normal ranges of eosinophil numbers in normal and abnormal gastric and intestinal mucosa are not well standardized. Also, the eosinophilic inflammatory process may be either patchy or diffuse and the detection of the eosinophilic infiltrates may vary depending on the method of biopsy fixation. Treatment has traditionally focused on resolution of symptoms, and, in some instances, eosinophil quantification in pre-treatment and post-treatment biopsies. Future evaluation and treatment of EGE may depend on precise serological biomarkers to aid in definition of the long-term natural history of the disorder and its response to pharmacological or biological forms of therapy.

INTRODUCTION

Eosinophilic gastroenteritis (EGE) is a distinct eosinophil-predominant inflammatory process in gastric or small intestinal mucosal biopsies. Although most published material has focused largely on the pediatric population, this manuscript focuses on the adult with EGE. Most often in adults, EGE is detected during endoscopic investigation for abdominal pain or diarrhea[1-4]. Although the endoscopic changes are non-specific (Figure 1), chronic or recurring symptoms are present and other causes of intestinal eosinophilia require exclusion (e.g. parasitic infections, medications)[1-4]. The mucosa of the stomach, intestine, or both may be involved most frequently. In one specific classification schema that included different forms of intestinal eosinophilic infiltration, involvement of the muscular layer or serosa was also described, but even in these, concomitant mucosal involvement was often present[5].

EGE has been considered an uncommon, even rare disorder but this may well depend on its definition as well as the method of detection. In a single clinical practice, only less than 1% of all upper endoscopic studies during an 8-year period showed changes that led to a diagnosis of EGE[6]. Biopsies are now commonly done during routine endoscopic evaluation, even if the mucosa is visually normal or if only non-specific changes are present. Finally, it is speculated that there may be some environmental factors (or allergen) in the diet or air that plays a critical role in the emergence of an eosinophil-predominant mucosal inflammatory process.

HISTOPATHOLOGICAL CRITERIA

Most often, the diagnosis of EGE is defined by histological evaluation of endoscopic biopsies. There are some potential diagnostic issues and pitfalls. First,

GE clinic

Figure 1 Endoscopic views of gastric antrum and gastric body showing non-specific erythematous and thickened mucosal folds with pre-pyloric pseudopolypoid change.

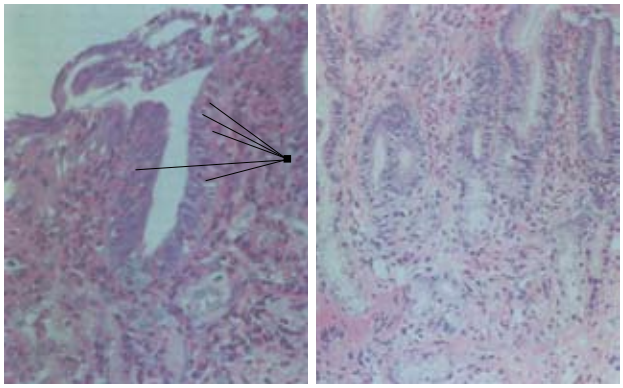

Figure 2 Photomicrographs show a formalin-fixed biopsy on the left with arrows delineating intraepithelial eosinophils along with numerous eosinophils in the lamina propria, while a Bouin's fixed biopsy on the right from an adjacent endoscopic biopsy shows a paucity of eosinophils..

pathologists, like endoscopists, have varying levels of expertise in mucosal biopsy interpretation. It is appreciated that there may be many "shades of grey" in the definition of EGE and the experience of the pathologist may determine disease recognition. To date, however, precise information on intra- and inter-observer error in the interpretation of biopsies in EGE is still needed. Second, eosinophils may normally be detected in the gastric and intestinal mucosa (as opposed to the normal esophagus), and only limited numbers of studies (mainly in children) have tried to quantify normal compared to abnormal numbers in health and different inflammatory disease states, e.g. ulcerative colitis[7,8]. Third, these studies are also limited, to some degree, by the inherent "patchy" nature of the eosinophilic inflammatory process in EGE since the numbers of eosinophils may differ in biopsies obtained from different sites. Finally, fixation methods may be critical in the definition of eosinophils in gastric and intestinal biopsies. For example, Bouin's solution (often used for gastric or intestinal biopsies), can result in "bleaching" of eosinophil granules making detection much more difficult. If EGE is suspected, routine formalin fixation has been shown to provide more optimal material for routine staining (Figure 2)[9].

CLINICAL FEATURES

Prior studies have suggested that EGE is a male-predominant clinical disorder[1]. Some believe that clinical features may reflect extent, location and depth of infiltration of this eosinophilic inflammatory process within the gastrointestinal tract[1,5]. Abdominal pain and diarrhea are common. Weight loss may occur, in part related to malabsorption. Iron deficiency associated with blood loss as well as protein-losing enteropathy may also be seen. If muscular layers are involved, obstruction or, even an acute abdomen has been recorded[1-4], while serosal involvement may be associated with evidence of ascites[5]. Peripheral blood eosinophilia has been recorded in up to 70%, but this is not specific for EGE and should lead to exclusion of other disorders, specifically parasitic infections[3]. In some with EGE, increased serum IgE levels may be seen, but this is also not specific. Endoscopic evaluation might permit definition of the extent of the inflammatory process in the upper gastrointestinal tract. In rare reports[10,11], celiac disease has been linked to EGE but as completely independent disorders.

Treatment is largely aimed at resolving symptoms. Medications used in EGE are largely based on empiric observation and experience. Because of the rarity of EGE, there are no controlled treatment trials available. Steroids have been used as a traditional form of therapy to reduce the inflammatory process[1-4], however, these may cause steroid-related effects, especially because of their recurring need over prolonged periods. Other remedies have been used but their effectiveness still requires definition. These include: proton pump inhibitors[5], mast cell stabilizers[12,13], ketotifen[9,14], leukotriene antagonists[15], octreotide[16] and surgical resection of involved intestinal segments[17]. This lengthening therapeutic list might be construed as a clear reflection of the limited forms of effective therapy that are currently available.

HYPEREOSINOPHILIC SYNDROMES

The hypereosinophilic syndromes (HES) represent a heterogeneous group of rare disorders that have been defined in the past by persistent blood eosinophilia for more than 6 mo with evidence of organ involvement. The cause is unknown. HES may include a broad

spectrum of disorders, including familial or genetically-based eosinophilia and more sinister neoplastic disorders, including eosinophilic leukemia[1,19]. About 25% of cases with HES, however, have eosinophilic infiltration in the gastrointestinal tract, and in some, this inflammatory process is reportedly localized only in gastric or intestinal mucosa.

The onset of HES is generally described between ages of 20 and 50 years with a male predominance[1]. Abdominal pain and diarrhea with malabsorption have been described. In comparison with those with disease localized in some other non-intestinal sites, involvement of the intestinal tract has been associated with a limited prognosis, lympho-proliferative disorders[20], and, in some, a fatal outcome[1]. Unfortunately, there may be little to distinguish EGE and HES, especially if the latter is early in the clinical course and localized to the gastric and intestinal mucosa alone. In some, steroids, immune-suppressants and even biological agents have been used[21]. Clearly, long-term clinical studies are needed to define and elucidate the natural history of EGE, a relatively unique inflammatory process, and to determine if there is a potential HES risk.

Abstract

The spectrum of drug-induced liver injury (DILI) is both diverse and complex. The first step in diagnosis is a suspicion of DILI based on careful consideration of recent comprehensive reports on the disease. There are some situations in which the suspicion of DILI is particularly strong. Exclusion of other possible etiologies according to the pattern of liver injury is essential for the diagnosis. In patients with suspected DILI, diagnostic scales, such as the Councils for International Organizations of Medical Sciences/ Roussel Uclaf Causality Assessment Method (CIOMS/ RUCAM) scale, may be helpful for the final diagnosis. Early management of DILI involves prompt withdrawal of the drug suspected of being responsible, according to serum levels of alanine aminotransferase (ALT), alkaline phosphatase (ALP), and total bilirubin (T-Bil). However, as DILI patients may show resolution of liver injury without discontinuation of the drug, it should be carefully evaluated whether the suspected drug should be discontinued immediately with adequate consideration of the importance of the medication.

INTRODUCTION

Drug-induced liver injury (DILI) is a common liver disease which generally occurs between 5 and 90 d after drug ingestion. The clinical picture of the disease is variable, ranging from transient mild elevation of liver enzymes to fulminant liver failure leading to death. DILI has been reported to be a cause of fulminant liver failure in 13%-30% of cases[1-3]. DILI is divided into three types: hepatocellular, cholestatic, and mixed according to the Councils for International Organizations of Medical Sciences (CIOMS)[4,5]. Hepatocellular type is defined by alanine aminotransferase (ALT) > 2 ULN (upper limits of normal) or R $\geqslant$ 5, where R is the ratio of serum activity of ALT/serum activity of alkaline phosphatase (ALP), both of which are expressed as multiples of the ULN. Liver injury is likely to be more severe in hepatocellular type than in cholestatic/mixed type, and patients with elevated bilirubin levels in hepatocellular liver injury indicating serious liver injury with fatalities, are found at a rate of 0.7 to 1.3/100 000 individuals receiving a given drug[2]. Cholestatic type is defined by ALP > 2 ULN or R $\leqslant$ 2 and mixed type is defined by ALT > 2 ULN and 2 < R < 5. Patients with cholestatic/ mixed type are likely to develop chronic disease more frequently than those with hepatocellular type[6]. For most drugs, the risk of liver injury is estimated to be 1-10/100 000 persons exposed. A recent report indicated that DILI occurs in 1/100 patients hospitalized in internal medicine departments[7]. Thus, DILI is not a rare condition and sometimes leads to serious disease. Rapid and accurate diagnosis of DILI is important in daily practice. However, diagnosis of DILI is not easy and is mainly based on circumstantial evidence. As there is no gold standard for diagnosis, it is essential to exclude other possible etiologies for accurate diagnosis. A number of scoring systems have been proposed,

but even experts may make different judgments using these systems[8]. This review summarizes recent trends regarding DILI and proposes practical guidelines for its diagnosis and early management.

RECENT REPORTS ON DILI

A recent report on DILI based on the database of the World Health Organization (WHO) indicated that the number of cases of DILI has been increasing since the 1990s[9]. The WHO began monitoring adverse drug reactions in 1968, and there are more than 3 million reports on their database (http://www.who-umc.org). This large database is useful for obtaining information on previous reports regarding adverse reactions to drugs. Acetaminophen, drugs against human immunodeficiency virus (HIV), troglitazone, anti-convulsants (such as valproate), analgesics, antibiotics, and anti-cancer drugs are common causative agents of DILI with fatalities (Table 1)[9]. Therefore, particular attention should be paid to patients taking one or more of these drugs who show liver injury. Analysis of 461 cases in Spain over a 10-year period indicated that amoxicillin/clavulanate was the most common drug involved in DILI (59/461 cases, 12.8%)[10]. Moreover, in addition to amoxicillin/clavulanate, they reported that bentazepam, atorvastatin, and captopril were frequent causative drugs leading to chronic liver damage[6]. In a retrospective study in Italy, hydroxymethylglutaryl-CoA reductase inhibitors were the most frequent causative drugs among 1069 cases of DILI (4.5% of cases of adverse drug reactions)[11]. Other studies also showed acetaminophen, anti-retroviral therapy, antibiotics, lipid-lowering drugs, and anti-convulsants to be responsible for DILI[12-18]. In recent analyses in Asia, traditional alternative medicines were reported to be the most common causes of DILI, in contrast to those in Western countries[19]. Table 2 summarizes the drugs suspected to be responsible for DILI and the types of liver injury reported in the literature from various regions[3,6,7,10,12,17-19]. In general, antibiotics, non-steroidal anti-inflammatory drugs, and anti-convulsants are frequent causative drugs of DILI. Importantly, although not shown in Table 2, two or more drugs were suspected to be responsible for DILI in about 10% of cases[10,13]. Furthermore, it is notable that the incidences of DILI caused by herbal remedies or traditional medicines have been increasing over the last decade. The causative drugs for DILI are therefore becoming more diverse and complex. The first and most important step in managing cases of suspected DILI is to gain a detailed understanding of the causative drugs. In the United States of America, the Food and Drug Administration (FDA) records drug toxicity (http://www.fda.gov/medwatch), and the Drug Induced Liver Injury Network was established in 2003 to collect data on DILI in a prospective manner[1]. A similar network is also in place in Spain[6]. A worldwide network which collects all the reports on adverse drug reactions is needed to provide comprehensive information on DILI, which would facilitate accurate diagnosis and early management.

Table 1 Common causative agents of drug-induced liver injury with fatalities fatalities

Drug	*n* (%)
Acetaminophen	305 (16.9)
Anti-HIV[1]	
Stavudine, didanosine, nevirapine, zidovudine	303 (16.8)
Troglitazone	211 (11.7)
Anticonvulsants (valproate, phenytoin)	187 (10.3)
Anti-cancer	223 (12.3)
Flutamide	59 (3.3)

PRACTICAL DIAGNOSIS OF DILI

Situations in which DILI should be suspected

In daily clinical practice, DILI can always be a cause of liver injury in patients taking medications. However, there are some situations in which DILI should be particularly suspected and are as follows[20]: (1) Start of a new drug in the past 3 mo, (2) Presence of rash or eosinophilia, (3) Mixed type (hepatocellular and cholestatic) liver injury, (4) Cholestasis with normal hepatobiliary imaging and (5) Acute or chronic hepatitis without autoantibodies or hypergammaglobulinemia. Although DILI cannot be excluded if patients with any type of liver injury do not meet these criteria, their consideration may lead to early diagnosis of DILI.

Risk factors for DILI

Recognition of risk factors provides clues for the diagnosis of DILI, and some scoring systems include these elements. Host factors which may be associated with DILI are listed in Table 3. Age, gender, pregnancy, and alcohol intake are estimated as risk factors for patients, and liver injury with these risk factors is thought to be related to acute cytolytic hepatitis[21]. In a recent analysis, age was reported to be the most important determinant in biochemical expression of amoxicillin/clavulanate hepatotoxicity, probably because of the slower drug elimination related to advanced age[22]. In contrast, adverse events associated with valproate or erythromycin are more common in childhood[23]. On the other hand, a retrospective study indicated that most patients with drug-induced acute liver failure undergoing

liver transplantation were female[24]. Thus, age and female gender may affect the clinical course of DILI. As immune responses to drugs and altered drug metabolism are possible mechanisms in DILI pathogenesis, different immune status or drug metabolism according to age or gender may lead to differences in the occurrence of DILI[25,26]. However, Shapiro and Lewis reported that factors such as age (over 55 years old), gender (female dominant), or the history of alcohol intake were not specific for DILI based on the evaluation of recent DILI cases using the CIOMS/RUCAM scale[27]. Therefore, risk factors for DILI must be analyzed carefully in future. Moreover, genetic factors for drug metabolism, such as polymorphisms of cytochrome P (CYP) 450 or deficiency of N-acetyltransferase, have been reported to contribute to DILI[28,29]. Interestingly, a recent report suggested an association between the daily dose of drug ingested and idiosyncratic DILI, and the number of cases and poor outcome of DILI were reported to increase in a dose-dependent manner[30]. Furthermore, underlying liver disease or systemic viral infection may increase susceptibility to DILI. In particular, DILI caused by anti-tuberculous therapy is known to be increased in patients with hepatitis B or C virus infection[31]. Anti-retroviral therapy in HIV infection was reported to induce severe hepatitis and lead to acute liver failure[32]. The mechanisms by which HIV infection predisposes patients to severe DILI are unknown, but activation or sensitization of the innate immune system by HIV infection may be involved. Moreover, hepatic steatosis in nonalcoholic fatty liver disease (NAFLD) increases the risk of DILI[33]. Mitochondrial dysfunction or the existence of oxidative stress seen in NAFLD may affect the occurrence and severity of DILI.

Clinical diagnosis of DILI

There are few clinical features associated specifically with DILI. Although fever, rash, arthralgia, and eosinophilia are symptoms and signs of an immunoallergic reaction to a drug, they can also be seen without taking any drugs and the frequencies in patients with DILI are not high. General fatigue, appetite loss, and splenomegaly, often seen in patients with viral hepatitis that may be helpful for differential diagnosis at initial presentation, are also

not common in non-fulminant DILI. As there are many causes of liver injury, it is essential to exclude other etiologies in the diagnosis of DILI. Other etiologies include viral hepatitis (hepatitis A virus, hepatitis B virus, hepatitis C virus, hepatitis E virus, EB virus, cytomegalovirus, human herpes virus-6, parvovirus B19, *etc*.), biliary diseases such as cholelithiasis, alcohol abuse, NAFLD, autoimmune liver diseases, and hereditary diseases, such as hemochromatosis, α_1-antitrypsin deficiency, and Wilson's disease. Among these possible causes of liver injury, diagnosis of acute onset autoimmune hepatitis (AIH) is sometimes difficult, because scores using the International Autoimmune Hepatitis Group scoring system for the diagnosis of AIH, serum IgG levels or antinuclear antibody titers are often low in acute AIH. Histological examination of the liver may be useful for the differential diagnosis. Taken together, a low threshold of suspicion, thorough history including recent and past drug exposure, exclusion of other possible etiologies, or occupational hazards with exposure to potential toxins, are important in making an accurate diagnosis of DILI[20,34]. Some clinical scales are available for the diagnosis of DILI. However, it is impractical to apply these diagnostic scales for each patient with liver injury taking medications. In addition, most patients take more than one drug, and identification of a single drug as a causative agent is difficult, even in cases where DILI is strongly suspected, using these scales. Moreover, patients with underlying liver or systemic diseases which also affect liver biochemical tests, complicate the diagnosis of DILI.

Clinical scales available for diagnosis of DILI (Table 3)

As there are no standard criteria for diagnosis of DILI, various clinical scales have been developed. The Naranjo Adverse Drug Reactions Probability Scale (NADRPS) was proposed in 1981 for assessment of adverse drug reactions[35]. NADRPS has been widely used for DILI due to its simplicity and wide applicability, despite not being developed specifically for diagnosis of DILI. Although simplicity is important for practical use, NADRPS has been reported to have low sensitivity and negative predictive values, and to exhibit a limited capability to distinguish among adjacent categories of probability such as "possible" and "probable"[36]. In the early 1990s, the diagnostic scale called the Council for International Organizations of Medical Sciences (CIOMS) or Roussel Uclaf Causality Assessment Method (RUCAM), was proposed at the International Consensus Meeting by Danan and Benichou[4]. It was also called the French method, because Danan had previously reported the diagnostic criteria for acute cytolytic hepatitis in France[21]. CIOMS/RUCAM is applied for classification of the pattern of liver injury, hepatocellular type, cholestatic type, or mixed type, as described above. This scale is determined by a score based on 7 criteria, including temporal relationship, clinical course (response after withdrawal of drug), risk factors, concomitant drugs, exclusion of other non-drug

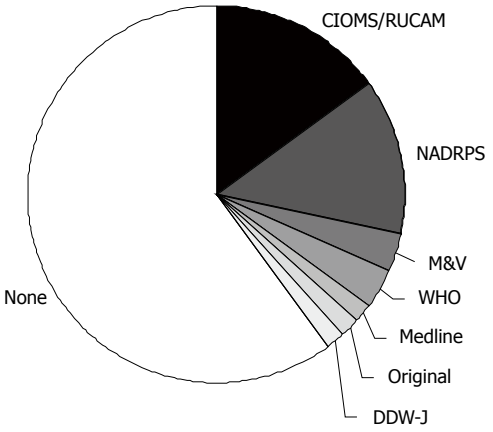

Figure 1 Percentages of methods for causality assessment utilized for diagnosis of DILI, reported during the last decade.

etiologies, likelihood of a reaction based on package labeling, and rechallenge. It has been widely used as a standardized scale with high reliability, reproducibility, and specificity. More recently, Maria and Victorino (M&V) reported a scale called the clinical diagnostic scale (CDS), which simplified the CIOMS/RUCAM using only 5 criteria[37]. It has often been noted that false negative judgments are often made in cholestatic DILI cases because the pattern of liver injury is not taken into consideration in the M&V scale[38]. Moreover, DILI cases with long latency periods and evolution to chronic disease after withdrawal (especially cholestatic type) were poorly diagnosed, and there was no agreement in cases of fulminant hepatitis[39]. The M&V scale emphasizes the immunoallergic reactions, such as extrahepatic manifestations[40]. In Japan, a diagnostic scale was proposed by reference to the CIOMS/RUCAM scale in Digestive Disease Week Japan (DDW-J) 2004, and includes a drug-lymphocyte stimulation test (DLST) as a diagnostic factor[41]. The DDW-J scale was reported to have higher sensitivity than the CIOMS/RUCAM (93.8% *vs* 77.8%, respectively) in the analysis of 127 Japanese patients. However, this scale must be evaluated in non-Japanese patients to verify its universal usefulness.

A review of 61 case reports of DILI in the PubMed database over the last decade regarding diagnostic methods used[42-102] (Figure 1, Table 4) revealed that the CIOMS/RUCAM was the most widely utilized for diagnosis of DILI (10/61 case reports, 16.4%), followed by NADRPS (8/61, 13.1%), M&V (CDS) (2/61, 3.3%), WHO database (2/61, 3.3%), Medline (1/61, 1.6%), Original (1/61, 1.6%), DDW-J (1/61, 1.6%), and none (38/61, 62.3%). The case reports using the WHO database[88,98] or Medline[77] based DILI diagnosis on reports of the suspected drug as a causative drug in the database in addition to circumstantial evidence (history of drug intake, onset of liver injury, and exclusion of other causes). In the case of original criteria[73], DILI diagnosis was made using the following criteria: occurrence of hepatic damage directly related to drug administration, exclusion of other causes of hepatitis, recovery of hepatic function tests after cessation of drug therapy, and liver histology. Although the CIOMS/RUCAM scale is the most widely used and thus currently seems to be the standard method for diagnosis of DILI, it should be emphasized that many physicians still make a diagnosis of DILI based on their own judgment probably because of the complexity of the scoring systems available.

Additional tests to confirm the diagnosis of DILI and identify a single causative drug

As mentioned above, patients are often taking several drugs only one of which is responsible for liver injury in most cases. However, even when clinical scales for DILI strongly suggest a given drug as a cause of liver injury, identification of the single causative drug cannot be established with these scales. Rechallenge with a potential causative drug to establish a diagnosis is one of the diagnostic methods in the CIOMS/RUCAM criteria[4,21]; however, it is not advised and may be contraindicated from an ethical viewpoint. As an alternative way to establish the diagnosis of DILI and the identification of a single causative drug, some additional tests using samples from the patient, such as peripheral blood, could be helpful. One of the most commonly used methods is DLST, which is performed as follows[103]: Lymphocytes collected from the heparinized peripheral blood of patients are incubated with various dilutions of the suspected causative drug. Lymphocyte proliferative response is evaluated by monitoring ^{3}H-thymidine uptake. DLST is widely used in Japan and is incorporated into the diagnostic criteria in Japan (DDW-J scale). However, sensitivity is around 50% and the lymphocyte response to the suspected causative drug may not necessarily be related to liver injury. Another test using peripheral blood of patients is the leukocyte migration test (LMT), which has been reported to be more useful than DLST[104]. This test involves assaying the chemotaxis of granulocytes from one chamber to another chamber containing mononuclear cells, due to the chemotactic factor produced by the mononuclear cells after incubation with the suspected drug solution. Furthermore, Murata *et al*[105] reported a cytokine production test as a method to analyze the immunological pathogenesis of DILI, which also showed high sensitivity for diagnosis. In this analysis, HepG2 cells, which reserve the activities of metabolic enzyme such as CYT450, are first incubated with the suspected drug diluents, and the mixtures of the extract and culture medium of HepG2 are then incubated with peripheral blood lymphocytes isolated from the patients. Intracytoplasmic cytokine profiles of the lymphocytes, such as interferon-γ, tumor necrosis factor-α, or interleukin-2, are finally evaluated by flow cytometry. Although these tests are useful methods for the diagnosis or identification of a single causative drug, they are not simple to perform, and may not be feasible for routine examination. However, if a single causative drug cannot be determined, patients may have to avoid several drugs, mostly non-hepatotoxic drugs, for the

rest of their lives, seriously limiting treatment of other diseases. Therefore, these tests should be considered in selected cases.

Role of histological examination of the liver for the diagnosis of DILI

The features of liver histology in drug-induced hepatitis

are as follows: (1) demarcated perivenular (acinar zone 3) necrosis; (2) minimal hepatitis with canalicular cholestasis; (3) poorly developed portal inflammatory reaction; (4) abundant neutrophils; (5) abundant eosinophils; and (6) epithelioid-cell granulomas[106]. However, liver histology in DILI may not be diagnostic in most cases. Moreover, centrilobular necrosis with minimal portal inflammation is relatively characteristic of DILI, but similar histological features can be seen in acute-onset autoimmune hepatitis. Plasma cell infiltration in portal tracts, which is often prominent in autoimmune hepatitis, may be helpful for differential diagnosis in such cases. The major role of histological examination is therefore to exclude other possible causes of liver injury rather than to make a final diagnosis of DILI. Therefore, it is not recommended as a routine or early examination for the diagnosis of DILI.

EARLY MANAGEMENT FOR DILI

As described above, DILI has a wide spectrum of manifestations, ranging from asymptomatic mild biochemical abnormalities to severe hepatitis with jaundice. In most cases of DILI, liver injury would be expected to improve following discontinuation of the drug suspected to be responsible. On the other hand, some DILI patients may even show resolution of liver injury without discontinuation of the drug. Therefore, it should be carefully evaluated whether the suspected drug should be discontinued with adequate consideration of the importance of the medication. However, once liver injury progresses to acute liver failure, this has a high fatality rate without liver transplantation[107]. Although there are no definitive criteria for cessation of the suspected causative drug, some textbooks suggest that ALT less than 5 × ULN and no symptoms allow continuation of the suspected drug with close observation, whereas ALT of more than 8 × ULN indicates the need to discontinue the suspected drug[108,109]. Another textbook suggests that the suspected drug should be stopped only when abnormalities in serum bilirubin, albumin, or prothrombin time-international normalized ratio (PT-INR) are found in addition to elevated serum ALT[20]. Zimmerman reported that elevation of transaminase activities in combination with jaundice suggests serious liver injury with fatalities. These findings were discussed at the National Institutes of Health in Bethesda, and are recognized as Hy's rule for monitoring DILI, which states that elevation of liver enzymes (AST or ALT more than 3 × ULN or ALP more than 1.5 × ULN) in combination with elevated bilirubin (more than 3 × ULN) at any time after starting a new drug may imply serious liver injury and the suspected drug should be stopped[110]. Two recent studies have shown that hepatocellular liver injury with jaundice is sometimes fatal even if the suspected drug is stopped[9,10]. On the other hand, a recent study showed that cases fulfilling Hy's rule did not always lead to death from DILI[18]. As many drugs can induce asymptomatic elevation of liver enzyme levels without severe hepatotoxicity, mild elevations in transaminases do not always require withdrawal of the causative drug. Based on these observations, the FDA recently proposed draft guidelines (http://www.fda.gov/cder/guidance/7507dft.htm) in which ALT greater than 8 × ULN, ALT greater than 5 × ULN for two weeks, ALT greater than 3 × ULN in association with serum bilirubin greater than 2 × ULN, more than 1.5 × PT-INR, or symptoms of liver injury should be used to predict severe hepatotoxicity and recommend discontinuing the drug[2]. Hepatocellular liver injury with severe jaundice should be treated carefully, and requires prompt referral to a center with hepatologists. As mentioned above, severe liver injury and fatality occur in cases of hepatocellular injury with jaundice. On the other hand, cholestatic DILI cases could be observed with continuation of the suspected causative drug, except if symptoms related to liver injury occur, such as jaundice, elevation of serum bilirubin (more than 3 × ULN), or prolongation of PT-INR (more than 1.5 × ULN). There have been no reports of beneficial therapies except the use of N-acetylcysteine for acetaminophen hepatotoxicity. Corticosteroid therapy may be used in DILI cases with evident hypersensitivity, but it does not have proven benefits[107]. Management of DILI involves prompt withdrawal of the drug suspected to be responsible. A positive de-challenge is a 50% decrease in serum ALT within 8 d of discontinuation of the suspected drug in the hepatocellular type, which is also included in the CIOMS/RUCAM criteria[5,21]. On the other hand, improvement of biliary enzymes after cessation of the suspected drug usually requires a longer period in cholestatic type. However, the time course after cessation of the suspected drug does not always help in early diagnosis and management of DILI, because some patients should be evaluated promptly and managed as suspected DILI on first presentation.

PROPOSAL OF PRACTICAL GUIDELINES FOR DIAGNOSIS AND EARLY TREATMENT OF DILI

Many drugs can cause abnormalities in liver function tests without any symptoms suggestive of liver disease. Preplanned liver function tests should be performed whenever treatment with a new drug is started. In patients with abnormalities in liver function tests without an obvious cause, a careful history, including not only hospital medications but also herbal remedies or supplements, should first be obtained. History taking should also include drug dosage, administration route, previous administration, any concomitant drugs, alcohol consumption, and underlying chronic liver disease and symptoms such as arthralgia. Moreover, family history of adverse drug reactions may be useful for the diagnosis of DILI. On physical examination, patients should be checked for fever, rash, or jaundice. In particular, jaundice should be evaluated carefully,

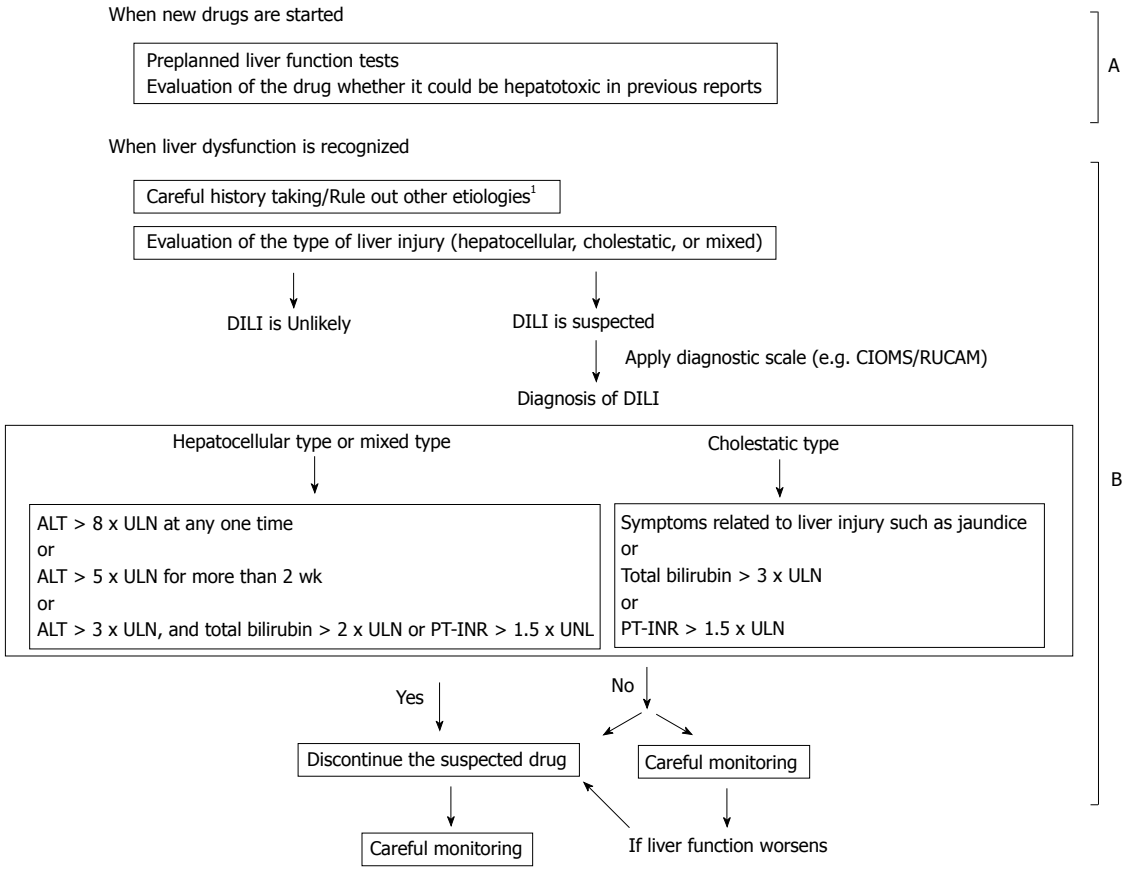

Figure 2 Algorithm for management of DILI. A: When new drugs are started; B: When liver dysfunction is recognized. The type, severity, and causes of liver injury should be assessed promptly. [1]Imaging studies such as ultrasonography should be performed in cases with suspected bile duct disorders.

Table 5 Examinations that should be performed in a patient with suspected DILI

Test	Subjects that can be evaluated
Hematological test[1]	Determination of the type of liver injury (the ratio of ALT and ALP)
Blood count (including eosinophils)	
Biochemical test[1]	
Aspartate aminotransferase (AST)	Possibility (e.g. Increase in eosinophil count, the existence of mixed type liver injury without any biliary disorders on imaging studies, High IgG level (> 2 g/dL) is suspicious of autoimmune hepatitis. Antibodies against hepatitis virus may be false-negative especially in the early phase of infection. Instead, measurement of viral RNA or DNA may be useful for the diagnosis. HDV (requires concomitant HBV infection) and HEV are relatively rare in advanced countries. Although, liver injury caused by EBV or CMV is also relatively rare, young patients with possible DILI should be checked for EBV or CMV).
Alanine aminotransferase (ALT)	
Lactate dehydrogenase	
γ-glutamyl transpeptidase (γ-GTP)	
Alkaline phosphatase (ALP)	
Total bilirubin (including direct and indirect bilirubin)	
Albumin	
Choline esterase (ChE)	
Total cholesterol (Cho)	
Coagulation test[1]	
Prothrombin time international ratio (PT-INR)	
Serological test[1]	
IgG, IgA, IgM	Severity (Marked increase or decrease in white blood cell count, decrease in platelet count. Increase in bilirubin level, decrease in albumin, ChE or Cho levels. Decrease in the ratio of direct/total bilirubin (< 0.67). Prolongation of PT-INR).
Anti-nuclear antibody (ANA)	
Anti-mitochondrial antibody (AMA or M2)	
Viral serology	
IgM anti-HA[1]	
HBsAg[1], IgM-HBc[1], anti-HBc, HBV-DNA	
HCV-Ab[1], HCV-RNA	
HDV-Ab, HDV-DNA	
HEV-Ab, HEV-RNA	
IgM-EBV	
IgM-CMV	
Imaging study	
Ultrasonography (US)[1]	

[1]Tests which should be carried out first. Ig: Immunoglobulin; HA: Hepatitis A; HBsAg: Hepatitis B surface antigen; HBc: Hepatitis B core; HBV: Hepatitis B virus; HCV: Hepatitis C virus; Ab: Antibody; HDV: Hepatitis D virus; HEV: Hepatitis E virus; EBV: Epstein-Barr virus; CMV: Cytomegalovirus.

because it is a sign of severe liver injury indicating the necessity for prompt cessation of the suspected drug. Liver function tests including serum transaminase, ALP, γ-glutamyl transpeptidase, and bilirubin, as well as hematological tests including eosinophil count and coagulation tests should be performed. Classification of the pattern of liver injury should be done as early as possible because clinical course, possible etiologies, and causative drugs are different for each pattern[111]. Other etiologies, such as viral infection, autoimmune liver disease, or biliary disease, should be excluded by serological tests or imaging studies if necessary. DILI cases with severe hepatitis showing elevation of serum bilirubin to more than 3 × ULN may lead to liver failure, and should be treated carefully with referral to the hepatologist after discontinuing all suspected drugs. The list of recommended tests which should be performed in the diagnosis of DILI in patients with liver injury are shown in Table 5. Although accidental readministration of the causative drug may be beneficial for diagnosis of DILI, it may lead to severe liver injury and may even be fatal, and so is not recommended. Moreover, the probability of DILI should also be evaluated using a diagnostic scoring system, such as the CIOMS/RUCAM criteria. However, there is as yet no gold standard set of diagnostic criteria. The initial treatment usually involves withdrawal of the suspected drug. If the causative drug cannot be discontinued because the patient is receiving many drugs or the underlying disease is serious, medications may be continued with careful monitoring. Additional tests, such as the DLST, LMT, or cytokine production test, may be beneficial to identify the causative drug (Figure 2).

CONCLUSION

The spectrum of DILI is both diverse and complex. Although liver injury is often mild and does not require treatment in these patients, DILI may lead to severe hepatitis with a risk of death. Therefore, adequate initial management after achieving an accurate diagnosis is important for physicians. Although the incidence of DILI is reported to be increasing, the precise frequency is difficult to estimate because of the lack of a worldwide monitoring system and the lack of a gold standard for diagnosis. Establishment of a worldwide network for monitoring the adverse events of drugs and a universal diagnostic system for DILI are important for accurate diagnosis, and may lead to better management of DILI.

Abstract

Vesicle-based trafficking of hepatocellular transporters involves delivery of the newly-synthesized carriers from the rough endoplasmic reticulum to either the plasma membrane domain or to an endosomal, submembrane compartment, followed by exocytic targeting to the plasma membrane. Once delivered to the plasma membrane, the transporters usually undergo recycling between the plasma membrane and the endosomal compartment, which usually serves as a reservoir of pre-existing transporters available on demand. The balance between exocytic targeting and endocytic internalization from/to this recycling compartment is therefore a chief determinant of the overall capability of the liver epithelium to secrete bile and to detoxify endo and xenobiotics. Hence, it is a highly regulated process. Impaired regulation of this balance may lead to abnormal localization of these transporters, which results in bile secretory failure due to endocytic internalization of key transporters involved in bile formation. This occurs in several experimental models of hepatocellular cholestasis, and in most human cholestatic liver diseases. This review describes the molecular bases involved in the biology of the dynamic localization of hepatocellular transporters and its regulation, with a focus on the involvement of signaling pathways in this process. Their alterations in different experimental models of cholestasis and in human cholestatic liver disease are reviewed. In addition, the causes explaining the pathological condition (e.g. disorganization of actin or actin-transporter linkers) and the mediators involved (e.g. activation of cholestatic signaling transduction pathways) are also discussed. Finally, several experimental therapeutic approaches based upon the administration of compounds known to stimulate exocytic insertion of canalicular transporters (e.g. cAMP, tauroursodeoxycholate) are described.

INTRODUCTION

Bile secretion is a highly-regulated process. Such regulation is aimed at coping with the physiological demand for hepatocellular transport of endo- and xenobiotics. This is achieved by modulation of the constitutive expression, dynamic localization or intrinsic activity of relevant transport systems located at the sinusoidal (basolateral) and canalicular (apical) membranes of the hepatocyte.

Modulation of carrier transport activity may occur at different time scales. Long-term regulations occur by changes in carrier turnover, which leads to modification of the synthesis-degradation balance. Altered synthesis rate involves transcriptional or translational changes in carrier expression. On the other hand, modification of the carrier degradation rate is a post-translational

process. This latter event may involve, as an initiating step, sustained internalization of the carrier protein from its plasma membrane domain, followed by lysosomal breakdown.

In contrast to this irreversible fate, transitory, reversible changes in transporter localization by vesicle-mediated insertion/internalization from/to an endosomal recycling compartment may occur as part of a short-term, physiological mechanism aimed at quickly modulating carrier density at the plasma membrane. This is a tightly regulated process, and the signaling mediators involved are being actively characterized.

Apart from its role in biliary physiology, changes in the proper localization of hepatocellular carriers also occur in a number of pathological conditions, and they may partly explain the cholestatic manifestations in these liver diseases. This has encouraged investigators to better understand the mechanisms involved in this particular pathomechanism at a molecular level, and to envisage and test in experimental models of cholestasis new therapeutic approaches based upon its prevention.

This article aims to give an overview of this subject, by summarizing the current information available in the literature on physiological regulation and cholestatic changes in hepatocellular carrier dynamic localization, as well as its beneficial modulation by therapeutic agents.

HEPATOCELLULAR TRANSPORT SYSTEMS

The hepatocyte is a polarized cell that expresses differential transport systems in its plasma membrane domains. These transporters play a key role in the vectorial transfer of solutes and water from sinusoidal blood into bile, thus contributing to bile formation and the biliary excretion of many xenobiotics. Most of these transport proteins have been identified by molecular cloning, and their transport properties characterized by functional studies. Their localization and transport function are shown in Figure 1.

Sinusoidal solute uptake transporters

Liver sinusoids possess a specific architecture that allows passage of organic compounds bound to albumin through endothelial fenestrae into the space of Disse, from where they can be taken up by the sinusoidal transport systems of the hepatocytes[1].

Basolateral uptake transporters can be divided into Na^+-dependent and Na^+-independent systems. Na^+-dependent uptake involves co-transport of solutes with Na^+, and is driven by the electrochemical Na^+ gradient generated and maintained by the Na^+/K^+-ATPase, which is strategically localized at the sinusoidal membrane. The Na^+-independent transport of organic anions is driven primarily by anion exchange.

Bile salts are the predominant organic solutes in bile, and the main determinants of bile flow[2]. Bile salts are mainly taken up by the Na^+/taurocholate co-transporting polypeptide (NTCP/Ntcp for humans and rodents, respectively; also known as SLC10A1/Slc10a1)[3]. A remaining fraction is taken up by a Na^+-independent transport system mediated by the organic anion-transporting polypeptide (OATP/Oatp) family of transporters[4,5]. In addition to conjugated and unconjugated bile salts, Oatps/OATPs accept other cholephilic compounds, including glucuronidated (and maybe unconjugated) bilirubin, exogenous organic anions (e.g. sulphobromophthalein), leukotrienes, estrogen-conjugates (e.g. estrone-3-sulfate or estradiol-17-β-d-glucuronide), thyroid hormones, mycotoxins, and numerous xenobiotics[3,6-8]. Four OATPs have been cloned and characterized from human liver, namely: OATP1A2 (SLCO1A2/SLC21A3; formerly, OATP-A), OATP1B1 (SLC21A6; formerly, OATP-C or LST-1), OATP1B3 (SLC21A8; formerly, OATP-8) and OATP2B1 (SLC21A9; formerly, OATP-B). There are three Oatps identified in rats, namely: Oatp1a1 (*Slc21a1*; formerly, Oatp1), Oatp1a4 (*Slc21a5*; formerly, Oatp2) and Oatp1b2 (*Slc21a10*; formerly, Oatp4 or Lst-1). Oatp1b2 is the rodent ortholog of both OATP1B1 and OATP1B3[9].

Hepatocellular uptake of organic cations is mediated by two separate transport systems, which depends on the substrate molecular size[10]. Thus, small (type Ⅰ) organic cations are taken up by the organic cation transporter, OCT1/Oct1 (SLC22A1/Slc22a1), which is electrogenic in nature. On the other hand, human OATP-A (but not the remaining members of the OATP family) and rat Oatp2 mediate the uptake of bulky (type Ⅱ) organic cations.

Canalicular solute export transporters

After traversing the cell by Fick's diffusion, mostly bound to high-affinity cytosolic proteins, cholephilic compounds are excreted into bile mainly by ATP-dependent pumps of the superfamily of ATP-binding cassette (ABC) transporters, in particular those belonging to the family of multidrug-resistance proteins, MDR/Mdr, or to the family of multidrug-resistance-associated proteins, MRP/Mrp.

MDRs/Mdrs are members of the ABC superfamily that were originally described in cancer cell lines, where they confer resistance to therapeutic agents. Three gene products were identified in rodents, Mdr1a (Abcb1a), Mdr1b (Abcb1b) and Mdr2 (Abcb4), and two in humans, MDR1 (ABCB1) and MDR 3 (ABCB4). MDR1/Mdr1 functions as an efflux pump for a wide range of amphiphilic, bulky type Ⅱ cationic drugs, together with other hydrophobic compounds, such as endogenous and exogenous metabolites or toxins, steroid hormones, hydrophobic peptides and even glycolipids[8]. Two closely related but functionally distinct Mdr1 isoforms, mdr1a and mdr1b are present in the murine but not in the human phenotype[11]. MDR3/Mdr2 functions as a flippase, which translocates phosphatidylcholine (PC) from the inner to the outer leaflet of the canalicular membrane, followed by release of PC-containing vesicles from the outer leaflet into bile, a process facilitated by the detergent properties of luminal bile salts[12].

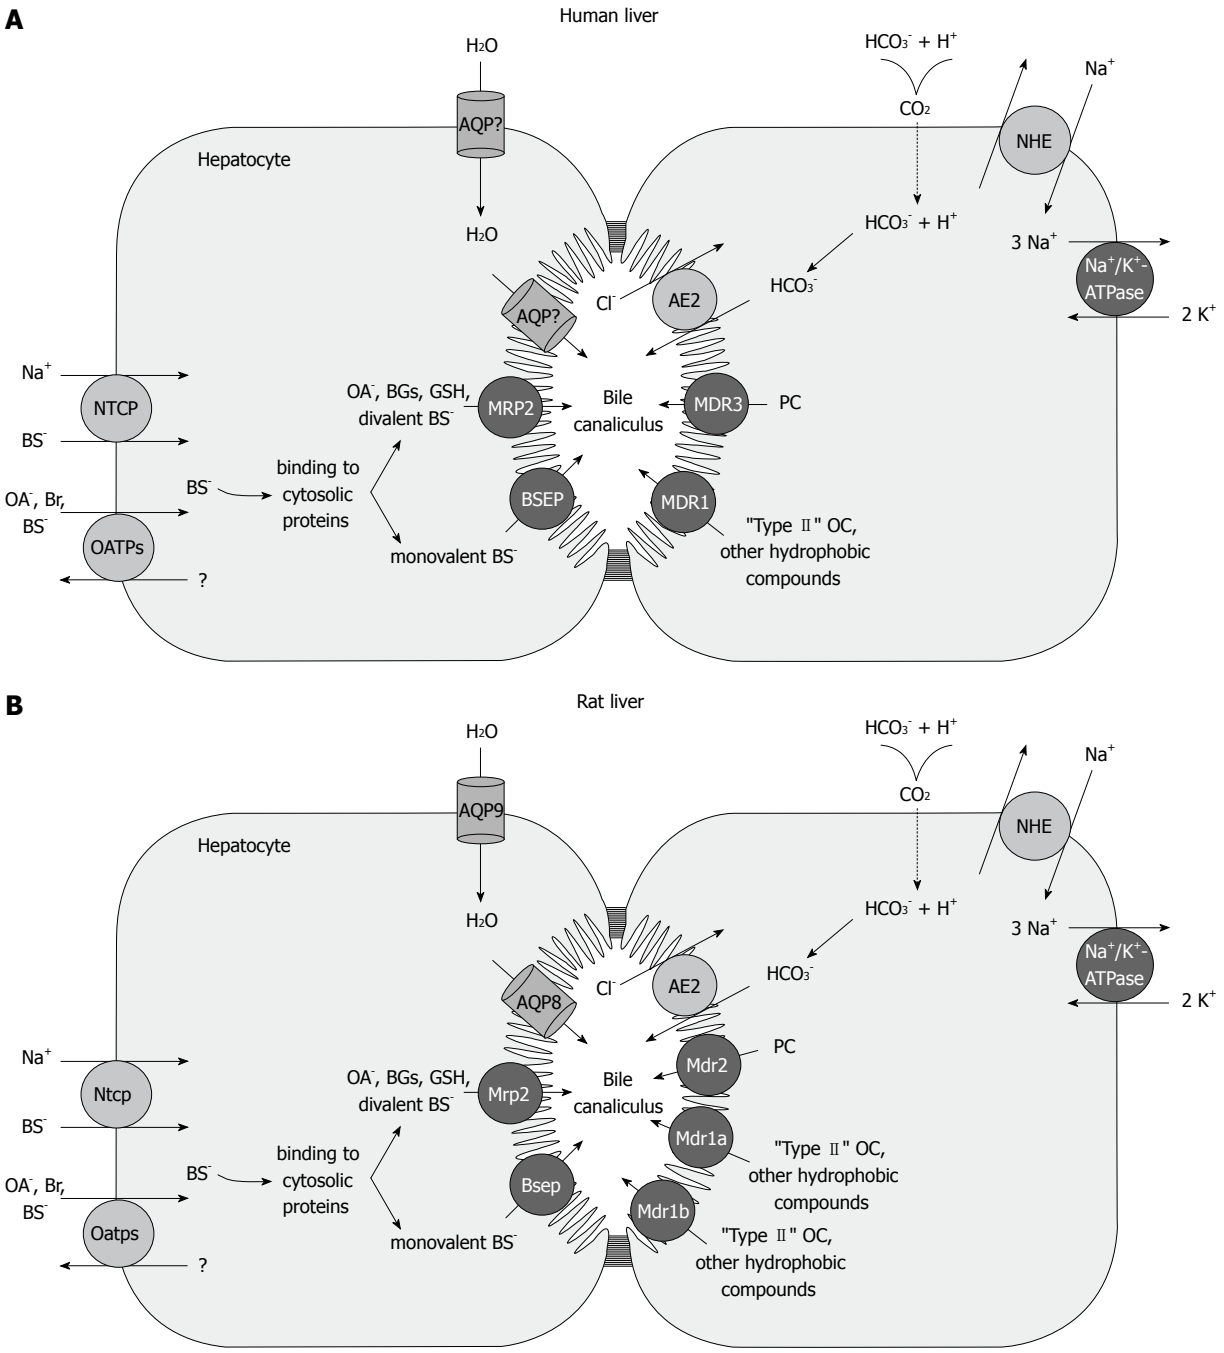

Figure 1 Localization and function of sinusoidal and canalicular hepatocellular transporters. A: humans; B: rodents. The Na^+-dependent sinusoidal uptake of bile salts is mediated by NTCP (human)/Ntcp (rat). The Na^+-independent hepatic uptake of organic anions (OA^-), Bile salts and type Ⅱ organic cations (OC^+) is mediated by members of the OATP/Oatp family. Sinusoidal uptake of type Ⅰ OC^+ is mediated by OCT1/Oct1. Transport across the canalicular membrane is driven mainly by ATP-dependent export pumps (black circles). MDR1/Mdr1a, Mdr1b mediates canalicular excretion of amphiphilic type Ⅱ OC^+ and other hydrophobic compounds. MDR3/Mdr2 functions as a phosphatidylcholine (PC) flippase. BSEP/Bsep mediates apical excretion of BSs. MRP2/Mrp2 transports non-bile-salt organic anions, such as bilirubin glucuronides, GSH, and sulfated/glucuronidated bile salts. Canalicular transport of HCO_3^- is mediated by the Cl^-/HCO_3^- exchanger AE2/Ae2. Aquaporins AQP9 and AQP8 are involved in the transport of water across the rat sinusoidal and the canalicular membrane, respectively. The nature of the water channels in human liver has yet to be characterized.

Monoanionic bile salts are excreted in the canalicular pole by the *bile salt export pump* (BSEP/Bsep; ABCB11/abcb11), another member of the MDR family[13]. In contrast, canalicular efflux of divalent, bipolar sulfated or glucuronidated bile salts is mediated by the multidrug-resistance-associated protein 2 (MRP2/Mrp2; ABCC2/Abcc2)[4,14]. This carrier is also engaged in the biliary excretion of many other organic anions, including glutathione S-conjugates (e.g. of leukotriene C4 or sulphobromophthalein, among others), glucuronides (e.g. of bilirubin and estrogens), and reduced (GSH) and oxidized glutathione (GSSG), the former with low affinity[15,16]. Both GSSG and GSH are major determinants of the so-called "canalicular bile-salt-independent bile flow"[17].

The canalicular membrane domain also contains the electroneutral anion exchanger 2 (AE2/Ae2; SLC4A2/slc4a2), which extrudes HCO_3^- by exchanging the anion

for biliary Cl^-[18]. It functions to regulate intracellular pH when hepatocytes are exposed to an alkaline load[18]. In addition, AE2/Ae2 plays a role in bile flow generation, since HCO_3^- excretion is thought to be an additional primary driving force of the canalicular bile-salt-independent bile flow[18,19]. Both in humans and rats, three transcript variants of AE2/Ae2 have been described, namely the full-length transcript AE2a/Ae2a, expressed from the upstream promoter in most tissues, and the alternative transcripts AE2b1/Ae2b1 and AE2b2/Ae2b2, expressed in a more tissue-restricted fashion (mainly in liver and kidney). AE2b1/2/Ae2b1/2 transcription is driven from overlapping promoter sequences within intron 2, which result in AE2/Ae2 protein isoforms with short N-terminal differences[20,21].

Water transporters

For a solute to drive blood-to-bile vectorial water transport primarily, resultant osmotic forces need to be associated with aquaporin (AQP)-mediated transcellular movement of water molecules from plasma to the bile canaliculus. Both immunochemical and functional studies have demonstrated the constitutive expression of the water channel AQP9 at the basolateral membrane of rat hepatocytes, and the regulated expression of the water channel AQP8 at the hepatocellular canalicular membrane domain[22-24]. As a result of it being inserted in the canalicular membrane on demand, AQP8 is suggested to play a role in bile formation, facilitating the osmotic movement of water under a choleretic stimulus[23,24]. AQP isoforms that mediate polarized water transport in human hepatocytes, if any, remain to be identified.

MECHANISMS OF NORMAL TRAFFICKING OF HEPATOCELLULAR TRANSPORTERS AND ITS REGULATION BY SIGNALING PATHWAYS

Basolateral transporters

NTCP/Ntcp: Basolateral targeting of NTCP is mediated by a sorting pathway that involves translocation of the protein from the endoplasmic reticulum (ER) to the Golgi apparatus, and from there to the plasma membrane, by a trans-Golgi-network-independent pathway[25]. The process may also involve microtubular and microfilamental motor proteins. A role for the cytoskeleton in NTCP translocation has been studied in detail using green fluorescent protein (GFP)-tagged NTCP expressed in the HepG2 cell line[26]. This study showed that targeting of NTCP to the plasma membrane consists of two steps: (1) delivery of NTCP to the region of the plasma membrane *via* microtubules, and (2) insertion of NTCP into the plasma membrane, by a microfilament-mediated mechanism; this actin requirement was also observed in isolated rat hepatocytes[27]. The latter step more likely involves targeting of NTCP from an early (recycling) endosomal compartment[28]. These NTCP/Ntcp-containing vesicles also express the microtubule-based motor proteins dynein and kinesin, and the actin-based motor myosin Ⅱa[28]. This compartment may serve as a reservoir of transporters for their rapid insertion into the sinusoidal membrane under a physiological stimulus that requires their function. It is therefore not surprising that recycling of NTCP/Ntcp from this compartment is a highly regulated process.

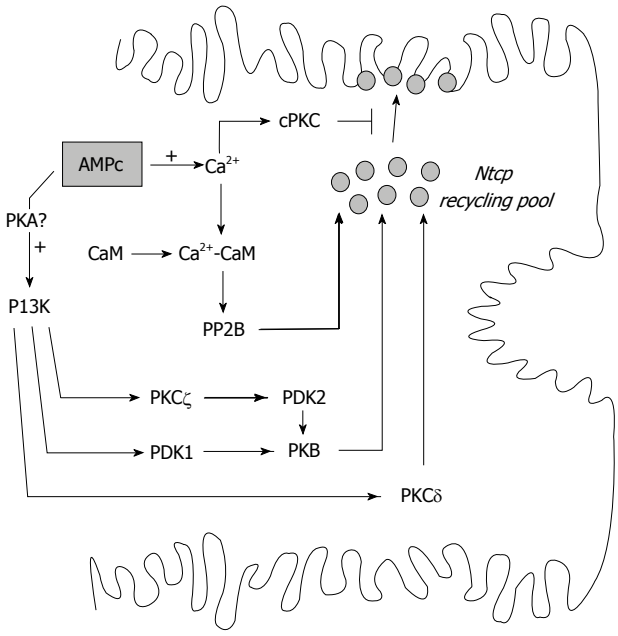

Figure 2 Signaling pathways that regulate the cAMP-induced exocytic insertion of Ntcp into the basolateral membrane. cAMP stimulatory effect involves elevations in cytosolic Ca^{2+} and activation of PI3K-dependent pathway, probably *via* protein kinase A (PKA). CaM complex activates phosphatase 2B (PP2B), which promotes insertion of Ntcp by dephosphorylation. This pathway is counter-regulated by cPKC. cAMP also stimulates Ntcp targeting by PI3K-dependent activation of PDK1 and subsequent PKB activation. Alternatively, PKB is activated by the concerted action of the atypical PKCζ and PDK2. Finally, cAMP/PI3K signaling stimulatory pathway may involve PKCδ.

The cAMP-elevating hormone glucagon and the permeant cAMP analog dibutyryl cAMP stimulate hepatocyte Ntcp maximal transport in rats by insertional exocytosis from intracellular vesicles that contain the transporter[29]. The signaling pathways evoked by cAMP that account for this stimulatory effect are depicted in Figure 2. Protein kinase A (PKA) activation[30], phosphatidylinositol 3-kinase (PI3K) activation[27,31] and elevations of cytosolic Ca^{2+}[30] all mediate the cAMP effect. Although the mechanism of PI3K activation by cAMP has not been elucidated as yet, there is evidence in other cell lines that the cAMP-dependent PKA can activate PI3K by phosphorylation of the PI3K regulatory subunit, p85[32]; if this applies to hepatocytes, this would explain the dual mediation of PKA and PI3K in the cAMP-stimulatory effect. The downstream mediators of the cAMP-PI3K signaling pathway are under debate, and may be multifactorial. The PI3K downstream enzyme, protein kinase B (PKB, also known as Akt), has been implicated[27,31]. Coincidently, hepatocellular swelling, which also evokes the PI3K/

PKB signaling pathway, favors Ntcp translocation to the plasma membrane as well[31,33]. The effect of PI3K/PKB on Ntcp translocation seems to be mediated by the PI3K-dependent activation of atypical protein kinase C zeta (PKCζ)[34]. PKCζ is downstream of PI3K, since PI3K products activate this PKC isoform[35,36]. The requirement of PKCζ for the PKB effect can be explained by PKCζ modulation of activators upstream of PKB. Activation of PKB requires phosphorylation by 3-phosphoinositide phosphate-dependent kinase 1 (PDK1), followed by phosphorylation by a second kinase, PDK2; this latter kinase phosphorylates and activates PKB fully only when associated with PKCζ[36,37]. In addition, a direct, non-PKB-mediated stimulatory role for PKCζ on Ntcp translocation has been suggested[34]. Apart from PKCζ, cAMP-stimulated PI3K phosphorylates the novel protein kinase C delta (PKCδ) at Thr-505, and the resulting activation seems to be involved in Ntcp membrane translocation as well[38]. The molecular target/s phosphorylated by PKB, PKCζ and PKCδ that ultimately account for the translocation of Ntcp are unknown. Ntcp itself seems not to be a target, since cAMP may promote dephosphorylation rather than phosphorylation of the carrier[39-41]. However, studies in transfected COS-7 and Madin-Darby canine kidney (MDCK) cells using GFP-fused Ntcp constructs that lack the cytoplasmic Ntcp tail, which serves as a signal for basolateral sorting, have demonstrated that this moiety has regulatory phosphorylation sites that are essential for cAMP-induced stimulation of Ntcp translocation[42]. The relevance of this finding needs to be tested in a more physiological context. Other possible phosphorylation targets, at least of PKCζ, are the microtubule motors that drive movement of Ntcp-containing vesicles. A majority (75%) of intracellular vesicles containing Ntcp were found to co-localize with PKCζ in rat hepatocytes, and the motility of these vesicles on microtubules, when assessed using an *in vitro* motility assay, was impaired by both PI3K and PKCζ inhibitors, and stimulated by PI3K products[28].

Apart from activating PKA and PI3K, cAMP induces elevations of cytosolic Ca^{2+} in hepatocytes[43,44]. The subsequent formation of the Ca^{2+}-calmodulin (CaM) complex influences Ntcp localization by activating the Ca^{2+}/CaM-dependent serine–threonine phosphatase PP2B (also known as calcineurin)[39]. cAMP promotes both serine and threonine dephosphorylation of Ntcp *via* PP2B[39-41], and dephosphorylated Ntcp is located preferentially in the plasma membrane[45]. Phosphorylated Ser-226 in the third cytoplasmic loop of Ntcp may be the target for cAMP-stimulated dephosphorylation[45]. This cAMP-dependent, Ca^{2+}-mediated pathway may be counter-regulated by activation of "classical" (Ca^{2+}-dependent) PKC (cPKC), since pan-specific activation of PKC with phorbol esters counteracts the cAMP-stimulatory effect[30].

OATP/Oatp: Unlike Ntcp, this family of transporters is not stored in intracellular vesicular compartments, and therefore regulation by trafficking is limited to modulation of its transfer from synthesis sites. Sorting of human OATP-C to the basolateral membrane is mediated by both the Golgi complex- and the vacuolar H^+-ATPase vesicle-mediated membrane sorting pathways, and cAMP positively regulates the first sorting mechanism *via* activation of PKA[46].

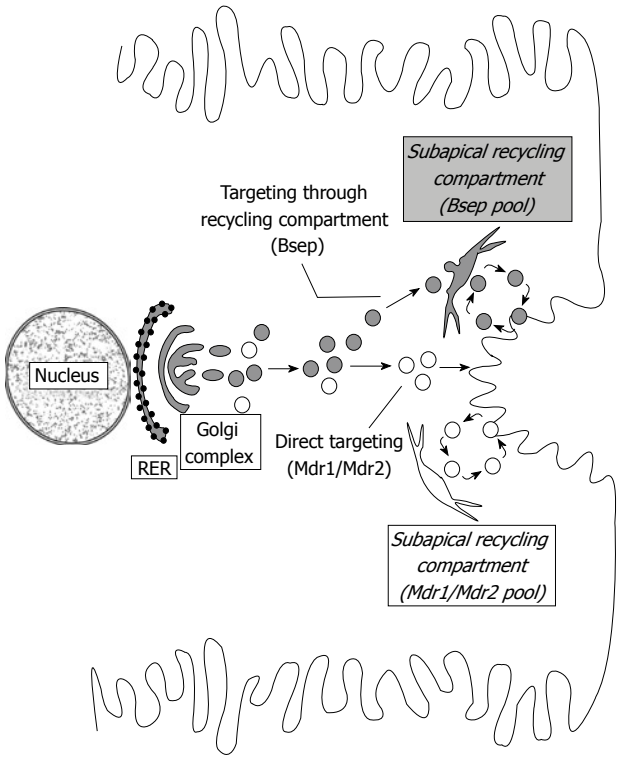

Figure 3 Routes involved in trafficking of canalicular transporters. The trafficking of vesicles delivering Bsep (gray vesicles) or Mdr1/Mdr2 (white vesicles) from the site of synthesis to the canalicular domain is distinct. Mdr1 and Mdr2 are directly targeted to the canalicular membrane, whereas Bsep is indirectly targeted *via* a subapical, endosomal compartment, which allows the recycling of transporters (exocytic insertion/endocytic internalization). Once targeted, Mdr1 and Mdr2 are also able to recycle between the subapical compartment and the canalicular membrane.

Canalicular transporters

ABC canalicular transporters: Vesicle-based trafficking steps of canalicular export pumps are depicted in Figure 3. Once synthesized by the rough ER, *de novo* ABC canalicular transporters belonging to either the MRP or the MDR family traffic *via* the Golgi complex directly to the apical membrane[47-49]. Pulse-chase studies using ^{35}S-methionine followed by immunoprecipitation of the ABC transporters from subcellular fractions have revealed that these transporters are targeted directly to the canalicular membrane, as at no time between passage through Golgi and arrival at the canalicular membrane are the ABC transporters localized at the sinusoidal membrane[49]. However, the post-Golgi trafficking differs among the ABC transporters studied. Mdr1 and Mdr2 are fully delivered to the canalicular membrane 30 min after ^{35}S-methionine administration[49]. This finding was confirmed for Mdr1 in WIF-B cells, a hybrid of rat hepatoma cells and human fibroblasts that has functional bile canaliculi[50]. Contrarily, Bsep only reaches

the canalicular membrane after 2 h, which suggests that, unlike Mdr1/2, Bsep is retained in an intracellular endosomal pool prior to delivery to the canalicular membrane[48]. This intrahepatic, large vesicular pool also serves as a reservoir of ABC transporters, which can be quickly recruited to the canalicular membrane on physiological demand that requires their function (e.g. increased biliary excretion of bile salts for lipid digestion/absorption during the post-prandial period). The recycling process involves exocytic insertion, followed by endocytic internalization once demand is satisfied[47,48].

Compelling evidence in the literature further supports the existence of this recycling compartment for canalicular hepatocellular transporters. Immunogold electron microscopy studies of rat hepatocytes have revealed that distribution of Bsep is not restricted to the canalicular membrane, but is also detected in electron-translucent vacuolar structures close to the apical, but not the basolateral membrane[51]. Pericanalicular localization of Mrp2, Bsep and Mdr1 has also been demonstrated by immunofluorescent staining in isolated rat hepatocyte couplets[52]. Finally, direct visualization of the recycling between the canalicular membrane and subapical endosomes has been observed for Bsep-GDP chimeras in WIF-B cells stably transfected with adenoviral Bsep-GFP constructs[53]. Chimeric Bsep co-localizes with the marker of recycling endosomes Rab11, and its recycling was microtubule- and microfilament-dependent in both ways[53]. On the contrary, and unlike the *de novo* transporter pathway, this recycling does not involve the Golgi complex, since it is unaffected by brefeldin A. This suggests that recycling represents an independent step in the whole trafficking of *de novo* ABC transporters to the canalicular membrane, and that only replenishment of this recycling compartment with newly-synthesized transporters is Golgi-dependent.

This large-range, Golgi-dependent vesicular trafficking of ABC transporters has been characterized by our group and others using the couplet model. Sorting of Mrp2 to the apical membrane has been analyzed by studying the spontaneous retargeting of the transporter after Mrp2 internalization that occurs during the isolation process[54,55]; this vesicle-based trafficking shares the route of newly-synthesized, apically-directed proteins, since it is sensitive to disruption of the Golgi complex function with brefeldin A[55]. Inhibitors of microtubule polymerization diminish, but do not completely block, the restoration of Mrp2 localization[54,55]. Re-establishment of hepatocyte couplet secretory polarity is instead strikingly dependent on microfilament organization[55]. A similar differential cytoskeletal dependency has been suggested to occur for Bsep, as inferred by functional studies upon restoration of the hepatocyte couplet capability to secrete apically the Bsep substrate, cholyl-lysylfluorescein (CLF), and also for Ca^{2+}/Mg^{2+}-ATPase, another canalicular transporter[56]. The vesicle motor protein myosin-Ⅱ may be crucially involved in the actin-dependent targeting of Bsep. Co-immunoprecipitation studies have identified myosin-Ⅱ regulatory light chain as a binding partner of BSEP, and reduced expression of this protein in dominant negative mutant MDCK cells reduces apical membrane BSEP levels[57]. Furthermore, pharmacological inhibition of myosin Ⅱ impedes delivery of newly synthesized transporter to the apical membrane in these cells[57]. These findings suggest that myosin-Ⅱ is required for BSEP trafficking to the apical membrane in polarized epithelial cells.

Trafficking of ABC transporters from their place of synthesis to the canalicular membrane is under signaling modulation. Studies using the re-polarization approach in hepatocyte couplets described above have shown that the spontaneous canalicular targeting of Mrp2 after isolation and culture is Ca^{2+}- but not PKA-dependent[55]. The Ca^{2+}-elevating compound thapsigargin (an inhibitor of the ER Ca^{2+}-ATPase) accelerates, whereas the intracellular Ca^{2+} chelator BAPTA/AM and the CaM inhibitor W7 greatly inhibit this process, which suggests Ca^{2+}-CaM dependency. On the other hand, the PKC-dependent signaling pathway is inhibitory in nature, since the PKC activator phorbol 12,13-dibutyrate inhibits this process, whereas both the pan-specific PKC inhibitor staurosporine and the specific inhibitor cPKC Gö6976 accelerate this process. This indicates that, under basal conditions, cPKC exerts an inhibitory effect on long-range trafficking of ABC transporters to the canalicular pole and that the stimulation induced by Ca^{2+} elevations may generate its own counter-regulatory mechanism, by activating cPKC. In this connection, selective activation of cPKC by administration of thymeleatoxin is associated with retrieval of Bsep and loss of bile salt secretory function in isolated rat perfused liver[58].

Both Roelofsen *et al*[54] and our group[55] have analyzed the influence of cAMP on the time-dependent re-targeting of Mrp2 after isolation-induced Mrp2 internalization. cAMP stimulates this process. This phenomenon is partially inhibited by inhibitors of microtubule polymerization. We have further examined this phenomenon by analyzing the involvement of signaling molecules downstream of cAMP, the cross talk with other signaling pathways, and the dependency of cAMP stimulus on cytoskeleton organization[55] (Figure 4). The cAMP-sensitive stimulatory pathway shares most downstream signaling constituents with the basal, spontaneous pathway described above, i.e. it is not PKA-dependent, but Ca^{2+}-dependent, *via* Ca^{2+}-CaM complex formation. This cAMP-dependent pathway is also counter-regulated by activation of cPKC[55]. Interestingly, a similar counter-regulatory cross-talk between cAMP- and PKC-dependent signaling pathways applies to the trafficking of other transporters, including Ae2[59] and Ntcp[30]. Another candidate to mediate cAMP-stimulatory effects is PI3K. Studies *in vivo* have revealed that cAMP-mediated stimulation of ABC transporter insertion is inhibited by the PI3K inhibitor wortmannin, and restored by phosphoinositide PI3K products[60]. PKCδ has been identified recently

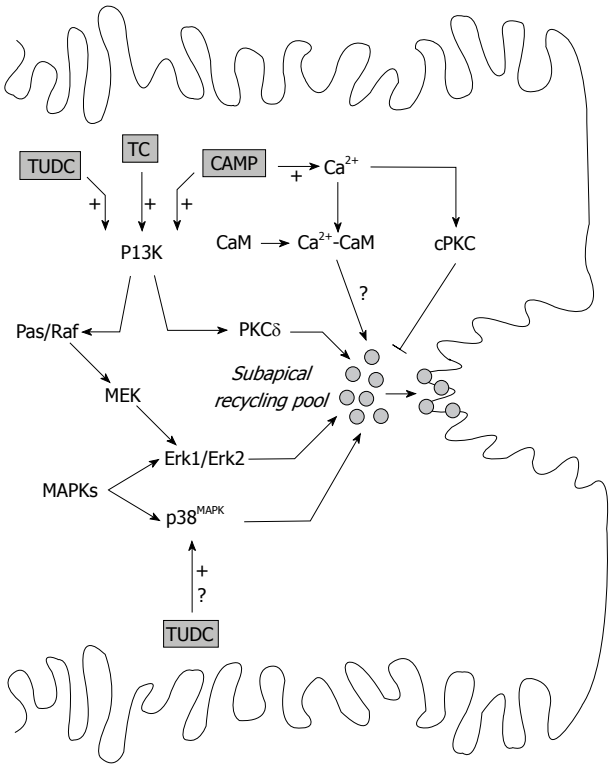

Figure 4 Signaling pathways involved in the exocytic insertion of canalicular transporters promoted by cAMP and by TC and TUDC. cAMP effect involves elevation in cytosolic Ca^{2+} and activation of the PI3K-dependent pathway. Formation of the CaM complex promotes apical insertion of transporters *via* unidentified mediators, and is counter-regulated by activation of cPKC. PI3K promotes exocytic insertion of canalicular transporters by activation of PKCδ and Erk-1 and Erk-2 of MAPK, *via* the Ras/Raf- MAPK kinase (MEK)-Erk-1/2 pathway. TC and TUDC also evoke the PI3K-dependent signaling pathway and promote insertion of canalicular transporters *via* the Ras/Raf-MEK-Erk-1/2 pathway. TUDC also stimulates canalicular carrier insertion by activation of MAPKs of the p38MAPK type, by an unknown mechanism.

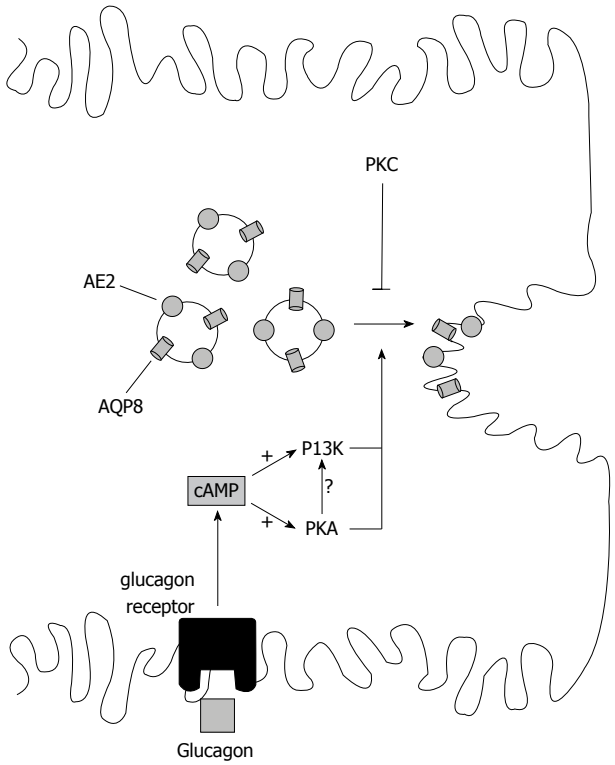

Figure 5 Signaling pathways involved in the co-stimulation of the canalicular targeting of AE2 and AQP8 by cAMP. AE2 and AQP8 are co-localized in the same population of pericanalicular vesicles, thus explaining common signaling modulation. cAMP stimulates AE2 and AQP8 targeting *via* activation of PKA. The PI3K pathway mediates the cAMP-stimulated, PKA-dependent targeting of AQP8, and probably that of AE2. cAMP effect on both transporters is counteracted by activation of PKC.

as a possible effector of the cAMP-dependent, PI3K-mediated pathways that leads to Mrp2 insertion[38]. The endogenous bile salt taurocholate (TC), which, as does cAMP, evokes the PI3K-dependent signaling pathway[61] and activates PKCδ[62], also promotes insertion of ABC transporters into the canalicular membrane in a PI3K-sensitive manner[61].

Another bile salt that stimulates exocytic insertion of canalicular transporters is tauroursodeoxycholate (TUDC)[63], but its action mechanism seems to involve another set of signaling molecules (Figure 4). TUDC activates within minutes mitogen-activated protein kinases (MAPKs) of both the $p38^{MAPK}$ type[63] and of the extracellular signal-regulated kinase (Erk) type (Erk-1 and Erk-2)[64]. These effects are causally linked to increased biliary excretion of bile salts and canalicular insertion of Bsep; the latter event having been demonstrated only for $p38^{MAPK}$[63]. The stimulus induced by TUDC on Erk-1/2, but not on $p38^{MAPK}$, is dependent on the sequential activation of PI3K and Ras/Raf[65]. The two MAPK-dependent pathways seem to act in parallel, and dual activation is required[63]. Studies in human hepatoblastoma HepG2 cells and in rat hepatocytes have shown that TUDC-stimulated insertion of BSEP involves not only increased targeting from the subapical compartment to the canalicular membrane, but also enhanced trafficking from the Golgi complex to the subapical compartment, and that $p38^{MAPK}$ may be a key signaling molecule in mediating this latter effect[66]. Coincidently, hypo-osmotic cell swelling, which shares with TUDC several downstream signaling effectors, also stimulates bile salt excretion by activation of Erk-1/2 and $p38^{MAPK}$[67], and both types of MAPKs are involved in hypotonicity-stimulated, microtubule-sensitive bile salt excretion[68,69].

AE2/Ae2: Apart from its functional localization in the canalicular membrane, the canalicular Cl^-/HCO_3^- exchanger AE2/Ae2 is present in pericanalicular vesicles[21,70], which migrate to the canalicular membrane on demand (Figure 5). The sorting in polarized liver cells of the three Ae2 variants, Ae2a, Ae2b1 and Ae2b2, has been studied using collagen-sandwiched primary rat hepatocytes[21]. After 72-96 h, GFP constructs from each recombinant Ae2 isoform co-localize in the canalicular membrane and in subapical, vesicular structures, and no signal is detected at the basolateral pole. This shared sorting of Ae2 isoforms is sensitive to the microtubule-disrupting agent colchicine, which suggests microtubule-dependent vesicular transport and exocytotic insertion of these transporter isoforms in the canalicular membrane.

Microtubule-dependence of Ae2 trafficking has been confirmed by functional studies. Ae2-mediated Cl^-/HCO_3^- exchange is increased in rat hepatocytes exposed to a bicarbonate-containing medium or in response to cAMP, and this increased activity is blocked with colchicine[59]. The cAMP-elevating hormone glucagon also stimulates this activity through a microtubule- and a cAMP-dependent, PKA-mediated mechanism[71]. The stimulation of Cl^-/HCO_3^- exchange activity by cAMP or glucagon is inhibited by PKC agonists[59,71], which suggests the existence of a counter-regulatory mechanism similar to that occurring for the targeting of Ntcp and ABC canalicular transporters (see above).

AQP8: This water canalicular channel is largely localized in intracellular vesicles in hepatocytes, as demonstrated by both subcellular fractionation[23], confocal immunofluorescence[23] and immunoelectron microscopy studies[72]. As a result of this property, it can be quickly inserted in the canalicular membrane on demand[24,73]. The cell-permeable cAMP analog dibutyryl cAMP induces redistribution of AQP8 to the canalicular membrane, and increases hepatocyte membrane water permeability in a microtubule-dependent manner[22,23]. Further studies in isolated rat hepatocytes[74] have shown that, as with AE2, AQP8 is inserted in the canalicular membrane by the cAMP-elevating hormone glucagon, by a process that involves both PKA and PI3K activation[75]., Immunofluorescent co-staining studies in WIF-B cells have shown intracellular co-localization of AQP8 and AE2, which suggests that these transporters are expressed in the same population of pericanalicular vesicles[76] (Figure 5). This explains the similar behavior of both transporters in response to a similar regulatory stimulus. Thus, apart from modulating the biliary secretion of osmotically-active solutes to the bile canaliculus *via* exocytic insertion of relevant carriers (e.g., BSEP, MRP2, AE2), hepatocytes can also modulate their canalicular membrane water permeability by inserting AQP8, thus facilitating the osmotic movement of water under choleretic stimulus.

ALTERATIONS OF THE DYNAMIC LOCALIZATION OF TRANSPORTERS IN LIVER DISEASE

Endocytic internalization of hepatocellular transporters is a common feature in liver disease. This applies mainly to those liver diseases that involve primary impairment in the capability of hepatocytes to produce bile (hepatocellular cholestasis). In these cases, changes in transporter localization may become a major pathomechanism that explains the secretory failure. Alternatively, changes in carrier localization can occur as a secondary consequence of a cholestatic manifestation caused by mechanical impediments to deliver bile to the duodenum (obstructive cholestasis). In this case, transporter mis-localization may aggravate/perpetuate the primary secretory halt. We summarize here the current evidence in the literature that alterations in the dynamic localization of transporters occur in experimental and human cholestatic liver disease.

Endocytic internalization of transporters in animal models of cholestasis

Endocytic internalization of the main canalicular transporters was first described in experimental models of cholestasis in rodents. Internalization of Mrp2 and Bsep into intracellular vesicles, mainly at the pericanalicular domain, has been shown to occur in experimental models of both obstructive and hepatocellular cholestasis.

Bile duct ligation (BDL): Experimental ligation of the common bile duct in the rat is an accepted model of obstructive cholestasis. BDL leads to a marked alteration in the pattern of staining of both Mrp2 and Bsep, as detected by indirect immunofluorescence microscopy. Paulusma *et al*[77] have found that, 48 h after BDL in rats, immunostaining of these transporters at the canalicular level becomes fuzzy, contrasting with the well-delimited detection in sham-operated controls. The authors have assumed that this represents mis-localization of the transporters to intracellular vesicles at a subapical compartment, next to the canaliculus. These alterations are accompanied by a severe impairment of the biliary excretion of model solutes. For example, Mrp2-mediated transport of the model substrate dinitrophenyl glutathione is substantially impaired in isolated hepatocytes from rats with BDL[77]. Endocytic internalization seems not to be circumscribed to Mrp2 or Bsep, as a similar phenomenon was observed for the canalicular enzymes dipeptidyl peptidase IV[78] and Ca^{2+}/Mg^{2+}-ATPase[79]. Altered localization of Mrp2 and Bsep may represent aggravation of the secretory dysfunction caused by the parallel decrease in the hepatocellular content of the carriers that also occurs in this disease[80,81], or even to be a causal factor of this reduction[77,82-85]. Indeed, Paulusma *et al*[77] have also found that, in contrast to that which is observed for Mrp2 protein content, mRNA levels are preserved after BDL, which suggests post-transcriptional downregulation of Mrp2 expression. They have postulated that endocytic internalization may represent the primary step toward enhanced breakdown of the endocytosed carriers. If maintained with time in chronic cholestatic conditions, this may cause redirection of the protein to the lysosomal compartment, followed by degradation.

The events leading to endocytic internalization of Mrp2 and Bsep in BDL rats remain uncertain. It is likely that accumulation of bile salts or other endogenous, potentially toxic compounds in the liver represents a causal factor. Bile salts are able to trigger oxidative stress[86,87], which in turn may explain the release of pro-inflammatory cytokines in BDL rats[88]. Both events have been involved in canalicular transporter internalization, as described below. We have found that the alteration in the normal pattern of localization of Mrp2, and that of the tight-junctional protein occludin, does not occur until 4 h after BDL in rats[78], in contrast

to the immediate response observed in drug-induced cholestasis (see next section). This suggests that BDL alterations are secondary to intracellular accumulation of deleterious endogenous compounds.

Drug-induced cholestasis: Administration to laboratory animals of drugs known to induce functional, hepatocellular cholestasis, or administration of endogenous compounds thought to be the etiological factors of human cholestatic liver diseases, has been used as an experimental tool to study the mechanisms of the disease. Administration of the cholestatic, naturally-occurring estrogen estradiol-17β-d-glucuronide ($E_2$17G)[89,90], the cholestatic monohydroxylated bile salt taurolithocholate (TLC)[91,92] and the cholestatic immunosuppressor drug cyclosporine A[93] all induce cholestasis in a short-term fashion, accompanied by endocytic internalization of Mrp2 and Bsep.

We have characterized in detail the mechanisms of transporter internalization in E_2-17G-induced cholestasis, an experimental model that reproduces in part pregnancy-induced cholestasis. After a single, i.v. administration of this compound, bile flow decreases in a dose-dependent fashion with a nadir at 20 min, and spontaneously recovers to normality by 2 h post-injection[94]. The cholestatic phase is associated with endocytic internalization of Mrp2 and Bsep, whereas the recovery phase occurs in parallel with the spontaneous re-insertion of subapical vesicles into the canalicular membrane[89,90]. While the internalization process is microtubule-independent, re-insertion is microtubule-dependent, and stimulated by cAMP[95]. We also found that repeated administration of E_2-17G to rats leads to both a deeper internalization of Mrp2 and an abnormal localization of a small fraction to the lateral membrane[78]. The latter phenomenon likely reflects loss of the fence between apical and basolateral domains caused by the simultaneous alteration of the tight-junctional structures[95,96]. Unlike Mrp2 and Bsep, AQP8 has a preserved localization in E_2-17G-induced cholestasis, and, like Mrp2 and Bsep, this water channel has a dual (intracellular plus plasma membrane) localization[97].

Lipopolysaccharide (LPS)-induced cholestasis: LPS is an endotoxin localized in the outer membrane of Gram-negative bacteria. The toxin induces cholestasis mainly by the release of pro-inflammatory cytokines, such as tumor necrosis factor-α and interleukin-1 by monocytes/macrophages and, in the liver, Kupffer cells[98]. Administration of LPS to laboratory animals represents, therefore, a good experimental model of inflammatory cholestatic diseases, not only of those caused by endotoxemia, but also those related to hepatitis caused by alcohol, autoimmune disease or drug intake.

LPS administration leads to endocytic internalization of Mrp2 and Bsep, which relocalizes in intracellular vesicular structures[99-101]. The time-dependency of the effect of LPS on Mrp2 internalization has been characterized by Kubitz *et al*[101]. These authors have found that, 3 h after LPS treatment, Mrp2 is found in intracellular vesicles in the vicinity of the canalicular membrane, and that these vesicles are deeply internalized after 6-12 h treatment. Endocytic internalization of ABC canalicular transporters seems to be specific, as localization of the canalicular enzyme dipeptidyl peptidase IV is not affected by the treatment. Mrp2 internalization is reversed by perfusing the liver with a hypo-osmotic buffer, a maneuver known to stimulate exocytic insertion of canalicular transporters under normal conditions[99,102]. However, this rescue of transporters occurs within 3 h of LPS administration, but not later on. It is possible that reversibility of the endocytic process depends on the degree of internalization of Mrp2, and that sustained internalization leads to delivery of the protein to the lysosomal compartment, followed by degradation. LPS effects can be prevented by administration of glucocorticoids[101] or by heat stress[103,104], two maneuvers that cause a decrease in synthesis and/or release of pro-inflammatory cytokines.

Oxidative-stress-induced cholestasis: Oxidative stress is a common feature in most liver diseases[105]. Radical oxygen species induce biliary secretory failure and cholestasis, even at low, pre-necrotic levels[106], and endocytic internalization of canalicular transporters may play a key role. We have shown that Bsep undergoes endocytic internalization into intracellular vesicles in isolated rat hepatocyte couplets when exposed to low levels of the pro-oxidizing compound tert-buthylhydroperoxyde (*t*BOOH)[107]. This is accompanied by a reduced capability to accumulate the fluorescent bile salt analogue CLF in their canalicular vacuoles. A similar phenomenon has been described for Mrp2 after exposure of isolated perfused rat livers to the pro-oxidant agents *t*BOOH[108], chloro-dinitrobenzene[108] and ethacrynic acid[109,110], or after hepatic ischemia-reperfusion[111].

Endocytic internalization of transporters in human cholestatic liver disease

Changes in canalicular export pumps have been shown to occur in many human cholestatic liver diseases. Unlike the situation in rodents, downregulation of the expression of these transporters in human cholestatic disease is mostly post-transcriptional in nature, therefore, internalization of these transporters followed by degradation may represent a crucial mechanism to explain the disease in humans.

Internalization of canalicular export pumps has been observed in virtually all kinds of human cholestasis, including: (1) obstructive extrahepatic cholestasis[112,113]; (2) inflammatory cholestasis associated with autoimmune hepatitis[113]; (3) mixed (obstructive plus inflammatory) cholestatic disease, such as primary biliary cirrhosis[114] and primary sclerosing cholangitis[113]; and (4) acute cholestasis induced by drugs, such as that triggered by

antibiotics, tiopronin, chlorpromazine and non-steroidal anti-inflammatory drugs[113,115]. Patients with obstructive cholestasis that are subjected to percutaneous transhepatic biliary drainage show different degrees of transporter dyslocalization, depending on the efficacy of the biliary drainage[112,113], which points to a central role for retained endogenous compounds in this pathomechanism.

Mechanisms of endocytic internalization in cholestasis: role of signaling pathways

The mechanisms by which endocytosis of canalicular transporters occurs in cholestasis remains poorly understood. At least in part, this may be because they are multifactorial.

Alterations of actin-cytoskeletal integrity by administration of the F-actin poison phalloidin[116], or secondary to the administration of pro-oxidant compounds, such as *t*BOOH[107] or the hydrophobic bile salts taurochenodeoxycholate[117], triggers canalicular transporter endocytosis. This may be related to the fact that actin cytoskeleton is involved in transcytosis processes by operating as a bridge between microtubules and the apical membrane itself, in a coordinated action of the microtubule- and the F-actin-based motor proteins, kinesin and myosin, respectively[118]. However, internalization of canalicular transporters also occurs with preserved actin organization, e.g. in E_2-17G-[89,90] or TLC-[92]induced cholestasis. In these cases, components of the microfilament network other than actin, but associated with it, may be independently affected. Actin can interact with, and possibly regulate, transmembrane proteins *via* binding to plasma membrane actin cross-linking proteins, such as the ezrin-radixin-moesin (ERM) family of proteins, or by binding to interacting-partner proteins, such as PDZK1 and HAX-1. These cytoskeleton-associated proteins are required for the biosynthetic targeting of transmembrane proteins from the *trans*-Golgi network to the proper membrane domain, and for their further cell-surface retention[119-121]. Mice that lack radixin, the main ERM protein in liver, develop conjugated hyperbilirubinemia associated with retrieval of Mrp2[122]. Furthermore, downregulation of radixin using interfering RNA technology in collagen-sandwich-cultured rat hepatocytes disturbed the normal development of canalicular structures, and dissociated canalicular export pumps from their normal location at the apical membrane. Inside the cell, the transporters are found to be largely associated with Rab11-containing endosomes[123]. Furthermore, a disturbed co-localization of MRP2/Mrp2 and radixin associated with endocytic internalization of the carrier is apparent in obstructive and estrogen-induced cholestasis in rats[124], and in several cholestatic liver diseases in humans, including primary biliary cirrhosis stage Ⅲ, drug-induced liver injury, obstructive jaundice, primary sclerosing cholangitis and autoimmune hepatitis[113,114]. On the contrary, alteration in cholestasis of the localization/function of interacting-partner proteins, such as PDZK1 (for Mrp2) and HAX-1 (for Bsep, Mdr2 Mrp1) remains

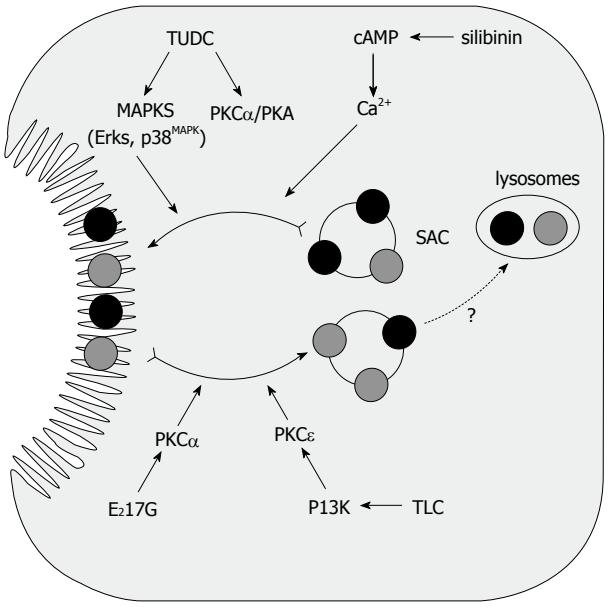

Figure 6 Endocytic internalization of canalicular transporters in $E_2$17G and in TLC-induced cholestasis. Protection from these cholestatic agents by the anticholestatic agents cAMP and TUDC is also shown. $E_2$17G and TLC induce endocytic internalization of canalicular transporters into the subapical compartment (SAC); this may lead to delivery to the lysosomal compartment, followed by degradation. $E_2$17G-induced activation of PKCα and TLC-induced, phosphatidylinositol 3-kinase (PI3K)-dependent activation of PKCε have been proposed to mediate this retrieval. Elevation of intracellular cAMP levels induced by administration of the permeant cAMP analogue DBcAMP, or by the phosphodiesterase inhibitor silibinin, prevents internalization, and accelerates re-insertion, *via* cytosolic Ca^{2+} elevations. On the other hand, TUDC prevents transporter endocytosis probably *via* co-stimulation of PKCα- and PKA-dependent pathways.

to be confirmed. This possibility however exists, since retention of Mrp2[122] and Oatp1a1[125] in the apical and the basolateral membranes, respectively, requires interaction with the PDZ-domain protein, PDZ1. In addition, there is evidence that HAX-1 participates in clathrin-mediated Bsep endocytosis from the canalicular plasma membrane[126].

Accumulating evidence indicates that changes in canalicular transporter localization that occur in cholestasis also depend on activation of critical intracellular signaling pathways (Figure 6). Representative examples are cPKC (mainly, PKCα in hepatocytes). Selective activation of cPKC induces endocytic internalization of Bsep from the canalicular membrane and cholestasis in the isolated perfused rat liver[58]. Coincidently, pan-specific activation of PKC also induces redistribution of MRP2 from the canalicular to the basolateral membrane in HepG2 cells[127]. A critical participation of cPKC in the endocytic internalization of Bsep and the associated bile-salt secretory failure has recently been demonstrated by our group in E_2-17G-induced cholestasis in rats[128]. A similar role for cPKC has also been reported in cholestasis associated with *t*BOOH-induced oxidative stress[107] (Figure 7). However, under oxidative stress, the type of canalicular protein that is internalized and the signaling molecule involved seem to depend on the magnitude of the oxidative challenge. Low concentrations of the oxidizing

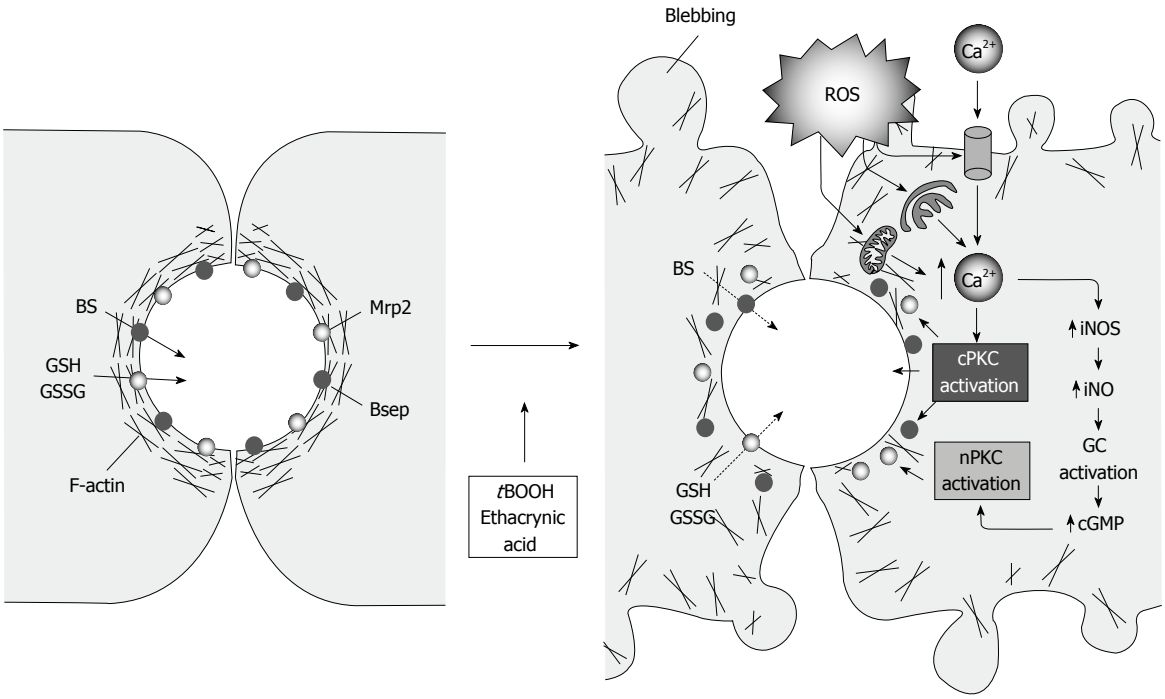

Figure 7 Endocytic internalization of canalicular transporters under oxidative stress. In normal cells, the pericanalicular arrangement of F-actin allows for the appropriate insertion of the canalicular transporters in their membrane domain. Reactive oxygen species produced by the administration of oxidizing compounds, such as tBOOH or ethacrynic acid, induces mobilization of Ca^{2+} across the plasma membrane and membranes of the calciosome (smooth ER and mitochondria), and the subsequent activation of cPKC. cPKC activation induces blebbing and redistribution of F-actin from the pericanalicular region to the cell body. This rearrangement, in turn, leads to canalicular transporter internalization. Moderate Ca^{2+} elevations may also activate iNOS, which induces NO-mediated guanylate cyclase activation and further cGMP-mediated activation of nPKC, which may internalize selectively Mrp2.

compound, ethacrynic acid, does not translocate cPKC, but novel PKC isoforms (nPKC). Under these conditions, the compound internalizes selectively Mrp2 without affecting Bsep, by a mechanism that probably involves Ca^{2+}-dependent activation of inducible nitric oxide (NO) synthase (iNOS), followed by NO-mediated cGMP increase, and further cGMP-activation of nPKC[110]. However, higher doses of ethacrynic acid, sufficient to activate cPKC isoforms, induce internalization of Bsep and Mrp2[110].

The nPKC isoform PKCε is also activated in TLC-induced cholestasis, and has been suggested to be involved in the TLC cholestatic effect[129]. This phenomenon occurs in a PI3K-dependent manner, which is consistent with the finding that PI3K products are potent activators of PKCε[130] (Figure 6). Since PI3K has been also shown to have pro-insertion properties (see above), this may be regarded as paradoxical. However, pro-exocytic and pro-endocytic effects of PI3K have been inferred by using pan-specific inhibitors of PI3K, and different isoforms of this kinase may have accounted for by these different effects.

Anticholestatic therapeutic approaches based upon modulation of dynamic carrier localization

As illustrated above for E2 17G-induced cholestasis, internalization of hepatocellular transporters in cholestasis is spontaneously reversed if the cholestatic insult is transient. This spontaneous recovery occurs by a microtubule-dependent re-targeting of the endocytosed transporters to the canalicular membrane[95]. Some experimental therapeutic approaches have been designed to prevent transporter internalization and/or to accelerate this re-insertion, so as to avoid irreversible consequences of sustained internalization (Figure 6). The therapeutic agents studied include the following.

cAMP: This second messenger partially prevents the impairment of bile flow and internalization of ABC transporters in experimental cholestasis, consistent with its capability to stimulate vesicle-mediated targeting of canalicular transporters[54,55,60]. The drop in bile flow and transport activity of Bsep[90] and Mrp2[89] in the acute phase of E2 17G-induced cholestasis can be partially prevented by cAMP. More significantly, cAMP shortens spontaneous recovery to normality of bile flow, Mrp2 function and Mrp2 localization[89]. A similar acceleration of the re-insertion of endocytosed transporters has been described by our group for Bsep in TLC-induced cholestasis[92]. In isolated rat hepatocyte couplets, a preventive effect of cAMP has been observed in E2 17G-[90,131] and TLC[92,131]-induced Bsep mis-localization. In this case, however, prevention by cAMP is complete. This protective effect is significantly blocked by the Ca^{2+} chelator, BAPTA/AM, but not by the PKA inhibitor, KT5720, which suggests involvement of Ca^{2+}-dependent signaling pathways. A similar anticholestatic mechanism in terms of the signaling modulators involved is afforded by silibinin, the active component of the hepatoprotector silymarin[131]. This most likely

results from the capability of silibinin to inhibit cAMP phosphodiesterase, thus increasing endogenous cAMP intracellular levels[131].

TUDC: This taurine-conjugate bile salt stimulates exocytic insertion of canalicular export pumps as part of its choleretic effect[63], and counteracts endocytic internalization of Bsep[134] and Mrp2[91] in TLC-induced cholestasis (Figure 6). The Ca^{2+}-sensitive, PKC isoform, PKCα, has been proposed to mediate its anticholestatic effect[91], *via* a cooperative PKCα/PKA-dependent mechanism[133]. This is in apparent contradiction with more recent findings that PKCα is cholestatic rather than hepatoprotective[58]. However, the biological response evoked by the interplay between different protein kinases (PKCα/PKA) may be different from that evoked by just one of them (PKCα). Furthermore, TUDC activates Erk[64] and $p38^{MAPK}$[63], and the cholestatic effect of PKCα may be overridden by the choleretic effects of these signal transduction pathways.

4-Phenylbutyrate (4-PBA): This compound has been shown to restore the reduced cell surface expression of cystic fibrosis transmembrane conductance regulator in cystic fibrosis patients, who have mutated forms of the protein, which suggests improved targeting of the transporter to its membrane domain. When the 4PBA-proinserting property was tested for Bsep in normal rats, it was observed that canalicular expression and bile-salt transport function were improved by this compound[134]. A possible mechanism that 4PBA treatment increases the cell-surface-resident Bsep is the interruption of the internalization process from the cell surface to the intracellular compartment, or promotion of recycling from the intracellular compartment back to the cell surface[134]. Stabilization of Bsep in the membrane by 4PBA has also been confirmed in MDCK cells for wild-type Bsep and Bsep with E297G and D482G mutations, which occurs in progressive familiar intrahepatic cholestasis type 2 (PFIC2). Since trafficking of these Bsep-mutated proteins is impaired in PFIC2[135], this agent may be a potential candidate to halt the progression of this genetic disease. Its efficacy in acquired cholestatic diseases remains to be ascertained.

FUTURE DIRECTIONS

The overwhelming progress in molecular biology techniques and the availability of *in vitro*, polarized cell models for the study of hepatobiliary function has greatly facilitated the characterization at a molecular level of the mechanism involved in the sorting of hepatobiliary transport systems from their sites of synthesis, and their recycling from/to endosomal compartments available on demand. However, the increasing number of new cytoskeletal, motor and signaling proteins that are being discovered as a result of these technological developments makes the characterization of their role in transporter trafficking an endless challenge.

Advances in the molecular field have promoted a parallel progress in the understanding of the consequences that the alterations in the mechanisms of trafficking have in liver disease. It is becoming increasingly evident that impairment in the dynamic localization of hepatocellular transporters is a common feature in hepatocellular cholestasis. However, the characterization of the molecular mechanisms that underlie this alteration is in its infancy. Many crucial questions remain to be answered, for example: (1) which are the signaling mediators that trigger endocytosis of canalicular transporters in each kind of cholestasis; (2) which are the molecular targets of these cholestatic mediators that ultimately govern carrier internalization?; and (3) can changes in localization of these transporters be not only prevented but, what is more important from the therapeutic point of view, reversed by factors that counteract these dysfunctions? Satisfactory answers to these questions would allow the design of new therapeutic strategies in cholestatic liver diseases to assure proper localization of transporters in an attempt to prevent their accelerated degradation. We hope that progress in experimental therapeutics based on this current information encourages clinical researchers to apply this knowledge to envisage better, innovative therapeutic alternatives for the treatment of human cholestatic liver disease.

Abstract

AIM: To evaluate the effects of interferon-α-2b (IFN-α-2b) on expression of cyclooxygenase-2 (COX-2) and vascular endothelial growth factor (VEGF) in human hepatocellular carcinoma (HCC) inoculated in nude mice and to study the underlying mechanism of IFN-α-2b against HCC growth.

METHODS: Thirty-two nude mice bearing human HCC were randomly divided into four groups (n = 8). On the 10th day after implantation of HCC cells, the mice in test groups (groups A, B and C) received IFN-α-2b at a serial dose (10 000 IU for group A, 20 000 IU for group B, 40 000 IU for group C sc daily) for 35 d. The mice in control group received normal saline (NS). The growth conditions of transplanted tumors were observed. Both genes and proteins of COX-2 and VEGF were detected by RT-PCR and Western blot. Apoptosis of tumor cells in nude mice was detected by TUNEL assay after treatment with IFN-α-2b.

RESULTS: Tumors were significantly smaller and had a lower weight in the IFN-α-2b treatment groups than those in the control group (P < 0.01), and the tumor growth inhibition rate in groups A, B and C was 27.78%, 65.22% and 49.64%, respectively. The expression levels of both genes and proteins of COX-2 and VEGF were much lower in the IFN-α-2b treatment groups than in the control group (P < 0.01). The apoptosis index (AI) of tumor cells in the IFN-α-2b treatment groups was markedly higher than that in the control group (P < 0.01). Group B had a higher inhibition rate of tumor growth, a lower expression level of COX-2 and VEGF and a higher AI than groups A and C (P < 0.05), but there was no significant difference between groups A and C.

CONCLUSION: The inhibitory effects of IFN-α-2b on implanted tumor growth and apoptosis may be associated with the down-regulation of COX-2 and VEGF expression. There is a dose-effect relationship. The medium dose of IFN-α-2b for inhibiting tumor growth is 20 000 IU/d.

INTRODUCTION

In recent years, studies have proved the inhibitory effects of interferon-α-2b (IFN-α-2b) on many kinds of tumors[1-3], but the effects of IFN-α-2b on expression of cyclooxygenase-2 (COX-2) and vascular endothelial growth factor (VEGF) in hepatocellular carcinoma (HCC) have not been extensively studied. This study investigated the effects of IFN-α-2b on COX-2 and VEGF expression in human HCC implanted in nude mice and the underlying mechanism of its inhibitory effect on the growth of HCC.

MATERIALS AND METHODS

Reagents

HCC cell line HepG2 was stored in our laboratory. Rabbit anti-human COX-2 polyclonal antibody (Santa Cruz, US) was purchased from Beijing Zhongshan Biotechnology Company, Ltd. Mouse anti-human VEGF polyclonal antibody (Neomarkers, USA), TRIzol and RT-PCR kits were from Jinmei Biotech Company, Ltd. Primers of RT-PCR were synthesized by Alpha Biotechnology Company (Wuhan, China). *In situ* apoptosis detection kits (Boehringer Mannheim, Germany) and ECL chemiluminescence detection kits (Pierce, US) were from Beijing Zhongshan Biotechnology Company, Ltd. IFN-α-2b injection (trade name: Interlong) was from Shenzhen Neptunus Interlong Bio-tech Holdings Company, Ltd (China).

Animal model

A transplantation tumor model of human HCC in nude mice was established. In brief, thirty-two 4-6 wk old female BALB/c nu/nu mice, weighing 18-20 g, bred in SPF rooms, were obtained from the Experimental Animal Center of Tongji Medical University, Huazhong University of Science and Technology (Wuhan, China). The concentration of single cell suspension of HepG2 cells was adjusted to 5×10^9/L at the exponential growth phase. The cell viability was kept above 95% assessed by Typan blue exclusion. Then, the cell suspension was inoculated subcutaneouly in the back of nude mice (0.2 mL/each mouse). The standard of tumor formation was defined as its nodus diameter (up to 0.5 cm). The rate of tumor formation was 100% 10 d after inoculation. The mice meeting the standard of tumor formation were randomly divided into 4 groups (n = 8).

Drugs and groups

Each nude mouse meeting the standard of tumor formation in groups A, B and C received 10 000 IU IFN-α-2b, 20 000 IU and 40 000 IU of IFN-α-2b, respectively, once a day for 35 d. Each nude mouse in control group received only 0.1 mL normal saline (NS), once a day for 35 d. Then, the mice were killed. The maximum and minimum diameters of tumor were measured with a sliding caliper and the weight of tumor was recorded. A certain number of samples were stored at -70℃. The rest samples were fixed in 10% formalin, imbedded in paraffin, and cut into serial sections for assay of *in situ* apoptosis. Volume of tumor (V) = ab2/2, inhibition ratio (%) = [(mean tumor weight of control group-mean tumor weight of test group)/ mean tumor weight of control group] × 100%.

RT-PCR assay

Total RNA was extracted with the TRIzol through one-step method, and its concentration and purity were detected using a DNA/RNA detector (Pharmarcia Company, British). cDNA was synthesized by a reverse transcription reaction of 4 μg of total RNA with oligo-$(dt)_{15}$ primers and retroviridase at 45℃ for 60 min, and stored at -20℃.

The sequences of primers used for semi-quantitative PCR are as follows: sense: 5'-CAAGT CCCTGAGCATCTACG-3' and anti-sense: 5'-CA TTCCTACCACCAGCAACC-3' for COX-2; sense: 5'-TTGCTGCTCTACCTCCAC-3' and anti-sense: 5'-AATGCTTTCTCCGCTCTG-3' for VEGF; sense: 5'-CAGAGCAAGAGAGGCAGCCT-3' and anti-sense: 5'-GGATAGCACAGCCTGGATAG-3' for β-actin. PCR conditions were as follows: 30 cycles at 94℃ for 1 min, at 54℃ for 30 s, and at 72℃ for 1 min for COX-2; 27 cycles at 94℃ for 1 min, at 56℃ for 30 s, and at 72℃ for 1 min for VEGF; 30 cycles at 94℃ for 1 min, at 59℃ for 30 s, and at 72℃ for 1 min for β-actin. The lengths of PCR products of COX-2, VEGF and β-actin were 490 bp, 417 bp and 250 bp, respectively. After separated by electrophoresis on 1.5% agarose gel, the bands of PCR products were scanned and a densitometric analysis was performed with a MUVB-20 gel analysis system (Ultralum Company, USA). The relative expression levels of COX-2 mRNA and VEGF mRNA were represented as absorbance ratios (COX-2/β-actin and VEGF/β-actin).

Western blot assay

The protein was extracted from tumor tissue through three-detergent methods. An equal quantity of protein was separated from each sample by electrophoresis on 10% SDS-PAGE gel, and then transferred to a nitrocellulose filter (NC filter) with a semidry transfer cell. The NC filter containing protein samples was incubated in a blocking buffer containing 5% nonfat dry milk for 2 h, then with the first antibody at a dilution of 1:250 in a blocking buffer overnight at 4℃. After washed with 0.1% TBS, the membrane was incubated at room temperature for 1 h with the second antibodies at a dilution of 1:5000 in a blocking buffer, then washed three times with 0.1% TBS, visualized, photographed and fixed through ECL according to its manufacturer's instructions. The absorbance value of protein bands was assessed with an image analysis system.

TUNEL assay

Paraffin-embedded tumor samples were cut into serial 4-5 μm thick serial sections, heated overnight at 58℃, and routinely deparaffinized and rehydrated. After digested by protease K for 15 min, the sections were incubated with TUNEL at 37℃ for 1 h. After digoxin-marked alkaline phosphatase antibody was added, the sections were colored with BCIP/NBT, dehydrated with alcoholic, air dried, and mounted. Positive cells were defined as hyacinthine particles distributing in nuclei. Five high power fields were randomly selected from each section. Results were expressed as mean values. Apoptosis index (AI) = [the number of apoptosis cells/ (the number of apoptosis cells+ the number of un-apoptosis cells)] × 100%.

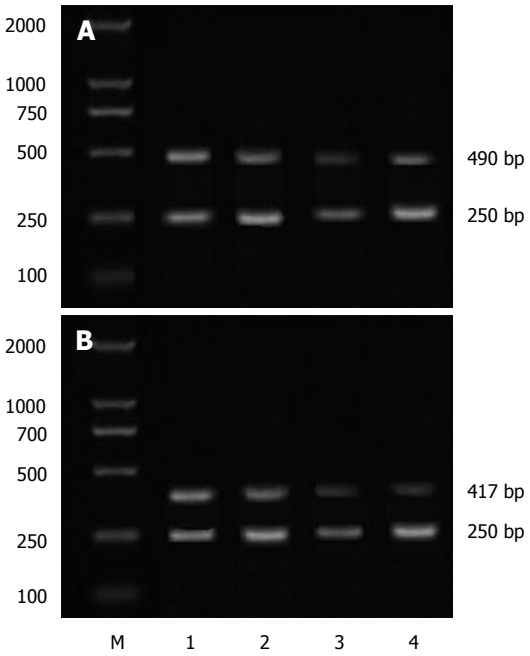

Figure 1 RT-PCR showing expression levels of COX-2 mRNA (A) and VEGF mRNA (B). M: Marker.

Statistical analysis

Data were presented as mean ± SD. SPSS 11.5 was employed to analyze the data. The total difference among groups was analyzed by ANOVA. *Q*-test was used for the comparison between two groups. $P < 0.05$ was considered statistically significant.

RESULTS

Inhibitory effect of IFN-α-2b on transplanted tumors of nude mice

The tumor growth in three IFN-α-2b treatment groups was inhibited at different degrees. The inhibition rate of tumors in groups A, B and C was 27.78%, 65.22% and 49.64%, respectively. The weight and volume of tumors were lower in three IFN-α-2b treatment groups than in control group ($P < 0.01$). The inhibitory effect was the greatest in group B, and significantly different from that in groups A and C ($P < 0.01$), but the difference was not statistically significant between groups A and C (Table 1).

Expression of COX-2 and VEGF mRNA in transplanted tumors of nude mice

RT-PCR showed that the expression levels of COX-2 and VEGF mRNA were lower in three IFN-α-2b treatment groups than in control group ($P < 0.01$). Meanwhile, their expression levels were significantly lower in group B than in groups A and C ($P < 0.05$), but the difference was not statistically significant between groups A and C (Table 2, Figure 1).

Expression of COX-2 and VEGF protein in transplanted tumors of nude mice

Western blot assay showed that the expression levels of COX-2 and VEGF protein were lower in three IFN-α-2b treatment groups than in control group ($P < 0.01$). Statistical analysis revealed similar results of COX-2 and VEGF mRNA in three IFN-α-2b treatment groups (Table 2, Figure 2).

Apoptosis of transplanted tumors of nude mice

TUNEL assay showed that the AI of tumor cells in the

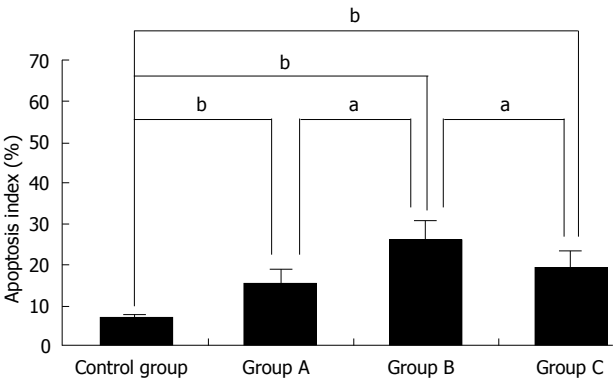

Figure 3 Changes in AI of transplanted HCC cells of nude mice. [a]*P* < 0.05, [b]*P* < 0.01 *vs* groups A and C.

4 groups was 6.39% ± 1.33%, 15.39% ± 3.09%, 25.53% ± 4.98% and 19.28% ± 3.82%, respectively, and was significantly higher in three IFN-α-2b treatment groups than in control group ($P < 0.01$). However, the AI in group B was higher than that in groups A and C ($P < 0.05$), but the difference was not statistically significant between groups A and C (Figures 3-4).

DISCUSSION

HCC is one of the malignant tumors that can lead patients to death[1], but the molecular mechanism of hepatocarcinogenesis has not been well understood. COX can be divided into two subtypes: COX-1 and COX-2. COX-2 is a rate-limiting enzyme of prostaglandin (PG) biosynthesis, encodes for 603 or 604 amino acids including 17 signal peptides of amino acid residues, contains 4 oligoses and 2 bands (molecular weight = 72 KDa and 74 KDa, respectively) in SDS-PAGE. Oshima *et al*[2] showed that the expression of COX-2 is up-regulated in colon tumors and its activity plays an important role in the process of tumorigenesis. Besides, the expression of COX-2 is also higher in liver, breast, tongue, prostatic, cutaneous and mouth dermoid cancers, *etc*[3-5].

It has been recently proved that COX-2 is also expressed in HCC at different degrees and HCC patients with a higher expression level of COX-2 have a higher recurrence rate, early metastasis and worse prognosis[6,7], suggesting that over-expression of COX-2 may be related with a worse prognosis of HCC. The five-year survival rate of HCC patients after operation is only 25%-39%. Some studies indicate that over-expression of COX-2 may promote oncogenesis by regulating the expression of some genes related to cell proliferation and apoptosis[6,7]. The underlying mechanism of COX-2 against oncogenesis may be through influencing many kinds of prostaglandin and thromboxan to bind to their corresponding receptors.

Angiogenesis plays an important role in tumorigenesis and tumor development. If no angiogenesis occurs, the volume of tumor can hardly be larger than 1-2 mm^3. The degree of angiogenesis depends on the rate of angiogenesis and anti-angiogenesis factors in tumor cells and adjacent host cells. The angiogenesis factors mainly include bFGF, VEGF, IL-8, MMP-2, MMP-9, *etc*. Among them, VEGF is most important, and plays a leading role in the growth, generation, recurrence and metastasis of tumors[8-11]. As a dipolymer, glucoprotein has a molecular weight of 34-46 kDa. VEGF exerts its biological effect by binding specifically to Flt1 and KDR/Flk1 exiting on the surface of vascular endothelial cells which belong to RTKⅢ receptors. A recent study showed that angiogenesis and VEGF play an important role in the recurrence and metastasis of HCC[12]. It was reported that the expression of VEGF is up-regulated in HCC and positively correlated with the recurrence and metastasis of HCC after operation[13].

Interferon (IFN) regulates the activity of cytokines which control cell function and replication, and inhibits the activity of tumor cells in many organs and tissues[14-16]. It has been shown that IFN-α decreases the sensitivity of vascular endothelial cells to VEGF and bFGF, as well as the vascularization of tumors[17].

The results of this study indicate that IFN-α-2b could significantly inhibit the growth of HCC in nude mice. The volume and weight of transplanted tumors decreased evidently in IFN-α-2b treatment groups. The expression levels of COX-2 and VEGF mRNA and protein as well as the AI increased significantly in IFN-α-2b treatment groups, indicating that the expression levels of COX-2 and VEGF are closely related with the growth of tumor and apoptosis of tumor cells. IFN-α-2b can down-regulate the expression levels of COX-2 and VEGF, but its mechanism remains unknown. Singer *et al*[18] reported that IFN-α exerts its effects through the NF-κB signal transduction pathway, and inhibitors of NF-κB can decrease the expression level of COX-2. A study about the effect of IFN-α on a signal transduction pathway showed that IFN-α could reduce the activity of NF-κB[19], suggesting that IFN-α-2b can decrease the activity of the NF-κB signal transduction pathway, inhibit the expression of COX-2 and the growth of HCC, and induce apoptosis. It has been shown that IFN-α can down-regulate the expression levels of angiogenesis factors, such as bFGF, VEGF, MMP-9 and IL-8, in different tumors of humans, then inhibit angiogenesis and the growth of tumors[20]. Tsujii *et al*[21] investigated the correlation between COX-2 and angiogenesis of colon carcinoma and found that colon carcinoma cells could secrete angiogenesis factors, such as VEGF, bFGF, TGF-β1 and PDGF, at a high concentration. Inhibitors of COX-2 can significantly depress the expression of angiogenesis factors, indicating that COX-2 can promote the growth of tumors, which is closely related with its effect on promoting angiogenesis. We hold that IFN-α-2b can inhibit HCC growth by inducing apoptosis of tumor cells through down-regulation of COX-2 expression and by inhibiting angiogenesis of tumors through down-regulation of VEGF expression. COX-2 may influence the expression of VEGF. The signal transduction between COX-2 and VEGF still needs to be further studied.

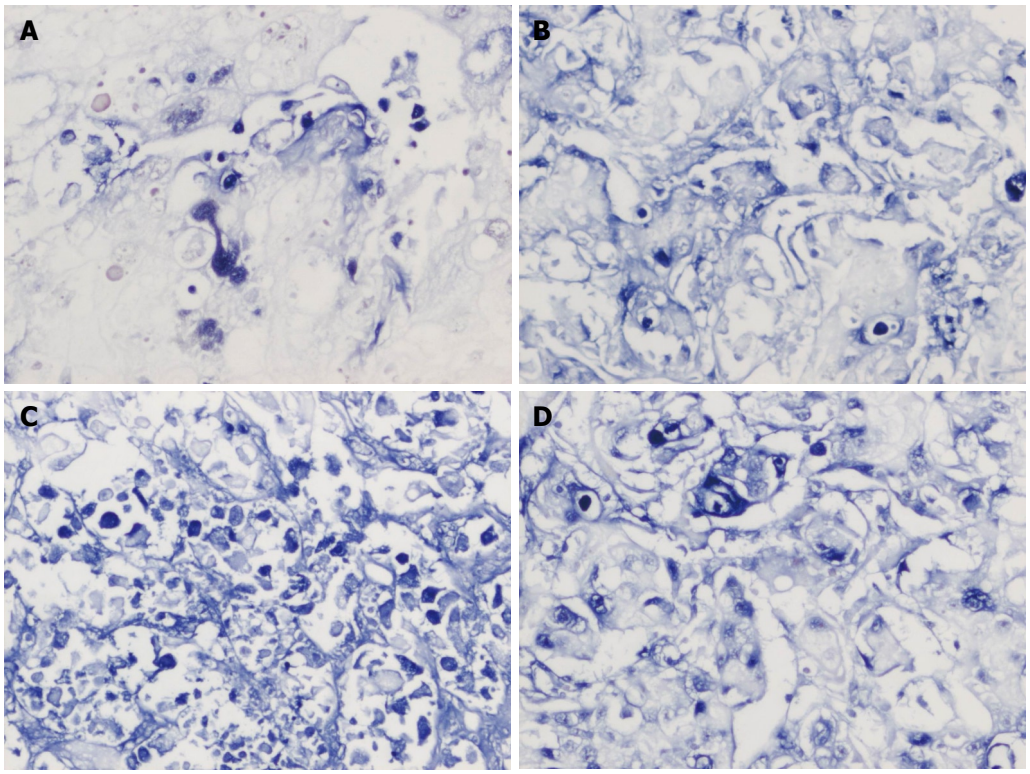

Figure 4 Apoptosis of transplanted HCC (TUNEL × 200). A: Control group; B: Group A; C: Group B; D: Group C.

In this study, the inhibitory effect of IFN-α-2b on HCC growth in nude mice showed a dose-effect relationship. The effect of IFN-α-2b was greater in group B than in groups A and C. However, there was no significant difference between groups A and C. Huang *et al*[22] have reported a similar result in nude mice bearing carcinoma of prostate after treatment with pegylated IFN-α-2b (PEG-IFN-α-2b). At present, no common view is available on the dose of IFN α. Wang *et al*[23] investigated the treatment of nude mice bearing orthotopically transplanted HCC with large doses of IFN-α (3×10^5 U/d and 6×10^5 U/d) and showed that IFN-α could inhibit metastasis and angiogenesis of HCC at a certain degree. Because the signal transduction of IFN is mediated by the JAK/STAT pathway, SOSC protein could down-regulate the signals of IFN by blocking up the JAK/STAT pathway. Although studies are available on the activity of STAT3 inhibited by SOSC3[24-26], further study is needed to show the maximally tolerated dose of IFN-α and its correlation with the signal transduction of STAT1.

It has been shown that nonsteroidal anti-inflammatory drugs (NSAIDs) and INF-α have a synergistic effect on the HCC cell line HepG2. NSAIDs up-regulate the transcription of ISRE, increase the activity and inhibitory effect of IFN-α on tumors, thus providing a new treatment modality for HCC with IFN α[27].

COMMENTS

Background

In recent years, the inhibitory effect of interferon-α-2b (IFN-α-2b) on many tumors has been proved, but its effect on the expression of cyclooxygenase-2 (COX-2) and vascular endothelial growth factor (VEGF) in hepatocellular carcinoma (HCC) has rarely been reported.

Research frontiers

HCC is one of the malignant tumors that can lead to death of patients, but the molecular mechanism of hepatocarcinogenesis remains poorly understood.

Innovations and breakthroughs

Studies have proved the inhibitory effects of interferon-α-2b (IFN-α-2b) on many kinds of tumors. However, the effects of IFN-α-2b on expression of cyclooxygenase-2 (COX-2) and vascular endothelial growth factor (VEGF) in hepatocellular carcinoma (HCC) have not been extensively studied. This study investigated the effects of IFN-α-2b on COX-2 and VEGF expression in human HCC implanted in nude mice and the underlying mechanism of its inhibitory effect on the growth of HCC.

Applications

This study investigated the effects of IFN-α-2b on COX-2 and VEGF expression in human HCC implanted in nude mice and the underlying mechanism of its inhibitory effect on the growth of HCC. The results show that IFN-α-2b can be used as an effective agent in the treatment of HCC.

Peer review

The study is well designed. The results of this study are interesting and seem to be reliable.

Abstract

AIM: To determine if blockade of P-selectin in the isolated blood-perfused cold *ex vivo* rat liver model protects the liver from ischemia-reperfusion injury.

METHODS: The effect of P-selectin blockade was assessed by employing an isolated blood-perfused cold *ex vivo* rat liver with or without P-selectin antibody treatment before and after 6 h of cold storage in University of Wisconsin solution.

RESULTS: In our isolated blood-perfused rat liver model, pre-treatment with P-selectin antibody failed to protect the liver from ischemia-reperfusion injury, as judged by the elevated aspartate aminotransferase activity. In addition, P-selectin antibody treatment did not significantly reduced hepatic polymorphonuclear leukocyte accumulation after 120 min of perfusion. Histological evaluation of liver sections obtained at 120 min of perfusion showed significant oncotic necrosis in liver sections of both ischemic control and P-selectin antibody-treated groups. However, total bile production after 120 min of perfusion was significantly greater in P-selectin antibody-treated livers, compared to control livers. No significant difference in P-selectin and ICAM-1 mRNAs and proteins, GSH, GSSG, and nuclear NF-κB was found between control and P-selectin antibody-treated livers.

CONCLUSION: In conclusion, we have shown that blockade of P-selectin alone failed to reduced polymorphonuclear leukocyte accumulation in the liver and protect hepatocytes from ischemia-reperfusion injury in the isolated blood-perfused cold-*ex vivo* rat liver model.

INTRODUCTION

Ischemia-reperfusion (I/R)[3] injury has been shown to play a major role in clinical and experimental hemorrhagic shock, organ resection, and transplantation[1-5]. The inflammatory component of I/R injury is mediated by pro-inflammatory cytokines such as TNF-α and IL-1β, and cellular adhesion molecules such as β2-integrins, ICAM-1, VCAM-1, and members of the selectin family, P-, E-, and L-selectin[6-8]. The sequence of events currently enjoying the most popularity as the mechanism responsible for I/R injury of the liver is: (1) KC are activated following I/R[9]; (2) During early reperfusion (0-2 h), KC are further activated by complement and produce significant vascular oxidative stress[10]; (3) KC also produce pro-inflammatory cytokines and chemokines, which is dependent on the activation of the redox-sensitive transcription factor NF-κB[11]. Activated hepatocytes and endothelial cells also produce reactive oxygen species (ROS) and contribute to the liver cytokine-chemokine milieu; (4) Cytokine mediated induction of adhesion molecules such as P- and E-selectins, ICAM-1, and VCAM-1 on the liver endothelium occur during reperfusion; (5)

PMNs accumulate in the liver as a result of P- and E-selectin-mediated rolling and margination on the liver endothelium, followed by ICAM-1-dependent firm adhesion. Although PMNs accumulate in the liver during early reperfusion, they do not contribute to liver injury until the latter phase (6-24 h) of I/R injury[10,12,13]; and (6) PMNs transmigrate to the liver parenchyma *via* ICAM-1 and VCAM-1, bind to hepatocytes *via* ICAM-1/β2-integrins (CD11b/CD18), and engage in a sustained production of ROS to produce intracellular oxidative stress in hepatocytes and cell death[14-17].

Following I/R of several organs or tissues, a general mechanism of selectin-dependent rolling of PMNs followed by firmer adhesion to endothelial cells by integrins and ICAM-1 is applicable to their vasculature (heart, lung, intestine, and cremaster muscle). Accordingly, numerous studies reported that anti-P-selectin therapy afforded protection to the liver from I/R injury[18-21]. However, this general mechanism may not be applicable to the liver[13,14]. Numerous reports suggest that P-selectin attenuates I/R injury of the liver by mediating the recruitment of PMNs[18-20], while other reports minimize its role in liver I/R injury and its role in recruiting PMNs in the inflamed liver vasculature[21-26]. Furthermore, hepatic PMNs accumulation, mediated by P-selectin expressed on endothelial cells of postsinusoidal venules, might not contribute significantly to liver injury, because there is no experimental evidence supporting extravasation of these neutrophils to the liver parenchyma[23,26]. In addition, a recent report by Kubes et al. suggest that the protective effect observed in the liver with anti-P-selectin therapy may be mostly secondary to the anti-P-selectin therapy of accompanying intestinal I/R injury[27].

If the above scenario is to hold, then blockade of P-selectin should prevent or attenuate I/R injury, at least during the latter phase of I/R injury in the warm in vivo liver model. Therefore, to investigate if P-selectin blockade alone protects the liver from I/R injury, we employed an antibody to P-selectin and a cold-*ex vivo* I/R rat liver model. The present study demonstrates that while anti-P-selectin treatment may increase total bile flow in livers subjected to I/R, it failed to protect hepatocytes in the isolated blood-perfused rat liver model.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats (250-350 g) were purchased Charles Rivers, Houston, TX). All an imals used in this study received a nutritionally balanced rodent diet, water ad libitum, and were cared for according to NIH guidelines.

Isolated-Perfused-Rat-Liver (IPRL) model

In brief, animals were anaesthetized with Nembutal (50-60 mg/kg bd. wt., ip, Sigma-Aldrich, St. Louis, MO), and under aseptic conditions, a laparotomy performed to access the liver for mobilization. Livers were carefully isolated from male Sprague-Dawley rats under Nembutal anesthesia after cannulation of the portal vein, common bile duct, and suprahepatic vena cava, while constantly perfused with oxygenated Krebs-Hensleit buffer (pH 7.4) *via* the portal vein[28]. Immediately after isolation, control and treated livers were flushed with 10 mL of pristine UW solution, and stored at 4℃ for 6 h. Livers in the treated group received an additional flush of 1 mL of UW solution containing 420 μg of P-selectin Ab (CD62P, Cat.#553716, PharMingen, San Diego, CA) *via* the portal vein before cold-*ex vivo* ischemia (storage) and immediately before perfusion. This antibody has been show to inhibit the binding of neutrophils to rat P-selectin in both in vitro and in vivo studies. Control livers were also flushed with 1 mL of pristine UW solution immediately before perfusion. At the end of cold storage, livers were perfused with syngenic rat blood (diluted with Krebs-Hensleit buffer (pH 7.4) to a hematocrit of 12%, total volume 100 mL) in a re-circulating perfusion system using a fully-jacketed isolated-perfusion-rat-liver apparatus (RGT #130003, Radnoti Glass Technology, Inc., Monrovia, CA) for 120 min, as previously described[10]. Prior to perfusion, the perfusion apparatus was primed with blood perfusate at 37℃. Oxygenation was done with a membrane-oxygenating chamber (PO_2 held > 250 mm Hg) monitored with inline-digital pressure transducer. Portal vein perfusate flow was continually adjusted to maintain portal pressures between 18 and 23 mm Hg, and monitored with inline-digital pressure transducer. Temperature, pH, and oxygen level were maintained throughout each experiment. Liver sections (snap-frozen in liquid nitrogen), blood perfusate, and bile (collected in pre-weighed eppendorf tubes) were collected every 30 min during perfusion. At the end of each experiment, sections of the liver were snap-frozen or placed in buffered-formalin, for blinded-histological evaluation of hematoxylin and eosin (HE) stained liver sections by a pathologist and determination of PMNs accumulation in the liver.

Plasma aspartate aminotransferase activity

Plasma AST activity was determined with a commercially available kit (#DG158K-U, Sigma Diagnostics, St. Louis, MO).

Histological analysis of liver injury

HE sections from formalin-fixed liver tissues obtained from sham-control and P-selectin Ab-treated livers were randomly selected and blindly analyzed for the degree of necrosis, hepatocellular vacuolization, glycogen depletion, zonal variations, and sinusoidal congestion, as measures of hepatic injury.

Polymorphonuclear leukocyte (PMNs) accumulation in the liver

PMNs accumulation in rat livers during perfusion was determined in formalin-fixed paraffin sections of the

liver obtained at each perfusion-sampling time point as previously described[29]. A commercially available kit (91-C, Sigma-Aldrich, St. Louis, MO) was used to stain for sinusoidal-sequestrated PMNs using the well-established Naphthol AS-D Chloroacetate esterase procedure, according to the manufacturer's directions. At least four random sections from each group were analyzed by viewing (blindly) fifty random high power fields (HPF, × 40) on each section. Results were expressed as number of PMNs/50HPF.

RT-PCR analysis of Liver P-selectin and ICAM-1 mRNAs

Total RNA was extracted from liver tissue using an UltraSpec Total RNA Isolation Kit (#BL-10050, Biotecx Laboratories Inc., Houston, TX). Complementary DNA (cDNA) was transcribed with 4 μg of total RNA, random hexamers, and a SuperScript Ⅱ Preamplification System (#18089-011, GIBCO BRL, Life Technologies, Grand Island, New York) according to the manufacturer's protocol. Using specific primers for p-selectin ICAM-1, and GAPDH, their cDNAs were amplified by polymerase chain reaction (PCR) under the following conditions: P-selectin and ICAM-1 (35 cycles, 94℃ for 60 s, 56℃ for 60 s, and 72℃ for 120 s), and GAPDH, (28 cycles, 94℃ for 60 s, 52℃ for 60 s, and 72℃ for 60 s). PCR reaction primers (Sigma-Genosys, Woodlands, TX) used were as follows: P-selectin forward primer (5'-TGTATCCAGCCTCTTGGGCATTCC-3') and P-selectin reverse primer (5'-TGGGACAGGAAGTGA TGTTACACC-3') to give an 350-bp product; ICAM-1 forward primer (5'-AGGTGTGATATCCGGTAG-3') and ICAM-1 reverse primer (5'-TGGGACAGGAA GTGATGTTACACC-3') to give an 595-bp product; GAPDH forward primer (5'-GCCAAGTATGACAT CAA-3') and GAPDH reverse primer (5'-CCATATT CATTGTCATACCA-3') to give a 203-bp product. All PCR products were electrophoresed on a 2% agarose gel (Fisher Scientific, Fair Lawn, NJ). Bands were visualized by post staining for 30 min with GelStar Nucleic Acid Gel Stain (FMC Bioproducts, Rockland, MA), and photographed. Photographs were digitized and evaluated as stated above. The relative expression of P-selectin and ICAM-1 messenger RNAs (mRNA) were assessed by taking the ratio of the intensity of the DNA bands of P-selectin and ICAM-1 to GAPDH band, and expressed as arbitrary units. To ensure an equal amount of RNA was used for all samples, RNA concentration was determined spectrophotometrically, and its integrity evaluate on agarose gel. DNA bands were digitized (Corel Photohouse 2.0, Ontario, Canada) and evaluated using an image analysis software (Scion Image Beta 3b, NIH Image modified for Windows by Scion Corporation, Frederick MD).

Western blot analysis of liver P-selectin and ICAM-1 proteins

Homogenates and supernatants of liver samples were prepared as described by Vural *et al*[30]. Proteins (P-selectin (14 μg) and ICAM-1 (27 μg)) in liver supernatants were separated on 6% NuPAGE gels (Invitrogen, Carlsbad, CA) and transferred to nitrocellulose membranes (Schleicher and Schuel, Dassel). Equal transfer to membranes was confirmed by staining the membranes with Ponceau S (Aldrich-Sigma, St. Louis, MO). P-selectin bands were detected on membranes by incubating with an anti-P-selectin-specific rabbit primary antibody diluted 1:100 (CD62P, PharMingen, San Diego, CA). A horseradish peroxidase-conjugated anti-rabbit secondary antibody (sc-2350, Santa Cruz Biotechnology, Inc., Santa Cruz, CA) diluted 1:1000 and an enhanced chemiluminescence (ECL) kit (Amersham Life Sciences, Piscataway, NJ) were used to visualize bands. ICAM-1 was detected on membranes by incubating with an anti-ICAM-1-specific mouse primary antibody (MCA1333R, Serotec, Raleigh, NC) diluted 1:50. A horseradish peroxidase-conjugated anti-mouse secondary antibody (Amersham Life Sciences, Piscataway, NJ) diluted 1:1000 was used to reveal ICAM-1 as described above. To ensure equal loading and normalize Western-blot bands of P-selectin and ICAM-1, membranes were also probed for β-actin. Membranes were immunoblotted for β-actin with an affinity purified goat polyclonal antibody diluted 1:500 (sc-1616, Santa Cruz Biotechnology, Inc., Santa Cruz, CA) and a horseradish peroxidase-conjugated anti-goat secondary antibody (sc-2350, Santa Cruz Biotechnology, Inc., Santa Cruz, CA) (diluted 1:1000). Actin bands were visualized with a commercially available ECL kit, as stated above.

Liver total (GSH + GSSG) and oxidized (GSSG) glutathione levels

Liver GSH + GSSG and GSSG levels were determined by the method of Tietze[31], as previously described by Jaeschke *et al*[14].

Liver nuclear factor-kappa B (NF-κB) activation

Activation of the redox-sensitive transcription factor NF-κB in control and P-selectin Ab-treated livers was measured using a commercially available ELISA kit (Trans-AM™ NF-κB p65 Transcription Factor Assay Kit, Active Motif, Carlsbad, CA). The assay was performed according to the manufacturer's procedure and as described by Renard *et al*[32]. Nuclear proteins were extracted according to the procedure of Osarogiagbon *et al*[33]. Approximately 100 mg of snap-frozen liver tissue was homogenized in 0.4 mL of cold TM buffer (10 mmol/L Tris-HCl, 1 mmol/L $MgCl_2$ (pH 7.0), containing complete™ protease inhibitors (Roche Diagnostics Corp., IN). Homogenates were centrifuged at 2000 r/min for 30 s, and the supernatant mixed with 200 μl of lysis buffer, incubated at 4℃ for 5 min, and centrifuged at 5000 r/min for 10 min. The nuclear pellets were reconstituted with lysis buffer, and centrifuged at 14000 r/min for 20 s at 4℃. Nuclear protein extract (15 μg) of each sample was used to assay for NF-κB activation. To ensure the specificity of the assay, the wild-type consensus oligonucleotide provided by the manufacturer served as a competitor to NF-κB binding.

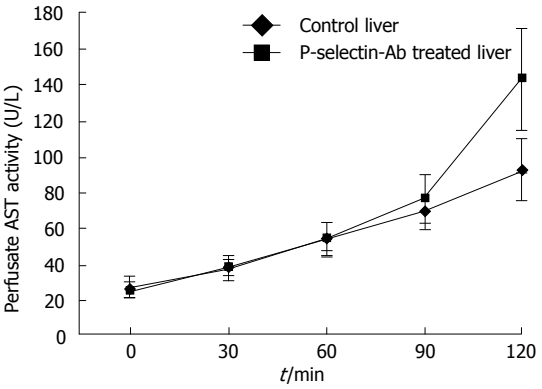

Figure 1 Perfusate aspartate aminotransferase (AST) activity in isolated-blood-perfused control and P-selectin-Ab treated rat livers after 6 h of cold ischemia.

Protein concentration

All protein concentrations were determined according to the method of Lowry *et al*[34].

Statistical analysis

Data were analyzed by unpaired Student's *t*-test or ANOVA. After ANOVA, results were subsequently subjected to Tukey's or Student-Newman Keuls non-parametric test to determined significant differences between groups.

RESULTS

Plasma AST activity, histologic analysis, and PMNs accumulation in the cold ex vivo -perfused liver

No significant difference in AST activity was found between control and P-selectin Ab-treated livers throughout the perfusion period (Figure 1). In addition, after 120 min of perfusion, similar degrees of point necrosis (solid arrows, Figure 2A, B) and inflammation (arrow heads, Figure 2C, D) were found in both cold *ex vivo*-perfused control and P-selectin Ab-treated livers. Similarly, no significant difference in hepatic PMNs accumulation was found between control and P-selectin Ab-treated livers after 120 min of perfusion (Figure 3).

Bile production in cold ex vivo-perfused liver

No significant difference in bile flow was found between control and P-selectin Ab-treated livers at individual sampling time-points throughout the perfusion period (data not shown). However, total bile production after 120 min of perfusion was significantly greater in P-selectin Ab-treated livers, compared to control (Figure 4).

RT-PCR analysis of P-selectin and ICAM-1 mRNAs in the cold-ex vivo perfused liver

No significant difference in P-selectin mRNA and protein was found between cold-*ex-vivo* perfused control and P-selectin Ab-treated livers throughout the entire perfusion period (Figure 5A, B). In contrast, a significant reduction in ICAM-1 mRNA was found between cold-*ex-vivo* perfused control and P-selectin Ab-treated livers at 60 min of perfusion (Figure 5A). However, although a corresponding reduction in ICAM-1 protein was found, it did not reach statistical significance (Figure 5B). No significant difference in ICAM-1 mRNA and protein was found between cold *ex-vivo*-perfused control and P-selectin Ab-treated livers at all other time points of the perfusion period (Figure 5).

Western blot analysis of P-selectin and ICAM-1 proteins in the cold-ex-vivo perfused liver

No significant difference in P-selectin and ICAM-1 proteins was found between cold *ex-vivo*-perfused control and P-selectin Ab-treated livers throughout the entire perfusion period (Figure 6A, B). Although P-selectin expression at 90 min of perfusion is clearly greater in control livers compared to Ab-treated livers, the intra-group variance precluded statistical significance.

GSH + GSSG and GSSG levels in the cold-ex vivo-perfused liver

No significant difference in GSH + GSSG and GSSG levels was found between cold *ex-vivo*-perfused control and P-selectin Ab-treated livers throughout the entire perfusion period (Figure 7).

NF-κB activation in cold ex vivo-perfused liver

No significant difference in NF-κB activation was found between cold *ex-vivo*-perfused control and P-selectin Ab-treated livers throughout the entire perfusion period (Figure 8).

DISCUSSION

Our study demonstrates that antibody-blockade of P-selectin alone failed to protect the rat liver from I/R injury in the IPRL model. However, as stated earlier, considerable evidence exist that suggests that P-selectin plays a major role in I/R injury[18-21]. Existing reports also suggest that P-selectin mediates I/R injury of the liver by mediating initial rolling and margination of PMNs in the liver vasculature[18-20]. However, other reports minimize its role in liver I/R injury, and its role in recruiting PMNs in the inflamed liver vasculature[21-26].

At present, no convincing evidence exist for P-selectin expression on the mouse, human, and rat sinusoidal endothelia under normal and inflammatory conditions[22,35,36], although a more recent study reported immunohistochemical evidence of P-selectin protein expression on the rat liver sinusoid endothelium after cold storage and orthotopic liver transplantation[37]. In the present study, the accumulation of PMNs in livers after P-selectin blockade is probably due to physical trapping, resulting from the swelling of sinusoidal cells (e.g. endothelial and Kupffer cells), direct vasoconstriction, reduced deformability of PMNs exposed to activated complement factors, and the pre-existing intimacy (endothelium massaging) PMNs share with the sinusoidal endothelium, compared to the postsinusoidal endothelium. Once PMNs are slowed in the sinusoids, firm adhesion and transmigration may be

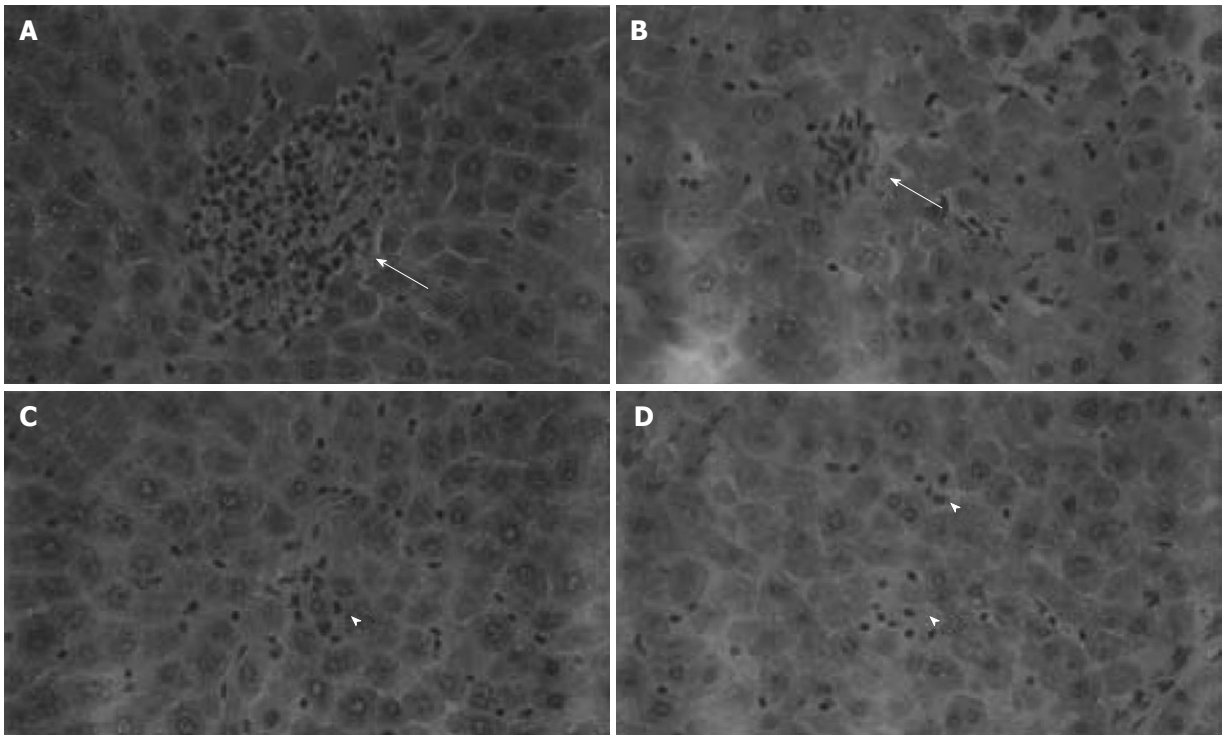

Figure 2 Histological analysis of isolated-blood-perfused control and P-selectin Ab-treated rat liver sections at 120 min perfusion after 6 h of cold ischemia (HE × 400). A, B: Point necroses in livers of control and P-selectin Ab-treated livers at 120 min perfusion (solid arrows); C, D: Inflammation in both control and P-selectin Ab-treated livers at 120 min of perfusion (arrow heads).

mediated by ICAM-1/β_2-integrins and VCAM-1/β_1-integrins[23,38]. Alternatively, other, as yet unidentified, adhesion molecules may play a major role in the sequestration and transmigration of PMNs in liver sinusoids.

P-selectin blockade failed to protect the liver from I/R injury in our cold *ex vivo* model, as judged by the time dependent increase in AST activity, PMNs accumulation, and the similar histological-injury pattern found in control and P-selectin Ab-treated livers. Our findings are not in agreement with results of other studies that reported protection of the liver in cold *ex vivo* model with P-selectin blockade alone using the P-selectin ligands sPSGL-1and rPSGL-Ig[19,39] or an antibody to PSGL-1[40]. However, P-selectin blockade did enhance total bile production by 120 min of perfusion, which agrees with earlier reports[39,40]. Exactly how P-selectin blockade enhanced total bile production remains unclear.

P-selectin and ICAM-1 have been reported to be primary mediators of PMNs sequestration in the liver following I/R[19,20,38,41]. However, in this study, P-selectin blockade had little or no effect on P-selectin and ICAM-1 mRNA and protein levels except for the significant decrease in ICAM-1 mRNA found at 60 min perfusion, which had a concomitant decrease in ICAM-1 protein that did not reach statistical significance. These results support our finding that P-selectin blockade did not significantly alter PMNs accumulation in the liver at 120 min perfusion. In fact, P-selectin blockade caused

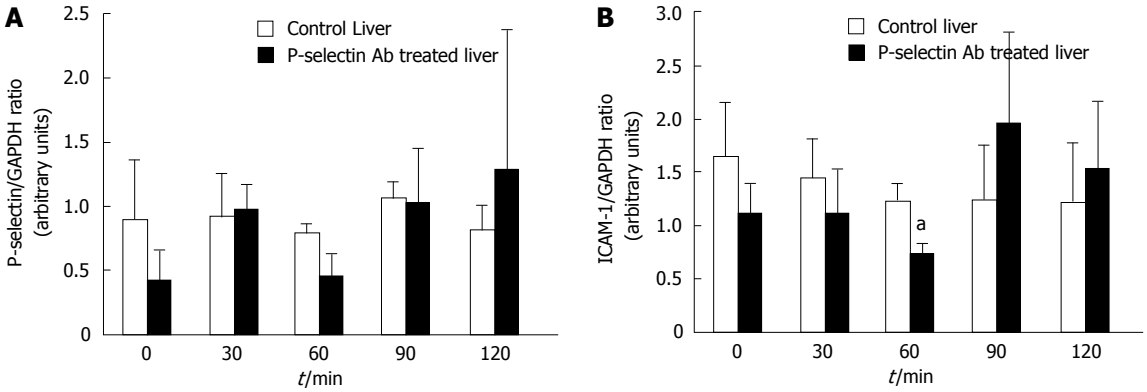

Figure 5 Semi-quantitative RT-PCR analysis of P-selectin and ICAM-1 mRNA levels in isolated-blood-perfused control and P-selectin Ab-treated rat livers after 6 h of cold ischemia. $^{a}P < 0.05$ *vs* control liver.

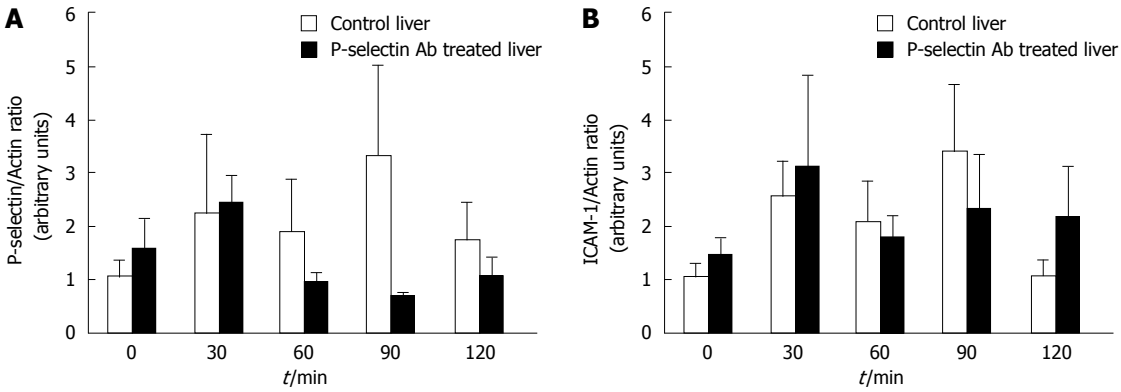

Figure 6 Western blot analysis of P-selectin and ICAM-1 protein levels in isolated-blood-perfused control and P-selectin Ab-treated rat livers after 6 h of cold ischemia.

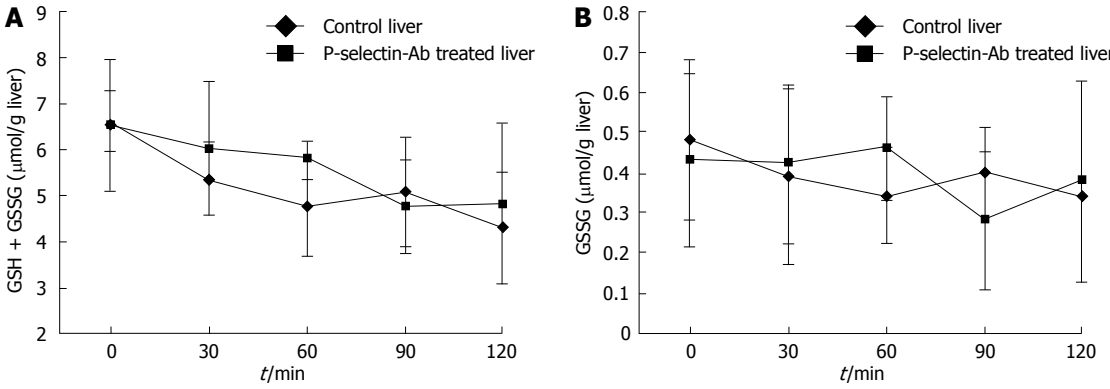

Figure 7 Reduced (GSH + GSSG) and oxidized (GSSG) glutathione levels in isolated-blood-perfused control and P-selectin Ab-treated rat livers after 6 h of cold ischemia.

an increase in PMNs accumulation in the liver, but not to a significant level. In addition, numerous studies have reported that ICAM-1 mediates firm adhesion and transmigration of PMNs in the liver following an inflammatory stimulus[42-47]. However, some studies have questioned the absolute role of ICAM-1 in PMNs sequestration in hepatic vasculature[21,48-52]. Furthermore, although the adhesion molecules ICAM-1 and VCAM-1 are expressed on cells lining the sinusoids, antibodies to selectins, integrins, and CAMs have all failed to prevent accumulation of PMNs in the liver sinusoids.

It is well documented that GSH plays a protective role in liver I/R injury[1,53-57]. GSH can react with ROS such as hydrogen peroxide, peroxynitrite, and hypochlorous acid generated by KC and PMNs. We measured liver GSH and GSSG levels in our cold *ex vivo* model and found no significant difference with P-selectin-blockade treatment. If significant oxidative stress occurred during reperfusion, an increase in liver GSSG should have occurred[1,53]. Although the major oxidative stress observed during perfusion is in the liver vasculature[1,53], we did not measure GSSG levels in the

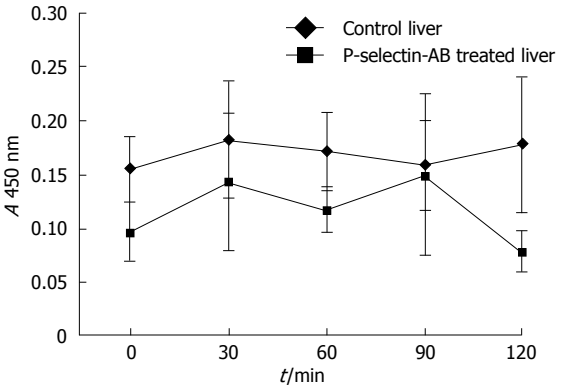

Figure 8 ELISA analysis of nuclear p65 as a measure of liver NF-κB activation in isolated-blood-perfused control and P-selectin Ab-treated rat livers after 6 h of cold ischemia.

perfusate. Nevertheless, recent evidence from livers reperfused after cold storage has shown that hepatocytes may also be a source oxidative changes capable of impairing liver function during reperfusion[58]. Therefore, in this study we should have detected any significant change in GSH or GSSG as an intracellular oxidative stress that occurred during reperfusion. The lack of significant change in liver total GSH and GSSG in our IPRL model may be taken as the absence/attenuation of oxidative stress in the liver[53]. An alternate explanation for our failure to detect liver oxidative stress is that the above study used a more sensitive fluorescence detection compared to the colorimetric method employed in this study.

NF-κB activation in the liver following I/R has been reported[42,43,59]. Its activation has been reported as a requirement for I/R-dependent TNF-α induction in the liver[59]. The inflammatory response following I/R of the liver is primarily mediated by cytokines (e.g. TNF-α, IL-1β) and adhesion molecules P-selectin and ICAM-1, and VCAM-1. Induction of all the above inflammatory mediators requires activation of the transcription factor NF-κB. In addition, existing evidence suggest that redox-sensitive transcription factors NF-κB activation mediates the gene expression of pro-inflammatory cytokines such as TNF-α and IL-1β[11]. Therefore, this study addressed the activation of liver NF-κB in our cold *ex vivo* model, and failed to detect any significant reduction in liver NF-κB activation with P-selectin blockade throughout the perfusion period. This finding supports our results for P-selectin and ICAM-1 expression, with the exception of ICAM-1 mRNA levels at 60 min perfusion. A corresponding decrease in NF-κB activation was found at 60 min perfusion with P-selectin blockade, but did not achieve statistical significance.

Although most studies that characterized the benefit of P-selectin blockade in liver I/R injury used monoclonal antibodies or recombinant P-selectin ligands, in the present study we used a polyclonal antibody. Our use of a polyclonal antibody is not unusual, since other investigators have employed polyclonal antibodies to investigate blockade of mediators involved in I/R injury[60]. It is likely that our results are not in agreement with earlier studies because we employed a polyclonal antibody and at a different dose. Alternately, the antibody may have reacted with activated platelets and complement factors, as was later found for the monoclonal antibody PB1.3 used in the initial report that reported that P-selectin blockade alone protected the liver form I/R injury[20]. Nonetheless, while the general mechanism of selectin-dependent rolling of PMNs followed by firmer adhesion to endothelial cells by integrins and ICAM-1 is applicable to the vasculature of some organs and tissues (heart, lung, intestine, and cremaster muscle), this might not be the case for the entire vasculature of the liver[23,24].

In summary, this study demonstrates that while P-selectin blockade alone increased total bile flow in the IPRL model, it failed to protect the liver from I/R injury.

Abstract

AIM: To investigate the most important aspects of hyperthermic intraperitoneal chemotherapy (HIPEC) that has been accepted as the standard treatment for pseudomyxoma peritonei (PMP), with special regard to morbidity, overall survival (OS) and disease free survival (DFS) over 10 years.

METHODS: Fifty-three patients affected by PMP underwent cytoreduction (CCR) and HIPEC with a "semi-closed" abdomen technique in our institution. The peritonectomy procedure and completeness of CCR were classified according to Sugarbaker criteria. Preoperative evaluation always included thoracic and abdominal CT scan to stage peritoneal disease and exclude distant metastases. Fifty-one patients in our series were treated with a protocol based on administration of cisplatinum 100 mg/m^2 plus mitomycin C 16 mg/m^2, at a temperature of 41.5℃ for 60 min. Anastomoses were always performed at the end of HIPEC. The mean duration of surgery was 12 h including HIPEC. Continuous monitoring of hepatic and renal functions and hydroelectrolytic balance was performed in the postoperative period.

RESULTS: Twenty-four patients presented with postoperative complications: surgical morbidity was observed in 16 patients and 6 patients were re-operated. All complications were successfully treated and no postoperative deaths were observed. Risk factors for postoperative morbidity were considered to be gender, age, body surface, duration of surgery, Peritoneal Cancer Index (PCI) and tumor residual value (CC score). No statistically significant correlation was found during the multivariate analysis: only the CC score was statistically significant. The OS in our experience was 81.8%, with a DFS of 80% at 5 years and of 70% at 10 years.

CONCLUSION: In our experience, even if HIPEC combined with cytoreductive surgery involves a high risk of morbidity, postoperative complications can be resolved favorably in most cases with correct patient selection and adequate postoperative care, thus minimizing mortality. The association of CCR and HIPEC can be considered as the standard treatment for PMP. The OS and DFS results confirm the validity of this combined approach for the treatment of this rare neoplasm. The impact of preoperative chemotherapy on OS, in our opinion, is due to a major aggressiveness of tumors in treated patients.

INTRODUCTION

Peritoneal carcinomatosis (PC) is one of the most common routes of dissemination of abdominal neoplasms; it may be present at the time of diagnosis of a primary tumor, but more frequently it arises as tumor recurrence after surgical treatment[1].

PC is frequently associated with colorectal cancer, gastric cancer, ovarian carcinoma, and appendiceal cancer. Neoplasms with positive peritoneal cytology

show high rates of peritoneal dissemination[2-6].

Pseudomyxoma peritonei (PMP) is a rare condition, with an incidence of 1/1 000 000 per year, characterized by copious mucus (so-called "jelly belly") containing rare epithelial cells. According to Ronnet, PMP was histologically classified into disseminated peritoneal adenomucinosi (DPAM), peritoneal mucinous carcinomatosis (PMCA) and an intermediate or discordant feature group (ID)[7]. Recent studies show that most cases of PMP originate from ruptured appendiceal tumors with progressive dissemination in the peritoneal cavity of mucin-producing epithelial-cells[8,9]. Lymph-nodal or hematogenous metastases are rare in PMP and evidence suggests it has a poor prognosis.

PC from PMP is generally considered a lethal disease, with a limited response to conventional chemotherapeutic treatments[10]. While systemic chemotherapy has little impact on the treatment of peritoneal disease, some centers have reported encouraging results with intraperitoneal hyperthermic chemoperfusion (HIPEC)[11,12].

This technique is based on surgical cytoreduction (CCR) of the primitive cancer, peritonectomy and HIPEC. The principle of locoregional treatments is to obtain an elevated and persistent drug concentration for the tumor, with a limited systemic concentration. Many studies reported an impact on overall survival (OS) and disease-free survival (DFS) in patients affected by carcinomatosis of mucinous cancers such as PMP[13,14] and in recent trials this combined approach has been proposed as standard treatment for PMP.

In this study we report the results of a 10-year experience with this type of treatment in our institution, where 53 patients with PMP were treated with CCR and HIPEC, with special reference to follow-up and risk factors for postoperative complications.

MATERIALS AND METHODS

For the present study, 53 patients (23 male and 30 female, mean age 58 years, range 32-72) with PMP who underwent surgical treatment and HIPEC between October 1998 and June 2008 at the Department of General Surgery and Surgical Oncology, San Giuseppe Hospital, were considered. Preoperative evaluation always included thoracic and abdominal CT scan to stage peritoneal disease and exclude distant metastases; upper digestive endoscopy and colonoscopy generally completed tumor staging. A careful preoperative evaluation of the patient's general condition was always performed, and included complete blood tests, electrocardiogram, cardiac ultrasound, and spirometry. The presence of hepatic or extra-abdominal metastases, poor general condition or performance status > 2 according to the Eastern Cooperative Oncology Group (ECOG) and an age of > 72 years were generally considered contraindications to the treatment. Informed consent was obtained from all patients[15].

Just after laparotomy, a complete intraoperative staging of peritoneal disease was performed using the peritoneal cancer index (PCI)[16]; the mean PCI was 22.

Surgical technique

The peritonectomy procedure was classified and performed according to Sugarbaker's criteria: (1) Central peritonectomy consists of the removal of previous scars, greater omentectomy (performed by stripping the superficial peritoneal layer of the transverse mesocolon) and a close dissection to the greater curvature of the stomach. Sometimes splenectomy could be necessary *en bloc* with the greater omentum and the left diaphragmatic peritoneum; (2) Left upper quadrant peritonectomy consists of the stripping of the peritoneal tumor tissue from beneath the left hemidiaphragm, left adrenal gland, distal portion of the pancreas, and the cephalad half of Gerota's fascia; (3) Right upper quadrant peritonectomy consists of right hemidiaphragmatic peritoneal stripping, removal of tumor from the right subhepatic space and from the surface of the liver by the stripping of the Glisson's capsule. Peritonectomy is concluded with the removal of the peritoneum covering the right kidney and Morrison's pouch; (4) Lesser omentum peritonectomy is performed after the cholecystectomy, and in this procedure the cancerous tissue which covers the common duct and hepatic artery is stripped from the base of gall bladder bed towards the duodenum. This phase is concluded by the stripping of omental bursa; (5) Pelvic peritonectomy with *en bloc* removal of pelvic peritoneum, sigmoid colon, rectum, uterus and salpingo-oophorectomy; (6) Peritonectomy of the lateral abdominal wall. Implants on the visceral serosa are removed by electrosurgical local dissection and the peritonectomies are variously combined with resections of viscera involved in tumor (total gastrectomy or total colectomy).

The completeness of CCR was also classified according to Sugarbaker's criteria[17] as: CCR-0 (no residual tumor) in 35 cases, CCR-1 (no residual nodule greater than 2.5 mm in diameter) in 18 cases, CCR-2 (no residual nodules greater than 25 mm) in none of the cases and CCR-3 (residual nodules greater than 25 mm) in none of the cases.

HIPEC was performed according to the "semi-closed" abdomen technique[18]. Five drain tubes are placed in the abdominal cavity. There are 2 inflow tubes, and they have multiple holes. They present 2 diffusion lines for the homogeneous distribution of drugs into the abdominal cavity (1 in the sovramesocolic branch, 1 in the pelvis). Three outflow tubes are placed respectively in the pelvis and in the subdiaphragmatic spaces. Backhaus forceps are used to close the cranial and caudal portion of abdominal wound. The skin is then suspended by a self-retaining retractor, placed at more or less 15 cm from the abdomen, by plastic self-blocking strings. This kind of placement creates the virtual cavity needed to perform HIPEC. The central portion of the wound is suspended by the retractor too and covered with a laparoscopic device with sterile drapes on it, with a hole in the middle. The drain tubes are connected to a perfusion system formed by 2 pumps and a heat exchanger to heat the perfusion liquid. The inflow and

outflow pumps are connected through a reservoir, so it is possible to achieve continuous circulation of the perfusate at the speed of more or less 1 L/min. The pumps are controlled by a computerized system that allows the checking of the flow rate and the temperature of the heat exchanger. Three intraperitoneal temperatures are checked by probes; the inflow temperature, outflow temperature, and the patient esophageal temperature. The amount of circulating perfusate required (solution for peritoneal dialysis) is calculated according to the patient's body surface. During perfusion, the surgeon mixes the perfusate by hand through the hole in the sterile drapes. When the ideal intraperitoneal temperature is reached, the drugs are added to the circuit and HIPEC is performed for 60 min. Fifty-one patients in our series were treated with a protocol based on administration of cisplatinum 100 mg/m^2 plus mitomycin C 16 mg/m^2, at a temperature of 41.5℃. Two patients were treated with mitomycin C 35 mg/m^2 for 60 min at a temperature of 40.5℃, according to the Netherland protocol, because of significant side effects from preoperative systemic chemotherapy with platinum. Anastomoses were always performed at the end of HIPEC. The mean duration of surgery was 12 h including HIPEC (range 8-16 h). At the end of the operation, the patient was admitted to the intensive care unit, and then returned to the surgical department when cardiovascular and pulmonary functions became stable. Continuous monitoring of hepatic and renal functions and hydroelectrolytic balance were performed afterwards. The primitive neoplasm was an appendicular adenocarcinoma in 37 patients (69.8%) and an appendicular adenoma in 16 patients (30.2%). Twenty-one patients (39.6%) with histological diagnosis of appendicular adenocarcinoma had been treated with systemic chemotherapy before our operation. Because of the massive involvement of viscera and peritoneum, in some selected patients we performed the treatment in steps. Three patients were treated in 2 steps, and 1 patient was treated in 3 steps. In these cases, we performed the upper abdominal CCR in the first step, then the patient was submitted to systemic chemotherapy for 2 or 3 mo. The second step consisted of lower abdominal CCR and peritoneal perfusion of the entire peritoneal cavity. The details of the CCR procedures are displayed in Table 1.

Table 1 Extent of CCR and HIPEC in 53 patients affected by PMP

Procedures	No.
Greater omentectomy	48
Left colectomy	30
Right colectomy	34
Total abdominal hysterectomy	16
Bilateral salpingo-oophorectomy	20
Splenectomy	40
Cholecystectomy	34
Small bowel partial resection	27
Total gastrectomy	5
Sub-total gastrectomy	3
Distal pancreatectomy	6
Rigth upper quadrant peritonectomy	47
Left upper quadrant peritonectomy	38
Pelvic peritonectomy	43

Statistical analysis

In this study the statistical analyses focused on postoperative complications: the histopathological, clinical and follow-up data were stored in a database. The presence of postoperative complications was considered as the dependent variable whereas gender, age, body mass index, primary tumor, previous systemic chemotherapy, operative time, stage of PCI, and CCR were covariates.

Multivariate analysis of factors was performed by the Cox proportional hazard model. OS was dated from the day of surgery to the time of death due to any causes; progression-free survival (PFS) was dated from the day of the surgery to the time of postoperative disease progression. The survival curves for both OS and PFS were calculated according to the Kaplan-Meier method. The log-rank test was used to assess the significance of the comparison between survival curves.

The Statistical Package for the Social Sciences software (version 11.0) (SPSS, Chicago, IL, USA) was used for statistical analysis: $P < 0.05$ was considered significant.

RESULTS

At the end of follow-up of the 53 patients, 5 and 10 year OS was 94% and 84.6%, respectively (Figure 1A). DFS was 80% and 70% at 5 and 10 years, respectively (Figure 1B).

OS according to the PCI, completeness of CCR (CC-score), histological type, and pre-operative chemotherapy (done *vs* not done) are shown in Figure 2A-D. At the time of the present analysis 48 patients are alive without disease. Two patients died due to systemic disease progression at 16 and 63 mo, respectively, after the operation; 3 patients are alive with disease and intraperitoneal relapse but are not undergoing a further operation, with follow-up of 57, 28, 24, 19, 10 mo, respectively. Three patients had intraperitoneal relapse and were treated with tumor resection followed by HIPEC: 1 of those patients is alive without disease 17 mo after the second surgical procedure; the other 2 patients were treated only with CCR and they are alive without disease after 24 mo of follow-up.

For calculation of the morbidity rate, we considered postoperative complications occurring during the hospital stay or within 30 d of surgery. In 24 patients (45%) we observed postoperative complications: surgical morbidity was observed in 16 patients (3 intestinal fistulas, 2 urinary tract perforations, 2 abdominal abscesses, 4 wound infections, 1 prolonged ileus, 2 postoperative haemorrhages, 1 abdominal wall dehiscence, 1 bleeding from a gastric ulcer) and medical complications were observed in 8 cases (1 arrhythmia, 3 grade 2 hematological toxicities, 1 acute renal failure, 1 cutaneous rash, 2 cases of sepsis). Six patients were

Table 2 Association between morbidity and clinical variables *n* (%)

Variable	No. of cases	With complications	Without complications	*P*-value
Gender				NS
Male	23	11 (46)	12 (41)	
Female	30	13 (54)	17 (59)	
Age (yr)		59 ± 10	56 ± 9	NS

re-operated and 1 patient underwent ureteric stenting. One patient with abdominal abscess was submitted to ultrasound-guided drainage and 1 patient with bleeding from a gastric ulcer was treated by endoscopic haemostasis. All other complications were successfully treated by medical therapy (Table 2). No postoperative deaths were observed. An analysis of risk factors for postoperative morbidity rate was performed. Gender, age, body surface, duration of surgery, PCI and tumor residual value were considered to be risk factors. No statistically significant correlation between the analyzed variables and the incidence of postoperative complications was found except for CC-score ($P < 0.017$) (Table 3).

Table 3 Postoperative complications observed in 24 patients. Multiple complications are included

Complication	No. of cases	Treatment (No. of cases)
Surgical		
Wound infection	4	Drainage
Urinary tract perforation	2	Reoperation (1); Urinary stenting (1)
Intestinal fistula	3	Reoperation
Abdominal abscess	2	US-guided drainage (1); medical (1)
Prolonged ileous	1	Medical
Bleeding from gastric ulcer	1	Endoscopic haemostasis
Intraabdominal bleeding	2	Reoperation
abdominal wall dehiscence	1	Conservative
Medical		
Grade ⩾ 2 hematological toxicity	3	Medical
Acute renal failure	1	Medical
Arrhythmias	1	Medical
Cutaneous rush	1	Medical
Sepsis	2	Medical

Final follow-up data from our experience indicated that survival probability may be good in patients with histological type appendicular adenoma who are optimally cytoreduced (CC-0). An interesting relief was related to whether preoperative chemotherapy was performed or not.

DISCUSSION

HIPEC associated with cytoreductive surgery is becoming a widely accepted procedure for the treatment of PMP.

Like reports in several studies, the results of our experience indicate that, even when combined with an aggressive surgical procedure, HIPEC is associated with an acceptable risk of postoperative complications and mortality[19-24]. The incidence of postoperative complications was similar to that of other reports[25-29]

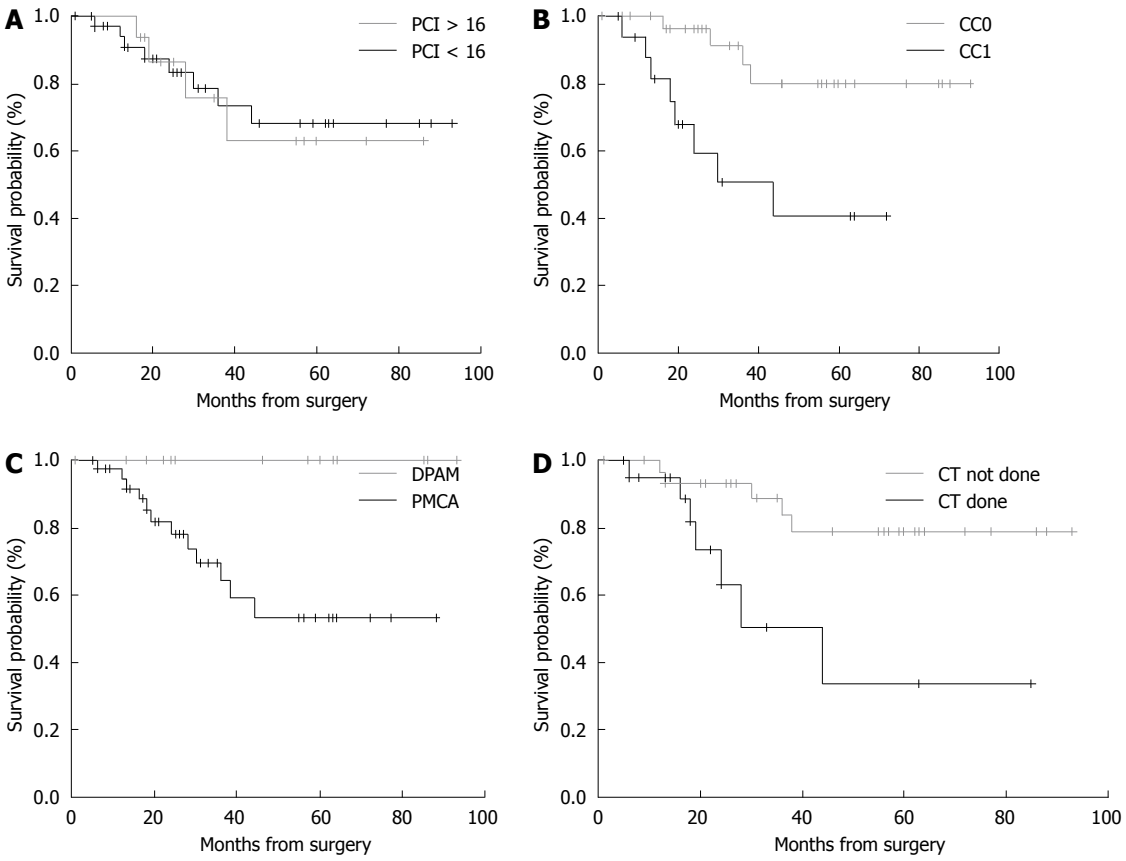

Figure 2 Overall survival (OS) in 53 cases of PMP. A: According to PCI status (P N.S.); B: According to the completeness of CCR ($P < 0.003$); C: According to the histological tumor type ($P < 0.014$); D: According to previous systemic chemotherapy ($P < 0.034$).

and major morbidity occurred in 45% of patients, which is also similar to other recent experiences[27,29,30]. All the complications were successfully treated with surgical or medical therapy. We believe that careful preoperative selection of patients, and adequate postoperative monitoring and care are crucial in order to minimize the incidence of postoperative complications in these patients.

The advanced stage of neoplastic disease and immunodeficiency status of patients previously subjected to chemotherapy were important factors that probably contributed to the occurrence of septic complications after an extended surgical procedure. In our series 1 patient underwent ultrasound-guided drainage of an abdominal abscess and in the others septic complications were successfully treated with medical therapy.

Intestinal fistula has been reported to be an important cause of morbidity and mortality in patients submitted to HIPEC, with an incidence rate ranging from 6% to 27%[21-23, 31-33]. Younan *et al*[32] reported that male gender, duration of surgery, and no previous systemic chemotherapy were independent predictors of bowel complications. The direct effect of HIPEC even in non-resective procedures can be associated with intestinal fistulas in the postoperative period[33,34]. We always performed anastomotic suture following HIPEC but in our series the 3 cases of intestinal fistula were due to intestinal perforation not involving anastomosis.

Recent studies have reported the duration and extent of surgery, visceral resections, PCI and incomplete CCR to be important risk factors for postoperative complications[21,26,31]. In our patients, we did not find this correlation, probably because of the limited number of cases. PCI > 16 was an independent predictor of postoperative morbidity only at univariate analysis and seemed to have an impact on the complication rate, but not on OS.

The largest series of PMP undergoing combined treatment was reported by Sugarbaker[35]: in this series completeness of CCR and Ronnet's criteria were the most important factors correlated with survival and morbidity[36].

Complete CCR was obtained in most of our patients. In our series, we didn't have patients with an elevated CC score (CC-2 or CC-3): as a consequence, even though the morbidity rate was high we did not find a correlation between cytoreductive status and complication rate. However, the CC-score in our experience was strictly correlated to DFS with an evident result between CC-0 and CC-1 patients ($P < 0.003$).

The limited number of patients in our series did not allow further stratifications and for these reasons, the potential impact of other factors on morbidity cannot be excluded.

Survival data indicate that high long-term survival could be achieved in patients with histological type DPAM *vs* PMCA ($P < 0.014$). Furthermore in the present series the adverse prognostic value of preoperative systemic

chemotherapy was a unexpected finding that may be not easy to explain: the patient that received chemotherapy had a poor prognosis compared to those that did not undergo chemotherapy ($P < 0.034$). The same evidence was observed in the series of Baratti *et al*[37].

The hypothesis was that after chemotherapy, mucinous appendiceal tumors change to a more invasive process: it is quite possible that differences in chemotherapy penetration of mucinous and solid tumours may result in persistence and progression of the more solid components of a non uniform tumor. Appendiceal tumors are described as having large areas of adenomucinosis with small, even minute, areas of more aggressive tissue: the penetration of chemotherapy drugs into the mucin that contains adenomatous epithelial cells may eradicate these cells but the small foci of solid tumor may not be completely penetrated by chemotherapy. It is possible that this process selected resistant and more aggressive tumor cell clones but the explanation for the poor results of the treatment in these patients requires further investigation.

In conclusion the present study confirms that an aggressive approach can improve survival in selected patients with PMP. Although HIPEC combined with CCR has a high risk of morbidity, postoperative complications could be resolved favorably in most cases with correct patient selection and adequate postoperative care, thus minimizing mortality. Residual tumor (CC), preoperative chemotherapy and histological type PCMA significantly influence the prognosis of these patients[20,37].

To improve this encouraging survival outcome, it is very important to unify the surgical experience of expertise centers and adequate patient selection. Our results suggest also the need of an integrated approach to this rare neoplasm to identify the biological aspect of PMP that influences the prognosis and the evolution of the disease.

COMMENTS

Background

Peritoneal carcinomatosis is generally considered a lethal disease, with a mean survival time of 6 mo after conventional chemotherapeutic treatments. Systemic chemotherapy has little impact on treatment of peritoneal disease, but some centres have reported encouraging results with intraperitoneal hyperthermic chemoperfusion (HIPEC). Locoregional treatments are considered a new frontier in the management of this condition: it is possible to achieve an elevated and persistent drug concentration in the tumor, with limited systemic effects. Many studies reported an impact on overall survival and disease-free interval in patients affected by carcinomatosis, of mucinous cancers such as pseudomyxoma peritonei (PMP) and in recent trials this combined approach has been proposed as standard treatment for PMP.

Research frontiers

The present study confirms that an aggressive approach can improve survival in selected patients with PMP. Although HIPEC combined with cytoreductive surgery involves a high risk of morbidity, postoperative complications can be resolved favorably in most cases with correct patient selection and adequate postoperative care, thus minimizing mortality. Residual tumor (CC), preoperative chemotherapy and histological type of PMP can be considered as independent variables able to significantly influence the prognosis of these patients. To improve this encouraging survival outcome, it is very important to unify the surgical experience of expertise centres. Our results suggest also the need for an integrated approach to this rare neoplasm to identify the biological aspects of PMP that influence the prognosis and the evolution of the disease.

Innovation and breakthroughs

In this paper we report a very important proof on the integrated approach to PMP. This lethal disease can be treated with good results: in fact 5 and 10 year overall survival was, respectively, 94% and 84.6% in our experience and disease free survival was 80% and 70% at 5 and 10 years, respectively.

Application

On future application, the end point of this approach would be to improve a standard treatment for this particular disease to reduce the surgical risk of major complications. Correct patient selection and adequate postoperative care may minimize the considerable complication rate that is very high (45%).

Peer review

This is a very interesting study on pseudomyxoma peritonei and its treatment with intraperitoneal hyperthermic chemoperfusion.

Abstract

AIM: To evaluate the effect of β-blockade on angiotensins in the splanchnic and peripheral circulation of cirrhotic patients and also to compare hemodynamic parameters during liver transplantation according to propranolol pre-treatment or not.

METHODS: Patients were allocated into two groups: outpatients with advanced liver disease(LD) and during liver transplantation(LT). Both groups were subdivided according to treatment with propranolol or not. Plasma was collected through peripheral venipuncture to determine plasma renin activity(PRA), Angiotensin(Ang) Ⅰ, Ang Ⅱ, and Ang-(1-7) levels by radioimmunoassay in LD group. During liver transplantation, hemodynamic parameters were determined and blood samples were obtained from the portal vein to measure renin angiotensin system(RAS) components.

RESULTS: PRA, Ang Ⅰ, Ang Ⅱ and Ang-(1-7) were significantly lower in the portal vein and periphery in all subgroups treated with propranolol as compared to non-treated. The relationships between Ang-(1-7) and Ang Ⅰ levels and between Ang Ⅱ and Ang Ⅰ were significantly increased in LD group receiving propranolol. The ratio between Ang-(1-7) and Ang Ⅱ remained unchanged in splanchnic and peripheral circulation in patients under β-blockade, whereas the relationship between Ang Ⅱ and Ang Ⅰ was significantly increased in splanchnic circulation of LT patients treated with propranolol. During liver transplantation, cardiac output and index as well systemic vascular resistance and index were reduced in propranolol-treated subgroup.

CONCLUSION: In LD group, propranolol treatment reduced RAS mediators, but did not change the ratio between Ang-(1-7) and Ang Ⅱ in splanchnic and peripheral circulation. Furthermore, the modification of hemodynamic parameters in propranolol treated patients was not associated with changes in the angiotensin ratio.

INTRODUCTION

The Renin-Angiotensin System(RAS) is a multilayered complex system. Previously, Angiotensin (Ang) Ⅱ was thought to be the principle active peptide, exerting its action through type Ⅰ and type Ⅱ receptors[1]. However, our understanding of the RAS has significantly

grown[1,2]. Additional active RAS peptides have been identified such as Ang Ⅲ, with actions similar to Ang Ⅱ and Ang Ⅳ, which exerts its activity at insulin-regulated amino peptidase receptors, and Ang-(1-7), which acts mainly through Mas receptors[1,2]. There is evidence that the RAS acts at the local tissue and even intracellular level through specific receptors by exerting paracrine, endocrine and intracrine functions[1,2]. Further, the system mediates a variety of opposing physiological actions including vasoconstriction/vasodilation, fibrosis/antifibrosis and inflammation/anti-inflammatory[1,2]. Therefore, the RAS is now viewed as a dual system composed of two arms: a vasoconstrictor arm formed by angiotensin converting enzyme(ACE)-Angiotensin (Ang) Ⅱ-AT1 receptor and a vasodilator arm with ACE2-Ang-(1-7)-Mas receptor. The ACE2-Ang-(1-7)-Mas arm mainly acts as a counter-regulatory mechanism for the vasoconstrictor arm[1]. According to this novel concept, the final functional effect of the RAS may reflect a balance between these two arms[2-5].

This novel view of the RAS makes the evaluation of this system in cirrhosis particularly challenging. In this regard, recent studies have suggested that the RAS seems to be involved in cirrhosis through its two main arms: the first (ACE-Ang Ⅱ-AT1) by inducing liver fibrosis[6] and maintaining the basal vascular tonus in cirrhosis[7] and the second [ACE2-Ang-(1-7)-Mas] by exerting an anti-fibrotic role[8,9] and probably by participating in the vasodilation of cirrhosis[10].

Non-selective β-adrenergic blockers have been widely used in treatment of portal hypertension in cirrhosis. β-blockers lower portal pressure by reducing portal blood flow as a consequence of a decreased cardiac output (β_1-receptor blockade) and arteriolar splanchnic vasoconstriction (β_2-receptor blockade)[11]. β-blockers also inhibit renin secretion[12]. However, the effect of propranolol on RAS mediators has still not been quantified, and neither have the hemodynamic changes that might occur during liver transplantation in cirrhotic patients pre-treated with propranolol. Since non-specific β blockade has been a standard approach to controlling the symptoms of portal hypertension and because the RAS seems to influence the outcome of portal hypertension and cirrhosis, it is reasonable to ask if there is a functional relationship between the RAS and beta-receptor system. For this purpose, we have taken in this study the first steps to understand how β1 and β2 blockade affects the RAS in cirrhotic patients. Thus, the aim of the present study was to compare the levels of plasma renin activity (PRA), Ang Ⅰ, Ang Ⅱ and Ang-(1-7), measured in the splanchnic and peripheral circulations of cirrhotic patients receiving or not propranolol and to evaluate the effect of previous administration of propranolol on hemodynamic parameters during liver transplantation.

MATERIALS AND METHODS

Patients

This cross-sectional study used a convenience sample recruited from either the Alfa Institute of Hepatology/Liver Transplantation or the Clinical Primary Care Center of our institution.

Table 1 Clinical characteristics and casual measurements of advanced liver disease outpatients (LD) treated with propranolol or not

Characteristics and measurements	LD with propranolol (n = 9)	LD without propranolol (n = 7)
Age (yrs)	45 ± 2	54 ± 5
Sex male/female	5 (55.6%)/4 (44.4%)	4 (57%)/3 (43%)
Child Pugh Score	9.8 ± 0.5	11.0 ± 0.8
MELD Score	27.1 ± 1.3	29.3 ± 2.1
Albumin (g/dL)	2.7 ± 0.2	2.4 ± 0.3
Bilirubin (mg/dL)	2.5 (1.3-5.1)	2.5 (1.2-7.1)
Creatinine (mg/dL)	1.2 (0.8-2.3)	1.0 (1.0-1.45)
INR (International Normalized Ratio)	1.62 (1.01-6.15)	1.55 (1.20-2.20)
Serum Na^+ (mEq/L)	133.0 ± 1.6	126.0 ± 2.7[a]

Data are expressed as mean ± SE or median (25 and 75 percentile), except for sex where number of patients and percentages are shown. [a]$P < 0.05$ for the comparison of LD with propranolol and LD without propranolol (unpaired t test for mean comparisons and Mann-Whitney test for median comparisons).

Table 2 Clinical characteristics and casual measurements of patients undergoing liver transplantation (LT) pre-treated with propranolol or not

Characteristics and measurements	LT with propranolol (n = 10)	LT without propranolol (n = 11)
Age (yr)	50.6 ± 3.4	50.0 ± 2.6
Sex male/female	3 (30%)/7 (70%)	7 (63.6%)/4 (36.4%)
Child Pugh Score	10.5 ± 0.4	11.2 ± 0.6
MELD Score	28.0 ± 1.1	29.8 ± 1.6
Albumin (g/dL)	2.81 ± 0.09	2.61 ± 0.15
Bilirubin (mg/dL)	3.38 ± 1.20	3.70 ± 0.87
Creatinine (mg/dL)	1.0 (1.0-1.45)	1.05 (0.75-1.50)
INR (International Normalized Ratio)	1.36 (1.32-1.95)	1.69 (1.24-2.11)
Serum Na^+ (mEq/L)	135.2 ± 1.0	130.1 ± 1.8[a]

Data are expressed as mean ± SE or median (25 and 75 percentile), except for sex where number of patients and percentages are shown. [a]$P < 0.05$ for the comparison of LT with propranolol and LT without propranolol (unpaired t test for mean comparisons and Mann-Whitney test for median comparisons).

Inclusion criteria

Patients diagnosed with hepatic cirrhosis defined through liver histopathology and/or ultrasonography findings were included in this study. Tables 1 and 2 display the Child-Pugh[13] and MELD[14] scores of our patients (all patients were on the waiting list for liver transplantation). The etiology of the liver disease was established in the majority of the subjects (69%), and included alcoholism, virus C, virus B and bile cirrhosis. The cirrhotic patients were allocated to two study groups: one group was composed of patients who had advanced liver disease and were seen in an outpatient clinic (LD, n = 16) and the second group was composed of liver transplant recipients during surgery (LT, n = 21). Each

of these two groups was further divided into patients who received propranolol and those who did not. The assistant physician was the only person responsible for the prescription and indication of propranolol treatment and the study protocol did not interfere with any medical prescriptions and recommendations. Thus, patients who were already on treatment with propranolol were then compared to those that did not receive treatment. As shown in Tables 1 and 2, the two subgroups of patients (treated *vs* non-treated) are comparable in the major demographic characteristics.

The LD group comprised outpatients with ascites and extra-hepatic complications such as encephalopathy and moderate to large esophageal varices (> 5 mm) with risk of bleeding. These patients were using diuretics (furosemide: 40-80 mg/d associated with spironolactone: 25-100 mg/d). Nine of these patients were also receiving propranolol for a mean period of 60 d (40-80 mg/d). The doses of propranolol were titrated to achieve a 20%-25% change in baseline heart rate.

The LT group included hospitalized cirrhotic patients with the same severity of liver disease as compared to LD group based on Child Pugh and MELD scores (Child Pugh: 11.0 ± 0.8 in LD *vs* 11.2 ± 1.2 in LT and MELD: 29.3 ± 2.1 in LD *vs* 29.8 ± 3.2 in LT, $P > 0.05$ for both comparisons). These patients also presented the same clinical and laboratorial features as the LD group and received the same diuretic treatment. The only difference between both groups is the fact that LT patients have been submitted to liver transplantation. Ten of the LT patients were using propranolol (40-80 mg/d) until the time of liver transplantation and their doses were also titrated to achieve a 20%-25% change in baseline heart rate.

Exclusion criteria

Co-morbidities such as diabetes, heart, pulmonary, autoimmune and neurological diseases automatically excluded subjects from the study. Patients receiving chronic treatment with angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, renin inhibitors and corticosteroids were also excluded from the study. During liver transplantation, blood collection was suspended whenever the subject presented acute hemodynamic disarrangements and needed to use a vasoconstrictor.

Ethical aspects

The Ethics Committee of the Federal University of Minas Gerais approved the study. Informed consent was obtained from all included subjects. The research protocol did not interfere with any medical recommendations or prescriptions. Subject follow-up was guaranteed even in cases of refusal to participate in the study.

Study protocol

Protocol 1 - Evaluation of circulating RAS in outpatients using or not using propranolol: Blood samples for PRA and angiotensin measurements were obtained from LD patients on a single occasion taking into account the inclusion and exclusion criteria for each group. Due to ethical reasons, no changes to the clinical approach were made for study purposes. Blood samples (10 mL) were collected through peripheral venipuncture in the morning after a fasting period of 8 h. All subjects rested in supine position for at least 30 min before blood sampling.

Protocol 2 - Evaluation of RAS and hemodynamic parameters during pre-anhepatic stage of liver transplantation in patients pre-treated with propranolol or not: In the LT group, blood sampling was performed during the pre-anhepatic stage of liver transplantation and samples were obtained from the portal vein (10 mL) to evaluate RAS mediators. Hemodynamic parameters (cardiac output, cardiac index, systemic vascular resistance and systemic vascular resistance index) were determined simultaneously with the blood sampling. These measurements were obtained through invasive continuous monitoring *via* a Swan-Ganz catheter (CCOMBO/SvO2, 110 cm/7.5 F, Edwards Lifesciences, Irvine, CA, USA), using Dixtal (DX 2020, Dixtal Biomedical, São Paulo, Brazil) and Vigilance (CEDV, Edwards Lifesciences, Irvine, CA, USA) monitors. Anesthesia for liver transplantation was induced by a rapid sequence of etomidate, fentanyl and succinylcholine and maintained by isoflurane (CAM~1.0) and atracurium until the blood sampling.

Blood collection: For all blood collections, samples were drawn into two sets of ice-cooled tubes-one containing 7.5% EDTA for PRA determinations and the other containing a cocktail of protease inhibitors for angiotensin measurements, as previously described[14]. Blood samples were centrifuged at × 2000 *g* for 20 min at 4℃ and plasma stored at -20℃[14].

Plasma extraction and radioimmunoassays: Plasma samples were extracted using Bond-Elut cartridges (Analytichem International, Harbor City, CA), as described elsewhere[15]. PRA as well as Ang Ⅰ, Ang Ⅱ and Ang-(1-7) concentrations were determined through radioimmunoassays, as detailed elsewhere[15]. The recovery of ^{125}I-labeled Ang Ⅰ, Ang Ⅱ, and Ang-(1-7) was 79.2% ± 2.3%, 86.9% ± 0.8% and 83.5% ± 0.9%, respectively. Results were expressed as nanograms of Ang I generated per mL of plasma per hour (ng Ang Ⅰ /mL per hour) for PRA and pg/mL of plasma for Ang measurements.

Statistical analysis

Gaussian distribution of variables was evaluated by the Shapiro normality test. Results were reported as mean ± SE or median, when appropriate. Unpaired *t* test was used for the comparison of means between groups. Mann-Whitney was used to compare non-parametric

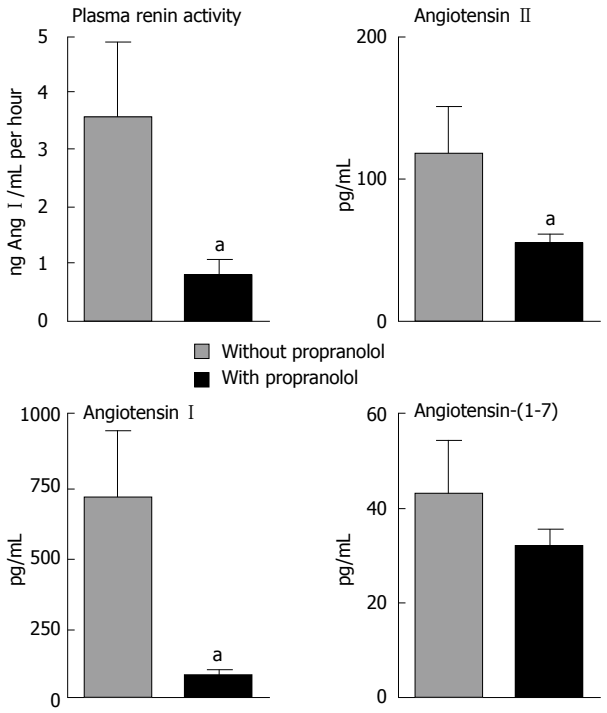

Figure 1 Peripheral circulating RAS profile in advanced liver disease outpatients (LD) receiving propranolol or not. Data are expressed as means ± SE. $^{a}P < 0.05$ for the comparison of LD with propranolol and LD without propranolol (unpaired *t* test).

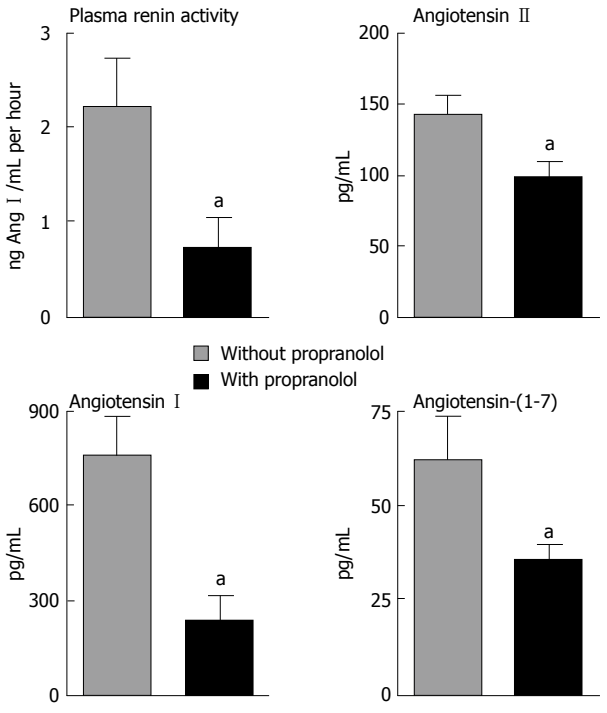

Figure 2 RAS profile of the splanchnic circulation in patients undergoing liver transplantation (LT), pre-treated with propranolol or not. Data are expressed as means ± SE. $^{a}P < 0.05$ for the comparison of LT with propranolol and LT without propranolol (unpaired *t* test).

data. The level of significance was set at $P < 0.05$. Graphpad PRISM was used for the statistical analyses.

RESULTS

Subject characteristics and casual measurements

The outpatients with liver cirrhosis (LD, $n = 16$) consisted of 9 males and 7 females from 44 to 66 years. The etiologies of liver failure in these subjects were: alcoholism in 4, bile cirrhosis in 1, virus C in 5, virus B in 1 and idiopathic causes in 5 patients. Clinical and laboratorial data revealed high Child Pugh and MELD scores that were very similar between the groups of patients using or not using propranolol (Table 1). Only serum sodium levels were significantly reduced in LD patients not receiving propranolol as compared to those treated with propanolol (Table 1).

Cirrhotic patients during liver transplantation (LT, $n = 21$) comprised 10 males and 11 females from 36 to 67 years. The etiologies for primary hepatic diseases in this group included virus C in 9, alcoholism in 4, bile cirrhosis in 2, virus B in 1 and idiopathic in 5 patients. The LT group without propranolol revealed reduced serum sodium levels compared to the LT group receiving propranolol. Other demographic characteristics and liver function scores were similar in both subgroups (Table 2).

Peripheral and splanchnic circulating RAS profile in LD and LT patients pre-treated with propranolol or not

As displayed in Figure 1, PRA and angiotensin I (Ang I) were lower in peripheral circulation of the LD group treated with propranolol in comparison to LD group not receiving propranolol (PRA: 3.54 ± 1.35 ng Ang I /mL per hour *vs* 0.77 ± 0.28 ng Ang I /mL per hour; Ang I: 717.2 ± 39.0 pg/mL *vs* 79.8 ± 24.8 pg/mL, $P < 0.05$ for both comparisons). As shown in Figure 2, the same profile was observed for the LT group pre-treated with propranolol, which also presented a significant reduction of the PRA and Ang I plasma levels in the portal vein when compared to the LT group that was not treated with propranolol (PRA: 2.20 ± 0.51 ng Ang I /mL per hour *vs* 0.74 ± 0.30 ng Ang I /mL per hour; Ang I: 764.2 ± 117.0 pg/mL *vs* 235.0 ± 75.6 pg/mL, $P < 0.05$ for both comparisons).

LD patients receiving propranolol also exhibited a significant reduction in the levels of Ang II in peripheral circulation when compared to LD patients not using propranolol (Ang II: 117.2 ± 33.5 pg/mL *vs* 53.9 ± 6.5 pg/mL, $P < 0.05$, Figure 1). The same reduction of Ang II levels was observed in splanchnic circulation (portal vein) of the LT group under β-blockade in comparison to LT group not treated with propranolol (Ang II: 143.4 ± 13.3 pg/mL *vs* 96.9 ± 12.6 pg/mL, $P < 0.05$, Figure 2). Plasma levels of Ang-(1-7) were also reduced in splanchnic circulation of the LT group that was previously treated with propranolol in comparison to non-treated LT group (62.3 ± 10.9 pg/mL *vs* 35.5 ± 3.8 pg/mL, $P < 0.05$, Figure 2), whereas plasma Ang-(1-7) in peripheral circulation of the LD group did not differ significantly despite treatment or not with propranolol (Figure 1).

Ratios between Ang-(1-7) and Ang I levels, between Ang II and Ang I, and between Ang-(1-7) and Ang II in LD and LT groups are displayed in Tables 3 and 4, respectively. The ratio between Ang-(1-7) and Ang I indirectly reflects ACE2 activity, whereas the

Table 3 Ratios between angiotensins in peripheral circulation of advanced liver disease outpatients (LD) treated with propranolol or not

Angiotensin ratios	LD with propranolol (n = 9)	LD without propranolol (n = 7)
Ang Ⅱ/Ang Ⅰ	1.24 ± 0.30	0.21 ± 0.05[a]
Ang-(1-7)/Ang Ⅰ	0.74 ± 0.19	0.09 ± 0.03[a]
Ang-(1-7)/Ang Ⅱ	0.62 ± 0.06	0.42 ± 0.09

Data are expressed as mean ± SE. [a]P < 0.05 for the comparison of NLD with propranolol and NLD without propranolol (unpaired t test).

Table 4 Ratios between angiotensins in splanchnic circulation of patients undergoing liver transplantation (LT) pre-treated with propranolol or not

Angiotensin ratios	LT with propranolol (n = 10)	LT without propranolol (n = 11)
Ang Ⅱ/Ang Ⅰ	0.46 (0.26-2.64)	0.19 (0.13-0.24)[a]
Ang-(1-7)/Ang Ⅰ	0.27 (0.06-0.91)	0.05 (0.04-0.11)
Ang-(1-7)/Ang Ⅱ	0.43 ± 0.08	0.52 ± 0.12

Data are expressed as mean ± SE or median (25 and 75 percentile). [a]P < 0.05 for the comparison of LT with propranolol and LT without propranolol (unpaired t test for mean comparisons and Mann-Whitney test for median comparisons).

ratio between Ang Ⅱ and Ang Ⅰ indirectly estimates ACE activity. Both ratios were significantly increased in peripheral circulation of the LD group using propranolol in comparison to LD patients not receiving the β-blocker (P < 0.01, Table 3). Only Ang Ⅱ/Ang Ⅰ ratio was increased in splanchnic circulation of the LT group pre-treated with propranolol in comparison to LT patients that had not received propranolol (P < 0.01, Table 4), whereas Ang-(1-7)/Ang Ⅰ did not significantly differ in splanchnic circulation of LT patients despite the previous treatment or not with propranolol. More importantly, the ratio between Ang-(1-7) and Ang Ⅱ, which could represent the final functional relationship between RAS mediators, did not differ in either peripheral circulation of the LD group or in splanchnic circulation of the LT group, independently of the previous use or not of the β-blocker.

Hemodynamic parameters during pre-anhepatic stage of liver transplantation in LT pre-treated with propranolol or not

In order to demonstrate that our LT patients pre-treated with propranolol were adequately β blocked, we measured hemodynamic parameters during pre-anhepatic stage of liver transplantation. Accordingly, in LT patients pre-treated with propranolol, the cardiac output (8.9 ± 0.9 L/min *vs* 5.6 ± 0.6 L/min) and cardiac index (4.7 ± 0.4 L/min per m^2 *vs* 3.2 ± 0.3 L/min per m^2) were reduced and the systemic vascular resistance (604.2 ± 65.0 × 877.5 ± 106.1 dyn.s/cm^5) and its index [(1036 ± 86) × (1399 ± 147)] dyn.s/cm^5 per m^2) were increased in comparison to patients that had not previously received propranolol (P < 0.05 for all comparisons, Figure 3).

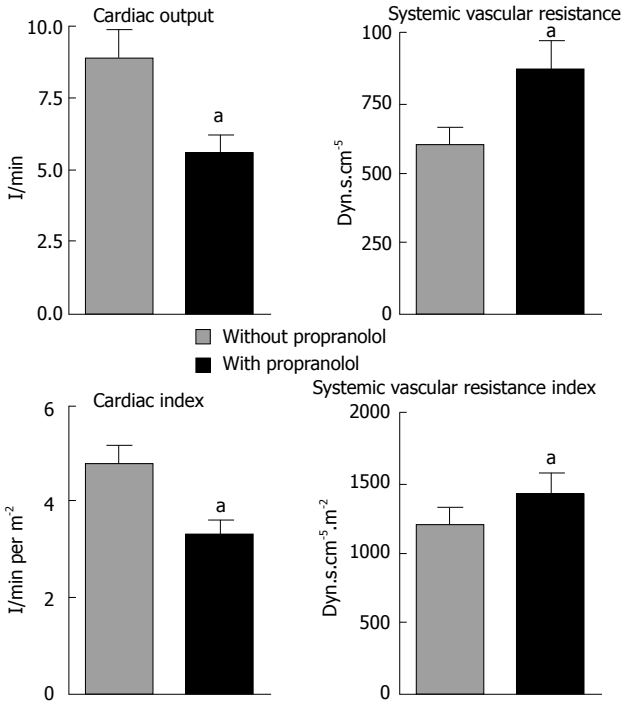

Figure 3 Hemodynamic parameters from cirrhotic patients during liver transplantation (LT) pre-treated with propranolol or not. Data are expressed as means ± SE. [a]P < 0.05 for the comparison of LT with propranolol and LT without propranolol (unpaired t test).

DISCUSSION

In general, our data showed that chronic treatment with propranolol in cirrhotic patients is characterized by marked changes in the precursors of RAS cascade (Renin and Ang Ⅰ) with repercussion in RAS two main arms at the splanchnic and peripheral circulation. On the other hand, no changes were detected in the ratio between the two main RAS mediators [Ang-(1-7)/Ang Ⅱ], which has been used to evaluate the final functional effect of the RAS. In parallel, the chronic use of propranolol produced hemodynamic changes, which were probably able to control the hyperdynamic circulation of cirrhotic patients. Taken together, these findings suggest that the reduction of hyperdynamic circulation produced by chronic treatment with propranolol in cirrhotic patients was associated with an overall RAS inhibition, but it was not due to changes in the balance between the two RAS arms: ACE-Ang-AT1 (vasoconstrictor) *versus* ACE2-Ang-(1-7)-Mas (vasodilator).

In splanchnic and peripheral circulation, the β-blockade in cirrhotic patients was characterized by reduced PRA and Ang Ⅰ levels. These RAS components can lead to the synthesis of both Ang Ⅱ and Ang-(1-7)[5,16]. The cirrhotic patients receiving propranolol have reduced Ang Ⅱ levels in the splanchnic and in the peripheral circulation as well as reduced Ang-(1-7) levels in the splanchnic circulation. In this regard, Blumenfeld *et al*[12] previously suggested that β-blockade reduced Ang Ⅱ levels and PRA in normotensive and hypertensive subjects by inhibiting prorenin processing to renin.

Ratios between angiotensins, especially the relationship between Ang-(1-7) and Ang Ⅱ, have been used to estimate the final functional RAS effect[2,3,4]. In this study, propranolol use was not able to change the ratio between Ang-(1-7) and Ang Ⅱ in splanchnic and peripheral circulation of non-compensated cirrhotic patients, although there was an absolute decrease in both angiotensins. In parallel, systemic vascular resistance (SVR) and its index increased and cardiac output (CO) and its index decreased in non-compensated cirrhotic patients treated with propranolol. Similar hemodynamic changes in cirrhotic patients receiving propranolol have already been reported[17-19] and attributed to β-adrenergic blockade[20]. Since the relationship between Ang-(1-7) and Ang Ⅱ remained unchanged in splanchnic and peripheral circulation of our cirrhotic patients, we could hypothesize that propranolol was not able to interfere with the final functional RAS effect upon vascular tone. Our data also suggest that the activity of the two main RAS enzymes, ACE and ACE2, were probably not reduced by propranolol use in cirrhotic patients, since the ratios between Ang Ⅱ and Ang I and between Ang-(1-7) and Ang I were increased in peripheral circulation and the ratio between Ang Ⅱ and Ang I was also elevated in splanchnic circulation. However, we can not exclude the possibility that other factors such as changes in the catabolism of Ang Ⅱ or Ang-(1-7) could have contributed to the reduction in absolute levels of each peptide.

In cirrhotic patients, arteriolar vasodilation and diuretic administration cause a decreased effective arterial blood volume that stimulates vasopressor systems leading to high levels of PRA, circulating norepinephrine, and vasopressin[21-23]. In this context, propranolol inhibits renin secretion and reduces vasodilation (SVR increase) in cirrhosis[17], leading to a reduction of the relative arterial hypovolemia. These actions could oppose the activated vasopressor systems (RAS, sympathetic nervous system and vasopressin) and may be involved in the amelioration of the hyperdynamic circulation observed in our cirrhotic patients.

It should also be pointed out that we are aware of the limitations of our study design. For example, peripheral blood samples generally represent the cumulative expression of RAS in multiple tissues and may not reliably reflect molecular activity in the splanchnic circulation. For this reason, we did manage to collect samples from the portal vein during liver transplantation. However, it is still difficult to compare these findings to the samples collected in peripheral blood from outpatients. Nevertheless, some aspects of this study may increase the strength of our findings, such as the utilization of strictly defined inclusion and exclusion criteria and the well-established protocol for the measurements of PRA and angiotensins[15].

In conclusion, results obtained with propranolol treatment in cirrhotic patients have been controversial[20,24]. While in advanced liver disease with significant reduction of the hepatic venous pressure gradient propanolol treatment decreased the risk of ascites, spontaneous bacterial peritonitis, hepatorenal syndrome and death[24], in unselected cirrhotic patients the same β-blocker was not able to prevent varices and was associated with an increased number of adverse events[20]. We believe that the use of propranolol in cirrhosis could change the prognosis of patients with hyperdynamic circulation and relative hypovolemia, but it is probably not able to interfere with potentially reversible liver fibrosis. Indeed, the use of propranolol did not alter the balance between the activity of the anti-fibrotic arm of the RAS, ACE2-Ang-(1-7)-Mas[8], and of the pro-fibrotic arm, ACE-Ang Ⅱ-AT1[6]. For this purpose, many studies have suggested that ACE inhibitors and AT1 receptor blockers seemed to be effective[25-29]. Their mechanisms of action probably involve not only the inhibition of Ang Ⅱ formation or action but also the augmentation of Ang-(1-7) levels or effects[5,29]. On the other hand, it should be mentioned that, mostly in advanced stages of cirrhosis, the ACE-Ang Ⅱ-AT1 arm contributes to the maintenance of basal vascular tonus[7] and therefore the use of AT1 receptor blockers or ACE inhibitors as antifibrotic therapies could not be well tolerated. Since propranolol administration seems to improve only the extrahepatic complications of the advanced cirrhotic patients, a possible therapeutic approach for human cirrhosis at this stage could be the combination of AT1 receptor blockers or ACE inhibitors with propranolol. Future studies with more powerful designs are obviously necessary to evaluate whether the use of propranolol at this stage of cirrhosis would enable the administration of AT1 receptor blockers or ACE inhibitors or even receptor Mas agonists to reduce liver fibrosis.

COMMENTS

Background

Recent studies have suggested that the Renin Angiotensin System (RAS) seems to be involved in cirrhosis. Non-selective β-adrenergic blockers have been widely used in treatment of portal hypertension in cirrhosis. However, the effect of propranolol on RAS mediators has still not been quantified. Since non-specific β blockade has been a standard approach to controlling the symptoms of portal hypertension and because the RAS seems to influence the outcome of portal hypertension and cirrhosis, it is reasonable to ask if there is a functional relationship between the RAS and beta-receptor system.

Research frontiers

This study represents an initial approach in understanding how non-specific β blockade affects RAS in cirrhotic patients by comparing the levels of plasma renin activity, Angiotensin (Ang) Ⅰ, Ang Ⅱ and Ang-(1-7), measured in the splanchnic and peripheral circulations of cirrhotic patients receiving or not receiving propranolol and by evaluating the effect of previous administration of propranolol on hemodynamic parameters during liver transplantation.

Innovations and breakthroughs

Chronic treatment with propranolol in cirrhotic patients is characterized by marked changes in the precursors of RAS cascade (Renin and Ang Ⅰ) with repercussion in RAS two main arms in the splanchnic and peripheral circulation. On the other hand, no changes were detected in the ratio between the two main RAS mediators [Ang-(1-7)/Ang Ⅱ]. Additionally, the treatment with propranolol seemed to be able to control the hyperdynamic circulation of cirrhotic patients probably due to an overall RAS inhibition, but without changes in the balance between the two RAS arms: ACE-Ang-AT1 (vasoconstrictor) *versus* ACE2-Ang-(1-7)-Mas (vasodilator).

Applications

Our data suggest that a possible therapeutic approach for advanced human cirrhosis could be the combination of AT1 receptor blockers or ACE inhibitors

with propranolol. Future studies with more powerful designs are obviously necessary to evaluate whether the use of propranolol at this stage of cirrhosis would enable the administration of AT1 receptor blockers or ACE inhibitors or even receptor Mas agonists to reduce liver fibrosis.

Peer review

In the current study, the investigators have taken the first steps to understand how β1 and β2 blockade affects RAS in patients. This is important because non-specific β blockade has been a standard approach to controlling the symptoms of portal hypertension.

Abstract

AIM: To determine the clinical data that might be useful for differentiating benign from malignant gallbladder (GB) polyps by comparing radiological methods, including abdominal ultrasonography (US) and computed tomography (CT) scanning, with postoperative pathology findings.

METHODS: Fifty-nine patients underwent laparoscopic cholecystectomy for a GB polyp of around 10 mm. They were divided into two groups, one with cholesterol polyps and the other with non-cholesterol polyps. Clinical features such as gender, age, symptoms, size and number of polyps, the presence of a GB stone, the radiologically measured maximum diameter of the polyp by US and CT scanning, and the measurements of diameter from postoperative pathology were recorded for comparative analysis.

RESULTS: Fifteen of the 41 cases with cholesterol polyps (36.6%) were detected with US but not CT scanning, whereas all 18 non-cholesterol polyps were observed using both methods. In the cholesterol polyp group, the maximum measured diameter of the polyp was smaller by CT scan than by US. Consequently, the discrepancy between those two scanning measurements was greater than for the non-cholesterol polyp group.

CONCLUSION: The clinical signs indicative of a cholesterol polyp include: (1) a polyp observed by US but not observable by CT scanning, (2) a smaller diameter on the CT scan compared to US, and (3) a discrepancy in its maximum diameter between US and CT measurements. In addition, US and the CT scan had low accuracy in predicting the polyp diameter compared to that determined by postoperative pathology.

INTRODUCTION

The development of radiological diagnostic tools such as ultrasonography (US) and computed tomography (CT) scanning has led to an increased frequency of the diagnosis of gallbladder (GB) lesions, such as GB polyps[1-3]. Because of the poor prognosis of GB malignancies, it is very important to distinguish between benign and malignant GB polyps so that malignant disease can be treated as soon as possible. Currently, clinical data such as the size and number of GB polyps and the age of the patient are used to help distinguish benign from malignant disease. Improved diagnostic methods are needed to differentiate between benign and malignant disease, and to determine which GB polyps

require surgical intervention[4-6].

Therefore, we evaluated clinical data to determine which factors would help distinguish benign from malignant GB polyps. We retrospectively analyzed the preoperative US and CT findings in patients with GB polyps and compared the results with their postoperative gross and microscopic findings.

MATERIALS AND METHODS

Fifty-nine patients who underwent laparoscopic cholecystectomy for a GB polyp of around 10 mm between January 2006 and August 2007 were enrolled in this study. We divided these patients into two groups, a cholesterol polyp group and a non-cholesterol polyp group. Data were collected for clinical features such as gender, age, symptoms, size and number of polyps, presence of a GB stone, radiological data from the preoperative US and CT scanning, and postoperative pathology data.

We compared the radiologically measured maximum diameters of the GB polyps obtained by one radiologist with the postoperatively obtained pathologic measurements of maximum diameters obtained by one pathologist. Results are reported as the mean ± standard deviation. For statistical analysis, a Chi-square, *t*-test and Fisher's Exact Test were used (SPSS version 15.0 software). A *P*-value < 0.05 was considered statistically significant.

RESULTS

Pathologic findings of the GB polyps

Of the 59 cases, 46 (78%) were pseudo-polyps such as a cholesterol polyp, inflammatory or hyperplastic polyp. Of these 46 pseudo-polyps, 41 (69.5%) were cholesterol polyps. True polyps were observed in 13 cases. Among the true polyps, 10 cases (17%) were adenomatous polyps and three cases (5.0%) were malignant.

Clinical findings of the GB polyps

Of the 59 patients, 37 patients were male and 22 were female. No difference was observed in gender ratios for the cholesterol polyp group (M:F = 25:16) and the non-cholesterol polyp group (M:F = 12:6 $P > 0.05$). The mean ages for each group were 40.98 ± 9.41 for the cholesterol polyp group and 48.39 ± 16.87 for the non-cholesterol polyp group. The former group had a significantly lower mean age ($P = 0.044$).

Five patients had presenting symptoms, which included three cases of indigestion, one case of right upper quadrant pain and discomfort and one case with fever suggesting cholecystitis. Three cases of cholesterol polyps (7.3%) and two cases of non-cholesterol polyps (11.1%) were associated with a GB stone. The factors associated with the metabolic syndrome were analyzed in the two groups. The mean body mass index (BMI) was 24.83 ± 2.92 kg/m^2 in the cholesterol polyp group and 23.80 ± 3.23 in the non-cholesterol polyp group; the mean homeostasis model assessment of insulin resistance (HOMA-IR) was 1.49 ± 1.85 and 1.26 ± 1.35 respectively, the mean HbA1c was 5.58 ± 0.74 (%) and 5.41 ± 0.23, respectively. The mean values for all these factors were slightly higher in the cholesterol polyp group but they were not statistically significant ($P > 0.05$) (Table 1).

Table 1 Clinical and laboratory characteristics of patients with gallbladder polyps (mean ± SD)

Histologic finding	Cholesterol polyp	Non cholesterol polyp	*P*-value
Age (yr)	40.98 ± 9.41	48.39 ±16.87	< 0.05
Sex (male/female)	25/16	12/6	0.677
Height (m)	1.6703 ± 0.09	1.65 ± 0.07	0.595
Weight (kg)	69.39 ± 13.26	64.85 ± 10.73	0.207
Cholelithiasis(case)	3	2	0.63
BMI (kg/m^2)	24.83 ± 2.92	23.80 ± 3.23	0.245
Fasting glucose (mg/dL)	97.05 ± 21.76	96.94 ± 15.0	0.985
Insulin (μIU/mL)	10.54 ± 3.63	9.47 ± 2.71	0.412
Homa-IR	1.49 ± 1.85	1.26 ± 1.35	0.64
HbA1c (%)	5.58 ± 0.74	5.41 ± 0.23	0.553
US size (mm)	9.95 ± 2.31	11.94 ± 4.02	< 0.05
CT size (mm)	6.77 ± 2.65	9.78 ± 5.19	< 0.05
Pathology size (mm)	4.83 ± 2.97	11.06 ± 5.11	< 0.01

Table 2 The number of polyps in cases with cholesterol and non-cholesterol polyps *n*(%)

		Cholesterol polyp	Non-cholesterol polyp	Total
Ultrasonographic findings ($P < 0.01$)				
Polyp number	Solitary	19 (46.3)	16 (88.8)	35 (59.3)
	Multiple	22 (53.7)	2 (11.1)	24 (40.7)
Total		41 (69.5)	18 (30.5)	59 (100.0)
Pathologic finding ($P < 0.01$)				
Polyp number	Solitary	11 (26.8)	15 (83.3)	26 (44.1)
	Multiple	30 (73.2)	3 (16.7)	33 (55.9)
Total		41 (69.5)	18 (30.5)	59 (100.0)

The number of GB polyps

In US, a single GB polyp was observed in 35 cases (59.3%) and multiple GB polyps were observed in 24 cases (40.7%). The proportion of multiple polyps in the cholesterol polyp group was 53.7% (22 out of 41 cases), which was higher than in the non-cholesterol polyp group (11.1%: 2 out of 18 cases, $P = 0.002$). For the postoperative pathology examinations, these proportions increased; 73.2% (30 out of 41 cases) and 16.7% (3 out of 18 cases), respectively ($P < 0.001$) (Table 2).

The discrepancy in maximum diameter between US and CT scanning

The preoperative mean maximum diameters measured by US in the cholesterol polyp group and the non-cholesterol polyp group were 9.95 ± 2.31 mm and 11.94 ± 4.02 mm, respectively, whereas for the CT scan they were 6.77 ± 2.65 mm and 9.78 ± 5.19 mm, respectively. The mean values for CT scanning tended to be smaller than for US.

The discrepancies in maximum diameters between US and CT scanning were 5.66 ± 3.87 mm in the

Table 3 The difference in the maximum polyp size between cholesterol and non-cholesterol polyps (mean ± SD)

	Cholesterol polyp	Non-cholesterol polyp	*P*-value
US-CT size difference (mm)	5.66 ± 3.87	2.17 ± 2.12	0
US size > CT size[1]	40/41	12/18	0.002
CT undetectable rate(%)	15/41 (36.6)	0/18 (0)	0.001
US-pathologic size difference (mm)	5.12 ± 3.42	0.89 ± 3.69	0

[1]Indicates number of patients having a larger size with US than CT.

Table 4 The correlation of size between cholesterol and non-cholesterol polyps

Correlation coefficients		Pathologic size	US size	CT size
Pathologic size	Non-cholesterol polyp	1	0.698[b]	0.746[b]
	Cholesterol polyp	1	0.181	0.324
US size	Non-cholesterol polyp	0.698[b]	1	0.925[d]
	Cholesterol polyp	0.181	1	0.427[c]
CT size	Non-cholesterol polyp	0.746[b]	0.925[d]	1
	Cholesterol polyp	0.324	0.427[c]	1

[b]$P < 0.01$ *vs* Pathologic size, [b]$P < 0.05$ *vs* US size.

cholesterol polyp group and 2.17 ± 2.12 mm in the non-cholesterol polyp group and this difference was statistically significant ($P < 0.01$). In 40 out of 41 cholesterol polyps (97.6%) and 12 out of 18 non-cholesterol polyps (66.6%) the diameters were smaller with CT scanning than with US ($P < 0.01$).

All 18 cases in the non-cholesterol polyp group were detected both by US and CT whereas 15 cases in the cholesterol polyp group among 41 (36.6%) were detected by US but not by CT scanning ($P < 0.01$, Table 3).

The discrepancy between preoperatively and postoperatively measured maximum polyp diameters

The pathologically measured mean maximum diameters were 4.83 ± 2.97 mm in the cholesterol polyp group and 11.06 ± 5.11 mm in the non-cholesterol polyp group ($P < 0.01$). When we compared these values with the preoperatively US measurements the discrepancies between preoperative and postoperative measurements were 5.12 ± 3.42 mm in the cholesterol polyps and 0.89 ± 3.69 mm in the non-cholesterol polyps ($P < 0.01$, Table 3).

The correlation between radiologically measured and pathologically measured polyp diameters

The non-cholesterol polyps showed statistically significant linear correlations between the actual maximum diameter from the pathology examination and the preoperative US measured diameter (correlation coefficient 0.698) and the CT measured diameter (correlation coefficient 0.746, $P < 0.01$). The cholesterol polyps, however, did not show this correlation ($P > 0.05$, Table 4).

DISCUSSION

The correct diagnosis of cholesterol polyps, which account for most of the pseudo-polyps of the GB, will help prevent unnecessary surgery and follow-up examinations. In this study, we attempted to characterize the features of the cholesterol polyp and determine accurate radiological predictive factors. Age is known to have a significant association with malignant polyps and is considered an independent risk factor[5-7]. This study also found that patients with non-cholesterol polyps had a higher mean age than did the patients in the cholesterol polyp group. Metabolic syndrome is also known to have a close relationship with the development of cholesterol polyps[2,8,9]. Although the patients with cholesterol polyps had higher levels of the BMI, HOMA-IR, and HbA1c, the differences did not reach statistical significance. The sample size might have been too small to detect any differences.

Regarding the number of polyps in the GB, it is also known that a single polyp is more likely to be a malignant polyp, which prompts the need for more aggressive interventions when a single polyp is identified compared to multiple polyps[5,10]. We found a similar tendency among our study population. The patients with cholesterol polyps more frequently had multiple polyps than did the patients with non-cholesterol polyps. It is well known that the size of a GB polyp is related to malignancy. Many studies have reported that a GB polyp ⩾ 10 mm has a high risk of being a malignancy and this size is one of the criteria for surgical intervention[4,11-13]. However, we also have observed that a benign polyp, such as a cholesterol polyp, can be as large as 10 mm. Therefore, size may not afford an accurate distinction between benign and malignant polyps[14,15].

In cases with a cholesterol polyp, we observed discrepancies in the size and number of polyps between the preoperative radiological measurements and the postoperative pathology measurements. The postoperative pathology of cholesterol polyps had a smaller size and higher multiplicity than did the preoperative radiological studies. A possible explanation for this finding is that the cholesterol polyp might be damaged during the laparoscopic cholecystectomy or during handling of the GB tissue considering its histological fragility and weakness. The cholesterol polyp had low correlation coefficients in the comparisons between the pathologically measured size after surgery and the radiologically measured sizes prior to surgery. Therefore, the radiological studies are limited in obtaining the correct measurements for cholesterol polyps.

In conclusion, the cholesterol polyp has a tendency to be observed more frequently in younger patients and has higher multiplicity. The predictive signs for a cholesterol polyp, a benign tumor, include: a polyp observable by US but not CT scanning, a discrepancy ⩾ 5 mm in the maximum diameter of the polyp between the US and CT measurements, a smaller diameter of the polyp by CT compared to US, and a low correlation between the diameter of the polyp from postoperative pathology and

the preoperative radiological measurements.

We suggest that it would be more efficient to make a flexible and tailored follow up plan or treatment plan for GB polyps based on the above mentioned signs rather than fixed or inflexible guidelines. In addition, the preoperative radiological measurement of diameter is of predictive value for the postoperatively measured actual diameter only for non-cholesterol polyps. For cholesterol polyps, the preoperative radiological measurements are limited in their prediction of postoperative pathology diameter. Therefore, methods that are more accurate for the preoperative diagnosis of cholesterol polyps are needed.

COMMENTS

Background

The development of radiological diagnostic tools has led to an increased frequency of the diagnosis of gallbladder (GB) lesions, such as GB polyps.

Research frontiers

It is very important to distinguish between benign and malignant GB polyps because of the poor prognosis of GB malignancies. Improved diagnostic methods are needed to differentiate benign from malignant disease, and to determine which GB polyps require surgical intervention.

Innovation and breakthroughs

The predictive signs for a cholesterol polyp, the most common benign GB polyp, include: a polyp observable by ultrasonography (US) but not computed tomography (CT) scanning, a discrepancy $\geqslant$ 5 mm in the maximum diameter of the polyp between US and CT measurements, a smaller diameter of the polyp by CT than by US.

Applications

This study should help to distinguish a cholesterol polyp from a non-cholesterol polyp. It would be more efficient to make a flexible and tailored follow up plan or treatment plan for GB polyps.

Peer review

The concept of this study is useful.

Abstract

AIM: To determine, by counting micronucleus (MN) frequencies, whether chromosomal or DNA damage have an effect on the pathogenesis of early colorectal adenocarcinoma (CRC).

METHODS: We analyzed MN frequencies in 21 patients with CRC, 24 patients with colon polyps [10 neoplastic polyps (NP) and 14 non-neoplastic polyps (NNP)] and 20 normal controls.

RESULTS: MN frequency was significantly increased in CRC patients and in NP patients compared with controls (3.72 ± 1.34, 3.58 ± 1.21 *vs* 1.97 ± 0.81, $P < 0.001$). However, there was no difference in the MN frequency between CRC patients and NP patients ($P > 0.05$). Similarly, there was no difference in the MN frequency between NNP patients (2.06 ± 0.85) and controls ($P > 0.05$).

CONCLUSION: Our results suggest increased chromosome/DNA instabilities may be associated with the pathogenesis of early CRC.

INTRODUCTION

Genomic instability plays an essential role in the development and progression of human colorectal cancer (CRC)[1]. Two major types of genetic instability have been described in CRC: chromosomal instability and microsatellite instability[1]. About 60% of CRCs develop through the chromosomal instability pathway, which is characterized by losses and gains of chromosomes (aneuploidy), as well as losses of heterozygosity[1].

CRC progresses through four distinct clinical stages that are described as dysplastic crypts, small benign tumors, malignant tumors invading surrounding tissues, and finally metastatic cancer. This progression involves several genetic changes such as inactivation of tumor suppressor genes and activation of oncogenes[2]. Mutations of the adenomatous polyposis coli (*APC*) gene are considered the earliest[3] and most prevalent genetic changes in colorectal tumorigenesis. More than 85% of colon cancers are estimated to have a somatic mutation of *APC*[4]. Furthermore, a large number of genes that trigger chromosomal instability have been identified in yeast in the past[5]. The underlying mechanisms leading to chromosomal instability in colorectal cancer remain to be characterized. The DNA double-strand break (DSB) is regarded as the most critical of all DNA lesions[6,7], and it has been shown that defects in the cellular response to DSBs can lead to genetic alteration, chromosomal instability, and ultimately malignant transformation[8].

The genome damage to the lymphocytes of peripheral blood has been widely used as a biomarker of genotoxic environmental factors, and long-term studies have demonstrated its validity and high clinical productivity[9]. Micronucleus (MN) is an acentric chromosome fragment or whole chromosome that is left behind during mitotic cellular division and appears in the cytoplasm of interphasic cells as a

small additional nucleus[10]. The formation of MN in dividing cells is the result of chromosome breakage due to unrepaired or mis-repaired DNA lesions, or chromosome malsegregation due to mitotic malfunction. These events may be induced by oxidative stress, exposure to clastogens or aneugens, genetic defects in cell cycle checkpoint and/or DNA repair genes, as well as deficiencies in nutrients required as co-factors in DNA metabolism and chromosome segregation machinery[11-14]. All these events can cause the formation of MN through chromosomal rearrangements, altered gene expression or aneuploidy, effects associated with the chromosome instability phenotype often seen in cancer[15,16].

The MN frequency test, widely accepted for *in vitro* and *in vivo* genotoxicity investigations, is a sensitive marker of genomic damage[17,18]. The presence of an association between MN induction and cancer development is supported by a number of observations. The most substantiated include: the high frequency of MN in untreated cancer patients and in subjects affected by cancer-prone congenital diseases, e.g. Bloom syndrome or ataxia telangiectasia[15,19], the presence of elevated MN frequencies in oral mucosa, used as a surrogate biomarker of cancer in clinical chemo-prevention trials[20], the correlation existing between genotoxic MN-inducing agents and carcinogenicity, e.g. ionizing and ultraviolet radiation[21,22].

A major question in cancer genetics is to what extent chromosome or genetic instability is an early event and thus a driving force of tumorigenesis?[23,24]. The aim of this study was to determine, by counting MN frequencies, whether chromosomal or DNA damage has an effect on the pathogenesis of early CRC.

MATERIALS AND METHODS

Patients

This study was conducted between May 2008 and September 2008 in the Erzurum Training and Research Hospital. Twenty-one patients with colorectal adenocarcinoma and 24 patients with colorectal polyps were studied. The study was conducted using colonoscopic specimens from subjects with the established diagnosis of colorectal polyps or colorectal adenocarcinoma in histologic analysis. Specimens were separated for each level and placed in 10% formalin solution. The pathologic specimens were reviewed independently by two pathologists.

Pathologists were blinded to the subject's clinical history, the colonoscopic findings, and the results of the Hematoxylin-Eosin staining assay. Pathologic reading was determined for each biopsy slide with an overall pathologic diagnosis determined for each subject.

We performed MN analysis in 21 (12 females and 9 males; mean age: 57.62 ± 10.84 years) patients with CRC, in 10 (4 females and 6 males; mean age: 52.44 ± 8.36 years) patients with NP, in 14 (6 females, 8 males; mean age: 52.92 ± 9.14 years) patients with NNP and in 20 (8 females and 12 males; mean age: 50.25 ± 9.38 years) healthy controls. The patients were selected from non-smoking and nonalcoholic subjects. None of the subjects had a history of viral infection, bacterial infection or any metabolic diseases. The patients had not been treated with chemotherapy or radiotherapy during the last 4 mo. The patient and control groups were chosen for their similar habits. The hospital Ethical Committee approved the human study. All patients were analyzed prior to treatment.

Micronucleus analysis

For MN analysis, 2 mL of heparinized blood was drawn from each individual. Lymphocyte cultures were established by adding 0.5 mL of whole blood to 5 mL karyotyping medium (Biological Industries, Beit Haemek, Israel) with 2% phytohaemagglutinin M (PHA; Biological Industries) according to standard techniques. The culture was kept at 37℃ for 72 h. Cytochalasin B (6 μg/mL, Sigma, USA) was added after 44 h of culture to block cytokinesis, allowing the identification of lymphocytes dividing in culture. Cells that had undergone the first mitosis were thus recognized as binucleated cells and were selectively screened for the presence of MN. The cells were then treated hypotonically with 0.075 mol/L KCl for 5 min at room temperature, and fixed in methanol/acetic acid (3:1). Cells were dropped onto slides and stained with 5% Giemsa in phosphate buffer (pH 6.8) for 5 min A thousand binucleated cells from each case were examined for MN by an experienced observer[25].

Statistical analysis

The MN rates were analyzed statistically by student's *t*-test. To evaluate the correlations between the age, sex, and MN rates, the coefficients of Spearman ρ correlation were calculated. A P value less than 0.05 was considered to be significant.

RESULTS

MN frequencies and clinical data obtained from the patient and control groups are shown in Table 1. According to these results, the mean MN frequency was significantly increased in CRC patients compared with controls (3.72 ± 1.34 *vs* 1.97 ± 0.81, $P < 0.001$). Similarly, the mean MN frequency was significantly increased in NP patients compared with controls (3.58 ± 1.21 *vs* 1.97 ± 0.81, $P < 0.001$). However, there was no difference in the mean MN frequency between CRC patients, and NP patients ($P > 0.05$). Similarly, there was no difference in mean MN frequency between NNP patients and controls (2.06 ± 0.85 *vs* 1.97 ± 0.81, $P > 0.05$). On the other hand, the mean MN frequencies did not correlate with patients' age or sex in the CRC patients (for each, $P > 0.05$). Similarly, the mean MN frequencies did not correlate with patients' age or sex in the colon polyp patients (for each, $P > 0.05$).

DISCUSSION

CRCs progress through a series of clinical and his-

Table 1 Micronucleus (MN) results of the patients with colorectal cancer and colon polyps and healthy controls (mean ± SE)

	Sex (F/M)	Age (yr)	Age at diagnosis (yr)	MN/1000 BN
CRC patients (n = 21)	12/9	57.62 ± 10.84	56.98 ± 9.45	3.72 ± 1.34
NP patients (n = 10)	4/6	52.44 ± 8.36	51.68 ± 8.54	3.58 ± 1.21
NNP patients (n = 14)	6/8	52.92 ± 9.14	50.48 ± 8.29	2.06 ± 0.85
Controls (n = 20)	8/12	50.25 ± 9.38		1.97 ± 0.81

CRC: Colorectal adenocarcinoma; NP: Neoplastic polyp; NNP: Non-neoplastic polyp.

topathological stages ranging from dysplastic crypts through small benign tumors to malignant cancers. This progression is the result of a series of genetic changes that involve activation of oncogenes and inactivations of tumor suppressor genes[26]. In colorectal cancer, chromosomal instability is the major form of genetic instability[27]. It is generally agreed that colorectal cancers develop as a consequence of accumulation of mutations in key genes such as *K-Ras, Apc*, and *p53* that are critical for regulating cell proliferation or cell cycle checkpoint control. In humans, the development from early adenomas to metastatic carcinomas takes somewhere from 20 to 40 years; it is believed that genetic instability plays a key role in accelerating the rate of mutation in cancerous cells[28].

CRCs exhibit a defect in chromosome segregation, leading to frequent gains or losses of chromosomes ($> 10^2$ per chromosome per generation)[28]. Chromosome instability has been detected in the smallest adenoma, suggesting that chromosome instability may occur at very early stages of colorectal carcinogenesis[29]. Extensive research during the past has led to the identification of genes that play a major role in the development of colorectal cancer. For example, mutations or deletions of the adenomatous polyposis coli (*APC*) gene, encoding a 310-kDa cytoplasmic protein[30,31], are commonly found in inherited familial adenomatous polyposis patients and in sporadic colorectal cancers[32,33]. Such mutations appear to be an early event during colorectal tumorigenesis[4].

The most commonly affected gene in sporadic colon cancer with defective DNA mismatch repair (MMR) is *hMLH1*, with the primary mechanism of gene inactivation being hypermethylation of the promoter[34]. These tumors account for approximately 15% of sporadic colon cancers. The majority of sporadic colon cancers (85%), however, are proficient in DNA MMR but show another form of genomic instability at the gross chromosomal level, which has been called chromosomal instability. Such chromosomal instability represents the end result of a number of processes, including mutations in mitotic checkpoint genes, microtubule spindle defects, and telomere dysfunction[35].

Two types of genetic instability have been identified, with chromosomal instability predominating[1,36]. The molecular basis for chromosomal instability is just beginning to be explored[37]. A large number of gene alterations can give rise to chromosomal instability in *Saccharomyces cerevisiae*[5,38]. These genes include those involved in chromosome condensation, sister-chromatid cohesion, kinetochore structure and function, and microtubule formation and dynamics as well as checkpoints that monitor the progress of the cell cycle. To date, the only genes implicated in aneuploidy in human tumor cells are those of the latter class. Heterozygous mutations in the mitotic spindle checkpoint gene *hBUB1* were detected in a small portion of colorectal tumors with the chromosomal instability[39].

The identification of aneuploidy at early stages of tumor formation in *MYH*- and *APC*-mutant polyps is interesting also in view of previous reports showing that loss of *APC* function in primary mouse cell lines results in chromosomal instability due to a kinetochore attachment defect at mitosis[36]. It is generally accepted that *APC*'s main tumor suppressing activity resides in its capacity to bind and regulate Wnt/β-catenin signal transduction[40]. However, additional *APC* functions in cytoskeletal organization, mitotic spindle assembly, cell migration, and apoptosis may play important roles in tumor progression and malignant transformation[40,41].

It has been demonstrated that chromosomes display nonrandom changes in cancer cells. These include structural rearrangements, e.g. deletions, amplifications or translocations that arise from breaks in DNA, as well as alterations in the number of intact chromosomes, known as whole-chromosome missegregations, originating from errors in cell division (mitosis). As a result of the accumulation of such processes, chromosomal instability is thought to play a key role in tumor development[40].

In the present study, we investigated whether cytogenetic abnormalities participate in the pathogenesis of early CRC. Cytogenetic endpoints are sensitive biomarkers that are widely accepted to evaluate chromosome damage[42,43]. MN assay provides a measure of both chromosome breakage and chromosome loss or nondisjunction in clastogenic and aneugenic events, respectively[11,13].

MN assay is a sensitive indicator of exogenously or endogenously caused genetic damage and MN frequency has become an important end point in genotoxicity testing both *in vivo* and *in vitro*[17,18]. Elevated levels of MN are indicative of defects in DNA repair and chromosome segregation which could result in generation of daughter cells with altered gene dosage, or deregulation of gene expression that could lead to the evolution of the chromosome instability phenotype often seen in cancer[10,11,15,21]. These considerations give

mechanistic support to a possible causal association between MN frequency and the risk of cancer. A recently published cohort study linking the frequency of micronuclei in lymphocytes of healthy subjects to the risk of cancer reported stomach cancer among the sites most specifically associated with micronuclei frequency[44]. Similar findings have also been reported for preneoplastic lesions of colon[45], esophagus[46] and cervix[47]. In particular, the higher risks noted for stomach and intestinal cancers, are in agreement with the literature, which emphasizes the role of chromosome rearrangements in the early stages of these tumours[47,48].

Our study, which showed increased MN frequencies in the lymphocytes of CRC and colon polyp patients, could support these observations, as the induction of changes in DNA that lead to mutations plays a role in carcinogenicity. Establishment of inherited susceptibility factors is important in recognizing individuals at a higher risk of developing CRC, so that they may benefit from early detection and prevention programs. Many investigators have demonstrated genomic instability and abnormalities in patients with CRC[49-51]. Further, experimental evidence shows that early colorectal adenomas have allelic imbalance[52]. *hCDC4* mutations have been shown to occur early in colorectal tumorigenesis[53].

An association between MN and cancer has been reported[19]. The causes of this association may be structural chromosomal aberrations and aneuploidy[19]. The presence of an association between the frequency of micronuclei in lymphocytes and cancer risk has been suggested[13,44]. Our findings of a high level of MN frequency in patients with CRC or NP seem to support this association. Thus, MN assay may be performed in lymphocytes as an indicator of genomic instability relevant to colorectal tumorigenesis.

In conclusion, our results indicate that the increased MN frequency in lymphocytes of patients with CRC and NP may reflect genomic instability or deficiency of DNA repair capacity. Further, these results suggest increased chromosome/DNA instabilities may be associated with the pathogenesis of early CRC.

COMMENTS

Background

It is known there is an increased micronucleus (MN) frequency rate in neoplastic disease. Colorectal adenocarcinoma (CRC) is a common cause of cancer-related deaths worldwide, despite improved diagnostic and therapeutic implications. Hence, early diagnosis has critical importance. The aim of this study was to determine, by counting MN frequencies, whether chromosomal or DNA damage has an effect on the pathogenesis of early CRC.

Research frontiers

The MN frequency test, widely accepted for in vitro and in vivo genotoxicity investigations, is a sensitive marker of genomic damage. Therefore, in this study, we aimed to determine, by assessing MN rates, whether genetic impairment and DNA damage have an effect on the pathogenesis of CRC.

Innovations and breakthroughs

Our results suggest increased genomic instability may be associated with the pathogenesis of early CRC. The identification of increased MN frequency rate in patients with colorectal lesions may be helpful in the early diagnosis of CRC.

Applications

MN analysis has come into use as a sensitive means of monitoring DNA damage. MN analysis may be used as a marker to estimate the risk of CRC.

Terminology

Micronucleus (MN): MN is an acentric chromosome fragment or whole chromosome that is left behind during mitotic cellular division and appears in the cytoplasm of interphasic cells as a small additional nucleus.

Peer review

This study indicated genetic impairment and genetic instability may play an important role in CRC. Further, MN frequency is a promising biomarker for assessing the risk of neoplastic progression in colorectal adenocarcinoma.

Abstract

AIM: To evaluate serum neopterin levels and their correlations with liver function tests and histological grade in children with hepatitis-B-related chronic liver disease.

METHODS: The study population comprised 48 patients with chronic active hepatitis B, 32 patients with hepatitis-B-related active liver cirrhosis and 40 normal controls. Serum neopterin was measured using an enzyme-linked immunosorbent assay.

RESULTS: The mean ± SD serum neopterin levels were 14.2 ± 5.6 nmol/L in patients with chronic hepatitis, 20.3 ± 7.9 nmol/L in patients with liver cirrhosis and 5.2 ± 1.4 nmol/L in control group. Serum neopterin levels were significantly higher in patients with chronic hepatitis (P = 0.005) and cirrhosis patients (P = 0.008), than in control subjects. Cirrhotic patients had significantly higher serum neopterin levels than patients with chronic hepatitis (P = 0.004). There was a positive correlation between serum neopterin levels and alanine aminotransferase levels in patients with chronic hepatitis (r = 0.41, P = 0.004) and cirrhotic patients (r = 0.39, P = 0.005). Positive correlations were detected between serum neopterin levels and inflammatory score in patients with chronic hepatitis (r = 0.51, P = 0.003) and cirrhotic patients (r = 0.49, P = 0.001).

CONCLUSION: Our results suggest that serum neopterin levels can be considered as a marker of inflammatory activity and severity of disease in children with hepatitis-B-related chronic liver disease.

INTRODUCTION

Neopterin is a pteridine derivative produced by macrophages activated under the control of gamma-interferon and released from T-cells by the activation of the cellular immune system[1]. It has been demonstrated that there is a relation between neopterin levels in biological materials, the changes in their elimination rates and various pathological conditions. In addition to its association with activation of cell-mediated immunity and with cell expansion, significant changes were seen in neopterin levels and elimination rates in viral diseases (for example viral hepatitis)[2,3], atypical phenylketonuria[4], organ and tissue rejection[5], autoimmune diseases (such as rheumatoid arthritis and systemic lupus erythematosus[6]), genital cancer and hematologic neoplastic disorders[7,8]. In all these cases, enhanced concentrations of neopterin have been shown to have prognostic significance[9].

In chronic active hepatitis, necrosis is observed as disseminated to the parenchyma and the perilobular consisting of lymphocytes and plasma cells. The gamma-interferon released from T-lymphocytes in the area stimulates and activates macrophages[10]. Lymphocytic cell infiltration was shown, in addition to the macrophages within the fibrous bands in the liver of patients with cirrhosis resulting from various etiologies[11]. Thus, it is suggested that neopterin secreted from the inflammation-activated macrophages can be an indication of the inflammation in the liver in chronic

liver diseases[10-12].

Studies in adult patients with acute hepatitis, chronic hepatitis and cirrhosis have shown that serum neopterin levels are elevated and this elevation is correlated with the severity of disease. However, there is no data about serum neopterin concentrations in children with chronic hepatitis B and liver cirrhosis. Therefore, we investigated serum neopterin concentrations in children with hepatitis-B-related chronic liver disease and correlated these concentrations with liver function tests and inflammatory activity of the liver. The aim of this study was to demonstrate a possible relationship between serum neopterin levels and severity of the disease.

MATERIALS AND METHODS

The study population comprised 48 patients with chronic active hepatitis B, 32 patients with hepatititis-B-related active liver cirrhosis and 40 normal controls. The control group consisted of otherwise healthy, age- and sex-matched children whose biochemical tests were also within normal limits. The study was performed according to the Declaration of Helsinki, and all parents gave informed consent for the participation of their children in the study.

Chronic active hepatitis B was diagnosed on the basis of Hepatitis B surface antigen (HbsAg) and Hepatitis B e antigen (HbeAg) positivity in serum for a period over 6 mo, positive HBV-DNA determined at least twice in one-month intervals (> 5 pg/mL), and evidence of chronic active hepatitis B in a liver biopsy carried out within the last 6 mo. None of the patients in this group had Hepatitis C or Hepatitis D infections, decompensated liver disorder, autoimmune hepatitis, α_1-antitrypsin deficiency, Wilson disease or any other liver disease. The patients were evaluated before no treatment was initiated.

Hepatitis-B-related active liver cirrhosis was diagnosed by clinical, serological, and biochemical tests as well as histopathological investigation of liver biopsy. The cirrhotic patients were classified by the Child-Pugh classification defined by Pugh *et al*[13].

Liver function tests (serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transpeptidase (GGT), alkaline phosphase (AP) and albumin) were also performed in all subjects using an autoanalyzer.

Serum neopterin levels were examined using an enzyme-linked immunosorbent assay (ELISA) kit (Neopterin ELISA, IBL Immuno-Biological-Laboratories, Hamburg).

All patients with chronic hepatitis and liver cirrhosis underwent liver biopsy. Liver biopsy was performed according to the Menghini technique. The biopsy material was kept in 10% formaldehyde solution and evaluated by a pathologist experienced in liver pathology. In the samples obtained from the patients with chronic hepatitis and liver cirrhosis, histological activity index (HAI) score was defined as suggested by Knodell *et al*[14] and modified by Desmet *et al*[15]. It was graded 0-18 by adding the scores for periportal ± bridging necrosis (0-10), intralobular degeneration and focal necrosis (0-4) and portal inflammation (0-4).

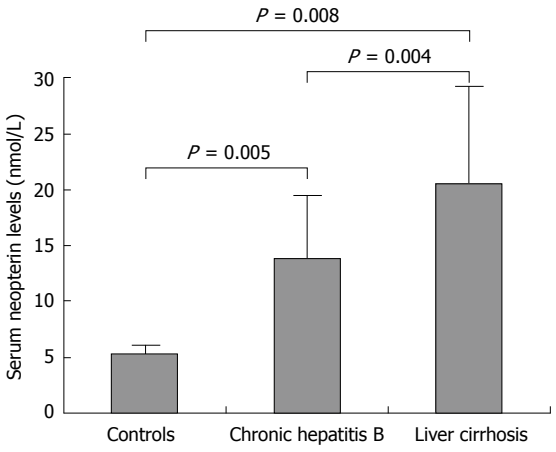

Figure 1 Serum neopterin levels in normal controls and patients with chronic hepatitis B and liver cirrhosis.

All data was shown in mean ± SD values. A Chi square test was used to analyze the categorical data, whereas an ANOVA test was used to compare the numerical data of the groups. The homogeneity of the intergroup variance was tested by the Levene method. If the variance was homogenous ($P > 0.05$), then the Tukey test was used, and if not ($P > 0.05$), then the Tamhane test was used to evaluate the significance of the difference between the groups. The correlations between serum neopterin levels and biochemical and histological parameters were determined by the Pearson correlation test. The differences between the groups were taken statistically significant if it is $P < 0.05$.

RESULTS

The characteristics of all the subjects are shown in Table 1. There were no significant differences between the three groups in terms of sex and age. Serum neopterin levels (mean ± SD) were found to be 14.2 ± 5.6 nmol/L (range 2.7-32) in patients with chronic active hepatitis B, 20.3 ± 7.9 nmol/L (range 12-41) in patients with hepatitis-B-related active liver cirrhosis and 5.2 ± 1.4 nmol/L (range 2.2-6.8) in controls. Serum neopterin levels were significantly elevated in patients with chronic hepatitis B ($P = 0.005$) and liver cirrhosis ($P = 0.008$) than in healthy controls. Patients with liver cirrhosis had higher serum neopterin levels compared to patients with chronic hepatitis B ($P = 0.008$) (Figure 1).

There was a positive significant correlation between serum neopterin levels and ALT levels ($r = 0.41$, $P = 0.004$). No significant correlations were found between serum neopterin levels and AST ($r = 0.18$, $P = 0.22$), GGT ($r = 0.33$, $P = 0.07$), AP ($r = 0.09$, $P = 0.64$), and albumin ($r = -0.34$, $P = 0.06$) levels in patients with chronic hepatitis B. A positive significant correlation was observed between neopterin levels and HAI ($r = 0.52$, $P = 0.001$) (Figure 2A).

According to the Child-Pugh classification, all of the 32 patients with liver cirrhosis were in stage A. In the liver

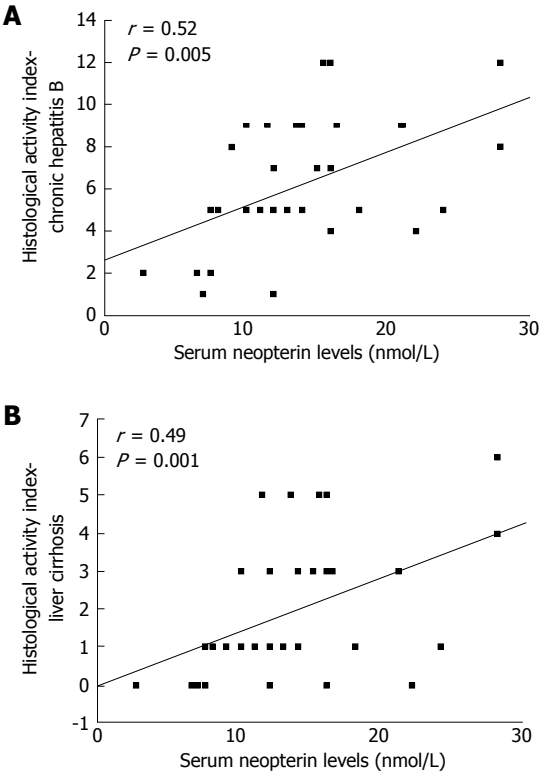

Figure 2 Correlation between serum nopterin levels and histological activity index. A: Chronic hepatitis B; B: Hepatitis-B-related liver cirrhosis.

cirrhosis group, serum neopterin levels were significantly related to ALT values ($r = 0.39$, $P = 0.005$) and HAI ($r = 0.49$, $P = 0.001$) (Figure 2B). There were no correlations between serum neopterin levels and AST ($r = 0.20$, $P = 0.517$), GGT ($r = 0.35$, $P = 0.263$), AP ($r = 0.09$, $P = 0.772$), and albumin ($r = -0.11$, $P = 0.731$) levels.

DISCUSSION

It has been reported that neopterin levels increase in body fluids and change in parallel to the activity of the disease in many infectious diseases and various malign disorders in which activation of the cellular immune system plays an important role in the pathogenesis[7,16,17]. It has been shown that the activation of cellular immune system stimulates the secretion of γ-interferon from the T lymphocytes, and γ-interferon is an effective inducer of neopterin release by monocytes/macrophages[10]. Gamma-interferon is produced by the stimulation of T-lymphocytes by several specific antigens, primarily viral antigens, thus it was found that the neopterin levels were especially elevated in viral infections.[3,17].

Evidence of elevation in neopterin levels in body fluids due to the activation of immune system, which was also supported by several studies involved in diseases leading to activation of the immune system, suggests that elevated neopterin can also be a marker for the follow-up of chronic liver disorders, especially of viral liver disorders[9]. However, since no such data is available related to children, our results can only be compared to results obtained from the studies carried out with adult patients.

It is suggested that serum neopterin levels can be used as a significant parameter for the differential diagnosis of non-infectious hepatitis and viral hepatitis[18]. Serum neopterin levels of the patients with acute and chronic hepatitis B were found to be significantly higher than the donors' serum. The relation between neopterin levels and severity of the disease has been proved, and it can be used in combination with clinical data as a prognostic evidence for the progress of the disease[19]. In asymptomatic HbsAg carriage, acute hepatitis, chronic inactive hepatitis, chronic active hepatitis, liver cirrhosis, hepatocellular carcinoma and alcoholic liver disease, serum and urine neopterin levels were found to be higher than in controls. The most elevated neopterin levels were seen in patients with acute hepatitis[20].

In adult patients with liver cirrhosis, serum neopterin levels were more elevated than non-cirrhotic patients and control groups[9,21] whereas out of non-cirrhotic patients, patients with chronic hepatitis B had also elevated neopterin levels[9].

Serum neopterin levels were elevated in patients with alcoholic cirrhosis[22]. Neopterin measurement was reported to be beneficial for the differential diagnosis of viral and alcoholic liver diseases, and it has been shown that patients with viral hepatitis had higher neopterin concentrations compared to patients with alcoholic liver diseases[20].

Serum and urine neopterin levels were elevated from baseline after the initiation of interferon therapy in HbeAg positive patients with chronic hepatitis B, and they remained markedly elevated during the treatment. However, the neopterin levels were restored rapidly to baseline values after the end of the therapy. Therefore

it was suggested that serum and urine neopterin levels could be a good marker of the cellular immunity during interferon treatment in the chronic hepatitis B infection[23].

In our study, serum neopterin levels was found to be markedly higher in the pediatric patients with chronic hepatitis B and liver cirrhosis than in healthy controls, which is in agreement with the data obtained from the adult patients. It was also higher in patients with cirrhosis when compared with chronic hepatitis B patients. The patients in the cirrhotic stage, independent of their etiology, have elevated concentrations of serum neopterin levels released from the activated macrophages. In those patients, substances that are considered to stimulate the macrophages such as immune complexes or endotoxins, increase in blood due to the lack of peptide clearance by the liver[24]. These mechanisms explain the highest concentrations of serum neopterin in patients with cirrhosis.

Although no correlation was found between serum neopterin levels and ALT, AST and AP levels in adults with various chronic liver diseases of various etiologies, a negative correlation was found with albumin[9]. While neopterin levels were found correlated with liver function tests in patients with acute hepatitis, this correlation was not verified in patients with chronic liver diseases[20]. However, in other studies, a correlation was found between serum neopterin levels and biochemical tests or liver inflammatory grading in patients with chronic hepatitis C and B[9,25]. We found a significant correlation between serum neopterin levels and ALT or HAI in children with hepatitis-B-related chronic hepatitis B and liver cirrhosis. This data agrees with the data obtained from the adult patients.

In conclusion, these results suggest that measurement of serum neopterin levels can be considered as a marker of inflammatory activity and severity of disease in children with hepatitis-B-related chronic liver disease. However, this needs to be further studied in children.

Abstract

AIM: In the present study, antibody and peripheral blood mononuclear cells (PBMC) proliferative responses against hepatitis C virus (HCV) antigens were evaluated in HCV chronically infected patients.

METHODS: Paired serum and PBMC samples were taken six months apart from 34 individuals, either treated or not, and tested by enzyme-linked immunosorbent assay (ELISA) and carboxyfluorescein succinimidyl ester staining.

RESULTS: Over 70% of the patients showed specific IgG and IgM against capsid, E1 and NS3, while HVR-1 was recognized by half of the patients. An increase in the levels of the anti-capsid IgM (P = 0.027) and IgG (P = 0.0006) was observed in six-month samples, compared to baseline. Similarly, a significantly higher percent of patients had detectable IgA reactivity to capsid (P = 0.017) and NS3 (P = 0.005) after six months, compared to baseline. Particularly, IgA against structural antigens positively correlated with hepatic damage (P = 0.036). IgG subclasses evaluation against capsid and NS3 revealed a positive recognition mediated by IgG1 in more than 80% of the individuals. On the contrary, less than 30% of the patients showed a positive proliferative response either of CD4+ or CD8+ T cells, being the capsid poorly recognized.

CONCLUSION: These results confirm that while the cellular immune response is narrow and weak, a broad and vigorous humoral response occurs in HCV chronic infection. The observed correlation between IgA and hepatic damage may have diagnostic significance, although it warrants further confirmation.

INTRODUCTION

Hepatitis C virus (HCV) constitutes a major health problem, since it is infecting an estimated 170 million people worldwide. Probably, the most characteristic feature of this virus is its propensity to cause chronic infection, which is established in the majority of cases and has become a leading indication to liver transplantation in Western countries[1]. The burden of HCV infection is even more dramatic due to the absence of preventive or therapeutic vaccines. Additionally, the best available treatments, based on pegylated interferon plus ribavirin, are generally effective only in 50% of cases[2]. Thus, the development of new treatments and prophylactic interventions is currently a priority.

Despite almost two decades of intense research, since its description by Choo and coworkers[3], correlates of protection have not been entirely established for HCV infection. The specific humoral response to acute infection is considered of relatively low titer and delayed in time from the moment of infection[4,5]. Antibodies directed to the capsid protein are the first ones to be detected[4], and have been determined to be principally of IgG and, secondly, of IgM classes in chronic infection[6]. Particularly, the significance of IgM anti-HCV capsid in chronic infection has been studied[7,8]. Results indicate that IgM anti-HCV capsid occurrence is directly related to viremia levels[8] and these antibodies have been found to decrease or disappear in patients in disease remission and increase when the disease reactivates after therapy[6]. Another feature reported as characteristic of HCV-specific antibody response is its restriction, except for the capsid, to the IgG1 isotype, the rest of the subclasses being poorly prevalent[4].

Evidence for a significant role of antibody responses in viral clearance seems conflicting, since it has been observed that subjects with antibody deficiencies may spontaneously clear HCV infection[9]. Several epitopes of the envelope glycoproteins have been identified as targets of neutralizing antibodies[10]. However, in the majority of the patients, chronic infection is established in spite of their presence[11], probably due to their absence or low titers in early phases of the infection[12].

On the other hand, the importance of a sustained, multispecific CD4+, as well as CD8+, T cell responses, targeting numerous epitopes early in infection, has been highlighted[13-16]. In persistently infected patients, CD4+ and CD8+ T cells are found at low frequencies in peripheral blood, but seem to be compartmentalized in the liver[17]. It has been demonstrated that, in most subjects, a detectable cell-mediated immune response is generated at the onset of acute infection, but this response progressively disappears in those where HCV infection becomes persistent[18]. Impaired production of interferon-gamma (IFN-γ) and interleukin- (IL-) 2, as well as incapability to proliferate *in vitro*, have been demonstrated for CD4+ T cells of chronically infected patients[18-20]. Similarly, CD8+ T cells of persistently infected subjects fail to produce IFN-γ and tumor necrosis factor-alpha (TNF-α) in functional assays[21,22].

In this work, we aimed at evaluating HCV-specific immune response in chronically infected patients, treated or untreated, using paired blood samples taken 6 months apart. IgG, IgM and IgA levels, as well as IgG1-4 subclasses and peripheral blood mononuclear cells proliferative responses against HCV core, envelope and NS3 antigens were measured. Additionally, we studied the relationship between immune parameters and patients' demographic characteristics.

MATERIALS AND METHODS

Study population

The study cohort included 34 patients with chronic HCV genotype 1 infection. The enrolment of patients was conducted at the National Institute of Gastroenterology (Havana, Cuba). Written informed consent was obtained from every patient prior to start of the study. All procedures were conducted in accordance with the national ethics guidelines and the Declaration of Helsinki, as revised in 1996. A patient with chronic HCV infection was defined as an individual with detectable HCV RNA and sustained liver injury for more than 6 mo, as monitored by liver function tests [alanine aminotransferase (ALT)/aspartate aminotransferase (AST)] and/or liver biopsy, scored according to the Ishak system. Patients were either treatment naïve or had been treated with the interferon-α (IFN-α) and ribavirin combination during the study period, except one subject who had received IFN-α monotherapy. Blood samples were taken at baseline (T = 0) and 6 mo later (T = 6). Demographic data of patients involved in the study are shown in Table 1.

Antigens

The recombinant proteins Co.120[23], E1.340[24] and NS3[25] are expressed in modified *Escherichia coli* and purified to 90%, except E1.340 which is purified to 85%. E2.680 recombinant protein is expressed in modified *Picchia pastoris* yeast and purified to 85%[26]. The HVR-1 peptide comprises amino acids 384-414 (TGTYVTGGTAARGVSQFTGLFTSGPSQKIQL) of the E2 protein[27]. All the recombinant proteins and the

HVR-1 synthetic peptide correspond to a genotype 1b strain. Peptide pools individually comprising the whole sequence of the capsid, E1 and E2 proteins of HCV-1a strain were also used for Peripheral blood mononuclear cells (PBMC) proliferation assays. These peptides were 18 amino acids in length, overlapping adjacent peptides by 10 amino acids. Peptide pools were kindly donated by Dr Naglaa Shoukry (Centre de Recherche du CHUM, Montreal, Canada).

Evaluation of antibody response against HCV antigens

To detect human antibodies to HCV structural antigens, 96-well microtiter plates (Costar, Cambridge, MA, USA) were coated with 100 μL of Co.120 (10 μg/mL), E1.340 (10 μg/mL), HVR-1 synthetic peptide (2 μg/mL) or NS3 (5 μg/mL) diluted in coating buffer (50 mmol/L carbonate buffer, pH 9.6) followed by 16-h incubation at 4℃. The wells were washed four times with 0.1% Tween 20 in phosphate buffered saline (0.14 mol/L NaCl, 0.003 mol/L KCl, 0.01 mol/L Na_2HPO_4, 0.001 mol/L KH_2PO_4, pH 7.5) (PBST) and blocked with 200 μL of PBST containing 2% skim milk (Oxoid Ltd, England) and 5% goat normal serum (blocking solution) for 1 h at 25℃. After four washes with PBST, each well received 100 μL of a 1:10 dilution of human sera in blocking solution and the plates were incubated at 37℃ for 1 h. Sera were diluted 1:80 in blocking solution for the evaluation of the specific response against E1.340. The plates were washed four times with PBST. Then, 100 μL of horseradish peroxidase-conjugated goat anti-human IgM, IgA or IgG secondary antibodies (Sigma, St Louis, USA), 1:10 000, 1:25 000 and 1:30 000 diluted, respectively, in PBST plus 2% skim milk, were added and the plates were incubated at 37℃ for 1 h, followed by four washes with PBST. IgG subclasses were evaluated with the secondary biotinylated antibodies against human IgG1, IgG2, IgG3 and IgG4 (Sigma-Aldrich, St Louis, USA) respectively diluted 1:24 000, 1:5000, 1:5000 and 1:1000 in blocking solution. After four washes with PBST, an additional 1 h incubation step at 37℃ with extravidin-peroxidase conjugate (Sigma, St Louis, USA), 1:1000 diluted in PBST plus 2% skim milk, was carried out followed by four washes with PBST. In every case, positive reactions were visualized with o-phenylenediamine (Sigma-Aldrich, St Louis, USA) 0.05% in substrate buffer (0.1 mol/L citric acid, 0.2 mol/L NaH_2PO_4, pH 5.0) with 0.015% H_2O_2 (Merck, Germany) as substrate. Reactions were stopped with 50 μL of 2.5 mol/L H_2SO_4. Measurement of absorbance (A) at 492 nm was made in a SensIdent Scan reader plate (Merck, Darmstadt, Germany). At least two human sera, anti-HCV negative by UMELISA (Center for Immunoassay, Cuba), were used as negative controls in each experiment. Anti-HCV positive human sera (as tested by UMELISA, Center for Immunoassay, Cuba), having a known antibody titre of at least 1:150 against the corresponding antigen, served as positive controls. The cut-off value to consider a positive antibody (Ab) response was established as twice the mean A_{492nm} of the negative control sera.

PBMC preparation

Blood anticoagulated with acid citrate dextrose (1:9) was processed within 2 h after sample collection. PBMC from HCV patients and a healthy individual were isolated using Ficoll-Paque PLUS density gradients (Amersham, Oslo, Norway), and adjusted to 5-10 × 10^6 cells/mL in freezing medium consisting of nine parts of foetal bovine serum (FBS; Hyclone) and one part of DMSO (Sigma, Deisenhofen, Germany). PBMC were stored for 16 h in 1℃ freezing containers (Nalgene Nunc International, Rochester, New York, USA) at 80℃ and then transferred into liquid nitrogen until use.

Evaluation of CD4+ and CD8+ T cell proliferative response against HCV antigens

T cell proliferation assays were used to analyze HCV specific T cell responses against proteins Co.120, E1.340, E2.680 and NS3 or peptide pools covering core, E1 and E2 HCV proteins, depending on patients' PBMC availability. Cryopreserved PBMC were thawed quickly in a 37℃ water bath, and washed twice with R10 medium. After a 16-h resting period at 37℃ and 50 mL/L of CO_2, cells were washed twice with PBS, adjusted to 20 × 10^6 cells/mL and labeled with 4 μmol/L of carboxyfluorescein succinimidyl ester (CFSE) for 8 min at room temperature in the dark. The reaction was stopped by adding 1 volume of human AB serum (Sigma-Aldrich, St. Louis, USA). Next, PBMC were washed twice with PBS and once with RPMI 1640 medium (Sigma-Aldrich, St. Louis, USA). Cells were finally adjusted to 2 × 10^6 cells/mL and stimulated or not with the peptide pools (1 μg/mL) and proteins (2 μg/mL, except for NS3, of which a concentration of 5 μg/mL was used) for 6 days at 37℃ and 50 mL/L of CO_2. Cells incubated with media alone were considered as negative control. Concanavalin A (ConA, Sigma-Aldrich, St. Louis, USA, 5 μg/mL) was used as positive control. Cells were harvested, stained with surface antibodies and analyzed by flow cytometry. Anti-CD4 allophycocyanin (APC) (clone # 11 830), anti-CD8 phycoerythrin (PE) (clone # 37 006) and anti-CD8 APC (clone # 37 006) monoclonal antibodies, 4 μg/mL, 2.5 μg/mL and 5 μg/mL respectively, were from R&D Systems (R&D Systems, Minneapolis, USA). The stimulation index (SI) was calculated by dividing the proliferative frequency (%) in the presence of antigen by the proliferative frequency (%) without antigen. The stimulation index was considered positive if $\geqslant$ 2.5 after peptide stimulation and $\geqslant$ 3 after protein stimulation.

Statistical analysis

GraphPad Prism version 4.00 statistical software (GraphPad Software, San Diego, CA) was generally used to carry out statistical analysis. Unpaired t test (for data sets with a Gaussian distribution and equal variances) and Mann Whitney test (for data sets with non-Gaussian distribution or different variances) were used to compare the magnitude of a given response between the two evaluated time points. For comparison of the number of

Table 2 Reactivity of the main antibody classes against core, E1, HVR-1 and NS3 antigens in sera taken at baseline

Isotypes	Percentage of patients with a positive response against the indicated antigen			
	Core	E1	HVR-1	NS3
IgG	91.1	70.8	51.5	88.2
IgM	76.4	78.7	5.8	79.4
IgA	52.9	39.3	12.1	50

Table 3 Reactivity of IgG subclasses against core and NS3 antigens in sera taken at baseline

IgG Subclasses	Percentage of patients with a positive response against the indicated antigen	
	Core	NS3
IgG1	85.2	82.3
IgG2	17.6	39.3
IgG3	11.7	12.1
IgG4	48.4	78.7

positive samples at the two evaluated moments, Fisher's exact test was used. Correlations between variables were analyzed by Spearman's rank correlation coefficient, using SPSS 11.5.1 Software for Windows. Significant differences were considered when $P < 0.05$.

RESULTS

Study subjects

The present study was designed to evaluate the specific immune response against HCV in genotype 1 chronically infected patients, in a 6-mo follow-up period. Of the 34 patients initially enrolled in the study, only 31 could be contacted for a second blood extraction 6 mo later. In this cohort, 73.5% of the patients were over 40 years of age, 67.6% had been treated with the standard combined therapy with IFN-α and ribavirin and only 11.7% of the individuals reported to consume alcohol. Over 73% of the patients had undergone a liver biopsy and of them, 64.7% showed a mild to moderate necro-inflammatory activity, as measured by Ishak scores. Table 1 summarizes the principal demographic characteristics.

Humoral immune response to HCV antigens

The reactivity to HCV antigens was assessed in serum samples from 34 patients chronically infected with HCV. All the patients displayed a positive antibody response against several of the evaluated antigens. At baseline, IgG and IgM reactivities were present in more than 70% of the individuals against Co.120, E1.340 and NS3 proteins (Table 2). Regarding the reactivity towards HVR-1, IgG could only be detected in half of the individuals; still, it was dominant over the rest of the evaluated classes. IgA was generally less frequently detected than IgG and IgM against all antigens.

The assessment of the reactivity of the IgG subclasses, at baseline, against the highly conserved capsid and NS3 antigens, revealed that their recognition was mediated by IgG1 in more than 80% of the patients (Table 3). At the same time, in 78.7% of the individuals a positive IgG4 response could be detected against NS3, while it was detectable only in nearly half of the samples against Co.120. IgG2 and IgG3 were detected in a small percent of the tested samples against both antigens (Table 3).

Table 4 Correlation between demographic variables and aspects of humoral response

	Alcohol consumption	Specific treatment	Hepatic damage[1]
IgM[2]	$R = -0.53^{b}$	$R = 0.313$	$R = 0.107$
	$P = 0.01$	$P = 0.071$	$P = 0.609$
IgA	$R = -0.402^{a}$	$R = 0.238$	$R = 0.422^{a}$
	$P = 0.019$	$P = 0.176$	$P = 0.036$
IgG[3]	$R = -0.383^{a}$	$R = 0.257$	$R = 0.100$
	$P = 0.028$	$P = 0.149$	$P = 0.635$
IgG4	$R = -0.717^{b}$	$R = 0.418^{a}$	$R = 0.401^{a}$
	$P = 0.000$	$P = 0.014$	$P = 0.047$

[1]Necro-inflammatory activity; [2]IgM positive response to HCV structural antigens; [3]IgG positive response to HCV HVR-1 peptide; R = Spearman's correlation coefficient; [a]Significant correlation at 0.05 level; [b]Significant correlation at 0.01 level.

The reactivity of the main classes IgM, IgA and IgG against Co.120 and NS3 was not only assessed at baseline (T = 0), but also 6 months later (T = 6) (Figure 1). The comparison of these two time points revealed that there was a significantly higher percentage of individuals with a positive IgA response against both antigens at T = 6 (Co.120 52.9% *vs* 88.4%, $P = 0.017$; NS3 50.5% *vs* 88.4%, $P = 0.005$). Interestingly, none of the patients lost the specific IgA reactivity from baseline to the end of the study: instead, the observed increase was totally due to *de novo* responses at T = 6. Regarding the magnitude of the response, a statistically significant difference was observed in the IgG and IgM classes against Co.120 (Figure 1A). The mean reactivity was higher at T = 6 when compared to baseline (IgM 0.6419 *vs* 0.9099, $P = 0.027$; IgG 0.7802 *vs* 0.9532, $P = 0.0006$).

Correlation analyses between demographic variables and humoral responses revealed that alcohol consumption was negatively correlated with the responses of the main classes IgM ($P = 0.01$), IgA ($P = 0.019$) and IgG ($P = 0.028$), as well as IgG4 ($P = 0.00000182$) (Table 4). On the other hand, positive IgG4 positively correlated with the fact of being treated ($P = 0.014$) and the grade of hepatic damage ($P = 0.047$). Additionally, the hepatic damage, expressed as necro-inflammatory activity, also correlated with IgA ($P = 0.036$), while fibrosis did not ($P = 0.487$).

T cell proliferative response to HCV antigens

PBMC were analyzed in a proliferation assay for their capacity to expand in response to stimulation with HCV antigens. Samples from both T = 0 and T = 6 were evaluated. Depending on patients PBMC availability, the response to the structural antigens was evaluated by stimulation with the corresponding recombinant protein and a peptide pool. Cells were surface-stained with anti-

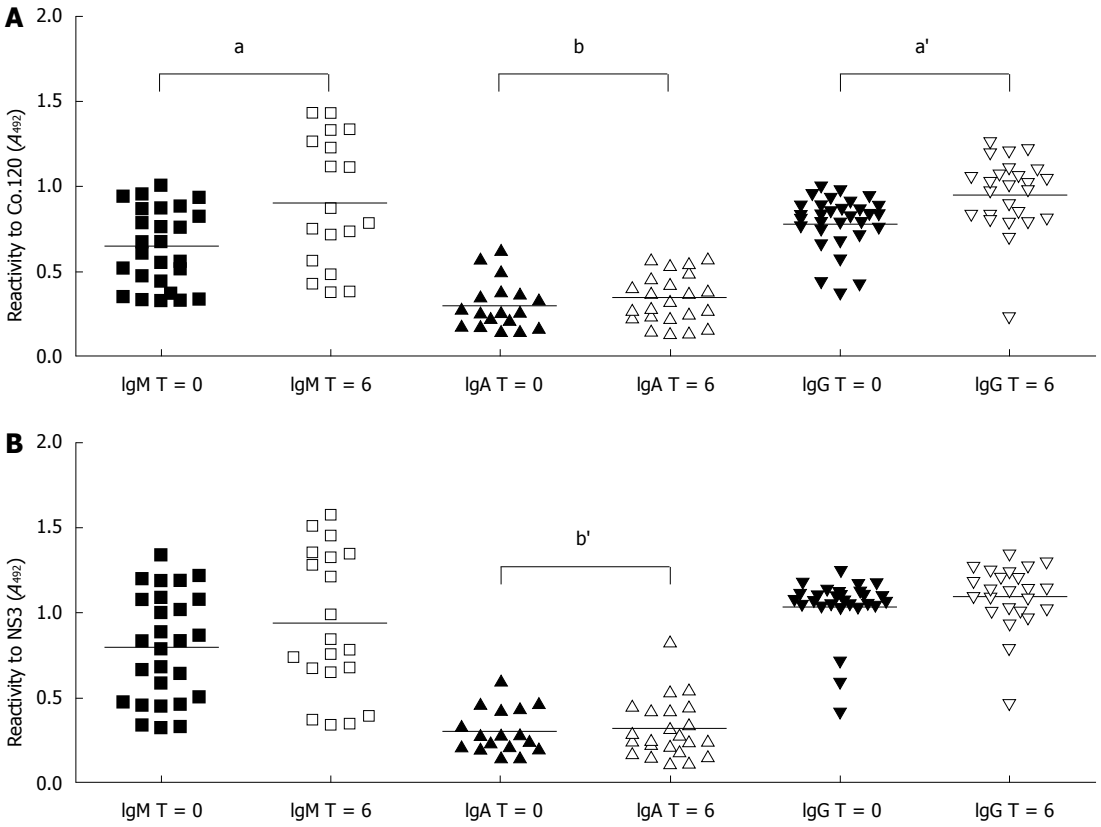

Figure 1 Comparison of antibody reactivity to HCV recombinant Co.120 (A) and NS3 (B) proteins in serum samples from baseline (T = 0) and 6 mo (T = 6) of follow-up. Symbols represent individual values. Only samples showing a positive reactivity are displayed. The horizontal lines represent mean values. Letters over brackets indicate statistical significance (a denotes differences in response magnitude, $^{a}P = 0.027$, $^{a}P = 0.0006$; b denotes differences in the number of positive samples, $^{b}P = 0.017$, $^{b}P = 0.005$).

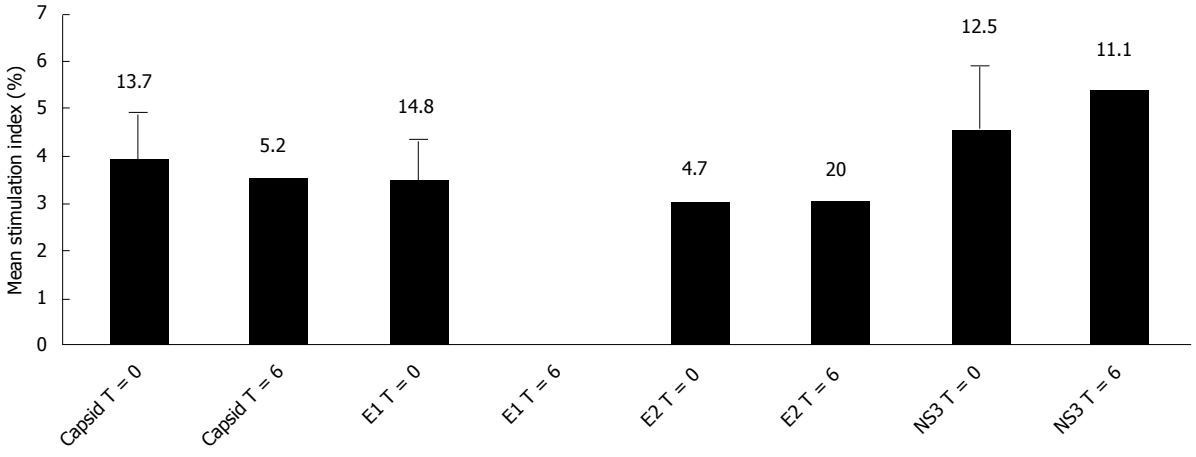

Figure 2 Comparison of CD8+ T cell proliferative response to HCV structural and non-structural antigens in baseline and six months follow up samples. Bars represent mean stimulation index of positive samples only. Error bars represent standard deviation of the mean. Numbers above bars indicate percent of positive samples.

CD4 to evaluate whether the CD4+ cell subpopulation proliferated when stimulated with specific HCV antigens. Particularly, a specific proliferative response was neither detected against the capsid and NS3 proteins at T = 0 nor to E2 at T = 6 (data not shown). Only 10% of the evaluated samples showed a positive response to the capsid at the end of the study, being this antigen the less frequently recognized. The highest percent of positive samples (25%) was detected towards E2 at baseline, followed by NS3 at T = 6 (20%), while E1 protein was always recognized by 14% of the individuals. None of the patients showed a positive proliferative response against more than one antigen.

On the other hand, the analysis of CD8+ cells allowed the identification of specific responses to all the tested antigens, except to E1 at T = 6 (Figure 2). However, these responses were present in less than 15% of the patients against each antigen. Two patients

showed a positive proliferative response simultaneously against the capsid and E1 proteins at T = 0, while another individual recognized E1 at baseline and also E2, 6 months later. CD8+ cells of only one individual proliferated against all tested antigens (capsid, envelope and NS3 proteins) at T = 0; unfortunately, this patient could not be contacted for a second blood sample, and therefore, the persistence of this peculiar response could not be assessed. Taking into account the results of both CD4+ and CD8+ cell proliferation, we did not detect any patient in which the two time-point samples were consistently positive throughout the study.

DISCUSSION

In this study, we assessed HCV-specific immune responses in a group of HCV chronically infected patients at two different time-points six months apart. The evaluation of the antibody response against viral antigens revealed that all the patients displayed a positive antibody response against several of the evaluated antigens. Specifically, in the majority of patients the reactivity was dominated by IgG and IgM, both in terms of number of positive patients and the magnitude of the response. Particularly, the presence of IgM anti-HCV-capsid antibodies have been regarded as a negative prognostic marker of response to treatment[28] and a factor associated to recurrence of hepatitis and its severity in HCV-infected liver transplant recipients[29]. Therefore, their presence in our cohort of chronic patients reinforces the notion of their inefficacy in this phase of the infection. Our results are in agreement with previous works reporting elevated prevalence of both immunoglobulin classes in chronically infected patients[7,30]. These studies only refer to the specific response to the capsid protein; our results extend this notion to other antigens such as E1 and NS3.

Among the IgG subtypes, IgG1 has been, by far, the most frequently found against all tested viral antigens[5,30]. Moreover, it has been reported that the antibody response to most HCV antigens is highly restricted to this subclass[31], the rest of the subclasses being rarely detected. This response restriction to IgG1 has lead studies aiming to find relations of antibody production to long-term outcome after therapy. In fact, it has been observed that IgG1 specific to an N-terminal epitope of the capsid protein decrease in complete responders, while remain unchanged in non-responders. Therefore, these antibodies have been proposed as markers of the efficacy of IFN-α therapy[30]. Our results showed a high prevalence of IgG1 against the capsid, and also against NS3, HCV's most conserved antigens. Nevertheless, 78.7% of the patients also showed a positive IgG4 response against NS3. It is of general knowledge that in chronic viral infections in humans, viral proteins generally elicit the IgG1 and IgG3 subtypes and to a lesser extent, IgG2 and IgG4. IgG4 has been frequently found dominating in responses to prolonged antigenic stimulation[32] and has been identified as a major component of circulating immune-complexes in chronic hepatitis B virus-infected individuals[33]. Given that antibodies of IgG4 subclass do not activate the complement system through the classic pathway and have a low affinity to Fc-γ receptors, their presence is considered a factor that may contribute to chronicity.

The assessment of correlations between immunological and demographic variables in our study revealed that IgM to structural antigens, IgG to the HVR-1, IgA and IgG4 responses negatively correlated with alcohol consumption, indicating that this habit may dampen the potentiality for generating a diverse immune response. In contrast, the fact of having been treated with the standard therapy positively correlated with the presence of IgG4 responses. Regarding the involvement of IgG4, it has been observed that the nonselective modulatory effect of IFN-α treatment may contribute to widen the diversity of specific IgG subclasses profiles in hepatitis B virus infection, contributing to the high participation of IgG4[34]. To our knowledge, this effect of antiviral therapy has not been assessed specifically in HCV infection, but seems a plausible hypothesis supporting our findings.

Another positive correlation that could be detected was that between hepatic damage, expressed as necro-inflammatory activity, and IgA response. It has been observed that TGF-β1, which is produced by hepatic stellate cells and Kupffer's cells, induces the isotype switching to IgA in B lymphocytes proliferating *in vitro*[35]. This cytokine is a prominent profibrogenic factor during inflammation, tissue regeneration and fibrogenesis[36] and in line with this, it has been demonstrated that HCV patients have elevated levels of circulating TGF-β1 *versus* controls[37]. To our knowledge, whether there is a direct relation between serum IgA and TGF-β1 circulating levels in HCV chronic patients has not been explored so far. Nevertheless, our results warrant further studies, although they do not point out to a direct correlation with fibrosis, but rather with the necro-inflammatory activity. On the other hand, the liver plays an important role in IgA clearance, and the loss of hepatic function due to chronic inflammation and damage may reduce normal IgA catabolism, and contribute to its accumulation in serum[38]. Therefore, the observed correlation might be probably indicating that IgA increase is a consequence, rather than a cause, of hepatic damage.

Additionally, IgG4 responses positively correlated with hepatic damage. As previously discussed, IgG4 has not been usually found as a dominant component of HCV specific immune response. Therefore, the implications of the presence of this subclass have not been explored so far in patients chronically infected with HCV. Nevertheless, a series of inflammatory and autoimmune diseases, in which IgG4 have a strong participation, have been described: these are known as IgG4-related sclerosing diseases[39]. In general, these disorders are characterized by high serum IgG4 levels, which are closely associated with disease activity, in a context of chronic lymphocyte infiltration and fibrosis of the affected organs[39]. Although the role of

IgG4 in these disorders remains obscure, it has been suggested that the formation and accumulation of immune complexes and the activation of the alternative complement pathway contribute to disease activity[39]. Further studies with larger cohort of patients are needed to definitively discern the real role of IgG4 in chronic hepatitis C as well as in other chronic inflammatory disorders.

We also evaluated the proliferative response of PBMC of chronic patients against stimulation with HCV antigens, in paired samples taken six months apart. Only a small percent of samples showed a positive response against each of the tested antigens. Moreover, the great majority of the patients displayed a detectable proliferation only to a single antigen and this response was never constant in the two evaluated time points. These results are in agreement with previous works reporting instability, low frequencies and a small number of targeted epitopes by both CD4+ and CD8+ T cells in peripheral blood of chronic patients[14,16,40]. The characteristic asymptomatic course of this disease hinders the accumulation of immunological data regarding the very early phase of the infection; therefore, it has been difficult, so far, to discriminate between primary T cell failure and early T cell exhaustion or deletion, once chronic infection has already been established. In fact, both phenomena seem to operate in different patients and equally lead to persistence[41]. Many mechanisms are postulated to be involved in T cell failure, namely impaired antigen presentation[42,43], reduced cytokine secretion by antigen presenting cells[44], immunomodulatory effects exerted by different viral factors[45,46] and increased levels of CD4 + $CD25^{high}$ Treg cells[47].

In summary these results confirm that in patients chronically infected with HCV, either naïve or non-responders to the standard therapy with IFN-α plus ribavirin, cellular proliferative responses are rarely detected, usually weak, not sustained and narrowly directed. On the other hand, the humoral response is characterized by a broad representation of antibody classes and subclasses, some of which have not been demonstrated to contribute to viral clearance, but rather to persistence. Particularly, the association of specific IgA response to necro-inflammatory activity paves the way to further studies to confirm its utility as an easy-to-measure marker of increased histological activity.

ACKNOWLEDGMENTS

We thank the patients for their willingness to participate into this study. We also thank Dr. Raffick-Pierre Sékaly and Dr. Naglaa Shoukry for training in determination of cellular immune response and Carmen Valenzuela and Dr. Julio C Alvarez for assisting in study design. We are grateful to Jeny Marante, Acacia Trujillo, Elena Ferrer and Aina Méndez for excellent technical assistance, MSc Hugo Nodarse and Dr. Luis Rivera for invaluable help in patient enrollment and Dr. Enrique Arús for assisting in the general coordination of the study. Dr. Santiago Dueñas-Carrera holds a Grant from PanAmerican Health Organization.

COMMENTS

Background

Correlates of protection against hepatitis C virus (HCV) are extensively pursued in nowadays research. Early, vigorous and sustained peripheral blood mononuclear cells (PBMC) proliferative responses specific to HCV have been regarded as pivotal for viral clearance. On the other hand, antibody responses' contribution is still controversial and the significance of specific antibody classes during chronic infection has been investigated.

Research frontiers

So far, in HCV infection, the most extensively studied antibodies are those directed to the capsid protein. Several data indicate that IgM anti-HCV capsid occurrence is directly related to viremia levels. Additionally, HCV-specific antibody response is regarded as restricted to the IgG1 isotype, except for the capsid. The rest of the classes and IgG subclasses have been found very rarely represented, and therefore their significance in acute and chronic HCV is unclear.

Innovations and breakthroughs

Correlation analysis between demographic variables and humoral response confirmed the negative influence of alcohol consumption on the immune response, particularly on responses of the main immunoglobulin classes. On the other hand, IgG4, an IgG subclass characteristic of chronic antigenic stimulation, positively correlated with the grade of necro-inflammatory activity and the fact of being treated with the standard therapy; the latter already demonstrated for hepatitis B virus (HBV), but not for HCV. Additionally, for the first time a positive correlation between necro-inflammatory activity with HCV-specific IgA was found.

Applications

Particularly, the association of specific IgA response to necro-inflammatory activity paves they way to further studies to confirm its utility as a non invasive, easy-to-measure marker of increased histological activity in chronic HCV infection.

Peer review

An interesting study assessing the humoral response in chronic HCV patients. The association of elevated IgG and globulins with fibrosis have been described as referenced. It is an interesting observation to find IgA specific to HCV antigens.

Abstract

AIM: To investigate the effect of hepatoma cells on up-regulation of programmed cell death-1 (PD-1), and the function of PD-1 on T cells.

METHODS: HepG2 or HepG2.2.1.5 cells were co-cultured with a lymphoma cell line-Jurkat cells. PD-1 expression was detected by flow cytometry. IL-2, INF-γ and IL-10 in culture supernatant were detected by enzyme-linked immunosorbent assay (ELISA). Cytotoxic action of T cells was determined by MTT reduction assay-direct mononuclear cell cytotoxicity assay.

RESULTS: The PD-1 expression on Jurkat cells increased by 16.17% ± 2.5% and 17.43% ± 2.2% after HepG2 or HepG2.2.1.5 cells were co-cultured for 48 h. The levels of IL-2, INF-γ and IL-10 in the culture supernatant were 202.9 ± 53.0 pg/mL, 88.6 ± 4.6 pg/mL and 63.7 ± 13.4 pg/mL respectively, which were significantly higher than those (102.9 ± 53 pg/mL, 39.3 ± 4.2 pg/mL, and 34.6 ±13.7 pg/mL) in the control group ($P < 0.05$). The OD value for MTT assay in the blocking group (0.29 ± 0.06) was significantly higher than that (0.19 ± 0.09) in the control group ($P < 0.05$).

CONCLUSION: PD-1 expression on Jurkat cells is up-regulated by hepatoma cells, cytokines and cytotoxic action are elevated after PD-1/PD-L1 is blocked.

INTRODUCTION

Programmed cell death-1 (PD-1), a member of the CD28 family, was first isolated from T cell hybridoma by subtractive hybridization in 1992[1], and is expressed on activated T and B cells[2]. PD-1 has been recently found to play a role in immunity regulation as an inhibitory co-signaling molecule[3]. Upon its ligands (PD-L1 and PD-L2) are ligated, PD-1 decreases T cell receptor (TCR)-mediated proliferation, cytokine production and cytolytic activity[4-7]. Barber *et al*[8] showed that up-regulation of PD-1 expression on T cells is associated with the exhaustion of T cells in lymphocytic choriomeningitis virus (LCMV) infection. The number of effective T cells increases and their function markedly improves when the interaction of PD-1 and PD-L is blocked. It was reported that PD-1 also plays a significant role in some autoimmune diseases[9-11] and viral infectious diseases, especially in chronic infectious diseases caused by human immunodeficiency virus (HIV)[12-14], hepatitis C virus (HCV)[15,16] and hepatitis B virus (HBV)[17-19]. There is evidence that PD-1 suppresses immune activation in PD-1-deficient mice with autoimmune disease[20]. Single-nucleotide polymorphisms at the PD-1 locus have also been identified in patients with autoimmune disorders such as systemic lupus erythematosus, rheumatoid arthritis, and type 1 diabetes[21].

Recent evidence from studies on tumors shows that the PD-1/PD-1 pathway might play a critical role in tumor immunity evasion[22-24]. PD-1 is up-regulated on tumor specific T cells and PD-L is up-regulated in tumor tissue[25-27]. As a result, the function of tumor specific T cells is suppressed, leading to the immune escaping of tumor cells, and the level of mRNA and PD-L1

protein can be detected in tumor tissues[25-27]. In addition, PD-1/PD-L interaction promotes apoptosis of T cells, induces clearance of specific T cells, and ultimately inhibits the anti-tumor immunity response[27]. Blocking the interaction of PD-1/PD-L with anti-PD-l antibody partially recovers the function of tumor specific T cells.

It was reported that the expression of PD-L can be induced by virus and cytokines such as IFN-α and INF-γ[28]. However, no evidence for the induced expression of PD-1 is available. Liver, an important immune organ, plays a critical role in immune regulation although it is prone to induce immune tolerance in many cases. The present study was designed to investigate whether hepatoma cells (HepG2 and HepG2.2.1.5) induce expression of PD-1 in T cells. The functional role of PD-1/PD-L interaction was also studied.

MATERIALS AND METHODS

Cell culture

Jurkat cells were cultured in RPMI 1640 medium (Gibco, USA), supplemented with 10% fetal calf serum, 300 μg/mL glutamine, 100 U/mL penicillin and 100 μg/mL streptomycin. HepG2.2.1.5 cells or HepG2 cells provide by Mountsinai Medical Center were cultured in complete DMEM (Gibco, USA) containing 380 μg/L G418.

Co-culture system

HepG2 and HepG2.2.1.5 cells were cultured in 6-well plates (5×10^5 cells/well) for 24 h and Jurkat cells (5×10^5 cells/well) were added and co-cultured for 48 h. The suspended cells were collected for analysis of PD-1. Jurkat cells were cultured solitarily for 48 h as controls.

Analysis of PD-1 expression

Cell surface expression of PD-1 was detected by flow cytometry after incubated with allophycocyanin (APC)-conjugated anti-PD-1 antibodies (eBioscience). Cells were collected and suspended in PBS containing 1% fetal calf serum (FCS). The cell density was adjusted to 1×10^6 cells/vial. After incubated with anti-PD-1 antibodies or matching isotype controls at 37℃ for 30 min, cells were washed with PBS and fixed in 2% paraformaldehyde for analysis. A total of 20000 gated cells were analyzed on Becton Dickinson FACS (Becton Dickinson, USA) using the CELLQuest™ software.

Blockade of PD-1/PD-L1 interaction

Antibody against human PD-L1 (eBioscience) was used to block PD-L1. Jurkat cells were activated with phytohemagglutinin (PHA) (2 μg/mL, Sigma, USA) and co-cultured with HepG2 or HepG2.2.1.5 cells. Anti-PD-L1 antibodies (25 μg/mL) were added into the culture to block the interaction of PD-1 and PD-L1 for 48 h. Mouse IgG, as a control antibody, was used in the control group. After cultured for 48 h, the supernatants of co-cultures were collected and stored at -80℃.

Analysis of cytokine secretion

Levels of IL-2, IL-10 and INF-γ in the supernatants were measured by ELISA (Ucytech, Netherlands) following its manufacturer's instructions.

Analysis of cytolytic activity

Cytolytic activity of Jurkat cells was detected by MTT assay. After co-cultured for 48 h, Jurkat cells were isolated and MTT was added to incubate HepG2.2.1.5 cells for 4 h, and bleached with DMSO. Finally, the cytolytic effect of Jurkat cells on HepG2.2.1.5 cells was analyzed on Bio-Rad 450 (USA).

Statistical analysis

Results were expressed as mean ± SD or percentage. Comparison between groups was made using Student's unpaired *t*-test. $P < 0.05$ was considered statistically significant. All analyses were performed using SPSS 13.0 for Windows.

Table 1 Up-regulated expression of PD-1 on T cells (n = 24, mean ± SD)

Groups		PD-1(%)
Controls		0.70 ± 0.03
Co-cultured	HepG2	16.17 ± 2.5[a]
	HepG2.2.1.5	17.43 ± 2.2[b]

[a]P = 0.000, [b]P = 0.000 *vs* control group.

RESULTS

Enhancement of PD-1 expression on Jurkat cells

PD-1 expression on Jurkat cells was determined by FACS analysis at 48 h after co-cultured with HepG2 or HepG2.2.1.5 cells. Jurkat cells were also cultured solitarily as controls. The expression of PD-1 was induced on Jurkat cells after co-culture with HepG2 or HepG2.2.1.5 cells for 48 h, which was significantly higher on Jurkat cells co-cultured with hepatoma cells than on controls (P = 0.000, Table 1).

Function restoration of T cells

Supernatants were collected from the blocking and control groups. To investigate the influence of cytokine production after PD-1/PD-L1 was blocked, the levels of IL-2, IL-10 and INF-γ were measured. After PD-L1 was blocked with specific antibodies, the levels of IL-2, IL-10 and INF-γ were much higher in the blocking group than in the control group (P = 0.000, Table 2).

Furthermore, the effect of the PD-1/PD-L1 pathway on cytolytic activity of T cells was also investigated by MTT assay. The A value (0.29 ± 0.06) in the blocking group was much higher than that (0.19 ± 0.09) in the control group (P = 0.000).

DISCUSSION

Activation of resting lymphocytes triggers expression of several products of the immunoglobulin superfamily of genes. These activation-induced antigens are involved in

Table 2 Secretion of cytokines by T cells (pg/mL, n = 24, mean ± SD)

Groups	IL-2	IFN-γ	IL-10
Control group	102.9 ± 53.0	39.3 ± 4.2	34.6 ± 13.7
Blocking group	202.9 ± 53.0[c]	88.6 ± 4.6[d]	63.7 ± 13.4[e]

[c]P = 0.000, [d]P = 0.000, [e]P = 0.000 *vs* control group.

many physiological and pathological processes including cell proliferation (IL-2R), functional differentiation (CTLA-4), and apoptosis (Fas)[29,30]. The expression patterns of these antigens are cell-specific, and have different regulation functions in different cells. PD-1, a member of the CD28 family, which was isolated from apoptosis-induced T cell hybridoma in 1992[1], is expressed on activated T and B cells[2].

Agata *et al*[2] showed that PD-1 expresses on activated T and B cells. Anti-CD3 and concanavalin A (ConA) can stimulate its expression on thymocytes and T cells in spleen, and anti-IgM antibody can stimulate its expression on B cells in spleen. Vibhakar *et al*[31] also demonstrated that PD-1 mRNA and protein levels in Jurkat cells are up-regulated in a time-dependent manner during phorbo ester (TPA)-induced differentiation, indicating that lymphocyte activators can up-regulate PD-1 expression on lymphocytes. Since PHA is another T cell activating agent, the expression of PD-1 in T cells can be detected after stimulation of PHA. A time-dependent up-regulation of hPD-1 was also observed during PHA induction (data not shown), and was used as a stimulus of Jurkat cells in our blocking experiment.

It was reported that, as an inhibitory co-stimulating molecular, PD-1 plays a role in immune regulation and is associated with the exhaustion of effective T cells[32-34]. Barber *et al*[8] showed that, in chronic viral infection diseases, PD-1 is highly expressed on the exhausted LCMV-specific CD8 T cells and blocking the PD-1/PD-L1 interaction during the chronic phase of infection can efficiently reanimate the exhausted CD8 T cells and promote clearance of the persisting virus. In contrast, PD-1 expression is transiently induced and declines quickly to its basal level in acute LCMV-Armstrong infection, thus promoting studies on other diseases associated with immune. Up-regulation of PD-1 expression on effective T cells leads to suppression of immune, which might be the underlying mechanism of immune evasion. PD-L1/PD-L2 expression in a variety of tumor cells has been detected in human tumors[35,25-27], while PD-1 over-expression on tumor specific T cells has also been observed[23]. Interaction of PD-1/PD-L1 promotes apoptosis of T cells, inhibits anti-tumor immune response of T cells, and stimulates growth of tumors[27]. Obstructing the interaction of PD-1/PD-L1 enhances the function of T cells, hampers development of tumors[22,23,26]. In the present study, tumor cells induced expression of PD-1 on T cells. After co-cultured with hepatoma cells, PD-1 was expressed on T cells, but not expressed on Jurkat cells after cultured for 48 h solitarily. PD-1 was expressed on T cells after Jurkat cells were co-cultured with the supernatant of hepatoma cells (data not shown), suggesting that hepatoma cells can up-regulate the expression of PD-1.

These findings lead to the clinical use of PD-1 blockers in the treatment of tumors. In chronic infectious diseases, virus can induce the expression of PD-1 on T cell. However, the precise mechanism PD-1 blockers still remains unclear. We observed the effect of tumor cells on PD-1 expression in T cells. Jurkat cells, a kind of $CD4^+$ T cells, can be used as target cells co-cultured with hepatoma cells. FACS analysis showed that tumor cells could induce PD-1 expression on T cells. In this study, HepG2.2.1.5 cells transferring HBV genome and HepG2 cells not transferring HBV genome could induce PD-1 expression, suggesting that HBV has no effect on PD-1 expression on T cells.

In addition, the function of PD-1 on T cells was also observed. Anti-PD-L1 antibody was used to block the interaction of PD-1 and PD-L1. PD-1 was induced by PHA, and PD-L1 was expressed in HepG2.2.1.5 cells identified by FACS (data not shown). Jurkat cells after activated by PHA were co-cultured with HepG2.2.1.5cells. Antibodies against human PD-L1 were added into the co-culture system as a blocking group, while mouse IgG was added as a control group. The levels of cytokines including IL-2, INF-γ and IL-10 in culture supernatant and the cytolytic activity of T cells were detected, which were significantly elevated in blocking group compared to the control group, suggesting that both Th1 and Th2 have immune responses can be restored and PD-1/PD-L that negatively regulates the immune reaction by blocking the PD-1/PD-L pathway can recover the function of T cells, which introduces a new theory of tumor immune evasion. This new mechanism of tumor immunology might provide a novel target for therapy.

COMMENTS

Background

Programmed cell death-1 (PD-1), originally isolated from apoptotic T cells, is a 55-kDa transmembrane protein with an extracellular IgV-like domain and a 97-amino acid cytoplasmic tail containing an immunotyrosine inhibitory motif (ITIM) and an immunotyrosine switch motif (ITSM). PD-1 has two ligands: PD-L1 and PD-L2, which are members of the CD28/B7 superfamily. The expressions of CD28, CTLA-4, and ICOS are limited in T cells. PD-1 can be expressed on activated T, B and myeloid cells. The expression of PD-L1 has been detected in many organ tissues, such as heart, lung, pancreas, muscle, and placenta, including lymphocytes and non-lymphocytes. The expression of PD-L2 is restricted in DC and macrophages.

Research frontiers

Recent findings suggest that PD-1/PD-L pathway plays a role in regulating tolerance and autoimmunity. The role of PD-1 and its ligands in regulating human autoimmune disease, infectious diseases and tumors has been investigated. Interaction of PD-1 and PD-L has been found to be important for controlling effective T cells. Significantly increased expression of PD-1 and PD-L1 in T and B macrophages/dendritic cells and tumor cells, associated with T-cell exhaustion and disease progression, immobilized auto-antibodies to PD-L, can stimulate T cell proliferation, cytokine production, and programmed cell death. The up-regulation of PD-L1 in tumors and PD-1 in T cells can lead to immune tolerance.

Innovations and breakthroughs

The present study demonstrated the effect of hepatoma cells on up-regulating

the expression of PD-1 in T cells. In addition, the function of PD-1 in T cells was assessed, showing that the cytokine production and cytotoxicity of T cells can be elevated by blocking the interaction of PD-1 and PD-L1.

Applications

The up-regulation of PD-1 in T cells by hepatoma cells has led to a new hypothesis that the PD-1 and PD-L pathway may be a means by which tumors evade T cell recognition. Manipulation of the PD-1 pathway can enhance immune response, and may become a novel strategy for the treatment of tumors.

Terminology

MTT is a direct mono-nuclear cell direct cytotoxicity assay used to detect the cytotoxicity of T cells. PHA is a T cell stimulus that can activate T cells. G418, a kind of antibiotics, is used in selective cell culture medium. G418 must be added into culture medium of HepG2.2.1.5 cells to support the selective survival of HepG2.2.1.5 cells.

Peer review

This is a very interesting study, showing that HCC-induced modulation of PD-1 expression in T-cells might contribute to immune evasion. This concept might hold its promise for new therapeutic interventions. The experiments support the authors' claim.

Abstract

AIM: To explore the effects of recombinant human growth hormone (rhGH) on intestinal mucosal epithelial cell proliferation and nutritional status in patients with enterocutaneous fistula.

METHODS: Eight patients with enterocutaneous fistulas received recombinant human growth hormone (10 μg/d) for 7 d. Image analysis and immunohistochemical techniques were used to analyse the expression of proliferating cell nuclear antigen (PCNA) in intestinal mucosal epithelial cells in biopsy samples from the patients who had undergone an endoscopic biopsy through the fistula at day 0, 4 and 7. Body weights, nitrogen excretion, serum levels of total proteins, albumin, prealbumin, transferrin and fibronectin were measured at day 0, 4 and 7.

RESULTS: Significant improvements occurred in the expression of PCNA in the intestinal mucosal epithelial cells at day 4 and 7 compared to day 0 (24.93 ± 3.41%, 30.46 ± 5.24% *vs* 12.92 ± 4.20%, $P < 0.01$). These changes were accompanied by the significant improvement of villus height (500.54 ± 53.79 μm, 459.03 ± 88.98 μm *vs* 210.94 ± 49.16 μm, $P < 0.01$), serum levels of total proteins (70.52 ± 5.13 g/L, 74.89 ± 5.16 g/L *vs* 63.51 ± 2.47 g/L, $P < 0.01$), albumin (39.44 ± 1.18 g/L, 42.39 ± 1.68 g/L *vs* 35.74 ± 1.75 g/L, $P < 0.01$) and fibronectin (236.3 ± 16.5 mg/L, 275.8 ± 16.9 mg/L *vs* 172.5 ± 21.4 mg/L, $P < 0.01$) at day 4 and 7, and prealbumin (286.38 ± 65.61 mg/L *vs* 180.88 ± 48.28 mg/L, $P < 0.05$), transferrin (2.61 ± 0.12 g/L *vs* 2.41 ± 0.14 g/L, $P < 0.05$) at day 7. Nitrogen excretion was significantly decreased at day 7 (3.40 ± 1.65 g/d *vs* 7.25 ± 3.92 g/d, $P < 0.05$). No change was observed in the body weight.

CONCLUSION: Recombinant human growth hormone could promote intestinal mucosal epithelial cell proliferation and protein synthesis in patients with enterocutaneous fistula.

INTRODUCTION

From the mid 1980s, recombinant human growth hormone (rhGH) has been applied clinically. Growth hormone is a peptide hormone which stimulates proliferation and differentiation of many kinds of cells. It also has anabolic effects on the modulation of energy and substance metabolism. Previous animal experiments[1-3] have demonstrated it could promote the structural repair of the intestinal mucosa in short bowel rats, but few studies have made direct observations of the effects of rhGH on intestinal mucosa in human. The objective of this study was to explore the effects of rhGH on intestinal mucosal proliferation and nutritional status in patients with enterocutaneous fistula.

Table 1 General state of the patients

Age (Yr)	Sex	Weight (kg)	Distance from ligament of tretiz (cm)	Rest energy expenditure (KJ)	Enteral nutrition energy (KJ)

MATERIALS AND METHODS

Study protocol

Eight patients (Table 1) with enterocutaneous fistula were injected with rhGH (10 U/d) for 7 d. Intestinal mucosa biopsies were performed by endoscopy through the fistula at 20 cm proximal to the fistula at day 0, 4 and 7. All the patients gave informed consent to participate in the study. This study was approved by the Ethical Committee of Jinling Hospital, Nanjing University. Biological tests revealed no signs of inflammation, metabolic disturbances or hepatic, renal and cardiac dysfunction before the patients were enrolled into the study. The subjects had a mean body mass index of 14.37 kg/m^2 (range 11.09-17.65 kg/m^2). For all the subjects, enteral nutrition (Peptisorb, Nutricia, Holland) was prescribed and taken by nasogastric or nasointestinal tube to maintain the metabolic balance. The formula contained 1 kcal/mL, and the total calories given according to the energy expenditure was determined by indirect calorimetry (MedGraphics, USA). Endoscopic biopsies were fixed in formalin for histological assessment.

Recombinant human growth hormone (rhGH)

rhGH (Saizen) was provided by Serono China Pte. Ltd, China. The dose of rhGH was 10 U/d administered once a day (8:00 pm) as a subcutaneous injection to an upper limb, beginning on day 1 and continued for 7 d.

Immunohistochemical staining

To assess the degree of cell proliferation, an immunohistochemical technique based on the proliferating cell nuclear antigen (PCNA) was used. Sections from tissue samples were dewaxed, taken through alcohol and then immersed for 10 min in 25% phosphate-buffered saline in methanol with 0.3% hydrogen peroxide to block endogenous peroxidase activity. Sections were subsequently taken to water and immunostained using the Vectastain ABC peroxidase kit (Vecta Laboratories, Burlingame, CA). 0.4% diaminobenzidine (DAB, Aldrich Co.) was employed as a chromogen and a light haematoxylin counterstain was used. Counts were carried out in 30 crypts per preparation under microscope (40 ×), using an automatic image analysis system (HPLAS-1000, Tongji qianping Ltd). A proliferation index was determined based on the ratio between PCNA-positive cells and the total number of cells per longitudinal crypt section at the base of the crypt. This index is equal to the quotient of the number of proliferating cells and the total number of cells multiplied by 100.

Table 2 Changes of intestinal mucosal villus height, PCNA and nitrogen excretion before and after treatment with rhGH

	The days when treated with rhGH		
	0	4	7
Villus height (μm)	210.94 ± 49.16	500.54 ± 53.79^b	459.03 ± 88.98^b
PCNA labelling index (%)	12.92 ± 4.20	24.93 ± 3.41^b	30.46 ± 5.24^b
Nitrogen excretion (g/d)	7.25 ± 3.92	4.64 ± 1.95	3.40 ± 1.65^a

All values are expressed as mean ± SD. $^aP < 0.05$, $^bP < 0.01$ *vs* day 0.

Mucosal height

Sections from tissue samples were fixed in 4% paraformaldehyde, dehydrated with alcohol and then paraffin-embedded. The formatted specimens were cut by sliding microtome and stained with hematoxylin and eosin. Samples were analyzed with the automatic image analysis device (HPLAS-1000, Tongji qianping Ltd), using a microscope at 10 ×. The total mucosal height from the base of the crypt to the villous tip was measured (10 measures per preparation, in the 10 highest villi of each sample, and the base of the crypts measurement reached the muscularis mucosae).

Biochemical assays and nitrogen excretion

Serum albumin, prealbumin, transferrin and fibronectin concentrations were determined by automatic biochemical analysis device (Beckman Coulter, USA).

Daily urinary and fecal nitrogen excretion was determined by the Kjeldahl method at day 0, 4 and 7.

Statistical analysis

Data were analyzed using a statistical software package for Windows (SPSS version 10.0, SPSS Inc, Chicago, IL, USA). All variables of each group were described by common statistical methods. Results are presented as mean ± SD. One-way ANOVA for repeated measures was performed in order to evaluate the differences among the three states of the study. The level of significance was set at P value of 0.05 or less.

RESULTS

Villus height and proliferative activity

Compared with the baseline, significant improvement occurred in the intestinal mucosal villus height at day 4 and 7 (both $P < 0.01$), which was accompanied by the increase of proliferative activity of epithelial cells assessed by the PCNA labelling index (both $P < 0.01$) (Table 2, Figure 1).

Nitrogen excretion, body weight and serum levels of protein

Nitrogen excretion was significantly decreased at day 7 (P

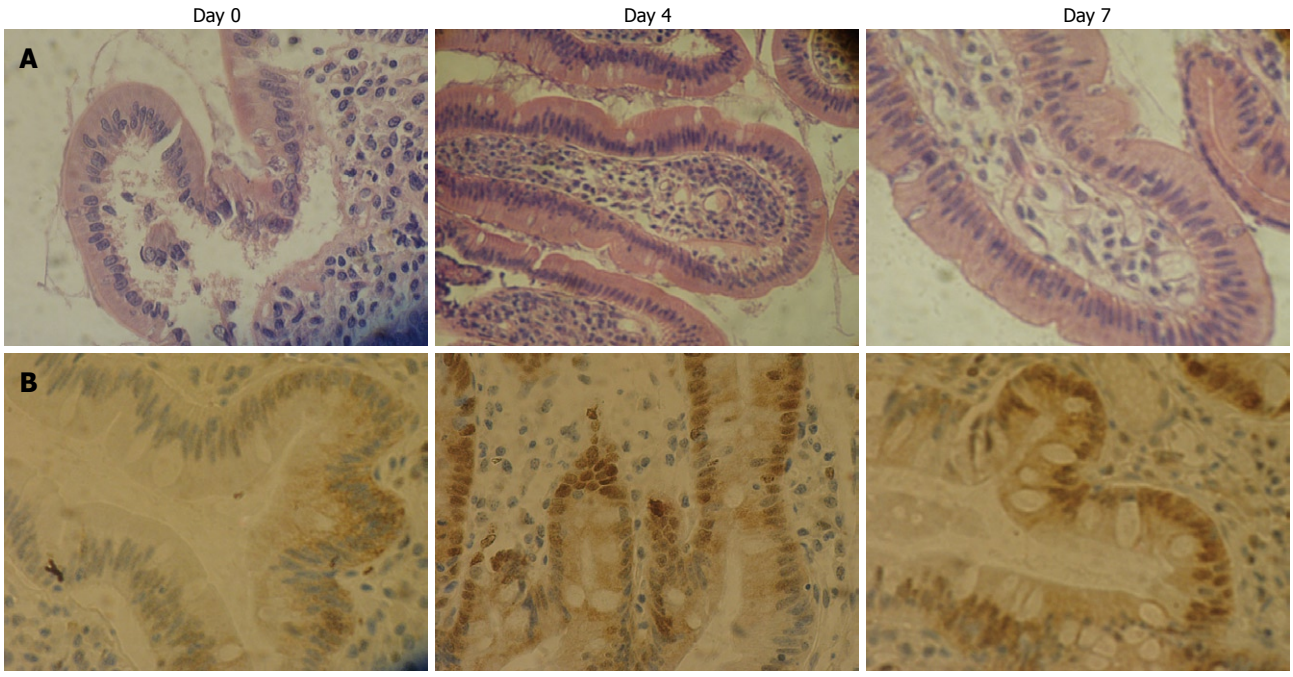

Figure 1 Villus height and proliferative activity. Significant improvements occurred in villus heights and in the expression of PCNA on the intestinal mucosal epithelial cells at day 4 and 7 ($P < 0.01$). A: Villus heights; B: PCNA labelling index.

Table 3 Changes in body weight and serum proteins before and after treatment with rhGH

	The days when treated with rhGH		
	0	4	7
Body weight (kg)	37.39 ± 12.48	38.64 ± 12.84	39.13 ± 12.19
Body mass index (kg/m^2)	14.37 ± 3.28	15.21 ± 3.41	15.40 ± 3.24
Total proteins (g/L)	63.51 ± 2.47	70.52 ± 5.13^b	74.89 ± 5.16^b
Albumin (g/L)	35.74 ± 1.75	39.44 ± 1.18^b	42.39 ± 1.68^b
Prealbumin (mg/L)	180.88 ± 48.28	231.38 ± 52.31	286.38 ± 65.61^a
Transferrin (g/L)	2.41 ± 0.14	2.49 ± 0.12	2.61 ± 0.12^a
Fibronectin (mg/L)	172.5 ± 21.4	236.3 ± 16.5^b	275.8 ± 16.9^b

All values are expressed as mean ± SD. $^aP < 0.05$, $^bP < 0.01$ *vs* day 0.

< 0.05) (Table 2). Serum levels of total proteins, albumin and fibronectin were significantly increased at day 4 and 7 (both $P < 0.01$). The levels of prealbumin and transferrin were increased at day 7 ($P < 0.05$) (Table 3). No change was observed in the body weight.

DISCUSSION

Previous studies have shown that GH stimulates bowel growth[1-4]. Administration of GH improves gut mucosal structure in animals with short bowel syndrome[5-7] and may promote the structural repair of the graft[8,9]. Experiments *in vitro* have also demonstrated that GH is involved in the regulation of crypt cell proliferation in the human small intestine[10-13].

The therapeutic efficacy of rhGH has been suggested by results of animal studies. In the present study the effects of rhGH in situ on the intestine of patients with enterocutaneous fistula were observed. Our results revealed that significant improvement occurred in the intestinal mucosal villus height at day 4 and 7, which was accompanied by the increase of proliferative activity of epithelial cells assessed by the PCNA labelling index.

Nutrient malabsorption often occurs in patients with gastrointestinal fistula[14-17], and it causes body weight loss, barrier damage, followed by bacterial translocation from the gastrointestinal tract to the mesenteric lymph nodes, and even blood. Administration of glutamine and growth hormone synergistically reduces bacterial translocation in sepsis[18,19]. Hormonal therapy with GH can improve weight gain in a rat model of severe short bowel syndrome. This improvement in weight gain was associated with an increase in nutrient transport at the cellular level and variable increases in villus size[20,21]. GH treatment increased [^{14}C] glucose and [^{3}H] palmitic acid plasma concentration after oral nutrient tolerance tests[22]. Clinical trials also showed that GH could promote positive nitrogen balance and protein synthesis[23-25]. However, there are some conflicting results: no improvement was observed in the absorption of total energy, carbohydrate, fat, nitrogen, or wet weight of stool or stool electrolytes compared with baseline and placebo measurements[26-28]. In the present study the body weights of the eight patients were maintained at normal level. All the patients showed positive nitrogen balance and the nitrogen excretion was significantly decreased at day 7. Serum levels of total proteins, albumin and fibronectin were significantly increased at day 4 and 7. And the levels of prealbumin and transferrin were increased at day 7.

GH stimulated the formation and deposition of collagen in both skin incisional wounds and in colonic anastomoses in rats[29,30].

After the trial all the eight patients underwent surgery to close the fistula and they recovered very well, and no fistula recurred.

In summary, our study shows that rhGH can promote intestinal mucosal epithelial cell proliferation and protein synthesis in patients with enterocutaneous fistula.

ACKNOWLEDGMENTS

We thank the staff of the Research Institute of General Surgery of Jinling hospital for helpful assistance. We also thank the staff of the Department of Pathology of Jinling hospital for technical assistance.

COMMENTS

Background

In some medical literature, hormonal therapy with GH has been shown to improve weight gain in a model of severe short bowel syndrome. This improvement in weight gain was associated with an increase in nutrient transport at the cellular level and variable increases in villus size. But there are some conflicting results: no improvement was observed in the absorption of total energy, carbohydrate, fat, nitrogen, or wet weight of stool or stool electrolytes compared with baseline and placebo measurements.

Research frontiers

This study has been carefully designed to investigate whether recombinant human growth hormone (rhGH) could increase the proliferative activity of epithelial cells and nutrient absorption in human. The results showed that rhGH could promote intestinal mucosal epithelial cell proliferation and protein synthesis in humans.

Innovations and breakthroughs

Few studies have made direct observations of the effects of rhGH on intestinal mucosa in humans. In this study, the effects of rhGH on intestinal mucosa proliferation were directly observed. Intestinal mucosal biopsies were performed by endoscopy through enterocutaneous fistula.

Applications

This study suggests that rhGH may reasonably be applied in a clinical setting.

Peer review

Although this is a very interesting study, it is just a preliminary observation. It should be verified in the future. Authors should comment on possible adverse effects of this drug.

Abstract

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive condition associated with exocrine pancreatic insufficiency, and is characterized by hypoplastic nasal alae, mental retardation, sensorineural hearing loss, short stature, scalp defects, dental abnormalities and abnormal hair patterns. Growth hormone deficiency, hypopituitarism, and impaired glucagon secretion response to insulin-induced hypoglycemia have been reported. Congenital heart defects have also been described in this condition. Mental retardation is typically moderate to severe in patients with JBS; however, normal intelligence can occur. In the pancreas, there is a selective defect of acinar tissue, whereas the islets of Langerhans and ducts are preserved. Diabetes has been reported in older children, suggesting the progressive nature of pancreatic disease. The molecular basis of JBS has recently been mapped to chromosome 15q15-q21 with identified mutations in the *UBR1* gene. We report the case of a 7-year-old female with pancreatic insufficiency and mild phenotypic features, in whom the diagnosis of JBS was established using recently described molecular testing for the *UBR1* gene.

Johanson-Blizzard syndrome with mild phenotypic features confirmed by *UBR1* gene testing. *World J Gastroenterol* 2008; 14(44): 6863-6866 Available from: URL: http://www.wjgnet.com/1007-9327/14/6863.asp DOI: http://dx.doi.org/10.3748/wjg.14.6863

INTRODUCTION

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive multisystem disorder in which the most characteristic feature is exocrine pancreatic insufficiency. Other common abnormalities include an abnormal facial appearance with a small beak-like nose, dental abnormalities, sensorineural hearing loss, midline scalp defects, hypothyroidism, genitourinary abnormalities, varying degrees of mental retardation, and growth failure[1,2]. In 2005 the disease-associated locus in individuals with this syndrome was mapped to chromosome 15q15-21 with identified mutations in the gene *UBR1* encoding a ubiquitin ligase of the N-end rule pathway[3]. We report the case of a 7-year-old patient recently diagnosed with JBS, confirmed by genetic testing, who has been followed for longstanding pancreatic insufficiency of unknown etiology, but with only mild phenotypic features of JBS, mild sensorineural hearing loss, and who is of normal intelligence.

CASE REPORT

The patient is a 7-year-old girl who was initially evaluated at 18 mo of age for a history of growth failure and increased stool frequency. She was a term infant, birth weight 3230 g, born to non-consanguineous parents. She was initially breast-fed and transitioned to a soy-based formula at 3 mo of age and lactose-free milk at 1 year. She tolerated the introduction of solid foods at 4 mo of age. She had a history of 3-5 large bulky stools per day that contained partially undigested food and were described as being occasionally oily. Her growth was below the

Table 1 Initial evaluation

Complete blood count
Hemoglobin 11.5 g/dL (normal, 10.5-13.5)
WBC 7420/μL (normal, 5.5-15.5)
ANC 1460/μL
Otherwise unremarkable
Complete metabolic panel
Total protein 6.6 g/dL (normal, 6-8.4)
Albumin 4.1 g/dL (normal, 3.5-5)
Alk phos 369 U/L (normal, 80-340)
Otherwise unremarkable
Lipase 8 U/L (normal, 12-70)
Amylase 49 U/L (normal, 0-137)
PT 11.6 s
Vitamin A and D levels were normal
Vitamin E 0.1 mg/dL (normal, 0.5-2)
Celiac antibody testing negative
Serum trypsinogen < 1.2 ng/mL (normal, 10-57)
TSH and free T4 were normal
Stool ova and parasites negative
Seventy-two fecal fat
Fecal fat quant 10.6 g/24 h (normal, < 7)
Coefficient of fat absorption 83%
Stool chymotrypsin < 3 U/10 g (normal, > 9)

Sweat test: 45 mmol/L (normal, 8-45); CFTR gene mutation analysis: No known deleterious mutations; Shwachman-Diamond gene analysis: Negative.

3rd percentile for weight and height. She was otherwise healthy, with the exception of having five ear infections between the ages of 6 and 18 mo, which ultimately required pressure-equalizing tube placement. Her developmental history was normal, other than starting to walk independently at 18 mo of age. Family history was negative for cystic fibrosis, celiac disease, chronic diarrhea and growth failure. Her physical examination was remarkable for a weight of 9.3 kg (7% ile) and a height of 77.6 cm (< 5% ile). Her initial laboratory evaluation is shown in Table 1. She had evidence of significant fat malabsorption; however, testing was negative for celiac disease, cystic fibrosis, and Shwachman-Diamond syndrome. Based on the presumed diagnosis of pancreatic insufficiency, she was started on pancreatic enzyme replacement and fat soluble vitamin supplementation. She gained weight and grew along the 5%-10% ile for height and weight on this regimen. She was otherwise healthy and did not have recurrent or frequent infections. Her development was normal.

At 5 years of age, she failed her routine kindergarten hearing screen. Her parents had previously not noted any problem with her hearing or speech. An audiology evaluation was abnormal demonstrating a mild-to-moderate bilateral asymmetric sensorineural hearing loss, greater on the left than the right. She was referred for genetic evaluation given the known association between JBS and sensorineural hearing loss with her history of pancreatic insufficiency. At that time, mild phenotypic features of JBS were identified, including an abnormal hair pattern, hypoplasia of the nasal alae, small teeth and a narrow upper lip (Figure 1). A computed tomography (CT) scan of her abdomen demonstrated complete fatty replacement of the pancreas with no visualized

Figure 1 Phenotypic features of JBS in our patient: abnormal hair pattern, nasal alae hypoplasia, small teeth and narrow upper lip (with permission from parents).

Figure 2 CT scan of the abdomen demonstrating fatty replacement of the pancreas (arrow).

gland residing in the pancreatic bed (Figure 2). Renal ultrasound to evaluate genitourinary abnormalities was negative.

Research testing for mutations in *UBR1* revealed two novel mutations that molecularly confirmed the diagnosis of JBS, IVS1+5G>C (c.81+G>C) a splice site mutation (paternally inherited, father had a mosaic mutation present in only a subset of cells) and exon 17, c.1979_1981delTTG (p.V660del, which is a deletion of a highly conserved valine that was maternally inherited (Figure 3). While abnormal splicing at the splice donor site of exon 1 is predicted to lead to no expression of a functional protein (functional null allele), the maternally inherited deletion may represent a hypomorphic mutation, conferring partial residual function. Indeed, analysis of mRNA from lymphoblastoid cells from the patient by RT-PCR and sequencing indicated that mRNA from the allele with the splice site mutation underwent early degradation (Figure 3). However, we cannot exclude the possibility that some production of a functional UBR1 protein may also result from a low level of normal splicing despite the splice donor mutation at position +5. Our patient has continued to do well on pancreatic enzyme replacement and is being followed by otolaryngology for her hearing loss. She was referred to dental services for her tooth abnormalities.

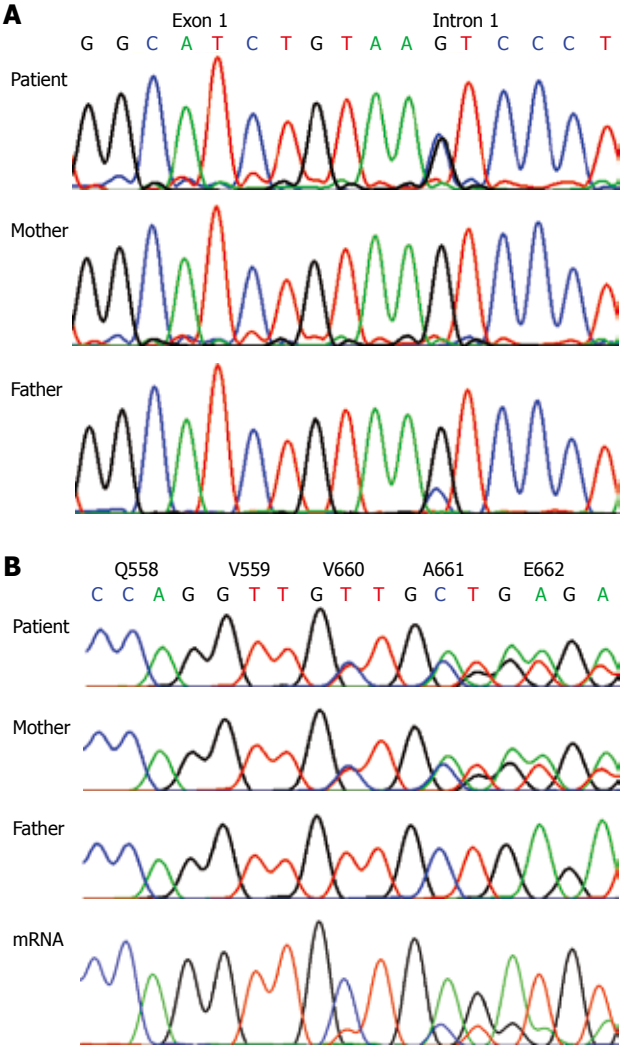

Figure 3 Diagram of the *UBR1* gene mutations in our patient and her parents. A: Exon 1-intron 1 transition showing a heterozygous nucleotide exchange at position +5 in the patient, IVS1+5G>C (c.81+G>C). Note the small peak in the father, indicating that he is mosaic for this mutation. B: Section of exon 17 showing a heterozygous 3 bp deletion in the patient and her mother, c.1978_1981delTTG (p.V660del), predicting the deletion of a highly conserved valine. In mRNA from lymphoblastoid cells from the patient the deletion is the predominant allele, indicating that mRNA from the allele with the splice site mutation is largely degradated.

DISCUSSION

JBS is a rare autosomal recessive multisystem disorder. The most prominent feature of this syndrome is exocrine pancreatic insufficiency. Other abnormalities include a characteristic facial appearance with a small beak-like nose (secondary to aplasia or hypoplasia of the nasal alae), long and narrow upper lip, small pointed chin, abnormalities of both deciduous and permanent teeth, sparse coarse hair/midline scalp defects, short stature in > 80%, hypothyroidism in 40%, sensorineural hearing loss in > 80%, mental retardation in 77%, imperforate anus in 39%, and genitourinary abnormalities in 38%[4]. Growth hormone deficiency, hypopituitarism, and impaired glucagon secretion response to insulin-induced hypoglycemia have been reported[5-7]. Congenital heart defects including atrial septal defect, ventricular septal defect, and dextrocardia with transposition of the great vessels have also been described in this condition[8]. Mental retardation is typically moderate to severe in patients with JBS, however, normal intelligence can occur[9]. Growth failure in patients with JBS typically begins in the intrauterine period and continues throughout childhood. Pancreatic hypoplasia with resultant exocrine insufficiency and malabsorption is thought to be responsible. In the pancreas of patients with this condition there is a selective defect of acinar tissue, whereas the islets of Langerhans and ducts are preserved[10,11]. This results in an almost complete absence of zymogens from duodenal juice, whereas bicarbonate secretion is much less impaired[10]. Diabetes has been reported in older children, suggesting the progressive nature of pancreatic disease[12,13].

The molecular basis of JBS has recently been mapped to chromosome 15q15-q21 with identified mutations in the *UBR1* gene[3,4]. *UBR1* expression is highest in predominantly skeletal muscle and pancreatic acinar cells. *UBR1* encodes one of several E3 ubiquitin ligases of the N-end rule pathway, an ubiquitin-dependent proteolytic pathway. Ubiquitylation and subsequent degradation of proteins at the proteasome is the universal mechanism for regulated protein degradation and the control of many intracellular protein levels[14-16]. *UBR1* is considered to play a critical role in the development and maintenance of acinar cells. In patients with JBS, destruction of acinar tissue which may begin *in utero* results in the development of exocrine pancreatic insufficiency and fatty replacement of the pancreas. Since the initial description of JBS in 1971, more than 60 cases have been reported[4]. The majority of these reports include children with significant pancreatic insufficiency, markedly abnormal facial features and moderate to severe mental retardation.

Our patient presented with pancreatic insufficiency and initially unrecognized mild phenotypic features of JBS. This diagnosis was only suspected when she failed a routine screening hearing test, without prior suspicion of hearing loss. In contrast to previous findings of biallelic *UBR1* mutations predicting complete loss of function in the majority of patients with JBS[3], in our patient, the maternally inherited deletion is thought to be a hypomorphic mutation conferring partial residual function and explaining the more subtle phenotype. This is the first evidence for genotype-phenotype correlation in JBS. The purpose of this report is to highlight the broader spectrum of this syndrome which may have been previously unrecognized prior to the availability of specialized genetic testing. Once the diagnosis of JBS is established, patients with this condition need to be screened for renal anomalies, referred for dental evaluation, monitored for the development of hypothyroidism and diabetes and provided with appropriate genetic counseling.

JBS is a rare cause of pancreatic insufficiency, usually associated with typical phenotypic features. The genetic basis for this syndrome has been recently identified, and is related to UBR1 deficiency which leads to perturbation of pancreatic acinar cells as well as other

organs. Gastroenterologists should be aware of the availability of genetic testing for JBS. Recognition of more subtle presentations of this syndrome may help to identify other patients with this autosomal recessive condition, previously thought to have idiopathic pancreatic insufficiency.

Abstract

Percutaneous aspiration and drainage of post-operative abdominal fluid collections is a well established standard technique. However, some fluid collections are not amenable to percutaneous drainage either due to location or the presence of surrounding visceral structures. Endoscopic Ultrasound (EUS) has been widely used for the drainage of pancreatitis-related abdominal fluid collections. However, there are no reports on the use of this technique in the post-operative setting. We report a case where the EUS-guided technique was used to drain a percutaneously inaccessible post-operative collection which had developed after Whipple's resection.

Jah A, Jamieson N, Huguet E, Griffiths W, Carroll N, Praseedom R. Endoscopic Ultrasound-guided drainage of an abdominal fluid collection following Whipple's resection. *World J Gastroenterol* 2008; 14(44): 6867-6868 Available from: URL: http://www.wjgnet.com/1007-9327/14/6867.asp DOI: http://dx.doi.org/10.3748/wjg.14.6867

INTRODUCTION

Drainage of post-operative abdominal fluid collections is generally carried out percutaneously under radiological guidance. However, some of these collections may be inaccessible to percutaneous drainage because of their location and surrounding vital structures.

We report a case where a post-operative fluid collection which developed after a Whipple's resection was successfully drained endoscopically under endoscopic ultrasound (EUS) guidance. Although widely used in pancreatitis, this is the first report of the use of this technique in a post-operative setting.

CASE REPORT

A 45 year old lady underwent Whipple's resection for cholangiocarcinoma of the distal common bile duct. Pancreatico-jejunostomy and hepatico-jejunostomy were performed on to a 70 cm Roux-en-Y jejunal loop and a gastrojejunostomy was fashioned using the end of the main jejunal segment continuous with the rest of the intestine.

Her initial recovery was uneventful but on the 9th post-operative day she developed pyrexia and vomiting suggestive of gastric outlet obstruction. A contrast-enhanced computerized tomogram (CT) showed a deep-seated fluid collection measuring 5.1 × 3.3 cm which was compressing and stretching the efferent jejunal loop distal to the gastrojejunostomy (Figure 1). Percutaneous drainage was deemed unsafe due to the surrounding bowel loops and blood vessels. However, its proximity to the gastrojejunostomy made it accessible endoscopically.

An EUS-endoscope (GF-UCT240, Olympus, UK) was passed through the gastrojejunostomy and the sero-sanguinous collection was aspirated to dryness under EUS guidance using a 19-gauge Echotip-Ultra needle (Wilson-Cook, Ireland) (Figure 2). The amylase level in the aspirate was normal and all the cultures were sterile. Following aspiration of the fluid collection the

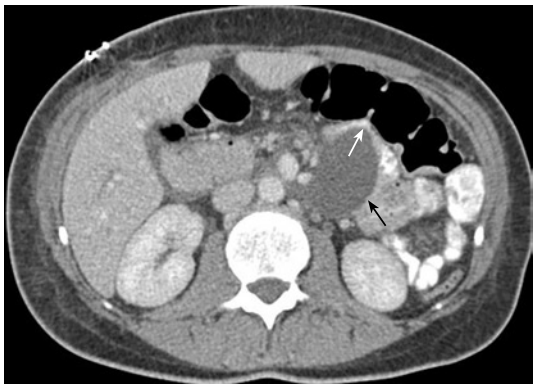

Figure 1 Contrast-enhanced CT showing the fluid collection (black arrow) compressing the efferent jejunal loop (white arrow) just distal to the gastrojejunostomy.

Figure 2 EUS showing the fluid collection (black arrow) with the needle in position for aspiration (white arrow).

vomiting and pyrexia settled, and the patient was able to recommence oral intake. There were no complications related to this procedure and she was discharged from hospital after three days. She was asymptomatic at her routine surgical outpatient review 6 wk later.

DISCUSSION

Abdominal fluid collections are common after Whipple's resection and are frequently situated in the pancreatic bed. They may be related to an anastomotic leak (generally pancreatic) and often cause mechanical and/or infective complications. These collections are generally deep-seated and are surrounded by major blood vessels. This combined with altered post-surgical anatomy (presence of Roux loops *etc*) often makes a direct percutaneous route for drainage impossible to find. In this patient, it was important to exclude a pancreatic leak and to resolve the gastric outlet obstruction. In such cases, a laparotomy would normally be necessary in the absence of a safe percutaneous option.

In contrast, endoscopic transmural drainage or aspiration with EUS guidance has greatly reduced the need for surgery in pancreatitis-related fluid collections and has now become a standard procedure for this condition in our unit. The safety of this technique and high success rates have been widely reported[1-3]. This experience prompted us to use the EUS-guided technique as an alternative route for drainage of this post-operative fluid collection where percutaneous approach was deemed unsafe.

In a patient with a visceral fluid collection, the feasibility of EUS-guided drainage should first be assessed with dual contrast-enhanced CT. Close proximity to the stomach or jejunum provides an easy endoscopic access to these collections. The technique of EUS-guided aspiration is well established[1-3].

We anticipate that the main role of EUS-guided aspiration of collections in the post-operative situation would be to allow much-needed sampling of fluid for microbiological and biochemical analysis. In patients with sepsis or mechanical complications such as obstruction secondary to collections, this technique would also be therapeutic. In stable patients this could eliminate the need for a laparotomy which would otherwise carry a much higher risk of morbidity and mortality. Thus, we conclude that EUS-guided aspiration/drainage should be considered in patients with otherwise inaccessible post-operative fluid collections.

Abstract

Most patients with hepatocellular carcinoma (HCC) are not eligible for curative treatment, which is resection or transplantation. Two recent series have emphasized the potential benefits of preoperative arterio-portal embolization prior to surgical resection of such tumours. This preoperative strategy offers a better disease free survival rate and a higher rate of total tumor necrosis. In case of non resectable HCC it is now widely accepted that transarterial chemoembolization (TACE) leads to a better survival when compared to conservative treatment. Thus, the question remains whether combined portal vein embolization (PVE) may enhance the proven efficiency of TACE in patients with unresectable HCC. We herein report the case of a 56-year-old cirrhotic woman with a voluminous HCC unsuitable for surgical resection. Yet, complete tumour necrosis and prolonged survival could be achieved after a combined porto-arterial embolization. This case emphasizes the potential synergistic effect of a combined arterio-portal embolization and the hypothetical survival benefit of such a procedure, in selected patients, with HCC not suitable for surgery or local ablative therapy.

INTRODUCTION

Despite a close observation of patients with liver cirrhosis, hepatocellular carcinoma (HCC) is often diagnosed at an advanced stage where no optimal treatment has been established[1-3] only few patients (20%-25%) will benefit of resection or liver transplantation[4], only chance to improve life expectancy. Actually, 80% to 90%[5] of HCC develop in cirrhotic patients with impaired liver function, limiting the possibility of safe major liver resections. If liver resection has shown a survival benefit, in case of cirrhosis, it's a risky procedure with a high prevalence of postoperative liver failure and should not be performed if the future liver remnant (FLR) is estimated to be less than 40%[6]. In those patients who are not suitable for surgery, treatment is palliative and survival is poor and correlated to TNM stage (TNM classification of primary liver cancer by the International Hepato-Pancreato-Biliary Association[7]) and liver damage severity[8]. Despite previous inconclusive randomized controlled trials comparing transarterial chemoembolization (TACE) to conservative treatment in unresectable HCC[9-11], Liovet *et al*[12] ultimately demonstrated that TACE led to an increased survival in selected patients with preserved liver function. TACE is now widely accepted as the procedure of choice in selected patients who are not eligible for

resection or local ablative therapy. However, the question remains whether combined portal embolization may enhance the proven efficiency of TACE in patients with unresectable hepatocellular carcinoma (HCC).

We herein report the case of a cirrhotic patient with advanced HCC in whom complete tumour necrosis and prolonged survival were observed following a combined porto-arterial embolization.

CASE REPORT

A 56-year-old woman with alcoholic cirrhosis, Child-Pugh A6 presented with an 80 mm HCC stage Ⅲ. The tumor developed in the right hepatic lobe, impinging on the median hepatic vein and in contact with the right glissonian pedicle (Figure 1A). There were two satellite nodules but the left hepatic lobe was free of tumor. The right portal vein was patent. The patient had stopped alcohol intake for 3 mo before admission. There was no past history of encephalopathy, ascites or upper gastro-intestinal bleeding despite stage I oesophageal varices. The clinical examination was normal. Liver biochemistry showed: A 74% prothrombin time, normal albumin level, bilirubin 50 μmol/L (N < 17), ASAT/ALAT: 59/66 UI/L (N < 40), gamma glutamyl transferase: 204 UI/L (N < 140), alkaline phosphatase: 105 UI/L (N < 80), platelet count was 126 000/mm^3. Alpha-foeto protein level was 108 μg/L (N < 5). The diagnosis of established alcoholic cirrhosis was confirmed by a percutaneous liver biopsy. As the surgical strategy was a right hepatectomy removing the median hepatic vein and the patient underwent a right portal vein embolization (PVE) prior to surgery (Figure 2A and B). After 4 wk the left lobe had gained 40%. During surgery, intra-abdominal exploration revealed moderate to severe portal hypertension with an enlarged spleen, mild ascites and dilated splanchnic veins. The liver appeared cirrhotic with regeneration nodules. Intraoperative ultrasound confirmed an 8 cm HCC, mainly involving segment V and Ⅷ, invading the median hepatic vein and close to the right glissonian pedicle. Peroperative observation precluded liver resection and separate biopsy of both tumor and liver parenchyma was done before abdominal closure. In view of previous right PVE, intra-arterial chemoembolization was thought to be unsafe and a supportive medical care was decided. During follow-up, a 20 mm intra-tumoral aneurysm of right arterial branch was diagnosed on computer tomography (CT) scan (Figure 1B), most probably related to an arterial trauma during intraoperative tumor biopsy. A supra-selective arterial embolization with coils was then undertaken with complete obliteration of the arterial aneurysm on control angiography (Figure 3A and B). A control CT scan performed 3 mo later showed complete necrosis of the tumor (Figure 1C) as suggested by return of alpha-foeto protein to normal value (6.8 μg/L). Disease-free survival lasted for two years. Multiple intra-hepatic and bone recurrence was diagnosed on progressive increase of alpha foeto-protein level. The patient ultimately died after a follow-up of three years.

DISCUSSION

In up to 90%, HCC develop in cirrhotic patients whose impaired liver function precludes major liver resections if FLR is less than 40%[6]. First reported by Makuuchi *et al*[13], PVE can be performed safely[14] in order to induce a homolateral liver parenchyma atrophy and a hypertrophy of the FLR, allowing resection in patients with large tumors or abnormal liver function[15]. Yet, this technique was initially described for patients with Klatskin tumors[13] and its' application to cirrhotic patients with HCC is debated by some authors who rather recommend a preoperative combined arterio-portal embolization[16]. HCC being hypervascular tumours mainly fed by an arterial blood flow, cessation of the portal's flow leads to a compensatory increased flow in the corresponding arterial territory[17] that may cause the tumor progress.

Recently, Ogata *et al* [18] have reported in a controlled trial the feasibility and efficacy of a sequential arterio-portal embolization, TACE followed by PVE after a 3 wk delay, before major liver resection in cirrhotic patients with HCC. When compared to PVE alone, this procedure offers a significantly higher rate of complete tumor necrosis (83% *vs* 5%, P < 0.001), a higher 5-year disease-free survival rate (37% *vs* 19%, P = 0.041) with a similar rate of morbidity. In this report the authors confirmed that complete tumor necrosis can be obtained by its complete blood flow privation (arterial and portal) and highlight the potential benefit of this sequence in term of prognosis. Moreover, in their report, the Beaujon's group[18] suggests that sequential embolization could effectively be an appropriate treatment itself in patients in whom surgery is precluded due to a poor degree of liver hypertrophy.

In case of unresectable HCC, efficacy of TACE is now admitted[19,20] with a benefit in survival when compared to conservative treatment. Yet, TACE alone leads to around 50% of complete tumour necrosis[21-23] whereas this rate is over 80% after sequential arterio-portal embolization and this may have an impact on survival curves[16,18]. Aoki *et al*[16] obtained a necrosis rate superior to 70% in 12/17 (71%) whereas Yamakada *et al*[24] observed a complete tumoral necrosis in 7/9 (78%) of the resected specimen after a sequential arterio-portal procedure with 1, 3 and 5 years survival rates of 87%, 72% and 51%, respectively.

Even though portal vein thrombosis, which is a frequent complication of HCC, is considered to be an absolute contraindication to TACE, due to increased risk of post procedure liver failure or infarction, efficacy and safety of TACE in such cases have been reported[25] in selected patients. Taken together, these observations suggest a good tolerance of liver parenchyma to ischemia when interval between portal and arterial occlusion is delayed[18]. Ogata *et al*[18] who have suggested a minimum of 3 wk between both procedures had lesser morbidity and aminotransferase levels as compared to Aoki *et al*[16] who performed both embolizations within a period of 7 d.

In the case herein reported, although our patient

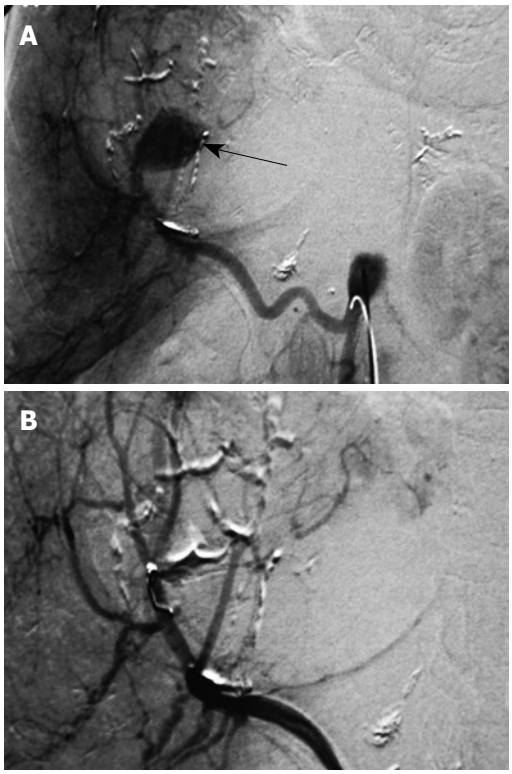

Figure 3 Arteriography. A: The arterial aneurysm developed on the HCC main feeding artery (black arrow), prior to embolization with coils; B: After complete arterial occlusion with coils.

was planned to have a major liver resection we did not perform a preoperative TACE before PVE, which is now systematic in our department. In this particular case, arterial embolization was performed after portal embolization and was indicated to treat a traumatic arterial aneurysm following a peroperative fine needle biopsy. Yet, it was well tolerated, had no consequence on liver function and led to a complete tumor necrosis with a prolonged survival. We agree that a porto-arterial sequence is unusual and do not recommend it that way, but this case fully illustrates the synergy of a combined embolization in term of tumor necrosis. We rather recommend a sequential arterio-portal sequence combining TACE and PVE as previously described[18], with a 3 wk delay between both procedures. In this view, we assume that tolerance is related to the sequence and its timing whereas efficacy is related to both, arterial and portal, HCC vascular exclusion.

Our report aims at giving further support to the combination of TACE and portal embolization in the treatment of voluminous HCC that cannot be treated by surgery or alternative therapy such as radiofrequency as previously hypothesized by others[18]. We assume that cirrhotic liver parenchyma has a relatively good tolerance to arterial and portal ischemia when the interval between both vascular occlusions is delayed (at least 3 wk). Proven efficacy of TACE might be enhanced by a combined sequential PVE. Patients With large HCC, not suitable for surgery or local ablative therapy, could effectively be treated with combined arterio-portal embolization with a limited morbidity and a likely benefit in survival.

Abstract

Lymphangioma of the pancreas is an extremely rare benign tumour of lymphatic origin, with fewer than 60 published cases. Histologically, it is polycystic, with the cysts separated by thin septa and lined with endothelial cells. Though congenital, it can affect all age groups, and occurs more frequently in females. Patients usually present with epigastric pain and an associated palpable mass. Complete excision is curative, even though, depending on the tumour location, surgery may be simple or involve extensive pancreatic resection and anastomoses. The authors present a 49-year-old woman in whom a polycystic septated mass, 35 mm x 35 mm in size, was discovered by ultrasonography (US) in the body of the pancreas during investigations for epigastric pain and nausea. At surgery, a well circumscribed polycystic tumor was completely excised, with preservation of the pancreatic duct. The postoperative recovery was uneventful. Histology confirmed a microcystic lymphangioma of the pancreas. Immunohistochemistry showed cystic endothelial cells reactivity to factor Ⅷ -RA (++), CD31 (+++) and CD34 (-). Postoperatively, abdominal pain disappeared and the patient remained symptomfree for 12 mo until now. Although extremely rare, lymphangioma of the pancreas should be taken into consideration as a differential diagnosis of a pancreatic cystic lesion, especially in women.

INTRODUCTION

Lymphangiomas are rare benign cystic tumours that probably occur as a result of congenital malformations of the lymphatics leading to the obstruction of local lymph flow and the development of lymphangiectasia. Histopathologically, they are composed of dilated cystic spaces containing proteinaceous eosinophilic fluid, seperated by fine septa and lined with endothelial cells[1]. These tumours present most frequently in childhood[2] and have an associated broad spectrum of clinical symptoms, depending on the disease location. They are most commonly found in the neck (75%) and the axillae (20%), though a variety of other sites have been described including the mediastinum, pleura, pericardium, groin, bones and the abdomen[2,3].

Lymphangioma of the pancreas is extremely rare accounting for less than 1% of these tumours[4], and with only 60 previously reported cases. We present the rare case of an adult with lymphangioma of the pancreas and review the literature.

CASE REPORT

A 49-year-old women presented with increasing upper abdominal pain and nausea in November 2007. She had a past medical history of a uterine myomectomy in 1997, and a hysterectomy and left oophorectomy in 2006. On examination, she was

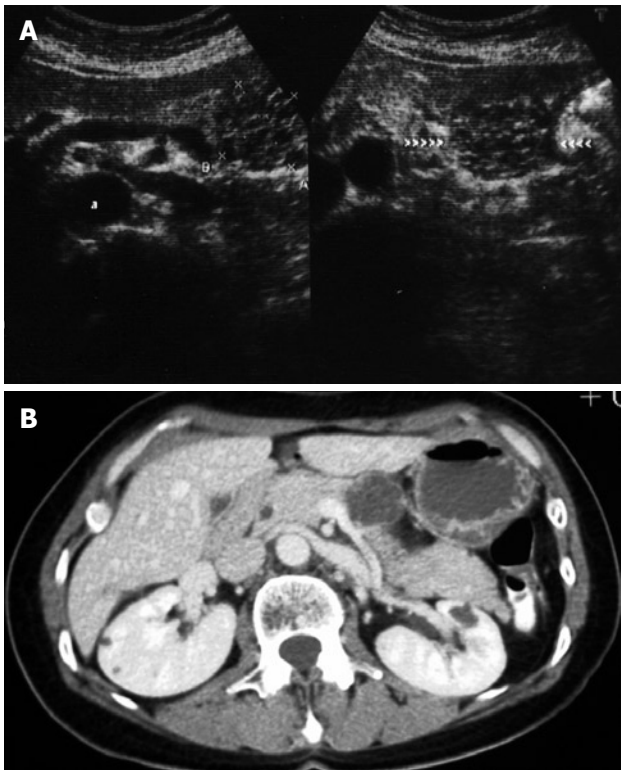

Figure 1 A well-circumscribed 35 mm polycystic lesion in the body of the pancreas, with thin septa within the lesion. A: US scan demonstrating the polycystic tumour of the body of the pancreas; B: CT scan showing the cystic tumour with fine septa.

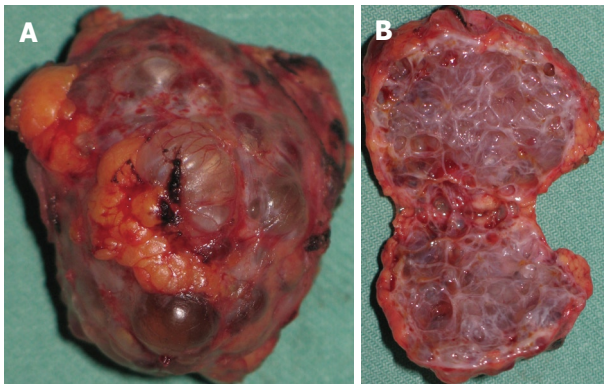

Figure 2 Tumour surrounded by normal pancreatic tissue. A: The excised polycystic mass; B: The tumour after sectioning.

found to be slightly tender at the epigastrium, and laboratory analyses were all within normal limits. An ultrasonography (US) and computer tomography (CT) scan revealed a well-circumscribed 35 mm polycystic lesion in the body of the pancreas, with thin septa within the lesion (Figure 1).

At laparotomy the lesion was found in the lower part of the body of the pancreas, and did not involve the main pancreatic duct. The lesion was completely excised and the main pancreatic duct was preserved. No other pathology was found within the abdomen, and the postoperative recovery was uneventful. Abdominal pain disappeared postoperatively and the patient has been doing well for the following 12 mo until now.

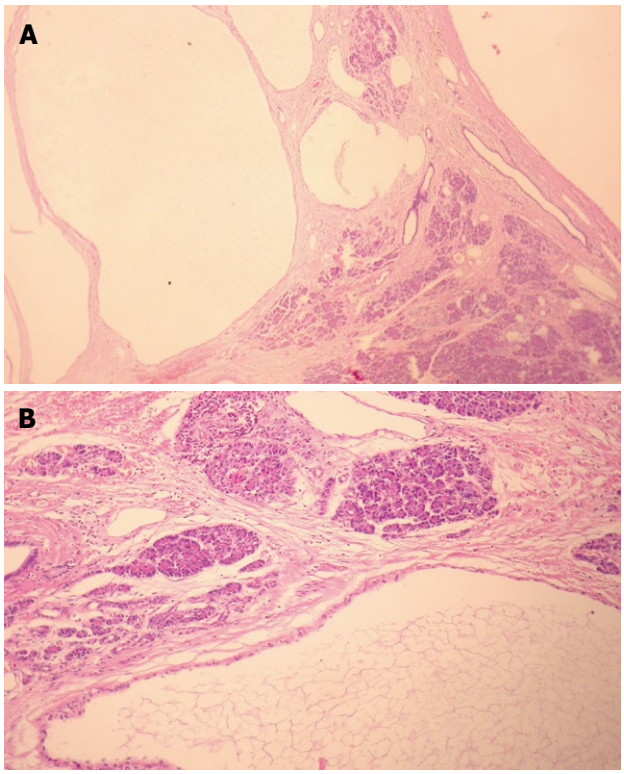

Figure 3 Microscopically all the sections (HE stain). A: Vascular spaces of the pancreatic cystic Lymphangioma containing predominantly clear fluid with few erythrocytes or lymphocytes (x 13); B: The cysts and dilated lymphatics in the surrounding pancreatic tissue are lined with a thin endothelial layer (x 64).

The tumour, measuring 34 mm × 32 mm × 29 mm, had a nodular, gray-blue surface and was surrounded by normal pancreatic tissue (Figure 2A). On sectioning, it had a honeycomb appearance with 1-7 mm polycystic spaces filled with murky haemorrhagic yellowish fluid (Figure 2B). Microscopically, all the sections showed a polycystic structure composed of ectatic lymphatics lined with endothelial cells (Figure 3). The cysts were separated by thin hypocellular septa similar in appearance to the thin capsule surrounding the tumour mass itself. No cell atypia was found. Immunohistochemistry showed immunoreactivity to the factor Ⅷ-R antigen (++), CD 31 positivity (+++) and CD 34 negativity (-). The final histological diagnosis was of microcystic lymphangioma of the pancreas.

DISCUSSION

Lymphangioma of the pancreas is rare, accounting for less than 1% of lymphangiomas[4]. It occurs more frequently in females and is often located in the distal pancreas[5]. The tumour size may vary between 3 and 20 cm in diameter (average 12 cm)[6]. Patients usually present with abdominal pain[5] and an associated palpable abdominal mass[7-9], although an acute abdomen has also been described[10]. Pancreatitis, weight loss, and laboratory abnormalities are not usual disease manifestations[1]. US typically shows a polycystic tumour, and calcifications, which are typical for cystadenomas of the pancreas, are very rare[11]. On CT, the tumour

is a well-circumscribed, encapsulated, water-isodense, polycystic tumour with thin septa, similar in appearance to cystadenomas, which occur far more frequently[1,12].

Differential diagnoses include pancreatic pseudocysts, mucinous and serous cystadenomas, other congenital cysts and pancreatic ductal carcinoma with cystic degeneration[1,13,14]. The final diagnosis is histological[1], with the endothelial cells showing immunohistochemical reactivity to factor VIII/R antigen, CD 31 (+) positivity[6,8] and CD 34 (-) negativity[6], as seen in our patient.

A complete surgical excision is curative[6,8,15], with incomplete excision being the only reason for recurrent disease[7]. Depending on the tumour location and size, complete excision may involve a simple marginal tumorectomy[10] or may require larger pancreatic resections with anastomoses.

Abstract

A 68-year-old female visited a local clinic with epigastralgia. A routine laboratory test revealed jaundice and liver dysfunction. She was referred to this hospital. Abdominal computed tomography (CT) and endoscopic retrograde cholangio-pancreatography (ERCP) revealed that the density of the entire pancreas had decreased, and showed dilatation of the common bile duct (CBD) and the main pancreatic duct (MPD). Pancreatic cancer was diagnosed by cytological examination analyzing the pancreatic juice obtained by ERCP. When jaundice had decreased the tumor was observed *via* laparotomy. No ascites, liver metastasis, or peritoneal dissemination was observed. The entire pancreas was a hard mass, and a needle biopsy was obtained from the head, body and tail of the pancreas. These biopsies diagnosed a poorly differentiated adenocarcinoma. Hepaticojejunostomy was thus performed, and postoperative progress was good. Chemotherapy with 1000 mg/body per week of gemcitabine was administered beginning 15 d postoperatively. However, the patient suffered relatively severe side effects, and it was necessary to change the dosing schedule of gemcitabine. Abdominal CT revealed a complete response (CR) after 3 treatments. Therefore, weekly chemotherapy was stopped and was changed to monthly administration. To date, for 4 years after chemotherapy, the tumor has not reappeared.

A patient with unresectable advanced pancreatic cancer achieving long-term survival with Gemcitabine chemotherapy. *World J Gastroenterol* 2008; 14(43): 6876-6880 Available from: URL: http://www.wjgnet.com/1007-9327/14/6876.asp DOI: http://dx.doi.org/10.3748/wjg.14.6876

INTRODUCTION

Only 10%-20% of patients with pancreatic cancer present with localized or potentially resectable disease at the time of diagnosis, and the majority of patients are diagnosed at either an unresectable or metastatic stage[1]. The prognosis of patients with advanced unresectable pancreatic cancer remains very poor. When pancreatic cancer is diagnosed, the disease progresses and curability remains unsatisfactory, especially in stage Ⅳb pancreatic cancer[2]. The Japanese Pancreatic Cancer Registry reported that the mean survival of patients with stage Ⅳb pancreatic cancer is 6.2 mo[3], and palliation for the relief of jaundice, duodenal obstruction, or pain is required for these patients. Recently, gemcitabine was developed for the treatment of advanced pancreatic cancer, and current studies have reported improvements in survival as well as clinical benefit in patients[4]. Burris et al. reported that gemcitabine was more effective than 5-fluorouracil in the alleviation of some disease-related symptoms and improved survival was seen in patients with advanced pancreatic cancer[5].

This report describes a case of advanced pancreatic cancer which was initially diagnosed during laparotomy as unresectable; however, the patient achieved long-term survival of over 4 years, following a treatment regimen of gemcitabine chemotherapy.

CASE REPORT

A 68-year-old female visited a local clinic complaining of epigastralgia. Routine laboratory tests revealed that she had jaundice (T. bil 6.5 mg/dL) and liver dysfunction

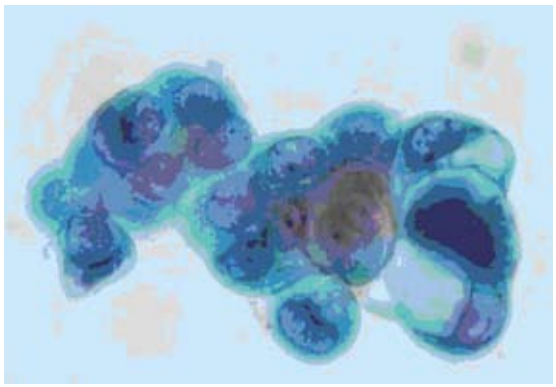

Figure 1 Cytological findings from pancreatic fluid. An adenocarcinoma was indicated.

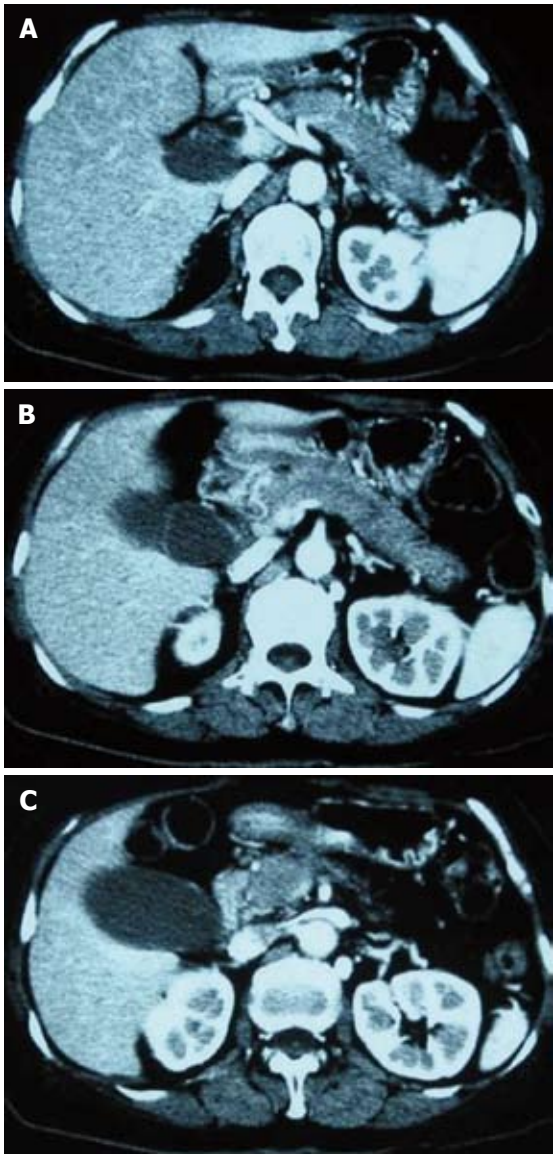

Figure 2 Abdominal CT before surgery. A low density area was observed throughout the entire pancreas, the common bile duct and main pancreatic duct were dilated, the intra-hepatic biliary duct was not dilated. CT: Computed tomography.

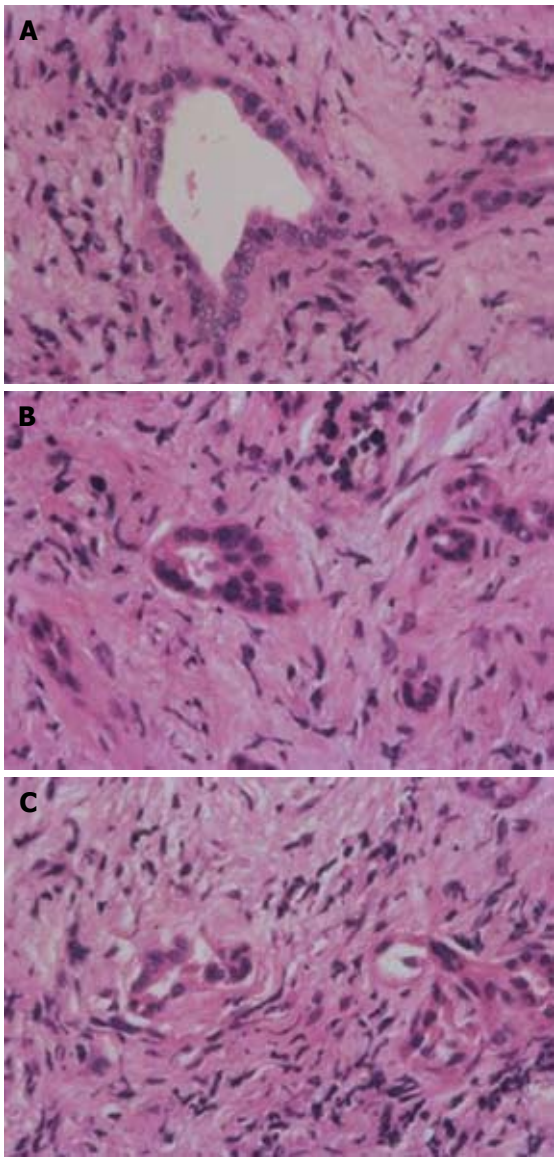

Figure 3 Needle biopsy performed during laparotomy. A: From the head; B: From the body; C: From the tail of the pancreas. All specimens were diagnosed as poorly differentiated adenocarcinoma.

(GOT 416 IU/L, GPT 489 IU/L, ALP 2055 IU/L and γGTP 190 IU/L). Initial laboratory studies included a serum total bilirubin value of 2.6 mg/dL, serum glutamic-oxaloacetic transaminase (GOT) of 416 U/L, serum glutamic-pyruvic transaminase (GPT) of 489 IU/L, alkaline phosphatase (ALP) of 2055 IU/L, and γ-glutamyl transferase (γGTP) of 190 IU/L. Her CA19-9 was not elevated (27.8 U/mL). She was referred to this hospital. She had a past history of rhabdomyosarcoma of the urinary bladder at the age of 56. On admission, abdominal computed tomography (CT) revealed that the density of the whole pancreas had decreased, and showed dilatation of the common bile duct (CBD) and the main pancreatic duct (MPD). In addition, stricture of the lower CBD was revealed on magnetic resonance cholangio-pancreatography (MRCP) (Figures 1 and 2). The MPD in the pancreas head appeared irregular on endoscopic retrograde cholangio-pancreatography (ERCP). The presence of pancreatic cancer or bleary duct cancer was suspected, because a cytological examination of the pancreatic juice obtained by ERCP

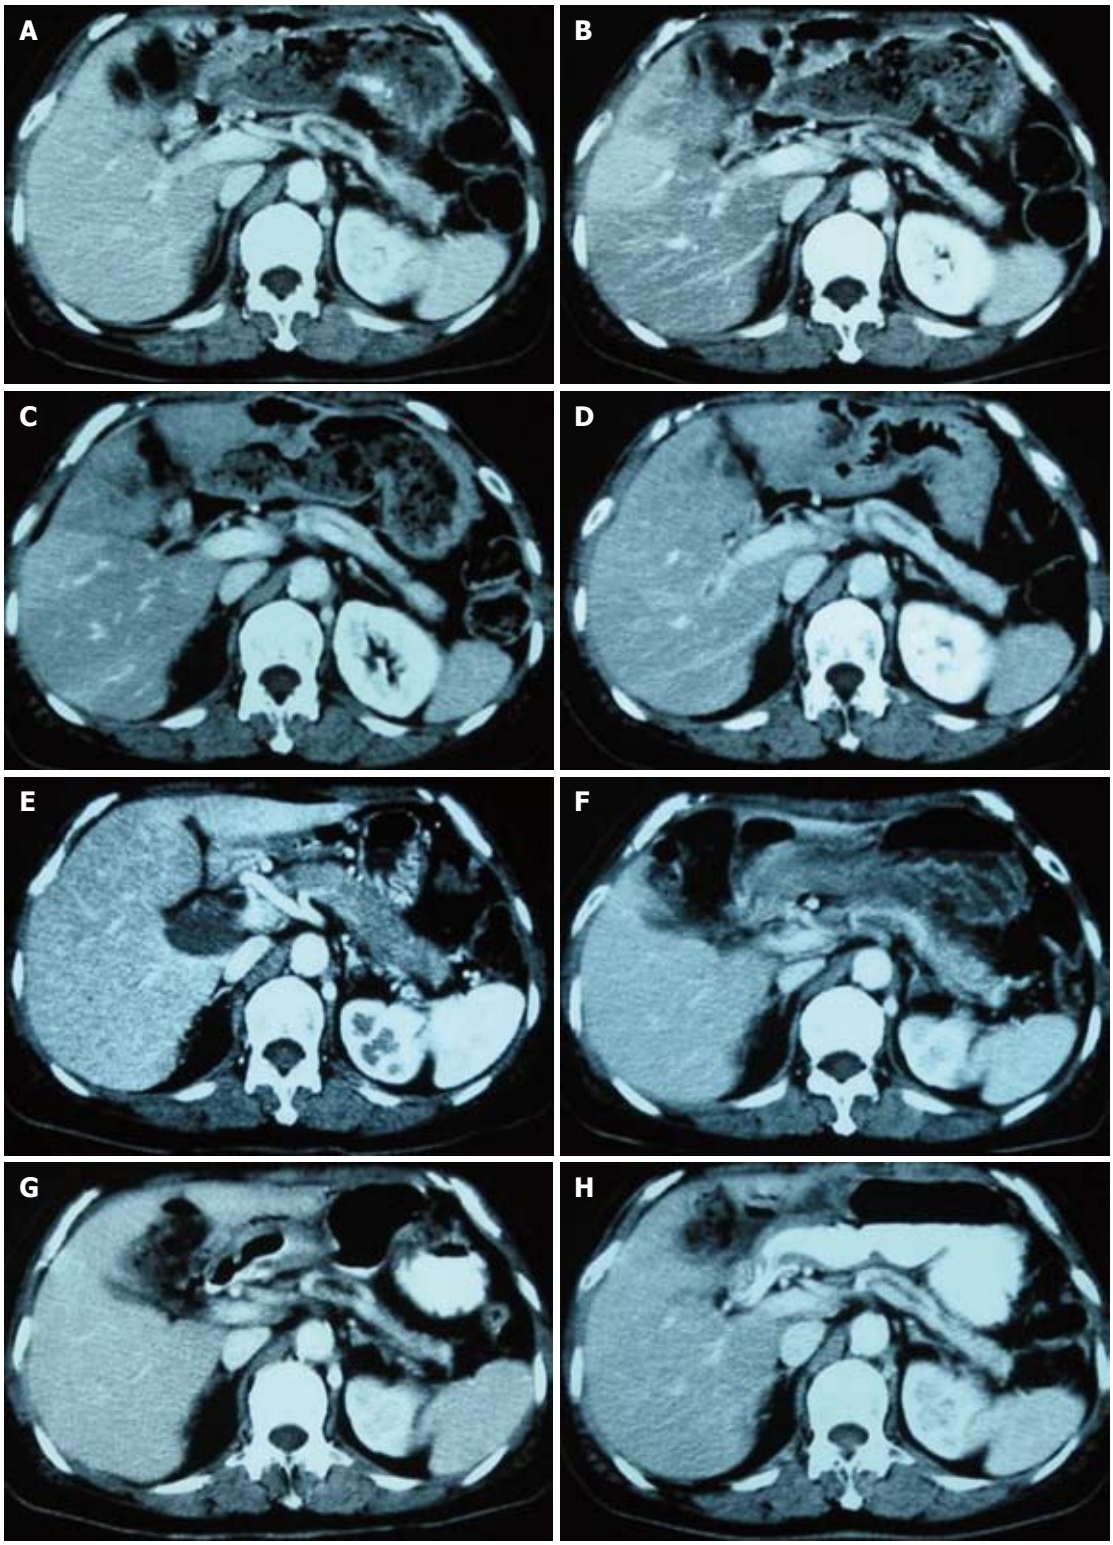

Figure 4 Abdominal CT. A: 12 mo after CTx; B: 16 mo after chemotherapy (CTx); C: 18 mo after CTx; D: 24 mo after CTx; E: preoperative; F: 1 mo after CTx; G: 2 mo after CTx; H: 6 mo after CTx; CT: Computed tomography; CTx: Chemotherapy.

detected adenocarcinoma cells. After amelioration of her jaundice by biliary drainage through percutaneous transhepatic gallbladder drainage (PTGBD), surgical treatment was selected based on a presumptive diagnosis of pancreatic cancer or biliary duct cancer. Laparotomy revealed no liver metastasis or peritoneal dissemination. The entire pancreas was hard, and a needle biopsy was obtained from the head, body, and tail of the pancreas. Examination of frozen sections revealed a poorly differentiated adenocarcinoma in each specimen (Figure 3). We therefore considered total pancreatectomy, however, a radical resection was considered excessive. Hepaticojejunostomy was performed. The postoperative course was uneventful. On postoperative day 14,

administration of chemotherapy with 1000 mg/body per week of gemcitabine was initiated. However, because the patient experienced adverse effects, such as eyelid swelling, larynx swelling, grade 1 fever and grade 3 leucopenia and neutropenia, the chemotherapy schedule was thus changed to biweekly, with the additional of granulocyte colony stimulating factor (G-CSF) (Figure 4).

After 3 courses of chemotherapy, an abdominal CT scan revealed a complete response (CR), in which the decrease in density of the entire pancreas had disappeared, and dilatation of the MPD had improved. Therefore, weekly chemotherapy was stopped after 3 courses, and changed to monthly chemotherapy with hospitalization. To date, 4 years after the initial chemotherapy, the tumor has not reappeared.

DISCUSSION

The incidence of pancreatic cancer has recently increased worldwide, and the prognosis of patients with this disease remains very poor[2,6]. Pancreatic cancer is a major cause of cancer-related mortality in Japan and remains one of the most aggressive diseases in the world. In fact, the National Registry of the Japan Pancreas Society reported that only 9.7% of these patients attained 5-year survival[7]. Early-stage diagnosis of pancreatic cancer is difficult because of the lack of specific early symptoms, and surgery with a curative intent can be performed in only 5%-20% of patients[2]. When the diagnosis is made, less than 10% of patients will survive for a year, and many require relief from jaundice and the symptoms of gastric outlet obstruction[2,5,8,9]. The prognosis for unresectable pancreatic cancer thus remains extremely poor.

Gemcitabine was recently developed for the treatment of advanced pancreatic cancer, and current studies have reported an improved survival as well as clinical benefit in patients treated with this agent[5,10]. Gemcitabine is a prodrug that requires initial intracellular phosphorylation by deoxycytidine kinase, ultimately undergoing phosphorylation to the active gemcitabine triphosphate, a cytotoxic agent that inhibits DNA synthesis.

Today an extensive pancreatic resection may not influence survival, although some studies have recommended an extensive resection for advanced pancreatic cancer[11,12]. Gemcitabine has been reported to be a strong factor in influencing the survival of patients after resection of pancreatic cancer, and the resection techniques used may not influence a patient's survival when gemcitabine is administered[9]. Although stage IVb pancreatic cancer without distant metastasis can technically be resected, it normally does not lead to a good recovery and a satisfactory QOL for the patient. As a result, gemcitabine may be the most effective clinically proven treatment for patients with stage IVb pancreatic cancer.

It is interesting that this case achieved a lengthy CR of 4 years after a gemcitabine dose of 800 mg/m^2 per month. The prognosis of pancreatic cancer is still poor, despite the findings in this patient who achieved long-term survival following the administration of gemcitabine for progressive pancreatic carcinoma which could not be excised. In addition, such a high success is surprising. Recently, the receptivity of anti-cancer drugs in cancer therapy has been shown to be remarkable, and there may be a specific mechanism which results in the high receptivity of gemcitabine in pancreatic cancer. The publication of further studies on the use of gemcitabine is therefore necessary. In several phase Ⅲ studies[5,13-23], objective responses were observed in 4.4%-17.3% of patients treated with gemcitabine alone. Progression-free survival in patients treated with gemcitabine alone was 2-4 mo and median survival was 5.4-7.3 mo for gemcitabine alone. In these studies, patients received either 1000 mg/m^2 per week of gemcitabine for 3 wk out of every 4 or for 7 wk out of every 8.

Total pancreatectomy results in complete ablation of the exocrine and endocrine pancreatic functions. Despite the administration of insulin and pancreatic enzyme replacement, total pancreatectomy often results in uncontrollable diabetes, as well as persistent diarrhea and steatorrhea, which compromises patients' nutritional status.

In this case, long-term CR and long-term survival were achieved without excision, however, this is a very rare case. The development of gemcitabine has brought about a change in the treatment of pancreatic cancer, but the effect is less than 20%, and the drug has yet to demonstrate satisfactory results. Gemcitabine may be used as second line treatment in patients who have failed first line therapy. Early detection of pancreatic cancer is important fin treatment selection, and gemcitabine has been shown to be effective in some pancreatic cancers, as it was in this case. When it is deemed that an aggressive operation would clearly be disadvantageous to a patient, then the patient may undergo conservative surgery followed by appropriate chemotherapy.

Abstract

Port site hernia develops through a fascial or peritoneal layer that was inadequate or not repaired. It is a rare complication of laparoscopic surgery which may lead to serious problems. Here, we present a 77-year-old female, diagnosed with a small bowel hernia through a 10-mm port site. We had performed ten cases of laparoscopy-assisted distal gastrectomy before this case. The patient complained of left lower abdominal pain with a palpable mass. Abdominal CT showed an incarcerated small bowel hernia and the patient underwent segmental resection of the strangulated small bowel through a minimally extended port site incision.

INTRODUCTION

Recently, laparoscopy-assisted gastrectomy (LAG) for early gastric cancer has been accepted as technically and oncologically safe and feasible. During LAG, 10 mm or larger trocars are used for traction of the intra-abdominal organs, and fascial defects created by those trocars are usually closed because of concern over the potential for small bowel hernia. Port site hernia is a rare complication following laparoscopic surgery: however, occurrence of this may be dangerous and, hence, may have a fatal outcome. Therefore, we report the clinical course of our case and prepare a review for the management of port site hernia.

CASE REPORT

A 77-year-old woman was admitted to our hospital for gastric cancer treatment. She had complained of dyspepsia and epigastric discomfort for 20 d: following gastrofiberoscopy, early gastric cancer (type I + IIa) was found at the prepyloric antrum. She had no past medical history except well-controlled hypertension, and no abnormalities were found during preoperative evaluation. During laparoscopic surgery, a total of 5 trocars were applied to perform surgical procedures, and all the trocars used were the bladed type. A 10 mm trocar was inserted into the abdominal cavity via the umbilicus to prepare the pneumoperitoneum for electro-laparoscopy. After sufficient inflation of the abdominal cavity, 5 mm and 12 mm trocars were placed into the right side, and 5 mm and 10 mm trocars were inserted into the left side. She underwent LAG with D1 + β lymph node dissection and Billorth-II gastrojejunostomy. The fascial defects at the 10 mm and 12 mm port sites were repaired by 2-0 absorbable vicryl sutures. The patient's recovery was progressing favorably, so we put her on a diet on the 2nd day after surgery, and no abnormalities were detected. On the 7th day after the operation, the patient complained of vague abdominal pain and vomiting, but those symptoms were alleviated by conservative support. The next day, however, the patient developed a fever (38℃) and manifested left lower quadrant abdominal pain with a palpable mass. Emergency ultrasonography and abdominal CT were performed, and a structure that looked like an abscess

Figure 1 Port site hernia located at the left flank on computed tomography. Arrow indicates hernia.

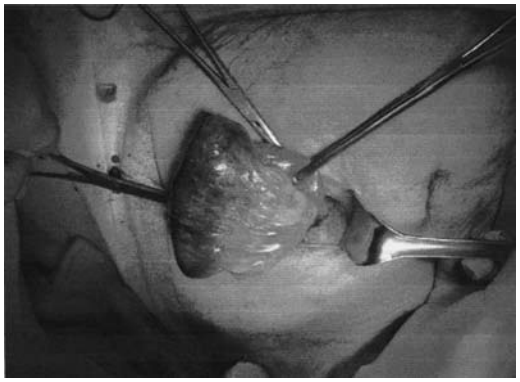

Figure 2 Strangulated small bowel was pulled through the extended port site.

or hernia of the small bowel was detected (Figure 1). We suspected an incarcerated port site or strangulated hernia of the small bowel and performed exploratory surgery. The port site incision that had been made on the left lower quadrant was transversely extended to about 4 cm long. After fascial layer sutures were untied, it was observed that the strangulated small bowel was pushing into a peritoneal defect in the abdominal wall (Figure 2). The length of incarcerated small bowel was about 10 cm long. After that was taken out through an extended incision, we carefully observed its viability and decided to remove a ischemic portion of the small bowel through an extended port site. Then we performed segmental resection of the strangulated small bowel and end-to-end anastomosis. After the operation, there were no specific events, and the patient recovered.

DISCUSSION

Port site hernia is a rare complication following laparoscopic surgery. Tonouchi *et al*[1] reported that the incidence of port site hernia was 0.65%-2.80% and classified port site hernia into three types. The early-onset type occurs immediately after the operation, the late-onset type develops after several months and the special-type presents as dehiscence of the whole abdominal wall. Relative to the size of the port site, Kadar *et al*[2] reported that incidence of port site hernia was 0.23% at a 10 mm port site and 3.1% at a 12 mm port site, and Mayol *et al*[3] reported umbilical port site hernia with an incidence of 1.6%. Port site hernia may occur at any time during the postoperative course, though our case occurred early during the postoperative course[4-6]. It is known that a port site of larger than 10 mm in diameter usually causes hernia while a 5 mm port site rarely causes hernia[5]. Hence, most surgeons routinely repair the fascia of 10 mm or larger port sites to prevent hernia.

In an experimental study of wounds relative to the type of trocar, Kolata *et al*[7] reported that a non-bladed trocar created smaller peritoneal port site wounds than a conventional pyramidal tip trocar and they hypothesized that a non-bladed type of trocar might reduce the chance of trocar wound hernia. Another study showed that a 10 mm or 12 mm port site created by a non-bladed trocar did not require fascial closure if it was placed in a non-midline position above the arcuate line[8]. Since the non-bladed trocar split the muscle rather than cutting it, it allowed the oblique muscle to reanneal together more readily. Moreover, this study suggested that misalignment of the fascial defect (created by the non-bladed trocar) aided inhibition of trocar site hernia. However, recently non-bladed trocars have mostly been used to access the port site; hence, many cases occur under this condition and some reports have suggested that herniation through the peritoneal defect might develop even though the fascial defect has been repaired. In our case, an intestinal hernia via peritoneal defect developed below the repaired fascial layer. Therefore, fascial and, if possible, peritoneal repair of port sites are necessary to prevent port site hernia.

Many methods and devices for closure of port sites have been introduced[9,10], and each of them has its merits and demerits. Generally, it is not difficult to repair port sites that are larger than 10 mm using a small retractor and hemostat unless a patient is severely obese. However, if the port site is less than 5 mm, it will be hard to close and extension of the port site may be necessary for repair. Some devices, such as a Deschamps needle, a suture carrier, and an Endoclose suture device (Tyco Auto Suture International, Inc. Norwalk, CT, USA) , may be helpful in repairing fascial and peritoneal defects[9]. In addition to direct repair of the port site, recently the port plug technique without suturing was introduced. Moreno-Sanz *et al*[10] reported that inserting a Bioabsorbable Hernia Plug (W.L Gore and Associates Inc, Flagstaff, AZ, USA) to the port site was safe and feasible as a way to prevent port site hernia. Before this unexpected event, trocar sites had been imprudently repaired. After that incident, we made every effort to repair the fascial and peritoneal defects of the port site using an extremely concaved needle and a hemostat as far as possible. After skin and subcutaneous tissue were retracted to opposite sites using small retractors, visualized fascia were clamped using a hemostat and the hemostat was then lifted to allow for detection of

the peritoneum. After the peritoneum was clamped by the hemostat, the two layers were closed separately or together. This technique was similar to the dual-hemostat technique introduced by Spalding *et al*[11] and was feasible and simple to perform unless a patient was severely obese.

Clinical courses of port site hernia are varied and depend on the degree of intestinal entry to the defect. Most patients present with vague abdominal pain, nausea, vomiting, a palpable or painful mass around port site, and fever if the bowel is incarcerated. If a patient complains of mild symptoms including nausea, vomiting and vague abdominal pain, early diagnosis may be delayed. Plain radiographs may be useful in some cases; however, plain radiographs only reveal the existence or nonexistence of the bowel obstruction. Therefore, they are limited in diagnosing port site hernia. In the case of Boughey *et al*[12], a definite diagnosis was achieved by explorative laparoscopic examination. Abdominal CT may be an effective diagnostic method if a patient complains of the symptoms described above without a palpable mass as it can differentiate adhesion from port site hernia and indicate the location of the port site hernia. Therefore, if atypical symptoms persist with obscure plain radiographs, abdominal CT is helpful in early diagnosis. Exploratory surgery with reduction of the incarcerated bowel is used to treat a port site hernia. According to previous reports, there are a few ways to access the abdominal cavity. One is a laparoscopic approach and another is an open approach through extension of the port site involved or other incision sites. Unless the incarcerated bowel is frankly ischemic, the laparoscopic approach is an acceptable method. In our case, we extended the port site and corrected the disorder because strangulation of the bowel was apparent.

In conclusion, it is necessary to repair the fascial and peritoneal layers to prevent port site hernia. Although port site hernia is rare, surgeons should keep this possibility in mind. Prompt intervention may reduce unfavorable events if port site hernia is suspected.

Abstract

Gastrointestinal stromal tumor is the most common mesenchymal tumor in the gastrointestinal tract. It may coexist with other type of cancers, and if so, the tumors usually involve the stomach. The most common associated cancers are gastrointestinal carcinomas. We report a 65-year-old woman with a history of gastric gastrointestinal stromal tumor who had undergone subtotal segmental gastrectomy. New polypoid lesions were detected on a follow-up gastroscopy one year later. The lesions were biopsied and found to be carcinoid tumors. There was serum hypergastrinemia, and type 1 gastric carcinoid tumor was diagnosed. A total gastrectomy was performed. Pathologic examination revealed both carcinoid tumors and a recurrent gastrointestinal stromal tumor.

INTRODUCTION

Gastrointestinal stromal tumors (GIST) are the most frequent mesenchymal tumors in the gastrointestinal tract. They may coexist with other types of cancers with a reported frequency from 4.5% to 33%[1,2]. The most common location of a GIST associated with other cancers is the stomach[1], and the most frequently associated tumor type is gastrointestinal adenocarcinoma[1,2]. Infrequently, other primary cancers have been reported along with GIST, including lymphoma, leukemia, breast cancer, prostate cancer, pancreatic adenocarcinoma, or lung cancer[1-4]. GIST has been reported to occur simultaneously with ileal carcinoid tumor[5]. We report a patient with both GIST and carcinoid tumor in the stomach, an association that has not been previously reported.

CASE REPORT

A 65-year-old woman had undergone subtotal segmental gastrectomy for a 5.5 cm GIST in the lower gastric corpus. The diagnosis was based on immunohistochemical staining that was diffusely positive for CD-117 and focally positive for CD-34 and smooth muscle actin; it was negative for desmin. The patient received periodic follow-up gastroscopy. One year after surgery, she was found to have two distinct sessile polypoid lesions in the cardia and lower body of the stomach (Figure 1). The lesion in the cardia, about 2 cm distal to the gastroesophageal junction was a 1.2 cm polyp with a central ulceration. The other lesion was a 0.6 cm mass on the anterior wall near the earlier anastomosis. Immunohistochemical staining of a biopsy specimen of the larger polyp was strongly positive for

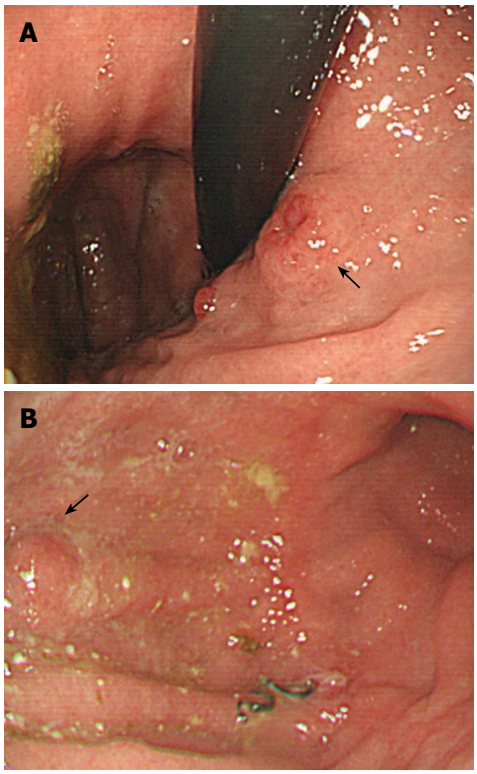

Figure 1 Gastroscopic findings. A: 1.2 cm ulcerated polyp in the cardia (arrow); B: 0.6 cm polyp on the anterior wall of the corpus near the previous anastomosis (arrow).

chromogranin-A, weakly positive for synaptophysin, and negative for CD56, neuron-specific enolase, and cytokeratin 7. Gastric carcinoid was therefore diagnosed. There was inflammation, but no *Helicobacter pylori* (*H pylori*) was found. The normal gastric body glands were atrophic and replaced by pyloric and intestinal glands. Abdominal ultrasonography, computerized tomography, barium small bowel series, and colonoscopy were performed to exclude other possible gastrointestinal tumors; there were no other abnormalities found. The patient denied any symptoms of diarrhea, palpitation, facial flushing, or weight loss, and there was no family history suggestive of similar disorders or multiple endocrine syndromes. Her abdominal examination was normal except for the previous surgical scar. The fasting serum gastrin level was 1920 pg/mL (normal 25-125 pg/mL). The 24-h urinary 5-HIAA level was normal. These findings were consistent with a type 1 hypergastrinemic gastric carcinoid tumor. Total gastrectomy was performed because the patient was concerned about further recurrences of gastric tumors. The pathologist reported two carcinoid tumors in the cardia and lower corpus near the previous anastomosis. There was no immunohistochemical evidence of GIST in the two carcinoid tumors (Figure 2). One dissected lymph node had metastatic carcinoid tumor. A 0.6 cm focal GIST was also found on the lesser curvature; and there was no carcinoid component on immunohistochemical staining (Figure 3). The pathologic slides from the first surgery were reviewed and immunohistochemical staining

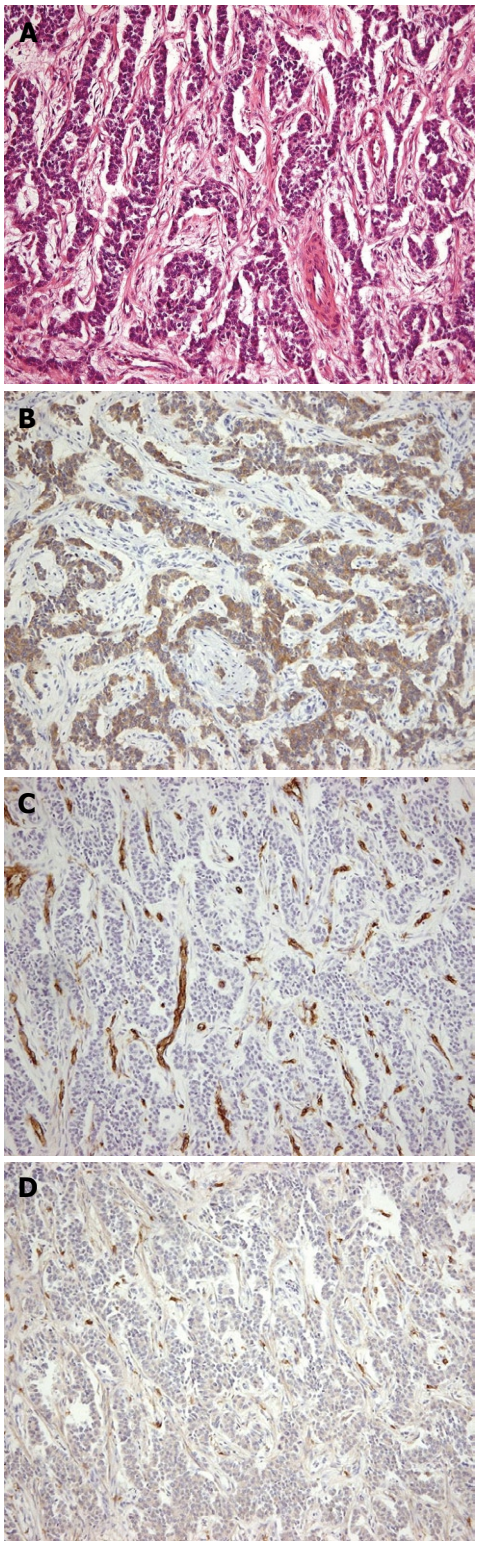

Figure 2 Carcinoid tumor. A: Uniform round-to-oval cells in trabeculae, nests, and gland-like structures (hematoxylin and eosin, × 100); B: Positive immunohistochemical staining for synaptophysin (× 100); C: Negative immunohistochemical staining for CD 34 (× 100); D: Negative immunohistochemical staining for CD 117 (× 100).

repeated, which showed no evidence of carcinoid tumor. Three weeks after the total gastrectomy, the patient's fasting gastrin level had returned to normal (72.40 pg/mL). She recovered uneventfully and has remained well for six months after surgery.

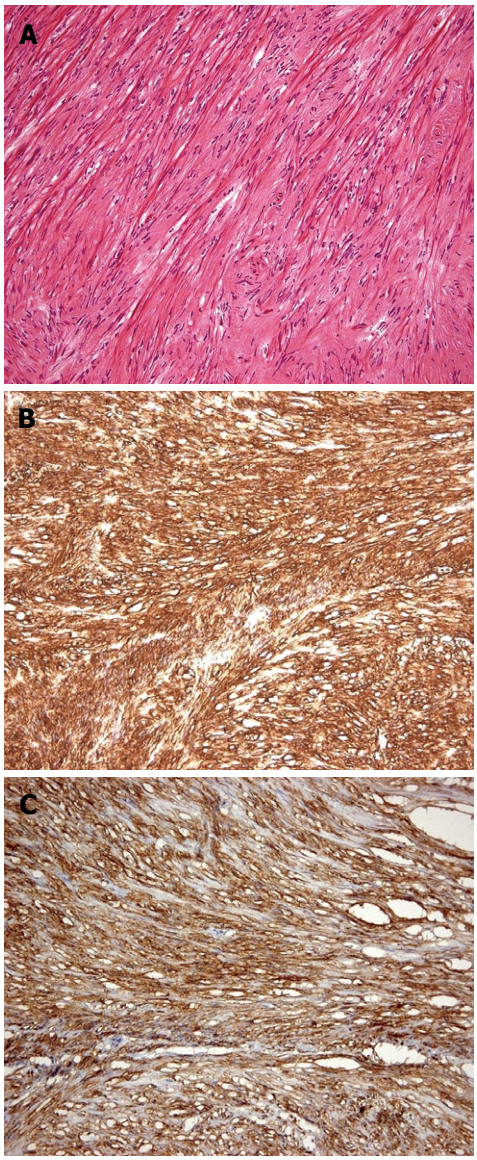

Figure 3 Recurrent gastrointestinal stromal tumor. A: Composed of spindle cells (hematoxylin and eosin × 100); B: Positive immunohistochemical staining for CD34 (× 100); C: Positive immunohistochemical staining for CD 117 (× 100).

DISCUSSION

This patient had metachronous gastric GIST and gastric carcinoid tumors, a previously unreported phenomenon. The tumors were confirmed by pathologic examination, including immunohistochemical studies, to be totally distinct neoplasms.

Gastrointestinal carcinoids comprised 73% of all carcinoid tumors in a large series, the most common sites being in the small bowel, appendix and rectum[6]. Gastric carcinoids are less common, reported as being only 8.7% of enteric carcinoids. Among all gastric cancers, carcinoids are quite rare, with a reported incidence of only 0.35%-1.77%[7]. Gastric carcinoid tumors may present with anemia caused by bleeding from an ulcerative mass, abdominal pain, or with a classical carcinoid syndrome. Histologically, the tumors have uniformly round cells growing in rosettes, cords, or trabecular patterns. Immunohistochemical stains are usually positive for chromogranin A or C and synaptophysin but negative for CD117. The latter marker distinguishes carcinoid from GIST, which is positive for CD117.

Gastric carcinoid tumors can be classified into four types: type 1, with enterochromaffin-like cells, chronic atrophic gastritis, achlorhydria, hypergastrinemia, and often pernicious anemia; type 2, with enterochromaffin-like cells, Zollinger-Ellison syndrome, multiple endocrine neoplasia type 1, and hypergastrinemia; type 3, with enterochromaffin-like cells but which is gastrin-independent and occurs sporadically; and type 4, with miscellaneous non-enterochromaffin-like endocrine cells[8-10]. The prognosis of types 1 and 2 gastric is better than that of types 3 or 4 gastric carcinoid tumors. The 5-year and 10-year survival rates were 96.1% and 73.9% for type 1 disease, compared with only 33.3% and 22.2% for type 4 gastric carcinoid tumors[9]. For type 1 gastric carcinoids, limited surgery, such as endoscopic mucosal resection[11] or partial gastrectomy is adequate, along with appropriate treatment for the hypergastrinemia[9,10,12]. Radical resection is recommended for types 3 and 4[9,10]. Our patient had type 1 gastric carcinoid with hypergastrinemia but no associated symptoms, such as Zollinger-Ellison syndrome or multiple endocrine neoplasia type 1. If she had had only the type 1 gastric carcinoid, more conservative surgery might have been considered. The history of the previous GIST, however, influenced the choice of total gastrectomy.

In a retrospective review of 200 patients with gastrointestinal GIST (with 78% or 39% in the stomach), DeMatteo *et al*[13] reported an overall 5-year survival rate of about 35%, but it depended on the extent of resection. For patients undergoing complete resection, the 5-year survival was 54%, with those patients surviving a median of 66 mo compared with 22 mo for those who had incomplete resection. The recurrence rate was 40% (median 24 mo' follow-up). The median disease-specific survival for pateints with local recurrence was 12 mo. Metastases usually occurred with tumors larger than 5 cm or with a mitotic index of more than 10 mitoses per 50 high power fields. The authors recommended complete surgical resection for GIST if possible.

In estimating our patient's prognosis, it is difficult to know if it should be predicted based on the locally recurrent GIST or the carcinoid metastatic to a lymph node. Carcinoid metastases to regional lymph nodes cannot be reliably predicted by tumor size or depth of invasion, their impact on survival is uncertain[14], and there is no recommended adjuvant treatment. However, type 1 carcinoid is fairly indolent and is less likely than the GIST to limit our patient's survival. We intend to monitor the patient at 6-12 mo intervals with computed tomography for GIST and using plasma chromogranin measurements and octreoscan for carcinoid. Adjuvant therapy with imatinib is an option for treating residual GIST, with evaluation of *c-Kit* and *PDGFRA* mutations a useful tool to predict efficacy[15,16]. There was also a clinical trial conducted by Yao *et al*[17], testing the imatinib in 27 carcinoid patients with a modest clinical

response of median overall survival of 36 mo. However, our patient's recurrent GIST was totally removed by gastrectomy, and the mitotic index was low. There would be no way of assessing treatment response and therefore no clear benefit, so imatinib is not indicated in this patient unless the GIST is found to recur on follow-up.

In conclusion, our patient had an apparently unique combination of two unusual gastric tumors. Accurate diagnosis of her GIST and carcinoid tumors, based on immunohistochemical studies, was important both for deciding on treatment and follow-up and in estimating prognosis. However, as this case clearly illustrates, a number of individual patient variables affect those decisions and estimates. Inevitably we must rely on clinical judgment which, while informed by what the evidence says about the diseases in general, must also take into account a patient's particular characteristics, needs, and preferences.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

WJG publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidermiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialities, and thus eventually improving the clinical practice and healthcare for patients.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No.62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Hereditary hemochromatosis (HH) is caused by chronic hyperabsorption of dietary iron. Progressive accumulation of excess iron within tissue parenchymal cells may lead to severe organ damage. The most prevalent type of HH is linked to mutations in the *HFE* gene, encoding an atypical major histocompatibility complex class I molecule. Shortly after its discovery in 1996, the hemochromatosis protein HFE was shown to physically interact with transferrin receptor 1 (TfR1) and impair the uptake of transferrin-bound iron in cells. However, these findings provided no clue why *HFE* mutations associate with systemic iron overload. It was later established that all forms of HH result from misregulation of hepcidin expression. This liver-derived circulating peptide hormone controls iron efflux from duodenal enterocytes and reticuloendothelial macrophages by promoting the degradation of the iron exporter ferroportin. Recent studies with animal models of HH uncover a crucial role of HFE as a hepatocyte iron sensor and upstream regulator of hepcidin. Thus, hepatocyte HFE is indispensable for signaling to hepcidin, presumably as a constituent of a larger iron-sensing complex. A working model postulates that the signaling activity of HFE is silenced when the protein is bound to TfR1. An increase in the iron saturation of plasma transferrin leads to displacement of TfR1 from HFE and assembly of the putative iron-sensing complex. In this way, iron uptake by the hepatocyte is translated into upregulation of hepcidin, reinforcing the concept that the liver is the major regulatory site for systemic iron homeostasis, and not merely an iron storage depot.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF IRON HOMEOSTASIS

Iron is essential for various physiological and metabolic pathways. However, unshielded iron is toxic, as a catalyst of free radical generation[1,2]. The adult human body contains a pool of 3-5 g of iron (about 55 mg and 44 mg per kilogram body weight in males and females, respectively), the majority of which (> 70%) is utilized by erythroid cells for heme synthesis and integration into hemoglobin[3]. A daily requirement of about 20-30 mg iron for erythropoiesis is mainly covered by recycling of the metal from senescent erythrocytes *via* reticuloendothelial macrophages. These cells metabolize heme and release iron into the circulation, where it is scavenged by plasma transferrin and delivered to tissues. A considerable amount of iron (about 1 g) is stored in the liver. Dietary iron absorption by duodenal enterocytes compensates for losses through bleeding or desquamation; a physiological rate of 1-2 mg/d suffices to maintain the body iron pool. This is subjected to feedback regulation and may adjust to fluctuations in iron demands.

In hereditary hemochromatosis (HH), disruption of this homeostatic loop leads to unrestricted dietary iron absorption at a rate that may reach 8-10 mg/d[4,5]. This

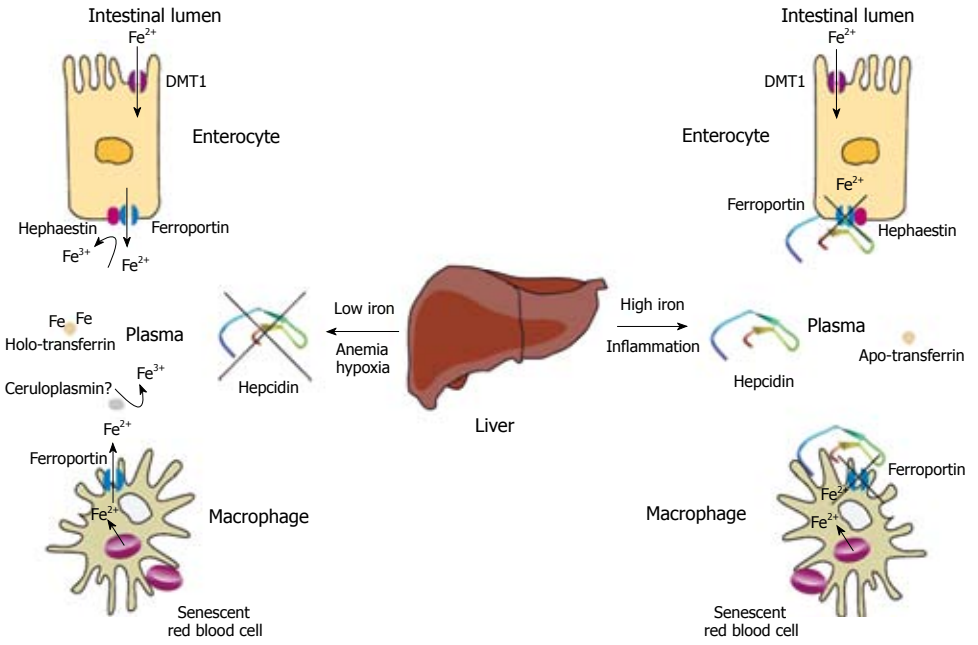

Figure 1 Regulation of iron efflux from enterocytes and macrophages by hepcidin. Duodenal enterocytes absorb dietary iron *via* DMT1 and reticuloendothelial macrophages phagocytose iron-loaded senescent red blood cells. Both cell types release ferrous iron (Fe^{2+}) into plasma via ferroportin, which is incorporated into transferrin following oxidation into the ferric form (Fe^{3+}) *via* hephaestin or ceruloplasmin. The secretion of the iron-regulatory hormone hepcidin from the liver in response to high body iron stores or inflammatory signals results in internalization and degradation of ferroportin, and retention of iron within enterocytes and macrophages. A decrease in body iron stores, a requirement of iron for erythropoiesis, or hypoxia, inhibit hepcidin expression, permitting dietary iron absorption by enterocytes and iron release from macrophages.

is accompanied by a gradual increase in the saturation of transferrin with iron (from physiological 30% up to 100%), a buildup of non-transferrin-bound iron and excessive accumulation of the metal in parenchymal cells of the liver, pancreas, pituitary, heart, joints and skin. Notably, macrophages and absorptive duodenal enterocytes are spared from iron loading and exhibit increased rates of iron release. Excessive iron deposition in the liver constitutes a risk factor for fibrosis, cirrhosis and hepatocellular cancer[6-8], and may exacerbate other types of liver disease[9,10]. Iron overload may also lead to cardiomyopathy, diabetes mellitus, hypogonadism, arthritis and skin pigmentation[3]. HH is efficiently treated by phlebotomy.

HORMONAL REGULATION OF IRON TRAFFIC BY HEPCIDIN

The discoveries of the divalent metal transporter (DMT1), the iron exporter ferroportin, and the iron regulatory hormone hepcidin provided a framework to understand the molecular mechanisms for systemic iron traffic and homeostasis[11,12]. DMT1 accounts for the absorption of ferrous ions across the apical membrane of duodenal enterocytes, but also for intracellular transport of transferrin-derived iron across the endosomal membrane in many cell types. Ferroportin mediates efflux of ferrous iron from enterocytes and macrophages to plasma transferrin. The transport of iron by DMT1 requires its reduction by ferric reductases (such as Dcytb or the Steap proteins), while its export by ferroportin is coupled by re-oxidation *via* ferroxidases (such as ceruloplasmin or hephaestin).

The ferroportin-mediated efflux of iron from enterocytes and macrophages defines a key regulatory checkpoint for iron homeostasis. This process is negatively controlled by hepcidin, a cysteine-rich peptide hormone that binds to ferroportin and promotes its internalization and lysosomal degradation[13]. Hepcidin is synthesized in hepatocytes as a pro-peptide, which undergoes proteolytic processing to form a bioactive molecule of 25 amino acids[14]. The mature peptide is secreted into plasma and orchestrates homeostatic responses to iron, erythropoiesis, hypoxia and inflammation. An increase in hepcidin levels, commonly encountered following dietary iron intake or in inflammation[15,16], impairs iron absorption by duodenal enterocytes and promotes retention of the metal within macrophages (Figure 1), limiting its availability for erythropoiesis. Excessive hepcidin expression, in response to prolonged inflammation, contributes to the anemia of chronic disease[17]. On the other hand, low hepcidin levels triggered by iron deficiency, hypoxia or phlebotomy[18] facilitate duodenal iron absorption and iron release from macrophages (Figure 1). Importantly, HH patients fail to mount an appropriate upregulation of hepcidin expression, despite high transferrin saturation and elevated body iron stores[19,20]. Thus, HH is largely based on the loss of feedback control in dietary iron absorption due to defects in the hepcidin pathway.

Juvenile hemochromatosis, a rare but severe form of hereditary iron overload results from genetic inactivation of the hepcidin gene[21] or mutations in hemojuvelin (HJV) associated with profound hepcidin deficiency[22]. The most prevalent form of HH is linked to mutations in HFE[23], while another less common but phenotypically indistinguishable HH subtype is caused by mutations in transferrin receptor 2 (TfR2)[24]. Iron overload patients with either HFE or TfR2 mutations exhibit inappropriately decreased hepcidin levels or blunted hepcidin responses[19,20,25,26]. Similar results were obtained with mouse models of iron overload, bearing targeted disruptions of the *HFE*[27-30], *HJV*[31,32] or *TfR2*[33] genes. These findings suggest that HFE, HJV and TfR2 are upstream regulators of hepcidin expression.

REGULATION OF HEPCIDIN EXPRESSION

Hepcidin is transcriptionally activated by distinct iron-

and cytokine-dependent pathways. The latter is mediated by IL-6 (and IL-1) *via* STAT3[34-36]. The iron-dependent pathway is less well characterized and involves proximal and distal promoter elements[37,38]. The lack of hepcidin expression, accompanied by iron overload, in mice carrying a hepatocyte-specific disruption of SMAD4[39] has linked iron-sensing with bone morphogenetic protein (BMP) signaling. In fact, BMP-2, -4 and -9 are potent inducers of hepcidin transcription, while hemojuvelin stimulates this pathway as a BMP co-receptor[40-42]. The CCAAT/enhancer-binding protein α (C/EBPα) appears necessary for basal hepcidin transcription[43].

Hepcidin expression is suppressed in anemia by a mechanism that requires erythropoietic activity[44,45]. At least in thalassemia patients, the silencing of hepcidin is mediated by overexpression of growth differentiation factor 15 (GDF15), a member of the transforming growth factor β (TGFβ) superfamily[46]. Erythropoietin (EPO) directly reduces the binding of C/EBPα to the hepcidin promoter *via* EPO receptor signaling[47]. Hepcidin is also negatively regulated by hypoxia[18]. Experiments in mice with hepatic disruption of HIF-1α provided evidence for the involvement of this transcription factor in the underlying pathway[48]. However, other reports suggested that the hypoxic downregulation of hepcidin is HIF-independent[49,50] and involves oxidative stress-mediated repression of C/EBPα and STAT3[49], or inhibition of 2-oxoglutarate dependent oxygenases[50]. Recent work revealed that the transmembrane serine protease TMPRSS6 negatively regulates signaling to hepcidin[51-55], by a yet unknown mechanism.

What is the role of HFE in hepcidin regulation?

DISCOVERY OF HFE AS THE HEMOCHROMATOSIS GENE

The *HFE* gene was elucidated by linkage disequilibrium and haplotype analysis from a large group of HH patients[23], culminating lengthy efforts to map the hemochromatosis locus. It encodes an atypical major histocompatibility complex (MHC) class I protein, which is processed *via* the Golgi network to the cell surface, following interaction with β2-microglobulin. Structural analysis revealed that in contrast to typical MHC class I homologues, HFE formed a smaller groove between the α1 and α2 subunits, which was predicted to preclude peptide antigen presentation[56]. The majority of HH patients carry an *HFE* C282Y substitution. This abrogates a disulphide bridge and prevents the association of HFE with β2-microglobulin, a necessary step for its processing and transport to the plasma membrane[57,58]. Unprocessed *HFE* C282Y undergoes proteasomal degradation following retention in the endoplasmic reticulum (ER), which promotes ER stress[59]. An *HFE* H63D mutation may also lead to HH, especially in the compound heterozygous state with C282Y. Homozygosity for the *HFE C282Y* genotype is highly prevalent (1:200) in populations of Northern European ancestry; however, the clinical penetrance is lower and remains a matter of debate[4-6,60,61]. It appears that HH is a multifactorial disease and the development of iron overload in individuals bearing disease-associated *HFE* mutations requires the contribution of additional, yet incompletely understood environmental, genetic and/or epigenetic factors[62]. Nevertheless, mice with either targeted disruption of the *HFE*[63,64] or β2-microglobulin[65,66] genes, or expressing orthologues of the *HFE* C282Y[67] or H63D[68] mutants, develop progressive iron overload, the degree of which depends on the genetic background of the animals[69-71]. Collectively, these findings underlie the significance of HFE in the control of body iron homeostasis.

EARLY MODELS FOR THE FUNCTION OF HFE

Biochemical[72,73] and crystallographic[74] studies revealed that HFE interacts with TfR1 (Kd about 60 nmol/L) and competes for the binding of transferrin to its receptor, which has a Kd of about 1 nmol/L[75]. However, considering that the physiological concentration of plasma diferric holotransferrin is about 5 μmol/L[76], HFE is unlikely to affect the rate of TfR1 endocytosis *in vivo*. In transfected cell lines, overexpressed HFE reduced the efficiency of the transferrin cycle[77] and promoted an iron-deficient phenotype[78-81], without or with co-expression of β2-microglobulin[82]. Notably, a similar phenotype was observed with an *HFE* W81A mutant that is unable to bind to TfR1, suggesting that the HFE-mediated decrease of intracellular iron levels is independent of the HFE/TfR1 interaction[83].

The above data did not shed much light on how HFE controls systemic iron homeostasis and rather created some confusion. The immunohistochemical detection of HFE in precursor enterocytes of the intestinal crypts[84] and its association with TfR1 in these cells[85] laid the foundation for the "crypt-programming model"[86]. This postulates that iron absorption is regulated by signals that are sensed by precursor enterocytes, which undergo maturation and migrate along the crypt-villus axis. An iron deficient status in the crypt cells would program mature enterocytes to absorb more dietary iron from the lumen. According to the crypt-programming model, HFE would serve to promote iron retention within crypt cells, possibly by increasing the uptake of plasma transferrin[87] and/or inhibiting iron efflux[88]. The model is supported by the iron deficient status manifested in duodenal biopsies from HH patients[89,90]. Experimental evidence has been provided that HFE may also facilitate iron accumulation[91] or retention[92] within macrophages, which are likewise iron-deficient in HH patients[93]. In the pre-hepcidin era, these findings have highlighted the enterocytes and macrophages as possible primary sites of the HFE regulatory function. Nonetheless, HFE is expressed in multiple cell types, including hepatocytes[94], the major producers of hepcidin.

LESSONS FROM ANIMAL MODELS I: THE SITE OF HFE REGULATORY FUNCTION

Definite clues as to the site of HFE regulatory function

in the context of systemic iron homeostasis were recently provided by experiments with genetically engineered mice, bearing a targeted, tissue-specific disruption of the *HFE* gene. The technology is based on the generation of animals carrying a "floxed" *HFE* allele, surrounded by loxP sites, which are specific targets of the Cre recombinase. Crossing of "floxed" *HFE* mice with a transgenic line expressing the Cre recombinase under the control of the villin promoter resulted in intestinal-specific disruption of HFE in the progeny[95]. Importantly, mice lacking HFE expression in the intestine did not show any signs of abnormal iron metabolism, at least with regard to liver iron content, serum iron parameters and serum ferritin levels. Moreover, they exhibited physiological expression of the mRNAs encoding liver hepcidin and the intestinal iron transporters DMT1 and ferroportin[95]. By showing that intestinal HFE expression is dispensable for the regulation of body iron homeostasis, these data challenge the validity of the "crypt-programming model" and raise the possibility for a critical role of HFE in the liver.

In a follow-up study, "floxed" *HFE* mice were crossed with transgenic animals expressing the Cre recombinase under the control of either the hepatocyte-specific albumin promoter, or the macrophage-specific lysozyme M promoter[96]. While HFE ablation in macrophages did not affect body iron metabolism, the disruption of HFE in hepatocytes recapitulated the hemochromatosis phenotype of null *HFE*-/-mice. Thus, mice lacking HFE expression in hepatocytes exhibited hyperabsorption of dietary iron, increased serum iron, transferrin saturation and iron deposition in the liver[96]. Taken together, the tissue-specific knock-out experiments demonstrate that hepatocyte HFE is necessary to promote appropriate hepcidin responses and thereby prevent iron overload.

These data also corroborate clinical findings, showing that the iron status of recipients of a liver transplant was largely dependent on the *HFE* genotype of the donors[97,98]. Nevertheless, a contribution of macrophage HFE to hepcidin regulation cannot be completely ruled out. While macrophages are dispensable for hepcidin expression in response to iron or inflammatory signals[99,100], bone marrow transplantation from wild type mice into irradiated *HFE*-/-counterparts corrected iron parameters and significantly increased hepcidin levels in the recipients[101]. Conceivably, this could be the result of intercellular communication and signaling to hepatocytes and/or HFE-mediated autocrine production of hepcidin in macrophages[102].

LESSONS FROM ANIMAL MODELS II: THE ROLE OF TFR1 IN THE CONTROL OF HFE ACTIVITY

How does HFE modulate signaling to hepcidin? Biochemical work showed that HFE not only interacts with TfR1, but also with TfR2[103]. Moreover, the HFE/TfR2 interaction leads to an increase in TfR2 levels[104]. TfR2 is primarily expressed in hepatocytes[105] and stabilized by diferric holo-transferrin[106,107]. While TfR1 mediates cellular iron uptake from circulating transferrin, TfR2 is thought to function as an upstream regulator of hepcidin, and possibly an iron sensor[14]. A testable prediction arising from the capacity of HFE to interact with both TfR1 and TfR2 would be that the choice of its binding partner is regulated by transferrin and, furthermore, this event is crucial for signaling to hepcidin.

This hypothesis was explored in a recent study, based on the idea to induce or abolish HFE/TfR1 interactions *in vivo*[108]. To this end, transgenic mice were engineered for expression of TfR1 mutants that prevent the binding of either transferrin (R654A) or HFE (L622A). In light of the early embryonic lethality of *TfR1*-/-mice[109], indicating an utmost importance for the interaction of TfR1 with transferrin, a TfR1 R654A cDNA was integrated by homologous recombination into the heterologous ROSA26 locus, maintaining endogenous wild type *TfR1* expression (thus, the transgenic product did not disrupt the transferrin cycle, excluding abnormalities of erythropoiesis). In contrast, the L622A mutation was introduced by homologous recombination within the TfR1 locus ("knock-in").

TfR1 R654A, that is unable to bind to transferrin, would be expected to constitutively associate with HFE. Transgenic mice expressing *TfR1* R654A developed iron overload, associated with decreased hepcidin mRNA levels, closely resembling the *HFE*-/-phenotype. On the other hand, TfR1 L622A, that is unable to bind to HFE, would be expected to be highly efficient in the uptake of transferrin-bound iron. Interestingly, transgenic mice expressing TfR1 L622A developed a mild hypochromic microcytic anemia, and exhibited decreased serum iron and elevated hepcidin mRNA levels. These results suggest that HFE stimulates hepcidin expression when it is free of TfR1. In support of this notion, the hepatocyte-specific transgenic overexpression of an HFE cDNA in *HFE*-/-mice substantially induced hepcidin mRNA expression to the extent that it not only corrected hepatic iron overload, but also promoted hypochromic microcytic anemia.

A MODEL FOR THE IRON REGULATORY FUNCTION OF HFE

A model accommodating the above findings postulates that under low serum iron conditions, hepatocyte HFE is predominantly bound to TfR1 (Figure 2A). An increase in transferrin saturation triggers the release of HFE from TfR1 and concomitantly stabilizes TfR2[106,107]. In that way, TfR1 becomes accessible for the binding and endocytosis of holo-transferrin, resulting in cellular iron uptake. At the same time, HFE associates with stabilized TfR2 and possibly other proteins, such as hemojuvelin and BMPs and their receptor (BMPR), to form a putative iron signaling complex that induces hepcidin transcription *via* Smad proteins (Figure 2B). Thus, an increase in the iron content of the hepatocyte is

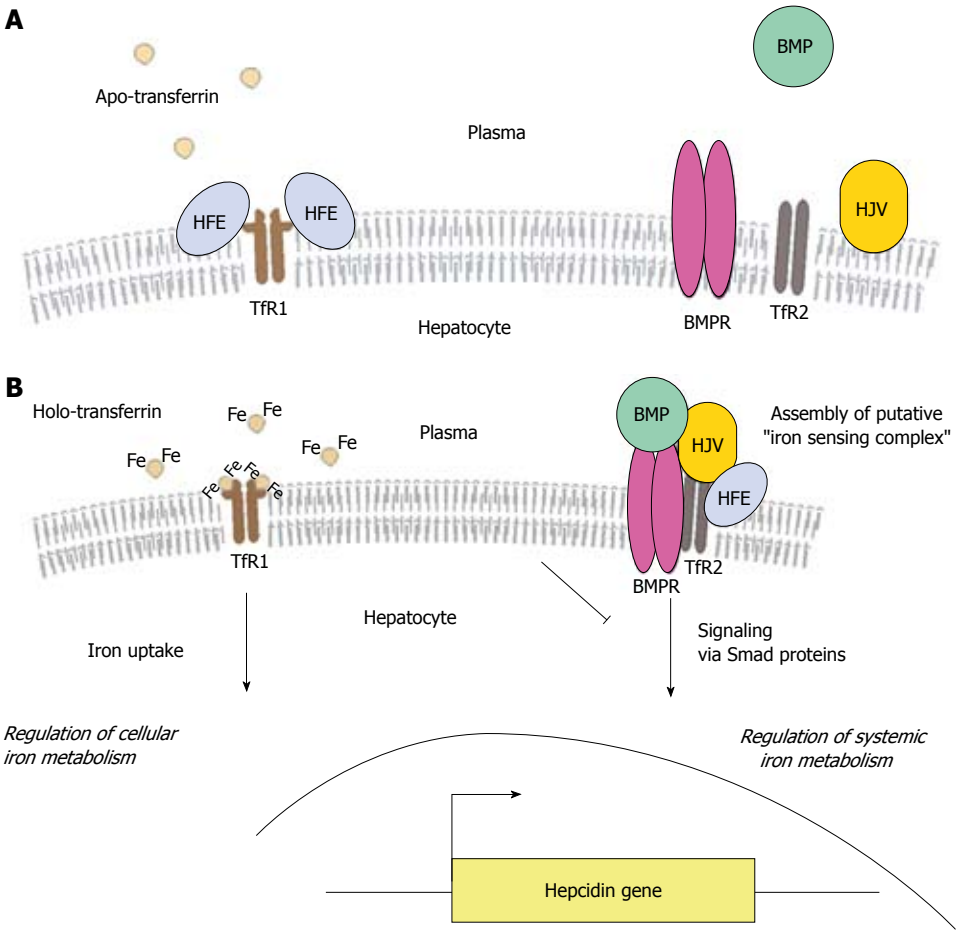

Figure 2 A model for HFE-mediated signaling to hepcidin in hepatocytes. A: At low plasma iron concentration, HFE is bound to TfR1 and other proteins involved in signaling to hepcidin remain silent; B: An increase in plasma iron levels results in displacement of HFE from TfR1, followed by iron uptake. This triggers the assembly of a putative "iron-sensing" complex, comprising of HFE, TfR2, BMPs (such as BMP-2, BMP-4 and BMP-9) and their receptor BMPR, and Hjv, which mediates signaling to activate hepcidin transcription via Smad proteins. Thus, the hepatocyte integrates signals for regulation of iron metabolism at the cellular and systemic level.

indirectly translated into a systemic regulatory response *via* hepcidin. Iron-dependent degradation of TfR1 mRNA by iron regulatory proteins[110] would terminate this process in a feedback loop. According to this model, HFE serves to sense alterations in transferrin saturation.

Considering that a number of HH patients with HFE C282Y mutations[25] and some *HFE*-/-mice[29] express normal (or close to normal) basal hepcidin mRNA levels but exhibit blunted hepcidin responses to dietary iron, it is conceivable that the role of HFE is somehow restricted to the fine-tuning of iron-dependent signaling to hepcidin. Along these lines, BMP-2, -4 and -9 can induce hepcidin mRNA transcription in *HFE*-/-and *TfR2*-/-hepatocytes[41]. Several reports have also shown that HFE is dispensable for signaling to hepcidin *via* the inflammatory pathway[29,41,111,112], even though opposing views exist[113].

Recent animal studies[95,96,108] have not entirely solved the mystery of HFE function, but have significantly advanced our understanding on how this protein regulates systemic iron homeostasis. First, they uncovered HFE as a hepatocyte iron sensor, necessary to prevent iron overload and sufficient to control hepcidin expression (at least at the mRNA level). And second, they demonstrated that HFE-dependent signaling to hepcidin is regulated by the interaction of HFE with TfR1.

OUTLOOK AND PERSPECTIVES

Several outstanding issues remain to be addressed. For example, the proposed function of HFE as a sensor of transferrin saturation requires experimental validation. The functional significance of the interaction between HFE and TfR2, as well as the role and composition of the putative iron-sensing complex await further investigation. It will be interesting to explore a potential functional redundancy between HFE and classical MHC class I molecules with regard to iron regulation, considering that mice lacking such molecules develop iron overload[114]. Conversely, the proposed capacity of HFE to engage into immune responses, following recognition by cytotoxic T lymphocytes[115], deserves additional attention, especially in light of immunological abnormalities of HH patients[116]. A possible connection between the unfolded protein response, caused by defective processing of HFE C282Y, and the hepcidin pathway would not be totally unexpected[117]. Finally, it will be important to examine whether HFE may also affect the maturation of hepcidin; this would necessitate analytical methods for direct measurement of the peptide in plasma[118,119] and in cell culture.

Abstract

The optimal approach to the management of several marginal cases with chronic hepatitis B virus (HBV) infection is controversial. Serum HBV DNA and aminotransferase levels, and the degree of necroinflammation and fibrosis determine the therapeutic decisions. All patients with elevated aminotransferase (> twice the upper limit of normal) and serum HBV DNA above 20 000 IU/mL should be treated. Liver biopsy is important for therapeutic decisions in cases with mild aminotransferase elevations and serum HBV DNA below 20 000 IU/mL. Chronic HBV patients who do not receive treatment should be followed for life. There are seven agents licensed for chronic hepatitis B: standard and pegylated interferon-alpha, lamivudine, adefovir, entecavir, telbivudine and tenofovir. One-year courses with pegylated interferon-alpha induce sustained off-therapy remission in 30%-32% of patients with HBeAg-positive chronic hepatitis B and in a smaller proportion of patients with HBeAg-negative chronic hepatitis B. Oral antivirals achieve initial on-therapy responses in the majority of patients, but are intended as long-term therapies. Viral suppression has favourable effects on patients' outcome and modifies the natural course of the disease. Viral resistance, however, is the major drawback of long-term oral antiviral therapy. Lamivudine monotherapy is associated with the highest and entecavir monotherapy with the lowest resistance rate so far. There has been no resistance to tenofovir, but after only 18 mo of treatment to date. The optimal first-line anti-HBV therapy with the best long-term cost/benefit ratio remains unclear. If oral antiviral agents are used, compliance should always be ascertained and HBV DNA levels should be regularly tested.

INTRODUCTION

Despite the universal vaccination of neonates and infants during the last years and the subsequent reduction in the incidence of new infections with hepatitis B virus (HBV), chronic HBV infection remains a significant public health problem worldwide[1,2]. It is estimated that there are approximately 400 000 000 people with chronic HBV infection and that more than 500 000 people die every year due to complications of HBV related chronic liver disease[2]. Although considerable improvements in the evaluation and treatment of patients with chronic HBV infection have occurred during the last decade, several issues regarding the optimal management of such patients still remain controversial. This short review focuses on two such controversies: the most appropriate treatment indications and the optimal therapeutic strategy for patients with chronic hepatitis B (CHB).

TREATMENT INDICATIONS

Every patient with chronic HBV infection is potentially infectious and at risk for liver complications and is ide-

ally a candidate for therapy, if the virus can be eradicated[3,4]. However, current medications rarely achieve viral eradication in patients with chronic HBV infection and therefore only patients who are at risk for progression to advanced liver disease should be considered for treatment[3,5,6]. Thus, the knowledge of the natural history and the significance of the elements used in the evaluation of disease are necessary for decisions on treatment indications. Moreover, the efficacy and safety of current therapies may also affect the treatment indications, as there is no reason to recommend an ineffective therapy to any patient, even if they have progressive liver disease.

In general, the natural history of chronic HBV infection includes four phases of variable duration distinguished by the presence of hepatitis B e antigen (HBeAg) or its antibody (anti-HBe) in the serum and the serum HBV DNA and aminotransferases levels[7-9]. It starts with an HBeAg-positive, immune-tolerant phase, characterized by high viremia, normal serum aminotransferases and minimal histological changes. The phase of HBeAg-positive CHB follows at a variable rate. It may also be called the HBeAg seroconversion phase and is characterized by positive HBeAg, high serum HBV DNA levels, elevated aminotransferases and active necroinflammation and/or fibrosis. The annual probability of HBeAg seroconversion (disappearance of HBeAg and development of anti-HBe) depends on several factors, such as the age of acute infection and HBV genotype, and is lower in Asian patients infected at birth (lower in those with genotype C than B) and higher in Caucasian patients infected during childhood, adolescence or adulthood[7,10-12]. If HBeAg seroconversion occurs, patients progress to the HBeAg-negative phases, which can be separated into the inactive carrier state and the HBeAg-negative CHB phase. The inactive chronic HBV carrier state is characterized by low levels of viral replication, normal aminotransferases and minimal histological lesions, while HBeAg-negative CHB is characterized by higher viral replication, elevated aminotransferases and active liver necroinflammation and fibrosis[9,13]. HBeAg-negative CHB may develop immediately after the HBeAg seroconversion phase or after several years of an inactive chronic carrier state[9], but many inactive chronic HBV carriers never progress to the HBeAg-negative CHB phase.

General indications for treatment in chronic hepatitis B

Significant histological lesions and progression of liver disease are observed almost exclusively in patients with HBeAg-positive and HBeAg-negative CHB, therefore these patients are considered as cases with widely accepted treatment indications. In clinical practice, HBeAg-positive or HBeAg-negative CHB can be diagnosed in patients with compensated chronic HBV infection (positive or negative HBeAg respectively) by evidence of viral replication (high serum HBV DNA levels) and biochemical and histological evidence of hepatocellular injury [increased alanine aminotransferase (ALT) activity and liver histological lesions at liver biopsy]. On the other hand, treatment indications are based on specific criteria and require certain cut-off points, which may sometimes be arbitrary due to the lack of strong data to support them. Treatment indications currently focus on serum HBV DNA levels, ALT activity and severity of liver histological lesions.

According to the most recent guidelines, treatment is recommended to all patients with either HBeAg-positive or HBeAg-negative CHB who have serum HBV DNA > 20 000 IU/mL and ALT higher than two times the upper limit of normal (> 2 xULN) for at least 3 mo[5,6,14]. In such cases, liver biopsy is considered to be optional, as it may offer prognostic information but it is not expected to affect the decision to treat. On the other hand, treatment is also recommended in HBeAg-positive CHB patients with ALT between 1-2 x ULN or HBeAg-negative CHB patients with ALT between 1-2 xULN and serum HBV DNA between 2000-20 000 IU/mL who have at least moderate necroinflammatory activity and/or significant fibrosis[5,6]. So, liver biopsy is mandatory in the latter cases with mild ALT elevations or relatively low viremia levels.

Controversial issues-The role of serum HBV DNA

All patients with chronic HBV infection are at increased risk for hepatocellular carcinoma (HCC) compared with the general population; while the risk increases substantially in patients with prolonged high viremia and cirrhosis[15,16]. Recent data suggest that patients with chronic HBV infection and HBV DNA above 10^4 copies/mL (approximately 2000 IU/mL) are at increased risk for cirrhosis and HCC regardless of ALT activity and are therefore possible candidates for treatment[16,17]. Such data have created some debate on whether patients in the HBeAg-positive immune tolerant phase, who have very high serum HBV DNA levels, should be left untreated. However, because they have minimal to mild histological liver lesions and the currently available agents may reduce viremia but offer minimal chances to induce HBeAg seroconversion[3,5,6], there is currently no widely accepted indication for treatment in such cases.

Despite the recent advances in the treatment indications, several issues remain unanswered, most probably because of the fluctuating activity of chronic HBV infection and the existence of patients who do not fulfil all criteria. HBeAg-negative CHB is defined as increased ALT/AST, serum HBV-DNA > 2000 IU/mL and moderate/severe necroinflammation, while inactive HBV carrier state is defined as persistently normal ALT/AST on ≥ 3-4 3-monthly determinations (then every 6-12 mo) and HBV-DNA < 2000 IU/mL[5]. However, it is well known that viremia levels fluctuate substantially in patients with HBeAg-negative CHB, often being lower than 2000 IU/mL. In one study that included mostly Chinese patients, 42% of cases with HBeAg-negative CHB occasionally had serum HBV DNA levels < 10 000 copies/mL (or approximately < 2000 IU/mL)[18]. In one recently published, prospective study from our group, 5% of HBeAg-negative CHB patients and 16% of their

serum samples had HBV DNA levels < 2000 IU/mL, while HBV DNA was persistently ⩾ 2000 IU/mL in 82% or occasionally < 2000 IU/mL in 18% of our HBeAg-negative CHB patients[19]. Although some patients may eventually develop HBV DNA levels > 2000 IU/mL after repeated testing, it is not clear how often and how many times HBV DNA determinations should be repeated. Since the current treatment indications include increased ALT and HBV DNA > 2000 IU/mL[5], HBeAg-negative patients with increased ALT/AST and HBV DNA < 2000 IU/mL are not considered for liver biopsy and are excluded from treatment. However, they may represent a sizeable proportion of HBeAg-negative CHB patients in clinical practice. In a retrospective, multicenter Greek study including 399 HBeAg-negative chronic HBV patients with increased ALT, at least moderate necroinflammation and/or moderate fibrosis were detected in the majority (62%) of such cases, who had HBV DNA < 2000 IU/mL and represented 14% of the total study population[20]. Therefore, liver biopsy is an useful tool in the evaluation of patients with persistent or transient mild transaminase elevations, regardless of the levels of serum HBV DNA.

On the other hand, if viremia is considered as the main criterion for performing a liver biopsy in order to decide the treatment indications, then the 2000 IU/mL cut-off serum HBV DNA level may cause a substantial proportion of inactive carriers to undergo unnecessary liver biopsies. In our prospective cohort of 150 HBeAg-negative chronic HBV patients with close biochemical and virological follow-up, a substantial proportion (22% of cases or 28% of 228 serum samples tested) of 85 patients with persistently normal ALT have HBV-DNA > 2000 IU/mL (2000-5000 IU/mL: 15%, 5000-20 000 IU/mL: 7%)[19]. According to our data, in 35 such HBeAg-negative cases with persistently normal ALT and HBV DNA > 2000 IU/mL, liver biopsies showed minimal necroinflammation in all but one (mild in one case) and minimal to mild fibrosis in 29 (83%) of them [fibrosis score of 2 in Ishak's scoring system was detected in the remaining 6 (17%) cases][20]. Thus, such cases seem to represent true inactive chronic HBV carriers, who require only close follow-up but no therapeutic intervention. It should be noted, however, that all HBeAg-negative cases with persistently normal ALT had HBV DNA < 20 000 IU/mL and that HBeAg-negative cases with persistently normal ALT and HBV DNA ⩾ 20 000 IU/mL are extremely rare in Greece. Close follow-up still remains the cornerstone of diagnosis. HBeAg-negative cases with relatively high normal ALT values (> 30 IU/L for men and > 20 IU/L for women) and/or serum HBV DNA ⩾ 2000 IU/mL warrant closer follow-up, because they are at increased risk of developing HBeAg-negative CHB in the future[19].

Indications for treatment in specific settings

Current guidelines support the view that all patients with decompensated liver disease and detectable serum HBV DNA should receive antiviral treatment regardless of aminotransferases and viremia levels[5]. The main goal of treatment in this group of severely ill patients is to completely inhibit viral replication in order to improve liver function and survival and, in case of liver transplantation, to prevent graft re-infection[21-23].

Another very important indication of anti-HBV therapy is the prevention of HBV reactivation in chronic HBV patients who are treated with corticosteroids or any other immunosuppressive therapy or cancer chemotherapy. It is well known that reactivation occurs in 29%-56% of chronic HBV carriers treated with chemotherapy and even in a small proportion of HBsAg negative and anti-HBc positive subjects regardless of anti-HBs status[24,25]. HBV reactivation after immunosuppressive therapy may have deleterious effects, often resulting in acute liver failure and death, therefore all patients who are going to be treated with any type of immunosuppression should be tested for HBsAg and receive pre-emptive anti-HBV therapy in case they are positive for HBsAg[5,26].

THERAPEUTIC STRATEGIES

In CHB, the more realistic therapeutic targets are suppression of HBV replication, induction of biochemical remission and ultimately prevention of cirrhosis and HCC[3,5,6]. Studies in non-Asian patients have shown that long-term benefits on survival are strongly linked to the induction of sustained HBeAg seroconversion in HBeAg-positive CHB[27-30] and with sustained biochemical and virological remission in HBeAg-negative CHB[31,32]. HBeAg seroconversion, however, may not be a sufficient therapeutic end-point in all patients with HBeAg-positive CHB, since some of them may subsequently develop HBeAg-negative CHB. This might depend on the patients' origin and perhaps the HBV genotype. Asian studies suggested that interferon-alpha (IFNα) induced HBeAg seroconversion improves the long-term outcome[33,34] but others reported no long-term benefit from IFNα therapy[35]. Thus, the induction of persistent biochemical and virological remission appears to be the most important therapeutic target in CHB, as the risk of major complications is strongly related to the viremia levels being independent of the HBeAg status[16,17,36]. Effective long-term antiviral therapy has been shown to prevent or diminish the development of decompensation and major complications in patients with advanced fibrosis or cirrhosis and to improve patients' outcome and survival[32,37,38].

Currently, there are seven drugs licensed for treatment of CHB: standard IFNa, pegylated IFNα-2a (Peg-IFNa-2a) (Peg-IFNα-2b is also licensed in some countries), lamivudine (LAM), adefovir dipivoxil (ADV), entecavir (ETV), telbivudine (TBV) and tenofovir disoproxil fumarate (TDF). These drugs may be broadly classified into (1) IFNalphas (standard or pegylated), which have both antiviral and immunomodulatory activities and are administered subcutaneously, and (2) the pure antiviral agents (LAM, ADV, ETV, TBV, TDF), which are analogs of natural nucleosides (LAM, ETV, TBV) or nucleotides (ADV, TDF) and are administered orally once daily.

Anti-HBV agents can be given as therapies of finite duration or as long-term therapies[4].

Therapies of finite duration

Therapies of finite duration are usually given for 12 mo and aim to induce sustained off-treatment response[3,4]. In current clinical practice, only IFNα/Peg-IFNα are used as therapy of finite duration in chronic hepatitis B, because sustained off-therapy responses after one-year courses with oral antivirals are rather limited.

In HBeAg-positive CHB, HBeAg seroconversion rates were reported to be 25%-33% with IFNα (5 MU daily or 10 MU thrice weekly for 4-6 mo) or Peg-IFNα (Peg-IFNα-2a: 180 μg/wk, Peg-IFNα-2b: 100 μg/wk for 12 mo)[39-41], 18%-22% after 12-mo courses with LAM (100 mg daily)[42-44], ETV (0.5 mg daily)[44], TBV (600 mg daily)[45] or TDF (300 mg daily) and only 12% with ADV (10 mg daily)[46]. The antiviral potency expressed by the reduction in serum HBV DNA levels differs among the anti-HBV agents (highest with TDF, ETV and TBV, intermediate with LAM and lowest with IFNα/Peg-IFNα and ADV), but these differences do not translate into different HBeAg seroconversion rates, at least within the first year of therapy. Patients with genotypes A and B respond better to IFNα/Peg-IFNα than those with genotypes D and C[34,40,41], while response rates to oral antivirals are not affected by the HBV genotype[5].

In HBeAg-negative CHB, cohort studies using insensitive virological assays showed that 12- or 24-mo courses of standard IFNα (3 or 5 MU thrice weekly) may achieve sustained long-term off-therapy biochemical and virological responses in 22%-30% of patients[47,48], who often (> 40%) clear HBsAg after some years[31,47]. More recently, Peg-IFNα-2α (180 μg/wk for 12 mo) was reported to induce biochemical and virological response rates of 35% at 24 wk post-treatment[49], which decreased with further follow-up to 25%-30% at 1-3 post-treatment years[49-51]. Again, 35% of sustained responders lost HBsAg over the 3-year post-treatment follow-up[51]. On the other hand, 12-mo courses with oral antivirals achieve high on-therapy response rates (> 75%), but sustained off-therapy responses are rare (< 8%-11%)[52-54] and therefore these agents are only given as long-term therapies.

Anti-HBV treatment is also given for finite duration in chronic inactive HBV carriers who receive immunosuppressive therapy[5,26]. In such cases, most of the data comes from pre-emptive LAM therapy, which has been shown to prevent or ameliorate the course of HBV reactivation[26,55,56]. However, it is anticipated that all oral anti-HBV agents will also be effective in the prevention of HBV reactivation, while the newer, more potent agents are expected to be more effective in patients who develop clinically apparent HBV reactivation after immunosuppressive therapy. Pre-emptive oral anti-HBV therapy should ideally start at least 2 wk before the onset of immunosuppressive therapy and should continue for at least 6-12 mo after the completion of immunosuppressive courses[5,26].

Long-term therapies

Long-term or "maintenance" therapy is the most commonly used treatment strategy in CHB, because IFNa/Peg-IFNa as a therapy of finite duration can achieve sustained off-therapy responses only in a minority of cases[3,4,57], while a proportion of patients do not wish to be treated with IFNα/Peg-IFNα because of the frequently anticipated side effects or cannot tolerate or have contraindications to IFNα/Peg-IFNα therapy[40,41,49]. Only oral antiviral agents are used as long-term therapies because of their good tolerability, safety profile and on-therapy efficacy[3,4,9]. In particular, for patients with HBV decompensated cirrhosis, life-long treatment with a potent oral anti-HBV agent is the only possible therapeutic option[5].

In HBeAg-positive CHB, prolongation of therapy with oral antiviral agents has been shown to increase the probability of HBeAg seroconversion, although the interpretation of most of such long-term data needs close scrutiny as protocols for treatment after one year have differed markedly. The duration of therapy after HBeAg seroconversion induced by oral antivirals seems to be rather important for the maintenance of response[5]. There are no good studies to define the optimal duration of antiviral therapy, but most experts and recommendations now agree that any oral antiviral agent should continue for at least 6 mo after HBeAg seroconversion in order to maximize the possibility of sustained off-therapy responses[5]. Thus, treatment may stop after a certain consolidation period in HBeAg-positive CHB patients who achieve HBeAg seroconversion.

In HBeAg-negative CHB, however, it is still unclear whether long-term courses with oral antivirals can induce sizeable sustained off-therapy response rates. In particular, there are some conflicting reports for long-term LAM courses[58,59] and one encouraging report for ADV[60]. In the latter study, 67% of 33 patients maintained sustained off-therapy biochemical and virological (HBV DNA < 50000 cp/mL) remission for a median of 17 mo after discontinuation of a 4-5-year effective ADV course[60]. Thus, sustained off-therapy responses may be achieved in a proportion for HBeAg-negative CHB patients treated successfully for some years with oral antiviral agents, but more studies are needed before firm conclusions can be drawn.

Viral resistance

The main limitation of long-term therapies with antiviral agents is the progressively increasing rates of viral resistance due to selection of treatment resistant HBV mutant strains[61-63]. The emergence of genotypic viral resistance is clinically expressed by the subsequent development of virological breakthrough or secondary antiviral treatment failure, which is usually defined as reappearance or $\geqslant 1$ $\log_{10}$ IU/mL increase after initial lack of detection or initial $\geqslant 1$ $\log_{10}$ IU/mL reduction of serum HBV DNA[5,64,65]. Genotypic resistance may be also detected in patients without virological response or with primary antiviral treatment failure (no or < 1

log_{10} IU/mL decrease of HBV DNA), while virological breakthroughs may also develop from non-compliance to therapy[5,61,65,66]. Virological breakthroughs are usually followed by biochemical breakthroughs[67,68], which eventually worsen liver histology[67,69] and may even result in decompensation and death, particularly in patients with pre-existing cirrhosis[21,22,32,66].

Viral resistance may develop under any anti-HBV oral agent, but the rate of resistance differs markedly among the different agents. Long-term LAM monotherapy results in rather high rates of resistance due to emergence of HBV strains with mutation within the YMDD motif (rtM204V/I with or without rtL180M)[61,63,64,70,71]. LAM resistance rates usually exceed 15%-20% at year-1 and 60%-65% at year-4[38,67,72,73]. Due to the high probability of resistance, LAM monotherapy is not currently considered as an optimal first-line long-term therapy for CHB[5,14]. However, LAM is still used in many countries because of its low cost. Resistance also increases progressively with prolongation of ADV monotherapy but at much slower rates compared to LAM[74]. There are no good long-term ADV data in naïve patients with HBeAg-positive CHB. In HBeAg-negative CHB, ADV resistant strains (rtN236T and/or rtA181V/T mutations)[63,71,75], first emerge during the second year of therapy reaching cumulative rates of 3% at week-96 and 29% at week-240[74]. Resistance to ETV in nucleoside naive CHB patients seems to be rather rare, since it has been detected in < 1.5% of naive patients treated with ETV monotherapy for up to five years[76]. ETV resistance requires selection of two LAM resistant mutations (rtM204V/I and rtL180M) and at least one additional substitution (rtI169, rtT184, rtS202, or rtM250)[77]. TBV also selects for mutations in the YMDD motif with only rtM204I resistant strains being detected to date[78]. TBV resistance has been observed in 4.4% and 21.6% of HBeAg-positive and 2.7% and 8.6% of HBeAg-negative CHB patients treated with TBV for 1 and 2 years, respectively[45,79]. No resistance to TDF has been reported to date after 18 mo of therapy in monoinfected CHB patients.

Resistance is the major limitation of long-term oral antiviral therapy, therefore its management is of great importance. First, there are several strategies to prevent the development of resistance. Such strategies include: (1) the use as first-line therapy of agents with high genetic barrier or low resistance profile, such as TDF and ETV; (2) the non-use of agents with high probability of resistance, such as LAM; and (3) the careful on-treatment monitoring and the prompt modification of therapy that does not result in complete suppression of HBV replication. Since residual viremia at 6 mo of TBV or LAM and at 12 mo of ADV monotherapy represents the strongest risk factor for subsequent resistance[74,80], some treatment algorithms suggest that antiviral therapy should be modified in CHB patients who remain viremic after the first 6 or 12 mo therapy with these agents.

Whatever strategy is adopted, resistance may eventually develop and therefore management of HBV strains with resistance against some agents is often required. The wide use of LAM monotherapy in CHB during the last 7-8 years, an anti-HBV therapeutic strategy with a poor resistance profile[63,65], has progressively increased the numbers of patients with LAM resistant HBV mutant strains[57,81]. ADV, ETV (1.0 mg daily) and TDF have been shown to be effective in patients with LAM resistance[65,82-85]. Pre-existing LAM resistant mutations favour the emergence of resistance to ETV[77,81], therefore the cumulative ETV resistance rates are substantially higher in LAM resistant than in naïve patients (6% at year-1 and 51% at year-5)[76]. These data make ETV a less attractive therapeutic option for the long-term treatment of patients with LAM resistance. The prompt addition of ADV to on-going LAM therapy was for years the treatment of choice for CHB patients with LAM resistance[5,14,57,65,86-89]. However, after the recent license of TDF, which is a more potent agent for both naïve and LAM resistant patients compared to ADV, TDF will probably be used for the treatment of patients with LAM resistance.

In vitro data and clinical studies reported that ADV resistant mutants are susceptible to LAM, ETV and TBV therapy[65,75,81,84,90]. Some recent *in vitro* data, however, suggested that LAM, ETV and TBV are effective against the N236T HBV mutant strain, which represents the most frequent ADV resistant mutant, while all three agents may have relatively reduced efficacy against the A181V HBV mutant strain, which seem to be more sensitive to TDF[81]. It should be noted that LAM should be avoided in patients with prior LAM resistance who develop ADV resistance under ADV monotherapy, as reintroduction of LAM was reported to be associated with rapid re-emergence of LAM resistant strains[66]. There are very few data regarding management of patients with ETV or TDV resistance. Since resistance against these two agents requires the presence of M204V/I (± L180M) mutations, LAM will be ineffective. However, according to in vitro resistance data and the type of resistant mutations, ADV or now, TDF, seem to be the most reasonable currently available therapeutic options for patients with ETV or TDV resistance due to lack of cross-resistance[14].

CONCLUSION

The decision to treat any patient with chronic HBV infection should be based on reasonable clinical judgment. Treatment should be given to all chronic HBV patients with HBV DNA > 20 000 IU/mL, elevated ALT > 2 xULN, regardless of HBeAg status. Liver biopsy does not affect the therapeutic decisions in this group of patients and therefore has only prognostic significance. In contrast to above, treatment indications remain debatable in the group of patients in the HBeAg-positive immunotolerant phase (high HBV DNA and normal ALT) as well as in marginal HBeAg-negative chronic HBV patients. Liver biopsy is extremely important for therapeutic decisions in patients with marginal ALT elevations (1-2 xULN) and/or relatively low HBV DNA levels (< 20 000 IU/mL). All existing data suggest that

there is no clear cut-off HBV DNA level to differentiate inactive chronic HBV carriers from HBeAg-negative CHB patients. Any such a cut-off level would not correctly diagnose a substantial proportion of inactive carriers perhaps leading to unnecessary liver biopsies as well as a proportion of HBeAg-negative CHB patients who may not receive appropriate treatment. In clinical practice, all HBeAg-negative patients with any persistent or transient mild ALT elevation may benefit from a liver biopsy regardless of viremia levels, while HBeAg-negative patients with persistently normal ALT and HBV DNA < 20 000 IU/mL should be followed for life.

Therapeutic strategies for CHB can be summarized as therapies of finite duration aiming to offer sustained off-therapy response and long-term therapies aiming to maintain remission under oral antiviral agents. Peg-IFNα, or even standard IFNa, therapy represents the only practical treatment given for finite duration, which offers a chance of sustained off-therapy response with a considerable probability of HBsAg loss. However, IFNα/Peg-IFNα therapy has relatively poor safety and tolerance profile, is contraindicated in specific patient populations and eventually achieves sustained off-therapy responses in the minority of CHB patients. Long-term treatment with oral anti-HBV agents represents the therapeutic option for the majority of chronic HBV patients who require treatment. They achieve high initial on-therapy biochemical and virological response rates, but viral resistance may develop with prolongation of therapy. Therefore, judicious use of oral anti-HBV agents is recommended, particularly in patients with mild liver disease. The optimal strategy for oral anti-HBV therapy with the best long-term cost/benefit ratio has not been completely clarified. LAM monotherapy is associated with the highest resistance rates and therefore is considered as a suboptimal first-line long-term monotherapy in CHB, However, despite the current availability of more potent agents with better resistance profile, such as ETV and TDF, which have become the treatment of choice in Western countries, LAM is still widely used in many parts of the world because of its low cost. Regardless of the anti-HBV agent used, compliance should always be ascertained and most current guidelines recommend HBV DNA testing at least every 6 mo for the prompt diagnosis of lack of response or virological breakthroughs and timely treatment modification. Whether the 6-monthly HBV DNA determinations are necessary during the long-term treatment with any anti-HBV agent, even those with very low resistance rates after 4-5 years of therapy, is currently unclear.

Abstract

There is an increased awareness that celiac disease may occur in the elderly although presentations with either diarrhea, weight loss or both may be less common causing delays in diagnosis for prolonged periods. Higher detection rates also seem evident owing to active case screening, largely through serodiagnostic measures. In some elderly patients who are genetically predisposed, it has been hypothesized that celiac disease might be precipitated late in life by an antigen, possibly from an infectious agent. As a result, peptide mimicry or other poorly-defined mechanisms may precipitate an autoimmune gluten-dependent clinical state. Although diarrhea and weight loss occur, only isolated iron deficiency anemia may be present at the time of initial diagnosis. In addition, the risk of other autoimmune disorders, particularly autoimmune thyroiditis, and bone disease, are increased. Osteopenia may also be associated with an increased risk of fractures. Finally, elderly celiacs have an increased risk of malignant intestinal disease, especially lymphoma.

INTRODUCTION

Celiac disease has been traditionally recognized in children and young adults, however, in recent years, detection in the elderly population has increased[1]. This is reflected historically in published clinical series from North America and Europe (e.g. about 7% in a Birmingham series were diagnosed after the age of 60 years, similar to a Mayo Clinic series of 4%[2]. Later, studies from the United Kingdom[3] recorded that about 25% were initially diagnosed in their seventh decade. Similar findings were also recorded in the United States[4], Sweden[5], Scotland[6], Ireland[7] and Canada[8]. In each, typical symptoms of impaired intestinal absorption, such as diarrhea or weight loss, while common, were less prominent compared to those with celiac disease diagnosed at a younger age, even though adult celiac disease was reported to be the most common cause of steatorrhea after the age of 50 years[9]. Others, however, have also recently emphasized the need to suspect celiac disease in the elderly, as even classical features of celiac disease may be ignored leading to prolonged delays in diagnosis[10-12].

CLINICAL PRESENTATION

A precise explanation for the apparent paucity of clinical findings in the elderly age group is still required. Firstly, this may be due, in part, to a limited mucosal extent of disease in the proximal duodenum and jejunum. As a result, symptoms and signs, such as diarrhea and weight loss, may be minimized. Instead, isolated deficiencies of specific nutrients, such as iron, may occur. Secondly, a low index of suspicion by the physician for celiac disease may lead to a delay in recognition or a distraction to other sinister disorders. For example, iron deficiency anemia may lead to studies to exclude colon cancer. Thirdly, some patients with elderly celiac disease may have cognitive impairment which makes the definition of some symptoms more difficult[13]. Occasionally, in those treated with a gluten-free diet, cognitive decline may be minimized or may resolve[11]. Finally, and most intriguing, recognition of celiac disease, in some cases, may not be delayed. Possibly, the disease may only be precipitated later in life by some environmental factor, such as a viral agent (e.g. adenovirus) or an as yet unidentified superantigen with a peptide structure that mimics, at a molecular level, the offending gluten peptide[14,15]. Especially intriguing is a recent report showing that in a biopsy-defined population,

celiac disease was more commonly found in the elderly than any other younger age group implying a critical need for active case finding, possibly through serological screening[16]. The reason for this late clinical definition of celiac disease needs to be further elucidated.

ASSOCIATED DISORDERS

A number of disorders have now been recognized in the elderly which might provide a clinical clue to underlying or occult celiac disease. In addition to isolated iron deficiency, folic acid or calcium deficiencies may also occur because the principal uptake site for these nutrients is also the proximal small intestine. Moreover, autoimmune disorders linked to adult celiac disease (and possibly with a similar etiopathogenesis) may be the predominant clinical manifestation of occult celiac disease, such as dermatitis herpetiformis[17,18] or autoimmune thyroiditis[19]. Celiac disease may also be associated with collagenous mucosal diseases (i.e. collagenous colitis)[20], as well as epithelial lymphocytosis of the stomach, colon and biliary tract[21-23]. In some patients, collagenous colitis may be a clue to underlying celiac disease[24], or may complicate celiac disease causing an apparently "refractory" diarrhea, despite a gluten-free diet. Finally, specific malignancies traditionally associated with celiac disease may occur, including lymphoma and small bowel adenocarcinoma[25,26].

Other disorders of the intestinal tract have been recorded. Gastric and duodenal ulcers may occur, but jejunal or ileal ulcers are especially worrying, since these may harbour a malignant small bowel lymphoma[25], especially if the presentation is associated with a free perforation of the small intestine[27]. Also, pancreatic calcification has been described, similar to the calcific pancreatitis noted in autoimmune pancreatitis, protein-energy malnutrition and long-term alcohol abuse[28].

LATENT CELIAC DISEASE

Latent celiac disease has also been documented in some elderly patients with dermatitis herpetiformis. In these patients, initial small bowel biopsies were architecturally normal (suggesting that celiac disease might not be present)[29]. Following a high gluten diet, however, histological changes of variable severity were induced, indicating that the small bowel mucosa was gluten-sensitive. In some biopsies, architectural changes were only mildly or moderately abnormal, but in others, changes were severely ("flat") abnormal. These small intestinal biopsy changes do not occur in normal volunteers fed high gluten-containing diets. Later, improvement in the small bowel biopsies occurred with gluten restriction. Similar changes were documented in serial small intestinal biopsies carried out in an elderly patient with intestinal lymphoma[30].

SPECIAL PROBLEMS IN ELDERLY CELIAC DISEASE

Anemia and abnormal laboratory tests

Up to 80% of elderly patients with celiac disease in a British series had anemia[31]. Iron deficiency was usually the cause but other nutrients may be deficient, such as folic acid, sometimes producing a dimorphic peripheral blood smear (if combined with iron deficiency). In these elderly patients, concomitant hypoalbuminemia with peripheral edema and ascites may also occur with hypocalcemia and hypomagnesemia[8]. Others may have liver chemistry test changes[23], initially believed, in some cases, to be related to alcohol overuse. In these patients, a hepatocellular injury profile may normalize with gluten restriction. In others with a cholestatic injury profile, lymphocytic sclerosing cholangitis or primary biliary cirrhosis may be present, but these do not improve with a gluten-free diet.

Bone disease and fractures

Bone disease may develop with few clinical features of malabsorption. Decreased bone mass is the most common form of metabolic bone disorder in celiac disease. Up to 70% of adult and elderly patients with celiac disease have a bone mineral density that is less than one standard deviation below normal controls (osteopenia)[32,33]. Men and post-menopausal women are affected more often than pre-menopausal women[33]. Reduced bone mineral density may also occur in treated patients with celiac disease[33,34].

The mechanism for osteopenia in celiac disease may be related, in part, to calcium malabsorption causing increased secretion of parathyroid hormone. Increased bone turnover leads to cortical bone loss. Impaired absorption of vitamin D may also occur. Pro-inflammatory and anti-inflammatory cytokines are believed to play an active role in the pathogenesis of osteopenia in celiac disease. Although celiacs may improve their bone mineral density with a gluten-free diet, the bone mass increment is limited in elderly patients and may be incomplete.

A higher prevalence of fractures also occurs in the peripheral skeleton of elderly celiacs. Most fractures occur before the diagnosis of celiac disease is initially defined and commonly occur in those with poor diet compliance. Most believe that a gluten-free diet is the most important factor providing protection from the risk of fracture. In a recent population-based study on long-term fracture risk[35], celiac disease was linked to an increased fracture risk before and after diagnosis. Appendicular and axial fractures were more common supporting a rationale for earlier detection of celiac disease and active management of bone disease before bone effects, specifically fractures, occur[35].

Recurrent or refractory disease

In well-defined celiac disease, recurrent diarrhea or malabsorption may occur. In an elderly celiac, this may be particularly disconcerting since the number of potentially serious disorders that may complicate the clinical course of celiac disease is significant[36]. In most, limited compliance to the gluten-free diet or inadvertent consumption of gluten remains the most common cause. Ubiquitous sources of gluten include the fillers in pill capsules, a particularly critical issue in this age group. In others, diarrhea or weight loss may be related

to another cause with no specific relationship to celiac disease (e.g. ischemic bowel disease, infectious diarrhea, colonic malignancy). Alternatively, other superimposed small intestinal histological changes may be present which could be related to impaired absorption of a specific nutrient (e.g. folic acid deficiency). In others, an associated cause, such as pancreatic exocrine insufficiency, may be present. Re-evaluation of the original diagnosis may be necessary to ensure that a separate diagnosis has not been overlooked. Sometimes, an associated complication may be responsible, e.g. collagenous or lymphocytic colitis, or a more serious complication may supervene, e.g. lymphoma[36].

In elderly patients with established celiac disease, a rare disorder, collagenous sprue, may develop[36]. In most of these patients, severe pan-malabsorption may occur with recurrent diarrhea, progressive weight loss and significant nutritional and electrolyte deficiencies. IgA-endomysial antibodies may also be detected in collagenous sprue, further evidence for an etiopathogenetic link with celiac disease[37]. In addition, collagenous sprue may be complicated by lymphoma[38]. Collagenous mucosal changes may also concomitantly occur in the colon, and rarely, these may completely disappear with treatment[39]. Most intriguing was the finding of complete histopathological resolution of collagenous small bowel and colonic involvement after resection of an unrelated colon cancer, suggesting the possibility of a paraneoplastic phenomenon[40].

Occasionally, no specific cause for persistent or refractory symptoms can be documented. Some have a poorly understood syndrome characterized by recurrent or persistent small bowel changes of variable severity, splenic hypofunction and cavitation of mesenteric lymph nodes. This disorder may also be complicated by lymphoma[41]. Others in this heterogeneous group remain severely symptomatic with malabsorption and profound wasting despite a gluten-free diet. Some may have a "clinically-resistant" form of celiac disease. Interestingly, a recent report documented persistent changes in elderly celiacs on a gluten-free diet and suggested that follow-up biopsies be done only after two years on a gluten-free diet to document histological recovery[42]. This suggests that the label of "refractory" may only be applied after an extended period of time. Others will be eventually proved to have a difficult-to-diagnose intestinal lymphoma[36].

CONCLUSION

Despite a paucity of symptoms, such as diarrhea and weight loss, celiac disease is becoming increasingly recognized in the elderly. Especially intriguing is a recent report which suggests that celiac disease occurs in the elderly more often than in any other age group, possibly related to serological screening. Other presentations in this elderly age group include iron deficiency anemia (often refractory to oral iron), other autoimmune disorders (dermatitis herpetiformis, thyroiditis), osteopenic bone disease, including fractures, and malignant intestinal disease, especially lymphoma. Diagnosis may be delayed due to limited symptoms, a low index of suspicion or diagnostic difficulties related to cognitive impairment. Conversely, celiac disease may not develop in the genetically predisposed until late in life, possibly being precipitated by an environmental factor. Finally, celiac disease diagnosed late in life is more often associated with recurrent or refractory disease and the appearance of lymphoma.

Abstract

Primary liver cancer remains one of the most lethal malignancies worldwide. Due to differences in prevalence of etiological factors the incidence of primary liver cancer varies among the world, with a peak in East-Asia. As this disease is still lethal in most of the cases, research has to be done to improve our understanding of the disease, offering insights for possible treatment options. For this purpose, animal models are widely used, especially mouse models. In this review, we describe the different types of mouse models used in liver cancer research, with emphasis on genetically engineered mice used in this field. We focus on hepatocellular carcinoma (HCC), as this is by far the most common type of primary liver cancer, accounting for 70%-85% of cases.

INTRODUCTION

The American Cancer Society has estimated that, in 2007, there were over 700 000 new cases of primary liver cancer worldwide. It is the fifth most common malignancy in men and the eighth in women. Liver cancer is among the most lethal cancers (five-year survival rates under 11%), which makes it the third most frequent cause of cancer death in men and the sixth in women[1]. Liver cancer consists of several histologically different primary hepatic malignancies, such as cholangiocarcinoma, hepatoblastoma and haemangiosarcoma, but hepatocellular carcinoma (HCC) is by far the most common type, accounting for 70%-85% of cases[1,2].

Cirrhosis (due to for instance hemochromatosis), chronic hepatitis B and C viral infections, chronic alcohol consumption, aflatoxin-B1 intake (from contaminated food) are the most important of the well-defined risk factors for HCC. Variations in the prevalence of these etiological factors mirror the geographical distribution of the incidence of HCC. The worldwide (age-adjusted) incidence per 100 000 persons is 14.9/5.5 (men/women), varying from 2.6/1.3 in Northern Europe to 35.4/12.6 in East Asia[2,3].

Animal models for human HCC can be helpful to our understanding of the (molecular) mechanisms underlying the pathogenesis of HCC. The laboratory mouse remains one of the best models to study cancer *in vivo* due to various features, such as the small size, the similarities to humans and the entirely sequenced genome and the similarities to humans[4].

For instance, the risk of HCC in males is approximately 2-5 times greater than in females[5,6]. This gender difference is seen in mice as well. Recently, Naugler *et al*[5] attributed this disparity to a higher serum interleukin-6 (IL-6) concentration in male than in female mice after administration of the chemical hepatocarcinogen diethylnitrosamine. IL-6 is secreted by Kupffer cells in response to, for example, necrotic hepatocytes. They demonstrated that estrogen inhibits the secretion of IL-6.

Since the spontaneous incidence of liver tumors in

the most frequently used strains of mice is < 4%, mouse models have been developed to induce HCC-formation[7,8].

None of the currently available mouse models meet all criteria of the ideal animal model, which include biologic, genetic, etiologic and therapeutic criteria[9]. Therefore, the most appropriate model for a particular experimental question should be used to answer the specific research question.

This review highlights the currently used mouse models for HCC, with emphasis on genetically engineered models.

CARCINOGEN-INDUCED MOUSE MODELS OF HCC

An etiological role for external agents in contributing to human HCC, also referred to as hepatocarcinogens, has been established by primarily epidemiological studies[9]. Examples of known human hepatocarcinogens include aflatoxins, ethanol and combined oral contraceptives[10]. Despite the fact that some of these chemicals are carcinogenic to the mouse liver as well, this is not true for all human hepatocarcinogens. For example, cirrhosis and liver cancer have not been observed in mice subjected to ethanol solely[10-12]. At the same time, hardly any of the mouse hepatocarcinogens have shown to be carcinogenic for humans (aflatoxin B1 and oral contraceptives belong to the exceptions). This discrepancy in response to carcinogens can probably be explained by species differences[9-11]. Nonetheless, carcinogen-induced mouse models are still frequently used for HCC research.

The (hepato) carcinogens are subdivided into two classes, namely genotoxic and non-genotoxic (or epigenetic) carcinogens. The genotoxic carcinogens can presumably cause cancer by forming DNA adducts, which lead to genetic changes of the target cell. These changes can direct normal cells to a preneoplastic state (initiation). The non-genotoxic carcinogens do not modify DNA structure, but generally stimulate the preneoplastic or initiated cells to evolve into a malignant neoplasm by controlling cell proliferation, apoptosis and cell differentiation[10,11,13]. Because of the high incidence of altered (or preneoplastic) hepatocytes in certain mouse strains (especially C3H and B6C3F1 mice, the latter corresponding to the progeny of C3H mice coupled to C57BL/6 mice), epigenetic carcinogens alone can be used to induce HCC-formation in these mice[8,11].

Many chemicals have been shown to induce HCCs in the mouse liver[10,14]. To date, the most frequently used hepatocarcinogens in mice are diethylnitrosamine (DEN) and phenobarbital (PB), although the carcinogenic effect of PB is controversial[8]. Furthermore, attention has been paid to the hepatocarcinogenic effect of peroxisome proliferators such as clofibrate and the experimental Wy-14.643[13].

The single most frequently used chemical for induction of HCCs in mice is DEN, a genotoxic carcinogen. DEN is typically administered to mice between 12 and 15 d of age by a single intraperitoneal injection (5 μg/g body weight). Using this protocol, originally described by Vesselinovitch and Mihailovich, 100% of B6C3F1 male mice developed HCCs, on average, 44 wk after intraperitoneal injection of DEN[15-17]. Less frequently used protocols for DEN-administration include intraperitoneal injection of a higher dose of DEN (for example 80-90 μg/g body weight) to older mice (4-5 wk of age) and intraperitoneal DEN-injection 36 h after a partial hepatectomy (mice 5-6 wk of age). These protocols are less efficient in producing HCCs than those previously mentioned[8]. DEN-induced mouse models of HCC are predominantly used to study the molecular mechanisms of (chemical) hepatocarcinogenesis. Furthermore, the influence of (trans) genes and chemicals that might prevent HCC development can be evaluated by means of this model.

In the background of carcinogen-induced mouse models for HCC, identifying chemicals that might be carcinogenic to humans is the major application of laboratory mice. For this purpose, chemicals are either administered to newborn mice in order to determine genotoxicity, or compounds are administered for longer periods (usually 2 years) to assess epigenetic carcinogenity[6,14]. However, because of the significant inconsistencies between mouse and human carcinogens, extrapolating the results of these mouse studies to the human situation remains difficult[18].

Carcinogen-induced mouse models for HCC are useful for establishing a relationship between carcinogen exposure and specific genetic changes[19]. However, the influences of sex, age and genetic background of the mice on the predictability of HCC-development remain disadvantages of these models.

IMPLANTATION MODELS OF HCC

Implantation models are among the most widely used models to accomplish HCC formation in mice, because of their suitability in studies for preclinical evaluation of anticancer agents. In implantation models that are currently used to induce HCC formation in mice, HCC cell lines or tumor tissue fragments are implanted in recipient mice. Here, we will give an impression of the approaches that can be used to obtain HCCs in these mice.

The earliest implantation model is the syngeneic transplantable tumor model, in which a HCC cell line or tissue fragment is implanted in mice of the strain from which the implant originates. To date, this model is less frequently used, because of the discovery that human tumor cell lines and tissue fragments can be implanted into immunodeficient mice. Nevertheless, this model is still required when anticancer agents are tested that work by activating the immune system (immune therapy)[20-22]. The unpredictability of the effectiveness of studied anticancer agents in human HCC and the small number of available murine cell lines are the most important disadvantages of this implantation model[20].

As mentioned, nowadays, primary human HCC cell lines or tissue fragments are implanted into immunocompromised mice (xenograft models).

The most widely used mouse for this approach is the nude mouse (*nu* -/-). These mice are athymic, hairless and have a deficiency of T lymphocytes as well as an impaired T and B cell function[23]. Next to nude mice, severe combined immunodeficient (SCID) mice are frequently used in xenograft models of HCC. These mice have a deficiency in number and function of both T and B lymphocytes[24]. Since the establishment of the first human HCC cell line in 1963[25], many human HCC cell lines have been described, of which the HepG2, the Hep3B, the SMMC-7721 and the HuH7 cell lines are the most commonly used.

In allograft models, murine HCC cell lines or tumor fragments are implanted in (not necessarily syngeneic) mice. The HCC grafts have been derived from spontaneously occurring HCCs in mice, from carcinogen-induced tumors or from genetically engineered mice (GEM), which is discussed in the last part of this review.

The above mentioned xenograft or allograft HCC cell suspension or tumor tissue fragments can be implanted into recipient mice, either at ectopic or at orthotopic sites. Ectopic implantation of tumor cells or fragments usually occurs subcutaneously. Orthotopic implantation can be accomplished by subserosal injection of HCC cells or by surgical orthotopical implantation (SOI) of tumor fragments. These fragments, approximately 1 mm^3 in size, are derived from surgical specimens of human HCCs or from pieces of subcutaneously grown HCC cells, either from human or mouse origin.

Xenografts of human HCCs growing subcutaneously in mice are predominantly used in the preclinical evaluation of anticancer agents. The rapid formation of tumors, the minimal labor that is required, the relative inexpensiveness and the ability to measure tumor size non-invasively are the main advantages of the ectopic, subcutaneous, application of grafts from human HCCs[21,22]. However, many research groups have described the importance of the microenvironment on the biological behaviour of malignant cells. For example, many tumor cell lines do not spontaneously metastasize when they are subcutaneously implanted, while they do metastasize when they are orthotopically implanted. Hence, the interaction of organ-specific factors (such as fibroblasts, endothelial cells and inflammatory cells) with tumor cells, is important for HCC development[21,26]. For this reason, therapeutic results obtained by an ectopic implantation model of a HCC graft must always be verified in orthotopic models.

These orthotopic implantation models mimic human HCCs in a better way with respect to tumor morphology, microenvironment, metastatic potential and the response to anticancer agents[27,28]. Furthermore, processes involved in local invasion, like angiogenesis, can be examined in their normal microenvironment[20]. Nonetheless, disadvantages of orthotopic implants of HCC xenografts include a more difficult surgical implantation procedure and more expensive procedures. Furthermore, tumor growth and response cannot be determined as easily as in ectopic transplantation models.

Despite the fact that (ectopic and orthotopic) xenograft implantation models are among the most widely used models for preclinical evaluation of anticancer agents, it has been demonstrated excessively that these models have a poor predictive value for the anti-tumor effects in patients. This can possibly be explained by the fact that the injected tumor cells are often cultured for a long period. Due to selection pressures in culture, these tumor cells have no longer maintained the original molecular characteristics and the heterogeneity of the patients' tumor[4,20,28,29]. By implanting a tumor fragment of a patient, the morphological and molecular characteristics of a patient's tumor are preserved better. However, establishing a parallel in vitro cell line from a patient's tumor is often very difficult.

The abovementioned features of implantation models are but a few arguments why implantation models are not ideal for the preclinical evaluation of anticancer agents. However, because of the suitability of these models, implantation models are still frequently used for this purpose.

GENETICALLY ENGINEERED MOUSE MODELS FOR HCC

The introduction of transgenic mouse models in the early 1980's made it possible to study the molecular features of human malignancies *in vivo*[30,31]. Since then, much progress has been made in techniques of producing GEM[4].

In studying the molecular mechanisms involved in hepatocarcinogenesis, GEM are particularly used to explore the role of a specific gene and to explore the interaction of different genes (e.g. oncogenes and tumor-suppressor genes) in the development of HCC. GEM is also suitable to investigate the role of specific genes in combination with a liver-specific carcinogen.

As is the case in other types of cancer, genetic alterations in various cellular pathways (including pathways involved in growth, apoptosis, proliferation and angiogenesis) are needed for the development of HCC. Although the exact genetic events in hepatocarcinogenesis are not entirely clear, there is evidence that the p53, Rb and Wnt/β-catenin pathways are involved[32,33]. Several transgenic mouse lineages that are nowadays used to induce formation of HCCs are transgenic in one of these pathways (Table 1). The most commonly used models will be discussed here.

Since the late 1980's, transgenic SV40 T-Ag (Simian Virus 40 T-antigen) mice have been studied extensively. The genome of the simian virus 40 (a DNA tumor virus) encodes two oncogenic proteins, the large and small T antigen (T-Ag and tAg, respectively, herein together referred to as T-Ag). After infection, large T-Ag can cause malignant transformation of the host cell primarily by inactivating the tumor-suppressor genes *p53* and *Rb*[34,35].

Research groups have reported the production of transgenic mice expressing SV40 T-Ag directed to the liver by the promoter/enhancer antithrombin-Ⅲ (AT Ⅲ)[36], albumin (Alb)[37] and α-1-antitrypsin (AAT)[38]. For

Table 1 Transgenic mouse models for HCC

Transgene	Promoter	Mouse strain	Percentage HCCs	Reference
c-myc	Alb	C57BL/6 × CBA/J	65% in males at 20 mo	40
TGF-α	MT	CD1	50% in males > 12 mo	77, 78
c-myc/TGF-α	Alb, MT	C57BL/6 × CBA/J × CD1	100% in males at 8 mo	40
SV40 T-Ag	ATⅢ	C57BL/6 × DBA2	100% at 8 mo	36
E2F-1	Alb	C57BL/6 × CBA/J	33%-60% at 12 mo	79, 80
c-myc/E2F-1	Alb	C57BL/6 × CBA/J	100% at 9 mo	80

example, Dubois *et al*[36] produced transgenic mice by putting the SV40 T-Ag under the control of the human ATⅢ promoter. In mouse lineages that expressed the highest level of the transgene, by the age of 8 mo, 100% of mice had developed HCCs and 10% had developed lung metastases.

Another commonly used transgenic mouse model was described by Murakami *et al*[39]. They generated double transgenic mice overexpressing c-myc and TGF-α in the liver (Alb-c-myc/MT-TGF-α mice) by crossing Alb/c-myc mice (transgenic mice overexpressing c-myc, directed by the albumin promoter) with MT/TGF-α mice (transgenic mice overexpressing TGF-α, directed by the metallothionein 1 promoter). Santoni-Rugiu *et al*[40] demonstrated that these mice developed HCCs substantially earlier and at a higher rate than single transgenic mice, overexpressing either c-myc or TGF-α. Within 8 mo after birth, 100% of male and 30% of female Alb-c-myc/MT-TGF-α mice had developed HCCs.

Although these conventional transgenic mouse models have been very useful to study the role of particular genes in hepatocarcinogenesis and to study the multistep nature of HCC development, one limitation of these models is the fact that the transgene is expressed in all hepatocytes, including the tumor microenvironment. Furthermore, the mutations are already present during embryogenesis and thus, might activate compensatory (molecular) pathways[26]. To overcome these limitations, mouse models have recently been developed in which the genetic alterations are induced in a tissue-specific and time-controlled fashion (conditional mouse models).

For instance, Lewis *et al*[41] used a retroviral transduction strategy to deliver oncogenes to hepatocytes *in situ*. They made use of the fact that mice do not express the TVA receptor, which is the receptor for the avian leukosis sarcoma virus subgroup A (ALSV-A). Lewis *et al*[41] generated TVA transgenic mice, in which TVA was specifically expressed within the liver. Delivery of ALSV-A viruses encoding PyMT (mouse polyoma virus middle T antigen, an oncogene) to these mice at the age of 2-3 d, subsequently led to tumor formation by the age of 4-6 mo (in 17 of 26 mice). They also exposed TVA transgenic mice that were deficient for p53 to PyMT-bearing ALSV-A viruses. Interestingly, the tumor incidence in these mice was not increased, but 6 of 16 p53 null mice that had developed HCCs, showed lung metastases (in contrast with 1 of 17 p53 wild-type mice). Consequently, this mouse model might be of value as a metastatic HCC model. Moreover, this model can be easily used to study the effect of other oncogenes in hepatocarcinogenesis, through the delivery of other oncogene-bearing ALSV-A viruses to TVA transgenic mice.

In addition, Lou *et al*[42] created mice with a regulated expression of liver-specific SV40 T-Ag. The SV40 T-Ag in these mice is preceded by a stop signal flanked by *loxP sites*. Hence, the SV40 T-Ag is expressed upon Cre-mediated excision, either by adenoviral expression of Cre recombinase or by administration of tamoxifen to mice that are transgenic for a liver-specific tamoxifen-inducible Cre. HCCs were observed in mice 5 mo after administration of adenoviral Cre recombinase or tamoxifen.

Several research groups employed alternative recombinase-mediated conditional gene-mutation strategies[32,33,43]. Colnot *et al* generated a mouse strain in which exon 14 of both *Apc* (adenomatous polyposis coli) alleles were flanked by *loxP* sites. The *Apc* alleles become invalidated (leading to β-catenin signaling) upon liver-targeted expression of Cre recombinase. Of these mice, 67% develop HCCs 8-9 mo after Cre recombinase administration[32,33].

Promising results have been published with these and other conditional mouse models to induce HCC-formation. Nonetheless, to date, these models are mainly used to study the effect of genetic alterations (mutation, deletion, or overexpression of a certain gene) on hepatocarcinogenesis and not to induce HCCs.

VIRAL HEPATOCARCINOGENESIS

More than 80% of HCCs in humans are attributable to infection with either hepatitis B virus (HBV) or hepatitis C virus (HCV) or both[44]. HBV- and HCV-related HCC are characteristically preceded by liver cirrhosis, though this is not always the case[45]. It may take more than 20 years for HCC to develop in HBV or HCV infected persons. For this reason, hepatocarcinogenesis due to viral hepatitis probably requires multiple steps of genetic alterations.

Finding the molecular mechanisms that drive these multiple steps by using cell-culture and non-genetic animal models is difficult. Therefore, in the past decades various animal models for investigation of viral hepatitis were developed. One problem in establishing such a model is that HBV and HCV require human hepatocytes to induce hepatitis, due to the stringent human tropism of these viruses[46,47].

In HBV research the finding of HBV-related viruses, e.g. the woodchuck hepatitis virus (WHV) and the ground squirrel hepatitis virus (GSHV), has provided opportunities for *in vivo* studies[46,48]. Another approach

for studying hepatitis B and C infection is the use of immunocompromised mice or rats. Recently, several animal models have been developed in which human hepatocytes or human liver tissue are transplanted into these animals. The transplanted hepatocytes in these animals can be infected with HBV or HCV *in vivo* or *ex vivo*. Alternatively, an already intrinsically infected specimen is transplanted[46,47]. These models are promising for the evaluation of therapeutics and prophylactics against hepatitis due to HBV or HCV, but are not useful to study HBV- or HCV-associated HCC. For that purpose, transgenic mice expressing HBV or HCV proteins represent a better model. In this section, the most frequently used transgenic mouse models for studying HBV- and HCV-associated HCC will be discussed.

By means of these models, two pathways have been proposed that might participate in the hepatocarcinogenic effect of chronic viral hepatitis. First, it is considered that chronic inflammation of the liver, continuous cell death and subsequent chronic hepatocyte regeneration due to viral hepatitis might increase the incidence of genetic alterations[48-53]. The second pathway encompasses a direct oncogenic effect of HBV or HCV on the infected hepatocyte. In the case of HBV (a DNA virus), this carcinogenic effect is believed to be accomplished through cis-activation or trans-activation of cellular genes. In cis-activation, genomic instability is a result of integration of HBV DNA into the host genome. In trans-activation, HBV proteins activate transcription of the HBV genome and host genes by binding to cellular sequences[48,50,51]. For HCV, a direct cytopathic effect has also been reported. As HCV is a RNA virus, it cannot integrate into the host genome. Therefore, other pathways must be of importance[52,53].

As a consequence of the chronic inflammatory state of the infected liver and the direct oncogenic effects of the hepatic viruses (as mentioned before), genetic alterations occur in various cellular pathways, which might eventually lead to the development of HCC. HBV proteins have been shown to manipulate the *p53*-, *Rb*-, *cyclinD1*- and *p21*-genes[51]. HCV is frequently associated with mutations of p53 and β-catenin[52,53].

HEPATITIS B VIRUS-ASSOCIATED HCC

Approximately 380 million people are chronically infected with HBV. These chronic HBV infected people have a 100-fold greater lifetime risk of developing HCC in comparison with non-carriers[3]. For this reason, HBV infection is the leading risk factor for the development of HCC. Worldwide, over 50% of HCC cases are associated with chronic HBV infection and the highest incidence of HCC is in South East Asia and sub-Saharan Africa, regions with a high prevalence of HBV infection[44,54].

As early as 1985, the first transgenic mouse models for investigating HBV infection were developed[55,56]. HBV transgenic mice have been created with the full HBV genome and with every single HBV gene, namely those encoding for the surface envelope proteins (large, middle and small), X protein (HBx), core and precore proteins.

It did not take long before the first transgenic mouse models for evaluation of HBV-associated hepatocarcinogenesis appeared. Until now, merely the large envelope protein and the HBx protein have displayed a carcinogenic role[48,57].

Chisari *et al*[58] described a mouse model in which transgenic mice were generated that carried an integrated HBV DNA fragment coding for the HBV large envelope polypeptides on a C57BL/6 genetic background. As a result, non-secretable hepatitis B surface antigen (HBsAg) particles formed that accumulated in the endoplasmic reticulum of the hepatocyte. In mice with 100% of the hepatocytes expressing HBsAg (lineage 50-4), liver injury begins at 2-3 mo of age; at 6 mo regenerative nodules appear and from the age of 15 mo HCCs develop.

Another HBV gene that has been extensively studied is the HBx gene. Though several research groups could not find evidence for a hepatocarcinogenic role of HBx in HBx transgenic mice[54,59], Kim *et al*[60] did report such a role in 1991. They produced HBx transgenic mice by injection of HBV DNA containing the HBx gene into single-cell embryos from CD1-mice. In these mice, liver tumors began to emerge after 8-10 mo. Both male and female transgenic mice died early in comparison with control CD1 mice, at the age of 11-15 mo *vs* 17-21 mo, respectively. On autopsy, 80%-91% of male transgenic mice and 60%-67% of female transgenic mice showed one or multiple HCCs. Yu *et al*[61] generated transgenic HBx mice using the same technique as Kim *et al*[60], but in a C57BL/6 genetic background and with a much weaker HBx expression in the liver. They reported an incidence of grossly identified HCCs and small neoplastic nodules, without signs of cirrhosis or inflammation, in 86% of 11-18 mo old HBx transgenic mice.

Possible explanations for the different outcome in transgenic mouse models for the hepatocarcinogenic role of HBx, may include a difference in mouse strains that were used. Male mice of the CD-1 strain develop spontaneous HCC in 5.7%[62], an incidence that is somewhat higher than the rate in for instance C57BL/6J mice (< 4.0%)[61]. In addition, the expression level of HBx-mRNA in the livers of transgenic mice and the type of HBx used may be different in the various studies. Finally, the integration site of HBx in the genome of the mice might influence the hepatocarcinogenic effect of HBx[57,61,63].

Efforts have been made to accomplish a model in which complete HBV genome transgenic mice demonstrate HCCs. Thus far, this has not been successful[63,64].

Nowadays, models based on the HBsAg transgenic mouse model of Chisari *et al* and the HBx transgenic mouse model of Kim *et al*[60] are commonly used to study mechanisms involved in hepatocarcinogenesis. These models are also applied to study possible synergistic relations between chemical carcinogens (such as aflatoxin B1 or diethyl nitrosamine) and HBV-infection[65-67]. Another application is the use of bitransgenic mouse models, in which mice are produced that are transgenic for a gene

of interest (such as *c-myc* or *TGF*-α) in conjunction with HBsAg or HBx[48,68,69]. For instance, Jakubczak *et al*[68] produced bitransgenic mice by pairing HBsAg transgenic mice described by Chisari *et al* to TGF-α transgenic mice. At 8 mo of age, 76% (13 of 17) of male bitransgenic mice developed HCCs, while TGF-α transgenic control mice showed HCC in only 6% (1 of 17) and HBsAg transgenic control mice in 0%. These bitransgenic mouse models can be used to investigate the effect of a particular gene on HBV-induced hepatocarcinogenesis.

HEPATITIS C VIRUS-ASSOCIATED HCC

Worldwide, approximately 30% of HCC cases are related to chronic HCV infection, making HCV the second most frequent cause of HCC[44]. In some areas, like Southern Europe and Japan, HCV infection is the strongest predisposing factor for HCC[70]. Patients infected with HCV have a risk of up to 35% for developing liver cirrhosis[47,70]. Thereafter, the cumulative risk of developing HCC in these cirrhotic patients is 1%-7% per year. HCC is the most frequent cause of death in HCV infected persons[47,70,71].

Various HCV proteins have been expressed in transgenic mice to study the pathogenesis of HCV-associated HCC, particularly the HCV polyprotein, the core protein and the core protein in combination with E1 and E2 envelope proteins. Interestingly, the expression of the core protein of HCV seems to be the major factor contributing to the hepatocarcinogenic effect of HCV infection, as transgenic mice that do not express this protein, no HCCs arise[47,52].

Moriya *et al*[72] were the first to describe such a transgenic mouse model. They generated transgenic mice that carried the HCV core gene. These mice showed histological features of steatosis in the liver, without inflammation, from the age of 3 mo and showed HCCs with close histological resemblance of HCCs in human chronic HCV infection, by the time they were 16 mo old. The incidence of HCC in 16-19 mo old male transgenic mice was 26% to 31%, in contrast to a low incidence in the female transgenic mice, which is in accordance with the human situation[73]. By means of such transgenic mouse models numerous molecular and pathogenetic pathways have been investigated that have led to a better understanding of HCV-associated hepatocarcinogenesis.

To study the role of HCV proteins other than the HCV core protein in hepatocarcinogenesis, Lerat *et al*[74] developed full-length HCV polyprotein transgenic mice and compared them with transgenic mice encoding merely the structural HCV proteins (including the core and the E1 and E2 envelope proteins). HCCs occurred (exclusively in males) in 5 of 38 transgenic mice expressing the full HCV polyprotein and in 1 of 43 transgenic mice expressing the structural HCV proteins. These findings suggest that HCV proteins, other than the HCV core protein, may endorse development of HCC as well, because in these mice the HCV protein levels are much lower in the first group[74].

The HCCs that develop in the mouse models described by Moriya *et al* and Lerat *et al* show proper (histological) resemblance to the corresponding lesions in patients with HCV-associated HCC. In the model described by Lerat *et al*[74], tumors develop regardless of the absence of detectable levels of the expression of HCV proteins, mimicking the situation in HCV infected patients. Furthermore, constitutive HCV gene expression results in immunological tolerance to the HCV genes, allowing the study of the direct hepatocarcinogenic effect of HCV proteins in the absence of an immune response to the viral proteins[52,74]. Disadvantages of these models are the possible significance of the genetic background of the mice and the relative unpredictability of HCC formation.

As described above for HBV, the HCV transgenic mouse models of Moriya *et al*, Lerat *et al* and comparable models, are presently used to study carcinogenic mechanisms in HCV-related HCC. In addition, these models are applied to study relations between carcinogens (like DEN) and HCV-infection in inducing HCC[75,76]. Furthermore, bitransgenic mouse models have been developed to investigate the effect of a particular gene on HCV-induced hepatocarcinogenesis.

CONCLUSION AND FUTURE PERSPECTIVES

Mouse models in cancer research are developed to imitate human carcinogenesis. Although the ideal animal model does not (yet) exist, mouse models can imitate parts of human carcinogenesis. To date, different types of mouse models are available to induce HCC, varying in complexity. The most appropriate model for a particular research question should be chosen to answer that specific question. Each approach has its own advantages and disadvantages, which are discussed in this review.

First, carcinogen-induced models are used to identify chemicals that might be carcinogenic to humans. Furthermore, these models are used for establishing a relationship between carcinogen exposure and specific genetic changes. In HCC, DEN is especially used to induce HCC. Major disadvantages remain the influence of sex, age and genetic background of the mice on the predictability of HCC-development. Moreover, there is a species difference in the response to hepatocarcinogens between humans and mice.

Next, because of their suitability, implantation models are still frequently used for the screening of different types of anticancer drugs. Nonetheless, these models have a poor predictive value for the anti-tumor effects in patients. This is probably the consequence of culturing the tumor cells for a long period, which alters the molecular characteristics and the heterogeneity of the original tumor.

Agents tested in mice with subcutaneously implanted tumors, should always be tested in orthotopic models as well, because of the importance of the microenvironment on the biological behaviour of malignant cells.

HCC is a result of different genetic mutations. Con-

ventional transgenic mouse models have been developed to study the role of different genes in HCC formation and to study molecular features involved in hepatocarcinogenesis. Limitations of these models include the expression of the transgene in all hepatocytes (hence, the tumor microenvironment as well) and the presence of the genetic alterations during embryogenesis (which might activate compensatory pathways). To overcome these problems, conditional mouse models have been developed recently. To date, these models are mainly used to study the effect of genetic alterations and, unfortunately, not to induce HCCs. Genetically engineered mouse models are also used in studying the role of viral hepatitis in HCC formation, as HBV and HCV require human hepatocytes to induce hepatitis and, consequently, hepatitis-induced hepatocarcinogenesis.

Highly sophisticated genetically engineered mouse models will become increasingly available and will help to answer a variety of research questions. Nevertheless, significant differences between mice and humans have to be taken into account when interpreting the (molecular) mechanisms of hepatocarcinogenesis. The most familiar of these (interspecies) differences are the much longer telomeres in mice, due to persistent telomerase expression in mice (as opposed to limited or absent telomerase expression in humans). Humans also differ from mice in respect to, for instance, their metabolism and immune system. To extrapolate the results from cancer studies in mice to humans, humanized mice should be generated and used in (genetically engineered) mouse models in the future.

This will bring us one step closer to the ideal animal model for cancer research.

As mentioned above, the adequate mouse model will be used depending on the research question. However, whether the impact of a possible carcinogen is investigated, the development of anticancer drugs or the genetic background of HCC formation is studied, all experiments have the goal to reduce the prevalence of HCC.

Abstract

AIM: To study the mechanism by which *Helicobacter pylori* (*H pylori*) damages human gallbladder epithelial cells (HGBEC).

METHODS: *H pylori* isolated from gallbladder were cultured in a liquid medium. Different concentration supernatants and sonicated extracts of *H pylori* cells were then added to HGBEC in a primary culture. The morphological changes in HGBEC as well as changes in the levels of alkaline phosphatase (ALP), lactate dehydrogenase (LDH) and glutamyltransferase (GGT) were measured.

RESULTS: According to the culture curve of HGBEC, it was convenient to study the changes in HGBEC by adding *H pylori* sonicated extracts and *H pylori* culture supernatants. Both *H pylori* sonicated extracts and *H pylori* culture supernatants had a significant influence on HGBEC morphology, i.e. HGBEC grew more slowly, their viability decreased and their detachment increased. Furthermore, HGBEC ruptured and died. The levels of ALP (33.84 ± 6.00 *vs* 27.01 ± 4.67, $P < 0.05$), LDH (168.37 ± 20.84 *vs* 55.51 ± 17.17, $P < 0.01$) and GGT (42.01 ± 6.18 *vs* 25.34 ± 4.33, $P < 0.01$) significantly increased in the HGBEC culture supernatant in a time- and concentration-dependent. The damage to HGBEC in *H pylori* culture liquid was more significant than that in *H pylori* sonicated extracts.

CONCLUSION: *H pylori* induces no obvious damage to HGBEC.

INTRODUCTION

Cholecystitis can be caused by many factors[1-6], of which *Helicobacter pylori* (*H pylori*) has been reported to cause gallbladder mucosa injury in the colonial region and inflammatory reaction[7-9]. In this study, in order to ascertain if the damage to gallbladder mucosa relates to *H pylori*, we explored the damaging effect of *H pylori* on human gallbladder epithelial cells (HGBEC) using an enriched liquid and a primary culture of HGBEC to show that *H pylori* is an important clinical etiological factor leading to cholecystitis.

MATERIALS AND METHODS

Materials

H pylori colonies extracted from the gallbladder were selected and transferred to a modified Brucella broth liquid medium, with a density of up to 10^7/L, and placed into a triangular filter which was then sealed with a vacuum lipid and connected to a rubber tube for air exchange. The rubber tube was clipped with hemostatic forceps so that the oxygen inside the filter was maintained at 50 mL/L. The rubber tube was then immobilized in a type THI-82 homeothermia oscillator (Shanghai Yuejin Medical Instrument Corporation) at 37℃, 150 r/min, and observed with regard to bacterial opacity at 24, 48 and 72 h. The extracted bacteria were used to determine the A660 value using a 721

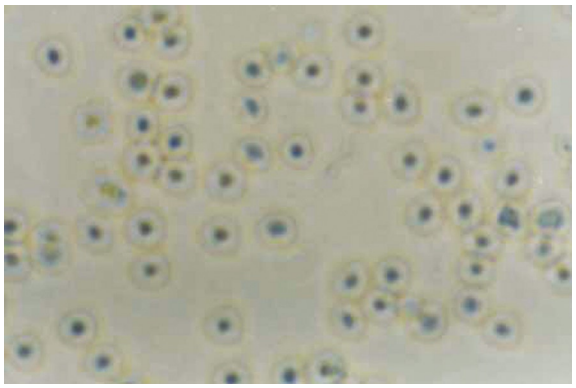

Figure 1 Culture of normal human gallbladder epithelial cells (HGBEC) (x 400).

spectrophotometer (1.0 A660 was approximately equal to 1×10^{11}/L) and the density of *H pylori* calculated. The bacterial status was observed *via* smeared Gram staining. The optimal growth period of *H pylori* was determined by the density and morphology of the bacteria. Thereafter, the liquid culture was terminated to allow the bacteria to adjust to 10^{11}/L for centrifugation, after which supernatants and precipitates were collected and frozen at -30℃ until use. *H pylori* grew well in the liquid culture medium and reached a live bacterial density of 10^{12}-10^{13}/L after shaking for 24-48 h, when the bacterial morphology was typical, but was atypical with less live bacteria and many spheroids after 72 h. Therefore, *H pylori* cultivated for 48 h was considered suitable for this study. HGBEC during their optimal growth period (6 d after primary culture) taken from the HGBEC growth curve was considered suitable for this study[10] (Figure 1). HGBEC cultured and supplemented with Brucella broth were used as controls.

Methods

An enriched liquid containing 10^{12}/L of *H pylori* was diluted to 10^{11}/L of *H pylori* using ultrapure water. The collected supernatants, following centrifugation, were diluted to a final density of 1/10 and 1/100 using ultrapure water, filtered using a 0.22 μm filter coat and frozen at -70℃ until use. The supernatants and ultrapure water were used to dilute the bacteria to a density of 10^{11}/L, where an ultrasound cell breaker, with an output of 80 W for 1 min/time was employed, until Gram staining showed that all *H pylori* were broken. *H pylori* were diluted to 1/10 and 1/100, filtered using a 0.22 μm filter coat and frozen at -70℃ until use. At the bacterial logarithmic growth period, different concentrations of supernatants from enriched *H pylori*, *H pylori* break liquid as well as Brucella broth, each 150 μL, were added and the morphological and anchoring changes in the cells were observed on days 1, 2, 3 and 4. Supernatants of the cell culture were kept at -30℃, and the cells were collected at the most typical stage and immobilized with 30 g/L glutaral for electron microscopic observation. Finally, assays to determine the levels of alkaline phosphatase (ALP), lactate dehydrogenase (LDH) and glutamyltransferase (GGT) in the cell culture supernatants were performed. The results were expressed as nKat/L.

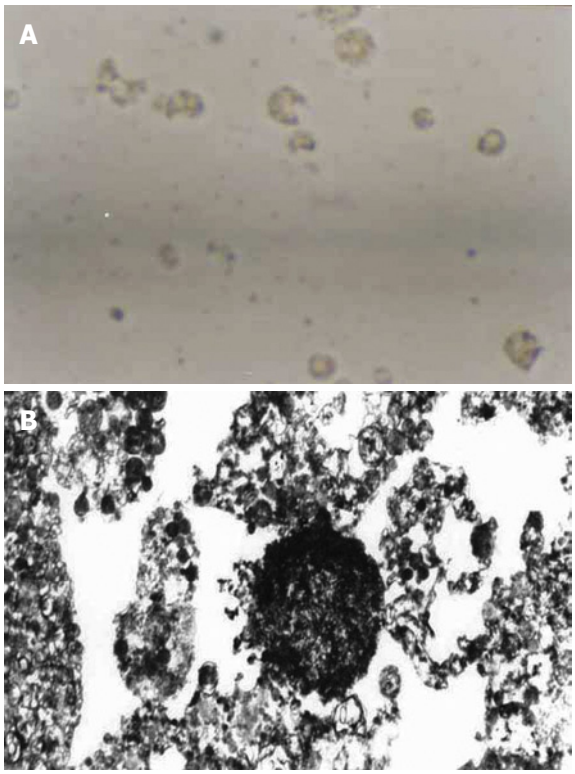

Figure 2 Four d after addition of enriched *H pylori*. A: dead HGBEC (x 400); B: HGBEC characterized by karyopyknosis, vacuoles and incomplete cell structure (x 6000).

Statistical analysis

SSAP 10.0 software was used for statistical analyses. Data were processed using the Student's *t* test and expressed as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

Morphological changes in HGBEC

From the second day after addition of *H pylori* supernatants, electron microscopy showed that cell division decreased and the anchored HGBEC loosened leading to dissociation. On day 3, the cell number significantly decreased, with rarefaction of the cytoplasm, reduced cell division, significant vacuoles, slow motion and deepened nuclei chromatin. On day 4, the cells ruptured into fragments and shrank, showing karyopyknosis, light color and different sizes, loss of adhesiveness and increased cell death (Figure 2A). The addition of diluted supernatants of *H pylori* to HGBEC alleviated the cell damage and prolonged survival time and anchoring time compared with HGBEC with added primary *H pylori*. The addition of 1/100 *H pylori* supernatants did not significantly change cell morphology, suggesting that the addition of 1/100 *H pylori* supernatants induced no obvious damage to HGBEC. The cell changes in the controls (Brucella broth added) were in accordance with the growth of

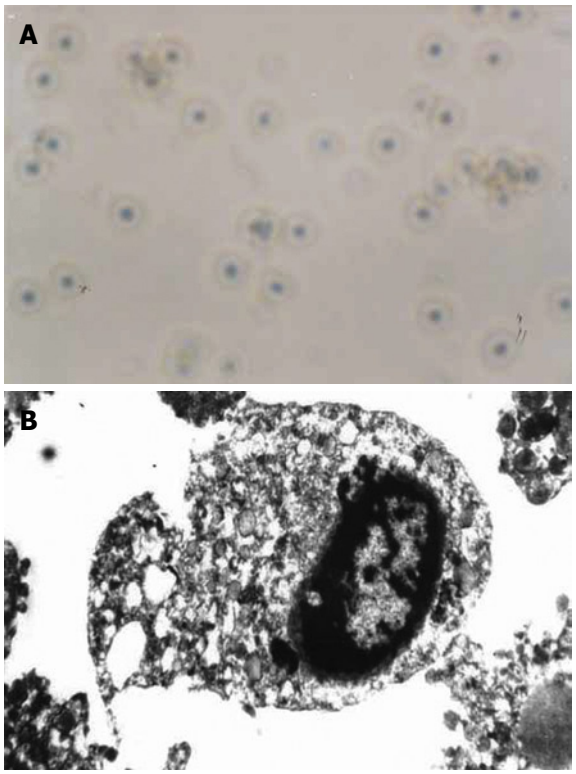

Figure 3 Four days after addition of *H pylori* sonicated extracts. A: Most HGBEC were normal, however, a few HGBEC died (x 400); B: Basically normal HGBEC and some cellular plasm under the vacuole (x 6000).

HGBEC receiving no other substance, i.e. at day 7, cell vitality was reduced, cell number decreased, and on day 14, all cultured HGBEC died. Electron microscopy showed the following characteristics in HGBEC supplemented with primary *H pylori* supernatants for 3 and 4 d. Cells were scattered and reduced in size, with rarefaction and swelling of the cytoplasm, mitochondrion swelling, myelin sheath changes and obvious vacuoles as well as karyopyknosis, assembled chromatin scattered to blocks, incomplete structure of cell nuclei and nuclear membrane in some regions, and even a dense body formed by the whole cell nuclei and hence the cell nuclei disappeared, leading to broken cells (Figure 2B). It was shown that *H pylori* supernatants had a significant damaging effect on HGBEC in a time- and dose-dependent manner, resulting in obvious vacuoles.

From the second day after the addition of sonicated extracts of *H pylori*, electron microscopy showed that the primary HGBEC had decreased cell division and had insignificant morphological changes. At day 3, the anchored cells were dissociated, with slow motion of free cells, morphological changes, decreased numbers, increased vacuoles, loss of HGBEC adhesiveness, cell malformation, karyopyknosis and even cell rupture or death, which was less than HGBEC exposed to *H pylori* supernatants with regard of injury severity. Sonicated extracts of *H pylori* at 1/10 exerted a slight damaging effect on HGBEC, but at 1/100 showed an insignificant damaging effect (Figure 3A). Under the electron microscope, the cells had irregular morphology and were reduced in size, with cytoplasm rarefaction, vacuoles, dilatation of endoplasmic reticulum and mitochondria, reduced nuclei, aggregation of chromatin and even cell rupture and death, which resulted in a slightly more overall damage compared with *H pylori* supernatants (Figure 3B).

Enzymological changes in HGBEC culture supernatants

In comparison with the controls, the three enzymological indices were significantly higher following the addition of different concentrations of enriched liquid into the HGBEC culture supernatants ($P < 0.01$) and still higher on days 2 and 3 following the addition of 1/10 enriched *H pylori* ($P < 0.01$). However, only the values for LDH and GGT were significantly higher on day 4 than those for the controls ($P < 0.01$). There were no significant differences with respect to the enzymological indices in the supernatants after the addition of 1/100 enriched *H pylori*, compared with the controls ($P > 0.05$). With the addition of the stock solution of enriched *H pylori* and 1/10 diluted fluid, the enzymological indices in the supernatants gradually increased with time ($P < 0.01$) with exception on days 3 and 4 (Figure 4).

ALP, LDH and GGT in the supernatants of the HGBEC culture significantly increased 2, 3 and 4 d after the addition of sonicated extracts of *H pylori*, compared with the controls ($P < 0.01$). The addition of 1/10 and 1/100 sonicated extracts of *H pylori* produced an insignificant effect on the enzymological indices in the supernatants ($P > 0.05$). From the second day after the addition of the stock solution of *H pylori*, the levels of ALP, LDH and GGT increased each day ($P < 0.01$) with the exception on days 3 and 4 ($P > 0.05$) (Figure 5).

The above-mentioned results showed that the supernatants of enriched *H pylori* significantly affected the enzymological indices of cultured HGBEC supernatants. The effect of *H pylori* on cell damage and permeability weakened with the gradual decrease in concentration of *H pylori* supernatants. The sonicated extracts of *H pylori* had similar effects, but were far weaker than those of the enriched *H pylori* supernatants.

DISCUSSION

The addition of enriched *H pylori* supernatants resulted in a rapid decrease in cell division, motion and adhesiveness of HGBEC, with obvious vacuoles, cell rupture and necrosis, and even cell death. The sonicated extracts of *H pylori* had similar effects, but were weaker. The reasons for the above changes may be that *H pylori* poisonous substances which permeate the liquid medium so that the supernatants of enriched *H pylori* contain many poisonous substances or metabolites when *H pylori* are under continual oscillation. When the supernatants enter the cultured HGBEC, the poisonous substances exert effects on the HGBEC which damage the cell membrane, increase permeability, induce rarefaction of cytoplasm, vacuoles, dilatation of mitochondria and endoplasmic reticulum, nuclei membrane and nuclei, leading to a decrease in cell division, disordered metabolism and even cell disruption and death[11-12]. The rarefaction of cytoplasm and

obvious vacuoles seen under the optic microscope and electron microscope are due to the actions of *H pylori* and other cells such as HeLa cells and hepatocytes, which contain vacuolating cytotoxin A (VacA)[13-14]. After VacA disrupts the function of the ion transport protein, which in turn affects the motion of the ion transport protein in HGBEC. The new vacuoles mainly consist of cell endoplasmic reticulum fused with lysosome. The formation of vacuoles in cells is a result of self-phagocytosis. Another *H pylori* toxin, cytotoxin-associated protein (CagA) has a high homogeneity with sodium passage and can affect the sodium pump of HGBEC which results in cell swelling, disruption and even death. We have hypothesized that the damaging effect of *H pylori*, isolated from gallbladder, on HEBEC and epithelial cells of gastric mucosa, is similar with respect to the method of action, i.e. by way of enzymes, toxins like VacA and CagA, urease, lipase, phospholipase A, hemolysin and lipopolysaccharide of *H pylori*[15-19]. In addition, *H pylori* may damage the epithelial cells of gallbladder mucosa and eventually result in cholecystitis by activating inflammatory cells and secreting inflammatory medium as well as by cellular immunity, humoral immunity and autoimmunity[20-22]. The toxic factors in *H pylori* can activate factors inhibiting cell proliferation, promote the expression of regulatory genes like *bcl-2*, *bax* and *fas* and finally induce cell apoptosis[11], which is consistent with the apoptosis we observed in HGBEC. The reason why the sonicated extracts of *H pylori* had a weaker damaging effect on HGBEC than the enriched *H pylori*, is probably because the main toxic factor within the sonicated extracts (lipopolysaccharide) is not a major toxic factor compared to VacA and CagA[23].

Determination of the ALP, LDH and GGT levels in HEBEC culture supernatants showed the

functional status of HGBEC and the integrity of cell membranous structures, as gallbladder epithelial cells containing ALP, LDH and GGT. Our study has clearly demonstrated that the addition of sonicated extracts or supernatants of *H pylori* to cultured HGBEC can, to a certain degree, raise the activity of these three enzymes in cell culture supernatants. With the decrease in cell vitality and enhanced disruption, the increased level of the three enzymes in cell culture supernatants was not due to cell function enhancement and an increase in enzyme synthesis, but to cell damage which resulted in the destruction of membranous structures and enzyme leaking into the supernatants, suggesting that the supernatants and sonicated extracts of *H pylori* can damage cell membranous structures, cause cell disruption and raise the levels of ALP, LDH and GGT in cell culture supernatants. The assayed enzyme levels in cell culture supernatants increased with time, with the exception on days 3 and 4, which reflected the increased enzyme leakage from the cells with aggravated HGBEC injury. Following cell disruption and death, the enzymes in the cells leaked and the content showed no increase in the cell culture supernatants, suggesting that *H pylori* can damage gallbladder epithelial cells and may be one of the factors leading to clinical cholecystitis.

Abstract

AIM: To investigate and evaluate the feasibility of the computer-aided screening diagnosis for enteric lesions in the capsule endoscopy (CE).

METHODS: After developing a series of algorithms for the screening diagnosis of the enteric lesions in CE based on their characteristic colors and contours, the normal and abnormal images obtained from 289 patients were respectively scanned and diagnosed by the CE readers and by the computer-aided screening for the enteric lesions with the image-processed software (IPS). The enteric lesions shown by the images included esoenteritis, mucosal ulcer and erosion, bleeding, space-occupying lesions, angioectasia, diverticula, parasites, etc. The images for the lesions or the suspected lesions confirmed by the CE readers and the computers were collected, and the effectiveness rate of the screening and the number of the scanned images were evaluated, respectively.

RESULTS: Compared with the diagnostic results obtained by the CE readers, the total effectiveness rate (sensitivity) in the screening of the commonly-encountered enteric lesions by IPS varied from 42.9% to 91.2%, with a median of 74.2%, though the specificity and the accuracy rates were still low, and the images for the rarely-encountered lesions were difficult to differentiate from the normal images. However, the number of the images screened by IPS was 5000 on average, and only 10%-15% of the original images were left behind. As a result, a large number of normal images were excluded, and the reading time decreased from 5 h to 1 h on average.

CONCLUSION: Though the total accuracy and specificity rates by the computer-aided screening for the enteric lesions with IPS are much lower than those by the CE readers, the computer-aided screening diagnosis can exclude a large number of the normal images and confine the enteric lesions to 5000 images on average, which can reduce the workload of the readers in the scanning of the images. This computer-aided screening technique can make a correct diagnosis as efficiently as possible in most of the patients.

INTRODUCTION

Depiction of the small intestines has still been a challenge because of their length and tortuosity. In the past time when some lesions occurred in an intestinal segment, they were usually difficult to identify because of a shortage of the efficiently used tools[1,2]. When the capsule endoscopy (CE) was introduced to the clinical practice in 2000, it became a revolutionary diagnostic tool in diagnosing small intestinal diseases[3]. Besides, there is growing evidence that CE may be used in diagnosing some diseases occurring in the colon and the esophagus[4,5]. Because of the incapability of its use in the insufflation, affusion, biopsy and therapy, when

compared with the balloon or push enteroscope[6-8], CE still has some limitations in diagnosing and treating the enteric lesions[9]; however, the patients are willing to accept it because it is painless and noninvasive. It is also much superior to the small intestinal radiology in management of some diseases[10].

CE is virtually a microcamera, which can create 2 images/s in the human gastrointestinal (GI) tract, obtain 40-60 thousand images of the GI lumen from the mouth to the anus before its batteries are exhausted[5].

The principal task of the CE readers is to scan all the images and find out what diseases occur in the GI tract, especially those occurring in the small intestines, because they cannot be detected by the routine gastroscopy or colonoscopy. So, the screening task is a heavy burden on the readers because there is a large number of images for them to screen. Though the number of the images for the lesions is smaller than 500 in most of the patients, the CE reader still has to scan ten thousands of the images one by one because the reader cannot make sure which images the lesions are in. As a rule, it would take 4-6 h at least for two readers (2-3 h for each reader) to finish this tiring work in our trial, and the 4-6 h was only the time for the two readers to finish scanning the images once. If there were some doubts and suspicions, much more time would be spent in repeating the scanning, which might do a great harm to the readers' eyes. In order to solve this problem, the high-speed reading (HSR) technique is the commonly-used method at the present time[11], and the reading time can be decreased to 0.5-1 h for one reader[12], but the work intensity is much greater, and some lesions may be missed, too[12,13]. So, if the computer-aided screening diagnosis with image-processed software (IPS) can be used to identify the images for the enteric lesions from a large number of the images that contain the normal ones, it will greatly decrease the workload of the readers for doing this kind of work and make a correct diagnosis as soon as possible.

However, the previous studies showed that the computer-aided diagnosis could not be as accurate as the one made by the reader because of the complexity and multiformity of the lesions in the GI tract[14]. So, our research focused on the feasibility of "screening" the normal images. After the exclusion of a large number of the normal images with the help of IPS, the remaining images can efficiently be evaluated; whether the images indicate the confirmed lesions or indicate only the suspected lesions, they can efficiently be preserved for a further diagnosis.

MATERIALS AND METHODS

Image-sample collection and pretreatment

All the images, derived from the CE produced by OMOM Capsule Endoscopic Company (OCEC), Chongqing City, China, were obtained from the Endoscopic Center of West China Hospital of Sichuan University or provided by OCEC directly. Two hundred and eighty-nine patients, with a median age of 54.2 years (range, 17-83 years), were included. All the patients finished the CE examination without any capsule retention. No lesions were found in 86 of the patients, but 1 lesion was found in 182 patients, 2 in 12 patients, 3 in 6 patients, and 4 in 3 patients. The enteric lesions included esoenteritis, mucosal ulcer and erosion, bleeding, space-occupying lesions, angioectasia, diverticula, parasites, *etc* (Table 1). All the images would be converted to the bitmap (BMP) format directly before they were analyzed by IPS[15].

Table 1 Proportions of enteric lesions and non-lesions in 289 patients

Enteric lesion	No. of lesions and non-lesions	Proportion (%)
Non-lesion	86	26.7
Common lesion		
Esoenteritis	42	13.0
Mucosal ulcer and erosion	47	14.6
Bleeding	61	18.9
Space-occupying lesion	28	8.7
Angioectasia		
Telangiectasis	5	1.6
Angioectasia	32	9.9
Angioma	7	2.2
Rare lesion		
Diverticulum	3	0.9
Parasite	5	1.7
Enteric stenosis	2	0.6
Intussusception	2	0.6
Enteric lymphangiectasis	2	0.6
Total	322	100.0

Algorithm analysis

In every enteric image obtained by CE, all the pictorial contents could be grouped as one of the following three categories: enteric mucosa, enteric lesions, and enteric contents. Each of them had its own characteristic colors, coloring distribution or borderlines of the body to the surroundings, which might be distinguished from one another by the computer-aided IPS in most of the images. According to the Tricolor Theory, the color of every dot in the image consisted of three types of the primary pels: red (R), green (G) and blue (B), whose chromatic values varied from 0 to 255. The characteristic color (primary hue of the enteric mucosa was R, with a common value greater than 100 (average value, 150-200), which was different from that of the lesions or that of the contents in the small intestines in most of the images. Besides esoenteritis and bleeding, there was a series of algorithms developed to simulate the scanning of the human eyes to "screen" a large number of the images for the normal mucosa.

Algorithm principle

The first step was to decide the analyzed region in the image. The dots with an R value (Rv) less than 100 would be excluded because they formed the "dark region", which was hard to be discerned even by the human eyes (Figure 1A and B), and the remaining dots would be contained for the analysis.

The second step was to exclude the region of the

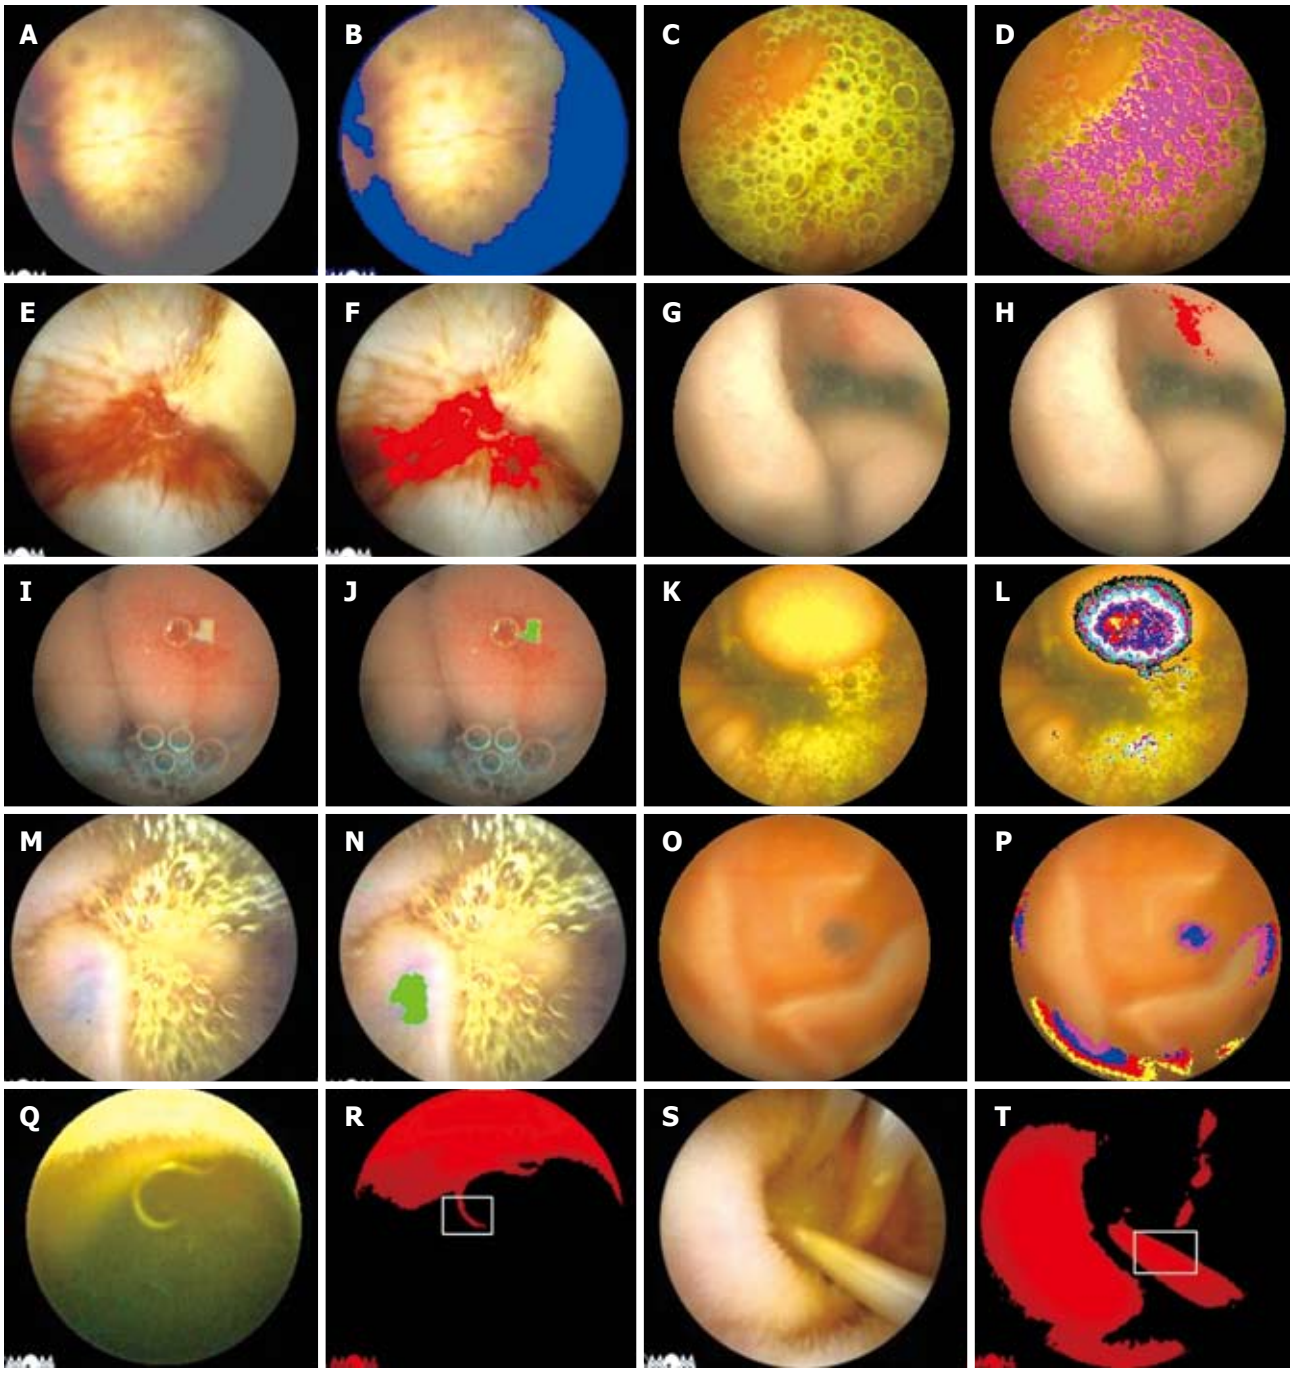

Figure 1 The screened results of enteric lesions by the IPS. A: Space-occupying lesions; B: The blue area in the image for the "dark region"; C: The enteric bile; D: The purple area in the image for the enteric bile; E: The enteric blood (bleeding); F: The red area in the image for the enteric blood; G: Esoenteritis; H: The red area in the image for esoenteritis; I: Mucosal ulcer; J: The green area in the image for mucosal ulcer; K: Space-occupying lesions; L: Different coloring circle in the image for space-occupying lesions; M: Venous angioma in the bright background; N: The green area in the image for venous angioma; O: Venous angioma in the dark background; P: The loop-closed distribution of Gv of the venous angiomain image; Q: Parasites (hook worms); R: The image of red components (Rv > 150) and the curvature of the double limits in the pane calculated; S: Parasites (ascarides); T: The image of red components (Rv > 150) and the linearity of the double limits in the pane calculated.

enteric contents, such as bile, spume *etc*., by their own characteristic colors.

In the bile region, Rv was less than 230, and the ratio of Rv to Gv was less than 1.1, which led to the characteristic color of yellow or green (Figure 1C and D); in the blood region, the usual Rv of the dots was less than 180 but greater than 120, the ratio of Rv to Gv was greater than 2, and the B value (Bv) was greater than 30 at least (Figure 1E and F).

The third step was to extract the characteristic colors and the coloring distribution of the common lesions in the small intestines.

In the region of esoenteritis, the Rv (> 180) of the dots was greater than Gv, and the remaining value subtracted Gv from Rv was greater than 60-70, and Bv varied from 60 to 90 (Figure 1G and H); furthermore, the difference (60-70) between Rv and Gv in the inflammatory region was greater than that (30-40) between

the background regions (mucosal regions) on average.

In the region of mucosal ulcer and erosion, Rv (> 170, < 200) was greater than Gv (> 150), but the remaining value subtracted Gv from Rv was less than 40, and Bv was greater than 100, so the mucosal ulcer and erosion in the image looked yellow and white appreciably, which was different from the color of the enteric bile. Rv in the region of mucosal ulcer and erosion was greater than that of the background region (mucosal region) by 30-40 on average (Figure 1I and J).

Generally speaking, in the region of space-occupying lesions, there was no characteristic color due to the lesions derived from the mucosal or submucosal tissues, but the space-occupying lesions had a characteristic protrusion into the enteric lumen, which led to a circular distribution of the degressive Gv, and Rv in the center of the circle was usually greater than 245 (Figure 1K and L).

Venous angioma was a special type of space-occupying lesions without any enteric protrusion, but it looked blue. In the bright background, the remaining value subtracted Gv from Rv (> 160, < 200) was less than 30, and Bv from Gv (> 150) less than 10 (Figure 1M and N). In the dark background, the remaining value subtracted Gv (> 70) from Rv (> 100, < 170) was less than 50. Bv was greater than 45, but the most important characteristic was that the lesion had the loop-closed distribution of Rv and Gv, which was different from that of the fringe of the image (Figure 1O and P).

Though the common parasites in the small intestines (Figure 1Q and S), mainly hook worms and ascarides, had no special body colors, but the double borderlines of the body to the surroundings (contour) usually existed clearly. Thus, a kind of the algorithm was developed to distinguish the parasites from the background mucosa or the enteric contents. Firstly, the chromatic pels of the parasites (Rv > 150, Gv > 120) in the bright visual field would be extracted. Secondly, as the double limits of the parasites in the extracted region had a similar curvature (hook worms) or linearity (ascarides), it could be calculated in some width and be judged by the software whether the parasites existed or not (Figure 1R and T). Finally, whether the screened results were accurate or not, the images about the esophagus, stomach and large intestine would be excluded if they were in the remaining images.

The rarely-encountered lesions, including diverticulum (Figure 2A), intussusception (Figure 2B), enteric stenosis (Figure 2C), enteric lymphangiectasis (Figure 2D), angioectasia (Figure 2E and F) *etc.*, because of the absence of characteristic colors or contours compared with the background mucosa, could not be picked out by the algorithm principles mentioned above, which will be explained in Discussion.

Supplementary algorithms

If there were several lesions in the image, the image processing would be terminated immediately for the saving of time if only one lesion or parts of the lesions were confirmed by any of the algorithms mentioned above.

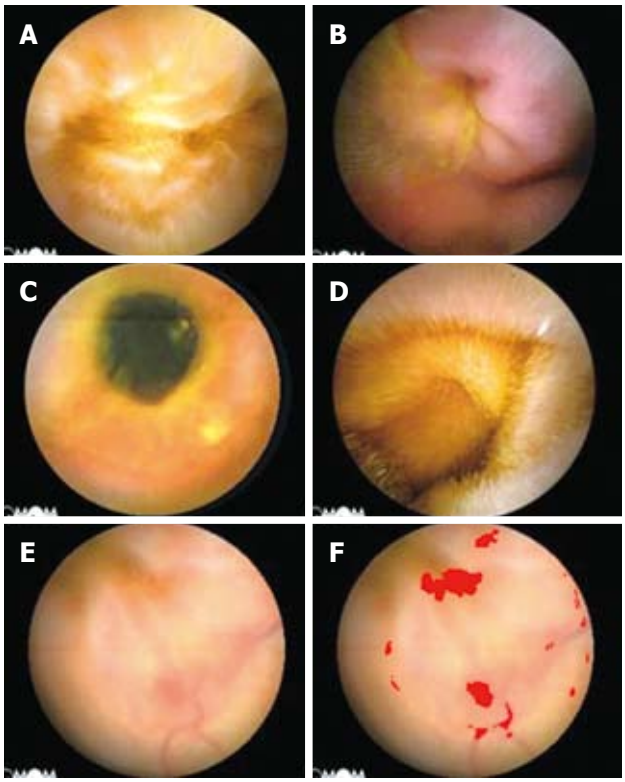

Figure 2 The enteric lesions not being recognised by the IPS. A: Enteric diverticulum; B: Intussusception; C: Enteric stenosis; D: Enteric lymphangiectasis; E: Angioectasia; F: The red area in the image for suspected bleeding, not angioectasia itself.

Software development and operation

IPS was developed and operated in the common personal computer (memory 1G, Intel® Pentium® Core 2 CPU 1.73GHz, Hard Disk 60GB at least), with Windows Operation System Xp or Vista® home basic.

Screening standard and evaluation

The gold standard for enteric lesions was the diagnostic conclusion drawn by the CE reader (the physician who reviews the CE study). In order to decrease the rate of misdiagnosis to a lowest extent, the primary images and the screened images by IPS from the same patient would respectively be scanned by two readers[13] with a speed of 20 000 images/h, and the marked images by IPS would be extracted out and ranked by the time-index in the images from the jejunum to the ileum, which would be scanned again by two readers and assessed whether those images of the lesions were preserved in the remaining images (screened results) and whether the lesions accorded with those of the readers' findings. If there was a series of continuous images of the confirmed lesions or the suspected lesions, only the first image and the last image would be marked out by IPS as shown by the index.

Inclusion standards for the screened results were: (1) A series of images for the lesions could be confirmed by IPS if one image was confirmed; (2) Only parts of the lesions in the images could be marked out by IPS.

Exclusion standards for the screened results were: None of the images for the lesions was picked out or

[b]*P* < 0.001, ST for the total images *vs* ST for the marked images by ISP in the group with lesions; [d]*P* < 0.001, ST for the total images *vs* ST for the marked images by ISP in the group without any lesions.

none of the marked parts in the images was the lesion itself.

Statistical analysis

Statistical analysis was performed using the SPSS software (ver.11.5). The correlation between two variables was evaluated using Pearson's χ^2, Fisher's exact test, and *u* test. Statistical significance was defined as $P < 0.05$.

RESULTS

Compared with the primary images in the left, the images in the right showed the suspected enteric lesions by different colors, such as red, blue, green, *etc.* (Figure 1F, H, J, L, N, P, R and T, and Figure 2F).

Screened results

In the 289 patients, the total number of the images varied from 41 358 to 62 874, with a median of 52 374 ± 4865 in the group with the confirmed lesions and 54 210 ± 3739 in the group without any lesions. Parts of the images in each patient were marked by at least one kind of color, and the number varied from 2353 to 18 732, with a median of 4156 ± 478 and 4219 ± 376, respectively, in the group with the lesions and the group without any lesions (Table 2). The mean time needed to read a CE study was 5.4 ± 1.2 h in the group with the lesions and 5.6 ± 1.3 h in the group without any lesions (Table 3). The mean time needed to read a CE study by a reader was 2.8 ± 0.7 h compared with the scanning time of 3.2 ± 0.6 h by IPS (most in 2.5-3.5 h, $P > 0.05$), and the number of the images for the lesions varied from 1 to 262 in the 236 patients.

For the common enteric lesions detected by CE, the effectiveness rate of the screened results (SRs) varied from 42.9% to 91.2%, with a median of 74.2%, but for the angioectasia and rare lesions, the effectiveness rate varied from 20% to 57.1%, with a median of only 22.9% (Table 4).

Table 4 Screened results (SR) of IPS in 289 patients

Enteric lesions	Effectiveness rate of SR (%)	False positive rate of SR (%)	*P*
Common lesion			
Esoenteritis	33/42 (78.6)	188/280 (67.1)	> 0.05
Mucosal ulcer/erosion	31/47 (66.0)	191/275 (69.5)	> 0.05
Bleeding	56/61 (91.8)	121/261 (46.4)	> 0.05
Space-occupying lesion	12/28 (42.9)	96/294 (32.7)	> 0.05
Angioectasia			
Telangiectasis	1/5 (20.0)	63/317 (19.9)	> 0.05
Angioectasia	3/32 (9.4)	37/290 (12.8)	> 0.05
Angioma	4/7 (57.1)	25/315 (7.9)	> 0.05
Rare lesion[1]	3/14 (21.4)	53/308 (17.2)	> 0.05

[1]The samples of the rare lesions were not enough, so they were pooled together for the research.

Table 5 Sensitivity, specificity, accuracy, positive/negative predictive value of SR for special lesions in 289 patients (%)

Enteric lesions	Sensitivity	Specificity	Accuracy	Positive pv	Negative pv
Common lesion					
Esoenteritis	78.6	32.9	38.8	14.9	91.1
Mucosal ulcer/erosion	66.0	30.5	35.7	14.0	84.0
Bleeding	91.8	53.6	60.9	31.6	96.6
Space-occupying lesion	42.9	67.3	65.2	11.1	92.5
Angioectasia					
Telangiectasis	20.0	80.1	79.2	1.6	98.4
Angioectasia	9.4	87.2	79.5	7.5	89.7
Angioma	57.1	92.1	91.3	13.8	98.9
Rare lesion[1]	21.4	82.8	80.1	5.4	5.9

pv: Predictive value. [1]Because the samples of the rare lesions were not enough, so they were pooled together for the research.

The screened results showed that the sensitivity rate (effectiveness rate of SRs) was higher than the specificity rate and the accuracy rate in the commonly-encountered lesions but lower in angioectasia and rarely-encountered lesions; the positive predictive value was low and the negative predictive value was high in all the lesions (Tables 4 and 5).

DISCUSSION

CE plays an important role in diagnosis of the small bowel diseases[16-18], such as bleeding[19-21], Crohn's disease[21-23], tumors[20], angioectasia[20], *etc.* With the bowel peristalsis, CE passes through the small intestines and takes pictures of the intestinal cavity, though the total number of the images in each patient can vary from 40 000 to 60 000, with a median of 50 000, and the definite

number of the images for the lesions is not greater than several hundreds in the patients. After the screening by the computer-aided diagnosis with the help of IPS, the number of the remaining images is only 10%-15% of the original ones (Table 2). Most of the lesions, especially the commonly-encountered enteric lesions, have been included and preserved, which can greatly reduce the workload on the readers and make an efficient diagnosis in most of the patients. However, one thing should be emphasized that the screened results provided by IPS are not the diseases themselves, but the lesions, because it was very difficult for IPS to make a diagnosis according to the lesions themselves just as the CE reader does; therefore, all the data in Table 4 only indicate the screening rates, not the diagnosis rates (Table 4).

The initial objective of this research was to make the diagnosis of the small bowel diseases directly, but the results were disappointing because of the complexity and the multiformity of the lesions. The complicated algorithm (Hidded Markov models, HMM[24,25] or artificial neural network, ANN[26-28]) was of a tryout. Though the diagnosis accuracy could be improved to some extent, the result was not satisfactory to the physicians, and the scanning time of IPS was much longer than that of the readers' performance; therefore, it could not be accepted in the clinical practice. So, we had to turn our steps just to "screening" the images for the lesions and making the normal images left behind. The results showed that about 75% of the images for the common lesions could be screened out and the scanning-time of IPS was limited to 2.5-3.5 h (average, 3.2 h) in most of the patients after the simple algorithms were used based on the characteristic colors, coloring distribution or contours, which proved its feasibility and availability in the clinical application in our trial.

Though a large number of the normal images were excluded and the reading time was decreased from 5 h to 1 h on average (Table 3), the total time (scanning time of IPS plus reading time of CE reader) spent on average in each CE study did not decrease significantly when compared with that of HSR. But with the development of the CE technology, when the IPS is installed in the image-receiver and the images can be analyzed directly just as the Personal Digital Assistant (PDA) does[29-31], the total time can be decreased.

As the images were taken by CE at random, CE could not control the azimuth angles and the luminosity as efficiently as the gastroscope or the colonoscope. As a result, the contrast between the diseased mucosa and the normal mucosa in some images was incorrectly changed. In the screened images, the great majority of the normal images (> 90%) were misdiagnosed (false positive) and some of the images for the lesions were missed out by IPS; therefore, the specificity, accuracy, and predictive value for the positivity were very low for most of the lesions (Table 5). Another problem of IPS was the deficiency of self-adjustment of the borderline between the diseased mucosa and the normal mucosa, which resulted in the fact that only part of the lesions in the image could be marked out (Figure 1F) or part of the normal mucosa was mistakenly marked out (Figure 2F). These were the reasons why the readers would scan the excluded images if they thought that the results obtained from IPS did not accord with the clinical manifestations of the patients given by the CE examination.

For the rarely-encountered lesions by CE, there was still a lack of an ideal discriminating algorithm. These lesions were not the main indications for the use of CE if much more time was consumed, the screening procession was prolonged and the clinical significance was lost. So, we did not develop any special algorithm aimed at those lesions. Another kind of the lesions, i.e., angioectasia, was difficult to be directly recognized because of the deficiency of characteristic colors and contours unless the lesions were accompanied by bleeding (Figure 2F). The proper algorithms have still been under development.

In conclusion, the result of this pilot study has indicated that the computer-aided screening diagnosis can be used as an efficient auxiliary measurement for the commonly-encountered enteric lesions when the images are taken by CE. We suggest that a further research should focus on improvement of the specificity rate and the screening rate for the rarely-encountered enteric lesions. If the robotistic and controllable CE[32] is used and more images with a better contrast are provided, the screening rate can be significantly enhanced.

COMMENTS

Background

Capsule endoscopy (CE), which is virtually a microcamera, is a revolutionary diagnostic tool in diagnosing small bowel diseases, and CE can obtain 40-60 thousand images of the GI tract, though the number of the images for the lesions is smaller than 500 in most of the patients. The CE reader still has to scan ten thousands of the images one by one because the reader cannot make sure which images the lesions are in. So, it may be a big burden on the CE reader's eyes and energy.

Research frontiers

In order to decrease the reading time, the high-speed reading (HSR) is the commonly-used method at present, the reading time can be decreased to 0.5-1 h for one reader, but the work intensity is much greater and some lesions may be missed.

Innovations and breakthroughs

In this pilot study, a kind of the image-processed software (IPS) aided by a computer was introduced to screen the large number of normal images, and only 10%-15% of the original images were left behind, of which most of the commonly-encountered lesions in the small intestines were preserved and diagnosed; therefore, the workload and the working time of the CE reader could be decreased significantly.

Applications

Though a large number of the normal images were excluded, and the reading time decreased significantly, the total time (scanning time of IPS plus reading time of a CE reader) spent on average in each CE study did not significantly decrease compared with that of HSR at present. But with the development of the CE technology and improvement of algorithms, when IPS is installed in the image-receiver and the images can be analyzed directly just as the Personal Digital Assistant (PDA) does, the total time can be decreased significantly.

Terminology

IPS is a kind of software installed in the computer workstation, which can identify the common lesions in the small intestines based on the characteristic colors and contours of the lesions. HSR system is a kind of software support system installed in the computer workstation, which can speed up the reading of the CE images.

Peer review

This article raises an interesting topic. Authors investigate and evaluate the feasibility of the computer-aided screening diagnosis for enteric lesions in the CE.

Abstract

AIM: To investigate the effects and possible mechanisms of Wy14643 on hepatic ischemia-reperfusion (I/R) injury in rats.

METHODS: Thirty male Sprague-Dawley rats weighing 220-280 g were randomly divided into five experimental groups: sham group (G1, *n* = 6): a sham operation was performed (except for liver I/R); I/R-untreated group (G2, *n* = 6): rats underwent liver ischemia for 90 min followed by reperfusion for 4 h; and I/R + Wy14643 groups (G3, G4, G5; *n* = 6): after the same surgical procedure as in group 2, animals were pretreated with Wy14643 at the dose of 1, 5 and 10 mg/kg 1 h before ischemia, respectively. Hepatic ischemia-reperfusion (I/R) was induced by clamping blood supply to the left lateral and median lobes of the liver for 90 min, and atraumatic clamp was removed for 4 h reperfusion. Blood samples and liver tissues were obtained at the end of reperfusion to assess serum and hepatic tissue homogenate aminotransferase (ALT), aspartate aminotransferase (AST), myeloperoxidase (MPO), serum interleukin-1β (IL-1β) and tumor necrosis factor alpha (TNF-α), as well as activity of superoxide dismutase (SOD) and content of malondialdehyde (MDA) in the hepatic tissue homogenate.

RESULTS: Hepatic I/R induced a significant increase in the serum levels of ALT, AST, TNF-α, IL-1β and MPO, as well as the levels of ALT, AST and MDA in the liver tissue homogenate, which were reduced by pretreatment with Wy14643 at the dose of 1, 5 and 10 mg/kg, respectively. The activity of SOD in the liver tissue homogenate was decreased after hepatic I/R, which was enhanced by Wy14643 pretreatment. In addition, serum and liver tissue homogenate ALT and AST in the Wy14643 10 mg/kg group were lower than in the Wy14643 1 mg/kg and 5 mg/kg groups, respectively.

CONCLUSION: Wy14643 pretreatment exerts significant protection against hepatic I/R injury in rats. The protective effects are possibly associated with enhancement of anti-oxidant and inhibition inflammation response.

INTRODUCTION

Interruption of hepatic inflow is a common procedure during trauma surgery, liver transplantation, and resectional surgery. However, the resulting period of hepatic ischemia and subsequent reperfusion can lead to liver injury and dysfunction through the initiation of a biphasic inflammatory response[1]. An excessive inflammation response is considered as a key mechanism of ischemia-reperfusion injury[2]. The acute phase of this response is characterized by activation of Kupffer cells and their subsequent production and release of reactive oxygen species, which may contribute to liver dysfunction and cell injury during reperfusion[3]. Proinflammatory cytokines, chemokines, and activated complement factors are responsible for neutrophil recruitment and the subsequent neutrophil-induced oxidant stress during the later reperfusion phase[4]. In addition, accumulated neutrophils release oxidants and

proteases that directly injure hepatocytes and vascular endothelial cells and may also obstruct hepatic sinusoids resulting in hepatic hypoperfusion[5].

Peroxisome proliferator-activated receptor-α (PPAR-α) is one of the three subtypes of the nuclear receptor PPAR family[6]. Activation of PPAR-α, by either natural ligands, such as polyunsaturated fatty acids and eicosanoids, or synthetic ligands, such as fibrates, Wy14643, stimulates target-gene transcription *via* the formation of heterodimeric transcription factor complexes with the retinoid X receptor[7]. PPAR-α has a wide range of effects on metabolism, cellular proliferation and the immune response[8]. Beyond metabolic effects, PPARα activation also induces anti-inflammatory and antioxidant effects in different organs. Several studies indicated that Wy14643 protected organs such as heart, kidney and brain against ischemia-reperfusion injury[9-12]. PPAR-α represses the expression of inflammatory-response genes *via* a mechanism termed ligand-dependent transrepression[13]. Direct binding of PPAR-α to NF-κB p65 was demonstrated by *in vitro* assays, suggesting that transrepression might be involved in direct interference with transcriptional activation by NF-κB, thus preventing the synthesis and release of cytokines (interleukin-1 and tumor necrosis factor α)[14,15]. Furthermore, PPAR-α activation induces the expression and activation of antioxidant enzymes such as superoxide dismutase(SOD), catalase and glutathione peroxidase[16,17]. PPAR-α is highly expressed in the liver, particularly in hepatic parenchymal cells, which can protect hepatocytes in the mice hepatic ischemia-reperfusion injury model[1]. But the effect of Wy14643 on hepatic ischemia-reperfusion injury was not clear. In the present study, we determined whether PPAR-α activation by the selective agonist Wy14643 may reduce hepatic I/R injury in rats through modulation of oxidative stress and inflammatory response.

MATERIALS AND METHODS

Chemicals

Wy14643, selective PPARα agonist, was purchased from Cayman Chemical (USA) and used as 1, 5 and 10 mg/kg homogenized in 20 mg/L ethanol *via* intraperitoneal (ip) route.

Ethanol was used to form a homogenized drug. Each dose was homogenized in 1ml ethanol and injected *via* ip. A previous study has found that 20 mg/L ethanol was not harmful to the liver[18].

Ethics and animals

Male Sprague-Dawley rats (weighing 220-280 g) were used in these experiments. Temperature and relative humidity were kept at 22 ± 2℃ and 50% ± 5%, respectively. All rats were obtained from the Center of Experimental Animals in Anhui Medical University. They were allowed free access to a commercial standard chow and water ad libitum before the experimental procedure began. All rats were acclimatized to our animal facility for at least 1 wk before experiment. Stressful stimuli were avoided. This project was approved by the Committee for Research and Animal Ethics of Anhui Medical University.

Experimental design

Rats were randomly divided into five experimental groups each containing six rats: (1) Sham (except for hepatic I/R), (2) Ischemia-reperfusion (I/R), (3) I/R + Wy14643 (1 mg/kg), (4) I/R + Wy14643 (5 mg/kg), and (5) I/R + Wy14643 (10 mg/kg). Partial hepatic ischemia was induced as described previously[1]. Briefly, each rat was weighed and anesthetized by intraperitoneal administration of 1.0 g/kg ethylurethanm. Anesthetized rats were placed onto a thermostatically controlled heating pad, a rectal temperature probe was inserted, and body temperature was monitored and maintained at 37℃. The abdomen was shaved and disinfected with 75% ethanol. A midline incision was performed; the first porta hepatis was exposed. An atraumatic clip was used to prevent blood supply to the left lateral and median lobes of the liver. After 90 min of partial hepatic ischemia, the clip was removed to recover hepatic reperfusion for 4 h. Sham control rats underwent the same protocol without vascular occlusion. Abdominal incision was closed in layers with 4-0 dexon and 2-0 nylon during reperfusion stage in order to prevent the loss of body fluid and quantity of heat.

Collection of blood and tissue samples

After 4 h of reperfusion, blood samples were drawn from aorta ventralis. The liver was carefully dissected out from its attachment, and totally excised. All rats were then sacrificed by hemorrhage. Blood samples were centrifuged with 4000 r/min for 15 min at 4℃, following collection of supernatant liquid, and were kept at -20℃ for biochemical analyses which were duplicated. Ischemia liver tissue was also divided into two parts, one part was fixed in 10 g/L glutaraldehyde to observe hepatic ultrastructure, the other part was snap frozen in liquid nitrogen. The samples were stored at -80℃ until assayed.

Ultrastructural assessment of liver tissue

Ischemia liver samples fixed in 10 g/L Glutaral, dehydrated, drying and surface gilding according to standard procedures. Electron microscope was used to assess the degree of hepatic damage.

Serum and hepatic tissue homogenate ALT and AST assay

Serum and hepatic tissue homogenate ALT and AST, a marker of hepatocellular injury, were measured using commercial available kit and the result was expressed as U/L as well as U/mg protein, respectively.

Total protein concentrations in liver homogenate samples were determined by the Coomassie blue method.

Serum and liver homogenate MPO assay

MPO activity in serum and hepatic tissue was detected by a spectrophotometric method, reflecting the number of polymorphonuclear neutrophils (PMN) in the liver.

This method uses 3, 3', 5, 5'-tetramethyl benzidine (TMB) as an oxidizable dye, and the reaction was started by adding hydrogen peroxide (H_2O_2) in the medium.

The assay kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Serum TNF-α and IL-1β assay

Serum TNF-α and IL-1β levels were determined with double antibody sandwich ABC-ELISA using a rat TNF-α and IL-1β kit method according to the manufacturer's instructions. The samples were compared with the standard curve and expressed as pg/mL. All assay kits were purchased from Shanghai Senxiong Technologyindustry Co. Ltd, China.

Hepatic tissue homogenate SOD and MDA assay

SOD activity was measured through the inhibition of nitroblue tetrazolium (NBT) reduction by O_2-generated by the xanthine/xanthine oxidase system. One SOD activity unit was defined as the enzyme amount causing 50% inhibition in 1 mL reaction solution per milligram tissue protein and the result was expressed as U/mg protein.

Liver homogenate malondialdehyde (MDA) concentration was measured using the thiobarbituric acid (TBA) method. The amount of lipid peroxides (LPO) was measured as the production of MDA, which in combination with TBA forms a pink chromogen compound whose absorbance at 532 nm was measured. The result was expressed as nmol/mg protein.

All assay kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Statistical analyses

All data were expressed as mean ± SD. The statistical significance of differences between groups was analyzed using the one-way analysis of variance (ANOVA) and methods of LSD with the SPSS11.5 for Windows XP statistical software package. The *P* values less than 0.05 were considered statistically significant.

RESULTS

Levels of serum and liver tissue homogenate ALT and AST

Liver function was examined by measuring serum and liver tissue levels of ALT and AST. Hepatic I/R caused a marked elevation of serum and liver tissue ALT as well as AST activity (serum ALT: 20 ± 4 U/L *vs* 485 ± 69 U/L, liver tissue homogenate ALT: 50 ± 10 U/mg protein *vs* 181 ± 16 U/mg protein, $P = 0.000$, $P = 0.000$, serum AST: 56 ± 5 U/L *vs* 252 ± 28 U/L, liver tissue homogenate AST: 20 ± 3 U/mg protein *vs* 46 ± 8 U/mg protein, $P = 0.000$, $P = 0.000$). The increase in serum and liver tissue homogenate ALT as well as AST activity induced by hepatic I/R was significantly attenuated by administration of Wy14643 at dose of 1, 5 and 10 mg/kg (serum ALT: 485 ± 69 U/L *vs* 386 ± 49 U/L, 259 ± 56 U/L, 139 ± 29 U/L, $P = 0.001$, $P = 0.000$, $P = 0.000$, liver tissue homogenate ALT: 181 ± 16 U/mg protein *vs* 164 ± 17 U/mg protein, 75 ± 13 U/mg protein, 47 ± 6 U/mg protein, $P = 0.031$, $P = 0.000$, $P = 0.000$, serum AST: 252 ± 28 U/L, 227 ± 30 U/L, 124 ± 19 U/L, 70 ± 8 U/L, $P = 0.048$, $P = 0.000$, $P = 0.000$, liver tissue homogenate AST: 46 ± 8 U/mg protein, 31 ± 7 U/mg protein, 22 ± 5 U/mg protein, 17 ± 4 U/mg protein, $P = 0.000$, $P = 0.000$, $P = 0.000$). The results demonstrated that Wy14643 has the dose-dependent protective effects on liver injury, and that alteration of ALT and AST activity in serum and liver tissue was coincident (Figure 1).

Ultrastructural alterations of liver tissue

The ultrastructural structure of cells was normal in the sham group. After 90 min of hepatic ischemia followed by reperfusion for 4 h, compared with the sham group, the occluded liver tissue from the I/R group was markedly damaged, with mitochondrion swollen, vacuolar degeneration and, mitochondrial crista destruction, marked decrease of rough endoplasmic reticulum and nucleus structure destruction under the electron microscope. Pretreatment of rats with 1, 5 and 10 mg/kg Wy14643 resulted in a significant amelioration of hepatic injury (Figure 2).

Levels of serum and liver tissue homogenate MPO

MPO activity in serum and liver tissue was detected, reflecting the number of polymorphonuclear neutrophils (PMN). The serum and liver tissue homogenate MPO activity was significantly increased after hepatic I/R compared with the sham group (serum MPO: 313 ± 55 U/L *vs* 574 ± 70 U/L, $P = 0.000$; liver tissue homogenate MPO: 0.23 ± 0.04 U/g *vs* 0.42 ± 0.06 U/g, $P = 0.000$). Pretreatment with Wy14643 at dose of 1, 5 and 10 mg/kg led to the marked reduction of MPO content compared with I/R group (serum MPO: 574 ± 70 U/L *vs* 479 ± 63 U/L, 334 ± 33 U/L, 365 ± 72 U/L, $P = 0.012$, $P = 0.000$, $P = 0.000$; liver tissue homogenate MPO: 0.42 ± 0.06 U/g *vs* 0.35 ± 0.05 U/g, 0.26 ± 0.02 U/g, 0.27 ± 0.03 U/g, $P = 0.010$, $P = 0.000$, $P = 0.000$). All these showed that Wy14643 reduced infiltration of leukocytes into the inflammatory sites (Figure 3).

Levels of TNF-α and IL-1β in serum

The TNF-α and IL-1β content was significantly higher after reperfusion in I/R group than in sham group (TNF-α: 1.37 ± 0.21 pg/mL *vs* 11.63 ± 1.11 pg/mL, $P = 0.000$; IL-1β: 78 ± 16 pg/mL *vs* 220 ± 30 pg/mL, $P = 0.000$), Pretreatment with Wy14643 1, 5 and 10 mg/kg resulted in the reduction in dependent-dose manner compared with the I/R group (TNF-α: 11.63 ± 1.11 pg/mL *vs* 10.83 ± 0.94 pg/mL, 9.89 ± 0.60 pg/mL, 9.29 ± 1.20 pg/mL $P = 0.132$, $P = 0.002$, $P = 0.000$; IL-1β: 220 ± 30 pg/mL *vs* 195 ± 27 pg/mL, 112 ± 17 pg/mL, 95 ± 20 pg/mL, $P = 0.070$, $P = 0.000$, $P = 0.000$) (Figure 3).

SOD activity in liver tissue homogenate

The levels of liver SOD lowered significantly after hepatic I/R compared with the sham group (SOD: 114.81 ± 1.13 U/mg protein *vs* 99.52 ± 1.68 U/mg protein, $P = 0.000$), after administration of Wy14643 1, 5 and 10

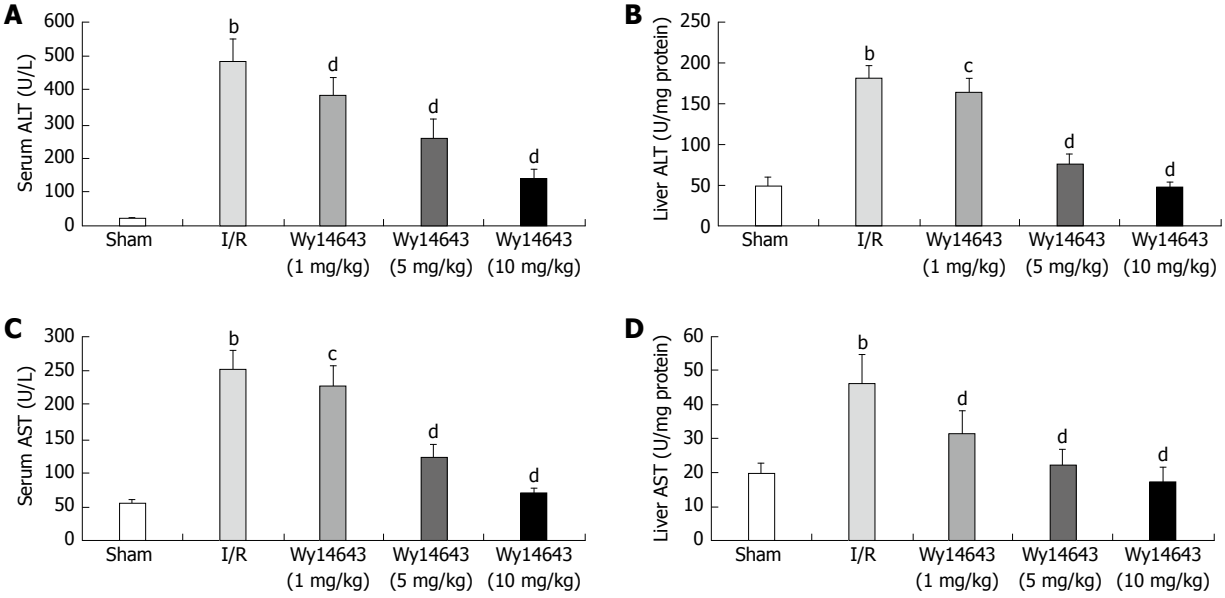

Figure 1 Levels of serum and liver tissue homogenate ALT and AST. Serum ALT (A), liver ALT (B), serum AST (C) and liver AST (D) levels in different groups (mean ± SD, $n = 6$). After 90 min of hepatic ischemia and 4 h of reperfusion, ALT and AST were determined with an ALT and AST assay kit. $^{b}P < 0.01$ *vs* sham group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* I/R group.

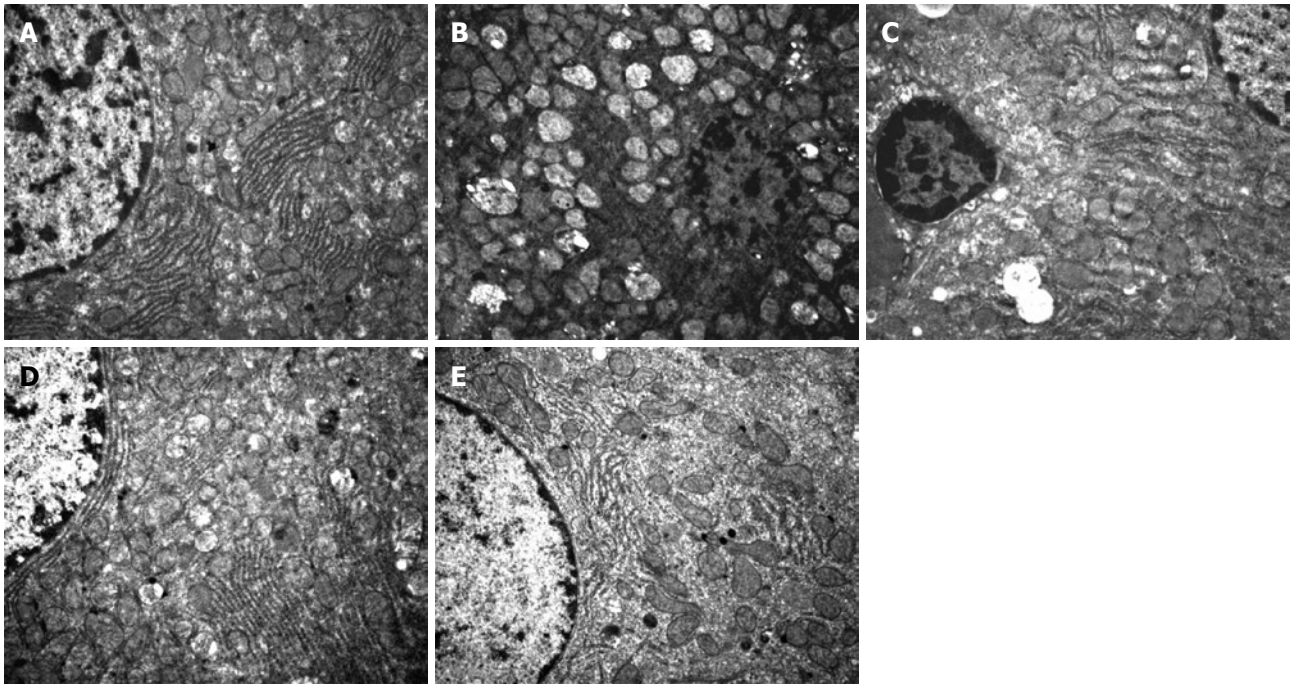

Figure 2 Ultrastructural alterations of liver tissue. A: Sham group. Normal appearance of mitochondrion, rough endoplasmic reticulum and nucleus structure; B: I/R group. Mitochondrion swelled significantly with vacuolar degeneration and mitochondrial crista destruction, marked decrease of rough endoplasmic reticulum and nucleus structure destruction; C: Wy14643 group (1 mg/kg). Mitochondrion swelled moderately, with mitochondrial crista interruption and vacuolar degeneration, increase of rough endoplasmic reticulum and nucleus structure destruction; D: Wy14643 group (5 mg/kg). Mitochondrion swelled mildly, with rough endoplasmic reticulu and normal nucleus structure; E: Wy14643 group (10 mg/kg). Normal appearance of mitochondrion, rough endoplasmic reticulum and nucleus structure.

mg/kg, SOD activity in liver was elevated (99.52 ± 1.68 U/mg protein *vs* 100.09 ± 3.75 U/mg protein, 103.45 ± 3.08 U/mg protein, 103.45 ± 1.73 U/mg protein, $P = 0.706$, $P = 0.014$, $P = 0.014$) (Figure 3).

MDA content in liver tissue homogenate

The MDA content as an index of lipid peroxidation became significantly higher after reperfusion in I/R group than in sham group (MDA: 6.48 ± 0.64 nmol/mg protein *vs* 11.36 ± 1.10 nmol/mg protein, $P = 0.000$). Pretreatment with Wy14643 1, 5 and 10 mg/kg caused marked reduction compared with the I/R group (MDA: 11.36 ± 1.10 nmol/mg protein *vs* 10.37 ± 0.99 nmol/mg protein, 6.59 ± 0.97 nmol/mg protein,7.50 ± 0.66 nmol/mg protein, $P = 0.066$, $P = 0.000$, $P = 0.000$) (Figure 3).

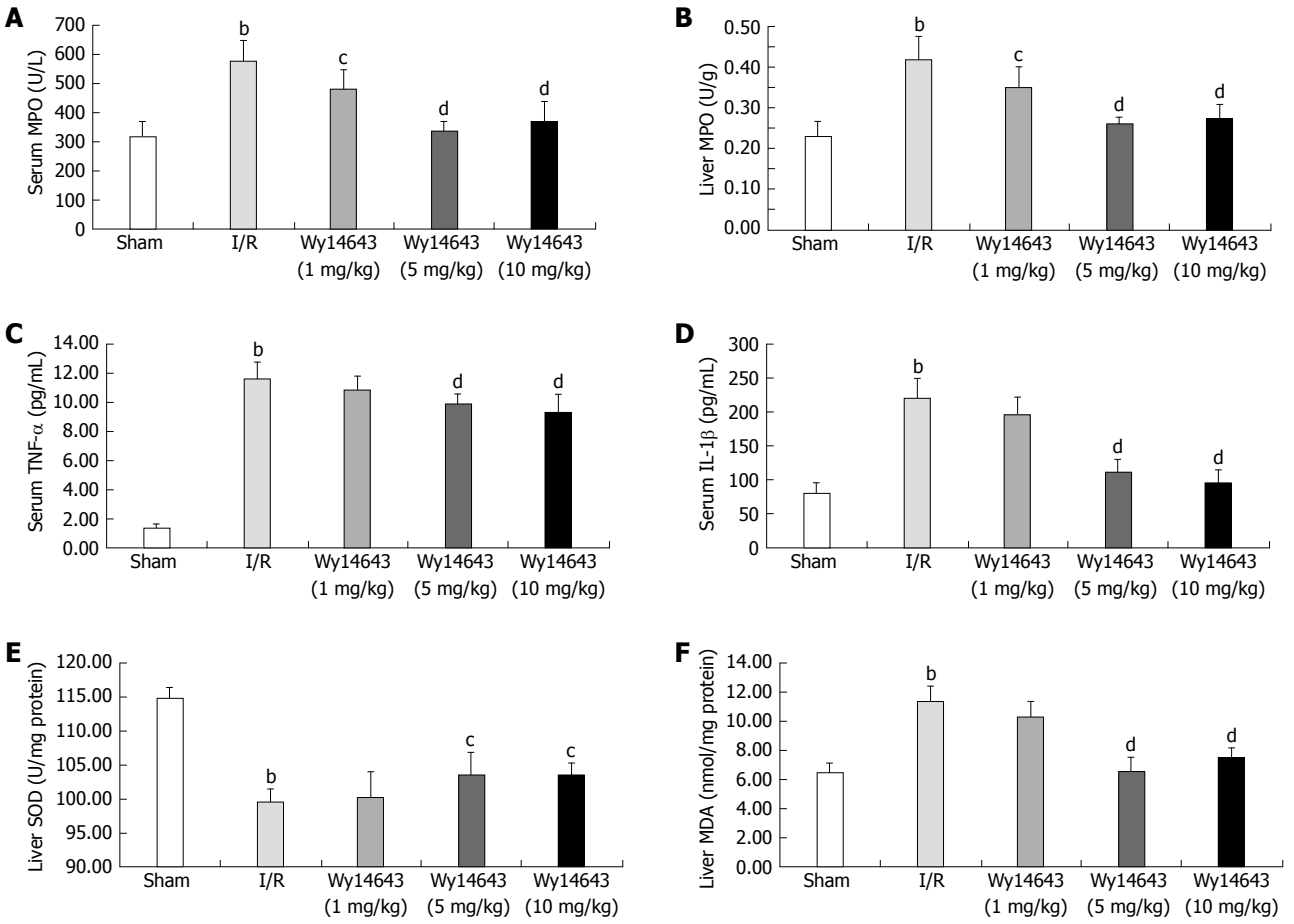

Figure 3 Activities of MPO in the serum (A), activities of MPO in the liver (B), serum TNF-α levels (C), serum IL-1β levels (D), activity of SOD in the liver (E) and content of MDA in the liver (F) in different groups (mean ± SD, *n* = 6). After 90 min of hepatic ischemia and 4 h of reperfusion, MPO, TNF-α, IL-1β, SOD and MDA were analyzed with an MPO, TNF-α, IL-1β, SOD and MDA assay kit. $^{b}P < 0.01$ *vs* sham group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* I/R group.

DISCUSSION

The present study provides noticeable evidence that the selective PPAR-α agonist Wy14643 protects the rat liver from hepatic I/R injury. This protective effect is demonstrated by reducing ALT and AST levels and is associated with an inhibition of oxidative stress and inflammatory response. An increase in serum and liver homogenate ALT and AST levels has been suggested to be an effective indicator of impaired liver parenchymal cells with hepatic I/R. Our results indicate that Wy14643 results in a marked reduction of ALT and AST levels with dose-dependent manner in the rat hepatic tissue homogenate compared with the sham group.

Hepatic ischemia-reperfusion is known to induce formation of reactive oxygen, as well as excessive inflammatory response, which is clearly recognized as a key mechanism of injury during reperfusion[2,19].

Hepatic ischemia activates Kupffer cells, which are the main sources of vascular reactive oxygen formation during the initial reperfusion period[20]. In addition to Kupffer cell-induced oxidant stress, with increasing length of the ischemic episode, components of NADPH oxidase are recruited to the cell surface leading to the priming for enhanced reactive oxygen formation[21]. Furthermore, ROS can activate diverse downstream signaling pathways, such as the transcription factor nuclear factor-κB (NF-κB), thus regulating expression of genes encoding a variety of proinflammatory proteins[22]. SOD, an oxygen radical scavenger which converts superoxide anion radicals present in the upper stream of reactive oxygen metabolism cascade, protects cells against damage. Lipid peroxidation, mediated by free oxygen radicals, is believed to be an important cause of destruction and damage to cell membranes. Membrane peroxidation can lead to changes in membrane fluidity and permeability and also to enhanced rates of protein degradation, eventually resulting in cell lysis[23]. MDA levels have been extensively used as markers of lipid peroxidation and lipid peroxidation damage in tissues, including cells and body fluids in both clinical and experimental studies[24,25]. In our study, we confirm that hepatic I/R caused significant increase of MDA, accompanied by SOD decrease. Administration of Wy14643 ip 1 h before I/R decreased lipid peroxidation in rats subjected to I/R and, at the same time, offered protection against SOD decrease. This finding is in agreement with other reports showing that Wy14643 enhances expression of antioxidant enzymes such as SOD and catalase in the rat liver[26].

TNF-α and IL-1β derived from activated Kupffer cells play an important role in the pathogenesis of hepatic ischemia-reperfusion injury. These cytokines

are capable of up-regulating adhesion molecules and causing polymorphonuclear neutrophils to adhere to endothelial cells. This causes microcirculation disturbance, which is thought to be a major mechanism of ischemia-reperfusion injury, including the "no-flow phenomenon"[27]. NF-κB is activated during I/R of the liver, and plays an important and complex role in the gene expression of proinflammatory cytokines (TNF-α and IL-1), which will lead to the tissue injury[28]. PPAR-α agonists may have the anti-inflammatory action, which are thought to be mediated through negative regulation of the transcription factors NF-κB and activator protein-1, resulting in decreased expression of their target genes[29,30]. Cuzzocrea *et al*[31] found that administration of Wy14643 before the onset of gut ischemia significantly reduced intestinal I/R injury in rats. The improved outcome was accompanied by reductions in neutrophil infiltration, proinflammatory cytokine(TNF-α and IL-1β) expression. Similarly, renal and liver I/R injury was reduced after Wy14643 pretreatment, partially due to its anti-inflammatory effects[1,32]. In mice, PPAR-α ligands attenuate cisplatin-induced ARF by repressing inflammation *via* inhibition of NF-κB binding activity, which attenuate neutrophil inflation and cytokine release(TNF-α and IL-1β)[33]. It is reported that Wy14643 lowers levels of TNF-α and IL-1β in plasma[34,35]. It is observed that pretreatment with PPAR-α agonists Wy14643 significantly decreased TNF-α and IL-1β in serum. Thus, the results showed that its reduction represents a further mechanism for hepatic protection by PPAR-α agonists.

MPO is an enzyme restricted mainly to polymorphonuclear neutrophils (PMNs), reflecting the number of PMNs in the serum and liver. The evidence indicated that Wy14643 reduced infiltration of the reperfused intestine with polymorphonuclear neutrophils[31]. Our result shows that Wy14643 significantly decreased the serum and liver MPO activity compared with the I/R group. That is to say, Wy14643 reduced infiltration of leukocytes into the inflammatory sites to decrease hepatic I/R injury. In the present study, the significant increase of MPO activity in the hepatic tissue homogenate after hepatic I/R is consistent with a previous study[36].

In summary, our results show that Wy14643 pretreatment protects liver injury induced by hepatic I/R. The protection effects are probably associated with enhancement of antioxidant capacities and inhibition of inflammation responses. However, the precise mechanisms of PPAR-α agonists need to be further investigated in the oxidative stress and inflammatory response implicated in the pathogenesis of hepatic I/R injury.

COMMENTS

Background

The peroxisome proliferator-activated receptor-alpha (PPAR-α) is a member of the nuclear receptor family of ligand-dependent transcription factors. Several studies indicated that PPARα protected organs such as heart, kidney and brain against ischemia-reperfusion injury. PPARα activation also induces anti-inflammatory and antioxidant effects. In addition, PPAR-α is highly expressed in the liver, particularly in hepatic parenchymal cells, which can protect hepatocytes in the mouse model of hepatic ischemia-reperfusion injury.

Research frontiers

In recent years, more attention has been paid to the effects of PPAR-α on the important organs such as heart, brain, liver and kidney. PPAR-α is a transcription factor that in some *in vitro* systems has been linked with down-regulation of proinflammatory mediators, thus implicating a potential role for PPAR-α in the regulation of inflammatory processes. Meanwhile, PPAR-α enhances expression of antioxidant enzymes such as SOD and catalase.

Innovations and breakthroughs

Wy14643 was shown to enhance antioxidant capacities and inhibit inflammation responses in some studies. The present study analyzed serum and hepatic tissue homogenate indexes such as ALT, AST, MPO, SOD, MDA,TNF-α and TNF-α. Ultrastructural alterations of liver tissue were also observed. These results all indicated that Wy14643 significantly mitigated hepatic I/R injury in a dose-dependent manner.

Applications

This study has indicated that PPAR-α agonist Wy14643 pretreatment protects liver injury induced by hepatic I/R. The protective effects may be associated with enhancement of antioxidant capacities and inhibition of inflammation responses. This may present a novel and attractive approach to prevent hepatic I/R injury.

Peer review

The research is important because authors demonstrated that Wy14643 pretreatment exerts significant protection against hepatic I/R injury in rats. The protective effects are possibly associated with enhancement of anti-oxidant and inhibition inflammation response.

Abstract

AIM: To develop a simplified and quick protocol to induce cirrhosis and standardize models of partial liver resection in rats.

METHODS: In Fischer F344 rats two modified protocols of phenobarbital-carbon tetrachloride (CCl_4) (dilution 50%) gavage to induce cirrhosis (frequency adjusted according to weight, but each subsequent dose was systematically administered) were tested, i.e. the rapid and slow protocols. Prothrombin time (PT) and total bilirubin (TB) were also evaluated. Animals from the rapid group underwent 15% hepatectomy and animals from the slow group underwent 70% hepatectomy.

RESULTS: Rapid protocol: This corresponded to 1 gavage/4 d over 6 wk (mortality 30%). Mean PT was 35.2 ± 2.8 s (normal: 14.5 s), and mean TB was 1.8 ± 0.2 mg/dL (normal: 0.1 mg/dL). Slow protocol: This corresponded to 1 gavage/6 d over 9 wk (mortality 10%). Mean PT was 11.8 ± 0.2 s (normal: 14.5 s), and mean TB was 0.4 ± 0.04 mg/dL (normal: 0.1 mg/dL). Pathological analyses were performed in both protocols which showed persistent cirrhosis at 3 mo. Rat mortality in the rapid gavage group who underwent 15% hepatectomy and in the slow gavage group who underwent 70% hepatectomy was 50% and 70%, respectively.

CONCLUSION: Our modified model is a simplified method to induce cirrhosis which is rapid (6 to 9 wk), efficient and stable up to 3 mo. Using this method, "Child Pugh A" or "Child Pugh BC" cirrhotic rats were obtained. Our models of cirrhosis and hepatectomy can be used in various situations focusing on postoperative survival.

INTRODUCTION

There is currently a worldwide epidemic of chronic liver disease (chronic viral hepatitis B and C, and hepatopathy associated with obesity *via* the non alcoholic steatohepatitis (NASH) syndrome. At the same time, the number of patients presenting with hepatocellular carcinoma and/or persistent end-stage hepatic function alteration have increased. These two complications have led to more frequent discussions on hepatic resection and transplantation. However, the scope for both these solutions is limited by postoperative mortality and the constantly growing shortage of donors.

This situation led physicians and surgeons to propose new therapeutic solutions[1]. These solutions include: (1) Reduced-sized orthotopic liver graft[2,3], hepatic transplantation with living donor[4] and xenogenic transplantation[5,6]; (2) Cellular therapy by transplantation of hepatocytes into the liver, spleen and peritoneum (isolated or encapsulated)[7,8] (autologous, allogeneic, xenogenic, free or encapsulated, genetically modified *ex vivo*)[9].

It is thus necessary to have animal models of cirrhosis, which make it possible to obtain compensated (equivalent to Child Pugh A) or decompensated cirrhosis (equivalent

to Child Pugh BC). At best, liver cirrhosis must be rapidly obtainable, and durable. It is also necessary to have standardized models of partial hepatic resection in these cirrhotic animals with reproducible mortality.

The most validated cirrhosis model in the rat is the carbon tetrachloride (CCl_4) (induced by phenobarbital) cirrhosis model[10]. Many protocols exist, which differ in the route of administration (gavage, intraperitoneal or subcutaneous injection), the dilution of CCl_4 (1/20 to 1/10), the frequency (1 to 4 wk) and the duration (8 to 28 wk) of CCl_4 administration. The efficiency of these protocols (70% to 100%), as well as the inherent toxic-mortality (20% to 90%) is variable in the literature[11]. The study in which the CCl_4 protocol for cirrhosis is best described is that of Kobayashi *et al*[12,13]. Here CCl_4 was given by gavage twice weekly and diluted to 10%. The amount of CCl_4 was decreased if body weight remained constant, and not administered if the weight decreased. The study was carried out over a 28-wk period. The animals were studied only when evidence of liver failure did not improve after CCl_4 was withheld for 4 wk. However, this reference protocol is too restrictive particularly for pilot studies[14].

The aim of this study was to establish a restrictive CCl_4 cirrhosis model which resulted in "Child Pugh A" or "Child Pugh BC" cirrhotic rats, which could be carried out easily, quickly and in a reproducible and durable way by modulating the dilution of CCl_4 and the duration and frequency of gavage. In addition, we tested different types of hepatectomy in terms of the resected volume ("minor or major") to obtain reproducible postoperative mortality.

MATERIALS AND METHODS

Animals

Male Fischer F344 rats (Iffa Credo, France) weighing 150-180 g were used. The rats were given free access to standard laboratory food and water throughout the experiments. Rats were acclimatized to our laboratory conditions for 7 d. All the procedures performed on the animals were in accordance with the European Committee on the Use and Care of Animals.

Induction of phenobarbital-carbon tetrachloride-induced liver cirrhosis

Rats were given phenobarbital (lyophilized 200 mg, Rhône-Poulenc Rorer, France) in their drinking water at a concentration of 0.5 g/L throughout the establishment of liver cirrhosis. Two weeks later, CCl_4 (diluted 50% in olive oil) was given intragastrically using a gavage needle at different intervals determined during preliminary experiments.

Rat weight was approximately 200 g at the time of first gavage. The initial dose was 0.08 mL (0.20 mL/kg of CCl_4). Each subsequent dose was systematically administered (even if weight remained stable or decreased) but adjusted based on changes in body weight: from 150 to 220 g, 0.06 to 0.09 mL (0.20 mL/kg of CCl_4); from 230 to 270 g, 0.12 to 0.14 mL (0.25 mL/kg); from 280 to 300 g, 0.17 to 0.18 mL (0.30 mL/kg); from 310 to 330 g, 0.22 to 0.23 mL (0.35 mL/kg); from 340 to 360 g, 0.27 to 0.29 mL (0.40 mL/kg); from 370 to 390 g, 0.33 to 0.35 mL (0.45 mL/kg). Various gavage protocols (frequency, duration of gavage, dose adjustment, mortality during gavage) were tested leading to the selection of two protocols (rapid protocol, slow protocol).

Once these two protocols (rapid and slow) were selected, 3 groups of 10 animals for each protocol were used as test groups to affirm that these protocols were reproducible in terms of mortality related to gavage, gravity of cirrhosis (ascites, splenomegaly, portal hypertension, biology, pathology) and persistence of the histological lesions with time.

Biology

Prothrombin time (PT) and total bilirubin (TB) were assessed in 5 rats in the rapid and slow protocol groups 3 wk after gavage interruption.

Histological examination

Representative liver blocks, obtained when the rats were sacrificed, were prepared to establish the gavage protocols or after partial hepatectomy. After routine paraffin wax processing, hematoxylin eosin and Masson's trichromie stained sections were obtained and the presence of cirrhosis was assessed under light microscopy. Pathological analyses were performed in rats 3 wk after gavage interruption (T0) and at regular intervals (2 wk, 5, 9, 13, 18 s).

Anesthesia

Partial hepatectomy was performed under ether inhalation anesthesia. The day before intervention, the animals were fasted for 12 h prior to surgery. Postoperatively, animals received glucose supplementation (immediate postoperative subcutaneous glucose 30%, and glucose 10% added to drinking water during the first 24 h) and animals were heated during the first 24 h.

Hepatectomy

Hepatectomy was performed in cirrhotic rats 3 wk after gavage interruption. The extent of hepatectomy was adjusted by excising various combinations of liver lobes that are known to have a predictable volume[15] according to the nature of the protocol and the observed postoperative mortality: 15% hepatectomy (epiploïc lobes, i.e. minor hepatectomy) and 70% hepatectomy (left lateral and median lobes, i.e. major hepatectomy) were chosen after preliminary experiments.

Two groups of 10 animals from the rapid group underwent 15% hepatectomy and two groups of 10 animals from the slow group underwent 70% hepatectomy. The postoperative day 1 mortality was noted. Pathologic examination of the resected specimen was carried out systematically.

RESULTS

Rapid and slow protocol gavage mortality

Rapid protocol: This corresponded to 1 gavage/4 d over

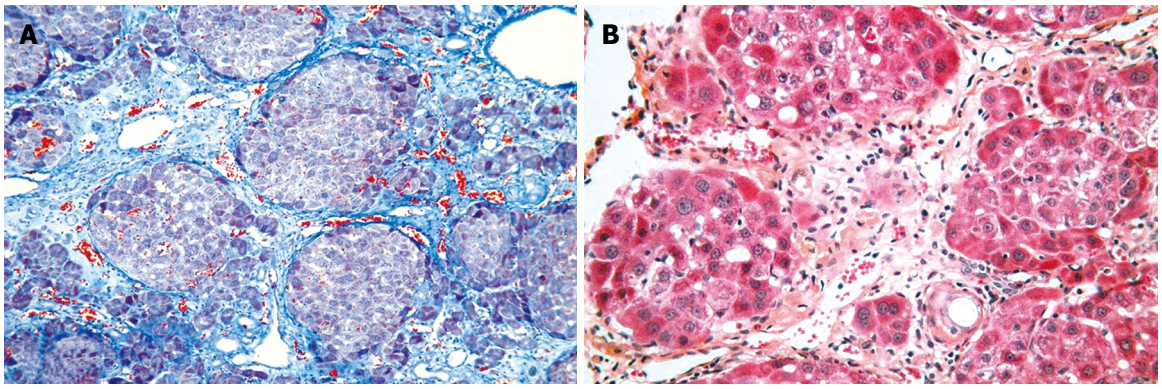

Figure 1 Rat liver after CCl_4 gavage. A: Rat liver [9 wk after T0 (12 wk after CCl4 gavage interruption)] extensive mutilating fibrosis, with nodules (cirrhosis). In the nodules separated by fibrous septa, hepatocytes with a basophil cytoplasm and a round nucleus are organized in fine spans (Masson's trichromie, × 10); B: Rat liver [6 wk after T0 (9 wk after CCl4 gavage interruption)] extensive mutilating fibrosis, with nodules (cirrhosis) (HE, × 10).

42 d (6 wk). Mortality in the rapid protocol was 30%, 30% and 40% (mean: 30%), from the first gavage to 3 wk after gavage interruption, respectively. In the surviving rats, 3 wk after gavage interruption, at the time of sacrifice, there were macroscopic micro nodular cirrhosis aspects in all animals, and ascites, splenomegaly and portal hypertension signs (at the level of the stomach) in 85%, 65% and 60% of animals, respectively.

Slow protocol: This corresponded to 1 gavage/6 d over 63 d (9 wk). Mortality in the rapid protocol was 10%, 20% and 10% (mean: 10%), from the first gavage to 3 wk after gavage interruption, respectively. In the surviving rats, 3 wk after gavage interruption, at the time of sacrifice, there were macroscopic micro nodular cirrhosis aspects in all animals, and ascites, splenomegaly and portal hypertension signs (at the level of the stomach) in 5%, 5% and 0% of animals, respectively.

Biology

Rapid protocol: In the surviving rats, 3 wk after gavage interruption, mean PT was 35.2 ± 2.8 s (normal: 14.5 s), and mean bilirubin was 1.8 ± 0.2 mg/dL (normal: 0.1 mg/dL) (n = 5).

Slow protocol: In the surviving rats, 3 wk after gavage interruption, mean PT was 11.8 ± 0.2 s (normal: 14.5 s), and mean bilirubin was 0.4 ± 0.04 mg/dL (normal: 0.1 mg/dL) (n = 5).

Pathological assessment

After both the rapid and slow protocols, all surviving rats presented with cirrhosis (T0 = 3 wk after gavage interruption) with extensive mutilating fibrosis and nodules (Figure 1). The cirrhosis aspects persisted on analyses performed at regular intervals (2 wk, 5, 9, 13, 18 s).

Mortality after partial hepatectomy

Mortality in the two groups of 10 animals from the rapid gavage group, who underwent 15% hepatectomy, was 50% at postoperative day 1. Mortality in the two groups of 10 animals from the slow gavage group, who underwent 70% hepatectomy, was 70% at postoperative day 1.

DISCUSSION

CCl_4 is widely used to induce experimental liver damage. The data from this study showed that our modified model is a simplified and improved method for inducing cirrhosis which was rapid (6 to 9 wk), efficient, stable up to 3 mo and which resulted in "Child Pugh A" or "Child Pugh BC" cirrhotic rats. Fifteen percent hepatectomy ("minor hepatectomy") in decompensated cirrhotic animals and 70% hepatectomy ("major hepatectomy") in compensated cirrhotic animals resulted in a postoperative mortality of 50% and 70%, respectively. These reproducible and high postoperative mortality rates can be used in protocols devoted to cellular therapy in chronic liver diseases[1,8]. Moreover, different series have studied the biological[16,17] and hemodynamic[18-20] variations induced by liver cirrhosis. Other authors have investigated various treatments in rats with liver cirrhosis[21-24].

In the Kobayashi *et al*[12,13], CCl_4 reference induced cirrhosis model, animals were studied only when evidence of liver failure did not improve after CCl_4 was withheld for 4 wk, following 28 wk of gavage. Overall, the length of the protocol was 8 mo. However, this protocol ensured the induction of cirrhosis which was slow, stable and very close to cirrhosis found in clinical practice. The main pitfall of this protocol was its length which is not compatible with small "pilot" or "preliminary" studies. In our study, serum albumin level, serum ammonia level and degree of encephalopathy (coma scale), are lacking, however, persistent histological alteration at 3 mo is, in our view, a major argument for the use of this method. To reinforce the pertinence of modified protocols for inducing cirrhosis in rats, at a recent congress, Quadrelli *et al*[25] presented a new approach to improve the model of cirrhotic liver induced by CCl_4, which associated gavage and subcutaneous injection of CCl_4. This new approach, associated with 45% mortality allowed cirrhosis induction in 60% of rats in a period of 9 wk.

We have found only 5 papers in the literature which reported mortality after hepatectomy (rational for the study of cirrhotic rats focusing on postoperative mortality) in various models of compensated "Child Pugh A" CCl_4 induced cirrhosis in rats. One of these studies reported a

postoperative mortality of 70% after 30% hepatectomy[26]. In the remaining four studies after 70% hepatectomy, a postoperative mortality of 15%, 20%, 25% and 40%, respectively was reported[27-30]. In this series, rat mortality after 70% hepatectomy in compensated "Child Pugh A" rats was higher, about 70% and could be explained by the more intensive gavage protocol used. However, the extent of the resection, i.e. 15% in decompensated cirrhotic animals, and 70% in compensated cirrhotic animals chosen in this series are compatible with minor and major hepatic resections performed in clinical practice in cirrhotic patients.

In conclusion, our modified model is a simplified method for inducing cirrhosis that is rapid (6 to 9 wk), efficient and stable up to 3 mo. It resulted in "Child Pugh A" or "Child Pugh BC" cirrhotic rats. Our models of cirrhosis and hepatectomy can be used in various situations focusing on postoperative survival.

ACKNOWLEDGMENTS

We thank Ms Fon and Ms Boudet for their precious help during the gavage protocols.

COMMENTS

Background

It is necessary to have animal models of compensated (equivalent to Child Pugh A) and decompensated cirrhosis (equivalent to Child Pugh BC) for various studies. At best, cirrhosis must be rapidly obtainable and durable. The most validated cirrhosis model in the rat is the carbon tetrachloride (CCl_4) (induced by phenobarbital) cirrhosis model. Many protocols exist, which differ in the route of administration (gavage, intraperitoneal, subcutaneous), the dilution of CCl_4, and in the frequency and the duration of CCl_4 administration. The efficiency of these protocols (70% to 100%), as well as the inherent toxic-mortality (20% to 90%) is variable in the literature.

Research frontiers

The establishment of an efficient and quick model of cirrhosis in rat with an acceptable rate of mortality has been the topic of several investigations in recent years.

Innovations and breakthroughs

This paper has reported a reproducible, rapid (6 to 9 wk), efficient and stable up to 3 mo model of liver cirrhosis, which resulted in "Child Pugh A" or "Child Pugh BC" cirrhotic rats.

Applications

Based on the results of this work, it is possible to standardize models of partial hepatic resection in cirrhotic rats with reproducible mortality. This rapid model is compatible with small "pilot" or "preliminary" studies. It can be used in protocols devoted to cellular therapy in chronic liver diseases, and in biological and hemodynamic variations induced by liver cirrhosis.

Terminology

The extent of hepatectomy was adjusted by excising various combinations of liver lobes that are known to have a predictable volume according to the nature of the protocol and the observed postoperative mortality: 15% hepatectomy (epiploïc lobes, i.e. minor hepatectomy) and 70% hepatectomy (left lateral and median lobes, i.e. major hepatectomy) were chosen after preliminary experiments.

Peer review

The data presented by the authors supports the possibility of a simplified method for inducing cirrhosis that is rapid, efficient and stable. The topic is very interesting because the model of "Child Pugh A" or "Child Pugh BC" cirrhosis and hepatectomy can be used in various situations focusing on postoperative survival.

Abstract

AIM: To investigate the prevalence of celiac disease (CD) in adult patients referred to an open access gastroenterology clinic in the south of Italy and submitted to esophago-gastro-duodenoscopy (EGD) for evaluation of refractory functional dyspepsia.

METHODS: Seven hundred and twenty six consecutive dyspeptic patients (282 male, 444 female; mean age 39.6 years, range 18-75 years) with unexplained prolonged dyspepsia were prospectively enrolled. Duodenal biopsies were taken and processed by standard staining. Histological evaluation was carried out according to the Marsh-Oberhuber criteria.

RESULTS: The endoscopic findings were: normal in 61.2%, peptic lesions in 20.5%, malignancies in 0.5%, miscellaneous in 16.7%. CD was endoscopically diagnosed in 8 patients (1.1%), histologically in 15 patients (2%). The endoscopic features alone showed a sensitivity of 34.8% and specificity of 100%, with a positive predictive value (PPV) of 100% and a negative predictive value (NPP) of 97.9%.

CONCLUSION: This prospective study showed that CD has a high prevalence (1:48) in adult dyspeptic patients and suggests the routine use of duodenal biopsy in this type of patient undergoing EGD.

INTRODUCTION

Celiac disease (CD) has been considered for years to be a rare pathology that affects, in particular, pediatric patients who present with a clinical picture of malabsorption[1]. The development of sensitive and specific serological tests and their administration to subjects who are apparently healthy has shown that: CD is still under diagnosed in all age groups; the form with obvious symptoms is found in only a limited number of cases; in most patients, particularly adults, the disease has an atypical symptomatology or is completely silent[2-5]. The latter characteristics are responsible for a the length of time needed to have a correct diagnosis and expose patients to the possible development of severe pathologies. With the aim of discovering the hidden proportion of subjects with CD[6] two different diagnostic approaches have been proposed: to carry out a screening on the apparently healthy population, or to apply case-finding in subjects that are believed to be at high risk for the disease[7,8].

As regards mass screening, at the moment there is no evidence that supports this approach, since in the apparently healthy population the prevalence of

CD varies in relationship with geographical areas[9]. Furthermore, a cost-effectiveness analysis in support of a mass screening program has not been performed.

Case-finding is believed to be the most appropriate diagnostic approach to adopt for asymptomatic patients or for patients with subtle clinical features. This approach is particularly effective and becomes more so if in the selection of subjects to be investigated their family doctors are involved[10-12]. The activation of a celiac awareness program in the primary-care setting focusing on selective serological screening of high risk groups has doubled the number of cases diagnosed from among the adult asymptomatic population[13].

It was recently observed that CD had a greater prevalence, with respect to the general population, in dyspeptic patients[14,15] and that 30%-40% of CD patients have dyspeptic symptoms[2]. These findings suggested that it would be useful to carry out, in subjects undergoing esophago-gastro-duodenoscopy (EGD), biopsies of the descending duodenum independently of the endoscopic aspect of the mucosa[16-20]. The aim of our study was to determine, by means of duodenal biopsies, the prevalence of CD in dyspeptic patients submitted to EGD in an open access Gastroenterology Outpatient Clinic of a University Hospital in the south of Italy.

MATERIALS AND METHODS

From January 2005 to June 2007, 5413 patients underwent EGD at the Gastroenterology Unit of the University Hospital Policlinic of Catania.

The study was approved by the Bioethical Committee of the Polyclinic and carried out on 726 patients (282 male, 444 female; mean age 39.6 years, range 18-75 years) prospectively enrolled.

All patients gave their written informed consent before being enrolled in the study. During the entire period of the study, the first two dyspeptic patients admitted in our unit to undergo an EGD for the first time were included.

Patients with a positive family history for CD, those affected by pathologies known to be associated with CD[21] and patients with gastroesophageal reflux disease were excluded. Dyspeptic symptomatology was classified according to Roma Ⅱ criteria as: Ulcer-like Dyspepsia, Dysmotility-like Dyspepsia, and Indeterminate Dyspepsia.

During EGD, other than the observation of the esophageal and gastric mucosa, a precise evaluation of the duodenal mucosa up to the distal duodenum was carried out and any anomalies were classified as: micro nodular pattern; mosaic pattern; scalloped folds and loss or decrease of duodenal folds[22].

The endoscopic observation was completed with a rapid urease test to detect the presence of *H pylori*, 5 biopsies of the gastric mucosa (2 antrum, 1 angulus and 2 body) consistent with the Sydney system recommendations, and 4 biopsies of the descending duodenum. The bioptic duodenal samples were orientated and mounted villous side up before being immersed in formalin for standard staining (HE). The histological examination was carried out by a pathologist who did not know the clinical details and endoscopic reports of the patients. The pathologist gave a diagnosis of CD based on standard coloration and classified the entity of mucosal damage according to Marsh-Oberhuber criteria[23,24]. In patients with histological diagnosis of CD the study was completed with a specific antibody test, anti-Tissue Transglutaminase antibodies (tTG) and anti-Endomysial antibodies (EMA), and the determination of the HLA haplotypes (DQ2- DQ8).

Prevalence, the relative risk and 95% CI were calculated using the Biostat Program.

Statistical analysis

The difference between mean and the difference between proportions were evaluated by the *t*-test and the χ^2 test respectively. In the case of abnormal distribution an appropriate non-parametric test was performed. We also estimated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPP) and their 95% CI of the endoscopic examinations, considering the histological evaluation of duodenal biopsies as the gold standard.

RESULTS

Over a 30 mo period 726 dyspeptic patients were enrolled: 102 (14%) ulcer-like dyspepsia, 344 (47.4%) dysmotility-like dyspepsia and 280 (38.6%) indeterminate dyspepsia. No adverse events were reported during the endoscopic procedures and bioptic sampling. The endoscopic findings were normal in 444 (61.2%) patients, peptic lesions (esophagitis, erosive gastritis, peptic ulcer) were present in 149 (20.5%), endoscopic findings suggestive for CD in 8 (1.1%), malignancies in 4 (0.5%) and miscellaneous (chemical gastropathy, lymphocytic gastritis, submucosal mass lesions, hyperplastic polyps, cystic fundal hyperplasia) in 121 (16.7%) (Table 1). Endoscopic markers of CD consisted of a decrease in the number of folds in 5 cases, an association with a mosaic pattern in 2 cases, and in the remaining 3 cases the endoscopic aspect of the mucosa was respectively micro nodular, mosaic and scalloped. These alterations of the mucosa were localized in 3 cases (37.5%) to DI and in 5 (62.5%) both to DI and DⅡ.

The histological diagnosis of CD was made in 15 patients (5 male, 10 female; mean age 39.9 years, range 20-61 years), 8 were already suspected of being affected by CD on endoscopic evidence and 7 had an apparently normal duodenal endoscopic picture. Histological damage was classified as ⅢC category of Marsh (Total Villous Atrophy) in 5 cases, ⅢB (Subtotal Villous Atrophy) in 8 and ⅢA (Partial Villous Atrophy) in 2 cases. None of the patients had histological alterations of Marsh I or Ⅱ. The general prevalence of CD in dyspeptic patients that we examined was 2% (1/48). As regards *H pylori,* 7/15 (46.6%) CD patients were positive and 322/721

Table 1 Clinical characteristics and endoscopic findings of enrolled patients (n = 726)

Dyspepsia	Non CD (%) n = 711	CD (%) n = 15	OR	95% CI	P
Sex (female; male)	434 (61.0) 277 (39)	10 (66.7) 5 (33.3)	1.28	0.45-3.60	0.6
Mean age (yr)	39.5 ± 14.5	39.9 ± 11.2	1.86	0.71-4.65	0.3
Type of dyspepsia					
Dysmotility-like dyspepsia (DD)	336 (47.2)	8 (53.3)	1.27	0.47-3.42	0.6
Indeterminate dyspepsia (ID)	273 (38.4)	7 (46.7)	2.21	0.82-5.97	0.1
Ulcer-like dyspepsia (UD)	102 (14)	0			
Endoscopic findings

13	F	39	DD	RF	STA	ⅢB
14	M	41	ID	RF	STA	ⅢC
15	F	45	ID	Sll	STA	ⅢB

PVA: Partial villous atrophy; STA: Subtotal villous atrophy; TVA: Total villous atrophy; DD: Dysmotility-like dispepsia; ID: Indeterminate dispepsia; UD: Ulcer-like dispepsia; RF: Reduced folds; Sll: Scalloped folds; NM: Nodular mucosa; MM: Mosaic mucosa.

(45.3%) patients with normal duodenal mucosa histology were positive. We did not find differences in clinical features and in mean intraepithelial leucocyte (IEL) count in *H pylori* -negative and *H pylori* -positive patients.

Of the 15 patients diagnosed as celiac, 8 reported dysmotility-like and 7 indeterminate dyspepsia. The type of dyspepsia, endoscopic findings and histological diagnoses are shown in Table 2.

The EMA and tTG antibodies were both present in all but one case, in which only EMA was positive; the HLA associated haplotypes were, respectively, DQ2 in 12 patients, DQ2-DQ8 in 2 patients and DQ8 in one patient.

DISCUSSION

Over the last thirty years it has been established that CD is not a rare disease, rather it should be considered as a global health problem. It is estimated that CD currently affects 2.5/3 million in both American and European populations[25]. This observation confirms that the awareness for this under-diagnosed disease in clinical practice should be increased.

Recent investigations have shown that most patients affected by CD, in particular adults, do not have the typical symptoms of the disease, thus they remain misdiagnosed, delaying the diagnosis until an older age. In a study conducted on paucisymptomatic patients over 65 years old that had seen both family doctors and specialists, it was documented that the correct diagnosis was made with an average delay of 28 years[26].

The misdiagnosis of CD for such a long period exposes patients to the risk of developing severe gluten-related complications such as intestinal lymphoma, autoimmune disorders or neurological diseases[27-29].

To identify the sub-clinical or silent forms of CD, the suggested algorithm consists of the search for specific antibodies in categories of patients known to be at risk. The definitive confirmation of the disease will, however, come from the histological evaluation of the duodenal mucosa.

In recent publications[11,30,31] a high prevalence of CD has also been found in adult patients classified as functional dyspeptic who did not respond to an adequate pharmacological therapy. To identify in this particular population the subjects whose symptoms are really due to CD, three alternate approaches have been proposed: (1) Carry out biopsies from the descending duodenum[16,17] in all functional dyspeptic patients undergoing EGDS even if endoscopy does not reveal any lesions typical of CD[22]; (2) Use magnification tools or immersion techniques to better characterize the duodenal mucosa[32]; (3) Test for specific antibodies and, if positive, carry out EGD with biopsies of the descending duodenum[33].

The first approach has been criticized due to its cost for the limited number of CD cases that could be identified and for the amount of work for the pathology services[34,35]. The second approach, a modified version of the so-called immersion technique (MIT), which based on recent data has a sensitivity and specificity of 100%, is considered impractical though further studies are needed to assess its efficacy in routine practice as a screening or case-finding tool[36]. The third approach has diagnostic limitations, since the test for anti-tTG and anti-EMA antibodies[37] are relatively poor for adult smoker patients[38,39] or in the presence of a slight or medium (Marsh I to Ⅱ) histological damage.

The above cited observations suggest that for both asymptomatic risk groups and symptomatic risk groups in the general population the threshold for biopsies must become lower[38]. In Spain duodenal biopsy performed during upper GI endoscopy has been incorporated in daily practice in digestive endoscopic services[40]. This choice should be adopted especially in geographical areas

where there is a high prevalence of CD in an apparently healthy population.

In our study the biopsies were carried out in patients where EGD was used to clarify a functional dyspeptic symptomatology that did not resolve after an adequate pharmacological treatment. It should be noted that as regards *H pylori* positivity the percentage of *H pylori*-positive celiac patients is similar to non-celiac patients and, as recently shown[41], clinical features of CD patients are unrelated to simultaneous presence of *H pylori* gastritis.

In this population the prevalence of CD was 2% (1/48 patients) two/four times more than that found using serological tests in the general population[42-45] and more than that reported in two studies conducted in Italy and Brazil on dyspeptic patients[14,30]. The data is, however, similar to that obtained in a study conducted on patients who reported chronic abdominal pain[46].

Concerning the demographic characteristics of the 15 celiac patients (mean age 39.9 years; male/female ratio 2:1) our data are in agreement with what has already been observed in a multicenter retrospective study[3] and in a screening study[47], both carried out in Italy. A higher prevalence of females among celiac patients (3% *vs* 1%) has also been reported in a retrospective evaluation[40] of adult patients referred to an endoscopy unit with mild digestive symptoms (dyspepsia, abdominal discomfort) or analytical alterations (anemia, iron deficiency or hypertransaminasemia).

The greater prevalence of CD among patients who reported dysmotility or indeterminate dyspesia may be related to autoimmune damage of the extrinsic autonomic system[48] and/or to an increase in neurotensin and enteroglucagon plasma levels which inhibit the motility of the upper gastrointestinal tract[49,50]. Moreover a delayed oro-cecal transit time[51] and a post-prandial decrease in gallbladder emptying rate[52] have been found in untreated CD patients. Normalization of oro-cecal transit time was observed after gluten withdrawal using a hydrogen lactulose breath test[50]. The diagnostic precision of the endoscopic observations [8/15 (53%)] was similar to that observed in other samples of dyspeptic patients[14] but lower than that found in patients at high risk of CD[23,33,53]. The discrepancy of our study compared with the latter could be explained by the fact that the operator paid more attention to the observation of the duodenal mucosa in the patients affected by pathologies already recognized as being at risk for CD.

In conclusion, based on the results that we have obtained it can be hypothesized that in patients who have been diagnosed as having refractory functional dyspepsia and for whom an EGD has been prescribed, endoscopic observation should be routinely completed with a biopsy of the descending duodenum as suggested by the guidelines of the working group on CD[24]. Particular attention should be given to females who report dysmotility or indeterminate dyspepsia. Such an approach could reveal another submerged part of the "Celiac Iceberg" but it must be validated as regards the cost effectiveness, bearing in mind the variable prevalence of the disease in different geographical areas. The development of new and more precise serologic and/or immunohistochemical tests[54] would allow correct selection of subjects who need a bioptic examination of duodenal mucosa.

COMMENTS

Background

Celiac disease (CD) has been considered for years to be a rare pathology that affects, above all, pediatric patients presenting with a clinical picture of malabsorption. The development of sensitive and specific serological tests and their administration to subjects who are apparently healthy has shown that: CD is still under diagnosed in all age groups; the form with obvious symptoms is found in only a limited number of cases; in most patients, particularly adults, the disease has an atypical symptomatology or is completely silent. It was recently observed that CD had a greater prevalence, with respect to the general population, in dyspeptic patients and that 30%-40% of CD patients have dyspeptic symptoms. These findings suggested that it would be useful to carry out, in subjects undergoing esophago-gastro-duodenoscopy (EGD), biopsies of the descending duodenum independently of the endoscopic aspect of the mucosa.

Research frontiers

Based on the results that authors have obtained it can be hypothesized that in patients who have been diagnosed as having refractory functional dyspepsia and for whom an EGD has been prescribed, endoscopic observation should be routinely completed with a biopsy of the descending duodenum as suggested by the guidelines of the working group on CD. Particular attention should be given to females who report dysmotility or indeterminate dyspepsia.

Innovations and breakthroughs

This is a prospective study undertaken in the Mediterranean area. All the other related or similar articles are mainly retrospective and from different geographical areas.

Applications

Such an approach could reveal another submerged part of the "Celiac Iceberg" but it must be validated as regards the cost effectiveness, bearing in mind the variable prevalence of the disease in various geographical areas.

Peer review

This is an interesting study, looking into the prevalence of histological and serological proof of CD in consecutive patients undergoing upper GI endoscopy because of dyspepsia. Because of the high CD prevalence found, the authors conclude that duodenal biopsies should routinely be taken at this indication.

Abstract

AIM: To infect mice with atypical *Campylobacter concisus* (*C. concisus*) for the first time.
METHODS: Three separate experiments were conducted in order to screen the ability of five clinical *C. concisus* isolates of intestinal origin and the ATCC 33237 type strain of oral origin to colonize and produce infection in immunocompetent BALB/cA mice. The majority of the BALB/cA mice were treated with cyclophosphamide prior to *C. concisus* inoculation to suppress immune functions. Inoculation of *C. concisus* was performed by the gastric route.
RESULTS: *C. concisus* was isolated from the liver, ileum and jejunum of cyclophosphamide-treated mice in the first experiment. No *C. concisus* strains were isolated in the two subsequent experiments. Mice infected with *C. concisus* showed a significant loss of body weight from day two through to day five of infection but this decreased at the end of the first week. Histopathological examination did not consistently find signs of inflammation in the gut, but occasionally microabscesses were found in the liver of infected animals.
CONCLUSION: Transient colonization with *C. concisus* was observed in mice with loss of body weight. Future studies should concentrate on the first few days after inoculation and in other strains of mice.

INTRODUCTION

The importance of *Campylobacter jejuni* (*C. jejuni*) and *C. coli* in causing diarrhoeal disease worldwide is well established[1]. However, a possible enteric pathogenic role for *Campylobacter* spp. other than *C. jejuni/coli* has not been established as yet, however, the potential pathogen *C. concisus* is at present the subject of investigation concerning its role in human gastrointestinal disease[2]. *Campylobacter concisus* (*C. concisus*) has been found in high proportions in patients with diarrhoeal disease, especially in tertiary hospital settings[3-6]. Other studies have shown *C. concisus* to possess virulence factors including a haemolytic phospholipase and cytotoxic activity caused by the Cytolethal Distending Toxin (CDT) as described in *C. jejuni*[7,8].

The presence of *C. concisus* in the gastrointestinal tract has been described by some investigators as that of a commensal as no statistical differences were found between symptomatic and asymptomatic carriers[9]. However, the fact that *C. concisus* is a heterogeneous

species with several subtypes and at least two genomospecies could in part account for the conflicting results[10-12]. To our knowledge, no reports of *C. concisus* in animal models have been presented.

Attempts to establish an animal model mimicking human campylobacteriosis using various animals have suffered from difficulties due to handling, lack of reproducibility, high costs and inadequate clinical pathology[13-17]. A major shortcoming of murine models is the inability to consistently reproduce the most common symptoms of enteritis following gastric inoculation, although sporadic colonization of the gastrointestinal tract has been achieved[18-20]. Colonization and development of gastrointestinal symptoms is augmented in immunodeficient or immune dysregulated mice and following pre-treatment with oral antibiotics or iron[21-24]. Consequently, no single animal model is widely accepted and applied in the study of *Campylobacter* infection. The objective of this study was to determine if five clinical *C. concisus* strains of intestinal origin and the type ATCC 33237 strain of oral origin could infect immunocompetent and immunodeficient mice and mimic human *Campylobacter* infections.

MATERIALS AND METHODS

Bacterial strains

The *C. concisus* reference and type ATCC 33237 strain of oral origin and five clinical isolates of *C. concisus* (RH10776.98, RH4204.98, RH4482.98, RH5097.98, RH15690.98) all from humans with diarrhoeal disease, were used. Strain details are given in Table 1. The isolates for inoculation were recovered from frozen storage, plated on 5% blood agar plates containing yeast extract (1%) and incubated in a microaerobic atmosphere (50 mL/L O_2, 100 mL/L H_2, 850 mL/L N_2) at 37℃ for 48 h as described previously[25]. The bacteria were harvested directly from plates into sterile phosphate buffered saline (PBS), washed and resuspended in PBS to the required cell density (10^9 CFU/mL) determined by optical density.

Test animals

Immunocompetent BALB/cA mice of both sexes (from the breeding colony of the University of Lund, Sweden), 6-7 wk old and with a mean weight of 16.7 g were used in the study. The mice were not defined as flora or specific pathogen free. The mice were housed in groups of a maximum of ten mice of equal gender per cage. All mice received vancomycin by intragastric intubation (0.3 mL, 80 μg/mL) three days prior to the *C. concisus* challenge. The mice had access, ad libitum, to water and standard food. Three days before the start of the experiments, faecal pellets were analysed for the presence of *Campylobacter* spp., and prior to all experiments 2-4 mice were sacrificed for baseline values with complete sampling including culture, PCR and histopathology of the stomach, liver, ileum, jejunum and colon tissue. All experiments were performed according to the recommendations of the Swedish Board of Animal Research and were approved by the Committee of Animal Ethics of the University of Lund.

Table 1 *C. concisus* **strains and patient data**

Strain	Origin	Diagnosis	No. of experiment	Protein group	AFLP group
ATCC 33237	Oral	Periodontitis	1 and 3	1	1
RH10776.98	Intestinal	Healthy traveller	1 and 3	2	2
RH4204.98	Intestinal	IBD	2 and 3	2	2
RH4482.98	Intestinal	NHL and IBD	2	2	1
RH5097.98	Intestinal	ALL (IR)	2	2	2
RH15690.98	Intestinal	ALL (IR)	2	2	-

NHL: Non Hogdkin Lymphoma; IBD: Inflammatory Bowel Disease; ALL: Acute Lymphoid Leukaemia; IR: In Remission; AFLP: Amplified Fragment Length Polymorphisms.

Experimental design

The study consisted of three experiments involving a total of 132 BALB/cA mice. Experiment 1 involved 22 animals, divided into 10 groups and the animals were inoculated with the type ATCC 33237 strain and the clinical isolate 10776.98. Half the mice received an intraperitoneal injection of cyclophosphamide (100 μL/10 g) three days before inoculation with the *C. concisus* strains in order to suppress normal immune systems by disrupting the T-cell population. The cyclophosphamide treated and untreated mice were kept in separate cages. Two mice were used for baseline values. Experiment 2 involved 54 animals, divided into 10 groups and the animals were inoculated with four clinical strains (RH4204.98; RH15690.98; RH4482.98; RH5097.98) or sham dosed with PBS. Half the mice received an intraperitoneal injection of cyclophosphamide (100 μL/10 g) three days before inoculation with the *C. concisus* strains. Four mice were used for baseline values. Experiment 3 involved 56 animals, divided into 13 groups and the animals were inoculated with the type ATCC 33237 strain, two clinical strains (RH4204.98; RH10776.98) or sham dosed with PBS. All mice received an intraperitoneal injection of cyclophosphamide (100 μL/10 g) three days before inoculation with *C. concisus* strains. Four mice were used for baseline values.

Inoculation of mice was performed by direct intragastric administration of 0.3 mL 10^9 CFU/mL or 0.3 mL of PBS by gastro-oesophageal tube (outer diameter 0.1 cm). Mice were challenged with a total of three equal doses of *C. concisus* on three consecutive days.

Evaluation of clinical status of the mice and necropsy

All animals were examined daily for signs of distress. The consistency of faecal pellets was also noted. Body weights of all mice in the third experiment were measured daily. Mice were euthanized by inhalation of carbon dioxide on day 7 (study 1: 3 mice; study 2: 5 mice; study 3: 5 mice), day 13 (study 1: 2 mice; study 2: 3 mice; study 3: 5 mice) and day 35 (study 1: 2 mice; study 2: 2 mice; study 3: 3 mice), and sampling from the stomach, liver, jejunum, ileum and colon was performed.

Identification of *C. concisus*

Microbiological culture: Faecal and tissue samples

Table 2 *P* values based in nominal weight changes from each *C. concisus* inoculated group compared to controls (n = 12), Weight (g) (*P*-value)

Day	Control group	Clinical strains		Type strain
		RH10776.98[1]	RH4204.98	ATCC 33237
0	16.0	17.2 (0.60)	16.9 (0.54)	16.6 (0.50)
1	16.4	17.5 (0.57)	16.9 (0.30)	16.6 (0.42)
2	16.7	17.2 (0.20)	16.4 (0.03)	16.6 (0.27)
3	16.8	17.0 (0.13)	16.6 (0.06)	15.4 (0.08)
4	17.3	17.5 (0.17)	16.7 (0.09)	16.5 (0.20)
5	17.5	17.3 (0.04)	16.8 (0.11)	16.6 (0.15)
6	18.1	18.1 (0.12)	17.6 (0.20)	17.4 (0.21)

[1]n = 12 from day 5. Weights are expressed as group mean. *P*-values are calculated using the Mann Whitney *U* test.

Table 3 Anatomical localization of *C. concisus* isolation (Experiment 1, day 7, n = 3)

	Stomach	Liver	Ileum	Jejunum	Colon	Stools
Culture	0	3	3	1	0	0
PCR	0	1	1	1	0	0

All isolations were from mice inoculated with the clinical strain RH10776.98.

were homogenized in PBS, plated onto blood agar containing yeast extract using the filter technique and incubated in a microaerobic environment for 48 h as previously described[25]. Identification was performed on phenotypic data according to On[26].

Detection by PCR: Specimens were stored at -18℃ until examination. DNA was extracted from faecal and tissue samples using DNeasy tissue minikit (Qiagen, Ballerup, Denmark) using a clean room procedure. Organ tissues were vortexed and manually degraded to homogenize the solutions before DNA extraction. Primers and amplification cycles were prepared according to Bastyns *et al*[27]. The mixture consisting of one forward primer MUC1 (5'-ATGAGTAGCGATAAATTGGG-3'), and two reverse primers CON1 (5'-CAGTATCGGCAATT CGCT-3') and CON2 (5'-GACAGTATCAAGGATTTA CG-3'). All *C. concisus* strains tested were PCR detectable when tested directly from agar plates prior to inoculation.

Histopathological examination

Specimens for histological examination were prepared throughout the study. Stomach, liver, small and large intestine were removed immediately after death, fixed in neutral buffered 4% formaldehyde, paraffin embedded and processed for histopathological evaluation. Sections were stained with haematoxylin and eosin and examined under a light microscope by an experienced pathologist. All examinations were performed blindly.

Statistical analysis

The loss of body weight in the various infected groups compared to the control group was evaluated using the Mann-Whitney *U*-test, with normalized weight ratios from day 1 of the experiment. Thus, for example, in Table 2 on day 2, the control group 0.7 (weight increase) is compared to ATCC 33237 0.0 (unchanged weight). Results were considered statistically significant when $P < 0.05$.

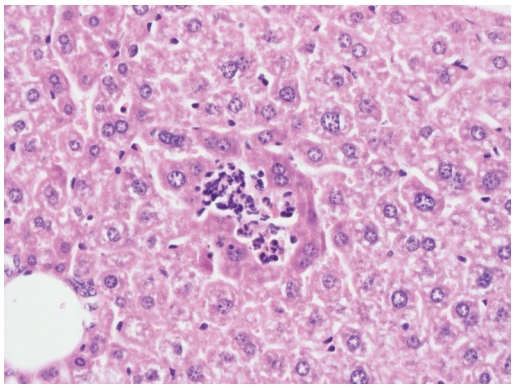

Figure 1 High power view of histological section of liver from experiment 1. Mouse inoculated with strain RH10776.98 in the non-treated group. A microabscess is seen in the centre. Haematoxylin-eosin (x 40).

RESULTS

Isolation of C. concisus

Culture: On day 7 of experiment 1, *C. concisus* was isolated from all three mice sacrificed in the cyclophosphamide-treated group, inoculated with the clinical isolate RH10776.98. All mice had positive liver and ileum cultures, whereas only one mouse had a positive jejunum culture (Table 3). Faecal pellets examined throughout the study were consistently negative. Tissue samples obtained on day 21 and day 56 were negative for *C. concisus*. Isolation of *C. concisus* was not obtained during the two subsequent experiments (2 and 3).

PCR: PCR testing of the samples yielded comparable results on day 7 of experiment 1, as all three mice sacrificed in the cyclophosphamide-treated group, inoculated with the clinical isolate RH10776.98, were PCR positive when analysing ileum tissue (Tables 2 and 3). Using PCR, *C. concisus* was not detected from liver or jejunum tissue. Tissue samples obtained on day 21 and day 56 were not positive for *C. concisus*. PCR results were consistently negative in the two subsequent experiments (2 and 3).

Histological examinations

Stomach: No evidence of inflammation or infection was noted throughout the study.

Liver: One mouse inoculated with the clinical isolate RH10776.98 and one mouse inoculated with the type ATCC 33237 strain, both from non-treated groups in experiment 1, harboured microabscesses in their livers (Figure 1). Megakaryocytes were occasionally noted in the livers of cyclophosphamide-treated groups, including the controls, but not in untreated controls. The three *C. concisus*-positive livers all showed evidence of megakaryocytes and haematopoiesis.

Jejunum: No evidence of inflammation or infection

was found, although oedema of intestinal villi was detected in the cyclophosphamide-treated control group. One mouse inoculated with the clinical *C. concisus* isolate RH15690.98, showed infiltration of lymphocytes as evidence of inflammation.

Ileum: Villi oedema was occasionally noted in the various untreated and treated groups, but not in controls. The three *C. concisus*-positive mice in experiment 1 had no signs of inflammation of the ileum.

Colon: Two mice in the untreated group infected with the type ATCC 33237 strain, showed evidence of inflammation and lymphocyte infiltration.

Clinical parameters

Loss of body weight: Compared to controls, the mice infected with the *C. concisus* strains RH4204.98 and RH 10776.98 showed a significant weight loss ($P < 0.05$), while ATCC 33237-infected mice showed a similar trend, however, this was only borderline significant ($P = 0.08$) (experiment 3). The effect was clear from day 2 but wore off on day 5. At the end of the first week, all three groups of *C. concisus*-infected mice showed a net gain less than one g of bodyweight. The controls had a slowly progressive net weight gain of two g. These results are summarized in Table 2. After the first week no differences in weight were observed between the groups.

Loose stools: On day 2 and 3 faecal pellets in *C. concisus*-inoculated groups were loose and slimy compared to control groups (experiment 3).

Mortality: Two mice in experiment 2 died after the second *C. concisus* inoculation with the clinical strains RH4204.98 and RH5097.98. One mouse inoculated with the clinical isolate RH10776.98 died on day 5 (experiment 3).

DISCUSSION

The present model mimics a relevant intragastric exposure to *C. concisus* infection in immunocompetent BALB/cA mice upon cyclophosphamide and vancomycin pretreatment. Taken together, the results indicate a transient colonization of liver and ileum, with clinical signs of illness seen as loss of body weight and loose stools, however, the lack of consistent *C. concisus* isolation is troublesome in the present model.

The reason for these discrepancies is not clear, but may predominately arise from (1) difficulties in isolation of *C. concisus* and (2) lack of tissue samples from sick animals. The problem encountered in the isolation of *C. concisus* from faecal pellets collected in the cages may have been due to swarming contamination of Proteus spp. on many of the blood agar plates, which obstructed identification of other bacteria including *C. concisus*. Using the filter technique reduced this problem but did not alleviate this swarming. A method to separate faecal pellets from urine might increase the isolation rate of *C. concisus* in future studies. In addition, the inoculation dose (0.3×10^9 CFU) may have limited the chance of persistent colonization and development of full scale illness, as many researchers report doses above 10^{10} CFU before the successful recovery of bacteria is achieved[20,21]. PCR detection was poor and refined techniques must be used, which could also solve the problem of swarming. In the clinical parameters assessed, loss of body weight and loose stools were most prominent on the first three days of infection; after that time the effects of colonization seemed to wear off. As the first mice were sacrificed on day 7, no symptomatic animals were sacrificed, leaving the cultivation of *C. concisus* and histopathological studies to determine the presence of inflammation only in asymptomatic mice.

The fact that *C. concisus* was isolated from the liver of infected animals is consistent with previous studies of *C. jejuni* extraintestinal manifestations[28-30], where histopathological lesions have been described, as opposed to the present study. There have been occasional reports of humans developing hepatitis due to *C. jejuni* infections[31,32]. In our study of 98 patients with *C. concisus* infection[5] none had hepatitis, although several had disturbed liver biochemistry. The presence of *Campylobacter* spp. in liver is an intriguing finding that merits further investigation.

Overall inflammatory changes in the present study were scarce and limited to a total of three mice. The absence of substantial histopathological findings could be due to localised patches of colonization in the GI-tract, or that the damaging effects of colonization were small and resolved quickly before the mice were sacrificed seven days post-inoculation. Some studies have reported similar findings of discrepancies between colonization and the absence of lesions on histological examination[23], whilst studies of infections on limited-flora SCID mice present with severe histopathological lesions when symptomatically sick mice are sacrificed[24]. Similar results were found in human studies, as histopathological evidence of intestinal damage is limited to sick patients and not found in asymptomatically colonized patients[33].

The present panel of six *C. concisus* strains (Table 1) showed only minor differences in clinical outcome, but the only isolated strain after inoculation was the clinical strain RH10776.98, originally from an otherwise healthy traveller with diarrhoea. We have previously shown clinical differences when applying protein profiles as well as DNA-based typing systems to differentiate clinical *C. concisus* strains[5,11,25]. The clinical strain RH10776.98 belonged to the protein profile group 2 and genomospecies 2, both of which consisted of predominately immunocompetent patients complaining of diarrhoeal disease. However, clinical differences were not apparent as the type ATCC strain of protein group 1 and genomospecies 1 was also able to induce a near significant and comparable weight loss. The fact that genetic differences exist and that many *Campylobacter* spp. exhibit interstrain differences in colonization has been shown previously[34,35]. However, more strains need to be tested to clarify the question of strain variability in

C. concisus infection.

Recently, a membrane bound haemolytic phospholipase has been identified in clinical *C. concisus* strains[7]. Also cytotoxic activity mimicking the Cytolethal Distending Toxin (CDT) has been found in the majority of tested *C. concisus* strains[8]. Taken together these findings suggest that a pathogenic role exists for at least certain subtypes of *C. concisus* strains. It is conceivable that *C. concisus* strains may differ in their pathogenicity due to the heterogeneity of the species[10-12,36].

Intragastric exposure to *C. concisus* infection in immunocompetent BALB/cA mice upon cyclophosphamide and vancomycin pretreatment resulted in transient colonization of liver, jejunum and ileum in a few mice. The symptoms were loss of body weight and loose stools. As most mice were not diseased, other strains of mice and increased dose levels of inoculum should be studied with a focus on the first days after inoculation. Future studies should concentrate on the first three days of infection and symptomatic mice should be sacrificed for optimal detection of histopathological changes, as the organism is rapidly cleared from the GI-tract and symptoms resolve.

COMMENTS

Background

Our knowledge of the etiological agent in infectious diarrhoea can at present only account for some 50% of the cases presenting with gastroenteritis. Lately, *Campylobacter concisus* (*C. concisus*) has been associated with gastroenteritis in humans, however clear evidence of a pathological role is lacking. At present only few clinical laboratories worldwide perform an active search for *C. concisus* strains in routine sampling from diarrhoeal patients. The present study aims to determine if *C. concisus* can cause diarrhoeal illness in mice.

Research frontiers

No study has addressed a pathogenic role of *C. concisus* in animal models. The demonstration of a pathogenic role of *C. concisus* in animals will fulfill Koch´s postulates and establish *C. concisus* as a pathogen to be considered in diarrhoeal disease. This study reports that transient colonization occurs and clinical symptoms are present in mice. However, the described model is not suitable for further research, as colonization is inconsistent and symptoms rapidly resolve.

Innovations and breakthroughs

This is the first study to report on *C. concisus* infection in mice.

Applications

This study proves that the colonization of mice GI tract and liver is possible and histopathological findings including microabscesses are present. Further studies using immunodeficient mice and focussing on the first days of infection are needed to justfully answer the question of pathogenicity. The liver pathology is an intriguing finding that merits attention in a human setting.

Peer review

The experimental study is focused on establishment of experimental infection with Campylobacter concisus in mice. The experiments are in the field of intestinal microbiology. Experimental cohorts are well clustered; important Campylobacter strains are used. The manuscript is well written.

Abstract

AIM: To investigate the effects of an enteral supplement containing antioxidants on circulating levels of antioxidants and indicators of oxidative stress after major gastrointestinal surgery.

METHODS: Twenty-one patients undergoing major upper gastrointestinal tract surgery were randomised in a single centre, open label study on the effect of postoperative enteral nutrition supplemented with antioxidants. The effect on circulating levels of antioxidants and indicators of oxidative stress, such as F2-isoprostane, was studied.

RESULTS: The antioxidant enteral supplement showed no adverse effects and was well tolerated. After surgery a decrease in the circulating levels of antioxidant parameters was observed. Only selenium and glutamine levels were restored to pre-operative values one week after surgery. F2-isoprostane increased in the first three postoperative days only in the antioxidant supplemented group. Lipopolysaccharide binding protein (LBP) levels decreased faster in the antioxidant group after surgery.

CONCLUSION: Despite lower antioxidant levels there was no increase in the circulating markers of oxidative stress on the first day after major abdominal surgery. The rise in F2-isoprostane in patients receiving the antioxidant supplement may be related to the conversion of antioxidants to oxidants which raises questions on antioxidant supplementation. Module AOX restored the postoperative decrease in selenium levels. The rapid decrease in LBP levels in the antioxidant group suggests a possible protective effect on gut wall integrity. Further studies are needed on the role of oxidative stress on outcome and the use of antioxidants in patients undergoing major abdominal surgery.

Antioxidant enriched enteral nutrition and oxidative stress after major gastrointestinal tract surgery. *World J Gastroenterol* 2008; 14(45): 6960-6969 Available from: URL: http://www.wjgnet.com/1007-9327/14/6960.asp DOI: http://dx.doi.org/10.3748/wjg.14.6960

INTRODUCTION

Major surgery and critical illness induce an immuno-

inflammatory response, which is accompanied by the production of reactive oxygen species (ROS) at the site of injury[1-5]. Oxidative stress is defined as a state in which the level of ROS exceeds the endogenous antioxidant defences of the host. Reactive oxygen species can cause direct cellular injury by damaging lipids, proteins and DNA. This might result in tissue injury and organ dysfunction. Therefore, oxidative stress probably plays a key role in the development of organ failure[6-12]. In situations of major surgery and critical illness, a redistribution of antioxidants occurs to tissues or organs in need. This results in a depletion of antioxidant stores that may be deleterious when oxidative stress is prolonged[13]. In these situations the supplementation of certain antioxidant amino acids (glutamine, cysteine) and antioxidant micronutrients (zinc, Vitamin C, Vitamin E, β-carotene, selenium) may improve outcome. There is little information on the effect of major abdominal surgery and antioxidant supplementation on the blood levels of parameters of antioxidant capacity and oxidative stress.

To protect the host from oxidative stress, humans have an extensive antioxidant defence system consisting of enzymatic and non-enzymatic factors. Enzymes which are involved in antioxidant function are superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px). Superoxide dismutase catalyzes dismutation of the superoxide anion into hydrogen peroxide[14]. Glutathione peroxidase reduces hydrogen peroxide and organic hydroperoxides into water or alcohol, and reverts two glutathione (GSH) molecules to glutathione disulfide (GSSG)[14,15]. For GSH-Px and SOD function, the trace elements selenium and zinc are important, respectively[16].

Among the non-enzymatic factors, alpha tocopherol (Vitamin E), Vitamin C, β-carotene, and GSH function as antioxidants. Vitamin E is the main fat-soluble antioxidant in humans. Vitamin E scavenges peroxyl radicals, produced during lipid peroxidation, which leads to a tocopherol radical[17,18]. Vitamin C, a potent intra- and extracellular antioxidant[19], scavenges superoxide, hydroxyl and peroxyl radicals, and reacts with hypochlorite and singlet oxygen[15]. β-carotene is a precursor of Vitamin A. The conjugated double-bonds of β-carotene are able to open and scavenge singlet molecular oxygen and peroxyl radicals[20]. Glutathione is an intracellular antioxidant and a co-enzyme of GSH-Px. Glutamine and cysteine are precursors of the antioxidant GSH[15]. Furthermore, selenium, GSH, Vitamin E and Vitamin C function synergistically to regenerate both water and fat-soluble antioxidants[10]. The extent of oxidative stress can be measured by determining the end-products of lipid peroxidation; malondialdehyde (MDA) and F_2-isoprostane[15,21,22].

The present study investigates the effect of antioxidant-supplemented enteral feeding on circulating factors of the antioxidant defence system and markers of oxidative stress in patients after major upper gastrointestinal tract surgery.

MATERIALS AND METHODS

Patients

From February 2002 until May 2003, twenty-one patients undergoing elective surgery of the oesophagus, stomach or pancreas, in the VU University Medical Center (Amsterdam, The Netherlands), were included in the study. Inclusion criteria were: eligible for jejunostomy feeding, between 18 and 75 years old, body mass index (BMI) below 35, written informed consent, and a surgical procedure of at least three hours. Exclusion criteria were: history of cardiovascular or kidney disease, weight loss of > 10% in last six months, steroids or investigational drug used in the last six weeks and human immunodeficiency virus (HIV) infection. The study was approved by the Ethics Committee of the VU University Medical Centre and conducted according to the Declaration of Helsinki.

Methods

The study was a prospective, open label, randomised clinical trial of two balanced groups in parallel design in one medical centre. On the first day after surgery, patients were randomly assigned to the control group and were started on standard tube feeding (Sondalis ISO®, Nestlé, Switzerland), or the treatment group, and were started on the same tube feeding in combination with Module AOX (Nestlé, Switzerland). Sondalis ISO® is a nutritionally balanced, complete liquid diet. Module AOX is a plastic unit containing powder which contains per unit 37 kcal, 7.4 g protein, 0.04 g lipid and 1.9 g carbohydrate. The contents of Sondalis ISO® and Module AOX are listed in Table 1. The dosages of the compounds in Module AOX were established with respect to safety aspects. One Module AOX unit was added to one pouch of Sondalis ISO® (500 mL), with a maximum intake of two devices of Module AOX per day. Module AOX was upstream connected to the enteral feeding pouch. After mixing with enteral feeding, the module was connected to the administration set and was ready for immediate consumption by the patient. Feeding pouches were weighed before the start of feeding and after being discarded. This made it possible to calculate exactly the daily intake of kcal and nutritional compounds.

Feeding was administered by a jejunostomy feeding tube and started on the first day after surgery. In the treatment group, Module AOX was added to the enteral feeding from the first day after surgery. Patients received two Modules AOX per day when feeding could be increased beyond 500 mL per day. Module AOX was administered for a minimum of five and a maximum of seven days. Patients were fed continuously. The intention was to give the patient 500 mL of feeding on the first day after surgery, 1000-1500 mL on the second day and 1500-2000 mL from the third day. The feeding schedule was adjusted according to the energy requirements of the patient, which was established using indirect calorimetry. Oral food intake was allowed from day five after the

Table 1 Contents of Sondalis ISO® and Module AOX

	Sondalis ISO® per 100 mL	Module AOX per unit
kcal	100	37
Protein (g)	3.8	7.4
Glutamine (g)	0.34	6

B-carotene (mg)	0	6
Zinc (mg)	1	6
Selenium (μg)	4.4	50

start of tube feeding. Patients were not allowed to receive additional Vitamins, amino acids or lipid solutions during the study period.

Endpoints of the study

The present study was part of a larger study testing the safety and tolerance of the supplemented ingredients. The effect of the intake of antioxidants (Module AOX, Nestlé, Switzerland) on indicators of oxidative stress was studied in a group of patients undergoing major elective surgery.

Levels of the administered nutritional compounds, indicators of oxidative stress after surgery and indicators of the inflammatory response after surgery were measured in plasma, serum and urine. F2-isoprostane (in urine) and malondialdehyde (MDA, in serum) were measured as parameters of oxidative stress. Total cysteine, Vitamin C, Vitamin E, β-carotene, zinc, selenium and GSH-Px were measured as parameters of antioxidant/oxidant status. Peripheral white blood cell count (WBC), Interleukin 6 (IL-6) and lipopolysaccharide-binding protein (LBP) were measured as parameters of surgery-induced inflammatory response.

Blood and urine samples were taken on the day before surgery (-1) and on day one (1), three (3), five (5) and seven (7) after surgery. The samples on day one (1) were taken before the start of enteral nutrition. All samples were taken between eight and ten a.m.

Preparation, storage and analysis of samples

Amino acids: Blood was collected on heparin. Plasma was separated immediately from the blood by centrifugation (2000 g) at 4℃ for ten minutes. Five hundreds μL of plasma was added to tubes containing 20 mg of solid sulfosalicyclic acid for deproteinizing, vortex mixed and subsequently stored at -80℃ until analysis. The concentration of glutamine was determined by reversed-phase high-performance liquid chromatography as previously described[23].

Cysteine: Blood was collected on heparin. Plasma was separated immediately from the blood by centrifugation (2000 g) at 4℃ for four minutes. Aliquots containing 500 μL of plasma were stored at -80℃ until analysis. Total cysteine concentrations were measured according to Malloy *et al*[24].

Vitamin E and β-carotene: Blood was collected in a serum separation tube. Blood was centrifuged (2000 g) at 20℃ for ten minutes and serum was stored at -80℃ until analysis. Serum vitamin E and β-carotene were determined as essentially described by Miller and Yang[25].

Vitamin C: Blood was collected in tubes containing EDTA (ethylenediaminetetraacetic acid). Plasma was separated immediately from the blood by centrifugation (1400 g) at 4℃ for ten minutes. Plasma was further purified by centrifugation (2700 g) at 4℃ for ten minutes. For the determination of total vitamin C (the sum of ascorbic acid and dehydroascorbic acid) plasma was stabilized by the addition of metaphosphoric acid[26] and stored at -80℃ until analysis. After deproteinization and enzymatic oxidation of ascorbic acid to dehydroascorbic acid, the latter was condensed with ortho-phenylenediamine to its derivative. This derivative was separated by reversed-phase high-performance liquid chromatography with fluorescence detection[27]. The between-assay coefficient of variation was < 4%.

Zinc and selenium: Serum was separated from the blood by centrifugation (2000 g) at 20℃ for ten minutes. Tubes cleaned with mineral-free water, were used to store serum at -80℃ until analysis. Zinc and selenium were determined by Zeeman corrected atomic absorption spectrometry. The flame was used for zinc determination. A graphite furnace and Palladium-modifier were used for the determination of selenium.

F2-Isoprostane [8-iso-Prostaglandin (PG) $F_{2\alpha}$]: Urine was collected in plastic tubes and stored at -80℃ until analysis. Urine 8-iso PGF 2α concentrations were determined using LC-MS/MS. Prior to analysis, the urine samples were thawed, mixed and centrifuged. Subsequently 0.1 mL of the labelled internal standard (10 ng/mL; 8-iso PGF 2α-d4, Cayman cat. 316350) was added to 1 mL of urine. The 'sample clean up procedure' was performed according to the method described by Bohnstedt *et al*[28]. Thereafter the samples were redissolved in 0.1 mL of 10% acetonitrile and 40 μL was injected into a Waters X-terra MS C18 column (3.5 μm, 2.1 mm × 100 mm; cat. 186000404) connected to a Quattro Micro (Waters, Milford, MA, USA) triple quadruple mass spectrometer running in negative electrospray ionization mode. Separation took place using a gradient from 7% to 33% acetonitrile, containing 0.3% ammonia. With this gradient the internal standard (357.2 > 197.3 amu) and 8-iso PGF 2α (353.2 > 193.3 amu) eluted at approximately nine minutes. The peak areas were then integrated and the ratios were calculated. The unknown samples were compared with a standard/internal standard calibrator (50 and 10 ng/mL, respectively) in order to calculate the 8-iso PGF 2α concentration in the urine samples. The within and between assay coefficients of variation were < 8% and < 9%, respectively. Finally, 8-iso PGF 2α was calculated in ng per mg creatinine in urine.

MDA: Serum was separated from the blood by centrifugation (2000 g) at 20℃ for ten minutes and stored at

-80℃ until analysis. Serum MDA concentrations were determined by high-performance liquid chromatography with fluorescence detection as described by van de Kerkhof *et al*[29].

GSH-Px: GSH-Px activity was determined in red cell hemolysate, left behind after separation of EDTA plasma and stored at -80℃. GSH-Px was measured as described by Karsdorp *et al*[30], using an Elan analyser (Merck, Germany).

WBC: WBC was measured using a Sysmex SE9000 analyzer (Sysmex Corporation, Kobe, Japan).

IL-6: IL-6 was measured with a commercially available automated solid-phase, two-site, two-step chemiluminescent immunometric assay according to the specifications of the manufacturer (Immulite®; DPC, Los Angeles, CA, USA). This assay employs a murine mAb against the IL-6 (capture antibody) and a polyclonal anti-IL-6-detecting antibody. The values were expressed in pg/mL based on the reference standard supplied by the manufacturer, with limits of detection between 2 and 1000 pg/mL.

LBP: LBP was measured in EDTA plasma with a commercially available automated solid-phase, two-site, two-step chemiluminescent immunometric assay according to the specifications of the manufacturer (Immulite®; DPC, Los Angeles, CA, USA). This assay employs a murine mAb against the LBP (capture antibody) and a polyclonal anti-LBP-detecting antibody. The values were expressed in μg/mL based on the reference standard supplied by the manufacturer, with the limits of detection between 0.2 and 200 μg/mL.

Statistical analysis

The interval/ratio variables were expressed as mean and standard deviation. The Mann-Whitney *U* test was performed to analyse patient characteristics, the tumour characteristics and the difference between the control and treatment group over time. Fischer's Exact test was performed to analyse the nominal variables of the patient and tumour characteristics. The Wilcoxon Signed Ranks Test was performed per group of patients to obtain the effect of the surgical intervention between the day before surgery (-1) and the first postoperative day (1). Differences between the control and the treatment group in the development of postoperative antioxidant and oxidant parameters were analysed using the general estimating equations (GEE) population averaged model. GEE is a linear regression technique, which is suitable for analysing results from a longitudinal study in which outcome variables are repeatedly measured in each individual[31]. Time is treated as a categorical variable, represented by dummies. In a single analysis the differences between the treatment and control group over time were analysed, corrected for baseline. The GEE analysis was performed following corrections for gender, age, smoking, chemotherapy before surgery, surgery (open or laparoscopic), duration of surgery, blood loss, tumour size or intake of calories. The Wilcoxon Signed Ranks test, the Mann-Whitney *U* test and the Fischer's Exact test were performed with SPSS 14.0 for Windows® (SPSS Inc. Chicago, IL, USA). GEE-analysis was performed with STATA® (version 7.0)[31]. For all analyses a *P*-value < 0.05 was considered significant.

RESULTS

No side-effects were observed following the administration of Module AOX. With regard to practicalities, the set-up of Module AOX was not found to be difficult by any of the nurses involved in the study. No serious events, such as occlusion of the tube were observed. As for tolerance, the daily weight of stools was not different between the control and the treatment group, the consistency of stools (liquid or soft, formed or hard) did not differ between the groups, nor did abdominal pain, but flatulence was less intense in the treatment group (data not shown).

Patient characteristics and follow-up

In total 27 patients were considered eligible for enrolment in the study, of which eleven were included in the control group and ten in the treatment group. Six patients were excluded from the study before randomization because no jejunostomy was available, which was necessary for the feeding route. In the control group, one patient died on the second day after surgery, before receiving enteral feeding. Another patient in the control group refused further blood sampling. According to the principle of 'intention to treat analysis', the results of all 21 patients were analyzed.

Patients received upper gastrointestinal tract surgery. No differences in the occurrence of postoperative complications, infectious and non-infectious, were found between the control and treatment group in the first week after surgery. Patients in the control group stayed an average of 2.5 ± 0.7 d and patients in the treatment group stayed an average of 3.7 ± 0.8 d on an intensive or medium care unit ($P = 0.236$). Baseline patient characteristics and tumour characteristics are given in Tables 2 and 3, respectively. The control and treatment groups were comparable with respect to anthropometrics, surgery and tumour characteristics.

Intake

Intake of Sondalis ISO® with or without Module AOX was started as soon as possible after surgery. Caloric intake was based on caloric requirements. However, the patients reached on average 60% of their daily caloric requirements, as measured on the day before surgery. In both groups, patients received a similar amount of calories during the treatment period (Figure 1). A plateau in intake was reached in both groups between three and five days after surgery. Table 4 shows the absolute intake of nutrients in the control and the treatment group. The

Table 2 Patient characteristics

	Control group $n = 11$	Treatment group $n = 10$	*P*-value

Positive lymph nodes (number if present)	1.36 ($n = 7$)	3.00 $n = 5$[1]	0.412[4]
Metastasis (observed during surgery/post-surgery histology)	27.3% ($n = 11$)	30% ($n = 10$)	1.000[3]

[1]One patient had 10 positive lymph nodes; [2]No information on one patient; [3]Fischer's Exact Test; [4]Mann-Whitney *U* Test.

treatment group consumed significantly more glutamine, cysteine, zinc, selenium, Vitamin C, Vitamin E and β-carotene than the control group ($P < 0.001$).

First postoperative day

Significant decreases in the levels of antioxidants were noticed in both groups on the first day after surgery (Table 5). Total cysteine was also reduced significantly by surgery in both groups on the first day after surgery (Table 5). GSH-Px, F2-isoprostane (Figure 2) and MDA were not affected on the first day after surgery in both groups. As for the inflammatory markers, IL-6 and LBP increased in both the control and treatment group. WBC count increased in the treatment group only (Table 5).

Levels of oxidative stress parameters when starting with Module AOX or standard nutrition

Changes in plasma or serum levels of the oxidative stress parameters and the antioxidant/oxidant parameters are shown in Table 6. Glutamine increased significantly in both groups ($P = 0.001$). Total cysteine increased after surgery in both groups ($P < 0.001$). Vitamin E increased in both groups ($P < 0.001$) and Vitamin C increased in the treatment group only ($P = 0.014$). Zinc increased significantly in both groups ($P < 0.001$), as well as selenium ($P = 0.003$), with a greater rise in the treatment group ($P = 0.006$). Only selenium and glutamine preoperative levels were attained one week after surgery. For all other parameters, the levels were below preoperative values after one week. During the first three days after surgery F2-isoprostane significantly increased in the treatment group compared with the control group ($P = 0.007$) (Figure 2). MDA did not change after surgery in both groups. GSH-Px eventually decreased in the control group ($P = 0.013$), as well as in the treatment group. IL-6 tended to decrease after surgery in both groups ($P = 0.062$). No change was observed in WBC after surgery, in either group. Lipopolysaccharide-binding protein showed a peak value at day three in the control group that was significantly higher than that in the treatment group ($P = 0.018$). In the treatment group LBP levels remained at the level of the first postoperative day (Figure 3).

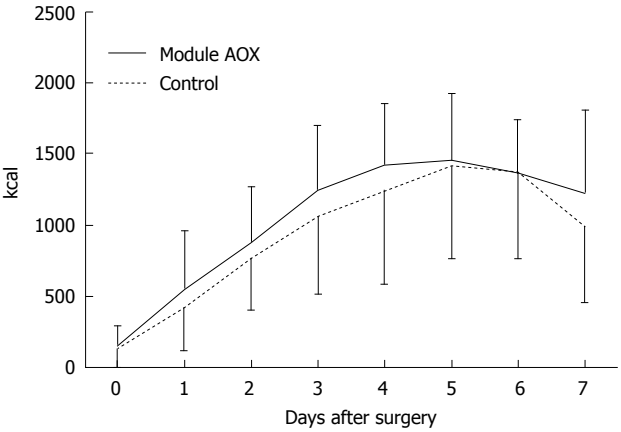

Figure 1 Intake of Kcal after surgery (mean ± SD). Caloric intake on the day before and on 7 d after surgery in the control and treatment groups. No significant difference in intake was observed between the groups.

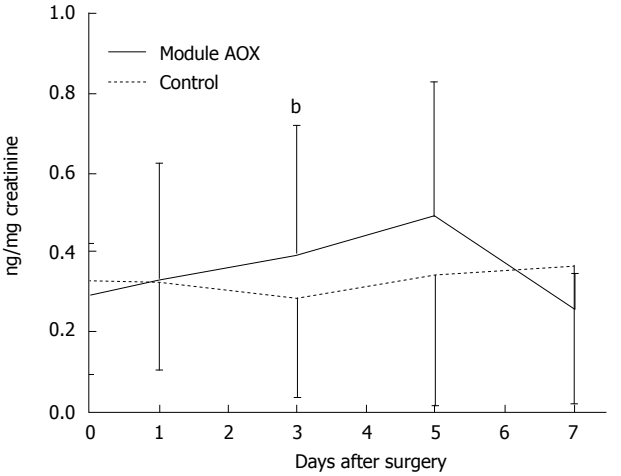

Figure 2 F2-Isoprostane after surgery (mean ± SD). Development of F2-isoprostane in urine (ng/mg creatinine) after surgery in the control and treatment groups. The difference between the two groups over time was observed to be significant between the first and the third day after surgery, $^bP < 0.01$.

DISCUSSION

The present study reports on the effects of an antioxidant

supplement for enteral nutrition on the indicators of oxidative stress and levels of antioxidants after major abdominal surgery. Major abdominal surgery induces oxidative stress that is associated with cellular dysfunction which may impair recovery. The rapid decrease in antioxidant levels on the first postoperative day indicates consumption to counter surgery-induced oxidative stress and is in accordance with earlier reports[32,33]. The levels of antioxidants could not be restored by the administration of Module AOX in the first five postoperative days, except for levels of selenium and glutamine (Table 5). These findings are in line with the results reported by Schroeder *et al*[33] who investigated the antioxidant enteral supplement Intestamin® (Fresenius Kabi) in similar major gastrointestinal tract surgical patients. They found that even at the higher dosage of glutamine, selenium, zinc, Vitamin C, Vitamin E and beta-carotene in Intestamin® compared to Module AOX, the antioxidant levels could

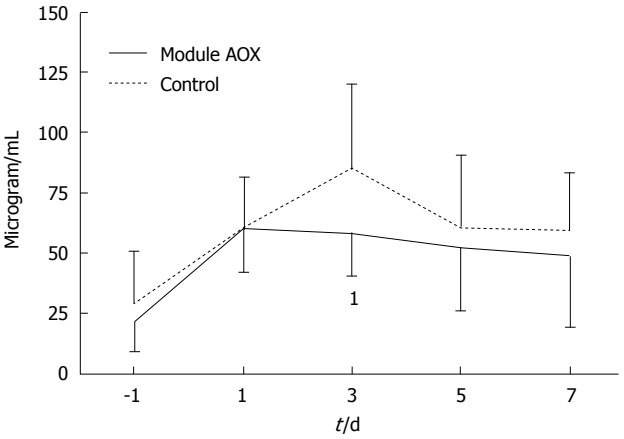

Figure 3 Development of LBP plasma concentration. Data represent means ± SD. [1]Indicates statistically significant difference between the control and treatment groups with respect to day 1.

not be raised to preoperative levels after five days of enteral nutrition. In contrast, in surgical critically ill patients, Intestamin® raised the plasma levels of glutamine, Vitamin C, Vitamin E and beta-carotene to normal levels at the third postoperative day[32]. A possible explanation for this discrepancy may be related to differences in the flow of antioxidants between cellular compartments in different patient populations and the capacity to absorb and metabolize supplemented antioxidants[34]. It should be noted that blood measurements only provide an approximation of the actual endogenous antioxidant defence status. Assessing antioxidant levels in other compartments or tissues is more difficult, but may better reflect the antioxidant defence status.

The blood concentrations of antioxidants present in Module AOX were significantly decreased on the first day after surgery. Only selenium and glutamine blood levels could be restored to preoperative levels, suggesting that the dosage of antioxidants was too low to influence blood levels. Theoretically, supplementing a combination of antioxidants that are depleted after surgery may have greater effects than supplying each antioxidant itself[10,35]. However, studies using some single antioxidant nutrients have shown important clinical results. This is especially true for glutamine which is considered a pharmaconutrient indispensable in critical illness. Glutamine appears beneficial in several patient groups, especially in those with burns, major trauma and after major surgery[36-39]. As an antioxidant, glutamine attenuates the inflammatory and oxidative stress response by enhancing plasma and tissue levels of glutathione[32]. The amount of glutamine supplementation recommended in a meta-analysis was 0.2-0.5 g per kg body weight which exceeds the amount of glutamine in Module AOX[39]. This may explain why there were no differences in glutamine levels between the control and Module AOX group after five days of nutrition.

As a single supplement, selenium is associated with decreased morbidity[16] and mortality[10] in critically ill patients. As a component of GSH-Px selenoenzymes,

Table 6 Postoperative response; 3, 5, 7 d after surgery

	Group	Day 3, *P*	Day 5, *P*	Day 7, *P*
Glutamine (μmol/L)	Control	494 (82)	566 (137)	624 (279)
		0.821	0.349	0.151
	Treatment	503 (91)	512 (108)	544 (83)
Vitamin C (μmol/L)	Control	18.3 (7.3)	23.1 (11.2)	32.2 (32.7)
		0.123	0.014	0.602
	Treatment	31.9 (13.5)	41.9 (13.9)	46.8 (16.6)

Data expressed as mean (standard deviation); MDA = malondialdehyde; GSH-Px = glutathione peroxidase; creat = creatinine; Hb = hemoglobin; GEE-analysis was used for statistical analysis; *P*, difference between the treatment and control group over time, corrected for baseline.

selenium inhibits nuclear factor kappa b (NFκB) which has a key role in the regulation of the expression of numerous cellular genes, particularly those involved in immune, inflammatory and stress responses. Therefore, by its effect on NFκB, selenium not only reduces inflammation, but also reduces oxidative stress and improves the defence mechanisms[40,41]. It is known that plasma GSH-Px is a sensitive marker of the response to antioxidant supplementation, especially selenium. Plasma GSH-Px declines in parallel with plasma selenium, while selenium supplementation restores the activity of the enzyme[16]. This is in contrast with the present study findings. Although the selenium plasma levels were raised after surgery in the treatment group, no difference in the plasma GSH-Px concentration was found. This suggests that the dosage of selenium given was insufficient to restore the activity of plasma GSH-Px.

Considering the above, one could argue that the dosages of glutamine and selenium are too low in Module AOX. However, increasing the dosages of antioxidants may be hazardous because at high intake some antioxidants may be toxic. In addition, as a consequence of their physical properties, some antioxidants also have pro-

oxidant effects. The capacity to scavenge free radicals is associated with the transformation of the scavenger into a free radical itself[16,34]. The possibility of an antioxidant acting as a pro-oxidant as well, could explain the unexpected increase in F2-isoprostane in the treatment group, although the dosages of the antioxidants used were low and established as safe. As for the other indicator of oxidative stress measured, MDA, no changes were observed in either of the groups. Similar to our findings, Preiser *et al*[42] also could not demonstrate any effect of an antioxidant-containing diet on levels of MDA in a randomised, double-blind, placebo-controlled study with critically ill patients during a seven day study period.

In the present study, malnutrition was an exclusion criterion, because it is an independent risk factor for the occurrence of postoperative infectious complications[43,44]. Kondrup *et al*[45] using the Nutritional Risk Screening (NRS 2002) examined how severity of illness and nutritional risk affected results in nutritional intervention studies. They found that better clinical effects were achieved in patients with a greater severity of illness and malnutrition[45]. It is possible that in the present study the patients who would have benefited most from antioxidant-enriched enteral nutrition, were excluded.

Lipopolysaccharide binding protein is an acute phase protein that is mainly synthesized by hepatocytes and its concentration in the circulation increases during inflammation[46]. At times of gut injury, such as during major surgery, LBP strongly modulates the response to endotoxins, which are present at the outer membrane of gram-negative bacteria (GNB). LBP-coated GNB are taken up mainly by monocytes and macrophages[46,47]. Endotoxins induce a receptor-mediated signalling cascade that leads to NF-κB activation and the transcription and subsequent release of cytokines and other proinflammatory mediators by monocytes and macrophages. Reactive oxygen species may be involved in the endotoxin-induced inflammatory response in two ways. Firstly, ROS may impair gut integrity by damaging the gut wall[48] inducing endotoxin translocation, and secondly ROS mediate endotoxin-induced NF-κB activation. It was demonstrated that neutralizing endotoxin, by recombinant bactericidal permeability increasing protein, lowered LBP levels in patients undergoing major liver resection[49]. In the Module AOX group, LBP levels decreased significantly compared to the control group which suggests that antioxidant supplementation modulates this acute phase response. This effect may be related to protection of gut integrity against ROS damage.

In major gastrointestinal tract surgical patients the oxidative stress parameters were not increased on the first postoperative day. Interestingly, in the antioxidant-supplemented group an increase in F2-isoprostane was observed during the first three postoperative days. This observation questions the use of antioxidants and further studies on the underlying mechanism are needed. A postoperative decrease in antioxidant levels occurred which could not be restored to the preoperative levels by Module AOX except for selenium levels. Larger multicenter studies are needed to further elucidate the effects of antioxidant-supplemented enteral nutrition in major gastrointestinal tract surgical patients. In such a trial, malnourished patients should also be included.

COMMENTS

Background

Major surgery and critical illness induce an immuno-inflammatory response, which is accompanied by the production of reactive oxygen species (ROS) at the site of injury. Reactive oxygen species can cause direct cellular injury by damaging lipids, proteins and DNA. In situations of major surgery and critical illness, a redistribution of antioxidants occurs to tissues or organs in need. This results in a depletion of antioxidant stores that may be deleterious when oxidative stress is prolonged. In these situations the supplementation of certain antioxidant amino acids (glutamine, cysteine) and antioxidant micronutrients (zinc, Vitamin C, Vitamin E, β-carotene, selenium) may improve outcome. The present study investigates the effect of antioxidant supplemented enteral feeding on circulating factors of the antioxidant defence system and markers of oxidative stress in patients after major upper gastrointestinal tract surgery.

Research frontiers

Theoretically, supplementing a combination of the antioxidants that are depleted after surgery may have greater effects than supplying each antioxidant itself. However, studies using some single antioxidant nutrients, like glutamine and selenium, have shown important clinical results, The effects of supplementation with combinations of antioxidants are still scarce, but the effects which are known are promising. Little is known about the effects of major abdominal surgery and antioxidant supplementation on the blood levels of parameters of antioxidant capacity and oxidative stress, which are important to know.

Innovations and breakthroughs

This study showed that oxidative stress parameters were not increased on the first postoperative day. A postoperative decrease in antioxidant levels occurred which could not be restored to the preoperative levels by Module AOX except for selenium levels. Interestingly, in the antioxidant-supplemented group, an increase in F2-isoprostane was observed during the first three postoperative days. This observation questions the use of antioxidants and further studies on the underlying mechanism are needed.

Applications

Larger multicenter studies are needed to further elucidate the effects of antioxidant-supplemented enteral nutrition in major gastrointestinal tract surgical patients. In such a trial, malnourished patients should also be included, since they might benefit most from such supplementation.

Peer review

This study investigates the effects of antioxidant enriched enteral nutrition on oxidative stress after major upper gastro-intestinal tract surgery. This study is well investigated and has some interesting findings.

Abstract

AIM: To analyze the risk factors of pancreatic leakage after pancreaticoduodenectomy.

METHODS: We retrospectively reviewed 172 consecutive patients who had undergone pancreaticoduodenectomy at Inha University Hospital between April 1996 and March 2006. We analyzed the pancreatic fistula rate according to the clinical characteristics, the pathologic and laboratory findings, and the anastomotic methods.

RESULTS: The incidence of developing pancreatic fistulas in patients older than 60 years of age was 21.7% (25/115), while the incidence was 8.8% (5/57) for younger patients; the difference was significant (P = 0.03). Patients with a dilated pancreatic duct had a lower rate of post-operative pancreatic fistulas than patients with a non-dilated duct (P = 0.001). Other factors, including clinical features, anastomotic methods, and pathologic diagnosis, did not show any statistical difference.

CONCLUSION: Our study demonstrated that pancreatic fistulas are related to age and a dilated pancreatic duct. The surgeon must take these risk factors into consideration when performing a pancreaticoduodenectomy.

INTRODUCTION

Pancreaticoduodenectomy (PD) is a commonly performed surgical procedure for managing duodenal trauma and various benign and malignant diseases of the periampullary region.

This procedure was first described by Whipple *et al*[1] in 1935. At that time, PD was technically difficult to perform and the mortality rate was reported to be > 30%[1]. Despite marked progress in the procedure and in the treatment of perioperative patients, the mortality rate is still reported to be 2%-10% in most hospitals[2,3]. The incidence of pancreatic fistulas remains a major cause of postoperative complications; it is reported that the incidence of pancreatic fistulas after PD is 6%-25%[4-12]. It is known that such pancreatic fistulas induce abscess formation, vascular injuries, rupture of pseudoaneurysms, and postoperative delayed hemorrhage, all resulting from inflammation around leakage sites due to stasis of fluid, including active pancreatic enzymes[13-16].

The aim of this study was to analyze the independent risk factors for pancreatic fistulas after PD.

MATERIALS AND METHODS

Between April 1996 and March 2006, 172 consecutive patients who had undergone PD at Inha University Hospital were retrospectively reviewed. The operations were performed by five surgeons, and pancreatic fistulas were investigated retrospectively by review of the patients'

medical records. A pancreatic fistula was defined as follows: from the 7th postoperative day on, the drainage output was > 50 cc a day and the drainage fluid amylase level was 3 times higher than the serum level[6].

We compared the pancreatic fistula rates based on gender, age, anastomotic method, preoperative serum total bilirubin level, serum albumin level, white blood cell (WBC) count, histologic diagnosis, texture of the remnant pancreas, and size of the pancreatic duct. The methods used for anastomosis included end-to-end anastomosis (dunking) between cross-sections of the jejunum and the pancreatic stump, and a pancreatic duct-to-jejunal mucosal anastomosis. The results were compared based on whether or not a feeding tube was placed into the duct, serving as a stent for the reconstruction and exteriorization of the duct from the anastomotic site through the lateral abdominal wall.

In all cases, somatostatin was used prophylactically for 7 d postoperatively. The statistical analyses of the correlations among multiple clinical factors were performed using independent t-tests and χ^2 tests, and a significant difference was considered when $P < 0.05$. The assessment of the statistical significance was carried out using multivariate analyses.

RESULTS

Leakage of the pancreaticojejunostomy occurred in 30 of 172 patients (17.4%), and the frequency of such leakage was analyzed and compared according to gender, age, anastomotic methods, operative findings, preoperative serum total bilirubin and albumin levels, preoperative WBC, and histopathologic diagnosis (Table 1).

Reoperations were carried out in 5 of 30 patients (16.7%) with leakage of the pancreaticojejunostomy; 4 patients had total pancreatectomies and 1 patient had a segmental resection of the small bowel. Among 172 patients, there were 4 deaths and the mortality rate was 2.3%; 1 patient underwent reoperation and 3 patients died during conservative management. There were 4 deaths in groups with leakage of the pancreaticojejunostomy.

Five surgeons operated on 95, 26, 19, 19, and 13 patients, respectively, in our hospital. The occurrences of pancreatic fistulas according to the surgeons were 17.9% (17/95), 23.1% (6/26), 15.8% (3/19), 10.5% (2/19), and 15.4% (2/13), respectively. There was no significant correlation between the surgeons and pancreatic fistulas ($P = 0.867$).

The mean age of the patients was 62.2 years, with a range of 33-87 years. Pancreatic fistulas occurred in 25 patients over 60 years of age (21.7%), and in 5 of 57 patients under 60 years of age (8.8%). The difference in the pancreatic fistula rates between the two groups was significant ($P = 0.016$).

With regard to gender, anastomotic method, pancreatic stenting, texture of the remnant pancreas, preoperative serum albumin level, total bilirubin level, and WBC count, there were no significant differences in pancreatic fistula rates.

The pancreatic duct size was included in the pathology reports and the patients were divided into 2 groups based on the main duct size, as follows: (1) patients with a dilated pancreatic main duct, defined as having a visible main duct and (2) a non-dilated pancreatic main duct, defined as having a non-visible main duct. Only 136 of 172 patients were classified according to pancreatic duct size. The number of patients with dilated and non-dilated pancreatic main ducts was 60 and 76, respectively. Pancreatic fistulas developed in 4 of 60 patients in the group with a dilated pancreatic main duct (6.6%), and in 21 of 76 patients in the group with a non-dilated pancreatic main duct (27.6%); there was a significant difference between the two groups ($P = 0.001$; Table 1).

Table 1 Pancreatic fistula rate based on clinical factors

Factors		Number of patients (%)	Leakage (%)	*P* value
Age (yr)	≥ 60	115 (66.9)	25 (21.7)	0.016
	< 60	57 (32.1)	5 (8.8)	
Gender	Male	116 (67.4)	19 (16.4)	0.606
	Female	56 (32.6)	11 (19.6)	
Type of anastomosis	Duct-to-mucosa	133 (77.3)	22 (16.5)	0.582
	End-to-end	39 (22.7)	8 (19.6)	
Pancreatic stent	Yes	58 (33.7)	11 (19.0)	0.712
	No	114 (66.3)	19 (16.7)	
Texture of remnant pancreas	Hard	61 (58.5)	7 (16.3)	0.392
	Soft	43 (41.5)	7 (23.0)	
Pancreatic duct size	Dilated	60 (44.1)	4 (6.6)	0.001
	Non-dilated	76 (55.9)	21 (27.6)	
Pre-op bilirubin	≥ 1.3 mg/dL	92 (54.5)	15 (16.3)	0.674
	< 1.3 mg/dL	80 (46.5)	15 (18.8)	
Pre-op albumin	≥ 3.1 g/dL	138 (80.2)	23 (16.7)	0.607
	< 3.1 g/dL	34 (19.8)	7 (20.6)	
Pre-op WBC	≥ 10000/mm^3	29 (16.9)	7 (24.1)	0.349
	< 10000/mm^3	143 (83.1)	23 (16.1)	

When the incidence of pancreatic fistulas was compared based on histopathologic diagnosis, pancreatic fistulas occurred in 6 of 37 patients (16.2%) diagnosed with carcinomas in the pancreatic head, in 8 of 46 patients (17.4%) diagnosed with carcinomas in the common bile duct (CBD), in 8 of 34 patients (23.5%) diagnosed with carcinomas of the ampulla of Vater, in 1 of 10 patients (10.0%) diagnosed with duodenal cancer, in 3 of 9 patients (33.3%) diagnosed with intraductal papillary mucinous tumors, in 0 of 6 patients (0%) diagnosed with chronic pancreatitis, in 2 of 22 patients (9.1%) diagnosed with gastric cancer and pancreatic invasion, in 1 of 4 patients (25.0%) with trauma to the pancreas, and in 1 of 4 patients (25.0%) diagnosed with gallbladder (GB) cancer (Table 2). Although patients diagnosed with chronic pancreatitis and gastric cancer with pancreatic invasion tended to develop pancreatic fistulas less frequently than other patients, there was no significant difference in the correlation between histopathologic diagnosis and pancreatic fistulas.

DISCUSSION

PD is technically difficult, and as a result, relatively high mortality (15%-30%) and complication rates (50%-75%) were reported before the 1980s. With advances in surgi-

Table 2 Pancreatic fistula based on histopathologic diagnosis

Name of disease	Number of patients (%)	Leakage (%)
Pancreatic head cancer	37 (21.5)	6 (16.2)
CBD cancer	46 (26.7)	8 (17.4)
Ampulla of Vater cancer	34 (19.8)	8 (23.5)
Duodenal cancer	10 (5.8)	1 (10.0)
Chronic pancreatitis	6 (3.5)	0 (0)
Intraductal papillary mucinous tumor	9 (5.2)	3 (33.2)
Gastric cancer	22 (12.8)	2 (9.1)
GB cancer	4 (2.3)	1 (25)
Trauma	4 (2.3)	1 (25)

cal techniques and perioperative care, the mortality rate associated with PD has since improved[17].

Most complications after PD commonly arise from failure in healing of the pancreaticojejunostomy, and have been described as pancreatic fistulas or anastomotic leakages by various authors.

Berberat *et al*[18] defined a pancreatic fistula as an anastomotic leak of the pancreaticojejunostomy demonstrated radiographically or intraoperatively, and as a prolonged or elevated output of amylase-rich fluid through an intraoperatively-placed drain (> 3 times the normal serum amylase level). Lowy *et al*[19] divided pancreatic fistulas into clinical leakage and biochemical leakage, in which the former referred to the amylase level of the fluid obtained through an intraoperatively-placed drain to be > 3 times the normal serum amylase level, with a high fever, leukocytosis, sepsis, and the need for drainage, while the latter referred to asymptomatic patients. We favor the definition described by Yeo *et al*[6] i.e. from the 7th postoperative day on, the drain output is > 50 cc a day and the drain fluid amylase level is 3 times higher than the serum amylase level. Using the Yeo *et al*[6] definition, we analyzed the risk factors for pancreatic leakage.

To place a tube as a stent and to determine how a pancreaticojejunostomy relates to pancreatic fistula formation requires more research[20]. Yeo *et al*[21] reported that pancreatic fistulas were correlated with anastomotic technique, operative time, a surgeon's skills and experience in performing a PD, tumor location, and co-morbid illnesses[21]. Bartoli *et al*[17] reported a difference in the degree of fibrosis of the remnant pancreas, and that anastomotic leakage occurred in 5% of patients with chronic pancreatitis and in 33% of patients with carcinoma of the CBD. Patients in whom the pancreatic texture has a hard consistency have been reported to be at lower risk for pancreatic leakage than those patients who have a pancreatic parenchyma with a soft or intermediate consistency[22,23]. The texture of the pancreatic parenchyma has been reported to be correlated with the pancreatic duct diameter[24], in considering the ease in performing a pancreatic duct-to-jejunum mucosa anastomosis, such a simple comparison requires more consideration. The pancreatic duct diameter has been correlated with pancreatic leakage[5], and our study showed that 136 (79.1%) patients had evidence of pancreatic duct dilatation by histopathologic reports, confirming the correlation between pancreatic duct size and pancreatic fistula development ($P = 0.001$). None of the 6 patients with chronic pancreatitis developed pancreatic leakage, and chronic pancreatitis induced pancreatic fistula less often than other pancreatic diseases; however, there was no statistical significance. We considered this result to reflect a small number of the population and because of the possible prediction of pancreatic duct dilatation in chronic pancreatitis, pancreatic duct diameter could be correlated with pancreatic leakage. However, in considering factors related to the texture of the remnant pancreas, the incidence of pancreatic fistulas in patients with a hard texture of the remnant pancreatic parenchyma was 16.3% (7/43) and was lower than that in patients with a soft texture [23% (14/61)], but this finding lacked statistical significance ($P = 0.392$). These results are considered to have no statistical significance because pancreatic texture was demonstrated in only 104 of 172 patients (60.5%).

In this study, the incidence of pancreatic fistulas in patients with gastric cancer with pancreatic invasion was 9.1% and was lower than that in patients with other diseases, again showing no statistical significance. Among 22 patients with gastric cancer with pancreatic invasion, 13 patients were < 60 years of age, suggesting that gastric cancer with pancreatic invasion affects a younger age group when compared with 57 patients < 60 years of age in the total population of 172 patients. These results were considered to be influenced by the bias arising from the difference between the older age group, a significant factor in our study, and the younger age group of patients with gastric cancer with pancreatic invasion.

Pancreatic leakage has been related to the presence or absence of co-morbid illnesses, and age has been correlated with the occurrence of pancreatic fistulas[21-23]. In our study, there was a significant correlation between age and pancreatic fistulas ($P = 0.03$).

With regard to the pancreaticojejunostomy technique, binding pancreaticojejunostomy significantly decreased postoperative complications and the pancreaticojejunostomy leakage rate[25-27]. In our study, the methods used for anastomosis were divided into end-to-end dunking anastomosis between cross-sections of the jejunum and the pancreatic stump, and pancreatic duct-to jejunal mucosal anastomosis. The results were compared based on whether or not a feeding tube, which serves as a stent for the reconstruction and exteriorization, was placed from the anastomotic site through the lateral abdominal wall.

Many previous reports have proposed that hard texture of the pancreatic parenchyma and a dilated pancreatic duct have a lower risk of pancreatic fistula formation owing to an ability to prevent pancreatic duct dilatation and shrinkage of the pancreaticojejunostomy after PD[16]. Conversely, in the case of a small pancreatic duct and a soft pancreas, an end-to-end invagination anastomosis or binding pancreaticojejunostomy significantly decreases postoperative complications[20,27]. In our study there was no significant difference in the incidence of pancreatic fistulas as a function of anastomotic technique.

Although there is a report that the preoperative serum total bilirubin level, duration of jaundice, surgery performed under emergent conditions, and preoperative serum albumin level can affect the occurrence of pancreatic fistulas[28], there was no significant difference among the preoperative serum total bilirubin level, albumin level, and leukocytosis in our study. The patients with pancreatic parenchyma of soft consistency produce a larger amount of pancreatic juice and have a higher risk of pancreatic leakage than those with a hard consistency[14]. Therefore, a variety of surgical methods have been attempted. Specifically, efforts to exteriorize the pancreatic fluid with a tube, to place a tube into the pancreatic duct, and to use synthetic somatostatin prophylactically have been attempted, but the reports have failed to show a statistically significant difference among the techniques[26,27].

In this study, it was demonstrated that there were no significant differences in the incidence of pancreatic fistulas based on surgical technique. Therefore, we are of the opinion that the surgical technique should be individualized based on the patient's condition and the surgeon's preferences.

We demonstrated several risk factors related to pancreatic leakage after PD; age and pancreatic duct size were significantly correlated with an increased incidence of pancreatic fistula. In conclusion, it is important that surgeons are aware of these risk factors for pancreatic fistula formation when performing a PD.

COMMENTS

Background

Pancreaticoduodenectomy is technically difficult, and as a result, relatively high mortality (15%-30%) and complication rates (50%-75%) were reported before the 1980s. With advances in surgical techniques and perioperative care, the mortality rate associated with PD has since improved.

Research frontiers

Most complications after PD commonly arise from failure in healing of the pancreaticojejunostomy, and have been described as pancreatic fistulas or anastomotic leakages by various authors.

Innovations and breakthroughs

The incidence of developing pancreatic fistulas in patients older than 60 years of age was 21.7% (25/115), while the incidence was 8.8% (5/57) for younger patients; the difference was significant (P = 0.03). The patients with a dilated pancreatic duct had a lower rate of post-operative pancreatic fistulas than the patients with a non-dilated duct (P = 0.001).

Applications

This study demonstrated that pancreatic fistulas are related to age and a dilated pancreatic duct. The surgeon must take these risk factors into consideration when performing a pancreaticoduodenectomy.

Peer review

A well organized paper about the risk factors affecting pancreatic fistulas after pancreaticoduodenectomy.

Abstract

AIM: To analyze the clinical characteristics of patients diagnosed with Fitz-Hugh-Curtis syndrome.

METHODS: The clinical courses of patients that visited St. Mary's Hospital with abdominal pain from January 2005 to December 2006 and were diagnosed with Fitz-Hugh-Curtis syndrome were examined.

RESULTS: Fitz-Hugh-Curtis syndrome was identified in 22 female patients of childbearing age; their mean age was 31.0 ± 8.1 years. Fourteen of these cases presented with pain in the upper right abdomen alone or together with pain in the lower abdomen, and six patients presented with pain only in the lower abdomen. The first impression at the time of visit was acute cholecystitis or cholangitis in 10 patients and acute appendicitis or pelvic inflammatory disease in eight patients. Twenty-one patients were diagnosed by abdominal computer tomography (CT), and the results of abdominal sonography were normal for 10 of these patients. *Chlamydia trichomatis* was isolated from 18 patients. Two patients underwent laparoscopic adhesiotomy and 20 patients were completely cured by antibiotic treatment.

CONCLUSION: For women of childbearing age with acute pain in the upper right abdomen alone or together with pain in the lower abdomen, Fitz-Hugh-Curtis syndrome should be considered during differential diagnosis. Moreover, in cases suspected to be Fitz-Hugh-Curtis syndrome, abdominal CT, rather than abdominal sonography, assists in the diagnosis.

INTRODUCTION

Acute abdominal pain is one of the most common symptoms experienced by patients visiting hospitals, particularly the emergency room. Pain in the right upper abdomen is a symptom of biliary diseases, such as gall bladder (GB) stones or cholecystitis, and it may also be present in duodenal ulcers, liver abscess, subphrenic abscess, herpes zoster infection, *etc*. In addition, pain in the right upper abdomen, alone or together with pain in the lower abdomen, is associated with Fitz-Hugh-Curtis syndrome, although this condition is infrequent among hospital patients.

Fitz-Hugh-Curtis syndrome is characterized by inflammation in perihepatic capsules with concomitant pelvic inflammation without involvement of hepatic parenchyma[1-3]. Most Fitz-Hugh-Curtis syndrome patients are women of childbearing age who visit hospitals because of acute pain and tenderness in the right upper abdomen. The pain in the right upper abdomen is caused by adhesion of the anterior hepatic surface and the abdominal wall[4]. The pain tends to

become more severe upon body movement, breathing, *etc*, and, thus, it is difficult to distinguish it from acute cholecystitis, pleurisy, right pyelonephritis, *etc* in many cases[5]. Furthermore, in some cases, it presents with pain in the lower abdomen only, without the characteristic pain in the right upper abdomen, and it is thus misdiagnosed as acute appendicitis or some other form of peritonitis[6].

Recently, with the development of imaging tests and antibiotics, Fitz-Hugh-Curtis syndrome has been classified as a benign disease that can be diagnosed and treated readily by non-invasive methods[7], for example, by abdominal computer tomography (CT) scan and oral antibiotics, respectively. Nevertheless, without sufficient understanding of this disease, it could be misdiagnosed as another acute disease with similar clinical symptoms, and thus patients may undergo unnecessary surgery or tests.

Until now, Fitz-Hugh-Curtis syndrome has been considered a gynecological disease; however, the major complaint is pain in the right upper abdomen. Hence, clinicians that focus on the digestive tract frequently encounter such patients during the primary diagnosis. This study analyzed the clinical characteristics of patients diagnosed with Fitz-Hugh-Curtis syndrome at our hospital.

MATERIALS AND METHODS

Patients

This study was performed with 22 patients that visited St. Mary's Hospital, Catholic University, from January 2005 to December 2006, due to abdominal pain and were diagnosed with Fitz-Hugh-Curtis syndrome. In the study, the diagnostic standard of Fitz-Hugh-Curtis syndrome was the following: (1) abdominal CT scan showed pelvic inflammation with contrast enhancement of hepatic capsules; (2) patients had an adhesion between the liver and the diaphragm or the liver and the anterior abdominal wall detected by laparoscopic surgery. CT images were acquired using multi-detector scanners, Lightspeed VCT (General Electric, Milwaukee, WI, USA). A total of 120 mL of iopromide, Ultravist 300 (Bayer Schering Pharma AG, Berlin, Germany) was administrated at a rate of 3 mL/s with an automatic power injector. Images were obtained before and at 60-70 s after iv contrast material injection. In all phases, scanning was initiated at the dome of the right hemidiaphragm and scans of the entire abdomen to the symphysis pubis were obtained. Slice thickness was 5 mm. To gain a definitive diagnosis of pathogens, we performed PCR tests, used sexually transmitted disease detection kits to detect *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Mycoplasma genitalium*, and performed serological tests, including enzyme immunoassay for Chlamydia IgM and ELISA for Chlamydia IgG.

Study design

We retrospectively reviewed the records of 22 patients who were diagnosed with Fitz-Hugh-Curtis syndrome. Patients' medical records, disease histories, physical and systemic examinations, and first impression by the clinicians that performed the initial diagnosis were examined. Laboratory tests, blood chemistry, serological tests, direct smears of specimens, and bacterial culture tests were performed. For radiological tests, the results of ultrasound tests and CT were examined. Diagnostic and therapeutic laparoscopic surgery, antibiotic treatments after diagnosis, and prognosis were examined for each patient.

RESULTS

Characteristic of patients

Our study sample included 22 Fitz-Hugh-Curtis syndrome patients diagnosed at our hospital. The patients were all women of childbearing age with a mean age of 31.0 ± 8.1 years (range 19-49 years). Their most recent sexual activity was between 3 d and 1 mo prior to the visit and the frequency of sexual activity was also provided. Except for two patients for whom symptoms were relatively meager and who were thus admitted through outpatient clinics, 20 patients visited the emergency room because of acute abdominal pain. The interval from the development of symptoms to a hospital visit was diverse, ranging from the same day to 2 wk, with an average of 5.8 ± 4.5 d (Table 1).

Chief complaint

The chief complaint requiring a visit to the hospital was pain in the right upper abdomen in seven patients (32%), pain in the right upper abdomen and pain in the lower abdomen in seven cases (32%), pain in the lower abdomen in six cases (27%), fever in one case (4.5%), and epigastric pain in one case (4.5%). With the exception of one case, fever was absent in the patients (Table 1).

First impression

After the first impression of the clinicians that examined the patients initially, 10 patients were diagnosed with acute cholecystitis or a GB stone, eight patients were diagnosed with acute appendicitis or pelvic inflammatory disease, and four patients were diagnosed with acute pyelonephritis, acute hepatitis, acute gastritis, or peptic ulcer disease (Table 1).

Test results

Various test methods were used for diagnosis. In 21 patients (95.5%), an abdominal CT scan was performed and Fitz-Hugh-Curtis syndrome was diagnosed according to its characteristics, the finding of contrast enhancement in the hepatic capsules. One of the patients was diagnosed as having Fitz-Hugh-Curtis syndrome by an abdominal CT scan and was treated; however, due to deterioration in her symptoms, laparoscopic surgery was performed and adhesion between the anterior side of the liver and the abdominal wall was confirmed. The remaining patient developed acute peritonitis during

Table 1 Clinical manifestation of 22 patients with Fitz-Hugh-Curtis syndrome

	mean ± SD (range)
Age (yr)	31.0 ± 8.1 (19-49)

pregnancy and was diagnosed by laparoscopic surgery without abdominal CT scan. Among the 21 patients diagnosed by abdominal CT scan, abdominal sonography was performed in 10 of them prior to abdominal CT scan and the results were normal in all cases.

According to blood chemistry tests, the number of leukocytes averaged 11.532/mm^3, which was slightly higher than normal. Liver function test results were within the normal range in most patients, with the exception of 1 patient with a result 4 times greater than the upper normal limit. ESR averaged 51.3 mm/h which was elevated five times more than normal (normal value, 0-10 mm/h). C-reactive protein (CRP) averaged 52.3 mg/L, which was over 10 times higher than normal (normal value, less than 5 mg/L). The serological antibody tests to *C. trichomatis* and PCR tests to six common sexually transmitted disease pathogens indicated the presence of *C. trichomatis* in 18 patients, *T. vaginalis* in one patient, *U. urealyticum* in one patient, and *M. hominis* in one patient. One patient was diagnosed during emergency surgery and, thus, the serology tests were not performed. Direct specimen smears were all negative. A cell culture test was performed for seven patients (three cases for *Streptococcus agalactiae*, one case for *U. urealyticum*, one case for *Staphylococcus aureus*, one case for *Candida albicans*, and one case for *Escherichia coli*) and the findings concurred with the results of the serological chlamydia antibody tests of and PCR tests performed to determine the presence of pathogens (Table 2).

Treatment and progress

Of 22 patients, 20 patients (91%) improved following general or combinatorial antibiotic therapy and conservative care. One patient did not respond to antibiotic therapy; her pain became more severe but her symptoms improved after adhesiotomy by laparoscopic surgery. One patient developed acute peritonitis during pregnancy and, thus, laparoscopic surgery was performed for the purpose of diagnosis and treatment; she improved after adhesiotomy. Doxycycline was administered as a single antibiotic to five patients, and in combination to 14 patients. For those patients that received combination therapy, triple drug therapy consisted of metronidazole and aminoglycoside with ampicillin/sulbactam or cephalosporin and dual drug therapy consisted of an aminoglycoside with ampicillin/sulbactam or metronidazole with cephalosporin. Three patients received 2 drug therapy for 1 wk and their clinical symptoms were improved (Table 3).

Table 2 Laboratory and radiographic study of 21[1] patients with Fitz-Hugh-Curtis syndrome, which was diagnosed by abdominal CT

	mean ± SD (range)
Laboratory study (n = 21)	
WBC (1000/mm^3)	11.5 ± 3.4 (3.5-16.2)
AST (IU/L)	22.1 ± 30.1 (10-156)
ALT (IU/L)	17.0 ± 24.8 (5-126)
ESR (mm/h)	51.2 ± 28.9 (18-120)
CRP (mg/L)	52.1 ± 41.9 (2-154)
	Positive result of number (%)
Serologic test or PCR (n = 21)	
C. trichomatis	18 (85.7)
T. vaginalis	1 (4.8)
U. urealyticum	1 (4.8)
M. hominis	1 (4.8)
Microbiologic culture (n = 21)	
S. agalactiae	3 (14.3)
U. urealyticum	1 (4.8)
S. aureus	1 (4.8)
C. albicans	1 (4.8)
E. coli	1 (4.8)
	Positive result of number (%)
Radiographic study[2]	
Abdomen CT (n = 21)	21 (100)
Abdomen ultrasonography (n = 10)	0 (0)

[1]Among the 22 patients, one was diagnosed by laparoscopic surgery without a study; [2]Abdominal CT was performed in 21 patients, and only 10 patients among them were investigated by abdominal ultrasonography.

DISCUSSION

Fitz-Hugh-Curtis syndrome is characterized by perihepatic inflammation appearing with pelvic inflammation primarily in women of childbearing age. It occurs in 12.0%-13.8% of pelvic inflammation cases[8,9]. In 1930, Curtis[1] reported the violin-string appearance between the anterior hepatic surface and the abdominal wall in gonorrhea patients. Furthermore, in 1934, Fitz-Hugh[2] reported gonococcal peritonitis accompanied by pain in the right upper abdomen. Previously, *N. gonorrhoeae* was considered to be the major pathogen of this syndrome; however, in 1985, Lopes-Zeno *et al*[4] showed that *C. trachomatis*, not *N. gonorrhoeae*, was the major pathogen. In the past, the definitive diagnosis was made using methods that confirmed adhesion in the vicinity of the liver by laparoscopic surgery or open abdominal surgery. Recently, the disease was diagnosed and experienced infrequently as it was diagnosed by non-invasive methods such as serological tests for specific antibodies to pathogens that induce pelvic inflammation,

Table 3 Clinical characteristics of 22 patients with Fitz-Hugh-Curtis syndrome

No.	Age	Symptom (pain)	Duration	Impression	Diagnosis	Treatment	Prog

RUQ: Right upper quadrant abdominal; RLQ: Right lower quadrant abdominal; PID: Pelvic inflammatory disease; GB: Gallbladder; CT: Computed tomography; Sono: Ultrasonography; Cepha: Cephalosporin; Amino: Aminoglycoside; Metro: Metronidazole; Amp: Ampicillin/sulbactam; Prog: Prognosis; Lapa: Laparoscopic adhesiolysis.

PCR, and abdominal CT scan.

It has been suggested that the mechanisms of development of Fitz-Hugh-Curtis syndrome include inflammation in hepatic capsules caused by inflammation in the reproductive system through the peritoneal cavity; migration of pathogens from the peritoneal membrane to the liver via blood; migration of pathogens from the peritoneal membrane to the liver through lymph ducts; and a hyperimmune response to *C. trichomatis*; nonetheless, the precise mechanism has not been elucidated yet[10].

The pain in the right upper abdomen that appears as the main symptom during the acute phase develops as a sudden sharp pain that becomes more severe in response to deep breathing, body movements, coughing, *etc*, and it develops as a result of congestion of hepatic capsules, spotted hemorrhage, and fibrous exudates. Occasionally, the pain may radiate to the right shoulder. Lower abdominal pain may appear simultaneously with the right upper abdomen pain or intermittently with the abdominal pain. If pain progresses to a chronic state without pain in the lower abdomen, the pain in the right upper abdomen generally appears continuously or may become dull.

In our study, 14 of 22 patients (64%) showed right upper quadrant (RUQ) pain; the typical symptom of Fitz-Hugh-Curtis syndrome. Seven of 14 patients displayed only RUQ pain, and in the other seven patients RUQ pain was accompanied by pain in the lower abdomen. The other eight patients (36%) had no typical RUQ pain symptom but experienced pain in the epigastrium or only in the lower abdomen, or they had fever and other systemic symptoms. Even when there is no pain in the right upper abdomen, which is the characteristic of Fitz-Hugh-Curtis syndrome when it occurs as perihepatic inflammation, the possibility of Fitz-Hugh-Curtis syndrome can not be ruled out completely[11,12]. Though it is not typical, diagnosis of Fitz-Hugh-Curtis syndrome with the major symptom of pain in the lower abdomen with pelvic inflammation or systemic symptoms should be considered. It has been reported that cases in which pain in the upper abdomen develops without pain in the lower abdomen are rare[13,14]; however, in this study, seven patients (32%) developed pain only in the right upper abdomen. This takes place in patients who have recovered from an acute episode of pelvic inflammatory disease without appropriate treatment[10]. These cases have to be cautiously differentiated from diseases for which the major symptom is pain in the right upper abdomen, such as acute cholecystitis. Although our study did not explore this, there are cases that display pain in the left upper abdomen by perisplenitis as the main symptom of Fitz-Hugh-Curtis syndrome. Hence, we think that cases of non-typical symptoms should be fully considered[15].

For the diagnosis of Fitz-Hugh-Curtis syndrome and the earlier findings of laboratory tests, the only method for definite diagnosis used to be assessment of adhesions in the vicinity of the liver by invasive laparoscopic surgery; however, diagnosis has recently been made possible by a non-invasive abdominal CT scan resulting in contrast enhancement in hepatic capsules caused by perihepatic inflammation during the acute phase of Fitz-Hugh-Curtis syndrome[7,16,17]. In this study, 21 cases (95.5%) were diagnosed by abdominal CT scan. Laparoscopic surgery was performed in only two patients for the purpose of diagnosis and

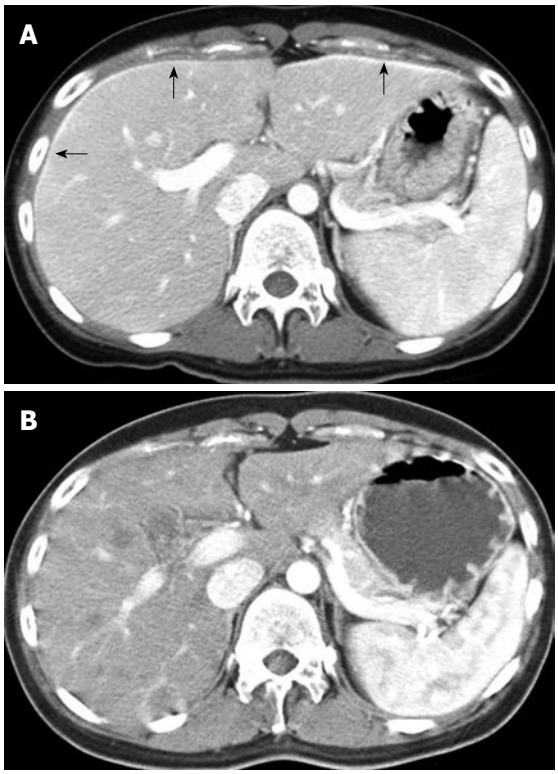

Figure 1 Contrast-enhanced CT. A: Linear enhancement of the surface at both lobes of the liver (arrow); B: CT images 1 mo after treatment indicate normal liver.

treatment. In addition, differential diagnosis of Fitz-Hugh-Curtis syndrome from hepato-biliary diseases was performed for patients presenting with pain in the right upper abdomen by abdominal sonography. In our study, abdominal sonography was performed on 10 patients in the emergency room. All of these patients showed normal findings. Because abdominal sonography observations are mainly concentrated on the GB or liver, which are usually considered major causes of pain in the right upper abdomen, there is a failure to notice pelvic inflammatory disease which can be observed in the pelvic cavity. There may also be discrepancies in the expertise of different sonographers. Although abdominal sonography is of great help as a primary diagnostic tool to prove the causality of pain in the right upper abdomen, there are clear limitations in using only abdominal sonography to diagnose Fitz-Hugh-Curtis syndrome. Therefore, in sexually active women of childbearing age presenting with pain in the right upper abdomen or pain in the right upper abdomen together with pain in the lower abdomen, that have normal liver function test results and for whom Fitz-Hugh-Curtis syndrome is strongly suspected, an abdominal CT scan may diagnose the syndrome more rapidly and accurately. For the identification of causative pathogens, uterine cervical specimens have been used most frequently, although rectal, urinary tract and salivary specimens can be used[10]. To confirm the presence of the major pathogen *C. trachomatis*, a culture test is widely applied and, more recently, ligase chain reaction (LCR), PCR, and a specific antibody test have been used to identify the pathogen. In our study, PCR and specific antibody tests were performed to identify the pathogen; tests were positive for *C. trichomatis* in 18 patients (82%), and testing for *N. gonorrhoeae*, which has been known to be the most prevalent pathogen in the past, was negative. Other pathogens were detected in the remaining three patients and it is thought that pathogens other than *C. trichomatis* that induce pelvic inflammation could be causative of Fitz-Hugh-Curtis syndrome. Lactobacilli maintain normal vagina flora, but if normal vagina flora is altered, an inflammation is usually induced by *G. vaginalis*, *C. albicans*, *T. vaginalis*, *M. hominis*, and the cervix becomes inflamed due to *C. trichomatis*, *N. gonorrhoeae*, *T. vaginalis*, and *C. albicans*. *C. trichomatis* and *N. gonorrhoeae* cause pelvic inflammation. Generally, the culture test is the basic test for the identification of causative pathogens; however, in our study, the major causative pathogen *C. trichomatis* was not identifiable by culture tests. *C. trichomatis* cannot be identified in general bacterial culture tests as culture tests for *C. trichomatis* require special media that is not used in general bacterial culture. Therefore, for cases suspected to be Fitz-Hugh-Curtis syndrome, culture tests should be performed using the special media for *C. trichomatis* to enable accurate diagnosis. Hepatic enzyme values are normal or slightly elevated in Fitz-Hugh-Curtis syndrome, which is of help in differentiating it from hepatitis[18]. In Fitz-Hugh-Curtis syndrome, the liver function test is normal or slightly elevated and the ESR, although still controversial, has been reported to be increased in some cases[19]. Recently, CRP has been reported to be a marker that reflects the clinical course of this disease[20,21]. In most of our cases, the results of liver function tests were normal except for one patient with a result four times greater than the upper normal limit, and leukocyte values were slightly increased. ESR were elevated five times and CRP was elevated over 10 times more than the normal in our study. However, it is difficult to diagnose Fitz-Hugh-Curtis syndrome definitely by serum biochemistry and serological tests; therefore, they are only partially able to aid in the diagnosis of Fitz-Hugh-Curtis syndrome.

Antibiotics against the identified causative bacteria were administered as treatment and, for cases that were unresponsive to antibiotic therapy, surgery was performed to remove the adhesion in the vicinity of the liver. Standardized treatments were not available so antibiotics targeting *C. trichomatis*, *N. gonorrhoeae*, gram negative bacilli, and anaerobic bacteria were administered. Oral antibiotics were administered for 2 wk and non-oral antibiotics were administered for 48 h after the improvement of clinical symptoms[22]. It has been reported that treatment reactions in most patients are good. This was the case in our study, with the exception of one case in which laparoscopic surgery was performed following the deterioration of symptoms. Most patients improved following antibiotic treatment. Moreover, the lesions were absent on abdominal CT scan performed after the treatment (Figure 1).

The diagnosis rate of Fitz-Hugh-Curtis syndrome has increased due to the recent development of

imaging tests. Most patients recover completely after treatment with appropriate antibiotics. Nevertheless, this syndrome is often misdiagnosed as other diseases with similar clinical symptoms which results in unnecessary treatment and hospital stays. Therefore, if sexually active women visit a hospital because of pain in the right upper abdomen or pain in the right upper abdomen and pain in the lower abdomen, Fitz-Hugh-Curtis syndrome should be considered. For patients suspected to have Fitz-Hugh-Curtis syndrome, an abdominal CT scan, rather than abdominal sonography, may be helpful since it provides a more rapid and accurate diagnosis.

ACKNOWLEDGMENTS

We acknowledge the help of Ka Young Kim from Korean Minjok Leadership Academy, who provided great support to data analysis and excellent secretarial assistance.

COMMENTS

Background

Fitz-Hugh-Curtis syndrome has been considered a gynecological disease; however, the major complaint is pain in the right upper abdomen. Hence, clinicians that focus on the digestive tract frequently encounter such patients during primary diagnosis.

Research frontiers

Fitz-Hugh-Curtis syndrome has been classified as a benign disease. Nevertheless, without sufficient understanding of this disease, it may be misdiagnosed as other acute diseases with similar clinical symptoms. This study analyzed the clinical characteristics of patients diagnosed with Fitz-Hugh-Curtis syndrome.

Innovations and breakthroughs

Abdominal sonography is of great help as a primary diagnostic tool to prove the causality of pain in the right upper abdomen. However, there is a clear limitation to diagnosis of Fitz-Hugh-Curtis syndrome by using only abdominal sonography. Because the observations are mainly concentrated on the hepato-biliary disease, there is a failure to notice pelvic inflammatory disease. For patients suspected to have Fitz-Hugh-Curtis syndrome, an abdominal CT scan, rather than abdominal sonography, may be helpful.

Applications

The results show that in sexually active women of childbearing age presenting with pain in the right upper abdomen or pain in the right upper abdomen together with pain in the lower abdomen and normal liver function test results, Fitz-Hugh-Curtis syndrome should be considered during differential diagnosis.

Terminology

Fitz-Hugh-Curtis syndrome is characterized by inflammation in perihepatic capsules with concomitant pelvic inflammation. Most Fitz-Hugh-Curtis syndrome patients visit hospitals due to acute pain and tenderness in the right upper abdomen. The diagnosis is made by a non-invasive abdominal CT scan resulting in contrast enhancement in hepatic capsules caused by perihepatic inflammation. The treatment is antibiotic therapy against the identified causative bacteria.

Peer review

This is an interesting study which was well organized. It demonstrated that although Fitz-Hugh-Curtis syndrome is a benign disease that can be diagnosed by non-invasive methods and treated by antibiotics, it is often misdiagnosed as other acute diseases which results in unnecessary treatment and hospital stays.

Abstract

AIM: To investigate the impact of mucin production on prognosis in colorectal cancer, in terms of overall survival (OS) and time to disease progression (TTP) in patients with mucinous compared to those with non-mucinous colorectal cancer (NMCRC), matched for age, gender, and tumor stage.

METHODS: Thirty five patients with mucinous colorectal cancer (MCRC) were matched for age, gender, and tumor stage with 35 controls having NMCRC. OS and TTP were compared among 4 groups divided according to mucin content: group A (50%-75% mucin), group B (75%-100% mucin), group C or controls (< 50% mucin). Group D consisted of all patients with tumors having < 75% mucin (controls and groups A together).

RESULTS: Median survival in MCRC and NMCRC groups was 46.2 and 112.9 mo, respectively (P = 0.26). OS in groups A and B was 70.1 and 32.8 mo (P = 0.46), and in groups B and D was 32.8 and 70.1 mo, respectively (P = 0.143). TTP in MCRC and NMCRC was 50.17 and 44.77 mo, respectively (P = 0.795). TTP in groups A, B, and D was 70.1, 24.8, and 65.5 mo, respectively. Twenty-eight percent of patients with MCRC had poorly differentiated adenocarcinoma versus 8.6% in NMCRC patients (P = 0.028).

CONCLUSION: MCRC is associated with a non-significant decrease in median survival and TTP, particularly when mucin content is > 75% of tumor volume. However, it tends to be more poorly differentiated. A larger study matching for stage and grade is needed.

Effect of mucin production on survival in colorectal cancer: A case-control study. *World J Gastroenterol* 2008; 14(45): 6981-6985 Available from: URL: http://www.wjgnet.com/1007-9327/14/6981.asp DOI: http://dx.doi.org/10.3748/wjg.14.6981

INTRODUCTION

Mucinous adenocarcinoma is a histological variant that accounts for 5% to 15% of cases of primary colorectal cancer[1]. It is defined as a tumor displaying extracellular mucin in more than 50% of the tumor volume. There is evidence that mucinous colorectal cancer (MCRC) may be a distinct biological and genetic entity compared with non-mucinous adenocarcinoma (NMCRC)[2,3]. Thus patients with MCRC may be younger[4,5], their tumors are more likely to be right-sided[6-8], and they present at a more advanced stage[3,4,6,8]. In addition, these tumors may have distinct mutations and cytogenetic abnormalities[2,9] and may be less likely to respond to chemotherapy[10-12]. There is, however, a lack of consensus in the published literature on whether the presence of mucin in colorectal tumors portends a poorer prognosis and worse survival or not.

Many studies suggest that MCRC is associated with poorer outcome and lower survival rates[10,13-15], but others deny this association[3,8,16,17]. The reasons for the conflicting reports are not clear. In many studies, there was no control for, age, sex, tumor stage or location[4,6,7,10]. In addition, the prognostic significance of having an extracellular mucinous component that is much larger than 50% is not known.

The aim of our study was to compare time to disease progression and overall survival (OS) of patients

with mucinous to those with NMCRC after matching all patients for age, gender, and tumor stage. We also evaluated the effect of increasing mucin percentage in tumor body on survival.

MATERIALS AND METHODS

A retrospective review of patients with colorectal cancer treated at the American University of Beirut-Medical Center between 1986 and 2003 identified 35 patients with MCRC and 750 patients with NMCRC.

For each patient with MCRC, a control with NMCRC was matched for age, gender and tumor stage, resulting in 70 cases and controls.

The patients' gender, age, comorbid medical illnesses, tumor location, stage, grade, organ metastasis, surgical resection, chemotherapy regimen, radiological intervention, and survival data were obtained from hospital medical records and recorded for each patient.

Patients were classified as having MCRC if mucin constituted more than 50% of the tumor volume by histological examination.

An average of 4 slides per patient was reviewed to determine mucin content.

To determine the correlation between the percentage of mucin component and tumor stage and survival, histological slides from all patients (cases and controls) initially reported as mucinous tumors were reviewed by two pathologists from AUB-MC to determine the percentage of mucin in the studied sections.

To study the impact of increasing mucin content on survival, two cut-off points (50% and 75% mucin) were chosen. Accordingly, MCRC patients were further divided into 2 subgroups: group A (50%-75% mucin) and group B (75%-100% mucin). Furthermore, NMCRC patients (controls) were designated as group C (< 50% mucin). Moreover, all patients with less than 75% mucin (including groups A and C) were combined into a new group (group D).

Primary tumors were divided into four locations: right-sided (if arising in the cecum, ascending colon or hepatic flexure), transverse colon, left-sided (arising in the splenic flexure, descending colon, or sigmoid colon), and tumors arising in the rectum or rectosigmoid junction of the colon.

Patients with signet-ring colorectal cancer were excluded from the study.

Statistical analysis

The study design was a retrospective case-control study and the case-to-control ratio was 1:1. The Kaplan-Meier method was used to estimate survival. Univariate analysis was performed using the chi-squared testing in SPSS 14.0 software. $P < 0.05$ was considered statistically significant. Univariate analysis was performed to determine if increasing mucin production had an effect on survival that is independent of age, gender, and tumor stage. The median follow-up time was 42 ± 31 mo for non-mucinous (median: 27) and 38 ± 23 (median: 32) for mucinous tumors.

Ⅲ	14 (40)	13 (37.1)
Ⅳ	7 (20)	8 (22.8)

RESULTS

Demographic data

Patients with MCRC in our study accounted for 4.7% of all colorectal cancers. The study included 70 patients, 40 males and 30 females. The mean age at diagnosis for all patients was 56.8 (22-83) years, 56.8 (28-81) years for the MCRC group, and 56.7 (28-81) years for the NMCRC group. Males constituted 57% of the patients in both groups.

Patients in the two groups showed similar concomitant medical problems, mostly heart disease, diabetes mellitus type Ⅱ, and hypertension (Table 1).

Clinical characteristics of the tumor

Both MCRC and NMCRC subgroups showed similar distributions of tumor location; the majority of tumors in both groups were located in the left colon and rectum (Table 2). The location of the tumor was not available in one patient.

Most tumors in both the MCRC and NMCRC groups were moderately or poorly differentiated (Table 2). Interestingly, 28.6% of tumors in the MCRC group were poorly differentiated versus 8.6% of those in the NMCRC group. ($P = 0.0028$). Moreover, 40% of group B tumors were of poor grade as compared to 11% of group D tumors ($P = 0.001$). Lymph nodes were involved in 37% of

Treatment		
Surgery	35 (100)	35 (100)
Chemotherapy	20 (57.1)	19 (54.3)
Neoadjuvant	5 (14.3)	3 (8.6)
Adjuvant	15 (42.9)	16 (45.7)
Type	5-Fu + leucovorin ± oxaliplatin	5-Fu + leucovorin ± oxaliplatin
Radiotherapy	11 (31.4)	8 (22.9)

patients in both subgroups (Table 3).

The liver was the most common organ affected by distant metastasis (22% *vs* 34%) followed by the lungs (11%) in cases and controls, respectively.

The two groups were similar in terms of local disease recurrence: 17% of MCRC patients versus 20% of NMCRC patients ($P > 0.05$).

Therapy

Patients in both groups were treated similarly. All patients were treated with surgical resection. Twenty patients from the mucinous group (57%) and 19 patients (54%) from the control group received neoadjuvant or adjuvant chemotherapy. Chemotherapy regimens were all 5-FU based, as a monotherapy or in combination. Radiotherapy was mainly given to patients with rectal cancer (Table 4).

Characteristics of mucinous subgroups

The exact mucin percentage was obtained on all 35 patients with MCRC.

Eleven patients had 50%-75% of tumor volume displaying mucin and were classified as group A. Mean age at presentation was 55 (36-73) years.

Twenty-Four patients had more than 75% of tumor volume displaying mucin and were classified as group B. Mean age at diagnosis was 59.5 (24-81) years.

Subgroup analysis shows that more than half of the patients in groups A, B, and controls (group C) presented at advanced disease stages (stages Ⅲ and Ⅳ): 54.5%, 66.7%, and 60%, respectively.

Survival analysis

Compared to patients with NMCRC, there was a non-

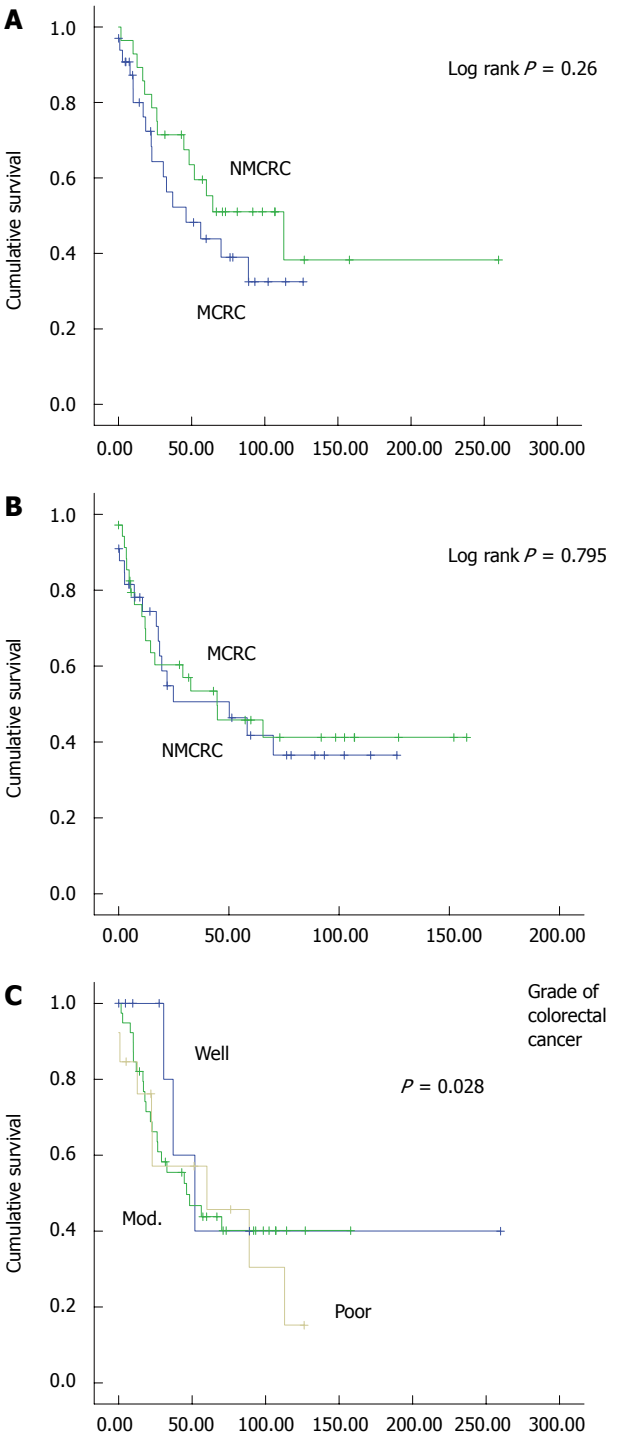

Figure 1 String diagram analyzed. A: Median survival of MCRC group: 46.2 mo compared to NMCRC group: 112.9 mo; B: Time to disease progression in MCRC and NMCRC patients; C: Survival of both MCRC and NMCRC as a function of tumor grade (well, moderate, and poor differentiation).

significant decrease in survival in patients with MCRC. Median survival of patients in the MCRC subgroup was 46.2 mo compared to 112.9 mo in the NMCRC subgroup ($P = 0.26$) (Figure 1A). Mucinous subgroups A and B had median OS of 70.1 and 32.8 mo, respectively ($P = 0.46$). Median OS was 32.8 and 70.1 mo in groups B and D, respectively ($P = 0.143$). TTP in MCRC and NMCRC was 50.17 *vs* 44.77 mo, respectively ($P = 0.795$) (Figure 1B). TTP in groups A, B, and D was 70.1, 24.8,

NS: Not significant.

and 65.5 mo ($P > 0.05$), respectively.

When survival of all patients was analyzed in relation with tumor grade, no difference in survival was noted among the various degrees of differentiation (Figure 1C).

DISCUSSION

Our results show that MCRC is associated with a non-significant decrease in median OS and TTP, compared to NMCRC. Similar results were obtained when OS and TTP were compared in patients with more than 75% mucin to those with less than 75% mucin.

In our report, we matched patients for age, gender, and stage of disease at presentation. Moreover, we found that patients in the two subgroups were similar in terms of tumor location. Furthermore, there was no difference in both arms with respect to presence of co-morbid illnesses, chemotherapy regimens received or radiotherapy administration. However, we noted that more MCRC patients presented with a higher tumor grade than NMCRC patients ($P = 0.028$).

The prognostic significance of mucin content in colorectal cancer remains a controversial issue. While some authors reported that patients with MCRC show no difference in survival outcome compared to patients with NMCRC[3,8,16-18], others found that MCRC is associated with worse survival[4-7,10,14].

The difference in survival was attributed to the advanced stage at which these tumors present[3,4,6,8,13], more invasion of adjacent viscera and more extensive lymph node involvement[7,15,16], increased incidence of distant metastasis[4,17], and decreased response to chemotherapy[10].

Most of the published series compared mucinous to nonmucinous subgroups of colorectal cancer without matching for age, stage, grade and location. Comparing non-matched groups may confound survival data since the difference in survival could be related to differences in tumor location, grade or stage, and not due to the presence of mucin in the tumor.

Five studies compared matched groups of patients[3,8,13,14,16] (Table 5). One study reported a statistically significant decrease in survival in MCRC[14] while the other four showed no difference in survival outcome[3,8,13,16].

The importance of matching for stage is reflected in the large population-based study done by Kang *et al*[8] where MCRC did show worse OS but similar stage-to-stage survival as the other non-mucinous subtypes of colorectal cancer. The difference in OS between MCRC and NMCRC was attributed to the difference in stage at presentation, with more mucinous tumors presenting at advanced disease stages. That study did not, however, examine the impact of high mucin content (> 75%) on survival, a factor that may be associated with an adverse prognosis.

In patients with mucin producing colon cancer, few studies have examined the clinical impact of increasing mucin content in colorectal cancer on progression free and OS. Tumors with high mucin content (80%) were associated with worse clinicopathological behavior, more aggressive phenotype, and poorer prognosis[5,19,20]. By contrast, tumors with moderate mucin content (60%-80%) were found to be indistinguishable from non-mucinous tumors. However, the different subgroups were not matched for age, stage, grade, or location.

The prognostic value of tumor grade in MCRCs has not been adequately investigated in matched studies. In a non-matched study by Enríquez *et al*[21], MCRC showed higher tumor grade that did not affect survival, which is in agreement with our data. Moreover, Connelly *et al*[16] excluded the poorly differentiated histology from their MCRC study because tumors with high grade tend to exhibit a distinct biological behavior and a worse prognosis[22,23]. However, Kang *et al*[8] controlled for tumor grade and concluded that MCRC and NMCRC patients show similar risks of dying.

Although our patients with MCRC had more poorly differentiated tumors ($P = 0.0028$), there was no apparent significant effect of grade on prognosis. Due to the small number of patients in our study, matching for tumor grade was not possible.

There are several limitations in our study. First, this was a case-control study with a relatively small number of subjects. The inability to adequately perform more subgroup analyses or to control for additional confounders because of small sample size is to be noted.

Second, this is a retrospective assessment with all the attendant limitations of this approach including the missing data, which leads to fewer patients included in multivariable models, generally increasing the risk for both type one and type two errors. Third, the cases seen represent a single tertiary center experience which might reduce the prevalence rate of MCRC reported here as compared to the higher prevalence rates in some studies that used data from national registries. Fourth, some of the trends observed in the study might have reached statistical significance if the study sample had been larger. However, despite the limitations of our study, very few studies have examined the effect of increasing mucin content on survival in colorectal patients which adds more value to the results of our study and others'.

In conclusion, high mucin content in colorectal cancer is associated with a nonsignificant decrease in OS and TTP. However, the presence of mucin in more than 75% of tumor volume may indicate a more aggressive pheno-

type that presents with a higher tumor grade and a possible subsequent decrease in OS and TTP. Larger studies in patients with MCRC with matching for stage and grade are warranted to examine the impact of mucin content on survival, especially those with more than 75% mucin content.

COMMENTS

Background

Mucinous adenocarcinoma is a histological variant that accounts for 5% to 15% of cases of primary colorectal cancer. There is evidence that mucinous colorectal cancer (MCRC) may be a distinct biological and genetic entity compared with non-mucinous adenocarcinoma.

Research frontiers

A retrospective review of patients with colorectal cancer treated at the American University of Beirut-Medical Center between 1986 and 2003 identified 35 patients with MCRC and 750 patients with NMCRC. To study the impact of increasing mucin content on survival, two cut-off points (50% and 75% mucin) were chosen. Univariate analysis was performed to determine if increasing mucin production had an effect on survival that is independent of age, gender, and tumor stage.

Innovations and breakthroughs

High mucin content in colorectal cancer is associated with a nonsignificant decrease in overall survival (OS) and time to disease progression (TTP). However, the presence of mucin in more than 75% of tumor volume may indicate a more aggressive phenotype that presents with a higher tumor grade and a possible subsequent decrease in OS and TTP.

Applications

MCRC is associated with a non-significant decrease in median survival and TTP, particularly when mucin content is > 75% of tumor volume. However, it tends to be more poorly differentiated. Larger studies in patients with MCRC with matching for stage and grade are warranted to examine the impact of mucin content on survival, especially those with more than 75% mucin content.

Peer review

It is an interesting manuscript trying to answer the question if the mucin production is related with survival in colorectal cancer.

Abstract

AIM: To evaluate the association and interaction of genetic polymorphisms in methylenetetrahydrofolate reductase (MTHER) and cytochrome P4502E1 (CYP4502E1), environment risk factors with esophageal cancer (EC) in Kazakh, a high EC incidence area of Xinjiang Uygur Autonomous Region, China.

METHODS: A 1:2 matched case-control study was conducted with 120 cases of EC and 240 population- or hospital-based controls. The controls were matched for sex, nationality, area of residence and age within a 5-year difference. MTHER and CYP4502E1 genotypes were identified by PCR-based restriction fragment length polymorphism (RFLP). A conditional logistic regression model was established to identify risk factors. The strata method was adopted in interaction analysis.

RESULTS: Low consumption of green vegetables and fresh fruits, alcohol drinking, and unsafe water (shallow well, or river) were found to be the risk factors for EC. Individuals with the MTHFR677 (C/T + T/T) genotype had a 2.62-fold (95% CI: 1.61-4.28) risk of developing EC compared with those who carried the C/C genotype. Individuals with the CYP4502E1C1/C1 genotype had a 3.00-fold (95% CI: 1.82-4.96) risk compared with those who carried the CYP4502E1 (C1/C2 + C2/C2) genotype. Gene-environment interaction analysis showed that MTHFR677 gene polymorphism was correlated with consumption of green vegetables and fresh fruit, while CYP4502E1 C1/C1 was correlated with alcohol drinking and unsafe drinking water. MTHFR and CYP4502E1 analysis of gene-gene interaction showed that individuals with the MTHFR677 (C/T + T/T) and CYP4502E1C1/C1 genotypes had a 7.41-fold (95% CI: 3.60-15.25) risk of developing EC compared with those who carried the MTHFR677C/C and CYP4502E1 RsaI C1/C2 + C2/C2 genes, and the interaction rate was higher than that of the two factors alone.

CONCLUSION: Low consumption of green vegetables and fresh fruits, alcohol drinking, and unsafe water (shallow well, or river) and polymorphisms in MTHFR and CYP4502E1 genes are important risk factors for EC. There is a synergistic interaction among polymorphisms in MTHFR and CYP4502E1 genes and environment factors. MTHFR and CYP4502E1 genes can be used as biomarkers for prevention of EC in Kazakh, Xinjiang Uygur Autonomous Region, China.

INTRODUCTION

Kazakh is an ethnic group with a high incidence and mortality rate of esophageal cancer (EC) in China. A national survey in 1990-1992 showed that the age-adjusted

mortality rate was 68.88 per 100 000 population for EC in Kazakh, and the rate was 14.95 per 100 000 population in Chinese nationality. The mortality rate for the same Kazakh population was 67.60 per 100 000 population in 2004-2005. The mortality rate of esophageal cancer in Kazakh has never been decreased over the last 15 years. Different risk factors for esophageal cancer have been reported in the world[1-5]. It was reported that deficiency in folate is caused by low consumption of green vegetables and fresh fruits, unsanitary drinking water, smoking, alcohol drinking, fast and irregular eating, eating of peppery food, frequent engorgement, eating out of date cake, history of esophagus or stomach illness and family history of EC are the risk factors for EC in Kazakh[6]. EC is caused by multi-factors, including environmental risk factors and genetic factors. In recent years, environmental and genetic susceptibilities and their interactions were used in evaluating the risks of EC[7-11]. Primary candidates for gene-environment interaction studies are those encoding enzymes related to the metabolism of established risk factors for cancer.

Methylenetetrahydrofolate reductase (MTHFR), a key enzyme in folate metabolism, which catalyzes 5, 10-methylene-tetrahydrofolate to 5-methyltetrahydrofolate[12]. A substitution of C to T at nucleotide 677 in MTHFR results in an alanine to valine substitution, which alters enzyme activity[13]. The *MTHFR C677T* polymorphism influences DNA methylation through an interaction with folate[14]. Alteration in DNA methylation, disruption of DNA integrity and DNA repair are believed to enhance carcinogenesis by altering the expression of critical tumor suppressor genes and proto-oncogenes[15]. Cytochrome P4502E1 (CYP4502E1), a member of the cytochrome P450 superfamily, is involved in the metabolic activation of many low molecular weight compounds, such as N-nitrosamines, aniline, vinyl chloride, and urethane[16-17]. N-nitrosamines present in tobacco and diet are well-recognized carcinogens involving cancer development at various sites, including the esophagus and stomach[18-19].

The high mortality rate in Kazakh population indicates that environment factors play an important role in the development of EC. However, only a few individuals in the high-risk Kazakh population develop EC, although all residents share very similar environment-related risk factors and life style, suggesting that host susceptibility factors, such as the MTHFR677 and CYP4502E1 gene polymorphisms, may play an important role in the increased risk for EC. This study analyzed the gene-environment and gene-gene interaction among the MTHER and CYP4502E1 gene polymorphisms, and environmental risk factors for EC in order to determine their relevance to EC prevention.

MATERIALS AND METHODS

Specimens

The 120 cases of esophageal cancer (confirmed by pathological diagnosis) came from inpatients and outpatients of six hospitals in the north of Xinjiang Uygur Autonomous Region between March 2005 and May 2007. Two hundred and forty population- or hospital-based controls were randomly selected and matched for sex, nationality, residence and age within a 5-year difference. The controls were confirmed to have no history of cancer and digestive system diseases. Specially trained interviewers administered a standardized questionnaire that included demographic characteristics (sex, age, area of birth and residence), lifestyle, smoking status, drinking alcohol status, history of stomach or esophagus diseases and family history of EC. Blood samples were collected and DNA was extracted for genotyping of *MTHFR* and CYP4502E1 genes.

Genotyping of MTHFR and CYP2E1

Sites MTHFR C677T and CYP4502E1 genotypes were analyzed by PCR-based restriction fragment length polymorphism (RFLP). The primers for MTHFR/CYP4502E1 were synthesized by Shengong Biotechnology Company (Shanghai, China). The sequences of PCR primers for the C677T site are 5'-TTTGAGGCTGACCTG AAGCACTTGAAGGAG-3' and 5'-GAGTGGTAGCCCTGGATGGGAAAGATCCCG-3'[20,21]. PCR was carried out in 25.0 μL reaction mixture containing 2.5 μL 10 × PCR buffer, 1.5 μL $MgCl_2$ (25 mmol/L), 0.5 μL dNTP (10 mmol/L), 0.5 μL forprimer (20 μmol/L), 0.5 μL revprimer (20 μmol/L), 0.2 μL Taq DNA polymerase (5 U/μL), 1.5 μL template DNA, and 17.8 μL nuclease free water. The reaction was initially carried out at 94℃ for 5 min followed by 35 cycles at 94℃ for 1 min, at 61℃ for 1 min, at 72℃ for 1 min, and a final extension at 72℃ for 8 min. The PCR products were digested with Hinf I at 37℃ for 13 h. The digested products were separated by electrophoresis on a 2.0% agarose gel. The 677C/C wild-type homozygotes were identified by the presence of only a 173-bp fragment; 677C/T heterozygotes were identified by the presence of 173-, 125-, and 48-bp fragments, and 677T/T homozygotes were identified by the presence of 125- and 48-bp fragments.

The CYP4502E1 was identified by amplifying genomic DNA with the forward primer 5'-CCAGTC GAGTCTACATTGTCA-3' and the reverse primer 5'-TTCATTCTGTCTTCTAACTGG-3'. PCR was performed in 25.0 μL mixture containing 2.5 μL 10 × PCR buffer (including $MgCl_2$), 2.0 μL dNTP (2.5 mmol/L), 0.5 μL forprimer (20 μmol/L), 0.5 μL revprimer (20 μmol/L), 0.2 μL Taq DNA polymerase (5 U/μL), 2.0 μL template DNA, and 17.3 μL nuclease free water. The reaction was initially carried out at 95℃ for 8 min followed by 35 cycles at 94℃ for 1 min, at 56℃ for 1 min, at 72℃ for 1 min, and a final extension at 72℃ for 8 min. The PCR products were digested with restriction enzyme RsaI at 37℃ for 4 h. The digested products were separated by electrophoresis on a 2.0% agarose gel. Three genotypes of CYP4502E1 resulting from digestion with the restriction enzyme RsaI were found: common homozygote C1/C1, heterozygote C1/C2, and rare homozygote C2/C2.

Quality control

DNA extraction and PCR were conducted at different time points. The genotypes of DNA samples were iden-

[1]ORs, 95% CIs and *P* values were calculated in a conditional logistic regression model.

tified without knowledge of the case-control status, and a 10% random sample set of case and controls was genotyped by different investigators and the reproducibility was 100%. Each PCR was performed with the controls as blank (without DNA template), positive and negative controls, respectively. When any of these controls failed, PCR was re-conducted. Twenty percent of the questionnaires were re-administered by different investigators and the consistency was 100%.

Statistical analysis

Statistical analyses were performed using the SPSS software. Cases and controls were compared for any differences in gender and age using χ^2 test and Mann-Whitney test, respectively. The probability of Hardy Weinberg equilibrium was assessed by χ^2 test. Conditional logistic regression was employed to calculate the odds ratio (OR) of MTHFR/CYP4502E1 polymorphisms. Gene-environment and gene-gene interactions were calculated by stratified analysis.

RESULTS

The number of male and female patients with EC was 81 and 39, respectively, who were matched for 162 male and 78 female controls. The mean age (± SD) of cases and controls was 59.0 ± 10.0 years and 58.4 ± 10.1 years, respectively. There was no significant difference in age between cases and controls ($t = 0.586$, $\nu = 358$, $P = 0.558$).

The distributions of environmental risk factors in cases and controls are summarized in Table 1. Low consumption of green vegetables and fresh fruits, alcohol drinking, and unsafe water (shallow well, or river) were found to be the risk factors for EC. The percentage of tobacco smoking in cases and controls was not significantly different.

[1]ORs, 95% CIs and *P* values were calculated in a conditional logistic regression model.

The genotype distributions of the MTHFR677 and CYP4502E1 RsaI in cases and controls are summarized in Table 2. The observed frequencies of three MTHFR677 genotypes in controls (C/C = 70.83%, C/T = 24.59%, and T/T = 4.58%) were not different from those detected in Hardy-Weinberg equilibrium ($\chi^2 = 3.34$, $\nu = 2$, $P = 0.188$). However, they were significantly different from those observed in cases (C/C = 50.00%, C/T = 44.17%, and T/T = 5.83%, $\chi^2 = 15.55$, $\nu = 2$, $P = 0.000$). Subjects who carried the MTHFR677C/T genotype had a 2.69-fold (95% CI: 1.63-4.44) risk of developing EC compared with those who carried the MTHFR677C/C genotype. The MTHFR677T/T genotype, which was rare both in cases and in controls, was associated only with a slightly increased risk of EC, without statistical significance (OR = 2.15, 95% CI = 0.77-5.98). Individuals with the MTHFR677 T allele were more prone to develop EC (OR = 2.62, 95% CI = 1.61-4.28).

The distribution of the CYP4502E1 RsaI genotypes in controls (C1/C1 = 53.33%, C1/C2 = 37.50%, and C2/C2 = 9.17%) was also in accordance with Hardy-Weinberg equilibrium ($\chi^2 = 0.921$, $\nu = 2$, $P = 0.631$) and significantly different from that of the CYP4502E1 RsaI genotypes in cases (C1/C1 = 78.33%, C1/C2 = 19.17%, and C2/C2 = 2.50%, $\chi^2 = 21.79$, $\nu = 2$, $P = 0.000$). The Odds ratio (OR) of developing esophageal cancer for the CYP4502E1 RsaI C1/C2 and C2/C2 genotypes was 0.37 (95% CI = 0.22-0.62) and 0.19 (95% CI = 0.05-0.66), respectively, compared to the CYP4502E1 RsaI C1/C1 genotype. Individuals with the CYP4502E1 RsaI C1/C1 genotype had a 3.00-fold (95% CI = 1.82-4.96) risk of developing EC compared with those who carried the CYP4502E1 RsaI C1/C2 + C2/C2 genotype.

The results of interaction between MTHFR677 gene polymorphism and consumption of green vegetables

Table 3 Interaction between MTHFR 677 and consumption of green vegetables, fresh fruits in EC

Consumption of vegetables and fruits	MTHFR 677 genotype	Case (*n*)	Control (*n*)	χ^2	*P*	OR (95% CI)

	Yes	C1/C1	34	85	10.11	0.001	3.47 (1.56-7.69)
	No	C1/C1	60	43	46.80	0.000	12.09 (5.47-26.74)

SIM: Synergic index of multiplication; $SIM1 = 7.10/(1.94 \times 2.70) = 1.36$, $RERI^1 = 7.10 - (1.94 + 2.70) + 1 = 3.46$, $API^1 = [7.10 - (1.94 + 2.70) + 1]/7.10 = 48.73\%$; $SIA^2 = 12.09/(4.33 + 3.47 - 1.00) = 1.78$, $RERI^2 = 12.09 - (4.33 + 3.47) + 1 = 5.29$, $API^2 = [12.09 - (4.33 + 3.47) + 1]/12.09 = 43.76\%$.

Table 5 Interaction between MTHFR 677 and CYP4502E1 Rsal gene polymorphisms in EC

MTHFR 677 genotype	CYP2E1 rsal genotype	Case (*n*)	Control (*n*)	χ^2	*P*	OR (95% CI)
C/C	C1/C2 + C2/C2	13	82	-	-	1.00
C/T + T/T	C1/C2 + C2/C2	13	30	5.30	0.021	2.73 (1.14-6.56)
C/C	C1/C1	47	88	12.91	0.000	3.37 (1.70-6.68)
C/T + T/T	C1/C1	47	40	33.44	0.000	7.41 (3.60-15.25)

$SIA = 7.41/(2.73 + 3.37 - 1.00) = 1.45$; $RERI = 7.41 - (2.73 + 3.37) + 1 = 2.31$; $API = [7.41 - (2.73 + 3.37) + 1]/7.41 = 31.17\%$.

and fresh fruit are listed in Table 3. Less consumption of green vegetables increased the OR in MTHFR677 T allele carriers (OR = 5.25, 95% CI = 2.66-10.39). The corresponding SIA, RERI and API were 1.23, 0.97, and 18.48%, respectively. Among carriers of the MTHFR677 T allele with occasional or less consumption of fresh fruits was significantly associated with an elevated risk of developing EC (OR = 9.00, 95% CI = 3.57-22.71) and the interaction rate was higher than that of the two factors alone. The corresponding SIA, RERI, and API were 1.30, 2.10, and 23.33%, respectively.

The results of interaction between the CYP4502E1 RsaI gene polymorphism and alcohol drinking as well as safe drinking water are shown in Table 4. Among carriers of the CYP4502E1C1/C1 genotype, alcohol drinking was significantly associated with an elevated risk of developing EC (OR = 7.10, 95% CI = 3.44-14.68), and the interaction rate was higher than the sum of the two factors alone. The corresponding SIM, RERI, and API were 1.36, 3.46, and 48.73%, respectively. Unsafe water increased the risk of developing EC among carriers of the CYP4502E1C1/C1 genotype (OR = 12.09, 95% CI = 5.47-26.74), and the interaction rate was higher than that of the other two factors. The corresponding SIA, RERI and API were 1.78, 5.29, and 43.76%, respectively.

A significant interaction between the MTHFR 677 genotype and CYP4502E1 RsaI genotype was found in EC risk (Table 5). Individuals who had both MTHFR677 (C/T + T/T) and CYP4502E1 RsaI C1/C1 genotypes had a 7.41-fold risk of developing EC (95% CI = 3.60-15.25) compared with those who carried MTHFR677C/C and CYP4502E1 RsaI C1/C2 + C2/C2 genotypes. The corresponding SIA, RERI and API were 1.45, 2.31 and 31.17%, respectively.

DISCUSSION

The results of the current study indicate that MTHFR677 and CYP4502E1 RsaI gene polymorphisms are the susceptibility factors for EC[22,23]. Cohort studies that simultaneously consider multiple genetic and environmental

factors possibly involved in esophageal carcinogenesis are needed to ascertain not only the relative contribution of these factors to tumor development but also the contributions of their putative interactions[24]. We observed a significant risk of having the MTHFR677 C/T + T/T and CYP4502E1C1/C1 genotypes in EC. There is a synergistic interaction among polymorphisms in MTHFR and CYP4502E1 genes and environment factors.

The studies conducted in high-risk areas showed the MTHFR677T allele increases the risk of developing EC[25,26]. However, no risk change has been observed among Caucasians in Germany and Japan[27,28]. Regional differences in folate consumption among populations may explain this inconsistency in the impact of T alleles[25], suggesting that gene-nutrient environment interactions between folate consumption and impact of the MTHFR 677T allele vary with folate intake. When folate intake is sufficient, individuals with the MTHFR CT or TT genotype may have a decreased risk of developing cancer, since decreased MTHFR activity associated with the 677TT polymorphism can lead to elevation in 5,10-methylene-tetrahydrofolate, facilitating DNA synthesis, while adequate provision of methyl donors can be ensured. In contrast, in the presence of low folate, DNA methylation and DNA synthesis/repair may be impaired, initiating carcinogenesis. Deficiency in folate is caused by low consumption of vegetables and fruit in the Kazakh population and MTHFR677 C/T + T/T genotype has a synergic interaction with less consumption of vegetables and fruit in EC. Our results are consistent with the reported findings[25,26].

Over-representation of variant CYP4502E1 Rsa1 alleles has been reported in gastric cancer[29] and a lower frequency of the RsaI variant allele has also been observed in patients with EC than in controls[30]. Individuals with the variant Rsa1 allele (c1/c2 or c2/c2) have a lower basal CYP450 2E1 activity. It was reported that the Cyp4592E1 C2/C2 genotype is associated with the decreased enzyme activity[31], adding biological plausibility to the protective effect of CYP4502E1 C2/C2 genotype observed in this study. Our observation is in agreement with the finding of recent studies showing that the C1/C1 genotype of CYP4502E1 is associated with the increased risk of developing EC[32-35]. However, contrary results have also been reported elsewhere[36-38]. Studies have shown inconsistent findings regarding the association between the CYP4502E1 polymorphism and EC. The reasons for these inconsistent findings are unknown. However, it may be due to the differences in ethnicity and life-style which can lead to variations in enzyme activity. The present findings indirectly support the hypothesis that environmental exposure to carcinogens plays a role in the etiology of EC. The CYP4502E1 polymorphism is involved in metabolism of various nitrosamines. Cigarette smoking, and alcohol drinking, unsafe drinking water containing chemicals including nitroso compound, were found to be the risk factors for EC in this study. A significant gene-environment interaction between the CYP4502E1 polymorphism and alcohol drinking and unsafe water was also observed in this study.

Selection bias and/or systematic error may occur in a case-control study because of inappropriate selection of subjects and other confounding factors. However, our study including a relatively large number of cases diagnosed in hospitals was matched for potential confounding variables. Solid and reproducible genotyping techniques can minimize systematic errors in measurement. For these reasons, the findings of our study could not solely attribute to bias.

In summary, MTHFR677 and CYP4502E1 RsaI gene polymorphisms are significantly correlated with EC, and MTHFR677 C/T or T/T genotype and CYP4502E1 C1/C1 wild type increase the susceptibility to EC in the Kazakh population of Xinjiang Uygur Autonomous Region, China. Interaction between MTHFR677 C/T + T/T genotype and less consumption of green vegetables and fresh fruits, as well as between CYP4502E1 C1/C1 and alcohol and unsafe drinking water is associated with the risk of developing EC. Gene-gene interaction between MTHFR 677 and CYP4502E1 RsaI can serve as a useful biomarker for prevention of EC in the Kazakh population.

The authors thank Dr. Mengiste Melese and Steve Pearson for their advice and support for the study.

COMMENTS

Background

Kazakh is an ethnic group with a high incidence and mortality rate of esophageal cancer (EC) in China. Epidemiological studies have demonstrated deficiency in folate caused by low consumption of green vegetables and fresh fruits, alcohol drinking, unsanitary drinking water (containing chemicals including nitroso compound) are the main risk factors for EC in Kazakh population. Genetic polymorphisms in the MTHFR677 and CYP4502E1 genes affect the metabolism of folate, alcohol, and N-nitrosamines. There have been some studies on the roles of folate and MTHFR677 genes, alcohol and the CYP2E1 genes in EC in Chinese Han population. However, their results were conflicting and little study in Kazakh population. Therefore, the aim of the present study was to evaluate the association and interaction of MTHER and CYP4502E1 and environment risk factors with EC in Kazakh population.

Research frontiers

Accumulating evidence from prior epidemiologic studies shows an association between deficiency in folate caused by low consumption of green vegetables and fresh fruits, alcohol drinking, unsanitary drinking water and EC in Kazakh population. The genetic polymorphisms of MTHFR affect the metabolism of folate and CYP4502E1 genetic polymorphisms also affect the metabolism of alcohol and N-nitrosamines. Polymorphisms in the MTHFR and CYP4502E1 genes are associated with the risk of EC in Kazakh.

Innovations and breakthroughs

This is the first study to show significant interactions of MTHFR677 and CYP4502E1 and consumption of green vegetables and fresh fruits, alcohol drinking, and unsafe waters (shallow well, or river) with EC in Kazakh population. Synergistic interactions were found in MTHFR677 gene polymorphism with consumption of green vegetables and fresh fruit, CYP4502E1 gene polymorphism with alcohol drinking and unsafe drinking water, MTHFR677 with CYP4502E1 genotypes for EC in Kazakh population, and the interaction rate was higher than that of the two factors alone.

Applications

The detection of MTHFR677 and CYP4502E1 genotypes may become a useful biomarker for EC in Kazakh population, and also help clinicians to diagnose EC earlier.

Terminology

Methylenetetrahydrofolate reductase (MTHFR), a key enzyme in folate metabolism responsible for circulating form of folate, 5-methyl-tetrahydrofolate,

which converts methionine to S-adenosylmethionine, the universal methyl donor for various intracellular methylation reactions, particularly DNA methylation. The cytochrome P450 2E1 (CYP4502E1), a member of the cytochrome P450 superfamily metabolizes a range of small organic compounds, including aniline and benzene as well as N-nitrosamines. Individuals frequently encounter different environmental conditions, and the physiological and behavioral responses to these conditions can depend on an individual's genetic makeup. This phenomenon is known as gene-environment interaction.

Peer review

This paper is interesting, and would accumulate new data on interaction of genetic polymorphisms and environment factors for esophageal cancer in Kazakh population.

Abstract

AIM: To investigate the effects of fluoxetine on depression-induced changes of mast cell morphology and protease-1 (rMCP-1) expression in rats.

METHODS: A Sprague-Dawley rat model of chronic stress-induced depression was established. Fifty experimental rats were randomly divided into the following groups: normal control group, fluoxetine + normal control group, depressed model group, saline + depressed model group, and fluoxetine + depressed model group. Laser scanning confocal microscopy (LSCM) immunofluorescence and RT-PCR techniques were used to investigate rMCP-1 expression in gastric antrum. Mast cell morphology was observed under transmission electron microscopy. ANOVA was used for statistical analysis among groups.

RESULTS: Morphologic observation indicated that depression induced mast cell proliferation, activation, and granule hyperplasia. Compared with the normal control group, the average immunofluorescence intensity of gastric antrum rMCP-1 significantly increased in depressed model group (37.4 ± 7.7 *vs* 24.5 ± 5.6, $P < 0.01$) or saline + depressed model group (39.9 ± 5.0 *vs* 24.5 ± 5.6, $P < 0.01$), while there was no significant difference between fluoxetine + normal control group (23.1 ± 3.4) or fluoxetine + depressed model group (26.1 ± 3.6) and normal control group. The average level of rMCP-1mRNA of gastric antrum significantly increased in depressed model group (0.759 ± 0.357 *vs* 0.476 ± 0.029, $P < 0.01$) or saline + depressed model group (0.781 ± 0.451 *vs* 0.476 ± 0.029, $P < 0.01$), while no significant difference was found between fluoxetine + normal control group (0.460 ± 0.027) or fluoxetine + depressed model group (0.488 ± 0.030) and normal control group. Fluoxetine showed partial inhibitive effects on mast cell ultrastructural alterations and de-regulated r*MCP-1* expression in gastric antrum of the depressed rat model.

CONCLUSION: Chronic stress can induce mast cell proliferation, activation, and granule hyperplasia in gastric antrum. Fluoxetine counteracts such changes in the depressed rat model.

INTRODUCTION

Mast cells are now recognized as "granular cells of the connective tissue", whose activation exacerbates allergic immune responses and as key players in the establishment of innate immunity as well as modulators of adaptive immune responses[1]. The role of mast cells in the gastrointestinal mucosa is not only to react to antigens, but also to actively regulate the barrier and transport properties of the intestinal epithelium. Mucosal mast cells respond to both IgE/antigen-dependent and non-IgE-dependent stimulation, releasing bioactive mediators into adjacent tissues where they induce physiological responses. Studies in models of hypersensitivity and stress

have provided evidence that changes in mucosal function are due to either direct action of mast cell mediators on epithelial receptors and/or indirect action *via* nerves/neurotransmitters[2]. Intestinal anaphylaxis is associated with disturbances in gut function that are antigen-specific and dependent on mast cell degranulation. During mucosal immunoglobulin E-mediated reactions, rat mast cell protease Ⅱ (rMCP-Ⅱ) is released and is associated with ultrastructural changes in the intestinal mucosa. The systemic appearance of this specific protease provides a serum marker of intestinal anaphylaxis. Psychological stress may trigger this sensitive alarm system *via* the brain-gut axis[3]. In clinical studies, it has become clear that psychological factors, especially anxiety and depression, play an important role in gastrointestinal diseases by precipitating exacerbation of symptoms[4,5]. Several studies have shown that the prevalence of chronic stressed disorders in patients with gastrointestinal symptoms is 60%-85%[6,7]. Stress often worsens the symptoms of gastrointestinal diseases, which might be explained by altered neuroendocrine and visceral sensory responses to stress[8].

Fluoxetine hydrochloride (fluoxetine) is a kind of selective serotonin reuptake inhibitors (SSRIs), which belong to a class of antidepressants used in the treatment of depression and anxiety disorders. SSRIs increase the extracellular expression of the neurotransmitter serotonin by inhibiting its reuptake into the presynaptic cells. Studies have suggested that SSRIs may promote the growth of new neural pathways or neurogenesis[9]. SSRIs may also protect against neurotoxicity caused by other compounds as well as from depression itself. Recent studies showed that pro-inflammatory cytokine processes took place during depression in addition to somatic diseases and it was possible that symptoms manifested in these psychiatric illnesses were being attenuated by the pharmacological effects of antidepressants on the immune system[10] SSRIs have been found to be immunomodulatory and anti-inflammatory against pro-inflammatory cytokine processes[11,12].

The aim of this study is to investigate the effects of fluoxetine hydrochloride (fluoxetine) on mast cell morphology and rMCP-1 expression in gastric antrum in a rat model of depression.

MATERIALS AND METHODS

Animals

Fifty healthy male Sprague-Dawley rats, weighing 250 ± 300 g, from the Animal Center, Hubei Academy of Preventive Medical Sciences, were used in the present study. The animals were fed standard rat chow, allowed access to tap water and acclimatized to the surroundings for 1 wk prior to the experiments.

Reagents

Cy3-conjugated goat anti-rabbit IgG, rMCP-1 rabbit anti-mouse antibody were purchased from Sigma Co., USA. Fluoxitine hydrochloride capsule was purchased from Lilly Co. Ltd. Other reagents used in the study were all of analytical grade.

Experimental protocols

All procedures were approved by the Animal Care Committee at the Medical Department of Wuhan University. A rat model of chronic stress-induced depression was established[13,14]. The rats received a variety of stressors for 21 d, including tail nip for 1 min, cold water swimming at 4℃ for 5 min, heat stress at 45℃ for 5 min, water deprivation for 24 h, food deprivation for 24 h, 12-h inverted light/dark cycle (7:00 a.m. lights off and 7:00 p.m. lights on), paw electric shock (electric current 1.0 mA10 s, every 1 min, lasting 10 s, 30 times). The animals were randomly divided into five groups (10 rats per group): normal control, fluoxetine + normal control, depressed model control, saline + depressed model, and fluoxetine + depressed model. The depressed animals were treated with saline and fluoxetine (10 mg/kg), respectively. A normal control group of rats without receiving any stress was included and housed in a separate room; food and water were freely available in their home cage.

Immunofluorescence histochemistry

The rats were anesthetized with urethane (5 mg/kg ip.) and rapidly killed by decapitation. The gastric antrum samples (1 cm × 1 cm) were perfused with 4% paraformaldehyde for immunofluorescence histology from each group. Each sample was cut into 30 sections and each section was cut 50-μm thick using a vibratome. Serial sections were placed on slides, three to a slide. The sections were numbered from 1 to 30. Ten sections were incubated. The staining procedure was as follows: (1) the sections were washed in phosphate-buffered saline (PBS), then pretreated with 0.25% Triton X-100 for 30 min at 37℃ and rinsed in PBS; (2) incubation for 12 h at 4℃ in a 1:100 dilution of the primary antibody of rMCP-1 in PBS; and (3) incubation with 1:200 diluted secondary antibody (Cy3 -conjugated goat anti-rabbit IgG) in PBS for 1 h at 37℃.The sections were washed three times for 10 min after incubation steps 1 to 3, respectively, and were finally mounted in 50 g/L glycerin.

Detection was carried out according to the kit instructions (Leica SP2 TCS AOBS made in Germany). The specimens were excited with a laser beam at a wavelength of 492 nm (Cy3). The sections were observed under a laser scanning confocal microscope (LSCM) and analyzed with a Leica Q500IW image analysis system in terms of Cy3 fluorescent intensity.

Electron microscopic analysis

For electron microscopic analysis, gastric antrum tissue sections were fixed in modified Karnovsky's medium containing 2% paraformaldehyde, 3% glutaraldehyde and 0.1% tannic acid in 0.1 mmol/L phosphate buffer (pH 7.4) and processed as before[15]. Each electron microscopic sample was divided into 5 blocks. Each block was cut into 10 sections (200 μm thick). Five sections selected

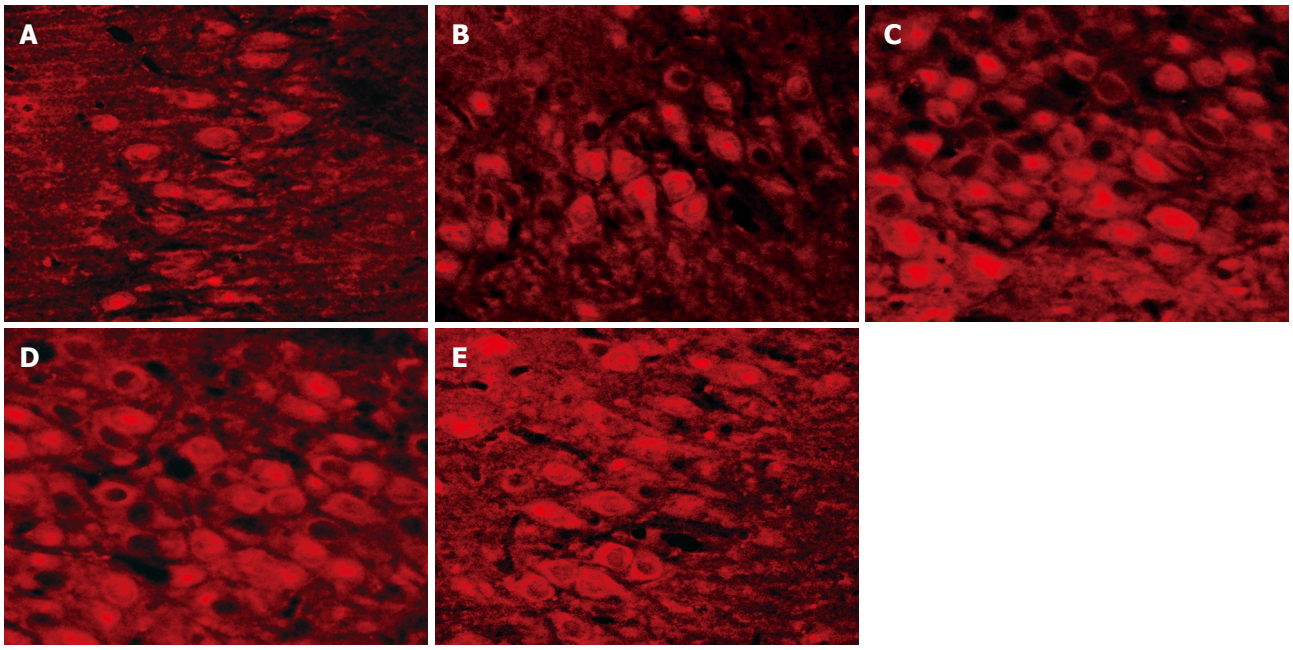

Figure 1 Gastric antrum tissue staining procedure include: (1) pretreatment with 0.25% Triton X-100; (2) incubation in the primary antibody of rMCP-1; (3) incubation with secondary antibody (Cy3 -conjugated goat anti-rabbit IgG). A: Expression of rMCP-1 in the normal control group; B: Expression of rMCP-1 in the fluoxetine + normal control group; C: Expression of rMCP-1 in the depressed model control group; D: Expression of rMCP-1 in the saline + depressed model group; E: Expression of rMCP-1 in the fluoxetine + depressed model group.

from 10 sections were observed. Ultrathin sections were placed onto copper gride, stained with uranyl acetate and lead citrate, and observed under a transmission electron microscope (Hitachi H-600, Japan). Mast cells were evaluated according to Letourneau[16]. Mast cells containing many intact electron-dense granules or containing empty granules were categorized as inactive and active cells, respectively. All mast cells were counted at magnification × 4000 in 30 visual fields.

Reverse Transcription-Polymerase Chain Reaction (RT-PCR)

To quantify the expression of rMCP-1 RNA, we performed a RT-PCR assay as described previously[17]. Total mRNA was isolated with TRIZOL (Invitrogen) according to the instructions of manufacturer. The primers for RT-PCR were as follows: rMCP-1 (237 bp), forward primer 5'-GCCTGTAAAAACTATTTT-3'; reverse primer 5'-CAGGCTGGTCAGATCCTGC-3'. GAPDH (217bp), forward primer 5'-GAAACCTGCCAAGTATGATG-3'; reverse primer 5'-ACCAGGAAATGAGCTTGAGA-3'. The reaction mixture was added to the RNA solution and incubated at 42℃ for 1 h, heated at 94℃ for 5 min, and chilled at 48℃. For PCR, the cDNA reaction mixture was diluted with 40 ml of PCR buffer and mixed with 50 pmol of the primers. The reaction was carried out in a DNA thermal cycler under the following conditions: 94℃ for 30 s, 58℃ for 30 s and 72℃ for 45 s. Following the reaction, the amplified products were analyzed by 1.5% agarose gel electrophoresis and visualized using ultravioletuorescence after staining with ethidium bromide. The relative content of rMCP-1 mRNA was calculated densitometrically based on the densitometric ratio between rMCP-1 and GAPDH.

Statistical analysis

Data were expressed as mean ± SE. Statistical analysis was performed using one-way ANOVA and the non-parametric Mann-Whitney *U* test between groups. *P* values less than 0.05 were considered statistically significant.

RESULTS

Immunofluorescence histochemical assay

LSCM was used to prepare immunofluorescence picture, and LSCM imaging system was used to analyze the rMCP-1 immunofluorescence intensity among groups. Compared with the normal control group, the average immunofluorescence intensity of gastric antrum rMCP-1 significantly increased in depressed model group or saline + depressed model group (Figure 1, Table 1, $P < 0.01$), while there was no significant difference between fluoxetine + normal control group or fluoxetine + depressed model group and normal control group. Compared with depressed model group, the average immunofluorescence intensity of gastric antrum rMCP-1 significantly decreased in fluoxetine + depressed model group (Figure 1, Table 1, $P < 0.01$), while there was no significant difference between saline + depressed model group and depressed model group. This confirmed that chronic stress induced mast cells to secrete rMCP-1 and fluoxetine inhibited this effect.

Ultrastructural morphology analysis

Compared with the normal control rats, the total number of mast cells/30 visual fields and the percentage of activated mast cells increased significantly, while the percentage of normal mast cells decreased significantly

Table 2 Ultrastructural morphologic changes of gastric tissue mast cells (n = 10, mean ± SE)

Group	Mast cells/30 visual fields	Normal mast cells (%)	Activated mast cells (%)
Normal control	24.0 ± 3.5	64.6 ± 9. 9	35.4 ± 3.7
Fluoxetine + control	22.2 ± 3.4[c]	69.8 ± 6.1[c]	30.2 ± 3.7[c]
Depressed	40.6 ± 3.9[b]	33.3 ± 4.7[b]	66.7 ± 4.9[b]
Saline + depressed	42.2 ± 3.7[b]	30.4 ± 3.7[b]	69.6 ± 4.7[b]
Fluoxetine + depressed	28.1 ± 3.3[a,d]	44.4 ± 5.6[a,d]	55.6 ± 5.6[a,d]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* normal control group; [c]$P < 0.05$, [d]$P < 0.01$ *vs* depressed model control group.

in chronic stress-induced depressed rats or saline + depressed model rats (Table 2, $P < 0.01$). In depressed rats treated with fluoxetine, the changes in total number of mast cells/30 visual fields and the percentage of activated or normal mast cells were between normal control group and depressed model rats (Table 2, $P < 0.05$).

In morphology, ultrastructural observations indicated that gastric antrum mast cells were rich and strictly in perivasculitis. In normal control rats or fluoxetine + normal control rats, the mast cells were spherical in shape with round nucleus, and contained electron-dense granules. Some secretary granules were intact with homogeneous electron dense content (Figure 2A and B). In chronic stress-induced depressed rats or saline + depressed rats, the mast cells were elongated with a fusiform nucleus, granules maldistributed and contained altered electron-dense content. The mast cells were proliferative, while the granules were also hyperplastic. Mast cell secretary granules exposed to the surface of the target and mast cells contained fibrillar material, empty granules and lipid bodies (Figure 2C and D). In depressed rats treated with fluoxetine, the morphological alterations were between normal control rats and depressed rats (Figure 2E).

Effects of fluoxetine on gastric antrum rMCP-1mRNA by RT-PCR

Compared with the normal control group, the average level of rMCP-1 mRNA of gastric antrum significantly increased in chronic stress-induced depressed model group or saline + depressed model group, while there was no significant difference between fluoxetine + normal control group or fluoxetine + depressed model group and normal control group. Compared with depressed model group, the average level of rMCP-1 mRNA of gastric antrum significantly decreased in fluoxetine + depressed model group, while there was no significant difference between saline + depressed model group and depressed model group (Figure 3, $P < 0.01$).

DISCUSSION

Mast cells are immunocytes, which are widely distributed throughout the gastrointestinal tract. Several stimuli (e.g.

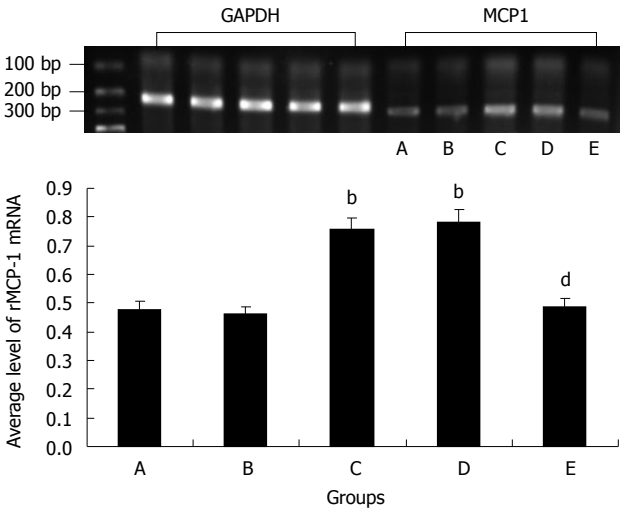

Figure 3 Photograph and the average level of rMCP-1 mRNA of rat gastric antrum by RT-PCR among groups. A: Control group; B: Fluoxetine + control group; C: Depressed model group; D: Saline + depressed model group; E: Fluoxetine + depressed model group; $^{b}P < 0.01$ *vs* normal control group; $^{d}P < 0.01$ *vs* depressed model control group. rMCP-1: rat mast cell protease-1.

allergens, neuropeptides and stress) lead to mast cell activation with consequent mediator release (e.g. histamine, protease, tryptase, chymase and prostanoids)[18,19]. A number of reports indicate that mast cells can be activated by acute stress[20]. Mast cell activation has also been reported in the intestine after repetitive exposure to odors, and acute exposure to cold, which is largely used to study gastric erosion formation induced by stress, and activates both gastric and colonic motility and transit in rats[21]. In this study, chronic stress induced rMCP-1 to release in depressed rats. Chronic unpredictable heterotypic stressors appeared to induce mast cell proliferation and activation, while mast cell granules proliferated. Mast cell secretary granules in depressed rats occurred more often, exposing to the surface of the target and mast cells contained fibrillar material, empty granules and lipid bodies. Studies on mast cells illustrated the remarkable facility of mast cell population to respond to the changes in the environment by significant alterations in multiple aspects of their phenotype, including morphology, mediator content, degranulation pattern and proliferative potential[22].

On the other hand, fluoxetine showed partial inhibitive effects on mast cell ultrastructural alterations and de-regulated r*MCP-1* mRNA expression in gastric antrum tissue in a rat model of depression. Fluoxetine is a serotonin reuptake inhibitor in the central nervous system as well as in mast cells. It depleted mast cell nuclear as well as cytoplasmic serotonin content[23]. Several researches found that antidepressants influenced histamine and serotonin secretion from rat peritoneal mast cells[24,25]. Maes[26] reported that various types of antidepressants, including SSRIs such as fluoxetine, had negative immunoregulatory effects. The negative immunoregulatory effects of antidepressants result from their effects on the cAMP-dependent protein kinase A (PKA) pathway. Chronic unpredicted mild stress can affect the PKA expression in rats and fluoxetine is antagonistic against it[27]. In addition, the effect of fluoxetine on r*MCP-1* expression was related to neuropeptide [e.g. substance P (SP), corticotropin-releasing hormone (CRH), vasoactive intestinal polypeptide (VIP)]. In severe depression, SP serum levels are increased[28]. The data indicate that SP serum levels might be related to response to antidepressant therapy[29]. In other reports, fluoxetine can improve depressed behavior, increase VIP expression and decrease CRH expression in plasma and the duodenal tissue of depressed rats. Clinically effective therapy with antidepressants normalizes the disturbed activity of the hypothalamic-pituitary-adrenal (HPA) axis, in part by decreasing SP, CRH or increasing VIP synthesis[30].

These findings will conduce to understand that chronic heterotypic stress may induce the immune responses in gastric mucosa. Treatment with fluoxetine can ameliorate pathological changes in gastric antrum of depressed rat model, suggesting that SSRIs are an effective therapeutic agent for some gastroduodenal diseases caused by psychological factors.

ACKNOWLEDGMENTS

We thank Dr. Shen-Lin Lei for his technical assistance.

COMMENTS

Background

In clinical studies, it has become clear that depression plays an important role in gastrointestinal diseases by precipitating exacerbation of symptoms. The stress may induce mast cell activation and degranulation.

Research frontiers

Some data strongly suggested that mast cells played an important role in pathophysiology of gastrointestinal diseases. Selective serotonin reuptake inhibitors (SSRIs) have been shown to be immunomodulatory and anti-inflammatory against proinflammatory cytokine processes.

Innovations and breakthroughs

The authors established a rat depression model, and observed the level of mast cell protease-1 (rMCP-1) expression in gastric antrum and the effects of fluoxetine on mast cell morphology and rMCP-1 expression in the depressed rats.

Applications

These findings will conduce to understand that chronic heterotypic stress may induce the immune responses in gastric mucosa. Treatment with fluoxetine can ameliorate pathological changes in gastric antrum of depressed rat model, suggesting that SSRIs are an effective therapeutic agent for some gastroduodenal diseases caused by psychological factors.

Terminology

Rat mast cell protease-1 (rMCP-1) is released and is associated with mast cell activation and degranulation.

Peer review

The authors of the present study showed that depression led to mast cell proliferation and activation in the gastric antrum. Fluoxetine counteracted such changes in gastric antrum in the depressed rat model.

Abstract

Dietary supplements represent an increasingly common source of drug-induced liver injury. Hydroxycut is a popular weight loss supplement which has previously been linked to hepatotoxicity, although the individual chemical components underlying liver injury remain poorly understood. We report two cases of acute hepatitis in the setting of Hydroxycut exposure and describe possible mechanisms of liver injury. We also comprehensively review and summarize the existing literature on commonly used weight loss supplements, and their individual components which have demonstrated potential for liver toxicity. An increased effort to screen for and educate patients and physicians about supplement-associated hepatotoxicity is warranted.

INTRODUCTION

Obesity has become an increasingly important public health problem in the United States. Recent data show that more than 30% of adults are obese and 65% overweight[1]. The use of dietary supplements for weight loss has become increasingly popular, as reflected by the $55.4 billion spent in the U.S. in 2006 for weight loss and diet control[2,3]. Based on a study by the National Center for Complementary and Alternative Medicine (NCCAM), 36% of adults are using some form of complementary or alternative medicine, which rises to 62% when including megavitamins or prayer. Although dietary and herbal supplements are governed under the DSHEA act of 1994, they are not presently regulated by the U.S. Federal Drug Administration, and the safety profiles of many are unknown. An increasing number of case reports have emerged which suggest causative supplement-associated liver toxicity. Hydroxycut is an herbal weight loss supplement that has been suspected to have possible liver toxicity. Herein we present two patients who experienced severe acute hepatitis in the setting of documented Hydroxycut exposure, and without alternative etiology after comprehensive serologic liver evaluation.

CASE REPORTS

Case 1

A 40-year-old female with a prior medical history notable only for hypothyroidism and diet-controlled hyperlipidemia presented to the Emergency Department with 3 d of new-onset crampy, mid-epigastric abdominal pain and non-bloody diarrhea. She noted subjective fevers and chills, and two isolated episodes of nausea and vomiting, anorexia and profound fatigue. She did not experience jaundice, icterus, pruritus, arthralgias, acholic stools or dark urine. One week prior to presentation, she began using Hydroxycut, 6 pills daily in preparation for a bodybuilding competition. Just prior to presentation she attended an office holiday party, although no other persons in attendance became ill. She did not smoke or drink. She otherwise does not take regular medications except for levothyroxine. She denied taking any other supplements or alternative medications. She was afebrile with stable vital signs, and normal body mass index. Her exam was notable only for mild mid-epigastric tender-

ness to palpation. She had no liver enlargement and no stigmata of chronic liver disease. Her laboratory profile on admission revealed an acute hepatitis with AST 1020 U/L and ALT 1150 U/L, total bilirubin 0.67 mg/dL, alkaline phosphatase 299 U/L, INR 0.96, white cell count 5.9 × 10^3/μL, hemoglobin 11.9 g/dL, platelet count 228/μL, and creatinine 0.9 mg/dL. Diagnostic evaluation was negative for hepatitis A, B, C, cytomegalovirus and Epstein-Barr virus, autoimmune liver disorders (ANA, ASMA), alpha-1 anti-trypsin deficiency, and ehrlichiosis. On day 2 of admission, her transaminases decreased to AST 399 U/L and ALT 647 U/L. On day 3, she was clinically well and discharged from the hospital. Upon outpatient follow-up, she had returned to her usual state of health with normalization of transaminases with AST 46 U/L and ALT 48 U/L. She has not experienced any further recurrence of symptoms or liver abnormalities within 10 mo of follow-up.

Case 2

A 33-year-old female with a prior medical history of a pituitary adenoma presented to the Emergency Department with 1 mo of new-onset jaundice. She reported a flu-like illness of 2 wk duration with nausea and crampy abdominal pain and began to experience jaundice, acholic stools, dark-colored urine, pruritus, and profound fatigue. These symptoms appeared to be improving during the week prior to admission except for worsening jaundice and fatigue. She noted that during the month prior to admission, she had taken Hydroxcut supplements for 2 wk to help achieve weight loss, but discontinued this medication upon onset of symptoms. She additionally reported eating lobster during the month prior to admission, but could not recall other individuals who became ill. Her only medication was Ortho-Novum contraceptive, which she had been taking for 2.5 years. Her social history was unremarkable without regular alcohol ingestion, and the absence of risk factors for chronic viral hepatitis. She was afebrile with stable vital signs, and normal body mass index. Her exam was notable only for jaundice and scleral icterus. She had no liver enlargement and no stigmata of chronic liver disease. Her laboratory profile at admission was notable for acute hepatitis with AST 934 U/L and ALT 1 570 U/L, total bilirubin 20.9 mg/dL, direct bilirubin 14.2 mg/dL, alkaline phosphatase 112 U/L, INR 1.08, white cell count 9.2 × 10^3/μL, hematocrit 42%, platelet count 414/μL, creatinine 0.8 mg/dL. Diagnostic evaluation was negative for hepatitis A, B, C, cytomegalovirus, Epstein-Barr virus, and herpes simplex virus infections. Her autoimmune profile revealed low titer increase in antinuclear antibody (ANA) and anti-smooth muscle antibody (ASMA) suggestive of an immune-mediated drug-induced hepatitis. Her jaundice eventually resolved and her liver function normalized.

DISCUSSION

The public's increasing demand for alternative medicine, the newly found global interest in phytomedicine and herbal therapies, the rising cost of conventional prescription drugs, and a loss of faith in Western medicine, have led to a rapid rise in the use of unregulated herbal supplements and therapies. An estimated 80% of the world population uses herbal medicines, largely outside the U.S.[4]. In a study performed at an outpatient liver clinic, over 21% of patients were taking herbal supplements in the setting of chronic liver disease[5]. The FDA describes dietary supplements as a product taken by mouth that contains a "dietary ingredient" intended to supplement the diet. The "dietary ingredients" in these products may include: vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. Most of these products have not been rigorously studied through placebo-controlled, blinded, randomized trials[6].

Table 1 Hydroxycut ingredients supplement facts (serving size 2 caplets)

Amount per serving	% daily value
Calcium (as hydroxycitrate) 156 mg	16[1]
Chromium (as polynicotinate) 133 mg	111[1]
Potassium (as hydroxycitrate) 218 mg	6[1]
Garcinia Cambogia (66% hydroxycitric acid)	[2]
Gymnema Sylvestre (25% gymnemic acid)	[2]
Soy Phospholipids	[2]
Rhodiola rosea extract (5% rosavins)	[2]
Green Tea as Camelia Sinensis (91 mg of EGCG)	[2]
White Tea as Camelia Sinensis (15% EGCG)	[2]
Oolong Tea as Camelia Sinensis (15% EGCG)	[2]
Caffeine anhydrous	[2]

[1]Percent daily values based on 2000 calory diet; [2]Daily values not established.

Hydroxycut is one of the most popular dietary supplements for weight loss on the market today, including two formulations Hydroxycut and Hydroxycut hardcore. Hydroxycut contains several different herbs, including: *Garcinia Cambogia* extract, chromium polynicotinate, *Gymnema sylvestre* extract and *Camellia Sinenesis* (*C. Sinenesis*) (Table 1). Both patients in this report used the dietary supplement Hydroxycut within a short time frame before presenting with acute hepatitis, suggesting Hydroxycut as the most likely etiology for acute liver injury. Neither patient had a history suggestive of other exposures or risk factors for viral hepatitis, alcoholic hepatitis, other toxin-mediated injury, or chronic liver disease. A comprehensive serologic and radiographic evaluation performed in both patients did not reveal alternative sources for liver toxicity. Although causation is difficult to confirm in cases of suspected drug-associated hepatotoxicity, the temporal relationship to acute liver injury and rapid resolution upon withdrawal of Hydroxycut make this likely. Hydroxycut has previously been associated with both a cholestatic and hepatocellular pattern of injury. The specific components likely implicated in liver toxicity include *G. Cambogia, Chromium*, and green tea root extract (*Camellia Sinensis*) based on prior data suggesting liver toxicity. Patient 1 experienced a more typical hepatocellular pattern of injury, patient 2 demonstrated an immune-mediated pattern of injury, which has not previously been described.

There has been one prior report of two cases of possible hepatotoxicity with Hydroxycut in the literature[7]; both cases were young males who had documented periods of Hydroxycut exposure and experienced similar clinical syndromes marked by fatigue, jaundice, and pruritus with marked hepatocellular or cholestatic pattern and complete resolution upon supplement withdrawal. Our case series validates the likely causative relationship between Hydroxycut exposure and liver toxicity, and further suggests that an autoimmune pattern of hepatotoxicity may be observed. Although less common, drug-associated autoimmune hepatitis has been reported in several herbal supplements including Greater Celadine, Dai-Saiko-To, and Black Cohosh. Herein we review key ingredients of Hydroxycut that have been implicated in liver toxicity.

G. Cambogia is a fruit native to southeastern Asia and western Africa used to make meals more "filling" [8]. Its main component hydroxycitric acid (HCA) is an inhibitor of the citrate cleavage enzyme (ATP citrate lyase) blocking de novo synthesis of fatty acids[9]. HCA was initially studied in rodents for the dietary treatment of obesity and the results seemed to be promising. Unfortunately randomized controlled trials in humans for this purpose showed very conflicting results. Nevertheless, HCA is a primary component of many weight loss supplements in the market, and similar to others in its class, the toxicity profile is poorly studied. In the recent literature a case of fatal liver failure was reported in a patient taking HCA and montelukast suggesting the synergistic hepatotoxic effect of these two agents[10]. There have also been reports of *G. Cambogia* toxicity by the WHO database, mostly describing an increase in hepatic enzymes[6].

Chromium is an essential trace element and cofactor to insulin most commonly occurring in hexavalent (Ⅵ) and trivalent (Ⅲ) states. The hexavalent form is found in the dye and leather industry and is responsible for occupational toxicity ranging from dermatitis to lung cancer[11]. In 1989, the National Academy of Sciences established an "estimated safe and adequate daily dietary intake" range for chromium of 50 to 200 mg[12]. In 2001 the Institute of Medicine and the National Academy of Sciences established Dietary Reference Intakes (DRI) for Chromium, ranging from 0.2 mg for infants to a maximum of 45 mg in lactating mothers[13]. Chromium is used in weight loss supplements due to purported effects of decreasing body fat and increasing basal metabolic rate[14,15]. A recent meta-analysis of available RCTs concluded that weight reduction with chromium although statistically significant was not clinically meaningful[2]. There have been case reports of chromium toxicity causing acute hepatitis, thrombocytopenia and renal failure due to both environmental[16,17] and dietary supplements[18]. Although renal failure requiring dialysis is a more common concern[19], those presenting with liver toxicity frequently elaborate aminotransferase elevations greater than 1000 mg/dL. Each Hydroxycut serving contains 133 mg of Chromium, which is taken three times daily, resulting in a cumulative daily consumption grater than twice the NAS safe maximum dose.

Camellia Sinensis is the scientific name for green tea, which is widely regarded by the public as safe, and commonly incorporated into supplements due to purported anti-cancer potential[20], weight reduction[21] and antioxidant properties[22]. Acute hepatotoxicity from *C. Sinensis* is well-described, and may range from acute hepatitis to acute liver failure. Based on 17 published cases in the literature[23-27], most cases appear to occur following large ingestions of green tea, with resolution following withdrawal, and recurrence with re-challenge[28]. Consequently, *C. Sinesis* has been banned in France and Spain, although it remains unregulated in weight loss supplements commercially available in the U.S.

Other Hydroxycut components for which liver toxicity have not been described include *Gymnema Sylvestre, Rhodiola Rosea*, and *Withania Somnifera. Gymnema Sylvestre* has been used to control hyperglycemia[29] and hyperlipidemia[30] in rats. Toxicity studies in rodents have not shown hepatotoxicity[31] and no case report of liver injury has been reported. Rhodiola Rosea extract is used to decrease fatigue[32] and improve exercise tolerance[33]. Withania Somnifera has been used for its anti-inflammatory properties[34,35]. Neither *R Rosea* or *W Somnifera* have been associated with liver toxicity, although *W Somnifera* may result in renal impairment in rats[36].

Of note, the more concentrated Hydroxycut Hard Core product contains additional herbal formulations such as White Willow extract and Yohimbine. These have not been demonstrated to result in liver injury, whereas Willow bark extract may have anti-inflammatory effects *in vitro*, this was not observed in patients with rheumatoid arthritis or osteoarthritis in a randomized controlled trial[37]. Yohimbine is an indole alkaloid from the bark of the African *Pausinystalia Yohimbe*, and serves as an alpha-2 receptor antagonist which may treat male impotence[38]. Although nausea, vomiting and abdominal pain have been described, liver toxicity has not been observed.

The FDA has issued warnings on several herbal supplements known to have hepatotoxic potential including Comfrey (2001), Kava (2002) and the dietary supplement Lipokinetix (2001). This review does not seek to provide a comprehensive review of all known hepatotoxins, but highlight a short list of ingredients within best selling weight loss supplements which have been demonstrated to have hepatotoxic potential.

Ephedra alkaloid, AKA *Ma Huang*, is the most commonly used weight loss supplement in the U.S.[4], and is well-known to have potentially deleterious cardiovascular and CNS effects[39], but has also been implicated in numerous cases of liver failure[40,41]. As such, dietary supplements containing ephedra were banned in the U.S. in April 2004[42], but remain widely available through unregulated internet sources in various forms, including the supplement *Leptoprin* (previously *Anorex*) which contains 20 mg of ephedrine, 200 mg of caffeine, 324 mg of aspirin, and unknown amounts of Green tea and cayenne. *Adipokinitex* came to the market to replace *Lipokinetix* which was removed in 2002 by Syntrax Innovations Inc. due to FDA

Table 2 Components of popular weight loss supplements

Brand name	Potentially hepatotoxic components
Hydroxycut	*Garcinia Cambogia*, Chromium, *Camelia Sinensis*
Ephedrasile Hardcore	*C. Sinensis*, Valerian, St John's wort
Zalestrim	C. Sinensis. Black Cohosh, Dong Quai
Slim-Citi	Hoodia
Ephedra	Mau Hang
Leptoril	*C. Sinenis,* Aspirin
Adipokinetix	*C. Sinensis*
Xenadrine	*C. Sinensis,* Ma Huang
Lipovox	*C. Sinensis*
Lean fire	*C. Sinensis*
Miracle Burn	Hoodia
7 DFB	Noni extract
Curvatrim	*C. Sinensis*, Dong Quai
Ambi-Slim	*C. Sinensis*, Garcinia Cambogia, Chromium, Valerian
TrimSpaX32	*C. Sinensis*, Hoodia Gordoni
Eroved	Hoodia, Garcinia Cambogia, Chromium
Zylorin	Hoodia, C. Sinensis, Chromium
Jet Fuel	*C. Sinensis,* Hoodia,
VPX redline	*C. Sinensis*
Metabolene	*C. Sinensis,* Chromium, Hoodia

Table 3 Patterns of injury in herbal hepatotoxicity

	Cholestatic	Hepatocellular	Autoimmune	Fulminant failure
Atractylis Gummifera[50]				X
Black Cohosh [51,52]			X	X
Callilepsis Laureola[53]				X
Camelia Sinensis[24-28]		X		X
Chapparral[54]	X			X
Chromium picolinate[18,19]		X		
Cascara Sagrada[55]	X			
Dai-Saiko-To[5]			X	
Garcinia Cambogia[7]	X	X		
Germander[56,57]		X		X
Greater Celadine[58,59]	X		X	
Jin Bu Huan[60]	X			
Kava[61-63]		X		
Noni[64]		X		
Paeonia[65]		X		
Paulina Cupana		X		
Penny Royal[66,67]				X
Senna[68]		X		
Shou wu pian[5]		X		
Syo-Saiko-To[69]	X	X		
Teucrium Polium[5]				X
Usnic Acid[70,71]		X		X
Valerian[72]		X		

warnings regarding reported cases of hepatotoxicity[43]. Although the Usnic acid has been removed from the formulation, this diet pill still contains Norephedrine or Norphenephrine and Green tea extracts. *Ephedrasil Hardcore*, a top selling diet pill, is a newer formulation of Ephedra following its ban in 2004, and contains many ingredients including Chromium, Yohimbine, and green tea extract.

Hoodia Gordoni, a popular supplement used for appetite suppression, and is derived from a cactus-like bush leaf native to southern Africa. Although initially isolated by Pfizer in the 1970s, research was discontinued due to liver toxicity found in early research studies. Despite these reports, this is a common ingredient in dietary supplements such as *Slim-Citi, Trim Spa X32* and *Ephedrine-P57*.

Zalestrim is another top selling supplement composed of green tea and Black Cohosh, which are described above as known sources of potential hepatotoxicity[44-48]. It also contains *Dong Quai,* which increases prothrombin time and thereby increases bleeding risk[49].

In summary, this case series and review of the literature highlight the potential hepatotoxicity of commonly used herbal supplements including Hydroxycut. Due to their loose regulation in the current drug marketplace, oversight of their use by physicians and regulators alike remains poor. Those supplements with potential liver toxicity are summarized in Tables 2 and 3, although further investigation is needed to better clarify the mechanisms and patterns of injury, and inform policy makers on those ingredients which require more vigorous regulation. The use of supplements is frequently not queried by physicians, and may not be reported in the same manner as prescription drugs by patients. As such, it is advisable that physicians ask specifically about the use of non-prescription drugs and supplements, warn patients with known liver disease about the potential consequences of their use, and to query patients specifically about possible supplement exposure in cases of acute or chronic liver injury. Increased attention to this issue by physicians and regulatory agencies may lead to more successful efforts to decrease the burden of drug-associated liver injury in the U.S.

Abstract

Systemic mastocytosis (SM) is a rare disease with abnormal proliferation and infiltration of mast cells in the skin, bone marrow, and viscera including the mucosal surfaces of the digestive tract. Gastrointestinal (GI) symptoms occur in 14%-85% of patients with systemic mastocytosis. The GI symptoms may be as frequent as the better known pruritus, urticaria pigmentosa, and flushing. In fact most recent studies show that the GI symptoms are especially important clinically due to the severity and chronicity of the effects that they produce. GI symptoms may include abdominal pain, diarrhea, nausea, vomiting, and bloating. A case of predominantly GI systemic mastocytosis with unique endoscopic images and pathologic confirmation is herein presented, as well as a current review of the GI manifestations of this disease including endoscopic appearances. Issues such as treatment and prognosis will not be discussed for the purposes of this paper.

INTRODUCTION

Systemic mastocytosis (SM) is characterized by abnormal growth and accumulation of mast cells in various organs[1]. SM represents a heterogeneous group of disorders with varying frequencies of GI disease[2]. Different studies report a wide array of GI involvement with a range from 14%-85% and more recent studies suggest that it comes as a close second commonest symptom next only to pruritus[2,3]. The differences in reported GI symptoms are thought to reflect the heterogeneous population of SM studied, methodology of studies, and the differences in the definition of mastocytosis[2]. Indeed the involvement of the GI tract has been shown to vary with the Metcalfe type of SM[4,5]. It must be stressed that while most patients have pruritus or urtication, these symptoms generally cause less significant discomfort for patients than the GI symptoms which are more distressing chronic complaints[6,7].

CASE REPORT

A 75-year-old man with a history of colonic polyps, hypertension, childhood tonsillectomy, and a remote smoking history presented with a complaint of "excessive mucus in the throat" for the past several years. The patient had a sensation of a "sore throat" for years along with more frequent bowel movements and increased flatus. There were no other gastrointestinal complaints. The patient subsequently had maculopapular rashes which on biopsy showed increased numbers of dermal mast cells highlighted by c-kit (CD 117) immunoperoxidase staining consistent with that of dermal mastocytosis (Figure 1 A). The haematoxylin and eosin stain (HE) is also included (Figure 1 B).

When seen by the gastroenterologist, the patient had no lymphadenopathy in the head and neck region but

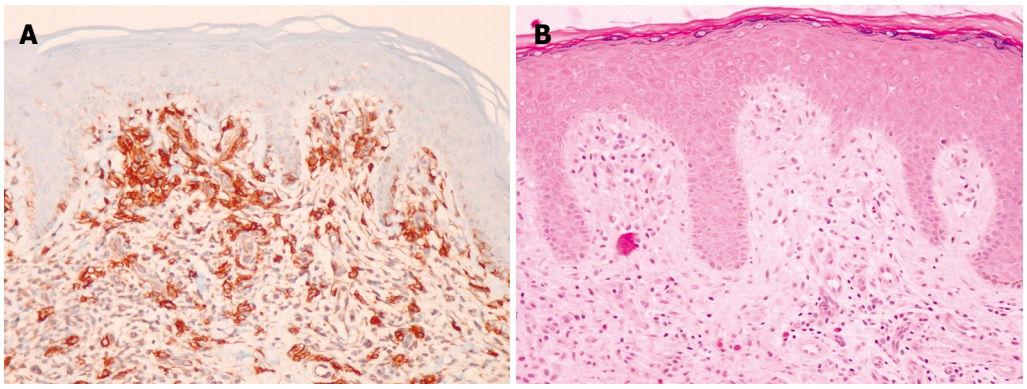

Figure 1 The patient subsequently had maculopapular rashes which on biopsy showed increased numbers of dermal mast cells highlighted by c-kit (CD 117) immunoperoxidase staining consistent with that of dermal mastocytosis. The haematoxylin and eosin stain (HE) is also included.

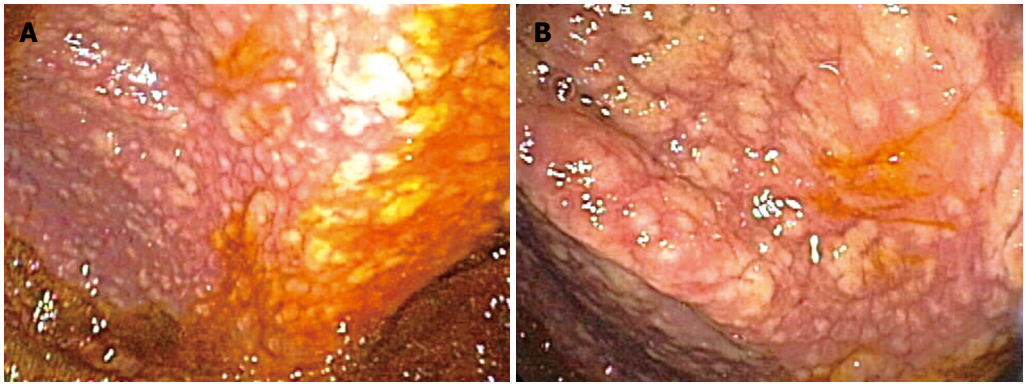

Figure 2 On colonoscopy a mucus type material adherent to the mucosa was present in the right colon along with a slightly raised appearance of the mucosa through areas of the transverse and right colon.

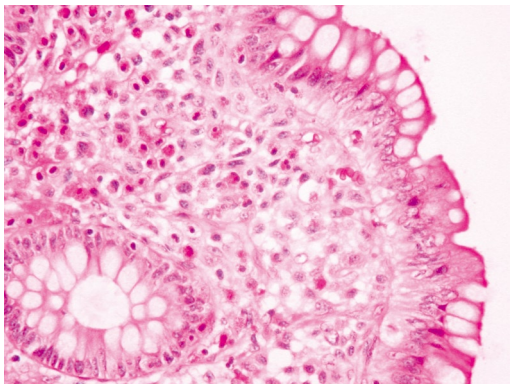

Figure 3 The biopsy in these colonic regions showed an increased number of mast cells with recruited eosinophils in the lamina propria (HE).

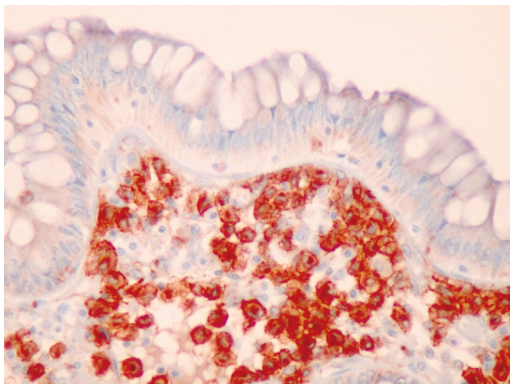

Figure 4 The mast cells are highlighted by positive c-kit staining.

did have tissues in the distal soft palate and pharynx appearing uniformly swollen and hyperemic. The respiratory, cardiovascular, and neurological exams were grossly normal. On abdominal exam there was no organomegaly, masses, tenderness, or inguinal lymphadenopathy. A ventral hernia was noted.

On colonoscopy a mucus type material adherent to the mucosa was present in the right colon along with a slightly raised appearance of the mucosa through areas of the transverse and right colon (Figure 2). The biopsy in these colonic regions showed an increased number of mast cells with recruited eosinophils in the lamina propria (Figure 3 HE). The mast cells are highlighted by positive c-kit staining (Figure 4).

Common GI complaints in SM include abdominal pain, diarrhea, nausea, and vomiting[2]. It appears that the frequency of various GI symptoms is less variable than their prevalence[2]. These symptoms are thought to be secondary to mast cell mediators on the GI tract. The most common symptom is abdominal pain (mean 51%) followed by diarrhea (mean 43%) and nausea or vomiting (mean 28%)[2]. Abdominal pain can be classified into two different types corresponding to different pathology. Epigastric dyspeptic pain is associated with ulcer disease and acid hypersecretion whereas no dyspeptic pain is characterized by lower abdominal cramps[8]. Diarrhea is thought to occur due to gastric acid hypersecretion, malabsorption caused by mucosal injury and edema, and altered bowel motility[8]. Moreover, diarrhea in SM can also be caused or contributed to by tissue infiltration by mast cells[3,9]. It is however worth noting that the mast cells themselves do not secrete gastrointestinal peptides that directly alter motility[3].

A common symptom in SM is facial flushing[10]. The flushing in SM can be distinguished from the flushing

Table 1 Endoscopic features reported in patients with systemic mastocytosis with gastrointestinal symptoms

Esophageal	Gastric and Duodenal	Small Intestine	Colon and Rectum
Esophagitis	Peptic ulcers	Thickened jejunal folds with edema	Nodular lesions
Esophageal stricture	Thickened gastric or duodenal folds	Dilated small bowel	Urticarial lesions in the rectum
Varices	Nodular mucosal lesions		Multiple polypoid lesions
	Urticarial lesions		Diffuse intestinal telangiectasias

seen in the rare but more prevalent carcinoid tumors in that carcinoid flushing is generally more widespread, patchy, violaceous, and evanescent, lasting only a few minutes, often occurs postprandially, and in the majority of cases not associated with hemodynamic changes[10]. Furthermore, the response to long acting somatostatin analogue octreotide, the specific pattern of mediator excretion, and aggravation of the flushing by epinephrine in the carcinoid case can assist in the differentiation[10,11]. In SM, the flushing tends to be more bright red, pruritic, and burning, and may be accompanied simultaneously by other symptoms of systemic mast cell degranulation including GI symptoms[10,12].

Other symptoms may also occur as a result of GI bleeding and peptic ulcer disease[2,3]. It is estimated that GI bleeding occurs in 11% of SM[2]. Contrary to previously reports it is estimated that peptic ulcer disease is an under diagnosed phenomena[2]. Indeed in a more recent prospective study within which nine patients had upper GI endoscopy, four of the nine patients had peptic ulcer disease[3]. Interestingly, hypersecretion of gastric acid is not consistently related to the level of serum histamine levels measured[3]. It may however be possible that a relationship between tissue concentration of histamine and GI manifestations may exist[3]. It is unclear what triggers the vasoactive mediators from mast cells but certain medications such as NSAIDS, opiate analgesics, procaine, and penicillin may be potential triggers[13].

Rarely, esophageal complaints in SM are made and include symptoms due to esophagitis and in some reports variceal bleeding secondary to portal hypertension that may develop in SM[14].

Signs of GI SM include steatorrhea, malabsorption, hepatomegaly, splenomegaly[2] and sometimes ascites secondary to portal hypertension. Steatorrhea can be measured by 72-h fecal fat excretion test, D-xylose tolerance test, and Shilling test. In SM steatorrhea is associated in 5%-67% of patients[7,15,16]. Hepatomegaly was found in 41%-72% of patients[12,17]. Mast cells are known to infiltrate the liver diffusely with or without portal fibrosis and rarely cirrhosis in 4% of patients[12]. Portal hypertension is also reported in association with SM[18,19] and is ascribed to pre- and post-sinusoidal block secondary to mast cell infiltration and or fibrosis[18]. Splenomegaly attributable to SM is thought to be due to mast cell infiltration that may accompany hepatomegaly[20,21]. Marked splenomegaly was found to be more common in aggressive SM[22]. Since SM is a rare entity a low clinical suspicion is required and usually the diagnosis is made on biopsy[10].

Case reports highlight some of the more unusual pathology. One such is SM and giant gastroduodenal ulcers associated with telangiectasia macularis eruptiva perstans which is thought to represent a cutaneous form of mastocytosis[8]. Rarely aggressive SM can be complicated by protein-losing enteropathy[23]. Other reports include initial misdiagnosis as SM can mimic inflammatory bowel disease[9,24] and Zollinger-Ellison syndrome[24].

Small intestinal pathology may reveal dilated loops of bowel and thickened, edematous or scalloped folds[6,25]. In the colon, urticarial lesions, diverticulitis, polypoid lesions, and diffuse intestinal telangiectasia may be seen (Figure 3)[25,26].

Diagnosis of SM is based on identification of neoplastic mast cells by morphologic, immunophenotypic, and/or genetic criteria in various organs. Specifics of the World Health Organization criteria for the diagnosis of SM based on a paper by Valent *et al*[27] will not be discussed. Currently there is no consensus GI biopsy criteria.

Needless to say, patients with obvious dermatological findings are diagnosed by clinicians more quickly as having SM. Unfortunately, patients lacking skin manifestations of SM have a delayed diagnosis even though they often have more aggressive disease, impaired liver function, ascites, malabsorption, and splenomegaly[28].

Interestingly our endoscopic images (Figure 2) from the colonic involvement look markedly different from previously published images by Scolapio *et al*[25]. In the pictures provided in this paper, the appearance of SM in the colon would be described as small mucosal nodules with focal areas of edema, urticarial, granular, and multiple purple-pigmented lesions. To date these are the first endoscopic images that contain all of these features although these findings have been reported in isolation or in pairs[25,29,30].

An earlier review by Jensen in 2000 has reported the following endoscopic findings which are displayed in a table[2]. (Table 1 adapted from Jensen[2]).

DISCUSSION

This report describes an interesting case of a rare cause of chronic diarrhea. It is important to consider this diagnosis in the work up of intractable diarrhea. The distinct endoscopic appearance of this disorder may at times be seen and it is recommended that this information be communicated to the pathologist responsible so that special stains may be performed, allowing the information to perhaps contribute to the diagnosis of SM. It is important to identify potential triggers for GI symptoms of SM as well as to initiate symptomatic treatments. Presently there is no cure for SM and it is recommended that cytoreductive therapy and ensuing management be

planned carefully with expert hematologists and hematopathologists.

Abstract

A 52 year-old male patient diagnosed of ankylosing spondylitis presented with an iron deficiency anemia after a ten-month treatment of methotrexate. He did not respond to treatment with oral iron not a proton pump inhibitor and an upper endoscopy was performed. The histological study of the duodenal biopsies showed villus atrophy. After removing the methotrexate, administrating intramuscular iron and undertaking a gluten-free diet, the histological and analytical alterations progressively resolved.

INTRODUCTION

Methotrexate is an immunosuppressive agent commonly used in the daily practice of many specialties. Methotrexate, in a weekly dose, can be used for years where its use is primarily limited by toxicity. The main side effects include renal or liver impairment, orointestinal mucositis, bone marrow toxicity and gastrointestinal side effects, such as nausea or vomiting, many of which can often be avoided by using low-doses of the drug, or combining it with folic acid supplementation[1].

Several cases of villus atrophy, after the use of immunosuppressors[2], have been reported in the medical literature; however, only one case of intestinal villus atrophy secondary to Methotrexate, has been described[3]. We present a second case of a sprue-like syndrome secondary to methotrexate treatment, this time in a paucisymptomatic patient.

CASE REPORT

A 52 year-old male patient was referred to our Gastroenterology out-patient clinic from the Rheumatology Department, as he presented with a progressively increasing iron deficiency anemia, that did not respond to proton pump inhibitors and iron taken orally.

He had been diagnosed of ankylosing spondylitis, HLA B-27 positive, in 2000, and was initially treated with the nonsteroidal antiinflammatory drugs (NSAIDs), salazopyrine and omeprazol. In April, 2002, treatment with salazopyrine was stopped, but prednisolone and methotrexate were added in October, 2002, because the patient had severe arthralgias. The arthralgias lessened with the new treatment, but analytical alterations were progresively seen. An analysis during December, 2002, showed normal hemoglobin (Hb 13.4 g/dL, VCM 87 and HCM 30.2) and iron (70 μg/dL), but in January, 2003, the hemoglobin level had decreased to 11.7 g/dL. By May, 2003, the asymptomatic patient presented with iron deficiency anemia (Hb 9.9 g/dL, Hto. 31%, VCM 71, HCM 22.9, platelets 489000, iron 22 μg/dL,

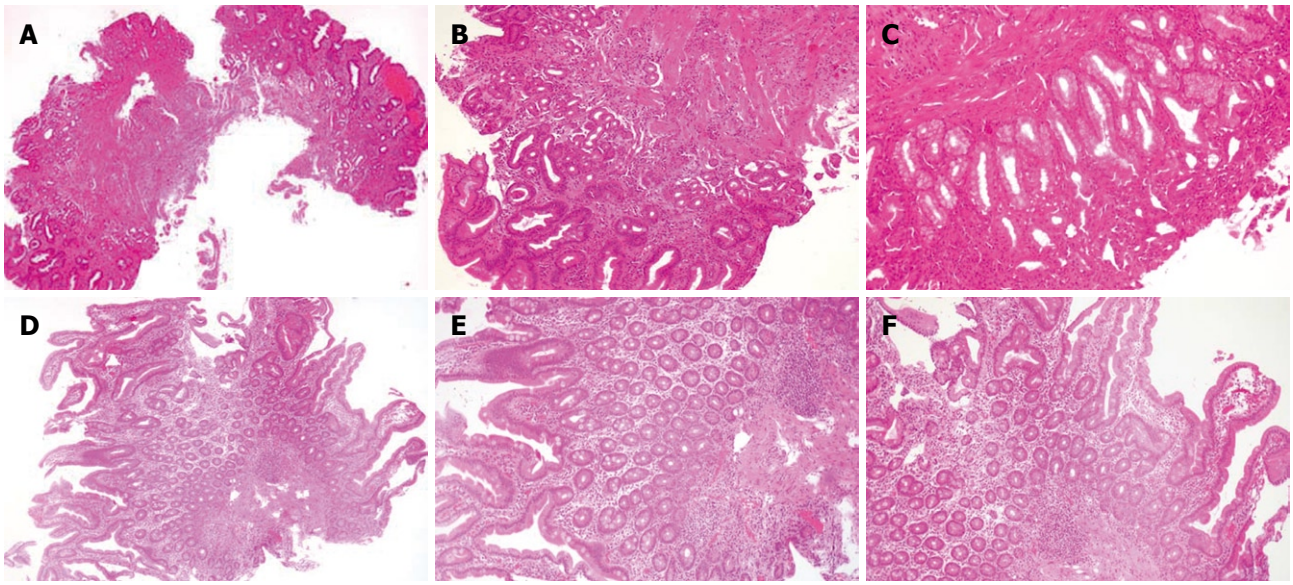

Figure 1 Biopsy of duodenum. A: Year 2003, (HE, x 40); B-C: Year 2003, (HE, x 100); D: Year 2005, (HE, x 40); E-F: Year 2005, (HE, x 100).

transferrine 366, IST 5% and ferritine 2 ng/dL), for which he received iron, taken orally, and was referred to the Gastroenterology Department.

He had no digestive symptoms, weight loss, or anorexia. The suspected diagnosis included: (1) gastric erosions secondary to NSAIDs, (2) a side-effect of Methotrexate, or (3) other causes of iron deficiency anemia. Therefore, an endoscopy and celiac sprue antibodies were requested, and treatment with oral iron and proton pump inhibitors continued.

The upper endoscopy showed a stomach with patched mucosa, alternating red and white areas, which continued in the first and second portions of the duodenum, in which many longitudinal erosions, covered with fibrin, were observed, macroscopically compatible with an Inflammatory Bowel Disease, or a Lymphoma.

However, the histological study showed intestinal biopsy with evidence of atrophy of the wall, with decreased thickness, increased collagenous fibers in the interstitium, mucosal flattening of the villi and small repare glands (Figure 1A). The mucosa shows a loss of glandular structure, with small and round reparing glands, covered by a cubical one-layer epithelium, with nuclei containing reactive atypia, with mild pleomorphism, larger in size and variable nucleoli. There was a fibrous stroma and a heterogeneous inflammatory infiltrate, with eosinophil leukocytes in moderate quantity (Figure 1B-C).

In July, since the hemogram was similar (Hb 9.2 g/dL), despite three months of oral iron, antibodies were negative, and taking into account the results of the upper endoscopy, an intestinal follow-through and a colonoscopy (which were both normal) were requested and methotrexate was discontinued.

Three months later, the iron deficiency anemia persisted and a gluten-free diet was tested. In January, 2004, after three months of a gluten-free diet and six months of not taking methotrexate, there was still a iron deficiency anemia with a hemoglobin of 9.4 g/dL, a new endoscopy was performed. The upper endoscopy showed a loss of duodenal folds and the urease test for *Helicobacter pylori* was negative. The histological study confirmed the existence of an atrophic gastritis and duodenitis. With the result of the endoscopy, the patient returned to our out-patient-clinic in March, 2004. He had an itchy eruption, made up of clusters of tiny blisters in the elbows and back, which was compatible with a Dermatitis Herpetiformis. He was referred to the Dermatology out-patient clinic, but was not visited until six weeks later where the skin lesions had spontaneously disappeared.

Treatment with intramuscular iron was initiated after the Dermatologic evaluation in April, 2004, and three months later the hemogram was almost normal; there was no anemia, (Hb 13.1 g/dL), but there was still a slight hypocromia and microcytosis. The intramuscular iron was stopped in December, 2004, when the still asymptomatic patient reached acceptable levels of iron, ferritine and transferrine (Fe 158 μg/dL, Transf. 275 mg/dL and FE 93 ng/mL) and had a normal hemogram (Hb 14.5 g/dL, Hto. 43%, VCM 84, HCM 28.5).

The patient was periodically seen in our out-patient clinic the following year. Analysis remained normal and a control upper endoscopy was carried out on December, 2005. It showed a dramatic change from the first one, which had been performed two years earlier, when the patient was undergoing treatment with methotrexate. The endoscopy was macroscopically normal.

The histological study showed an intestinal biopsy with normal wall thickness, normal size and number of villi, as well as normal gland and stromal density (Figure 1D). Many intestinal glands, covered by a one-layer cylindrical epithelium with goblet cells, were observed. Between them, the interstitium showed very mild inflammation with a decrease in the fibrous weft. Inflammatory cells were heterogeneously composed of

lymphocytes and plasmatic cells (Figure 1E-F).

The patient remains asymptomatic, from a gastrointestinal point of view, and without anemia or ferropenia. We have not rechallenged methotrexate for ethical reasons.

DISCUSSION

The interest of this case is the appearance of a sprue-like syndrome after the use of methotrexate, and its complete resolution, following the removal of the drug. Although several cases of small-bowel villus atrophy have been described with other immunosuppresive agents, like Azatioprine[2], to our knowledge, only one similar case has been described regarding methotrexate[3]. The latter presented a case of diarrhea, progressive weight loss and general malaise after two years of low-dose methotrexate. Biopsies taken during the treatment showed small-bowel villus atrophy and confirmation of mucosal healing was carried out months after removal of methotrexate.
