Abstract

Acute pancreatitis (AP) is a common and potentially lethal acute inflammatory process with a highly variable clinical course. It is still unclear why some patients progress to organ failure and others do not. Ability to predict which patients will develop severe disease is limited. Routine clinical and laboratory data and multi-factorial clinical scores measured on admission and during the first 48 h of hospitalization are currently the standards of care used to estimate the magnitude of the inflammatory response to injury. Current literature highlights several common environmental, metabolic and genetic factors that increase the risk of AP development and subsequent adverse sequelae. Several cytokines have been found to play a critical role in the pathogenesis of AP by driving the subsequent inflammatory response, to include tumor necrosis factor-α (TNF-α), Interleukin-1 (IL-1), IL-6 and monocyte chemotactic protein-1 (MCP-1). Large, prospective studies are still needed to address these questions by identifying AP risk factors and serum biomarkers of severe disease.

INTRODUCTION

Acute pancreatitis (AP) is a common and potentially lethal acute inflammatory process with a highly variable clinical course. It accounts for greater than 300 000 emergency room visits annually in the US, which is steadily increasing, with a mean length of hospital stay of 7 d[1].

Approximately 20% of affected individuals will develop a severe clinical course in association with the development of a systemic inflammatory response syndrome (SIRS), multiple organ failure (MOF), and on occasion death. Despite substantial animal model research[2], it is still unclear as to why some patients progress to organ failure and others do not, or at what step in the inflammatory cascade will an intervention have an impact upon disease progression. Predictive disease severity scoring systems are widely used in clinical practice; but in reality they reflect the inflammatory response rather than the severity of the insult experienced by the pancreatic parenchyma.

Several clinical and molecular pre-AP susceptibility and severity factors have been identified which may modify an individual's predisposition to AP, and the associated risk of severity. Obesity is one such important factor. An elevated BMI ($\geq$ 30 kg/m^2) significantly increases the extent of AP severity (OR, 2.6; 95% CI, 1.5-4.6) and is implicated in both local and systemic complications[3]. The severity risk increases at an OR of 1.2 per 5 units of BMI. Severe AP is associated with android fat distribution, increased waist-hip ratio (> 1.0) and appears to correlate with an "overactive" immune response.

Alcohol consumption is another risk factor associated with severe AP as it lowers the threshold for intrapancreatic trypsin activation and shifts pancreatic acinar cell death from apoptosis to necrosis as demonstrated in alcohol-fed animals[4]. Our group reaffirmed this finding in human subjects consuming two or more alcoholic drinks per day[5]. Furthermore, active tobacco smoking has been suggested as a susceptibility

factor for AP (RR, 2.14; 95% CI, 1.48-3.09)[6].

In preliminary genetic susceptibility factor studies, the presence of a single nucleotide polymorphism in the gene of a potent chemokine, named monocyte chemotactic protein-1 (MCP-1), at position -2518 A/G predicted that the inflammatory response to AP would be systemic and associated with death[7]. The G allele was present in 86% of severe pancreatitis cases, 46% of mild pancreatitis cases and 43% of controls. The presence of the G allele increased the risk of developing severe AP seven fold (OR, 7.7; 95% CI, 1.6-100).

Routine clinical and laboratory data and multifactorial clinical scores measured on admission and during the first 48 h of hospitalization are currently the standards of care used to estimate the magnitude of the inflammatory response to injury, and to predict whether or not intensive care support is needed to address inflammation-associated complications. Admission hematocrit, C-reactive protein (CRP) at 48 h, Ranson's criteria and the Acute Physiology and Chronic Health Evaluation (APACHE-Ⅱ) scores are the most popular. In addition, a variety of cytokines, chemokines, and other markers of the inflammatory response have been evaluated as predictors of severe AP, as well as markers of development of specific organ-system failure.

Collectively, the literature highlights several common environmental, metabolic and genetic factors that are predisposing factors increasing the risk of AP development and subsequent adverse sequelae. The mechanisms by which such factors increase the risk of severe disease, and whether or not they directly interact with or potentiate one another remains speculative. Knowledge of the inflammatory cascade is important in recognizing when the peak response occurs for various cytokines and inflammatory mediators.

Several reports have evaluated patients with endoscopic retrograde cholangiopancreatography (ERCP) induced pancreatitis, and studied post-ERCP cytokine profiles. Cytokines play a critical role in the pathogenesis of AP by driving the subsequent inflammatory response. Patients with post-ERCP AP have an amylase and lipase increase within the first hour reaching a maximum value between 4 h and 12 h following ERCP[8]. Interleukin-6 (IL-6) increases to a maximal concentration at 24-48 h, and the highest CRP concentrations are established 72 h following an ERCP. In another study, in patients who developed post-ERCP pancreatitis, the serum levels of these cytokines including tumor necrosis factor-α (TNF-α), IL-1, IL-6, IL-8, and IL-10 rose significantly at 8 and 24 h but not at 1 h and 4 h when compared to patients without pancreatitis[9]. These data suggest that serum markers (amylase/lipase) are detected early, but that the acute inflammatory response does not fully develop until at least 8-12 h after the initial pancreatic insult. These data may be useful for determining the extent of pancreatic injury, the timing of the acute inflammatory response and for assessing such inflammatory markers in equation-based models.

TNF-α

TNF-α is a pleiotropic cytokine expressed in acinar cells, and is a key regulator of other pro-inflammatory cytokines and leukocyte adhesion molecules which acts as a priming activator of immune cells[10]. It is also a cell death signal through the TNF-α-related apoptosis induced ligand (TRAIL) receptor pathway, with the potential to cause severe tissue damage. TNF-α plays a pivotal role in severe AP, acting early in the disease course, and is quickly cleared. As a result of its rapid clearance, TNF-α serum levels are less useful as biomarkers of early events than downstream cytokines (e.g. IL-6). To limit the systemic effect of TNF-α, the body releases TNF-α inhibitors. The soluble TNF receptor (sTNFR) attenuates the effects of TNF-α by binding to TNF-α in the serum and thus acts as an anti-inflammatory molecule. sTNFR levels have been found to predict severity in AP with an accuracy of 96%, and also to have a high sensitivity for mortality[11].

IL-1

IL-1 is another major pro-inflammatory cytokine that can drive the SIRS response. It has recently been shown to be the major cytokine mediating inflammation in sterile necrosis[12], which is often problematic in severe AP. In contrast to TNF-α, IL-6 does not directly cause pancreatic damage[13]. It has been used as a biomarker of disease severity and has similar accuracy to IL-6 in predicting severe AP on admission (82% *vs* 88%)[11]. IL-1 receptor antagonist (IL1-RA) levels also correlate with the inflammatory response and severity in AP and may in fact be superior to IL-6 or CRP within the first 48 h.

IL-6

IL-6 is a multifunctional cytokine released by macrophages in response to tissue injury and constitutes the principal mediator in the synthesis of acute-phase proteins, in addition to transitioning the acute inflammatory response to a chronic response. It is an accurate early predictor of severity in AP, with a sensitivity range of 89% to 100% and 90% accuracy within the initial 24 h[11]. It has also been shown to be superior to CRP and the APACHE-Ⅱ score at 24 h following admission.

MCP-1

MCP-1 is a potent chemokine which is released early in the inflammatory process. MCP-1 serum concentrations have been shown to display a dramatic increase in patients with AP who develop local complications or remote organ failure. A close correlation has also been found between the incidence of remote organ failure and the degree of MCP-1 level elevation[7,14]. As highlighted earlier, a common single nucleotide polymorphism on the MCP-1 gene is shown to predispose to severe AP. Macrophage migration inhibitory factor (MIF) is a unique chemokine; that participates in inflammation, immune response and cell growth. Serum MIF levels

have been found to be higher in patients with severe AP than patients with mild disease[11].

Although altering the inflammatory response in animals translates into a possible benefit, the potential translational benefit to humans has not been confirmed to date. For example, the platelet activating factor (PAF) inhibitor, Lexipafant displayed early promise. However, it was not deemed to be an effective treatment in a large, multi-national study of 1500 patients[15]. Although IL-10 decreases the severity of AP in mouse models, and could be of potential benefit in humans, sufficiently powered human studies have yet to be reported in the literature.

The discriminatory power of general prediction schemes improved considerably in the early 1990's. Indeed, Ranson's criteria and APACHE Ⅱ score achieved reasonable discrimination with receiver-operating characteristic curve (ROC) area under the curve (AUC) values approaching 0.8 in most validation studies. Yet, these classification tools are designed to predict ICU mortality and not potentially preventable complications; they are, therefore, least useful in the middle prediction range where the clinician needs most support and information to direct management. Although these tools are of assistance in medical decision making at the extreme end of the prediction range, their use has been confined to a global ICU performance assessment and criteria for clinical trial enrolment.

Successful prediction of individual outcomes is undoubtedly one of the holy grails in the care of the critically ill. Remarkably, although progress has been made along all those fronts in risks and markers for severe AP, little has been achieved in translating data and quantitative tools into clinically useful and appealing predictive knowledge for physicians managing patients with AP.

Large, prospective studies are needed to address these questions by identifying AP risk factors and serum biomarkers of severe disease. Such data could be potentially used to develop patient-specific predictive algorithms of AP risk and to guide the treatment decision-making process early in the disease course. Such studies could aim to: firstly, determine the role of demographic, environmental, genetic and physiological variables on the initiation, progression, severity and clinical outcomes of AP; secondly to identify biomarkers that reflect the extent of pancreatic injury and the acute inflammatory response which are critical in the assessment of the activity of potentially pathologic cascades; thirdly to build advanced statistical models based on pre-injury risk factors and biomarkers of pancreatic injury and inflammation to accurately predict primary and secondary outcomes of AP, including organ failure, complications and death; and finally to guide the research on inflammatory cascade blocking agents administered early in the disease course based on patient-specific predictive algorithms.

Abstract

Hypnosis is a therapeutic technique that primarily involves attentive receptive concentration. Even though a small number of health professionals are trained in hypnosis and lingering myths and misconceptions associated with this method have hampered its widespread use to treat medical conditions, hypnotherapy has gained relevance as an effective treatment for irritable bowel syndrome not responsive to standard care. More recently, a few studies have addressed the potential influence of hypnosis on upper digestive function and disease. This paper reviews the efficacy of hypnosis in the modulation of upper digestive motor and secretory function. The present evidence of the effectiveness of hypnotherapy as a treatment for functional and organic diseases of the upper bowel is also summarized, coupled with a discussion of potential mechanisms of its therapeutic action.

INTRODUCTION

Hypnosis can be defined as an altered state of consciousness, different from both sleep and normal wakefulness, characterized by highly focused attention and heightened compliance with suggestion[1]. As a rule, the onset of this state is facilitated by eye closure. A number of other phenomena are often described as associated with hypnosis, including altered perception of passage of time, partial or complete amnesia for the events experienced, and attenuation of stress experiences[1-3]. In addition, subjects may show enhanced compliance to suggestion given during hypnosis meant to influence favorably their behavior after the trance state has been terminated (post-hypnotic suggestion)[1]. Furthermore, a more contentious property of hypnosis is either increased access to memories, feelings, and perceptions which are normally kept below the level of conscious awareness, or *vice versa* enhanced suppression of these from the conscious mind[4-6].

Clinical hypnosis is the method of deliberately inducing the state of hypnosis in a patient through verbal guidance, and making use of its characteristic properties for targeted therapeutic purposes. The possibilities of hypnosis as a healing method stem principally from the heightened responsiveness to suggestion in this altered mental state. Hypnotic and post-hypnotic suggestions can be used to facilitate desired therapeutic changes in feelings, behavior and physiology, and this can be useful not only for mental health purposes, but also in medicine[1]. Although a single hypnosis session targeting a simple symptom or bodily function can sometimes yield useful results, treatment of complex psychological and somatic conditions with hypnosis typically requires a structured form of therapeutic intervention, hypnotherapy, administered in a series of several therapy sessions[1].

Hypnosis has a long history of application as a clinical tool in medicine, dating back to the early 18th

Century, when it was used with considerable success for the purpose of inducing anesthesia during surgery in thousands of cases, predominantly by British physicians. Only the availability of chemical anesthesia with ether and chloroform in 1846 and 1847 made this application obsolete[7].

In the latter half of the 19th century, hypnosis became prominently utilized in the treatment of psychiatric conditions like hysteria by some of Europe's foremost authorities in neurology and psychiatry of that time, such as Sigmund Freud in Austria and Jean-Martin Charcot in France[8]. Ever since then, hypnosis has been more widely recognized as a treatment aid for mental health problems than for physical ailments. However, medical uses of hypnosis continued, and sufficient experience with various advantageous medical applications gradually accumulated for the technique of clinical hypnosis to earn formal acceptance in mainstream medicine[7,8]. Hypnosis gained official approval as a medical treatment, first by the British Medical Association in 1955 and then by the American Medical Association in 1958, in a report that stated that hypnosis had "definite and proper applications in medicine and dentistry", and recommended that physicians should receive training in the technique[7,8]. However, even today, most medical school curricula in the U.S. and elsewhere provide no training or education in hypnosis. Although clinical hypnosis is currently practiced by thousands of health professionals in many Western countries, it is practiced by a variety of professional disciplines, including psychologists, counselors, clinical social workers, dentists, nurses and nurse practitioners, but relatively few physicians[7,8]. In many places, the great majority of practitioners providing hypnosis are mental health professionals who rarely use it to treat physical conditions. Additionally, hypnosis services are commonly offered also by large numbers of lay hypnotherapists without any qualifications or formal education in treating medical problems[8]. These limitations, as well as myths, misconceptions and apprehensions that still linger in the public's mind from the exploitation and inaccurate portrayal of hypnosis in stage shows, movies and other popular media, has continued to hamper a widespread proper medical use of hypnosis.

Nonetheless, several medical applications of clinical hypnosis have been sufficiently investigated and considered effective in multiple formal studies. A review by a 1995 National Institutes of Health panel in the U.S. concluded that there is "strong evidence for the use of hypnosis in alleviating pain associated with cancer"[9]. Published systematic reviews of randomized clinical trials have also deemed hypnosis to be effective for treating nausea and vomiting associated with cancer chemotherapy[10] as well as the most promising psychological treatment for controlling procedure-related pain and distress in children and adolescents[11]. Furthermore, three separate systematic reviews published in the past three years[12-14] have concluded that hypnotherapy is an effective treatment for irritable bowel syndrome.

Research on the use of hypnosis for gastrointestinal disorders began with a randomized placebo-controlled study of hypnotherapy for treatment-refractory irritable bowel syndrome (IBS) in England, published in the Lancet in 1984[15]. In this study, by Peter Whorwell and colleagues in Manchester, England, the investigators randomly allocated 30 patients with IBS which was refractory to standard medical care, to either seven sessions of hypnotherapy or to the same amount of supportive psychotherapy plus placebo pills. The hypnosis approach used was a structured intervention developed by this Manchester team called gut-focused hypnotherapy. This technique aims primarily to normalize disordered bowel function, but additionally provides relaxation, coping skills, and ego-strengthening suggestion[16]. After the treatment, the patients in the hypnosis group showed substantial improvement in all cardinal IBS symptoms, and were significantly more improved on all outcome variables than the supportive psychotherapy group[15]. In a later paper, the investigators reported that the benefits of hypnotherapy in the same group of patients persisted up to 18 mo[17].

This study, albeit small, was a landmark trial, demonstrating for the first time the substantial possibilities that hypnosis offers for ameliorating gastrointestinal symptoms. Since then, positive results on the efficacy of hypnotherapy as a treatment for IBS have been reported by independent investigators both in uncontrolled and controlled trials (Table 1)[18-22]. The Manchester group has created a Hypnotherapy Unit, where this mode of therapy is routinely offered to functional GI patients who do not gain satisfactory benefit from more conventional medical treatment[16]. This group recently reported the long-term outcomes of the first 250 IBS patients treated in their clinic[22,23]. The results show an impressive 71% overall response rate to treatment, more than 50% average reduction in bowel symptom severity, and with four out of five treatment responders maintaining the full therapeutic benefit for one to five years after treatment termination[22,23].

The Manchester group has also expanded their experience from IBS therapy to other functional bowel disorders[16]. They demonstrated that functional esophageal disorders and functional gastroduodenal disorders are also suitable targets for hypnotherapy, with equally satisfactory results (Table 1)[24,25]. A small, but significant group of papers now provides evidence that hypnosis and hypnotherapy may effectively influence upper digestive function and disease. The aim of this review is to focus on this literature and to highlight the potential of hypnotherapy as a treatment option for upper digestive functional disorders.

HYPNOSIS AND UPPER DIGESTIVE FUNCTION

Gastric acid production is the bowel function where the influence of hypnosis was first investigated[26,27]. In the past, gastric acid secretion was an important research domain for gastroenterologists and its responsiveness to

Table 1 Randomized controlled trials of hypnosis treatment for severe functional bowel disorders

Authors & yr	No. of patients	Control treatment	Positive outcome	Follow-up (mo)
A: Irritable bowel syndrome				
Whorwell *et al* (1984)	30	Psychotherapy plus Placebo Pill	Hypnosis 100% $P < 0.0001$	12
Galovski & Blanchard (1998)	11	Waiting List	Hypnosis 82% $P = 0.016$	2

Note: Randomized controlled studies run in primary care are not reported for different patient population.

emotions and psychological stress were documented[28,29]. This interest was driven by the belief that peptic ulcer disease was a psychosomatic disease, and excess gastric acid secretion the pathophysiological mechanism linking emotion to the disease[30,31]. As a consequence, acid secretion was an attractive parameter to attempt to influence by hypnosis. A few studies were published in the nineteen sixties and early seventies examining the gastric secretory responses to hypnotic conditions, where either food-related (hunger-eating) or emotion-related (sleep-relaxation) suggestions were provided[27-29]. These early studies were flawed by small samples and questionable research methodology, and produced contradictory results. In 1989, however, Klein and Spiegel published a well-designed trial investigating the ability of hypnosis to modulate gastric acid secretion in highly hypnotizable healthy volunteers, as defined by accepted scales of trance depth[32]. The study was conducted in two centers, by two experienced hypnotherapists using two different hypnosis induction techniques. After naso-gastric intubation, gastric secretion was measured both basally and after pentagastrin stimulation in two separate studies. In the first study (acid stimulation test), acid secretion was collected in 28 subjects (13 females, age range 18-60 years) after hypnotic instructions to visualize and eat the most delicious meal possible. All the sensory aspects of the eating process, including food appearance, aroma, texture and taste, were explored and reinforced by hypnotic suggestions from the therapist. The second study consisted of two separate sessions that were held in random order. In the no-hypnosis session, the peak acid output (PAO) was obtained after maximal pentagastrin stimulation in 17 subjects (7 females, age range 18-60 years), but hypnosis was not provided. The procedure for the hypnosis sessions was the same, but deep muscle relaxation and intense imagery to divert one's attention from eating were provided. Imagery involved either lying on a beach, watching a sunset, or meeting a friend somewhere else. In both studies, none of the subjects reported difficulty in following the hypnotic suggestion or adverse side effects. Hypnotic suggestion of eating significantly increased gastric acid output compared to basal conditions[32]. In addition, the pentagastrin-stimulated PAO was significantly lowered in the averting-food hypnosis condition compared to the no-hypnosis session[32]. The authors concluded that gastric acid secretion may be modulated by hypnosis in highly hypnotizable subjects. Treatment mechanisms of action were left unexplored. But, the authors postulated that hypnosis influenced cognitive processing within the central nervous system[32]. Since the relevance of gastric secretion in peptic ulcer disease has diminished, no other centers have tried to replicate these positive results.

Two additional studies have evaluated the influence of hypnosis on upper digestive transit. In 1991 Beugerie *et al* studied the ability of hypnosis to modulate the orocaecal transit time of 10 g lactulose in six healthy volunteers[33]. Orocaecal transit time was measured by the hydrogen breath test. Oral ingestion of a poorly absorbable carbohydrate (lactulose) results in a sustained rise in breath hydrogen, which occurs within minutes of the substrate entering the cecum[34]. The orocaecal transit time is the interval elapsing from the ingestion of the substrate to the evidence of a persistent increment in breath hydrogen concentration[34]. It is commonly considered a non-invasive, reliable index of small bowel transit, particularly when lactulose is included in a caloric meal to securely interrupt the fasting motility pattern of the small bowel[35]. The subjects in this trial were recruited irrespectively to their hypnotizability, but two of them had previously been hypnotized. Orocaecal transit was evaluated on three occasions in random order: (A) control session without hypnosis; (B) hypnotic session with suggestion of deep relaxation; (C) hypnotic session with visualization of a cascading waterfall to promote transit acceleration[33]. All hypnosis sessions were started just before orocaecal transit and maintained till the transit time elapsed. The mean orocaecal transit time was significantly longer during the hypnotic relaxation session compared to the control session[33]. On the contrary, the hypnotic acceleration session did not result in significant modification of small bowel transit time[33]. The small sample size and the limited breath technique used (lactulose not administered together with a caloric test meal) did flaw the results of this study. However, it was the first study showing an influence of hypnosis on upper digestive function in individuals not selected for high hypnotizability.

The potential influence of hypnosis on gastric emptying rates has been evaluated only recently, by Chiarioni and coworkers in Italy[36]. In this study, the gastric emptying rate of a typical Mediterranean meal

(pasta with meat sauce, cheese, bread) was tested by a non-invasive ultrasonography technique. Real-time ultrasonography was used to measure the diameters of the gastric antrum in the sagittal plane passing through the aorta. Serial measurements were taken before the meal, immediately after eating and at 30 min intervals thereafter to obtain total emptying time of the meal. The total emptying time of the meal has been validated as reliable index of gastric motor function both in health and in disease when compared with total emptying time measured by gastric scintigraphy[37]. Gastric emptying rates and epigastric sensations were evaluated in 11 healthy volunteers from the hospital staff and in 15 patients with severe functional dyspepsia unresponsive to standard care under three conditions according to a fixed schedule to avoid a carry-over effect: (A) basal session, (B) prokinetic drug session (cisapride 10 mg po 30 min before meal), and (C) hypnosis session (90 min hypnosis session 30 min after finishing meal). An additional session was run in eight healthy volunteers while listening to relaxing music, to address the potential influence of both repeated testing and posture. Cisapride is a prokinetic agent that has been shown to significantly improve both gastric emptying and symptoms in functional dyspepsia compared to placebo, before being withdrawn from the market for its cardiovascular side-effects[38,39]. The method of progressive relaxation by verbal suggestion was used for hypnosis induction. Techniques to deepen the hypnosis included induction of limb heaviness and warmth. The hypnotically warmed hand was then placed over the epigastrium to associate suggestion of improved well being and gastric function mediated by the warmth of the hand. Imagery was provided of water flowing in a river and in a waterfall. This was related to suggestions for improved well-being and gastric function, derived from the gut-oriented suggestions developed by the Manchester group to treat irritable bowel syndrome[16]. The hypnosis session was completed by the classic Hartland's ego-strengthening technique, providing direct and broad hypnotic suggestions to increase the patient's confidence[40]. In patients with functional dyspepsia, gastric emptying was significantly shortened by cisapride and even more by hypnosis compared to the basal session[36]. In healthy volunteers, gastric emptying was significantly accelerated by hypnosis, but not by cisapride, compared to the basal session[36]. The relaxing music session did not influence gastric emptying rates. Epigastric sensations (i.e. fullness and discomfort) were significantly improved by hypnosis in the dyspeptic patients, but not by cisapride[36]. Interestingly, symptomatic improvement did not correlate with improved gastric motor function, leaving the mechanism/s of action of hypnosis unexplained[36]. Limitations of the study were lack of randomization and the highly selected study population.

HYPNOTHERAPY TO TREAT UPPER DIGESTIVE DISEASES

Hypnotherapy delivered as a structured, multi-session focused intervention has been most extensively used to treat IBS according to the protocols of the Manchester group or the North Carolina group[13,16]. However, the Manchester group has also provided experimental evidence to support the use of hypnotherapy in some upper digestive diseases. The first of these was a controlled study to prevent relapse of peptic ulcer[41]. The investigation was published in 1988 when peptic ulcer was considered to be a psychosomatic disorder caused by increased gastric secretion[30,31]. Thirty patients with frequently relapsing duodenal ulcer were randomized to receive either seven sessions of gut-focused hypnotherapy plus ranitidine 150 mg twice daily or seven routine consultations at a GI clinic without hypnosis plus the same ranitidine dosage over a 10-wk interval[41]. Hypnosis was induced with an arm-levitation technique followed by a combination of standard deepening procedures. The subject was then asked to place her/his hand over the abdomen, feel a sense of warm beneath the hand, and relate this to the control of gastric secretions. Reinforcement by visualization was used depending on the patient's ability. Patients were also given an audio tape for daily autohypnosis. At one year follow-up, all the subjects in the no-hypnosis group had relapsed while only 53% in the hypnotherapy group showed endoscopic evidence of relapsing duodenal ulcer[41]. The authors concluded that hypnotherapy is helpful in maintaining remission in those patients with peptic ulcer who are prone to relapse[41]. Shortly after the study, consensus developed that Helicobacter pylori infection of the stomach is the primary cause of peptic ulcer disease, and hypnotherapy was, therefore, not pursued further as potential treatment for peptic disease[42]. Nonetheless, this remains the first study to investigate the efficacy of hypnotherapy to treat upper digestive diseases.

Recently, the Manchester group assessed the efficacy of hypnotherapy for upper digestive functional diseases in two controlled trials; one on functional dyspepsia (FD) and the other for non-cardiac chest pain (NCCP)[24,25]. Functional dyspepsia refers to symptoms thought to originate in the gastroduodenal region in the absence of any organic or metabolic disease that is likely to explain the symptoms[43]. Postprandial fullness, early satiety, epigastric pain and/or burning may be reported as symptoms in FD[43]. Delayed gastric emptying, abnormal gastric tone, altered visceral perception, and autonomic imbalance have all been considered as potential etiologic factors[43,44]. In addition, comorbidity with psychiatric disorders, especially anxiety disorders, is reported to be high in FD[45]. Up to 30% of people in the community report having dyspeptic symptoms each year[43,45]. Symptomatic drug treatment, especially proton pump inhibitor medications, are often used for FD symptoms. But, the results are unsatisfactory[43,44,46]. To investigate the efficacy of hypnotherapy in FD, Calvert and coworkers randomly assigned 126 FD patients to receive either 12 hypnotherapy sessions, supportive therapy plus placebo tablets, or medical treatment with ranitidine 150 mg twice daily[24]. Patients underwent a 16-wk

treatment phase followed by a 40-wk follow-up phase where no further study interventions were undertaken. Hypnosis was induced using eye fixation followed by progressive muscular relaxation and deepened by standard procedures. The patients were then asked to place their hands on their abdomens and imagine a reduction of all symptoms. Suggestions of improvement in gastric motor function, sensitivity and gut secretion activity were also given. Reinforcement by appropriate visualization processes were administered as well. At the short term follow-up (16 wk), hypnotherapy significantly ameliorated symptoms compared to both the supportive therapy and the medical treatment groups[25]. Analogous improvements were observed when quality of life scores (QOL) were considered. Anxiety scores were lower after hypnotherapy; but there was no correlation between improvement in anxiety and FD symptom improvement[24]. No differences were evident between groups in terms of depression scores. Improvement in FD symptoms and QOL were well-maintained at long term follow-up (56 wk)[24]. In addition, patients in the hypnotherapy group were significantly less likely to consult the referring physician and to establish additional drug treatments than were the subjects in the other two groups[24]. The authors concluded that hypnotherapy is an effective treatment for functional dyspepsia both in the short and long term, but the mechanism/s of action remained speculative[24]. Hypnotherapy seems also to be cost-effective for the observed reduction in medication use and consultation rate at long term follow-up. This study was methodologically sound by most standards: (A) study design and sample size were both adequate, and (B) the double placebo control condition plus the standard care arm were likely to have produced a high expectation of therapeutic effect. Replication of these positive results by independent investigators is eagerly awaited.

Recently, the Manchester group has extended the application of hypnotherapy to non-cardiac chest pain, a condition later redefined as functional chest pain of presumed esophageal origin by the Rome Ⅲ Committee[25,47]. This functional disorder refers to relapsing episodes of unexplained chest pain that is usually located in the midline of the chest and of visceral quality[47]. The pain involved may be similar in nature to the one reported by angina patients, and by those affected by other esophageal disorders including achalasia and gastro-esophageal reflux disease (GERD)[47]. To diagnose functional chest pain, heart disease needs to be excluded as well as structural esophageal diseases, GERD, and esophageal motility disorders with defined histopathologic bases (i.e. achalasia, scleroderma of the esophagus)[47]. Epidemiology of functional chest pain is ill defined; but one should consider that 15%-30% of coronary angiograms performed for chest pain are negative for ischemic heart disease[47,48]. Disordered esophageal motility, altered visceral perception, and abnormal central signal processing with secondary errors in autonomic response have all been reported, alone or in combination, as potential causative factors[47]. In addition, overrepresentation of psychiatric disorders, particularly depression, anxiety and somatization disorders, have been described in functional chest pain of presumed esophageal origin[49]. Quality of life is impaired in continued pain and spontaneous recovery is rare[47]. In these patients, a therapeutic trial with proton pump inhibitors is mandatory to exclude symptomatic reflux disease[50]. Antidepressants may be of help, but their continuous use is associated with a high rate of side effects[47,51].

To address the effect of hypnotherapy in NCPP, the Manchester group randomized 28 patients with functional chest pain to receive either 12 sessions of individualized hypnotherapy or 12 sessions of supportive listening plus placebo tablets to control for expectancy and equalize the amount of time spent with a clinician[25]. All the patients were referred by the local cardiothoracic center after negative coronary angiography for angina-like chest pain. Reflux disease as a potential causative factor of chest pain was excluded in all subjects either by normal 24 h pH monitoring or by non-responsiveness to a proton pump inhibitor trial. Hypnosis was induced by eye closure, followed by progressive muscle relaxation and deepened by standard techniques. Suggestions focused on improved esophageal functioning and sensitivity were then introduced by using both imagery and conditioning techniques. In addition, direct suggestions of reduced pain and improved general health were given on a repetitive basis at each session. After treatment, 80% of patients in the hypnotherapy group described their chest pain as completely better or moderately better, compared to only 23% of patients in the control group[25]. This benefit persisted long-term (2 years), as reported by the authors in a follow-up paper[52]. Hypnotherapy also resulted in a significantly greater reduction in pain intensity scores, greater improvements in quality of life, and a greater reduction in medication usage when compared to the control treatment[25]. There were no significant differences between treatment groups in terms of improvement of either anxiety or depression scores as assessed by the Hospital anxiety and depression scale[25].

Limitations of this trial include the small sample size and the high patient selection. As in previous studies, the mechanism of action of hypnosis was left unexplored in this study. However, it remains the only randomized trial to show that hypnotherapy is effective treatment for functional chest pain, a disabling disorder that responds poorly to conventional care. Therefore, additional larger studies evaluating the effect of hypnotherapy on functional chest pain of presumed esophageal origin should be pursued.

MECHANISM OF ACTION OF HYPNOSIS AND HYPNOTHERAPY

The mechanism of action of hypnosis is ill defined; but we may speculate that many factors possibly contribute to its influence on physiological function and symptoms in the upper digestive tract. Abnormal motor activity and

altered autonomic function have both been reported in functional gastroduodenal and esophageal diseases[43,47]. In functional dyspepsia, delayed gastric emptying seems particularly common in patients complaining of nausea, fullness and vomiting; but this is controversial[43,53]. Other disturbances of gastroduodenal motility have been described in functional dyspepsia (e.g. antral hypomotility, gastric dysrhythmia, reduced frequency of interdigestive migrating motor complexes); but their relationship to the symptoms is less documented[43]. On the contrary, evidence of increased gastric visceral perception (so-called hypersensitivity) in a subset of functional dyspepsia patients is well documented in the literature[43,54]. This altered perception may be mediated by the autonomic imbalance both on a cortical and a peripheral level often described in functional bowel disorders[55]. Hypnosis induces a state of profound relaxation consistent with a generalized decrement in sympathetic nervous system activity[1,3]. This relaxation response is not specific to hypnosis, but may be induced by different techniques such as autogenic training, yoga, and meditation[3]. The physiological changes of the relaxation response include simultaneous lowering of blood pressure, heart and respiratory rates, which are opposite to those induced by stressful events[3]. These changes are actually distinct from those observed during sleep and characterize a wakeful hypometabolic state[56]. In addition, the relaxation response seems to last longer than the actual hypnosis interval[3]. A distinct feature of the relaxation response is that its action seems to be mediated through a reduction in epinephrine end-organ responsivity[3]. Stress has been shown to increase gastric acid secretion, and it used to be considered a risk factor to developing peptic ulcer disease[30,57]. We may speculate a potential influence of hypnosis on gastric secretion through modulation of the sympathetic tone. In addition, experimental stress delays gastric emptying and increases plasma levels of noradrenaline plus accelerating small bowel transit[58-60]. Therefore, the capability of a single session of hypnosis either to accelerate gastric emptying or to slow small bowel transit may be secondary to the relaxation response. However, a recent study investigating hypnosis mechanisms of action showed that hypnotherapy did not change cardiovascular responses in IBS[23]. The only parameter of sympathetic tone that was significantly decreased by hypnotherapy was skin conductance, a measure reflecting sweat gland responses to stress[23].

The effect of hypnosis in gastric visceral sensitivity has not been investigated. However, in IBS the influence of hypnotherapy on rectal perception has been evaluated with controversial results. The Manchester group provided experimental evidence that hypnosis improved rectal sensitivity; but this was not confirmed by a recent study by the North Carolina group[23,61]. In addition, one should consider that significant symptom improvement has been reported in functional bowel diseases without correlating with gut sensorimotor functioning modifications[23,36,12]. Therefore, the symptomatic improvement observed after hypnosis should also be related to some modulation of perception at a cortical level. Brain imaging studies have shown a variety of alterations in cortical activation pattern to visceral sensitive stimulation (rectal distension, esophageal distension and acid perfusion) in patients with functional bowel disorders compared with controls[62]. However, a consistent finding has been the reported excessive activation of the anterior cingulated cortex where the affective response to pain is elaborated[62]. It has also been shown that non-painful esophageal distension activated the somatosensory and anterior cingulated cortex while visual stimulation activated a different central area (visual cortex), thus postulating a more specific response to visceral stimulation[63]. Studies on somatic pain have shown that hypnosis is capable of decreasing reported pain sensation in response to pain-inducing stimuli, while the neurophysiological reactions of spontaneous and evoked EEG were unaffected (i.e. cerebral potentials were modified as the subject was actually feeling pain)[64]. Further supporting evidence has been given by studies on somatic pain analgesia where hypnosis reduced activity of the anterior cingulate cortex, but not that of the somatosensory cortex[65]. This dissociation of sensory and affective components of pain under hypnosis would also be consistent with the new "dissociation theory" to explain the effectiveness of hypnotherapy in psychopathology[1,8,66]. There is growing evidence that patients with IBS, functional chest pain and probably functional dyspepsia show increased levels of vigilance toward gut pain related sensations, easily interpreting them as symptoms of disease as a consequence[62,67,68]. Modulating the affective component of pain ratings may be one of the therapeutic mechanisms of hypnotherapy in functional bowel disease.

An additional reason for the effectiveness of hypnotherapy in functional bowel diseases could be related to the focus of many protocols on reducing the catastrophising cognitions commonly present in these patients[67,68]. Gonsalkorale and coworkers reported that hypnotherapy improved symptom-related cognitions in IBS by using a dedicated cognitive scale[69]. In this study, improved cognitive scores correlated with symptomatic improvement[69]. Finally, the role of the placebo effect of hypnotherapy needs to be considered in producing the beneficial hypnotherapy outcomes observed. In many hypnotherapy trials patients affected by severe, unremitting symptoms of functional bowel disorder have been included[13,24,25,36]. The motivation to undergo a new treatment and therapy expectancy in these patients are predicted to be high[70]. In addition, the most powerful placebo effect is to be expected in patients suffering from chronic pain syndromes[70]. In this context, the placebo effect is stronger when complex interventions such as hypnotherapy are provided[70]. Unfortunately, to undertake a double blind controlled trial of treatments such as hypnotherapy is almost impossible because the recipient will know what treatment is provided and establishing a sham hypnosis therapy is not doable[16]. Therefore, appropriate control treatments (e.g. supportive

listening and placebo pills) are desirable options when designing a meaningful trial of hypnotherapy[13,16]. However, the results of such placebo-controlled studies conducted so far on hypnosis for IBS[15,24] and FD, using a powerful double placebo of inert pills combined with supportive listening, suggest that the placebo effect only plays a small role in the therapeutic impact of hypnotherapy on these conditions.

LIMITATIONS OF HYPNOTHERAPY IN UPPER DIGESTIVE DISEASES

Only two studies, coming from the same center, have tested the efficacy of hypnotherapy in the treatment of upper digestive functional diseases[24,25]. These studies provide encouraging evidence that hypnotherapy is effective treatment for functional dyspepsia and functional chest pain of presumed esophageal origin[19,20]. However, these results need to be replicated in less selected populations, and by independent investigators before a more widespread use of hypnotherapy to treat upper digestive dysfunction can be recommended. In addition, hypnotherapy is a time consuming, labor intensive and costly treatment, and the number of health care providers trained in hypnosis is limited. Non-medical qualified hypnotherapists and hypnosis audiotapes may reduce costs, but the effectiveness of these alternative delivery methods on outcomes have not been thoroughly investigated[13,16]. Specific knowledge in gut-directed hypnosis is required to obtain successful outcomes in treating gastrointestinal disorders, and such training has not been widely available[13,16]. In an effort to overcome this problem, some centers are providing gut-focused hypnosis scripts to treat IBS[13]. Finally, skepticism by some patients and physicians about the use of a psychological intervention for a gut disease may deter them from trying this treatment option. This may be particularly true for hypnosis because of the aura of magic and mystery associated with it.

CONCLUSION

Hypnosis is an altered state of consciousness characterized by highly focused attention and heightened compliance with suggestion[1]. Clinical hypnosis can be used to treat a range of complex psychological or somatic diseases, but this generally requires a structured form of hypnotherapy intervention consisting of several sessions[1,8]. Hypnosis has a long history of applications in medicine, and is now formally recognized as a valuable aid for various medical problems. However, a limited number of health professionals offer hypnotherapy for medical problems, and it has traditionally been hampered by misconceptions shrouding this psychological intervention[8,16]. Yet, sufficient evidence has amassed over the years to firmly support the effectiveness of hypnotherapy for various pain problems, as well as to treat IBS, a complex and prevalent functional disorder of the lower bowel[12,13,16]. Recently, a few studies have addressed the potential influence of both single-session hypnosis and a course of hypnotherapy on upper digestive function and diseases with encouraging results.

Hypnosis delivered on a single session by an expert therapist has been shown capable of modulating gastric secretion and accelerating gastric emptying in healthy volunteers[32,36]. In addition, hypnosis has improved gastric emptying and epigastric sensations in severe functional dyspepsia[36]. Small bowel transit may also be influenced by hypnosis[33].

In the past, hypnotherapy has been used with a successful outcome to decrease the relapsing rate of peptic ulcer disease[41]. More recently, two randomized controlled trials have shown hypnotherapy to be a highly effective treatment for functional dyspepsia and functional chest pain of presumed esophageal origin unresponsive to standard care[24,25]. In both of these upper gastrointestinal diseases, clinical benefits were well maintained at long-term follow-ups[24,52]. However, both of these studies were carried out by the same research team -- the Manchester group in England[16]. Additional well designed studies from independent investigators are eagerly awaited to substantiate the efficacy of hypnotherapy in this domain.

Abstract

Alterations of normal function of interstitial cells of Cajal (ICC) are reported in many intestinal disorders. Diagnosis of their involvement is rare (infrequent), but necessary to propose a specific treatment. This article reviews the place of ICC in the pathogenesis of achalasia, gastroesophageal reflux disease, infantile hypertrophic pyloric stenosis, chronic intestinal pseudo-obstruction and slow transit constipation. Moreover we discuss the role of the Cajal cells in the development of stromal tumors of the gastrointestinal tract.

INTRODUCTION

Digestive motility is highly coordinated and consists of local, non-propulsive mixing (segmental) and propulsive (peristaltic) movements. Mixing movements are produced by intrinsic pacemakers generating rhythmic contractions and peristalsis by intrinsic excitatory and inhibitory neural reflex pathways[1,2].

Even in the absence of stimulation, most regions of the gastrointestinal tract can generate some spontaneous electrical and mechanical activity. Recordings made from isolated muscle cells in the gastrointestinal tract show a regular discharge recorded as plateau and slow potentials. These pacemaker potentials are generated by a specialized population of cells, known as interstitial cells of Cajal (ICC)[3].

Together with the enteric nervous system, composed of both the myenteric (inter-muscular) plexus and the submucosal plexus, the ICC plays a major role in gastrointestinal motility[4]. The ICC was firstly described by Cajal SR in 1911[5]. He characterized "interstitial neurons" as "primitive accessory components that could modify smooth muscle contraction, subject themselves to regulation from principal neurons". Cajal provided detailed pictures of methylene blue-stained networks of interstitial cells, which were described as spindle shaped or stellate cells with long, ramified cell processes and large, oval, nuclei with sparse perinuclear cytoplasm, and intercalated between autonomic nerve endings and smooth muscle cells[5].

ICC constitutes networks that are widely distributed within the submucosal, intra-muscular and inter-muscular layers of the gastrointestinal tract from the lower esophagus to the internal anal sphincter.

These cells are defined by the expression of the CD117 (c-kit) protein which is a membrane receptor with tyrosine kinase activity[3,4,6].

In the past decade, knowledge of the role of ICC in the digestive physiology and pathology has progressed. In this review, we highlight some of these advances which could have clinical impact either in pathogenesis or treatment.

ESOPHAGUS

Achalasia

Achalasia is characterized by relaxation failure of lower

esophageal sphincter (LES) and lack of peristaltic contraction of esophageal body[7]. The etiology of this disorder is unknown and may be "idiopathic" or secondary to malignancy (local invasion or a paraneoplastic manifestation).

In primary or idiopathic achalasia, the failure of deglutitive inhibition is responsible for aperistalsis. This dysfunction is due to a loss of inhibitory nerves and progressive degeneration of ganglion cells containing vasoactive intestinal peptide (VIP) and nitric oxide (NO). Hypertensive LES is thought to result from a combination of the lack of tonic inhibitory nitrergic influence and an unopposed cholinergic activity.

The mechanism of inflammatory process responsible of these alterations is unclear. It is suggested to be an autoimmune disorder induced by a viral or food antigen in a patient genetically predisposed to the disease[8,9]. ICC involvement in achalasia is debated[10,11].

Electronic microscope studies of muscle coat of LES in seven patients with achalasia showed that muscle wall components (nerve endings, smooth muscle cells, ICC and connective tissue) were modified. ICC ultrastructure was altered, namely clear cytoplasm, fewer mitochondria, and scarce smooth endoplasmic reticulum. A reduced number of contacts between nerves and ICC were reported. Specific changes in smooth muscle cells were also documented, whereas the nerve endings had a normal ultrastructure. Alterations in older patients were more pronounced[12]. Since the LES components specifically altered in achalasia are the nerve endings and ICC, they are regarded as principally responsible for abnormal motility[12].

Achalasia is uncommon among pediatric population and some authors consider it as a different entity. Rare familial forms, combining early onset achalasia, alacrymia, ACTH insensitivity and dysautonomia, are known as Allgrove's syndrome or "four A" syndrome. Allgrove's syndrome is inherited in an autosomal recessive mode and may express in adulthood. Massive loss of neural elements and neuronal NO synthase as well as a marked fibrotic process of the muscle layers of the cardia have been observed in this syndrome[13]. ICC in cardia was also markedly decreased or absent while ICC (and neural structures) were preserved in pylorus[13].

Gastro-esophageal reflux disease (GERD)

GERD is a highly prevalent condition. Typical symptoms of heartburn and acid regurgitation are encountered in 15%-20% of the general population[14].

GERD represents the most common cause of esophagitis that may be complicated with esophageal ulcers, peptic stenosis and Barrett's esophagus, which carries a high risk of esophageal adenocarcinoma[14].

The role of the ICC in inhibitory transmission in the LES is still discussed.

In W/W_v mutant mice (lack of ICC) LOS pressure was lower than wild-type mice but a normal swallow still induced LOS relaxation, arguing against the role of ICC in inhibitory transmission[15]. Another study demonstrated that in W/W_v animals, cholinergic and nitrergic neurotransmission is greatly reduced pleading for the role of ICC in mediating neural inputs[16]. However enteric neurons, varicose processes, and the ability to release neurotransmitters are not reduced, and smooth muscle cells demonstrate responsiveness to exogenous transmitters[16].

Loss of ICC during development or in pathologic conditions would significantly compromise the ability of GI muscles to generate typical motor reflexes[17].

Esophagitis itself may be at the origin of an alteration of normal function of the Cajal cells: in advanced stages of GERD, inflammatory changes in the esophageal wall will also involve the ICC. That way, the more severe the esophagitis, the more severe is the ICC impairment. This destruction leads to loss of effective contraction of esophagus, maintaining reflux and thus aggravating the symptoms[18].

STOMACH

Gastroparesis

Delayed gastric emptying can be secondary to muscular, neural, humoral causes or use of anticholinergic and opiates medicines. In the absence of an identified cause, gastroparesis is termed as idiopathic[19]. Clinical features of gastroparesis are frequently indistinguishable from true mechanical obstruction and severity of symptoms is variable. Most patients present with early satiety, nausea, and abdominal pain. In some cases, symptoms can be highly incapacitating: chronic abdominal pain and vomiting leading to dehydration, electrolyte imbalance, nutritional impairment and weight loss[20,21].

ICC is involved in regulation of gastric emptying by generating slow waves.

A decrease in ICC density ranged from 60% to 100% depending on the area investigated was demonstrated in histologic studies of stomach of type 1 diabetic patients[6]. The number of immunopositive cells for c-kit was significantly decreased in the corpus and antrum of the gastroparesis patients compared with control tissues[21]. The loss of intra muscular ICC and associated nerves in the gastric fundus could explain the low basal gastric tone and increased compliance of the stomach. The hypomotility of the antrum can also be explained by the absence of slow wave generation by the ICC[21,22].

Infantile hypertrophic pyloric stenosis

This is a congenital disorder characterized by functional gastric-outlet obstruction. Dysfunction of pyloric inhibition has been implicated in the pathophysiology of hypertrophic pyloric stenosis. Normal inhibition process is mediated by peptidergic and NO enteric nerves and also may involve ICC. Although myenteric neurons appear normal, those innervating the circular-muscle layer of the pyloric sphincter lack NO synthetase[21]. In children with hypertrophic pyloric stenosis, there was a significant decrease in the number of ICC[22,23]. The following observations were made using electron microscopy in gastric specimens from patients with pyloric stenosis versus normal controls[24]. Muscle cells were primarily in a

proliferative phase and exhibited very few gap junctions between smooth muscle cells or ICC: (1) Near absence of nerve fibers containing large granular vesicles in the circular muscle layer; (2) Fewer nerve cell bodies in the myenteric plexus and lower total number of ganglia; (3) Decreased number of ICC. These findings may plead for a role of ICC in the pathogenesis.

SMALL INTESTINE AND COLON

Idiopathic chronic intestinal pseudo-obstruction (CIIP)

CIIP is characterized by defective gastrointestinal propulsion together with symptoms and signs of bowel obstruction in the absence of any lesions or mechanical obstacle[25]. CIIP is regarded as a neuropathy, myopathy or both[26,27].

A possible role played by the ICC is demonstrated by the alterations in ICC network reported in patients with CIIP. Electron microscopy and immunochemistry studies showed a decreased number of ICCs along with structural abnormalities such as loss of processes and damaged intracellular cytoskeleton and organelles[28].

Slow transit constipation (STC)

This is a very prevalent motility problem, but its mechanisms are unclear. Studies found that ICC density in the colon of patients with constipation was significantly decreased compared with those of normal patients[29]. Expression of *c-kit* mRNA and c-kit protein was significantly decreased in the colon of STC, suggesting that the c-kit signal pathway may play an important role in ICC reduction in STC[30-32].

Since slow-transit constipation is secondary to problems with the ENS, ICC, or smooth muscle cells, replacement of the missing or defective cells would be an attractive way of treatment[31]. Growing precursors of the defective cells from stem cells should be easy, but the distribution of the cells to their proper locations is still problematic[31,32]. For the moment this is a promise of genetic treatment.

TUMORS OF GASTROINTESTINAL TRACT

Gastrointestinal stromal tumors (GISTs)

GISTs have been recognized as a biologically distinctive tumor type, different from smooth muscle and neural tumors of the gastrointestinal tract. They constitute the majority of gastrointestinal mesenchymal tumors[33].

GISTs originate from the ICC. Their origin from the ICC has been proven by their immunophenotypic (CD117 positive) and ultrastructural resemblance and also by the presence of an embryonic smooth muscle myosin similar to the one present in the ICC[33-36] (Table 1). Approximately 80% of GISTs also express CD34.

Annual incidence of clinically detected new cases of GISTs in the United States has increased to 5000-6000 per year due to better diagnosis, and incidence is rising. Uncommonly, GISTs arise in families, and in these patients germline mutations of c-kit have been identified particularly in exons 11 and 13. A diffuse hyperplasia of the ICC, which is regarded as a pre-neoplastic lesion is noted in these patients[33]. The patients with exon 11 mutations develop cutaneous mastocytosis with or without cutaneous hyperpigmentation, but those with exon 13 mutations do not have these features[33,34]. The tumors under 3 cm in diameter are mostly benign, but all GISTs have a malignant potential[35].

Table 1 Immunohistochemical analysis of GI mesenchymal tumors[35,36]

Tumor	Positive immunohistochemical staining
GIST	CD 117
	CD 34
Malignant GIST	Ki 67
Smooth muscle tumor	Smooth muscle actin
	Desmin
Schwannoma	S100
Glomus tumor	Smooth muscle actin
	Vimentin

The majority of GISTs occurs in the stomach (60%-70%), small intestine (20%-30%) and only 10% or less in the esophagus, colon and rectum, and they affect mainly middle aged patients. Similar tumors, sometimes known as extra-gastrointestinal stromal tumors (E-GIST), may arise in the omentum, mesentery, or retroperitoneum and at least one case of pancreatic tumor was described[37,38]. The presence of ICC in normal pancreas was demonstrated recently[39].

The symptoms may vary from none or slight abdominal discomfort to brisk gastrointestinal hemorrhage, perforation or obstruction.

Imatinib mesylate, a synthetic tyrosine kinase inhibitor developed for the use in the management of interferon resistant chronic myeloid leukemia (CML), was shown to be effective against a number of other tyrosine kinases including c-kit and platelet derived growth factor (PDGF) and now it is considered to be the drug of choice for metastatic and inoperable GIST's[33,34].

CONCLUSION

Knowledge on the role of ICC in gastrointestinal disorders is increasing. However, with the exception of GIST's, no major breakthrough has been made in treatment. Further studies may provide new treatments.

Abstract

Intrahepatic cholangiocarcinoma (ICC) is a rare primary liver cancer with a global increasing trend in recent years. Symptoms tend to be vague and insidious in development, often are diagnosed at an advanced stage when only palliative approaches can be used with a median survival rate of months. Comparing with HCC, ICC tends to spread to lymph nodes early, and is rarely limited to the regional lymph nodes, with a frequent postoperative recurrence. Surgery is the only choice of curative therapy for ICC, but recently no consensus has been established for operation. Thus, more data from multiple centers and more cases are needed. Generally speaking, current adjunctive therapy cannot clearly improve survival. Further research is needed to find more effective radio- and chemotherapeutic regimens.

EPIDEMIOLOGY

Intrahepatic cholangiocarcinoma (ICC) is a rare malignant tumor which arises from the epithelial cells of intrahepatic bile ducts (beyond the second order bile ducts). The incidence of ICC is reported to be only about 10% of primary liver cancers. But, recent studies from several countries have indicated that the incidence of ICC is increasing which cannot be solely explained by reclassification and improved detection[1-10]. The rate of ICC for males is greater than that for females; but ICC is less distinct than hepatocellular carcinoma and usually occurs after the sixth decade of life[1-10]. A recent study reported that in addition to the established risk factors such choledochal cysts, chronic cholangitis, inflammatory bowel disease, primary sclerosing cholangitis (PSC) parasitic infections, drug or toxin exposure, and genetic risks, other conditions such as biliary cirrhosis, cholelithiasis, alcoholic liver disease, nonspecific cirrhosis, are significantly associated with ICC[11]. The incidence of diabetes, thyrotoxicosis, chronic pancreatitis, obesity, chronic nonalcoholic liver disease, HCV/HBV infection, chronic typhoid carrier state and smoking, is increasing, suggesting that these conditions might partly explain the trends of ICC in incidence[12]. However, many tumors arise in the absence of any known predisposition[13-17]. Despite the global increase, regional, racial, ethnic, gender and age variations occur. Moreover, it was reported that the incidence of ICC has decreased in Denmark[18,19]. ICC has the worst prognosis of any tumor arising in the liver; its 5-year survival is poor, and accompanied by a high recurrence rate. The overall 5-year survival rate ranges 13%-42%[20-22]. Chu *et al*[23] showed that the median survival after conservative therapy and hepatic resection is 1.8 mo and 12.2 mo, respectively.

DIAGNOSIS

Recent advances have been made in diagnosis of ICC with MRCP combined MRI, CT, positron-emission tomography scanning (PET) with [F-18] fluorodeoxyglucose (FDG), virtual three-dimensional images and optical coherence tomography (OCT), a high-resolution imaging technique that produces cross-sectional images *in vivo*[24,25], endoscopic retrograde cholangiography (ERCP) with brush cytology and biopsy, endoscopic ultrasound with guided fine-needle aspiration, advanced cytological tests including fluorescent *in situ* hybridization or

digital image analysis (DIA), cholangioscopy (peroral cholangioscopy, percutaneous cholangioscopy, transpapillary cholangioscopy)[26,27]. Sandwich enzyme-linked immunosorbent assay can show a 71% sensitivity and 90% specificity for new tumor markers in serum and bile including genomic and proteomic markers [such as CA199, CEA and mucin5, subtypes A and C (MUC5AC)][28]. On the other hand, most patients present too late to be diagnosed at an advanced stage when only palliative approaches can be used with a median survival of months.

Macroscopic aspect

ICC is defined as a kind of tumor originating from the second branch (segmental branch) or the proximal branch of bile duct[29] and further classified into hilar type and peripheral type. The former arises from the large intrahepatic biliary epithelium (segmental branches) having histological features of a papillary epithelial component or a large tubular component. The latter arises from small biliary epithelium (smaller than segmental branches) with histological features of small-sized glands in a fibrotic background, closely packed, somewhat distorted small ducts, and cordlike structure, but lacking large glands, and Shinichi Aishima, *etc*. It was recently reported that ICC is associated with different predispositions when arising from different levels of the biliary tree and likely to show an aggressive course even in cases of a small tumor arising from the large biliary duct[30,31].

Histological aspect

ICC, arising from cholangiocytes, is a moderately- to well-differentiated tubular adenocarcinoma. Papillary adenocarcinoma, signet-ring carcinoma, squamous cell or muco-epidermoid carcinoma and lymphoepithelioma-like forms are rare histological variants. The most outstanding histological feature is the presence of abundant desmoplastic stroma in ICC compared with HCC, leading to a low diagnostic yield of random biopsies. Desmoplasia may also cause capsular retraction. According to the degree of stromal desmoplasia in the tumor and Kajiyama, Kiyoshi, *etc*, ICC is microscopically categorized into scirrhous-type (SICC) and nonscirrhous-type (NSICC). The frequencies of lymphatic permeation, perineural invasion and the proliferative activity measured by MIB-1 immunostaining, monoclonal antibody specific for Ki-67 [a nuclear antigen expressed throughout the cell cycle (G_1, S-G_2 and M), but absent in quiescent cells (G_0)], were significantly higher in SICC than in NSICC, and serosal invasion, vascular invasion, lymph nodes metastases also tend to be more frequent in SICC and are closely related to the prognosis[32].

Classification

Three types of ICC have been established using the TNM staging system and the classification system established by the Liver Cancer Study Group of Japan: mass-forming type (MF), periductal-infiltration type (PI) and intraductal growth type (IG). MF type forms a definite round-shaped mass with an expansive growth pattern, but without fibrous capsule, and locates in the liver parenchyma. The border between cancerous and non-cancerous portions is distinct, and this type of ICC does not invade the major branch of the portal triad. PI type is defined as a mass extending longitudinally along the bile duct, occasionally involves the surrounding blood vessels and/or hepatic parenchyma, often resulting in dilatation of the peripheral bile duct. IG type proliferates towards the lumen of bile duct papillary or like a tumor thrombus, occasionally involving superficial extension. This type of ICC is usually detected in a thick bile duct[29].

Table 1 Staging system for ICC proposed by Liver Cancer Study Group of Japan

T1: Meet requirements (single nodule, tumor 2 cm or less and no portal vein, hepatic vein and serous membrane invasion)			
T2: Meet two of the three requirements			
T3: Meet one of the three requirements			
T4: Meet none of the three requirements			
N1: No metastasis to lymph node			
N2: Metastasis to any lymph nodes			
M0: No distant metastasis			
M1: Positive distant metastasis			
Stage Ⅰ	T1	N0	M0
Stage Ⅱ	T2	N0	M0
Stage Ⅲ	T3	N0	M0
Stage ⅣA	T4	N0	M0
	Or any T	N1	M0
Stage ⅣB	Any T	Any N	M1

Staging system

ICC is a rare type of primary liver cancer, accounting only for 5%-10% of all liver cancers, and has a low resectability rate. So the International Union against Cancer (UICC) defined the TNM staging system solely from clinical experience in treating HCC[33]. Based on the distinct difference in the mechanism and biologic behavior between HCC and ICC, the Liver Cancer Study Group of Japan has proposed a new TNM staging system for the MF type of ICC (Table 1)[34]. Serosal invasion is not a T-factor component in the UICC tumor staging system. Uenishi *et al*[35] retrospectively analyzed sixty-three patients who underwent hepatic resection for mass-forming intrahepatic cholangiocarcinoma between January 1983 and December 2003, and found that that serosal invasion has no impact on survival of patients after hepatic resection for MF type of ICC. Another staging system used for MF type of ICC, defined a solitary tumor without vascular invasion as stage Ⅰ, a solitary tumor with vascular invasion as stage Ⅱ, multiple tumor with or without vascular invasion as stage ⅢA, tumor with regional lymph node metastasis as stage ⅢB, tumor with distant metastases as stage Ⅳ. In this system, tumor size is excluded from T factor. It is likely that the influence of tumor size on its prognosis cannot be evaluated because the number of small tumors is too small[36].

Table 2 Lymph node groups by tumor location

	N1	N2	N3
Right lobe	Hepatoduodenal ligament	Along left gastric artery Along common hepatic artery Along celiac artery Posterior surface of pancreas head	Distant
Left lobe	Right cardiac region	Along left gastric artery	
	Lesser curvature of stomach	Along common hepatic artery	
		Along celiac artery	Distant
	Hepatoduodenal ligament	Posterior surface of pancreas head	

N3 distant: Abdominal aorta, root of the mesentery, inferior vena cava, *etc.*

Spreading mode

The spreading modes of ICC, such as sinusoidal invasion, spreading along duct walls and periductal tissue, growth replacing the biliary epithelium or intraductal growth, spreading along Glisson's sheath (lymphatic involvement, perineural or intraneural invasion, permeation of the portal connective tissue and vascular involvement) have been reported[37-40]. Nakajima *et al*[37] reported that sinusoidal invasion and portal vein invasion are the most frequent mode of intrahepatic spread. Different macroscopic types of ICC have different modes of spread. The MF type of ICC tends to invade the liver *via* the portal vein system and Glisson's sheath when the tumor increases in size with a frequent remnant hepatic recurrence. The PI type of ICC has a tendency to infiltrate making it difficult to get clear margins during hepatectomy, and to spread along Glisson's sheath *via* lymphatic vessels, thus invading connective tissue and major vessels at the hilum and hepatoduodenal ligament. The IG type of ICC has an extremely favorable prognosis after surgical resection compared with the other two types. Moreover, this type of ICC has a lower rate of lymphatic or intrahepatic metastasis and recurrence after curative surgical resection[37-39]. Yamamoto *et al*[40] suggested that anatomic and extensive hepatectomy is a rational procedure for MF type of ICC, and hepatectomy with extrahepatic duct excision and hilar lymph node resection is a rational procedure for IP and MF types of ICC with biliary invasion. The Liver Cancer Study Group of Japan has proposed a criterion for the invasion degrees of ICC: (1) no tumor invasion of the portal vein, hepatic vein, or bile duct; (2) tumor invasion distal to the second branch of the portal vein or bile duct and/or invasion of a branch of the hepatic vein; (3) tumor invasion of the second branch of the portal vein or the bile duct, the major hepatic veins and/or the short hepatic veins; (4) tumor invasion of the first branch of the portal vein or of the bile duct and tumor invasion of the inferior vena cava[29].

Lymph node metastasis

The most outstanding pattern of ICC compared with HCC is early lymphatic spread. The findings in the majority recent literature indicate that lymph node status is an important prognostic factor for patients undergoing hepatic resection[41-47]. Yet nodal status does not affect survival after aggressive surgical treatment in patients with ICC[48], and some long-term survivors with positive lymph nodes have also been reported[49-51]. It was reported that the rate of metastasis for ICC to hilar lymph nodes is about 50%[41,42,52]. Nakagawa *et al*[43] reported that the positive rate of lymph nodes in patients with lymph node dissection is 47%, 33%, 17%, 13%, 10%, 3%, respectively. Regarding the pattern of lymph node spread, the Liver Cancer Study Group of Japan has proposed a classification of regional lymph nodes in liver cancer (Table 2) and three major routes of lymphatic spread of ICC: hepatoduodenal route, cardiac route (through the lesser omentum to the cardiac portion of the stomach and the gastric lesser curvature), and diaphragmatic route[48]. Hepatoduodenal ligament is the most common site of nodal metastasis in ICC patients irrespective of the tumor location. Almost all patients are involved in positive lymph nodes of the hepatoduodenal ligament or along the common hepatic artery, lymph nodes are also found in about half of the patients involving the left lobe of liver[43,44,53-56]. Nozaki *et al*[57] reported that extensive lymph node metastasis was observed in most patients, only 3 (20%) of 15 patients with lymph node metastasis had regional lymph node metastasis. Shimada *et al*[47] has reported the similar observations, suggesting that lymph node metastasis of ICC is rarely limited to the regional lymph nodes.

Surgical treatment

Surgery is the only choice of curative therapy for ICC. However, only a few patients are suitable for surgery. Good results depend on comprehensive preoperative evaluation, patient selection and discreet operation.

EVALUATION

Assessment of resectability

Tumors that are medically fit for hepatic resection must be completely resected with negative histological margins, no evidence of metastases, disseminated disease, and extensive lymphadenopathy. The following factors must be considered. (1) Biliary tract invasion: bilateral involvement of hepatic ducts to the level of the secondary biliary radicals, atrophy of one liver lobe with contralateral secondary biliary radical involvement is a contraindication to resection. (2) Lymph node metastasis: Inoue *et al*[46] reported that the outcome of 16 patients with lymph node metastasis, accounting for 31.4% of all patients, was quite poor. Their median survival time was 14.1 mo and none of them survived 5 years except for one patient with the IG type of ICC, suggesting that the presence of lymph node metastasis in the MF type of ICC is a sign of non-curability. However, a longer survival time (over 5 years) in ICC patients with lymph node metastasis has been described[54,58]. (3) Vessel invasion: Based on some

centers' support for resection of ICC with vascular reconstruction *en bloc*, involvement of the main hepatic artery or portal vein is the relative contraindication to resection[40,59]. (4) Intrahepatic metastasis: Intrahepatic metastasis in the remaining liver is considered unfit for hepatic resection, and disseminated disease should not undergo hepatectomy. (5) Hepatic functional reserve: It is important to accurately estimate liver reserve function before hepatectomy to avoid postoperative liver failure. Methods to evaluate liver function, including routine examinations of aminotransferase, bilirubin, albumin, prothrombin time, Child-Pugh classification, and hepatic imaging providing volumetric information, indocyanine green (ICG) test. The indocyanine green retention rate at 15 min [ICG (R15)] has recently been considered a sensitive marker for liver reserve function. Nevertheless, it remains imperfect. Moreover, how to evaluate the maximal hepatic resection volume according to liver reserve function remains controversial. Trimethadione (TMO) tolerance test can show the Child-Pugh score in evaluation of cirrhosis. Hepatic 99mTc-diethylenetriamine pentaacetic acid-galactosyl-human serum albumin (99mTc-GSA) clearance test can show postoperative hepatic function and liver stiffness assessed quantitatively with a tactile sensor. The combination of Child-Pugh score, presence of ascites, serum bilirubin levels, indocyanine green retention (ICG R15) value, and remnant liver CT volumetry as well as age, diabetes, cardiopulmonary function, and general performance need to be taken into consideration preoperatively. Other factors affecting respectability include the size and extent of the tumor[60].

Evaluation modalities

Ultrasound can diagnose biliary dilatation and suspected cholangiocarcinoma by localizing the site of obstruction and excluding gallstones. Color Doppler can detect tumor-induced compression/thrombosis of the portal vein or hepatic artery. However, ultrasound is non-specific, often misses small perihilar, extrahepatic, and periampullary tumors, and is not good at defining the extent of tumor.

CT can detect biliary dilatation, intrahepatic cholangiocarcinoma greater than 1 cm in diameter, small liver metastases, lymphadenopathy, biliary obstruction, suspected perihilar tumor or tumor involving the portal venous/arterial system. However, CT can only establish the resectability in 60% of cases[61], and cannot usually define the extent of cholangiocar-cinoma because of the sclerosis and fibrosis of surrounding tissue. In addition, CT cannot accurately differentiate ICC from PSC[62].

MRI along with MRCP can detect ICC and assess preoperative ICC patients by investigating all involved structures, such as the bile ducts, vessels, and hepatic parenchyma, which are important factors for prognosis. Some new tissue-specific MR contrast agents with hepatobiliary and reticuloendothelial cell affinity, such as gadobenate, and ultra-small iron-oxide (USPIO) particles contrast agents with lymph node specificity can be used to detect and assess tumor invasion[63-65]. MRCP may have some potential advantages over CT in identifying intrahepatic mass lesions, and can provide a three-dimensional computerized reconstruction of the biliary tree allowing assessment of bile ducts both above and below a stricture. The non-invasively acquired cholangiographic images obtained by MRCP are comparable with invasive cholangiographies (ERCP and PTC), high positive and negative predictive values for detecting the level and features of biliary obstructions[61,66-68]. Owing to its intrinsically high tissue contrast and multiplanar capability, MRCP is superior to ERCP for defining the anatomy of tumor and assessing its respectability. However, the tendency of MRCP to understage the extent of cholangiocarcinoma has been reported[69]. MRI is not superior to CT in identifying lymph node metastasis.

PET scanning with the focal accumulation of nucleotide tracer 18-fluorodeoxyglucose (FDG) is an emerging staging technique for many cancers. This technique can detect nodular cholangiocarcinoma as small as 1 cm in diameter, but is less sensitive to infiltrating tumors[70]. FDG-PET has a higher specificity for lymphadenopathy than CT, although there is no difference in sensitivity between them[71,72]. In a retrospective study, 21 patients with ICC underwent CT, MRI and PET for lymph node metastasis, which were concordant in 16 patients and discordant in 5 patients (positive FDG-PET in three, positive CT and MRI in two). Moreover, PET may has some superiority over CT and MRI in detecting distant metastases[71].

The above non-invasive techniques may be complementary and sometimes are all necessary as part of surgical assessment depending on the clinical situation. Furthermore, invasive modalities are also needed sometimes to assess the resectability and predict the prognosis. In most cases, ERCP/PTC is replaced by MRCP, but ERCP with OCT can provide more information for surgical plan[21]. Another advantage of these techniques over MRCP is that washing, brushing and intraductal biopsies can be obtained for cytopathologic analysis, adding some new cytological tests, such as DIA, fluorescent *in situ* hybridization, so that the sensitivity increases, especially to patients with PSC or apparent biliary obstruction[73,74]. But, negative cytology from brushings does not exclude malignancy. Preoperative (percutaneous choledochoscope) and intraoperative vholedochoscope with biopsy can help to make an early diagnosis. Blood vessel involvement is an important prognosis factor. As a means of evaluating vascular invasion, hypovascular or hypervascular lesion, concomitant vascular resection and reconstruction, angiography should be reserved in some cases. Percutaneous transhepatic portography (PTP) and retrograde selective hepatic venography should be selected. Virtual 3D is a new kind of technique for constructing three-dimensional virtual images of the portal vein, hepatic artery, and bile ducts. On account of it, accurate knowledge of partial anatomy can be gotten. Preoperative planning for complex biliary

surgery especially lesions invading the hepatic hilum may be improved[75]. ICC in patients with lymphadenopathy is often missed on preoperative imaging. Endoscopic ultrasound can be useful in identifying local lymph node enlargement and allows a good view of distal extrahepatic biliary tree and vasculature[26]. The sensitivity of fine needle aspiration of the tumor mass or its surrounding lymph nodes and endoscopic ultrasound is greater than ERCP with brushings in detecting malignancy[26,27,76]. Endoscopic ultrasound-guided regional lymph node sampling can be performed in early disease to assess the respectability or eligibility for transplantation[77]. However, endoscopic aspiration of hilar masses is not recommended because of the potential of tumor seeding. Laparoscopy is gradually replaced by ultrasonography and other imaging studies, but has identified a third case of peritoneal and superficial liver metastases[51,78,79].

OPERATION

Hepatectomy

It was recently reported that aggressive surgical strategies in the treatment of ICC can significantly increase the survival of ICC patients[14,80,81]. Yamamoto *et al*[82] and Ohashi *et al*[83] suggested that anatomic and extensive hepatectomy is the rational procedure for mass-forming ICC, while hepatectomy with extrahepatic duct excision, and hilar lymph nodal resection is the rational procedure for infiltrating ICC. The 3- and 5-year survival rates of ICC patients after curative resection (n = 56, 53% and 50%, respectively) were significantly higher than those of patients after non-curative resection (n = 67, 7% and 2% respectively, $P < 0.0001$). In 54 patients followed-up after curative resection, the rate of recurrence after surgery was 46%. The rate of recurrence was significantly higher in patients with various mass-forming ICC tumors ($P = 0.039$) than in those with other types of tumors or tumors > 3 cm in diameter than in those with tumors > 3 cm or < less 3 cm ($P = 0.006$)[84]. Kim *et al*[85] reported that the median survival time after non-curative resection is 3.0 mo. Chu *et al*[22] showed the the median survival time is 1.8 mo and 2.9 mo, respectively, after conservative management and palliative operations. Only a curative resection can prolong survival. ICC has no characteristic symptoms at its early stage and is often at its advanced stage when it is diagnosed. Consequently, the resectability rate is usually low, extended hepatectomy possibly in combination with resection of other structures (e.g. extrahepatic bile duct, portal vein and inferior vena cava) is generally required. Wu *et al*[86] described a case of initially unresectable, locally advanced intrahepatic cholangiocarcinoma that showed a remarkable regression after transcatheter arterial chemoembolization with degradable starch microspheres, allowing for subsequent successful curative resection. In a retrospectively study, Yamamoto *et al*[40] allocated 83 patients who had undergone resection to a standard surgery group (n = 56), in which the patients underwent hepatectomy alone or hepatectomy with bile duct resection, and an extended surgery group (n = 27), in which the patients underwent the standard operation combined with vessel resection and/or pancreatectomy. The 5-year survival rate was significantly higher in the standard surgery group (30%) than in the extended surgery group (10%, $P = 0.0061$). So they concluded that extended surgery does not improve the curative resection rate or the surgical outcome of ICC[40].

Lymphadenectomy

ICC frequently demonstrates lymphatic spread. Lymph node metastasis is a significant prognostic factor for IHCC. Whether lymph nodes are dissected, and what is the extent of dissection remain the two important questions to be solved. No consensus has been reached concerning the indications and value of lymph node dissection for ICC. Hepatectomy with extensive lymph node dissection is the standard operation for intrahepatic cholangiocarcinoma in Japan. However, lymph node dissection may not always be effective in reducing tumor recurrence. Chu *et al*[22] and Shimada *et al*[47] that lymph node dissection alone is not likely to improve the prognosis without further control of liver metastases. However, there are reported cases of long-term survival after extended surgical resection of intrahepatic cholangiocarcinoma with extensive lymph node metastasis[56,87].

Transplantation

Pichlmayr *et al*[88] reported that the median survival time of 18 patients with IHCC after liver transplantation was 5.0 mo, and the 1-year survival rate was 13.9%. Casavilla *et al*[89] performed liver transplantation for patients with unresectable tumor (n = 12) or advanced cirrhosis (n = 8) and found that the mortality within 30 d was 7.4%. Overall, the tumor-free survival rates were 64% and 57%, respectively at 1 year, 34% and 34%, respectively at 3 years, and 26% and 27%, respectively at 5 years after operation. About 59.3% patients experienced tumor recurrence. When patients with positive margins, multiple tumors, and lymph node involvement were excluded, the patient survival rate was 74%, 64% and 62%, at 1, 3, and 5 years, respectively after operation. A Mayo Clinic group[90] used preoperative irradiation and chemotherapy for patients with unresectable cholangiocarcinoma above the cystic duct without intrahepatic or extrahepatic metastases. Patients initially received external-beam irradiation plus bolus fluorouracil (5-FU), followed by brachytherapy with iridium and concomitant protracted venous infusion of 5-FU. 5-FU was then administered continuously through an ambulatory infusion pump until OLT. After irradiation, patients underwent an exploratory laparotomy to exclude metastatic disease. The patients have a median follow-up time of 44 mo (range 17-83 mo, 7 of 9 patients > 36 mo). Only 1 patient developed tumor relapse. The group concluded that OLT in combination with preoperative irradiation and chemotherapy is associated with prolonged disease-free, and overall survival in highly selected patients with early-stage cholangiocarcinoma[90]. A comparison of recent series is shown in Table 3.

Table 3 Comparison of recent series

Authors	Yr	Countries	Procedure (patients)	Prognosis (%)				Tumor recurrence (%)
				Median (mo)	1 yr	3 yr	5 yr	
Pichlmayr *et al*[88]	1995	Germany	Hepatic resection (32)	12.8

Adjunctive therapy

Recurrence of ICC is due to failure in surgery, warranting consideration of adjuvant treatments. Neither adjuvant nor neoadjuvant therapy, however, has been shown to improve survival. Roayaie *et al*[91] performed chemo-radiation therapy for postoperative patients with positive resection margins or nodal invasion and did not find any difference in the actuarial disease-free survival between the patients with or without adjuvant chemo-radiation. Sanz-Altamira *et al*[92] used 5-fluorouracil, leucovorin, and carboplatin in patients with unresectable biliary tree carcinoma and found that 21% of the patients had significant responses. Ando *et al*[93] treated an IHCC patient with postoperative recurrence of multiple liver metastases, and a complete response was noted 1 year after the patient underwent 4 courses of hepatic arterial infusion therapy *via* a subcutaneously implanted injection port and received cisplatin. The research of Furuse *et al*[94] showed that, of the twenty-four patients not amenable to surgery, three had a response rate of 12.5%, thirteen had a stable disease, seven had a progressive disease, and one was not evaluated. Lee *et al*[95] treated 24 patients immunohistochemically proven cholangiocarcinoma patients with gemcitabine and cisplatin. Of these 24 patients, 5 had a partial response, 12 had a stable disease, and 7 had a progressive disease during treatment. These patients had a median survival time of 9.30 mo. In a study by Feisthammel *et al*[96], the response rate was 10% for patients with inoperable intrahepatic cholangiocarcinoma (n = 17) or gallbladder cancer (n = 13) after treatment with irinotecan followed by folinic acid and 5-FU, and an additional 10% of patients had a stable disease. The median overall survival time of was 166 d and 273 d, respectively and median progression-free survival time of intrahepatic cholangiocarcinoma and gallbladder cancer patients was 166-273 d, and 84-159 d, respectively. These results suggest that the present therapy is a useful option for advanced IHCC. Rai *et al*[97] reported a 59-year old lady who underwent orthotopic liver transplantation (OLT) for intrahepatic cholangiocarcinoma recurrence 13 mo after transplantation in spite of adjuvant chemotherapy. She survived 18 mo after her recurrent tumor was treated with radiofrequency ablation, suggesting that radiofrequency ablation can be used in treatment of recurrent tumor after liver transplantation.

9th NPY Meeting was held for the first time in Japan in March 2008, which was organized by Akio Inui, Professor and Chairman, Department of Psychosomatic Internal Medicine, Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan.

This TOPIC HIGHLIGHT is the "ghrelin version" of the proceedings of 9th NPY Meeting and presents examples of the critical interplay in ghrelin-NPY pathway in response to environmental, pharmacological and genetic challenges in the stomach and hypothalamus. Other major topics in connection with NPY and related peptides are published in the special issue of Nutrition, thus together representing a comprehensive review of state of the art knowledge of the operation in regulating multiple physiological functions in the periphery and CNS.

These papers are written by leaders in their respective scientific fields by the use of various approaches and models to examine the secretion and action of ghrelin, including manometric and force transducer methods to measure physiological and ghrelin peptides-induced GI motility, electrophysiology to measure neuronal activity in NPY neurons, NPY receptor knockout and other animal models to examine appetite, secretion of stomach ghrelin and leptin or gastric acid, and human studies in relation to *Helicobacter pylori*.

Abstract

Ghrelin causes interdigestive contractions of the stomach in rats. However, it remains unknown whether ghrelin causes interdigestive contractions in the small intestine. Four strain gauge transducers were implanted on the antrum, duodenum, proximal and distal jejunum. After an overnight fast, gastrointestinal (GI) contractions were recorded in freely moving conscious rats. Spontaneous phase Ⅲ-like contractions were observed at every 13-16 min in rat GI tract. The fasted motor patterns were replaced by the fed motor pattern immediately after food intake. Two minutes after finishing the spontaneous phase Ⅲ-like contractions in the antrum, acyl ghrelin (0.8, 2.4 and 8.0 μg/kg per min) was continuously infused for 30 min. Three-five minutes after the starting ghrelin infusion, augmented phase Ⅲ-like contractions were observed at the antrum, duodenum, and jejunum. Ghrelin infusion (0.8, 2.4 and 8.0 μg/kg per min) significantly increased motility index of phase Ⅲ-like contractions at the antrum and jejunum in a dose dependent manner, compared to that of saline injection. Thus, it is likely that exogenously administered ghrelin causes phase Ⅲ-like contraction at the antrum, which migrates to the duodenum and jejunum. The possible role of 5-HT, in addition to ghrelin, in mediating intestinal migrating motor complex (MMC), is discussed.

Taniguchi H, Ariga H, Zheng J, Ludwig K, Takahashi T. Effects of ghrelin on interdigestive contractions of the rat gastrointestinal tract. *World J Gastroenterol* 2008; 14(41): 6299-6302 Available from: URL: http://www.wjgnet.com/1007-9327/14/6299.asp DOI: http://dx.doi.org/10.3748/wjg.14.6299

GHRELIN AND INTERDIGESTIVE GASTRIC MOTILITY

In the interdigestive state, the stomach and small intestine show a remarkable motor pattern, known as the migrating motor complex (MMC)[1]. MMC consists of three phases; phase I (period of motor quiescence), phase Ⅱ (period of irregular low amplitude contractions) and phase Ⅲ (period of regular high amplitude contractions). In humans and dogs, MMC is usually observed every 90-120 min in the interdigestive state. In contrast, in rats, MMC cycle is less than 20 min and not so regular, compared to humans and dogs[2,3]. Exogenously administered motilin does not induce phase Ⅲ-like contractions in rats. Motilin or its receptors are not found in rats[4].

Ghrelin, a 28-amino acid peptide, was discovered as the endogenous ligand for growth hormone secretagogue receptor (GHS-R) from the rat stomach[5]. Because of a structural resemblance to motilin, ghrelin is known as the motilin-related peptide[6,7]. Ghrelin administration causes phase Ⅲ-like contraction at the antrum and duodenum in conscious rats[3,8]. We recently showed that gastric spontaneous phase Ⅲ-like contractions were abolished by ghrelin receptor antagonists[9]. This suggests that endogenous ghrelin regulates spontaneous phase Ⅲ-like contractions of the rat stomach.

However, it still remains unknown whether ghrelin regulates intestinal phase Ⅲ-like contractions in rats. In the current study, we investigated whether exogenously administered ghrelin stimulates phase Ⅲ-like contractions of gastrointestinal (GI) tract in conscious rats.

EFFECTS OF GHRELIN ON THE INTERDIGESTIVE GI CONTRACTIONS

Male Sprague-Dawley rats weighing 280-340 g were kept

in-group cages under conditions of controlled temperature (22-24℃), humidity and light (12 h light cycle starting at 7:00 am) with free access to laboratory chow and water. Protocols describing the use of rats were approved by the Institutional Animal Care and Use Committee of Zablocki VA Medical Center (Milwaukee) and carried out in accordance with the National Institute of Health "Guide for the Care and Use of Laboratory Animals". All efforts were made to minimize animal suffering and to reduce the number of animal in experiments.

After overnight fasting, the rats were anesthetized with intraperitoneal injection of pentobarbital sodium (45 mg/kg). Through a midline laparotomy, strain gauge transducers were implanted on the serosal surface of the antrum, duodenum and jejunum. Duodenal transducers were implanted at 5 cm distal from the pylorus. Jejunal transducers were implanted at 15 cm (the proximal jejunum: J-1) and 25 cm (the distal jejunum: J-2) distal from the pylorus, respectively. The wires from transducer were exteriorized through abdominal wall, ran under skin toward the back. Intravenous catheter was inserted into right jugular vein, and similarly exteriorized to the back, as previously reported[2,9]. The catheter was filled with heparinized saline (100 U/mL) to prevent coagulation. Wires and a catheter were protected by a protective jacket (Star Medical, Tokyo, Japan). After the surgery, rats were housed individual and were allowed to recover for one week before the experiments.

After the implantation of transducers, rats were given food once daily at 12:00 pm-16:00 pm, as previously reported[2]. Experiments of GI motility recording were started at 9:00 am every day. The wires from the transducer were connected to the recording system (PowerLab model 8SP, ADI instruments, Colorado Springs, CO). GI contractions were measured with free access to water in freely moving conscious rats. Spontaneous phase Ⅲ-like contractions were observed for 2-3 h. Phase Ⅲ-like contractions were defined as clustered potent contractions with amplitude of more than 4 g, as previously reported[10].

Fujino *et al*[3] reported that bolus injection of acyl ghrelin (1 g/rat; iv) induced phase Ⅲ-like contraction in conscious rats. In general, bolus injection of certain peptides abruptly increased its plasma level. In our previous study, acyl ghrelin (0.8 μg/kg per min) was continuously infused for 5 min and potent phase Ⅲ-like contractions were observed in the antrum in rats[9]. In our current study, acyl ghrelin (0.8, 2.4 and 8.0 μg/kg per min) was continuously infused for 30 min. Acyl ghrelin was purchased from Tocris Cookson (Ellisville, MO).

Motility index (MI), area under the curve, was calculated using a computer-assisted system (PowerLab, ADInstruments, Colorado Springs, CO). MI in GI tract was compared thirty minutes before and during the infusion of acyl ghrelin. Saline infused rats served as controls.

Results were shown as mean ± SE. ANOVA followed by student's *t*-test was used to assess the difference among groups. A P value < 0.05 was considered to be statistically significant.

It has been showed that spontaneous phase Ⅲ-like contractions are observed at 12-15 min intervals of the stomach[3,9,10] in conscious rats. In our current study, cyclic changes of contractions were detected in the antrum, duodenum, J-1 and J-2 including a quiescence period (phase Ⅰ-like contractions) followed by a grouping of strong contractions (phase Ⅲ-like contractions). Spontaneous phase Ⅲ-like contractions were observed at every 13-16 min in rat GI tract. The fasted motor patterns were replaced by the fed motor pattern immediately after food intake[11].

Two minutes after finishing the spontaneous phase Ⅲ-like contractions in the antrum, acyl ghrelin (0.8, 2.4 and 8.0 μg/kg per min) was continuously infused for 30 min. Three-five minutes after the starting ghrelin infusion, augmented phase Ⅲ-like contractions were observed at the antrum, duodenum, J-1 and J-2 (Figure 1).

Ghrelin infusion (0.8, 2.4 and 8.0 μg/kg per min) significantly increased MI of phase Ⅲ-like contractions at the antrum and jejunum compared to that of saline injection, in a dose-dependent manner (Figure 2).

It is well established that exogenously administered ghrelin causes phase Ⅲ-like contractions in the interdigestive state at the antrum and duodenum in rats[3]. However, it is not clear whether intestinal phase Ⅲ-like contractions are affected by ghrelin administration.

We evaluated the effects of peripherally infused ghrelin on gastrointestinal phase Ⅲ-like contractions in freely moving conscious rats. We demonstrated that ghrelin infusion induced phase Ⅲ-like contractions in the antrum, duodenum, proximal and distal jejunum in a dose-dependent manner (0.8-80 μg/kg per min). This suggests that gastric phase Ⅲ-like contractions induced by exogenously administered ghrelin migrate distally to the small intestine.

We have previously shown that GHS-R antagonists significantly inhibited spontaneous phase Ⅲ-like contractions in conscious rats[9], suggesting that endogenously released ghrelin regulates spontaneous phase Ⅲ-like contractions. We also showed the correlation between the plasma ghrelin levels and occurrence of gastric phase Ⅰ- and Ⅲ-like contractions of the antrum[9]. However, it is not clear whether intestinal phase Ⅲ-like contractions are regulated by endogenously released ghrelin. Previous report showed that ghrelin stimulates motility in the rat small intestine and that the stimulatory effect of ghrelin is mediated *via* cholinergic neurons of the myenteric plexus[12].

Our recent study showed that GHS-R antagonists inhibited phase Ⅲ-like contractions at the antrum, but not the duodenum and the jejunum[11]. Previous studies also showed that GHS-R antagonists did not affect phase Ⅲ-like contractions in the duodenum[8].

It is likely that exogenously administered ghrelin (a pharmacological dose of ghrelin) causes phase-Ⅲ like contraction at the antrum, which migrates to the jejunum. In contrast, endogenously released ghrelin causes spontaneous phase Ⅲ-like contractions at the antrum, which do not migrate to the small intestine.

It has been demonstrated that 5-HT is involved in mediating interdigestive contractions of the small intes-

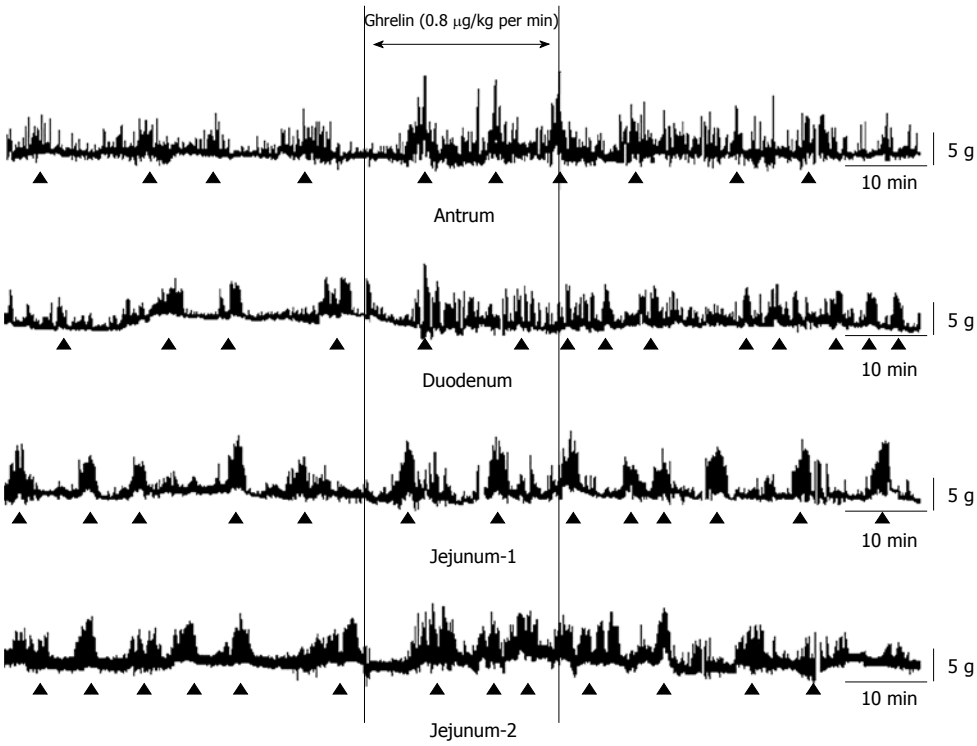

Figure 1 Effect of ghrelin infusion (0.8 μg/kg per min) on spontaneous phase Ⅲ-like contractions in conscious rats. Two minutes after finishing the spontaneous phase Ⅲ-like contractions in the antrum, acyl ghrelin (0.8 μg/kg per min) was continuously infused for 30 min. Three-five minutes after starting the ghrelin infusion, phase Ⅲ-like contractions were observed in response to ghrelin infusion at the antrum, duodenum, jejunum-1 and jejunum-2 (▲ indicates phase Ⅲ-like contractions).

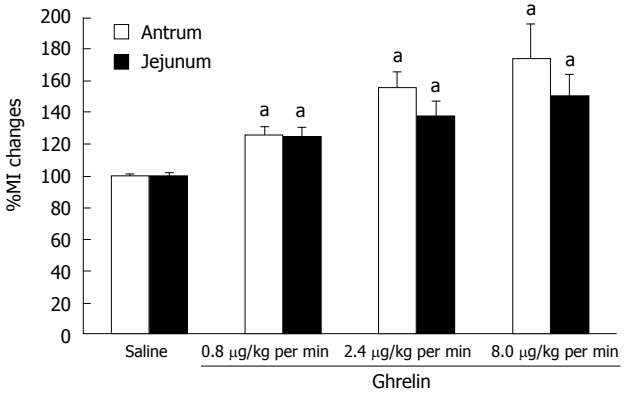

Figure 2 Effect of ghrelin on % changes of MI of phase Ⅲ-like contractions of GI tract ($^aP < 0.05$ *vs* saline, $n = 5$). Ghrelin infusion (0.8, 2.4 and 8.0 μg/kg) dose-dependently increased MI of phase Ⅲ-like contractions of the antrum and jejunum ($^aP < 0.05$ *vs* saline, $n = 5$).

tine in rats[13]. Subcutaneous or intravenous administration of 5-HT can induce intestinal migrating myoelectrical activity in rats[14,15]. Intestinal migrating myoelectrical activity was reduced by a 5-HT_3 antagonist, but not by a 5-HT_4 antagonist in conscious rats[15]. However, others showed that intestinal migrating myoelectrical activity was reduced by a 5-HT_4 antagonist, as well as a 5-HT_3 antagonist[16].

Our recent study showed that phase Ⅲ-like contractions at the jejunum, not the antrum and duodenum, were significantly attenuated by 5-HT_4 antagonists. In contrast, 5-HT_3 antagonists did not affect phase Ⅲ-like contractions in all of upper GI tract[11]. These suggest that spontaneous phase Ⅲ-like contractions at the jejunum is mediated *via* 5-HT_4 receptors, but not 5-HT_3 receptors.

5-HT_3 receptors[17] and 5-HT_4 receptors[18] are located on the cholinergic neurons of the myenteric plexus as well as sensory neurons of the intestinal mucosa[19]. Nerve endings of sensory neurons may well be the targets for the 5-HT released from enterochromaffin (EC) cells[20]. It is generally accepted that 5-HT stimulates intrinsic nerve fibers *via* 5-HT_4 receptors[21], while 5-HT stimulates extrinsic nerve fibers *via* 5-HT_3 receptors[19,22] in rats.

5-HT_3 receptors are located on the nerve terminal of vagal afferent of the duodenal mucosa in rats[23]. 5-HT released by mucosal stimuli initiates peristalsis by activating 5-HT_4 receptors on sensory CGRP neurons of the rat colon *in vitro*[24]. These suggest that 5-HT_4 receptors play a major role in mediating an intrinsic neural reflex. It is conceivable that luminally released 5-HT from duodenal EC cells initially stimulates duodenal phase Ⅲ-like contractions *via* 5-HT_4 receptors located on intrinsic primary afferent neurons (IPAN).

It has been shown that ghrelin receptors are synthesized in vagal afferent neurons and transported to the afferent terminal. This is the major pathway conveying ghrelin signals for starvation and growth hormone secretion to the brain[25]. Blockade of the gastric vagal neuron by vagotomy or perivagal application of capsaicin abolished ghrelin-induced feeding, GH secretion, and activation of NPY-producing and GHRH-producing neurons[25]. Ghrelin-induced acid secretion is also abolished by bilateral vagotomy[26].

Our recent study showed that spontaneous phase Ⅲ-like contractions were completely disappeared in vagotomized rats[11]. These results suggest that ghrelin-induced spontaneous phase-Ⅲ like is mediated *via* vagal pathways.

Spontaneous phase Ⅲ-like contractions are mainly regulated by ghrelin in the antrum, while spontaneous phase Ⅲ-like contractions are regulated by 5-HT in the jejunum. Released ghrelin from the gastric mucosa initi-

ates gastric phase Ⅲ-like contractions *via* vagal dependent pathways. Released 5-HT from intestinal EC cells induces intestinal phase Ⅲ-like contractions *via* IPAN in rats.

Abstract

The cancer-associated anorexia-cachexia syndrome is observed in 80% of patients with advanced-stage cancer, and is one of the major obstacles in chemotherapy. Ghrelin is a orexigenic hormone that has been proposed to prevent anorexia. Aim of the study was to determine whether the addition of the ghrelin agonist growth hormone releasing peptide 2 (GHRP-2) to cytotoxic therapy with 5-fluorouracil (5-FU) prevents the anorexia associated with chemotherapy in cancer cachectic mice. Thirty-three BALB/c female tumour-bearing mice were randomized to receive a solution containing: (a) placebo; (b) GHRP-2; (c) 5-FU; or (d) 5-FU + GHRP-2. Ten BALB/c no tumour-bearing mice received placebo solution. Food intake and survival were checked. Six hours after the drug injection the cumulative food intake was significantly increased in mice treated with the combination of 5-FU + GHRP-2 *versus* the 5-FU alone (P = 0.0096). On day 3, the cumulative food intake of mice treated with GHRP-2, 5-FU and 5-FU + GHRP-2 significantly increased compared with naive and vehicle groups (P = 0.0007, P = 0.0038 and P = 0.0166, respectively). The median survival time was longer in 5-FU + GHRP-2 treated mice than in those with 5-FU, although it was not significant (18 d *versus* 15.5 d, P = 0.7). For the first time, we demonstrated that the addition of GHRP-2 to cytotoxic therapy with 5-FU improved appetite in tumour-bearing mice with anorexia/cachexia syndrome in early stage. These data suggest that GHRP-2 may improve the efficacy of therapy and the quality of life of cancer patients thank to the amelioration of their nutritional state.

CHEMOTHERAPY-INDUCED ANOREXIA

Chemotherapy is the most effective treatment for most cancer patients because of its systemic distribution. Despite the recent advances in the treatment, many patients do not respond to therapy, and die of their diseases. The cancer-associated anorexia-cachexia syndrome is observed in 80% of patients with advanced-stage cancer, and it is a very powerful prognostic indicator of poor outcome and poor quality of life. This syndrome is also one of the major obstacles in cancer chemotherapy[1].

Ghrelin is the natural ligand of growth hormone secretagogue receptor. Growth hormone releasing peptide 2 (GHRP-2) is a synthetic compound that acts as a potent agonist of GHS receptor[2]. Increasing evidences support that GHRP-2, like ghrelin[3], exerts orexigenic

proprieties. Administration of GHRP-2 has shown to increase food intake and body weight in rodents[4] and in healthy men[5]. Since ghrelin has a short half-life, the more stable GHRP-2 was preferred in this experiment.

Aim of the study was to determine whether the addition of GHRP-2 to cytotoxic therapy with 5-fluorouracil (5-FU) prevents anorexia associated with chemotherapy in cancer cachectic mice[6]. Secondary aims were to examine the chronic effects of GHRP-2 on reduced appetite and survival in this animal model.

MURINE MODEL OF CANCER

Six-weeks-old female BALB/c mice (19-24 g) were housed individually in equal plastic cages and received *ad libitum* standard diet and tap water in a regulated environment. The murine colon cancer cell line (colon 26) was supplied by Dr. Hayashi (Kitazato University, Kanagawa, Japan). Colon 26 cancer cells (5×10^5) were dissolved in a 100 μL volume of PBS containing 0.02% EDTA and then implanted in the abdominal cavity of female BALB/c mice by intraperitoneal administration. Seven days later, when mice manifested the first symptoms of anorexia and cachexia, the tumour-bearing mice were randomized in 4 groups, each of them composed by: (a) 11 mice receiving 5% glucoside solution + PBS (vehicle); (b) 12 mice receiving GHRP-2 + 5% glucoside solution; (c) 12 mice receiving 5FU + PBS; and (d) 15 mice receiving 5-FU + GHRP-2. Ten BALB/c no tumour-bearing mice received 5% glucoside solution + PBS (naïve). The day of randomisation was considered as day 0 of the experiment. GHRP-2 (DalaDβNalAlaTrpDPheLysNH2) was supplied by Prof. Bowers (Tulane University, New Orleans, USA). It was dissolved in PBS and was subcutaneously administered at dose of 10 μg/mouse daily. 5-fluorouracil (Kyowa Hakko Kogyo Co. Ldt, Tokyo, Japan) was dissolved in 5% glucoside solution and then intraperitoneally administered at dose of 100 mg/kg weekly. In the acute experiment, food intake and body weight were measured at 0, 1, 2, 4 and 6 h after the first injection of the drugs and then daily. Food intake was evaluated by subtracting uneaten food from initially pre-measured food and checking for food spillage. All the experiments were approved by the animal care committees at the Kobe University and the Kagoshima University (Japan). Results are expressed as mean ± SE. Analysis of variance (ANOVA) followed by Bonferroni's *t* test was used to assess the differences among groups. *P*-values < 0.05 were considered significant. The survival curves after tumour implantation were analyzed by Kaplan-Meier survival test.

GHRELIN AGONIST GHRP-2 REVERSES CHEMOTHERAPY-INDUCED ANOREXIA

The median survival time was longer in the group treated with 5-FU + GHRP-2 than in the group treated with 5-FU, although it was not significant (18 d *versus* 15.5 d, *P* = 0.7) as shown in Figure 1. At day 0, 6 h after the drug injection, the cumulative food intake was significantly

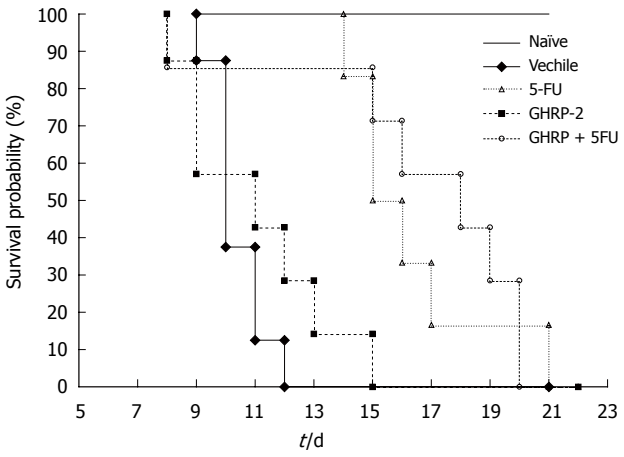

Figure 1 Kaplan-Meier curve of overall survival in colon 26-bearing mice (Naïve: 10 mice; Vehicle: 11 mice; GHRP-2: 12 mice; 5-FU: 12 mice; 5-FU + GHRP-2: 15 mice).

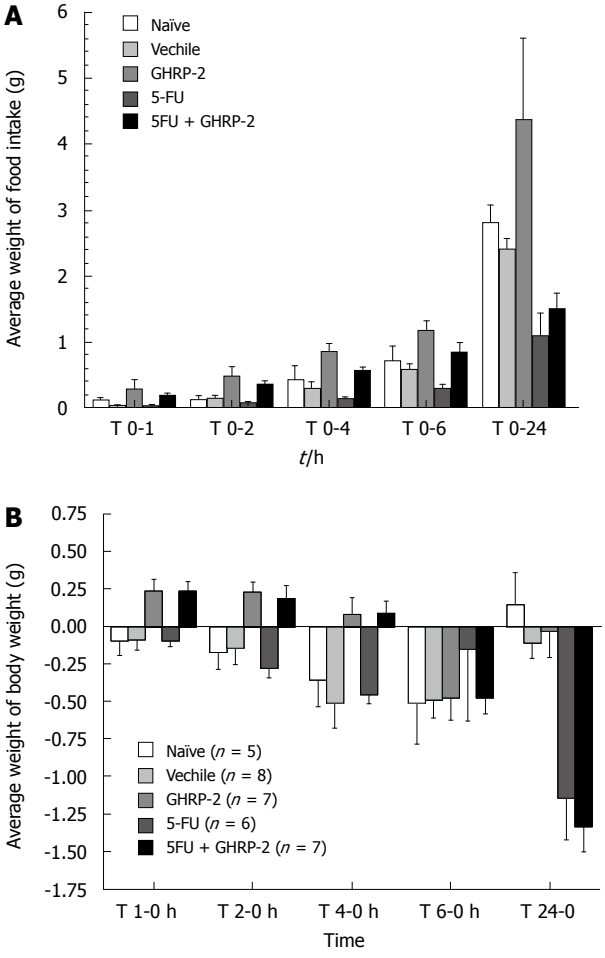

Figure 2 GHRP-2 reverses reduced food intake and body weight by 5-FU administration in colon 26-bearing mice-acute experiments. A: Food intake; B: Body weight.

increased in mice treated with the combination of 5-FU + GHRP-2 *versus* the 5-FU alone (*P* = 0.0096, Figure 2A). At day 0, 4 h after the drug injection, the cumulative body weight of the group treated with 5-FU + GHRP-2 showed a reduced loss of body weight compared with the group treated with 5-FU (*P* = 0.0074, Figure 2B). At day

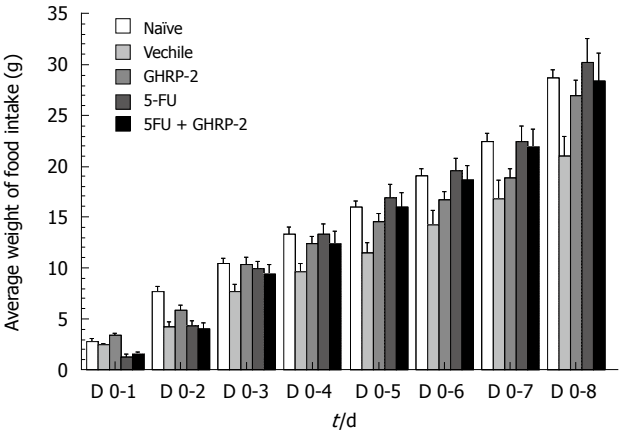

Figure 3 GHRP-2 increases cumulative food intake compared to vehicle controls in colon 26-bearing mice-chronic experiments.

2, the groups treated with 5-FU and 5-FU + GHRP-2 showed a higher loss of cumulative body weight compared with the group treated with GHRP-2 alone (P = 0.0003 and $P < 0.0001$, respectively, Figure 3). However, from day 3 to 5, the cumulative food intake of mice treated with 5-FU and 5-FU + GHRP-2 significantly increased compared with naive and vehicle groups (P = 0.0038 and P = 0.0166, respectively, Figure 3). The cumulative food intake was significantly increased in mice treated with GHRP-2 respect to naïve and vehicle groups throughout the observation period (P = 0.0007 and P = 0.0004, respectively, Figure 3). We could not follow the body weight changes since the tumour-bearing mice developed ascites after the inoculation of cancer cells into the abdominal cavity.

THERAPEUTIC ROLE OF GHRP-2 IN CANCER ANOREXIA-CACHEXIA

Up to 50% of cancer patients report changes in eating behavior at time of diagnosis, leading to weight loss[3]. This study suggests that the addition of GHRP-2 to cytotoxic therapy with 5-FU improved appetite in tumour-bearing mice with anorexia/cachexia syndrome in early stages, although a statistically significant improvement in survival was not achieved compared with mice treated with 5-FU. It is likely that GHRP-2 may overcome any resistance to the appetite-stimulating effects of ghrelin in cachectic animals and cancer patients with appetite loss. In our experiment GHRP-2 has shown to be a short-lasting, acute potent agent, which mimics the orexigenic effects of ghrelin[4,5]. In this study, we demonstrated for the first time that GHRP-2 reversed loss of food intake and body weight in tumour-bearing mice treated with chemotherapy. It is likely that preventing loss of appetite and weight associated with chemotherapy helps mice remain in a relatively balanced condition of electrolytes and hydration, thereby decreasing the side effect and increasing the efficacy of 5-FU. The characteristic of a long acting drug which allows to increased interval of time between two consecutive administrations of the drug, may be a further improve the quality of life in cancer patients.

This study has some limitations. The first is the difficulty to determinate if the survival and the weight loss experienced by tumour-bearing mice was due to tumour burden or to the efficacy or side effect of the 5-FU administration. Secondary, although GHRP-2 did increase the cumulative food intake in tumour-bearing mice, there was a lack of significant difference among groups in survival analysis which should be examined under various chemotherapy conditions and tumour models.

Due to the amelioration of the nutritional state, and of the side effects of chemotherapy, GHRP-2 may offer an interesting treatment for cachexia associated with cancer in order to improve the efficacy of therapy and the quality of life of cancer patients.

ACKNOWLEDGMENTS

The authors would like to thank Ueno N, PhD, MD and Professor Mantovani G for the scientific support and for their valuable comments.

Abstract

Ghrelin was isolated as an endogenous ligand for the GH secretagogue receptor from the rat stomach. Although physiological effects of ghrelin have been revealed by numerous studies, the regulation of stomach ghrelin remains obscure, and the factor that directly regulates ghrelin expression and production has not been identified. Here, we show some data regarding the characteristic features of ghrelin cells and the regulation of stomach ghrelin. In the gastrointestinal tract, ghrelin cells were identified as opened- and closed-type cells, and it was found that the number of ghrelin cells decreased from the stomach to the colon. The postnatal change in number of ghrelin cells in the stomach showed a sexually dimorphic pattern, indicating a role of estrogen in the regulation of stomach ghrelin. *In vitro* studies revealed that estrogen stimulated both ghrelin expression and production and that treatment with formestane, an aromatase (estrogen synthetase) inhibitor, decreased ghrelin expression level. On the other hand, leptin was found to inhibit both basal and estrogen-stimulated ghrelin expression. Moreover, both aromatase mRNA-expressing cells and leptin cells were found to be located close to ghrelin cells in the gastric mucosa. Furthermore, we found an inverse relationship between gastric ghrelin and leptin levels in a fasting state, and we revealed relative changes in expression of gastric ghrelin, estrogen and leptin in the postnatal rats. We propose that gastric estrogen and leptin directly regulate stomach ghrelin and that the balance control through gastric estrogen and leptin contributes to the altered ghrelin expression level in some physiological states.

INTRODUCTION

Ghrelin, a 28-amino-acid peptide with an essential n-octanoyl modification on the third amino acid, was purified as an endogenous ligand for the growth hormone (GH) secretagogue receptor from rat stomach in 1999[1]. In initial studies, ghrelin was shown to stimulate GH release from the pituitary both *in vivo* and *in vitro*[1,2], and ghrelin was later found to be also deeply involved in the regulation of feeding behavior and energy homeostasis[3-7].

Ghrelin is predominantly produced in the stomach[1]. Date *et al*[8] further revealed that X/A-like cells in the stomach were responsible for ghrelin production. They also found that in the gastrointestinal tract, the greatest amount of ghrelin was in the gastric mucosa, and smaller amounts were in the small and large intestines[8]. However, the detailed distribution and morphological characteristics of ghrelin cells in the whole gastrointestinal tract have not been elucidated.

On the other hand, it has been reported that both the expression and secretion of ghrelin are mainly influenced by changes in energy balance, *i.e.* increased by fasting and decreased after refeeding[3,9-11]. In addition, many other factors such as leptin, insulin, somatostatin and vagal activity have also been shown to be involved in the regulation of stomach ghrelin[9,12-14]. However, the factor that directly regulates ghrelin expression or production remains unclear, and little is known about the regulation of gastric ghrelin expression in various physiological states.

Therefore, in this review, we summarize the data obtained by our group regarding the distribution and morphological characteristics of gastrointestinal ghrelin cells, postnatal changes in stomach ghrelin, and the regulation of stomach ghrelin in some physiological states.

DISTRIBUTION OF GHRELIN CELLS IN THE RAT GASTROINTESTINAL TRACT

It was found that plasma ghrelin-like immunoreactivity levels were reduced by 65% in totally gastrectomized patients, suggesting that the stomach is the major source of circulating ghrelin[15]. To investigate the morphological characteristics and distribution of ghrelin cells, we used anti-acylated rat ghrelin antiserum to detect ghrelin-immunopositive (ip) cells in the rat gastrointestinal tract in a previous study[16]. We found that ghrelin cells were present throughout the whole gastrointestinal mucosa from the stomach to the colon, and that they could be classified into two types, *i.e.* closed-type cells (Figure 1A) and lumen-contacted opened-type cells (Figure 1B). Interestingly, in ghrelin cells, des-acylated ghrelin was found to be mainly localized to the perinucleus, while acylated ghrelin was found to be distributed in the periphery of the cytoplasm. These findings suggest that des-acylated ghrelin, which is from the Golgi complex, undergoes acylation in secretory granules in the periphery of the cytoplasm.

Further morphometric analysis revealed that the largest number of ghrelin cells was in the stomach and the next-largest number was in the duodenum, and very small numbers of ghrelin cells were observed in the ileum, cecum and colon[16]. These findings are in agreement with the results of another study regarding gastrointestinal ghrelin content[8]. On the other hand, in the stomach, very few opened-type ghrelin cells were observed; but it was found that the percentages of opened-type ghrelin cells in all ghrelin cells in various regions of the gastrointestine gradually increased in the direction from the stomach to the lower intestine, being particularly high in the ileum, cecum and colon[16]. It is generally accepted that opened-type endocrine cells in the gastrointestinal tract are mainly regulated by luminal signals, whereas closed-type cells in the gastrointestinal tract receive modulation from hormones, neuronal stimulation or mechanical distension[17]. Therefore, the distinct distributions of opened- and closed-type ghrelin cells in the gastrointestine suggest that the ghrelin cells may be modulated by different stimulators and may play different physiological roles in various regions of the gastrointestinal tract.

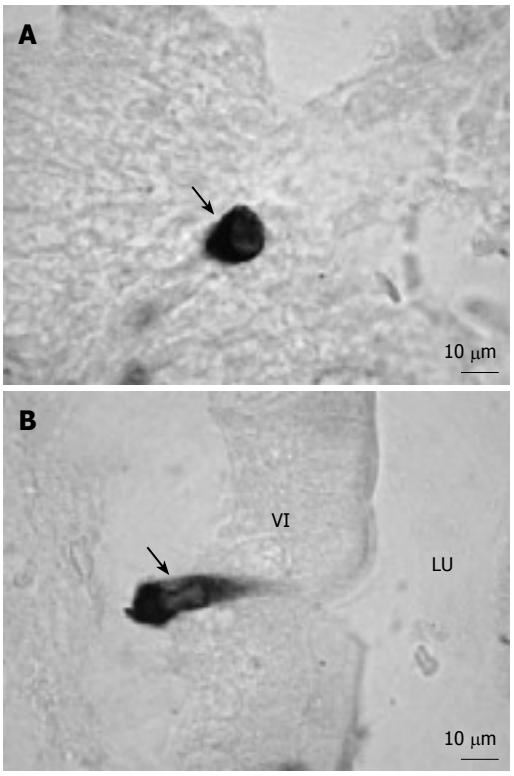

Figure 1 Representative microphotographs of ghrelin-ip cells in the rat gastrointestinal tract[16]. A: Closed-type ghrelin cells (arrow) were found in the crypt of the duodenum; B: Opened-type ghrelin cells (arrow) in contact with the lumen were found in the villi of the duodenum. Bar = 10 μm. VI: Villi; LU: Lumen.

POSTNATAL CHANGES IN STOMACH GHRELIN

In a recent study, the mRNA expression level of gastric ghrelin was shown to be elevated progressively during the second and third postnatal weeks[18]. Gualillo *et al*[19] also reported a gradual increase in the expression level of the gastric ghrelin gene after birth in the rat (up to 90 days). In agreement with these results, we found that gastric ghrelin expression was detectable just after birth in both male and female rats, and that expression levels of gastric ghrelin gradually increased during postnatal development (up to 8 wk of age) (Figure 2A and B).

Accordingly, ghrelin-ip and ghrelin mRNA-expressing cells were also observed just after birth[20]. At 1 wk of age, these ghrelin cells were mainly localized in the glandular base of the fundic gland, and then the distribution of ghrelin cells gradually extended from the glandular base to the glandular neck with increasing age in both sexes[20]. An interesting finding in that study was that two kinds of stained ghrelin cells, weakly stained and strongly stained cells, were found in female rats at the early stage of development (1 and 3 wk of age), whereas staining in most of the ghrelin cells was strong in male rats and 7-wk-old female rats[20]. With increasing age, weakly stained cells were replaced by

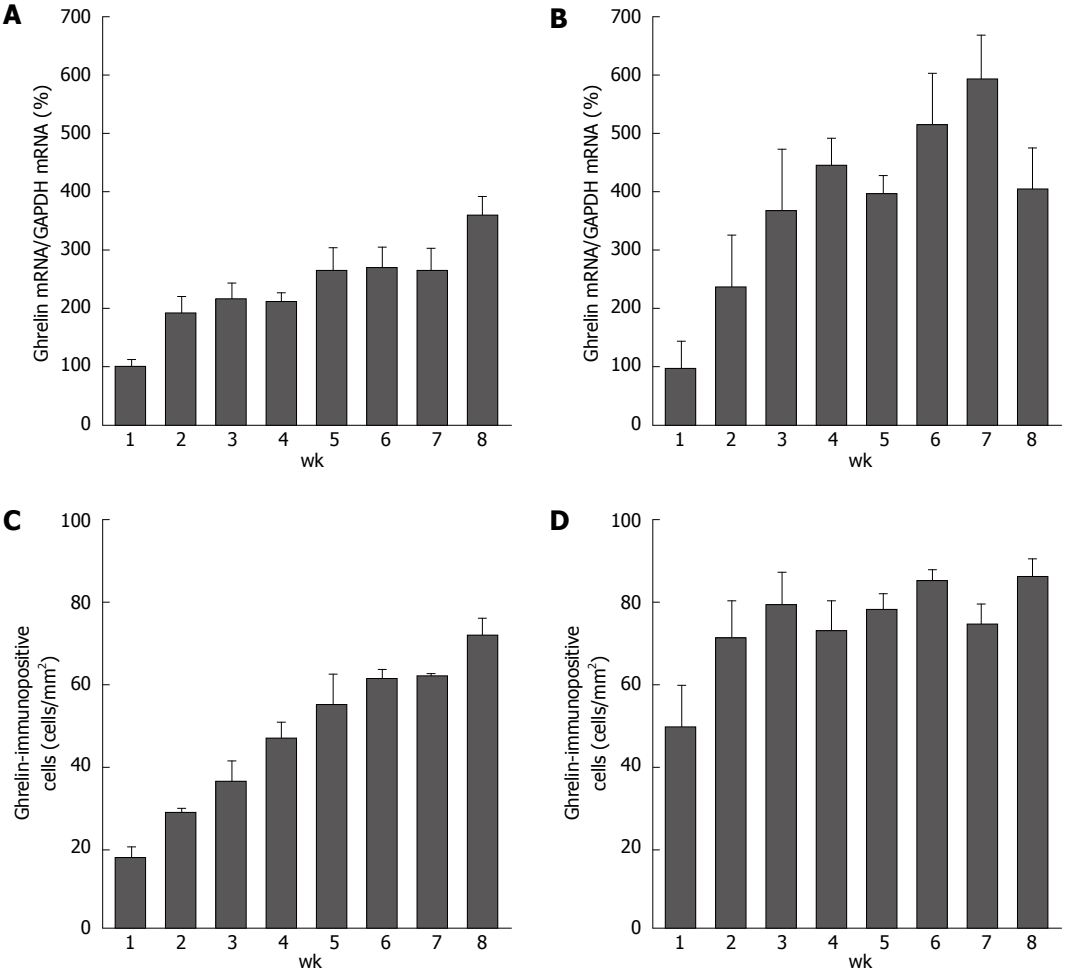

Figure 2 Changes in ghrelin mRNA levels and the densities of ghrelin-ip cells during the postneonatal period in the rat stomach[20]. The data in (A) and (B) are shown as the % of 1-wk-old (1 wk) rats (100%) and each bar represents the mean ± SE (n = 3). A: Ghrelin mRNA levels in the male stomach; B: Ghrelin mRNA levels in the female stomach; C: The densities of ghrelin-ip cells (cells/mm^2) in the male stomach; D: The densities of ghrelin-ip cells (cells/mm^2) in the female stomach.

strongly stained cells, resulting in almost no change in the density of ghrelin cells in female rats throughout the whole period of postnatal development (Figure 2D), in contrast to the increase in ghrelin mRNA expression level. On the other hand, in male rats, ghrelin cell density showed an age-dependent increase after birth (Figure 2C), and the increase was in concert with the increase in ghrelin expression level. The sexual dimorphism of ghrelin cell density suggests that ghrelin cells in female rats differentiate at an earlier stage of development than they do in male rats, and that sex steroids such as estrogen may be involved in the regulation of stomach ghrelin.

REGULATION OF STOMACH GHRELIN BY GASTRIC ESTROGEN AND LEPTIN IN SOME PHYSIOLOGICAL STATES

Regulatory role of gastric estrogen

A role of estrogen in the regulation of stomach ghrelin has also been suggested by several studies. In a previous study, the levels of gastric ghrelin mRNA and plasma ghrelin and the number of ghrelin cells were found to be transiently increased by ovariectomy in female rats[21]. In addition, it was found that ghrelin cells express estrogen receptor α (ERα)[21]. On the other hand, Ueyama *et al*[22] recently demonstrated that aromatase, an estrogen synthetase, is expressed in parietal cells of the rat stomach and that gastric parietal cells are capable of producing and secreting a substantial amount of estrogen. These findings indicate that gastric estrogen plays a role in the regulation of stomach ghrelin.

Therefore, in a previous study, using isolated stomach cells, which are rich in ghrelin cells, we determined the direct effect of estrogen on stomach ghrelin expression and production[23]. In that study, we found that estrogen treatment significantly stimulated ghrelin mRNA expression (Figure 3A) and production in a dose-dependent manner and that treatment of minced stomach tissue with formestane, an aromatase inhibitor, decreased ghrelin expression level[23]. Given that a significant increase in estrogen concentration in the portal vein compared with that in the artery was observed in intact rats, but not in gastrectomized rats[22], the concentration of gastric estrogen must be higher than that of plasma estrogen. Moreover, neither the gastric ghrelin expression nor the plasma

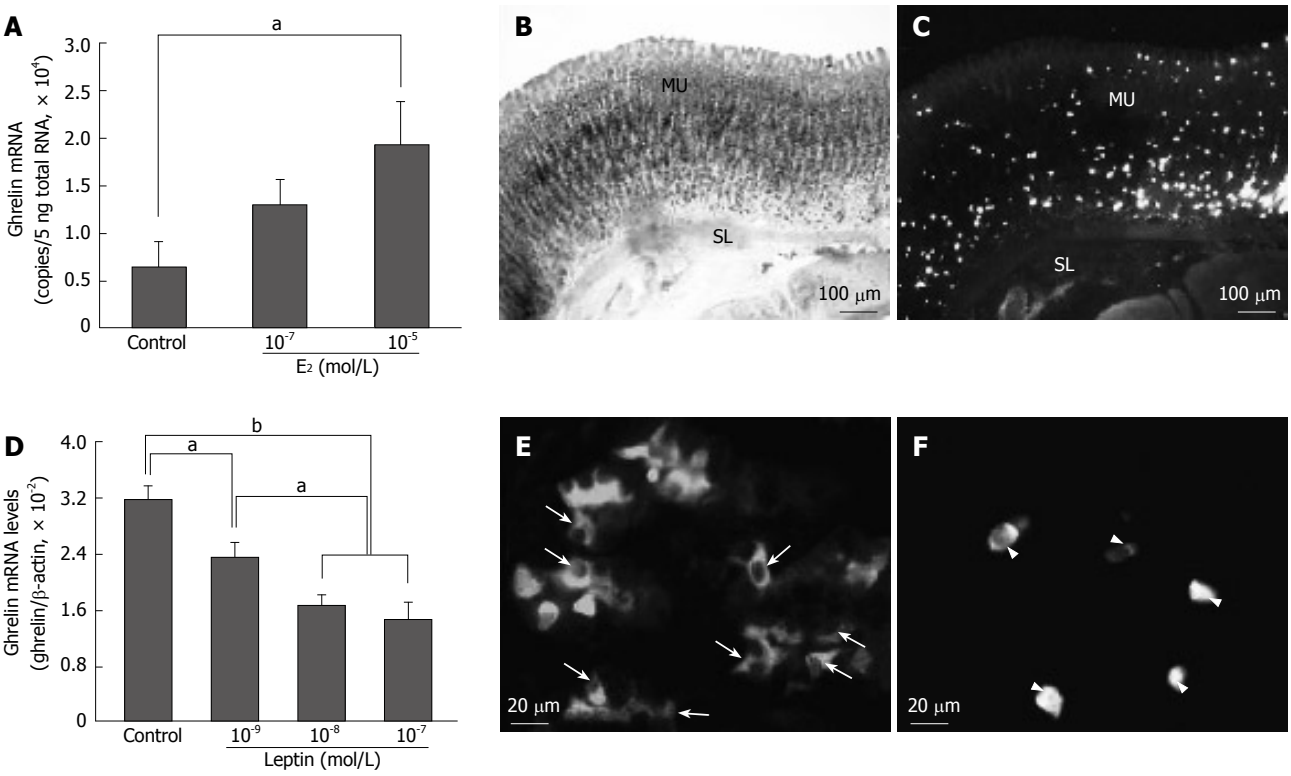

Figure 3 ***In vitro*** **effects of estrogen and leptin on ghrelin mRNA expression and distributions of aromatase mRNA-expressing, leptin-ip and ghrelin-ip cells in the gastric mucosa[23,27].** A: Changes in ghrelin mRNA expression after estrogen treatment; B: Aromatase mRNA-expressing cells were found in the glandular body of the fundic gland; C: Ghrelin-ip cells were found sporadically throughout the gastric mucosa; D: Changes in ghrelin mRNA expression after leptin treatment. Ghrelin mRNA level is expressed relative to β-actin mRNA level; E: Leptin-ip cells (arrow) were found in the lower half of the fundic gland; F: Ghrelin-ip cells (arrowhead) were found in the gastric mucosa. (A, D) Data are presented as mean ± SE. *n* = 3-4/group. $^{a}P < 0.05$; $^{b}P < 0.01$. Bar = 100 μm (B, C) and 20 μm (E, F) respectively. MU: Mucosa; SL: Smooth muscle layer.

ghrelin concentration was altered by gonadectomy[23]. Furthermore, ghrelin cells and aromatase mRNA-expressing cells were found to be located close together in the gastric mucosa (Figure 3B and C), suggesting that ghrelin cells are exposed to gastric estrogen. All of these results strongly suggest that estrogen produced in the stomach directly stimulates ghrelin expression and production in the rat stomach.

Regulatory role of gastric leptin

Reciprocal circadian rhythms in circulating ghrelin and leptin levels and antagonistic hypothalamus-mediated control of appetite by ghrelin and leptin have been revealed by several studies[3,6,24]; however, results of studies on the modulation of ghrelin expression by leptin are inconsistent. One group showed that leptin administration to rats for five days stimulated gastric ghrelin mRNA expression[11], whereas another group reported the opposite results[9]. Due to these conflicting results, the role of leptin in regulation of ghrelin expression remains unclear. On the other hand, leptin was initially thought to be adipocyte-derived[25], and it has also been identified in various tissues, including the stomach[26]. The fact that the release of gastric leptin is rapidly stimulated by food intake or CCK treatment suggests that gastric leptin is involved in the short-term control of energy balance[26], although adipocyte leptin is known to be a long-term regulator of energy balance.

In contrast to the stimulatory effect of estrogen, in another study, we found that leptin inhibits both basal (Figure 3D) and estrogen-stimulated ghrelin expression *in vitro*[27]. The fact that both long and short forms of the leptin receptor have been identified in the human and rat gastric mucosa[28,29] strongly suggests that the gastric epithelium could be a direct target of gastric leptin. Consistent with results of these studies, mRNAs of both OB-Ra and OB-Rb were found to be expressed in the rat gastric fundus, and no inhibitory effect of leptin on ghrelin expression was observed in leptin receptor-defective Zucker fatty (fa/fa) rats, indicating that leptin inhibits ghrelin expression *via* the leptin receptor[27]. Furthermore, it was revealed that leptin cells were mainly located in the lower half of the gastric mucosa, where most of the ghrelin cells were tightly surrounded by leptin cells (Figure 3E and F), suggesting that gastric leptin has a paracrine role in regulation of ghrelin cells, and that ghrelin cells may be exposed to a higher concentration of gastric leptin than that of plasma leptin since leptin infusion at 0.1 nmol/L, which can mimic the plasma leptin concentration under basal conditions in rats, has been shown to be incapable of suppressing ghrelin release from the isolated rat stomach[30].

Relative changes in gastric ghrelin, estrogen and leptin levels in some physiological states

Direct regulation of stomach ghrelin by gastric estrogen

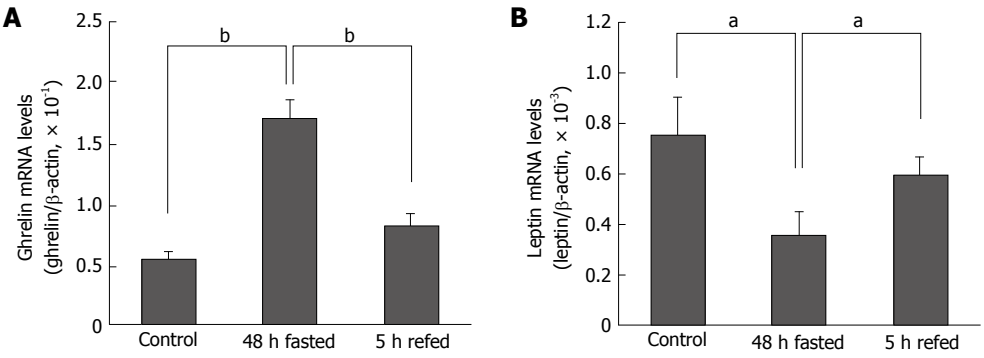

Figure 4 mRNA expression levels of gastric ghrelin and leptin under different feeding conditions[27]. (A) Effects of 48 h of fasting and 5 h of refeeding on gastric ghrelin expression; (B) Effects of 48 h of fasting and 5 h of refeeding on gastric leptin expression. Ghrelin and leptin mRNA levels are expressed relative to β-actin mRNA levels. Data are presented as mean ± SE. n = 3-4/group. $^{a}P < 0.05$; $^{b}P < 0.01$.

and leptin raises the possibility that gastric estrogen and leptin contribute to the altered ghrelin level in some physiological states. It is generally accepted that the most important physiological state for the regulation of stomach ghrelin is fasting. Results of numerous studies have shown that levels of both ghrelin expression and secretion are increased by fasting and decreased after refeeding[3,9-11]. Therefore, in a recent study, we determined the changes in gastric estrogen and leptin levels in relation to gastric ghrelin expression level under a fasting condition[27]. In that study, however, neither the expression level of gastric aromatase nor the concentration of estrogen in the portal vein was altered by fasting[27], although the expression level of gastric ghrelin was significantly elevated as predicted (Figure 4A). In contrast, both gastric leptin expression (Figure 4B) and concentrations were found to be significantly decreased by fasting[27]. In addition, refeeding of fasted animals induced an increase in gastric leptin expression level (Figure 4B), which was also opposite to the decreased gastric ghrelin expression level after food intake (Figure 4A).

In another study, relative changes in expressions of gastric ghrelin, aromatase and leptin in postnatal rats were investigated. We found that gastric ghrelin expression levels significantly increased from 2 wk of age to 4 wk of age. Similarly, gastric aromatase expression level was also significantly elevated in 4-wk-old rats compared with the level in 2-wk-old rats. In contrast, gastric leptin expression level decreased from 2 wk of age to 4 wk of age.

Although the mechanism underlying the fluctuations in gastric estrogen and leptin levels in a certain physiological state remains to be elucidated, these fluctuations in gastric estrogen and leptin levels together with the fact that estrogen and leptin produced in the stomach directly regulate gastric ghrelin expression led us to propose a regulatory model of stomach ghrelin expression in some physiological states. Under a basal (fed) condition, the expression of gastric ghrelin is maintained at a certain level due to a balance between positive regulation from gastric estrogen and negative regulation from gastric leptin. In postnatal development, gastric estrogen level increases and gastric leptin level decreases with increasing age, resulting in gradual elevation of ghrelin expression level during postnatal development. Similarly, under a fasting condition, when fasting reduces gastric leptin level with no change in gastric estrogen level, this balance is also broken by attenuated negative regulation due to decreased gastric leptin level and finally results in increased ghrelin expression. These two models do not, however, exclude the possibility of involvement of other factors such as neural control through the vagal nerve system or other hormones inside and outside the stomach such as gastric somatostatin and insulin. But, we believe that the balance control through gastric estrogen and leptin at least partially contributes to the altered ghrelin expression level in some physiological states.

CONCLUSION

In the gastrointestinal tract, ghrelin cells were identified as opened- and closed-type cells. The greatest number of ghrelin cells was found in the stomach, and it was found that the number of opened-type cells gradually increases in the direction from the stomach to the lower intestine. Stomach ghrelin cells in female rats differentiate at an earlier stage of development than they do in male rats. Gastric estrogen and leptin directly regulate ghrelin expression and production in the stomach, and the balance control through positive regulation from gastric estrogen and negative regulation from gastric leptin contributes to the altered ghrelin expression level in some physiological states. These findings provide new insights into the physiological regulation of stomach ghrelin, and may be important for the development of methods for controlling high ghrelin expression levels in some negative energy balance states, which directly contribute to increased food intake and adiposity. However, the regulatory mechanism of ghrelin is thought to be more complicated, and may involve other factors such as vagal activity and hormones outside the stomach. Further studies are necessary to elucidate the roles of these factors.

Abstract

Neuropeptide Y (NPY) is a potent neurotransmitter for feeding. Besides NPY, orexigenic neuropeptides such as agouti-related protein (AgRP), and anorexigenic neuropeptides such as α-melatonin stimulating hormone (MSH) and cocaine-amphetamine-regulated transcript (CART) are also involved in central feeding regulation. During fasting, NPY and AgRP gene expressions are up-regulated and POMC and CART gene expressions are down-regulated in hypothalamus. Based on the network of peptidergic neurons, the former are involved in positive feeding regulation, and the latter are involved in negative feeding, which exert these feeding-regulated peptides especially in paraventricular nucleus (PVN). To clarify the compensatory mechanism of knock-out of NPY system on feeding, change in gene expressions of appetite-related neuropeptides and the feeding behavior was studied in NPY Y5-KO mice. Food intake was increased in Y5-KO mice. Fasting increased the amounts of food and water intake in the KO mice more profoundly. These data indicated the compensatory phenomenon of feeding behavior in Y5-KO mice. RT-PCR and ISH suggested that the compensation of feeding is due to change in gene expressions of AgRP, CART and POMC in hypothalamus. Thus, these findings indicated that the compensatory mechanism involves change in POMC/CART gene expression in arcuate nucleus (ARC). The POMC/CART gene expression is important for central compensatory regulation in feeding behavior.

Feeding behavior and gene expression of appetite-related neuropeptides in mice lacking for neuropeptide Y Y5 receptor subclass. *World J Gastroenterol* 2008; 14(41): 6312-6317 Available from: URL: http://www.wjgnet.com/1007-9327/14/6312.asp DOI: http://dx.doi.org/10.3748/wjg.14.6312

INTRODUCTION

Feeding behavior is a complicated process to regulate the body weight. The body weight is determined by balance between calorie intake mainly by feeding and energy consumption including exercise, body temperature and metabolism. Obesity derived from excess of food intake results in the metabolic syndrome, diabetes mellitus and associated cardiovascular diseases. Since hyperphagia contributes onset and progression of the metabolic syndrome and so on, central feeding regulation is an important issue to be clarified[1,2].

Feeding behavior is regulated strictly by more than 20 appetite-related neuropeptides which are expressed in feeding center in central hypothalamus[1-4]. The main regulation to control feeding are the opposing controls between the orexigenic NPY (neuropeptide Y)/AgRP (agouti-related protein) neurons and the anorexigenic POMC (proopiomelanocortin)/CART (cocaine-amphetamine-regulated transcript) neurons, which originate from the arcuate nucleus (ARC) to the paraventricular nucleus (PVN)[3-6]. The main pathway of two opposite neuron groups obtain and integrate nutritional informations, and communicate information regarding nutrient status and energy stores to the second-order neurons of feeding regulation in PVN[3,5,6]. Among these appetite-related neuropeptides, NPY is the endogenous, strongest orexigenic neuropeptide and fasting induces the most re-

markable increase in NPY gene expression in hypothalamus, indicating its principal and physiological relevance in feeding regulation[3-7].

We have been studying the regulatory mechanism of NPY gene expression in hypothalamus, so as to elucidate the mechanism of feeding-related regulation of NPY gene expression[8-11]. Leptin is an anti-obesity hormone derived from adipose tissue and reduces the NPY gene expression in hypothalamus. This inhibition of NPY gene expression by leptin is shown to be due to activation of SOCS3 in the NPY neurons in arcuate nucleus[11].

In contrast the NPY receptors have been classified into at least 6 subclasses (Y1-y6). Y1, Y2, Y4, Y5, and y6 receptors have been cloned and Y1, Y2 and Y5 receptors are mainly involved in central feeding regulation in hypothalamic ARC and PVN[12-19]. NPY-induced marked induction of feeding behavior intracerebroventricular (icv) is mediated through mainly Y1 and Y5 receptors in mammalians[13,15,16]. Interestingly, although activation of Y1 and Y5 receptors is involved in NPY-induced hyperphagia, the Y1-KO (knockout) and Y5-KO mice develop the late-onset obesity with increase in food intake and adiposity, while NPY-KO mice did not change the feeding behavior or body weight[17,20]. This implies a compensatory mechanism in feeding behavior in these KO mice, which is important for understanding the long-term treatment with the current Y1 and Y5 receptor antagonists for anti-obesity drugs. In addition the compensation against the orexigenic NPY system has not been elucidated to date yet. Therefore, first we chose the Y5-KO mice to investigate the central compensatory mechanism for knockout of NPY system, since the expression of Y5 receptor is much restricted in the brain[16,18,21]. Then we characterized change in the feeding behavior and gene expressions of various appetite-related neuropeptides in the hypothalamus of the NPY Y5-KO mice.

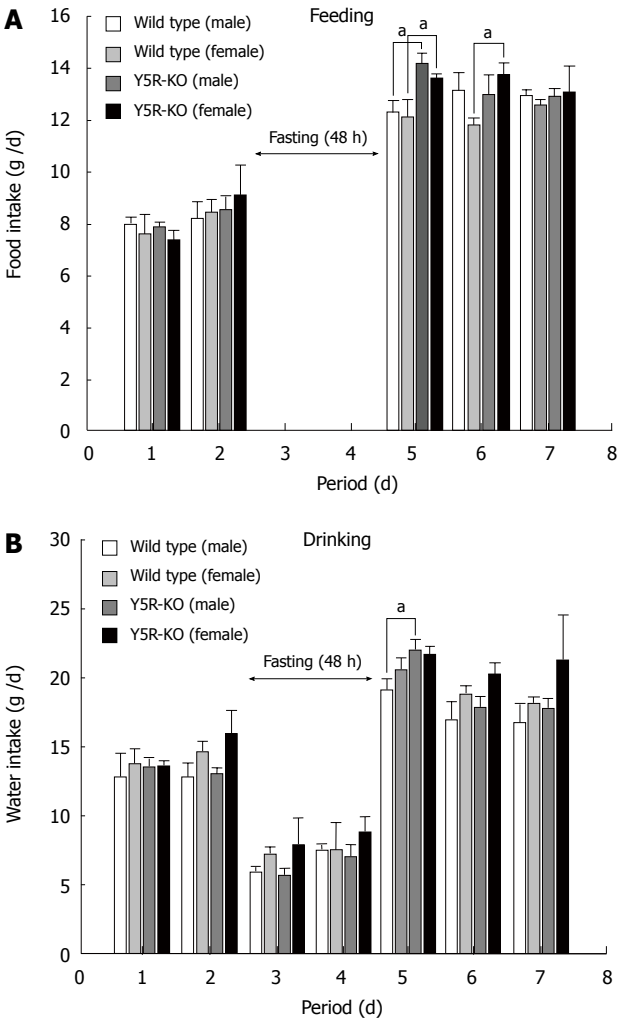

Figure 1 Fasting (48 h)-induced change in food intake (A) and water intake (B) in NPY Y5-KO mice. Fasting (48 h)-induced change in daily amounts of food intake and water intake in Y5-KO mice was measured and compared with those in wild-type (C57BL/6N) mice at 10 wk old. $^{a}P < 0.05$ (unpaired Student's *t* test).

FEEDING BEHAVIOR IN WILD-TYPE C57BL/6N MICE

NPY is the endogenous neuropeptide with most orexigenic potency in hypothalamus, and its injection icv or direct injection into PVN in hypothalamus produces marked increase in feeding behavior in rodents[13-16]. Fasting or central glucoprivation evoked by 2-deoxyglucose (2DG) induces eating with simultaneous increase in orexigenic NPY and AgRP gene expressions in ARC, followed by augmented NPY peptide release[7,8]. Since this fasting-induced food intake is significantly inhibited by selective Y1 or Y5 antagonists, the induction is mediated through Y1 and Y5 receptors (apparently, mainly through Y1 receptors in mice)[13,16]. This NPY/AgRP neurons are essential for feeding in adult mice[22].

In our experiments with male 10-wk-old wild-type mice, fasting for 48 h increased daily food intake and daily water intake by 53% and 50%, respectively (Figure 1). The increase in food intake followed by the concomitant increase in the orexigenic NPY and AgRP gene expressions and decrease in the anorexigenic POMC gene expression in ARC[4]. RT-PCR indicated that NPY and AgRP gene expression is increased remarkably and galanin gene expression is increased moderately, while orexin, MCH, CART or POMC mRNA did not change significantly. These findings suggested that fasting-induced food intake is involved markedly in NPY/AgRP gene expression and moderately in galanin gene expression in ARC in wild-type mice. NPY and AgRP coexist in the same neurons in ARC, and NPY and AgRP gene expressions were increased simultaneously and remarkably by fasting[4,7,8].

In contrast to the concept that the NPY system plays a pivotal role in central feeding regulation, the following studies have performed that in the NPY-KO and NPY Y1-KO mice their body weights or feeding behaviors did not change or that in NPY Y5-KO mice the body weight and food intake increased conversely[17,18,20]. This suggested the existence of a compensatory mechanism other than the NPY system. The existence of multiple

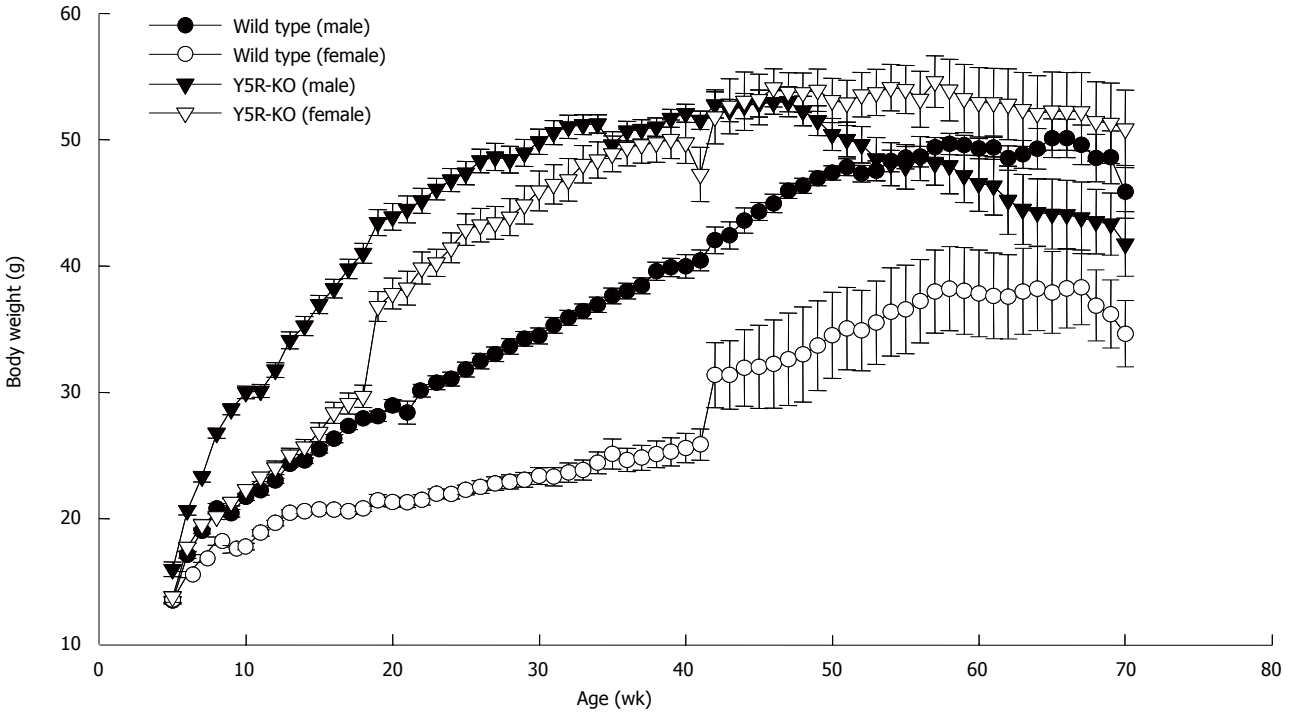

Figure 2 Growth curves of wild-type (C57BL/6N) and NPY Y5-KO mice from 4 to 69 wk old. Data are the mean ± SE. From 4 to 40 wk old, the body weight of Y5-KO mice was twice as much as that of wild-type mice.

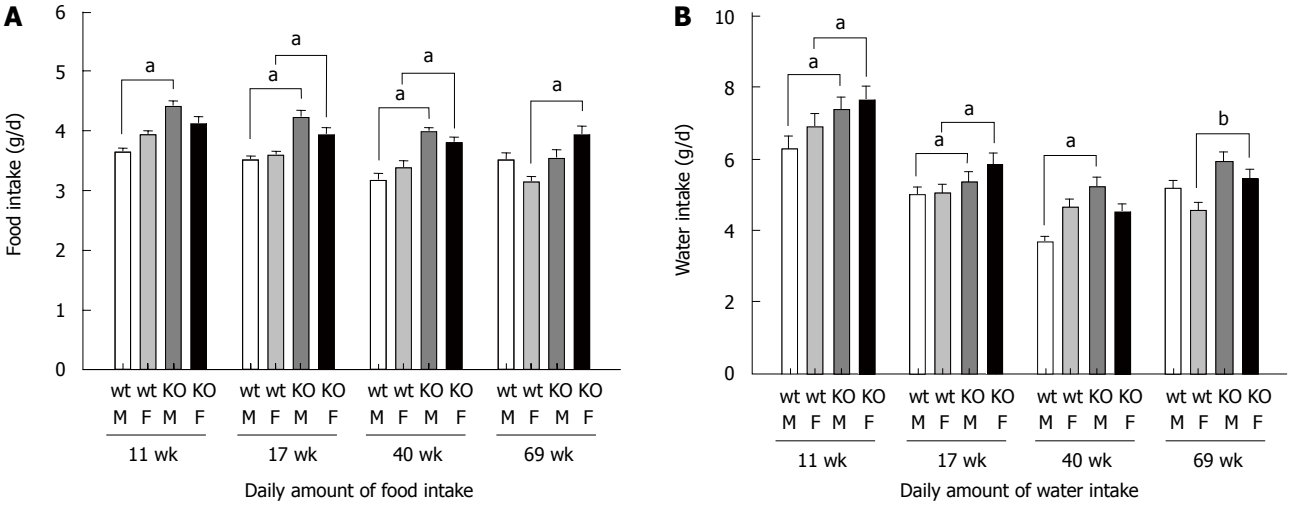

Figure 3 Change in feeding and drinking in NPY Y5-KO mice. Daily amounts of food intake (A) and water intake (B) in Y5-KO mice were measured and compared with those in wild-type (C57BL/6N) mice at the same age (from 11 to 69 wk old). $^{a}P < 0.05$, $^{b}P < 0.01$ (unpaired Student's *t* test). M: Male; F: Female.

feeding-regulatory systems is very important for the homeostasis of body weight. Therefore, we tried to elucidate the compensatory system except for NPY by using NPY Y5-KO mice.

COMPENSATORY FEEDING BEHAVIOR IN NPY Y5-KO MICE

As shown in Figure 2, growth curve of wild-type and NPY Y5-KO mice from 4 to 69 wk old. Although NPY is an orexigenic peptide, obviously Y5-KO mice have obese phenotype. From 4 to 40 wk old, the body weight of Y5-KO mice was twice as much as that of wild-type mice. The increase was observed in both male and female gender but more remarkably in female gender. Because NPY is related with regulation of release of female gonadotropins from pituitary glands, and because female in human being tends to be fatty after menopause, activation through Y5 receptors may be involved in suppression of onset and progression of obesity in female.

As shown in Figure 3, when Y5-KO mice were freely fed, their daily food intake and daily water intake were significantly higher than those of wild-type mice at any age. This suggested that overeating in Y5-KO mice produced obesity of the mice. Next, we measured the fasting (48 h)-induced change in food intake in Y5-KO mice

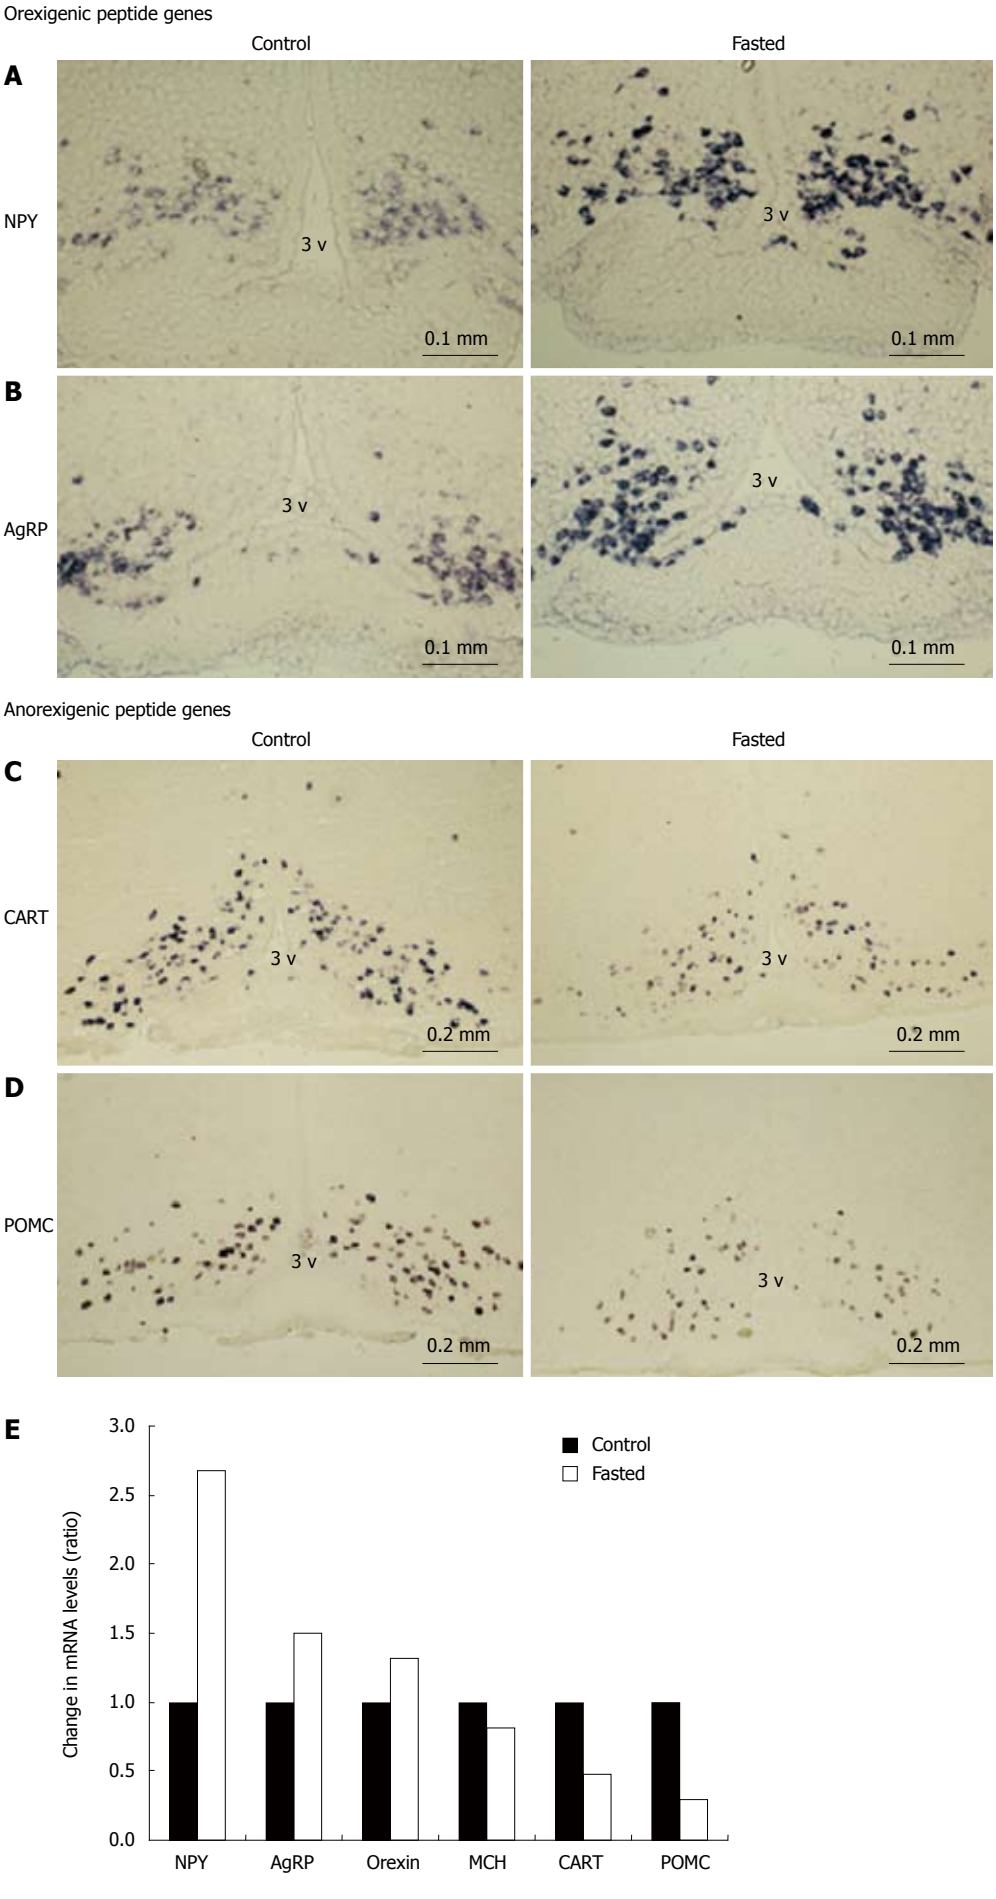

Figure 4 Effect of fasting on appetite-related gene expression in hypothalamus. Fasting (48 h)-induced change in gene expression of appetite-related genes (A: NPY; B: AgRP; C: CART; D: POMC) in Y5-KO mice was measured in the hypothalamus and change in signal intensity was quantitated in panel E at 10 wk old. 3v: Third ventricle; NPY: neuropeptide Y; AgRP: agouti-related protein; MCH: melanin-concentrating hormone; CART: cocaine-amphetamine-regulated transcript; POMC: proopiomelanocortin.

(Figure 1A). Compared with fasting-induced food intake in wild-type mice, obviously fasting-induced feeding was augmented by about 2 times. The fasting-induced water intake in Y5-KO mice was significantly increased following increase in food intake (Figure 1B). Thus, obesity in NPY Y5-KO mice is probably due to overeating *ad libitum* and on fasting.

To deny the possibility that obesity might be due to decrease in energy consumption, the decrease rate in body weight was studied during fasting (48 h) in Y5-KO mice. The body weght loss in 2 d of Y5-KO mice was almost the same to that in wild-type mice (data not shown). This indicated that the energy consumption rate is not changed in Y5-KO mice, but the obesity in Y5-KO mice is simply due to increased food intake *ad libitum* and on fasting.

CHANGE IN GENE EXPRESSION OF APPETITE-RELATED PEPTIDES IN HYPOTHALAMUS

The compensatory feeding behavior might be due to change in gene expressions of appetite-related neuropeptides other than NPY. Therefore, the change in gene expression of feeding-regulating peptides in hypothalamus was investigated, first, when NPY Y5-KO mice were fed freely. Under ordinary conditions in NPY Y5-KO mice the NPY and AgRP gene expressions were diminished probably due to disuse[4]. The decrease in NPY and AgRP gene expression which expresses in the same neuron group in ARC may be due to increased leptin level following obesity in Y5-KO mice. The gene expression of orexin, MCH, or CART was not changed in hypothalamus; but the POMC gene expression was significantly decreased by RT-PCR and ISH, suggesting that the synthesis of anorexigenic POMC-derived peptides such as -MSH is decreased. This decrease in POMC gene expression appears to be the principal cause of the compensatory overeating.

AUGMENTATION OF FASTING-INDUCED CHANGE IN GENE EXPRESSION IN NPY Y5-KO MICE

Fasting for 48 h produces augmented the fasting-induced food intake, with the concomitant increase in the orexigenic NPY and AgRP gene expressions and decrease in the anorexigenic POMC gene expression in ARC in wild-type mice[4]. Obviously the fasting-induced feeding behavior is augmented in Y5-KO mice (Figure 1). Next we investigated whether changes in gene expressions of appetite-regulated neuropeptides in hypothalamus are involved in 48 h-fasting-induced induced feeding behavior (Figure 4). NPY and AgRP gene expressions were induced by 48 h-fasting more profoundly in NPY Y5-KO mice than those in wild-type mice (Figure 4A and B). In contrast, CART and POMC gene expression were conversely decreased more markedly by fasting in Y5-KO mice. In contrast orexin and MCH (melanin-concentrating hormone) gene expressions were not changed by fasting in the mouse hypothalamus (Figure 4E). Thus, the augmentation of fasting-induced feeding behavior in NPY Y5-KO mice was accompanied by the concomitant fasting-induced changes in NPY/AgRP (both increase) and POMC/CART (both decrease) gene expression. Because the NPY system probably dysfunctions in NPY Y5-KO mice, the concomitant increase in AgRP gene expression and decrease in POMC and CART gene expression are the cause of fasting-induced augmentation of feeding behavior in NPY Y5-KO mice. The compensatory mechanism of feeding is probably due to overfunction of compensation by POMC and partly CART gene expressions which results in the late-onset obesity in Y5-KO mice.

CONCLUSION

Feeding behavior and energy balance are regulated in complicated manner by networks of neurons with classical neurotransmitters and appetite-related peptides. In this article, we showed that the compensatory feeding behavior occurs in NPY Y5-KO mice when the NPY system is probably inhibited, so that the late-onset obesity has appeared. This is probably due to the compensatory change in POMC gene expression. At present the mechanism of compensatory change in POMC/AgRP gene expression is still unknown, and remains to be clarified. This compensatory mechanism is not dependent on the technical procedure of knockout mice. Questions regarding when the compensatory mechanism was been completed, and whether the compensation might occur essential only in adult brain[22,23].

The investigation about the regulation of NPY, AgRP and POMC gene expression in hypothalamic nuclei is useful for elucidation of central feeding regulation and also for development of novel anti-obesity drugs in future.

Abstract

Three peptides, ghrelin, des-acyl ghrelin and obestatin are derived from a common prohormone, preproghrelin by posttranslational processing, originating from endocrine cells in the stomach. To examine the effects of these peptides, we applied the manometric measurement of gastrointestinal motility in freely moving conscious rat models. Ghrelin exerts stimulatory effects on the motility of antrum and duodenum in both fed and fasted state of animals. Des-acyl ghrelin exerts inhibitory effects on the motility of antrum, but not on the motility of duodenum in the fasted state of animals. Obestatin exerts inhibitory effects on the motility of antrum and duodenum in the fed state, but not in the fasted state of animals. NPY Y2 or Y4 receptors in the brain may mediate the action of ghrelin, CRF type 2 receptors in the brain mediate the action of des-acyl ghrelin, whereas CRF type 1 and type 2 receptors in the brain mediate the action of obestatin. Vagal afferent pathways might be involved in the action of ghrelin, but not involved in the action of des-acyl ghrelin, whereas vagal afferent pathways might be partially involved in the action of obestatin.

INTRODUCTION

Ghrelin, des-acyl ghrelin and obestatin are derived from a prohormone, preproghrelin by posttranslational processing. Ghrelin was first identified as endogenous ligand for growth hormone secretagogue receptors (GHS-R) with O-n-octanoyl acid modification at serine 3 position[1]. On the other hand, des-acyl ghrelin has no O-n-octanoyl acid modification[1]. Obestatin was predicted to be formed from preproghelin by a bioinformatic approach[2]. Obestatin was initially reported to be endogenous ligand for orphan G protein-coupled receptor GPR39[2]; however, recent studies have found no specific binding of obestatin to various types of GPR39-expressing cells[3-5]. Ghrelin is a potent stimulator of food intake and gastrointestinal motility[6], while des-acyl ghrelin exerts opposite effects on food intake and gastrointestinal motility[7]. The effects of obestatin on food intake and gastrointestinal motility have been controversial[8-13]. Very recently we have reported that obestatin exerts inhibitory action on gastroduodenal motility in the fed state of conscious rats[14]. Previous studies have shown that food intake and gastroduodenal motility are tightly related. For example, feeding stimulatory peptides such as NPY and ghrelin stimulate gastroduodenal motility[15,16], while feeding inhibitory peptides such as CRF and urocortin inhibit the gastroduodenal motility[17]. Here, we overview different effects of ghrelin, des-acyl ghrelin and obestatin on gastroduodenal motility by using freely moving conscious rat models.

MANOMETRIC MEASUREMENT OF GASTROINTESTINAL MOTILITY IN CONSCIOUS RATS

We developed freely moving conscious rat model to

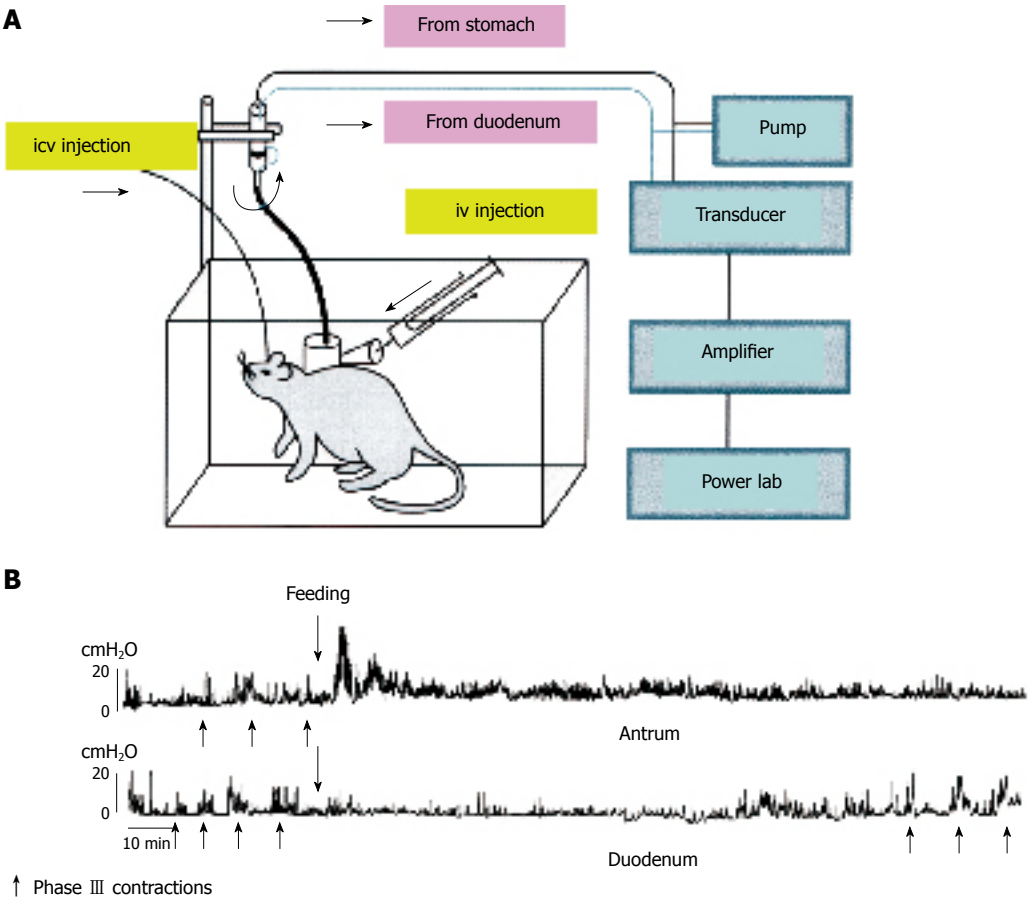

Figure 1 Measurement of gastrointestinal motility. A: Manometric measurement of gastroduo-denal motility in freely moving conscious rats; B: Fasted and fed motor activities in the antrum and duodenum. Phase Ⅲ-like contractions are indicated by arrows.

measure the gastrointestinal motility[15] (Figure 1A). This model permits the measurement of gastrointestinal motility in animals in the physiological fed and fasted states by a manometric method[15]. In the fasted state, the cyclic change of pressure waves were detected in both antrum and duodenum, including the quiescence period during which relatively low amplitude contractions occur (phase I-like contractions), followed by a grouping of strong contractions (phase Ⅲ-like contractions) (Figure 1B). The frequency of the onset of phase Ⅲ-like contractions was 5.3 ± 0.5/h (n = 6) in the antrum and 5.6 ± 0.8/h (n = 6) in the duodenum[16]. After food intake, such fasted motor pattern was disrupted and replaced by a fed motor pattern, which consisted of irregular contractions of high frequency (Figure 1B). The fed pattern continued for 85.7 ± 6.8 min (n = 5) in the duodenum and for more than 240 min in the antrum when rats were given 3 g of chow, and then replaced by the fasted motor pattern[14].

GHRELIN AND GASTRODUODENAL MOTILITY

Intracerebroventricular (icv) and intravenous (iv) injection of ghrelin stimulated the % motor index (%MI) in the antrum and induced the fasted motor activity in the duodenum when given in the fed state of animals[16] (Figure 2A). Icv and iv injection of ghrelin increased the frequency of phase Ⅲ-like contractions in both antrum and duodenum when given in the fasted state of animals[16]. The effects of iv injection of ghrelin on gastroduodenal motility were blocked by iv injection of GHS-R antagonist, but not by icv injection of GHS-R antagonist[16] (Figure 2B). In vagotomized animals, iv injection of ghrelin-induced the fasted motility in both antrum and duodenum when given in the fed state, iv injection of GHS-R antagonist completely blocked phase Ⅲ-like contractions in both antrum and duodenum[16]. Immunoneutralization of NPY in the brain blocked the stimulatory effects of ghrelin on the gastroduodenal motility[16] (Figure 2C). These results indicate that ghrelin released from the stomach may act on the ghrelin receptor on vagal afferent nerve terminals and NPY neurons in the brain may mediate the action of ghrelin on the gastroduodenal motility. *C-Fos* expression in the arcuate nucleus (ARC) in the hypothalamus and in the nucleus tractus solitarius (NTS) induced by intraperitoneal (ip) injection of ghrelin confirmed this effect (Figure 2D). Our previous study showed that immunoneutralization of NPY in the brain completely blocked the phase Ⅲ-like contractions in the duodenum of normal rats, and Y2 and Y4 receptor agonists induced the phase Ⅲ-like contractions in the duodenum when given in the fed state of animals[15]. Combined together, in normal animals ghrelin may stimulate gastroduodenal motility by activating the GHS-R on vagal afferent nerve terminals and affect NPY neurons in the hypothalamus, Y2 and/or Y4 receptors in the brain may mediate the action of ghrelin (Figure 3). Once the brain mechanism is eliminated by truncal vagotomy, ghrelin might be primarily involved in the regulation of fasted molility through GHS-R on the stomach and duodenum.

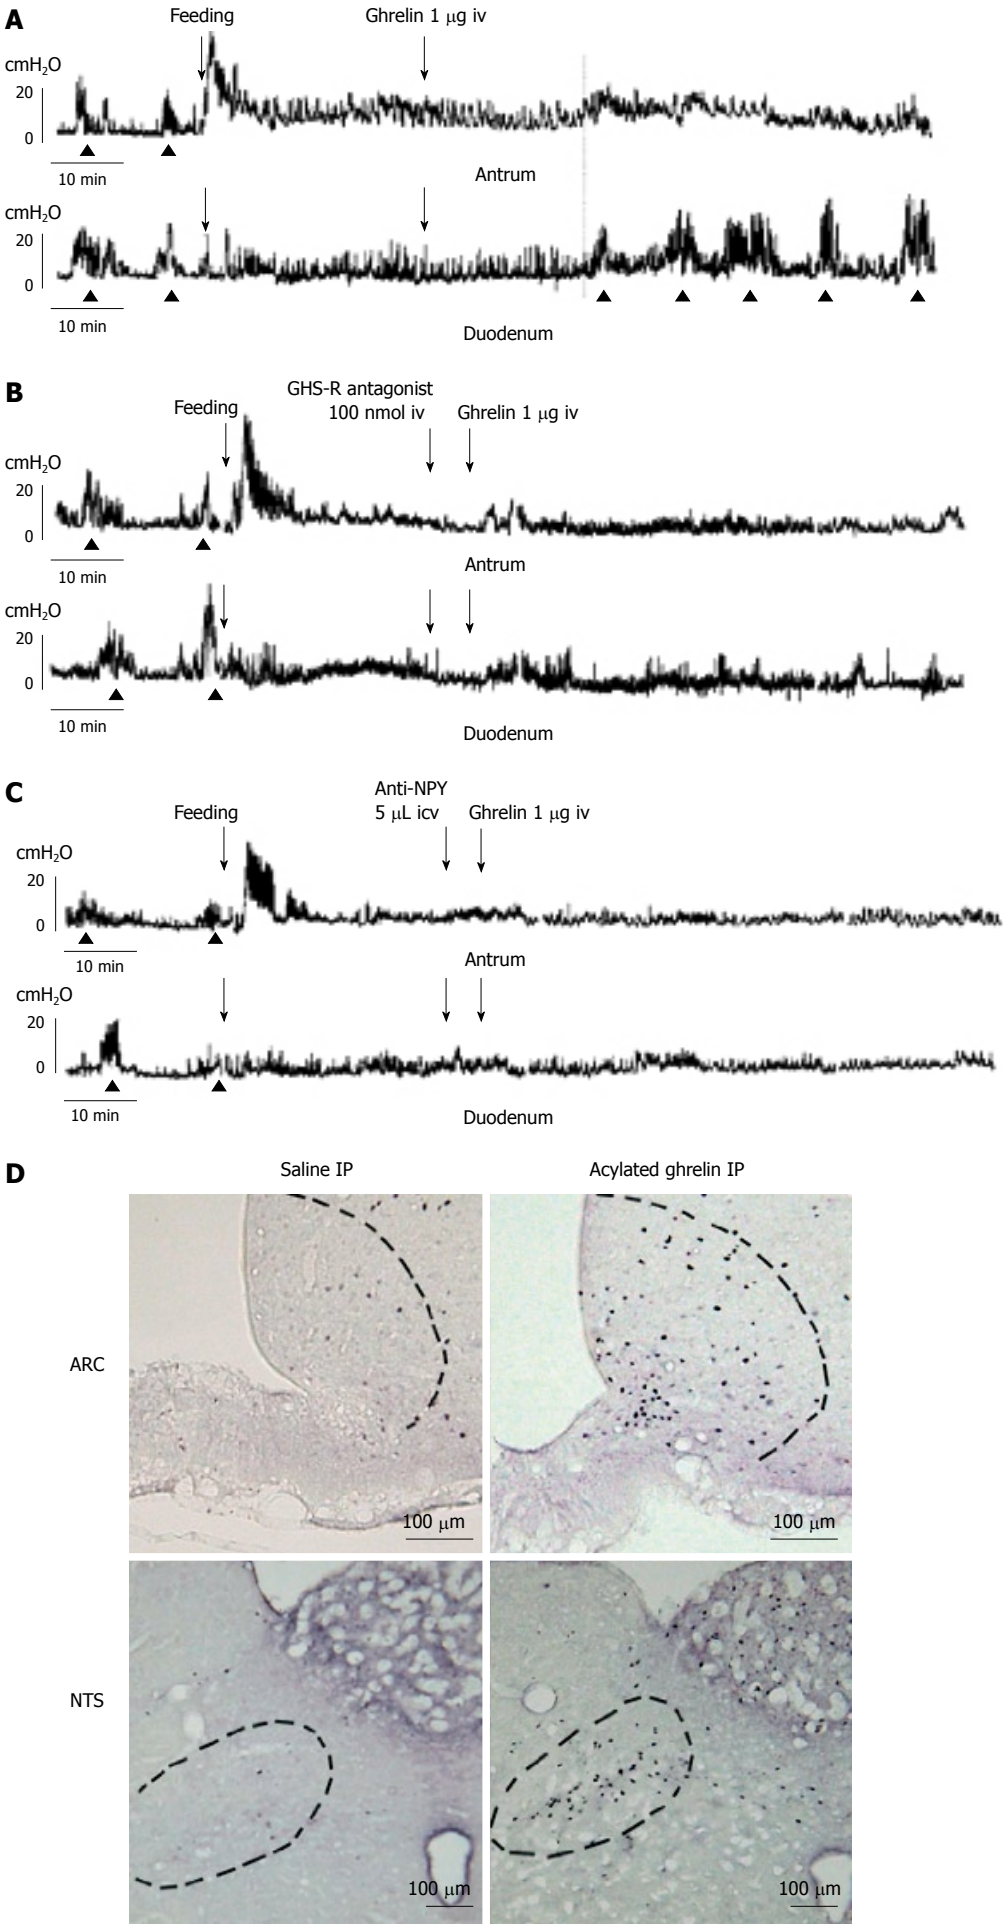

Figure 2 Ghrelin and gastroduodenal motility. A: Effects of iv injection of ghrelin on the fed motor activity of the antrum and duodenum. Iv injection of ghrelin induces the fasted pattern in the duodenum and increases the motor activity in the antrum; B: Iv injection of GHS-R antagonist completely blocks the effect of iv injection of ghrelin; C: Icv injection of NPY antiserum completely blocks the effect of iv injection of ghrelin; D: The density of c-Fos-positive cells in the arcuate nucleus (ARC) and nucleus tractus solitarius (NTS) increases with ip injection of ghrelin compared to saline-injected control.

Figure 3 Summary diagram of different effects of ghrelin, des-acyl ghrelin and obestatin on the gastroduodenal motility and brain mechanisms mediating the action of these peptide.

Human ghrelin has a structural resemblance to human motilin, and human ghrelin receptors exhibit a 50% identity with human motilin receptors[18]. Therefore, the role of ghrelin in the gastrointestinal motility is comparable with that of motilin[19,20]. Motilin originates from the endocrine cells in the duodenum[19], while ghrelin originates from the endocrine cells in the stomach[21], both of them are involved in the regulation of phase Ⅲ contractions in the gastrointestinal tracts. Motilin induces fasted motility in the stomach and duodenum when it is given peripherally, but not when given centrally[20,22], while ghrelin induces fasted motility in the duodenum when it is given both peripherally and centrally[16]. Since it is known that gastric acidification modulates the action of motilin[23], we examined the relationship between the effects of ghrelin on gastroduodenal motility and intragastric pH. The results showed that within 30 min after feeding, low intragastric pH (pH 2.5 ± 0.2) inhibited the effects iv injected ghrelin on gastroduodenal motility, and that this effect was reversed by an increase of intragastric pH (pH 5.4 ± 0.6) within 60 min after feeding, or by pretreatment of famotidine (intragastric pH 6.0-6.7)[16]. These results suggest that the sensitivity of the GHS-R in the gastrointestinal tract might be inhibited by low intragastric pH.

DES-ACYL GHRELIN AND GASTRODUODENAL MOTILITY

Central and peripheral administration of des-acyl ghrelin has been shown to significantly decrease food intake in food-deprived mice and decrease gastric emptying[6]. Transgenic mice with overexpression of the des-acyl ghrelin gene exhibited a decrease in body weight, food intake and fat mass weight accompanied by moderately decreased linear growth compared with their nontransgenic littermates[6]. In rats, des-acyl ghrelin injected intraperitoneally (ip) effectively decreased food intake in food-deprived rats, and decreased the dark-phase food intake in free-feeding rats, but failed to decrease the light-phase food intake in free-feeding rats[7].

Icv and iv injections of des-acyl ghrelin disrupted fasted motility in the antrum, but not in the duodenum[7] (Figire 4A). The frequencies of fasted motility in the antrum were decreased to 58.9% and 54.5% by des-acyl ghrelin injcted icv and iv, respectively[7]. However icv and iv injections of des-acyl ghrelin did not alter fed motor activity in both the antrum and duodenum[7] (Figure 4A). These data indicate that the dominant role of exogenous des-acyl ghrelin affects fasted motility in the antrum, but not in the duodenum. The results showed that capsaicin

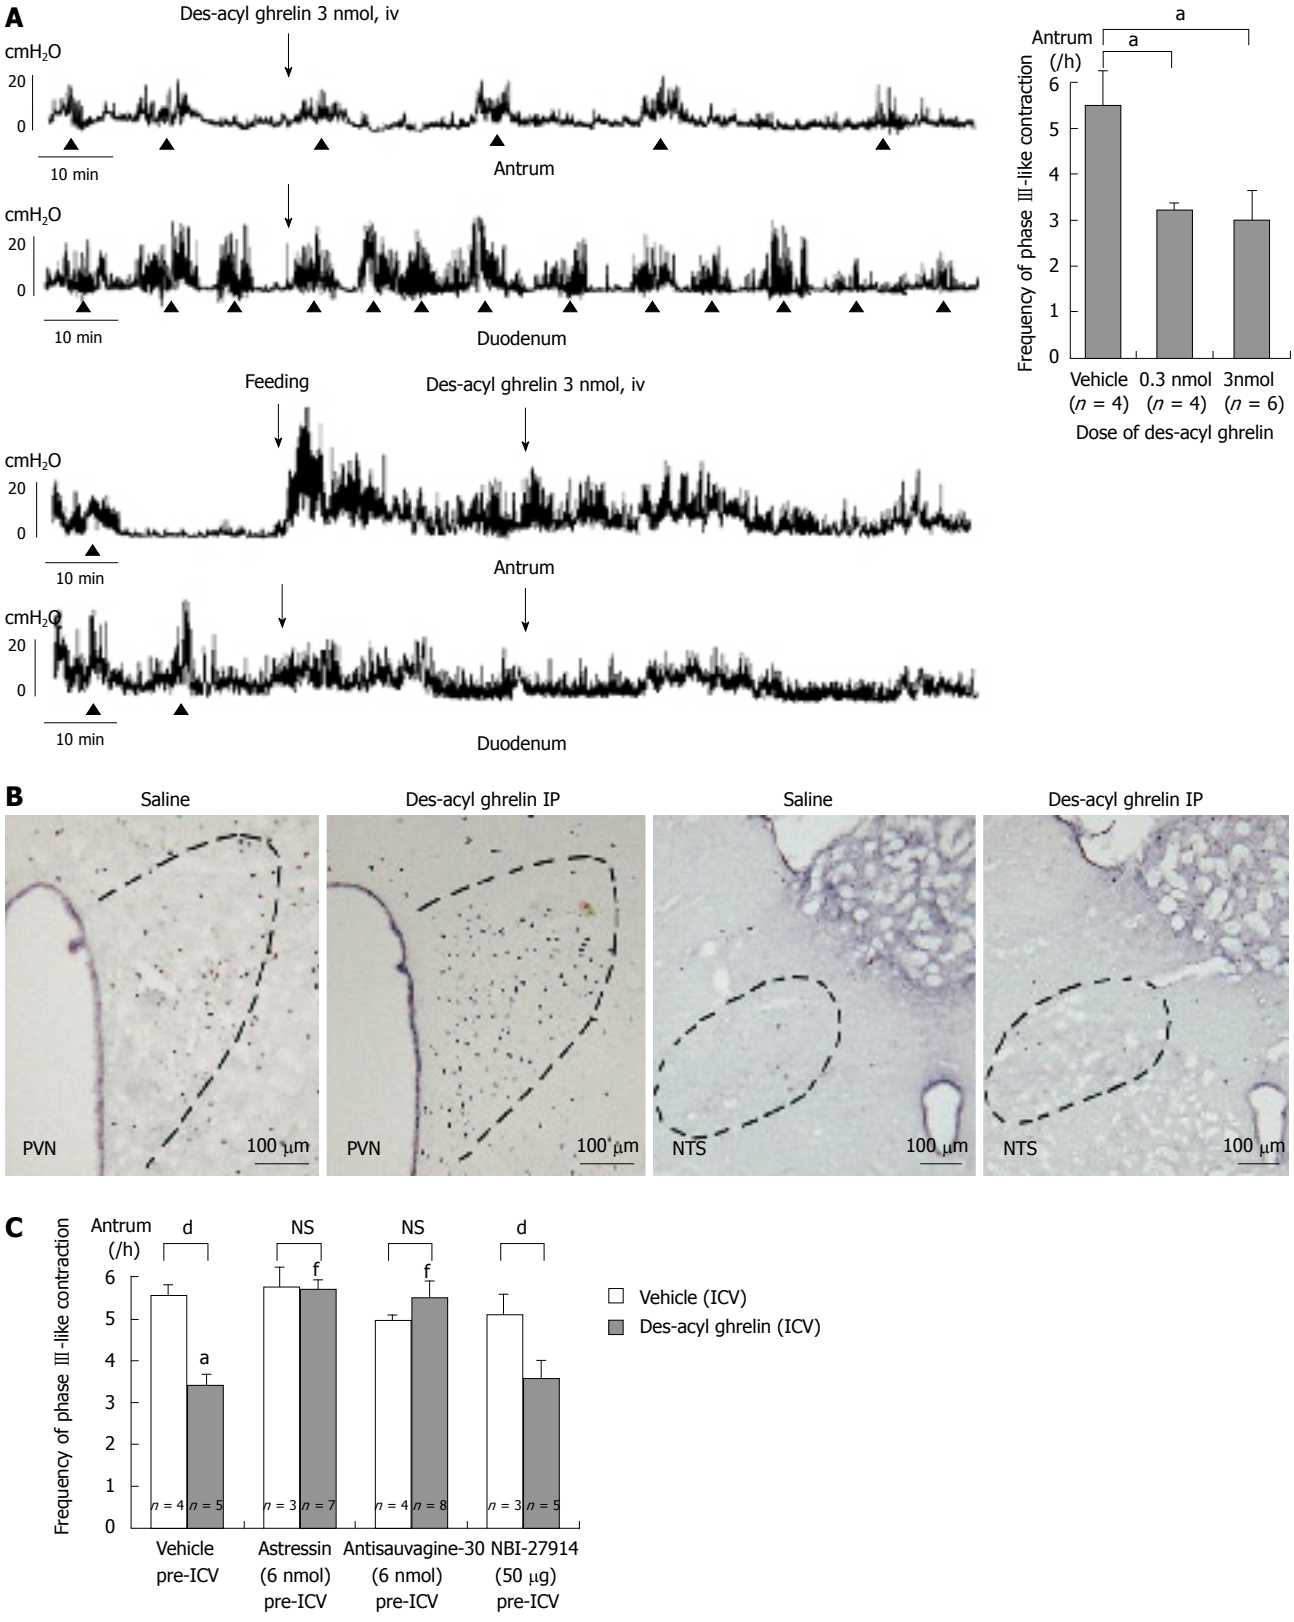

Figure 4 Des-acyl ghrelin and gastroduodenal motility. A: Effects of iv injection of des-acyl ghrelin on the fasted and fed motor activities of the antrum and duodenum. Iv injection of des-acyl ghrelin decreases the frequency of phase Ⅲ-like contractions in the antrum, but not in the duodenum. Iv injection of des-acyl ghrelin does not affect fed motor activity in both antrum and duodenum. [a]$P < 0.05$; B: The density of c-Fos-positive cells in the paraventricular nucleus (PVN) is increased by ip injection of des-acyl ghrelin compared to saline-injected control, whereas that in the NTS is not altered; C: The decreased frequency of phase Ⅲ-like contractions induced by iv injection of des-acyl ghrelin is restored to normal in pretreatment of nonselective CRF receptor antagonist astressin and the selective CRF type 2 receptor antagonist antisauvagine-30, but not CRF type 1 receptor antagonist NBI-27914. [d]$P < 0.01$, [f]$P < 0.001$ compared with a.

treatment did not alter the disruptive effect of iv injection of des-acyl ghrelin on fasted motility in the antrum[7]. These results were consistent with electrophysiological studies, which showed that peripheral administration of

ghrelin suppressed firing of the vagal afferent pathways, whereas des-acyl ghrelin had no effect on vagal afferent pathways[24]. Difference in the involvement of vagal afferent pathways in the action of ghrelin and des-acy ghrelin was confirmed by c-*Fos* expression in the NTS. Ip injection of ghrelin significantly increased the density of c-*Fos*-positive cells in the NTS (Figure 2D), while ip injection of des-acyl ghrelin induced no change in the density of c-*Fos*-positive cells in the NTS compared with vehicle-injected controls[7] (Figure 4B). Taken together, these results suggest that peripherally administered des-acyl ghrelin may cross the blood-brain barrier (BBB) and act directly on the brain receptor and disrupt the fasted motility in the antrum (Figure 3).

The results showed that the centrally administered CRF type 2 receptor antagonist, but not the CRF type 1 receptor antagonist, blocked the effects of centrally and peripherally administered des-acyl ghrelin on gastric motility[7] (Figure 4C). Among two CRF receptor subtypes, CRF type 1 receptor is highly involved in anxiety-related behavior and CRF type 2 receptor is involved in regulating food intake and peripheral functions such as gastric acid secretion or gastric emptying. CRF is a relatively selective ligand for CRF type 1 receptor, whereas urocortin is a ligand more selective for CRF type 2 receptor[25,26]. The density of c-*Fos*-positive cells in the paraventricular nucleus (PVN) was significantly increased by ip injection of des-acyl ghrelin compared to vehicle-injected controls[7] (Figure 4B). These data suggest that peripherally administered des-acyl ghrelin may activate neurons in the PVN by crossing the BBB, and exert inhibitory effects on the antral motility *via* CRF type 2 receptor in the brain (Figure 3).

OBESTATIN AND GASTRODUODENAL MOTILITY

Zhang *et al*[2] first reported that ip injection of obestatin suppressed cumulative food intake, decreased body weight gain, and inhibited gastric emptying and jejunal muscle contraction in mice. Since then, however, the inhibitory effects of obestatin on food intake and gastrointestinal motility have remained controversial[8-13]. Most of the previous studies which showed the negative effects of obestatin on the gastrointestinal motility have only measured the gastric emptying or MMC cycle time as indices for motor activity. In our previous study, for more precise analysis, motor activity in both fed and fasted states was quantified by the %MI, and we measured the time taken to the initiation of phase Ⅲ-like contractions in the antrum and duodenum of conscious rats[14].

Results showed that motor activity in the antrum and duodenum was inhibited when obestatin was given iv to conscious rats in the fed state, but not when it was given in the fasted state[14]. Iv injection of obestatin decreased the %MI of fed motility in the antrum and prolonged the time before the return of fasted motility in the duodenum[14] (Figure 5A). Such inhibitory actions were the opposite of those obtained with ghrelin[16]. The results showed that the inhibitory action of obestatin appeared 30-90 min after iv injection[14] (Figure 5A), which is consistent with the timing of the effects of iv injection of ghrelin (approximately 30 min) on gastroduodenal motility[16] (Figure 2A). Iv injection of obestatin induced a significant increase in the number of c-*Fos*-positive cells in the PVN compared to saline-injected controls[14] (Figure 5B). Immunofluorescence overlap staining showed that the PVN neurons activated by iv injection of obestatin contain CRF or urocortin 2[14] (Figure 5B). The involvement of CRF type 1 and type 2 receptors in the action of obestatin on the gastroduodenal motility was examined[14]. Results showed that the inhibitory action of iv injection of obestatin on the motor activities in the antrum and duodenum were blocked by icv injection of CRF type 1 and type 2 receptor antagonists, suggesting that both types of CRF receptors in the brain may mediate the action of peripherally injected obestatin on gastroduodenal motility[14] (Figure 5C). The results showed that vagal afferent nerve blockade by capsaicin reverses the inhibitory effects of obestatin on duodenal motility, but does not alter the inhibitory effects of obestatin on antral motility[14]. These results suggest that vagal afferent pathways might be involved partially, but not entirely, in the action of obestatin. Involvement of vagal afferent pathways was confirmed by the finding that the number of c-*Fos*-positive neurons in the NTS was increased by iv injection of obestatin[14]. In addition to vagal afferent pathways, it is possible that circulating obestatin acts on brain targets directly by crossing the BBB, because a previous study has shown that there is a rapid influx of iv-injected ^{125}I-labeled obestatin from the blood to the brain[27]. Therefore, the lack of effects of obestatin on antral motility during capsaicin treatment might be explained by direct action of peripherally injected obestatin on brain targets by crossing the BBB, similar to what has been observed for des-acyl ghrelin. We further examined whether obestatin can antagonize the stimulatory effects of ghrelin on gastroduodenal motility[14]. We found that obestatin failed to antagonize the ability of ghrelin either to stimulate the %MI in the antrum or to accelerate the initiation of fasted motility in the duodenum when administrated in the fed state[14]. These results were consistent with previous studies in which obestatin failed to antagonize the ability of ghrelin to stimulate gastric emptying or to shorten the MMC cycle time[8].

GPR39 was initially proposed as the receptor for obestatin[2], and GPR39 expression has been detected in peripheral organs such as the duodenum and kidney, but not in the pituitary or hypothalamus[4]. However recent publications indicate that obestatin is unlikely to be the endogenous ligand for GPR39 on the basis of a lack of specific binding of obestatin to GPR39 receptor-expressing cells[2,4,5,28]. Nevertheless, although binding of obestatin to the receptor GPR39 remains controversial, the functional effect of obestatin on gastrointestinal motility has been clearly demonstrated in our study.

In conclusion, our study indicates that obestatin inhibits gastroduodenal motility in the fed state, but not in

CRF-positive or urocortin 2-positive neurons are overlapped with c-Fos-positive neurons in the PVN; C: The decrease in %MI that is observed 30-60 min after iv injection of obestatin is reversed by icv injection of the CRF type 1 antagonist NBI-27914 and the CRF type 2 receptor antagonist antisauvagine-30. The elongation of the time between injection of obestatin and initiation of phase Ⅲ-like contractions in the duodenum induced by iv injection of obestatin is also reversed by icv injection of NBI-27914 and antisauvagine-30. $^{c}P < 0.05$, $^{f}P < 0.01$, compared with vehicle-injected controls.

the fasted state of conscious rats. In the brain, CRF- and urocortin 2-containing neurons might be activated by iv injection of obestatin, and at the level, CRF type1 and type 2 receptors might be involved in the inhibitory action of obestatin on antral and duodenal motility (Figure 3). Vagal afferent pathways might be involved partially, but not entirely, in these actions of obestatin (Figure 3).

Abstract

Ghrelin is primarily secreted from the stomach and has been implicated in the coordination of eating behavior and weight regulation. Ghrelin also plays an essential role in the mechanism of gastric mucosal defense. Thus, it is important to clarify which diseases primarily influence changes in plasma ghrelin concentrations. *Helicobacter pylori* (*H pylori*) infection is involved in the pathogenesis of gastritis, gastric and duodenal ulcer, gastric carcinoma, and mucosa-associated lymphoid tissue lymphoma. *H pylori* eradication is related to body weight change. Compared, *H pylori* infected and negative subjects with normal body mass index, plasma ghrelin concentration, gastric ghrelin mRNA, and the number of ghrelin producing cells in gastric mucosa are significantly lower in *H pylori* infected subjects than in *H pylori*-negative controls. Plasma ghrelin concentration decreases with the progression of gastric atrophy. Impaired gastric ghrelin production in association with atrophic gastritis induced by *H pylori* infection accounts for the decrease in plasma ghrelin concentration. However, the ratio of plasma acylated ghrelin to total ghrelin levels is higher in patients with chronic atrophic gastritis than in healthy subjects. This may result from the compensatory increase in plasma active ghrelin concentration in response to gastric atrophy. After *H pylori* eradication, gastric preproghrelin mRNA expression is increased nearly 4-fold in most cases. However, changes in plasma ghrelin concentrations before and after *H pylori* cure are not associated with the gastric ghrelin production. Plasma ghrelin changes are inversely correlated with both body weight change and initial plasma ghrelin levels.

INTRODUCTION

Ghrelin, a 28 amino acid peptide isolated from rat and human stomach, possesses strong growth hormone-releasing activity and plays central as well as peripheral roles in food intake, gastric motility, and acid secretion[1-3]. Ghrelin has been shown to evoke weight gain by actions in the hypothalamus[3]. Plasma ghrelin concentrations rise before meals and fall after meals. This peptide also contributes to the regulation of both somatic growth and adipose tissue mass, and is therefore, a short-term, meal-related orexigen as well as a long-term regulator of body weight[4,5]. Circulating ghrelin concentrations in newborns are not associated with gender, body weight, or hormonal parameter[6]. In children and adults, however, plasma ghrelin concentrations are lower in obese subjects compared with those with normal body weight and lean subjects[7]. The decrease of plasma ghrelin concentrations appears to compensate for the positive energy balance in obese individuals[7].

SOURCES OF GHRELIN AND *HELICOBACTER PYLORI* (*H PYLORI*) INFECTION

Ghrelin is predominantly produced by the stomach[8], whereas substantially lower amounts are derived from bowel[9], pituitary, kidney, placenta, hypothalamus[8], lung, kidney, and A-cells of the pancreatic islet. Thus, it is important to clarify which organ primarily influences changes in plasma ghrelin concentrations in various diseases. Although the majority of circulating ghrelin is produced in the stomach, other sources may increase or decrease ghrelin secretion in a compensatory manner. After gastrectomy, for example, plasma ghrelin level is

surprisingly reduced only by 65%[5].

The gastric ghrelin is produced in X/A like-cells of enteroendocrine cells/oxyntic glands in the mammalian gastric mucosa[9]. Thus, there exists the possibility that chronic persistent damage of the gastric mucosa, such as chronic gastritis, might affect ghrelin production, leading to changes in food intake and body weight. *H pylori* is a gram-negative bacterium that colonizes the stomach. *H pylori* infection is involved in the pathogenesis of gastritis, gastric and duodenal ulcer, gastric carcinoma, and mucosa-associated lymphoid tissue lymphoma[10-12]. More than 50% of the adult population is infected with *H pylori* worldwide. *H pylori* infection first leads to atrophic gastritis and intestinal metaplasia, which may further lead to dysplasia and gastric carcinoma. Thus, it is an intriguing question whether *H pylori* infection affects gastric ghrelin production and consequently alters plasma ghrelin concentration.

RELATIONSHIP BETWEEN PLASMA GHRELIN LEVELS AND BODY MASS INDEX IN *H PYLORI* INFECTED PATIENTS

In determining whether ghrelin is involved in long-term energy homeostasis, several studies have found that circulating ghrelin is elevated in individuals with anorexia nervosa[7], reduced in obesity[7,13,14] and normalized with weight gain[13] or weight loss. Circulating ghrelin levels are negatively correlated with the percentage of body fat, fat mass, body mass index (BMI), body weight, insulin, leptin, and T3 in cross-sectional and longitudinal studies examining anorexia nervosa and obesity. In *H pylori*-infected subjects, however, the correlation between BMI and circulating ghrelin levels was weak[15,16]. This suggested that *H pylori* infection could affect plasma ghrelin levels strongly.

EFFECT OF *H PYLORI* INFECTION ON PLASMA GHRELIN LEVELS

Several investigators reported the relationship between plasma ghrelin levels and *H pylori* infection. Nwokolo *et al*[17] reported that plasma ghrelin concentrations increased after the eradication of *H pylori*. On the contrary, Gokcel *et al*[18] reported that *H pylori* infection has no effect on plasma ghrelin levels. Although the relationship between *H pylori* infection and plasma ghrelin concentrations had been still controversial in Western countries, Japanese investigators revealed the effects of *H pylori* infection on plasma ghrelin concentrations[17,18]. The direct relationship between *H pylori* infection and gastric ghrelin production, which could influence plasma ghrelin concentrations, have been demonstrated. Osawa *et al*[19] and Tatsuguchi *et al*[16] investigated the association of *H pylori* infection with gastric ghrelin production in the human stomach concomitantly examining plasma ghrelin concentrations.

PLASMA GHRELIN CONCENTRATIONS ARE LOWER IN *H PYLORI*-POSITIVE SUBJECTS

Several investigators clarified the effect of *H pylori* infection on plasma ghrelin levels. Plasma ghrelin concentrations were significantly lower in *H pylori*-positive patients than in *H pylori*-negative controls[15,16,19]. Its level is obviously independent of sex and BMI and varied among *H pylori* infected subjects even with same BMI[15]. Mean plasma ghrelin levels in *H pylori*-positive subjects remain two-third of those of *H pylori*-negative subjects[19]. In addition to several clinical factors including BMI, food intake, and serum insulin levels[7,20], *H pylori* infection is also another determinant of plasma ghrelin levels as well as body mass index.

EXPRESSION LEVELS OF GASTRIC GHRELIN ARE LOWER IN *H PYLORI*-POSITIVE SUBJECTS

It is important to focus on the gastric mucosa in order to better understand the effects of *H pylori* infection on the alteration of ghrelin expression. Gastric ghrelin mRNA levels were much lower in *H pylori*-positive patients than in *H pylori*-negative controls using real-time quantitative RT-PCR[16,19]. The median of gastric ghrelin mRNA expression levels in *H pylori*-positive subjects was less than one 45th of that in *H pylori*-negative controls[19]. Moreover, plasma ghrelin concentrations were in parallel with the gastric ghrelin mRNA expression levels in *H pylori*-positive patients. Therefore, the attenuation of the ghrelin production in the gastric mucosa accounts for the decrease in the plasma ghrelin concentrations in *H pylori*-positive individuals[19].

GHRELIN-PRODUCING CELLS IN THE GASTRIC MUCOSA ARE FEWER IN *H PYLORI*-POSITIVE SUBJECTS

Ghrelin immuno-reactive cells are seen in the lower half of fundic epithelial glands[9]. Immunoreactivity is concentrated in the basal cytoplasm of the positive cells. The number of ghrelin-positive cells in the gastric mucosa of *H pylori*-positive individuals was significantly lower than those of *H pylori*-negative individuals[19]. Furthermore, the numbers of ghrelin-positive cells in the gastric mucosa fell significantly in accompaniment to the decrease in plasma ghrelin concentrations in *H pylori*-positive subjects[16,19]. These results reinforce the fact that the attenuation of the gastric ghrelin production caused by *H pylori* infection accounts for the decrease in the plasma ghrelin concentrations in *H pylori*-positive individuals.

PLASMA GHRELIN CONCENTRATIONS ARE ASSOCIATED WITH THE DEGREE OF GASTRIC ATROPHY IN *H PYLORI*-POSITIVE SUBJECTS

Since *H pylori* infection first induces gastric atrophy in its pathological course, it is important to clarify the association between plasma ghrelin concentration and degree of gastric atrophy in *H pylori*-positive patients. Several reports revealed that groups of *H pylori*-positive subjects with higher degrees of gastric atrophy tended to have lower plasma ghrelin concentrations, leading to a negative association between plasma ghrelin concentration and gastric atrophy grade[15,16,19]. Moreover, activity and topography of gastritis affects circulating ghrelin levels[21]. Histological severity of mononuclear cell infiltration and glandular atrophy of the corpus significantly influenced the expression levels of ghrelin mRNA, its peptide contents and the density of immunoreactive cells, indicating that gastric ghrelin biosynthesis seems to be affected by chronic mucosal inflammation and/or atrophy in association with *H pylori* infection. In addition, plasma ghrelin concentrations in *H pylori*-positive patients correlated with serum pepsinogen I concentration as well as pepsinogen I / Ⅱ ratio. Pepsinogen I and pepsinogen Ⅱ differ in their location in the stomach. Both are located in the chief and mucous neck cells of the oxyntic gland mucosa in the gastric corpus but only pepsinogen Ⅱ is present in the gastric antrum. A pepsinogen I / Ⅱ ratio < 3 is considered to be a reliable marker for severe atrophic gastritis[22]. Serum levels of pepsinogen I as well as the ratio of pepsinogen I / Ⅱ fell significantly as plasma ghrelin concentrations decreased, indicating the positive association between plasma ghrelin and pepsinogen I concentrations as well as pepsinogen I / Ⅱ ratios in *H pylori*-positive patients[19]. Collectively, these results reveal that plasma ghrelin concentrations are associated with the progression of gastric atrophy. Although geographical differences in the prevalence of atrophic gastritis in Asians and Westerners would require additional consideration, these findings strongly suggest that the reduction of ghrelin-producing cells in the gastric mucosa by *H pylori* infection results in the lower plasma ghrelin concentration in *H pylori*-positive patients.

Checchi *et al*[23] reported that serum ghrelin levels are negatively affected by autoimmune gastritis as well as by *H pylori* associated gastritis, and represent the most sensitive and specific noninvasive markers for selecting those patients at high risk for having gastric damage. Of particular interest is the fact that the measurement of serum ghrelin levels is superior to that of pepsinogen I / Ⅱ ratio and serum gastrin to predict gastric damage.

STOMACH REGULATES ENERGY BALANCE *VIA* ACYLATED GHRELIN AND DESACYLATED GHRELIN

It is known that ghrelin circulates in two different forms: the so-called acylated ghrelin, octanoylated, in serine 3, and the so-called desacylated, without the octanoyl group[24]. This latter form is dramatically less potent on the GHS-receptor than the acylated form[25]. Acylated ghrelin is involved in the regulation of GH secretion, energy balance, gastrointestinal motility, cardiac performance, and anxiety[8]. Administered acylated ghrelin induces body weight gain and adiposity by promoting food intake and decreasing fat use or energy expenditure[26]. In contrast to acylated ghrelin, desacylated ghrelin induces a negative energy balance by decreasing food intake and delaying gastric emptying[27]. The effect is mediated *via* the hypothalamus. Although derived from the same precursor, the inverse effects of these two peptides suggest that the stomach might be involved as an endocrine organ in the regulation of the energy balance.

PLASMA ACYLATED GHRELIN LEVELS ARE HIGHER IN PATIENTS WITH CHRONIC ATROPHIC GASTRITIS

Total plasma ghrelin concentrations decrease in patients with gastric atrophy secondary to *H pylori* infection, and the levels are related to the degree of atrophy. These finding might be explained by the loss of ghrelin-producing cells caused by inflammatory and/or atrophic changes. Campana *et al*[28] reported that plasma acylated ghrelin levels were higher in patients with chronic atrophic gastritis than in healthy subjects. This opposite tendency compared to total plasma ghrelin concentration may result from the compensatory increase in plasma active ghrelin concentration in response to gastric atrophy. This hypothesis seems to be supported by a recent report showing that a significant decrease in gastric pH was found after injection of exogenous ghrelin. Gastric atrophy causes an increase gastric pH, leading to an increase in serum gastrin levels. Both the increase in acylated ghrelin and gastrin could represent a compensatory mechanism to stimulate gastric acid production.

GHRELIN HAS A PROTECTIVE EFFECT AGAINST MUCOSAL INJURY OF STOMACH

H pylori infection induces gastric mucosal damage including gastric ulcer and chronic gastritis. It is an intriguing question whether lower plasma ghrelin level in *H pylori*-infected patients affects gastric mucosa. Sibilia *et al*[29] reported that ghrelin protects against ethanol-induced gastric ulcers in rats. Similarly, Konturek *et al*[30] reported that ghrelin expression of gastric mucosa is enhanced after exposure to ethanol, and ghrelin exhibits a strong gastroprotection due to its anti-inflammatory action mediated by prostaglandins. The gastroprotective effect of ghrelin is accompanied by a significant rise in the gastric blood flow, which is known to play an essential role in the mechanism of gastric mucosal defense. This ghrelin-induced hyperemia could be prob-

ably attributed to the direct vasodilatory effect of this peptide.

PLASMA GHRELIN LEVEL AND BODY WEIGHT

Eradication of *H pylori* has been a standard therapy for peptic ulcer disease[10,11] and improves gastritis[10]. Much attention has recently been directed to the relationship between obesity and *H pylori* infection. Several studies showed that *H pylori* infection is inversely related to obesity. For example, Wu *et al*[31] reported that the seropositivity of *H pylori* infection was significantly lower in morbid obesity patients. Furuta *et al*[32] showed the body weight gain after *H pylori* cure. As ghrelin is mainly synthesized and secreted by gastric mucosa, it has been assumed that the inverse effect of *H pylori* infection on body weight may attribute to the difference of plasma ghrelin concentrations in patients with or without *H pylori* infection[33]. This hypothesis states that an increase of gastric ghrelin production after *H pylori* cure may elevate plasma ghrelin concentration resulting in body weight gain.

PLASMA GHRELIN LEVELS AND BODY WEIGHT GAIN AFTER *H PYLORI* ERADICATION

Do plasma ghrelin levels affect body weight gain after *H pylori* eradication, or body weight gain affect plasma ghrelin levels? Gastric ghrelin production is decreased by *H pylori* infection and increased by eradication therapy[19]. As ghrelin is a body weight regulating peptide, much attention has been paid to the nutritional status and the dynamics of gastric and plasma ghrelin in response to *H pylori* infection[31,32]. In this respect, Nwokolo *et al*[17] reported that plasma ghrelin levels increased at 6 wk after *H pylori* cure in 10 patients in UK. Because plasma ghrelin levels increased significantly by 75%, they proposed that increased ghrelin following *H pylori* eradication may play a role in obesity. This could lead to increased appetite and weight gain, and contribute to the increasing obesity seen in Western populations where *H pylori* prevalence is low. Also, Czesnikiewicz-Guzik *et al*[34] reported that plasma ghrelin levels increased significantly to two-fold levels at 4 wk after *H pylori* cure in 41 patients in Poland. After Nwokolo's report, it has been believed that plasma ghrelin concentrations will increase after *H pylori* cure due to the increase of gastric ghrelin production, leading to body weight gain[16]. However, their reports suggested that plasma ghrelin levels increased, but did not reveal a changes of plasma ghrelin levels in patients with body weight gain after *H pylori* cure. Plasma ghrelin levels decrease as a compensatory effect in obesity patients who has positive energy balance. Therefore, it is questionable whether plasma ghrelin levels increase in a condition of body weight gain after eradication. Another study found that plasma ghrelin levels were unaffected[35]. In fact, plasma ghrelin concentration is not simply regulated by the levels of gastric ghrelin production. Even in healthy humans, plasma ghrelin concentration is tightly correlated with body weight[7]. Therefore, it has been proposed[36] that it should be re-examined whether the rise in plasma ghrelin following *H pylori* eradication exists and whether it can be an important determinant of body weight increase. It is possible that only a subpopulation of infected patients may show a rise in ghrelin following eradication.

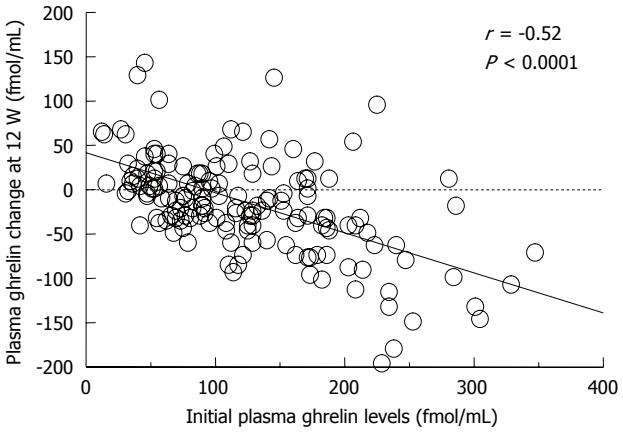

Figure 1 The relationship between the initial plasma ghrelin levels and the change in plasma ghrelin levels at 12 wk after *H pylori* cure. The change was obtained by subtracting the levels before the treatment from the levels at 12 wk after. The change in 12 wk correlated inversely with initial plasma ghrelin levels. This figure is cited from *J Gastroenterol* 2006; 41: 954.

DISPARATE CHANGES IN PLASMA GHRELIN AFTER *H PYLORI* CURE

The effect of *H pylori* eradication on plasma ghrelin concentration was reported in 134 Japanese patients[37]. Interestingly, mean plasma ghrelin concentrations decreased significantly from 120 fmol/mL before *H pylori* eradication to 103 fmol/mL at 12 wk after *H pylori* eradication. However, its levels after treatment changed diversely among enrolled patients. In fact, levels increased in 50 patients and decreased in 84 patients. There are some potential mechanisms leading to disparate changes in plasma ghrelin levels after *H pylori* eradication. The relationship between the initial plasma ghrelin levels and their changes were analyzed after *H pylori* cure. Figure 1 shows the relationship between the initial plasma ghrelin levels, and the changes in plasma ghrelin concentration at 12 wk after *H pylori* cure. Interestingly, higher initial plasma ghrelin levels decreased after the cure, but lower initial plasma ghrelin levels did not change significantly. The change of plasma ghrelin concentration after 12 wk was inversely correlated with the initial plasma ghrelin levels.

EXPRESSION LEVELS OF GASTRIC GHRELIN INCREASES AFTER *H PYLORI* CURE

The effect of *H pylori* eradication on the ghrelin pro-

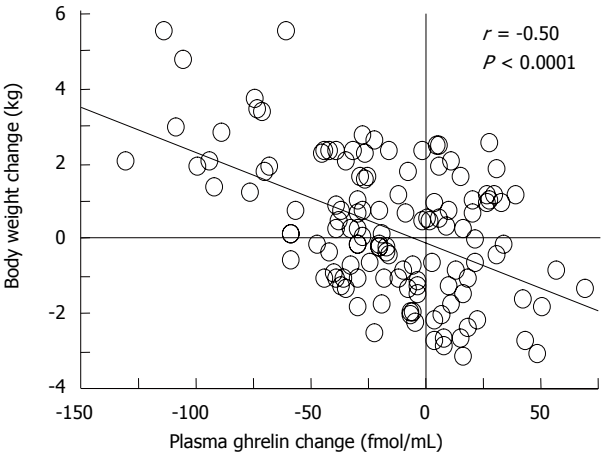

Figure 2 The relationship between the plasma ghrelin change and body weight change at 12 wk after *H pylori* cure. The alteration of plasma ghrelin levels correlated inversely with body weight change after *H pylori* cure. This figure is cited from *J Gastroenterol* 2006; 41: 954.

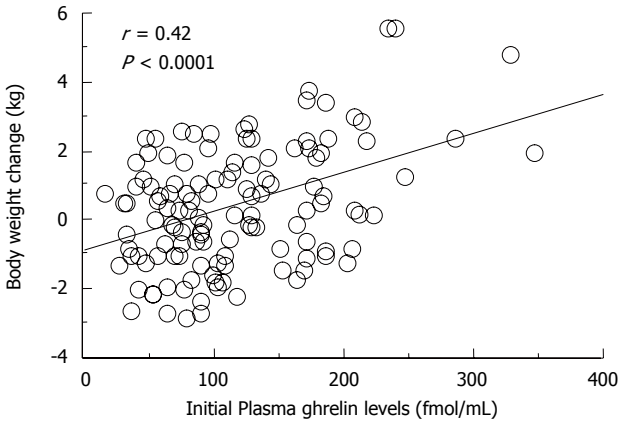

Figure 3 The relationship between the initial plasma ghrelin levels and body weight change at 12 wk after *H pylori* cure. Initial plasma ghrelin levels correlated positively with body weight changes. This figure is cited from *J Gastroenterol* 2006; 41: 954.

duction in the gastric mucosa was reported in several studies. Tatsuguchi *et al*[16] reported that ghrelin immunoreactive cells increase in the gastric mucosa after *H pylori* eradication irrespective of the recovery of glandular atrophy. Osawa *et al*[37] also reported that the number of ghrelin positive cells per oxyntic gland was increased in 77 patients and was unchanged in 57 patients after *H pylori* eradication. The number of ghrelin producing cells tend to increase despite the change of plasma ghrelin levels before and after *H pylori* cure. In recent reports, gastric glandular atrophy recovers gradually over the long term after *H pylori* eradication. Arkkila *et al*[38] reported that atrophy can diminish or even disappear, especially in the antrum, during a 1-year follow-up after eradication of infection. If glandular atrophy recovers by *H pylori* cure, the number of ghrelin producing cell may increase more and more. Osawa *et al*[37] compared gastric preproghrelin mRNA expression levels before and 12 wk after treatment using the corpus mucosa. Median preproghrelin mRNA expression was increased nearly 4-fold after *H pylori* cure. Preproghrelin mRNA expression was also increased in the antral mucosa. No correlation was observed between the changes in plasma ghrelin and those of gastric preproghrelin mRNA or ghrelin positive cells after *H pylori* cure. Similarly, Isomoto *et al*[21] reported that preproghrelin mRNA expression was increased in the corpus mucosa at 4 wk after *H pylori* cure. Therefore, gastric ghrelin production is enhanced after *H pylori* eradication even in patients with decreased plasma ghrelin concentrations.

BODY WEIGHT CHANGES CORRELATE INVERSELY WITH CHANGES IN PLASMA GHRELIN CONCENTRATION

Body weight gain is a well-known effect of *H pylori* eradication and plasma ghrelin concentration is influenced by body weight change[38,39]. The question as to whether ghrelin is involved in weight gain after *H pylori* cure has been discussed[19]. Figure 2 showed clearly that the change in plasma ghrelin is inversely correlated with body weight change after *H pylori* cure[37]. Plasma ghrelin decreased in 23 of 28 patients (82%) with more than 2 kg of weight gain, and in all 7 patients with more than 3 kg of weight gain. These data suggest that plasma ghrelin concentration after *H pylori* cure is more strongly influenced by body weight change than the increase of gastric preproghrelin mRNA and ghrelin producing cells.

In contrast, patients with less than 2 kg of body weight gain or with body weight loss had minor changes of plasma ghrelin levels. Increased plasma ghrelin levels after the cure in European studies can be associated with patients having minor change of body weight. The racial difference of enrolled subjects may account for the discrepancy. In this respect, Asians including Japanese are more prone to central adiposity than are white individuals[40]. As body fat storage is closely associated with plasma ghrelin levels, the racial difference of body fat distribution may account for the discrepancy.

INITIAL PLASMA GHRELIN LEVELS CAN BE A PREDICTIVE FACTOR OF BODY WEIGHT GAIN AFTER *H PYLORI* ERADICATION

Initial plasma ghrelin levels before eradication therapy were significantly higher in those whose plasma ghrelin decreased after treatment[37]. In addition, these subjects had a significantly greater increase in body weight than those with increased plasma ghrelin after treatment. Figure 3 shows the positive correlation between the initial plasma ghrelin levels and body weight changes. In particular, 12 of 14 patients (86%) with more than 200 fmol/mL of initial ghrelin levels had an increase in body weight, suggesting high levels of initial plasma ghrelin can be a predictive factor of body weight gain after *H pylori* eradication. The correlation between initial

plasma ghrelin levels and weight changes suggests the participation of ghrelin in the weight gain after *H pylori* eradication. The weight gain after *H pylori* eradication does not simply result from an increase in plasma ghrelin by the recovery of gastric ghrelin production.

However, additional research is needed to clarify the relationship between the body weight gain and the plasma ghrelin levels after *H pylori* cure in Western population.

CONCLUSION

Plasma ghrelin concentrations are influenced by the presence of chronic gastritis in association with *H pylori* infection. The decrease in gastric ghrelin production accounts for lower concentrations of plasma ghrelin in *H pylori*-positive individuals. Gastric ghrelin production increases after *H pylori* cure. Plasma ghrelin concentrations decrease in subjects with body weight gain after *H pylori* cure. Initial plasma ghrelin levels before eradication can be a predictive factor for body weight gain after *H pylori* cure.

Abstract

Ghrelin, a novel growth hormone-releasing peptide, was originally isolated from rat and human stomach. Ghrelin has been known to increase the secretion of growth hormone (GH), food intake, and body weight gain when administered peripherally or centrally. Ghrelin is also known to stimulate the gastric motility and the secretion of gastric acid. In the previous studies, the action of ghrelin on acid secretion was shown to be as strong as that of histamine and gastrin in *in-vivo* experiment. In the studies, the mechanism for the action of ghrelin was also investigated. It was shown that vagotomy completely inhibited the action of ghrelin on the secretion of gastric acid suggesting that vagal nerve is involved in the mechanism for the action of ghrelin on acid secretion. As famotidine did not inhibit ghrelin-induced acid secretion in the study by Masuda *et al*, they concluded that histamine was not involved in the action of ghrelin on acid secretion. However, we have shown that famotidine completely inhibited ghrelin-induced acid secretion and histidine decarboxylase (HDC) mRNA was increased in gastric mucosa by ghrelin injection which is inhibited by vagotomy Our results indicate that histamine is involved in the action of ghrelin on acid secretion. Furthermore synergistic action of gastrin and ghrelin on gastric acid secretion was shown. Although gastrin has important roles in postprandial secretion of gastric acid, ghrelin may be related to acid secretion during fasting period or at night. However, further studies are needed to elucidate the physiological role of ghrelin in acid secretion.

GHRELIN AND THE REGULATION OF GASTRIC ACID SECRETION

Ghrelin, a novel growth-hormone-releasing peptide, was originally isolated from rat and human stomachs[1] and was demonstrated to localize in the endocrine cells of the stomach and hypothalamus[1,2]. Ghrelin has been known as a multifunctional hormone. Ghrelin increases secretion of growth hormone (GH), food intake, and body weight gain when administered peripherally or centrally[1,3-9]. Ghrelin has also positive cardiovascular effects. In humans, infusion of ghrelin decreases systemic vascular resistance and increases cardiac output in patients with heart failure. On the functions of stomach, ghrelin was also known to stimulate gastric motility and the secretion of gastric acid when administered peripherally or centrally[10,11]. As ghrelin has such multiple actions on many organs, physiological roles of ghrelin *in vivo* might be important even if many of them are not elucidated.

The mechanism for the action of ghrelin on feeding, growth hormone secretion and the secretion of gastric acid was studied and demonstrated that the vagal nerve was involved in the action of ghrelin[10-12]. When ghrelin was administered peripherally, ghrelin induced c-fos expression in the neurons of the arcuate nucleus of rats[12]. However, ghrelin did not induce c-fos expression in the neuron in both capsaicin-treated rats and vagotomized rats[12]. The effects of ghrelin on feeding were also abolished with capsaisin treatment and vagotomy[12]. These results suggest that gastric vagal afferent is the major pathway conveying ghrelin's signals for starvation and GH secretion to the brain. On the action of ghrelin on the secretion of gastric acid, vagal nerve was indicated to be involved in the action of ghrelin[10]. Masuda and coworkers indicated that the action of ghrelin on the secretion of gastric acid was abolished by the pretreatment

with atropine or bilateral cervical vagotomy[10]. Date and co-workers demonstrated that intracerebroventricular (ICV) administration of ghrelin induced the increase in the secretion of gastric acid and vagotomy and the pretreatment with atropine abolished the action of ghrelin[11]. They also demonstrated that ICV administration of ghrelin induced c-fos expression in the neurons of the nucleus of the solitary tract (NTS) and the dorsal motor nucleus of the vagus nerve (DMX)[11]. Taken together, these results suggest that vagal nerve plays important roles in the action of ghrelin on the secretion of gastric acid.

GHRELIN AND HISTAMINE RELEASE

As dictated above, ghrelin stimulates the secretion of gastric acid[10,11]. The mechanism for the action of ghrelin on acid secretion was also demonstrated that the vagal nerve was involved in the action of ghrelin[10,11]. However, the details of the mechanism after the activation of vagal nerve by ghrelin administration remains to be elucidated.

In the mechanism for acid secretion, vagal nerve has been known to play an important role, especially in the regulation by central nervous system[13] and in the stimulation by the distenstion of stomach[14]. Vagal nerve has stimulatory and inhibitory actions on acid secretion[15,16] and it contains and releases several neurotransmitters such as acetylcholine[17], gastrin-releaseing peptide (GRP)[18], substance P[19]. Calcitonin gene-related peptide[19] and pituitary adenylate cyclase activating peptide (PACAP)[20]. Among these, GRP has a stimulatory action on gastrin release from G cells[21]. Gastrin released by GRP stimulation is the most important physiological secretagogue and it has a primary role in postprandial acid secretion[22]. Gastrin stimulates acid secretion *via* enterochromaffin-like cells (ECL cell)[23]. Another transmitter, PACA, was also found to increase histamine release from ECL cell[24]. PACAP-immunoreactive nerve fibers are abundant in the gastric mucosa of both rat and humans[25] and gastric ECL cells possesses PACAP receptors(PAC1)[26]. Gastrin is now known as major stimulant of histamine release from gastric ECL cells[27]. Histamine released from ECL cells acts on parietal cells through H_2 receptor[28]. It was indicated that the activation of vagal nerve induced an increase in histamine release from gastric mucosa[29]. Accordingly it is plausible that histamine release may be involved in the increased acid secretion induced by administration of ghrelin.

In a previous report, Masuda *et al*[10] demonstrated that vagal nerve is involved in the action of ghrelin on acid secretion. However, they concluded that histamine was not involved in the action of ghrelin on acid secretion, as famotidine did not inhibited ghrelin-induced acid secretion[10]. Tthe mechanism that was demonstrated by Masuda seemed to require further investigation**,** because the vagal stimulation[29], as well as transmitter PACAP, is known to increase release of histamine from ECL cells[24]. Therefore, if ghrelin administration stimulates the vagal nerve, an increase in histamine release would consequently occur.

Previously we attempted to clarify whether histamine

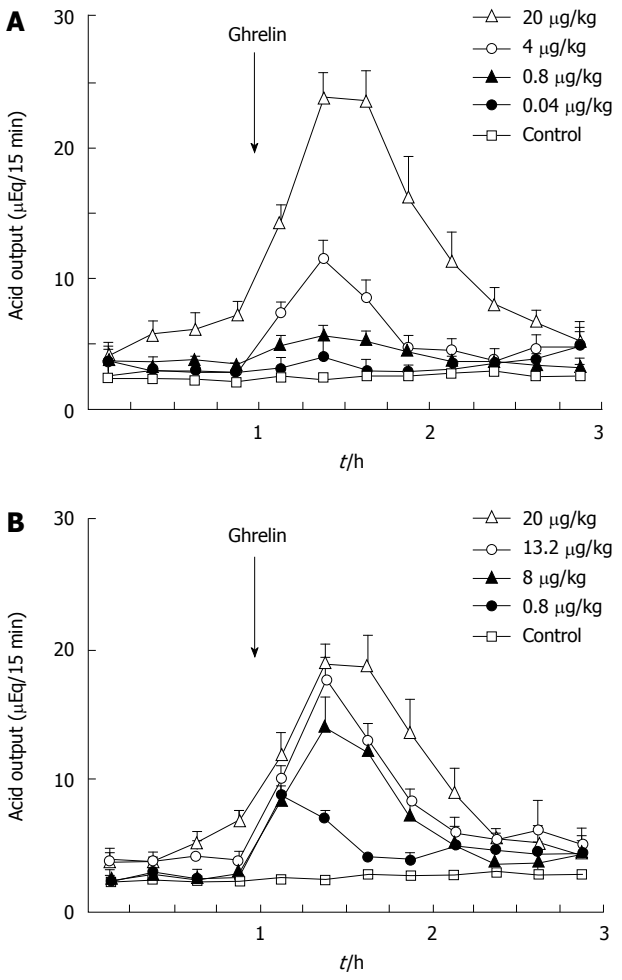

Figure 1 Effects of rat ghrelin (A) and gastrin-17 (B) on acid output in gastric lumen-perfused rats. A: Time course of acid output by Ⅳ administration of ghrelin (0.04, 0.8, 4, 20 μg/kg) in gastric lumen perfused rats; B: Time course of acid output by Ⅳ administration of gastrin (0.8, 8, 13.2 and 20 μg/kg) in gastric lumen perfused rats. Saline was administered in control rats. Each value represents the mean ± SE of acid output at 15 min intervals. *n* = 4, 5, 6, 7. Reprinted with permission[30].

is involved in the action of ghrelin[30]. In our study, ghrelin (0.8-20 μg/kg) dose-dependently increased gastric acid secretion and the action of ghrelin (20 μg/kg, 6×10^{-9} mol/kg) on acid secretion was almost as efficient as that of gastrin (20 μg/kg, 9.2×10^{-9} mol/kg) (Figure 1) [30]. The study demonstrated that vagotomy abolished the increase in acid secretion by ghrelin administration (Figure 2)[30] and also that famotidine completely inhibited the stimulatory action of ghrelin [30]. Furthermore, administration of ghrelin significantly increased HDC mRNA concentration of gastric mucosa (Figure 3) [30]. Vagotomy also abolished the increase in HDC mRNA by ghrelin administration (Figure 4) [30]. Furthermore, in the study, isolated vascularly-perfused stomachs that lacked vagal innervation were prepared in order to examine the effect of ghrelin on histamine release. Although the infusion of gastrin (2.1 μg/10 min) increased histamine release, ghrelin (5 μg/10 min) did not induce histamine release from isolated rat stomachs. Taken together, the results demonstrate the mechanism of action of ghrelin involves the vagal nerve as well as increases in release and synthesis of histamine,

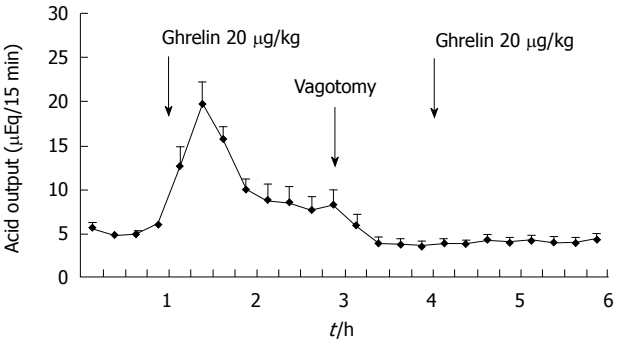

Figure 2 Effect of famotidine on ghrelin-stimulated acid output in gastric lumen-perfused rats. Time course of acid output by the Ⅳ administration of famotidine (0.33 mg/kg) and ghrelin (20 μg/kg) in gastric lumen-perfused rats. Famotidine was administered intravenously 15 min before ghrelin injection. Each value represents the mean ± SE of acid output at 15 min intervals. n = 4. Reprinted with permission[30].

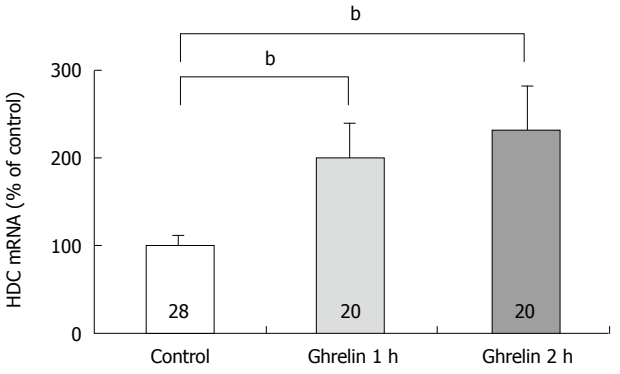

Figure 3 Effect of ghrelin on the concentration of HDC mRNA in rat gatsric mucosa. Ghrelin (20 μg/kg) was administered intravenously. The concentration of HDC mRNA was measured by real time RT-PCR using LightCycler. Control: The concentration of HDC mRNA in gastric mucosa of rats with saline administration. 1 h; the concentration of HDC mRNA in gastric mucosa of rats with ghrelin administration, the stomachs were excised 1 h after the administration. 2 h; the concentration of HDC mRNA in gastric mucosa of rats with ghrelin administration, the stomachs were excised 2 h after the administration. Each value represents the mean ± SE of HDC mRNA demonstrated as % of control. n = 28, 20, 20. ^bP < 0.01. Reprinted with permission[30].

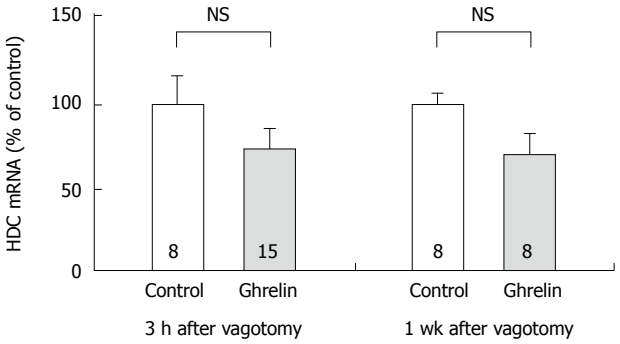

Figure 4 Effect of vagotomy on the concentration of HDC mRNA in rat gastric mucosa stimulated by ghrelin administration. Subdiaphragmatic vagotomy was performed in rats 3 h or 7 d before the experiments. Ghrelin (20 μg/kg) was administered Ⅳ. The concentration of HDC mRNA was measured by real time RT-PCR using Light Cycler. Control: The concentration of HDC mRNA in gastric mucosa of rats with saline administration. Ghrelin: The concentration of HDC mRNA in gastric mucosa of rats with ghrelin administration, the stomachs were excised 2 h after the administration. 3 h after vagotomy, the experiments were performed 3 h after vagotomy. 1 wk after vagotomy, the experiments were performed 7 d after vagotomy. Each value represents the mean ± SE of HDC mRNA demonstrated as % of control. n = 8 or 15. NS: Not significant. Reprinted with permission[30].

consequently induces the stimulation of parietal cells.

The reason that Masuda *et al* did not observe the inhibitory effect of famotidine on the action of ghrelin is unclear. However, there is a difference between the administration methods in the study by Matsuda *et al* and those used in our study. We administered ghrelin intravenously, while Matsuda *et al* administered ghrelin subcutaneously. The difference in the results may thus be due to the difference in the administration methods.

GHRELIN AND GASTRIN IN THE MECHANISM FOR THE REGULATION OF GASTRIC ACID SECRETION

Gastrin is known to be released into the circulation in response to food[31], and to play an important roles in increasing postprandial acid secretion[22], and to exert activity on ECL cells[23]. It was shown that vagotomy did not affect the maximal response of acid secretion to gastrin administration thus indicating that the action of gastrin was not primarily dependent on vagal nerve[32]. On the other hand, ghrelin is released during fasting period, and food intake suppresses its release[33]. As vagotomy completely abolished ghrelin-induced acid secretion and HDC mRNA production, ghrelin is thought to induce histamine release *via* vagal nerve activation, consequently resulting in increased acid secretion by parietal cells. Accordingly the mechanism for the secretion of ghrelin appears to differ from that of gastrin.

Recently, however, synergistic action of ghrelin and ghrelin on gastric acid secretion was reported from two groups[34,35]. Fukumoto *et al* have shown that Ⅳ administration of gastrin induced transient increases of ghrelin levels within 10 minutes and that simultaneous administration of both gastrin and ghrelin resulted in a synergistic increase of gastric acid secretion in rat[35]. They supposed that gastrin may directly stimulate ghrelin release and both hormones may increase gastric acid secretion synergistically[35]. We also presented the data that shows synergistic effects of gastrin and ghrelin on gastric acid secretion and histamine production by gastric mucosa which involves the vagal nerve[34]. Circulating ghrelin decreases soon after the initiation of feeding, gastrin oppositely increase with food intake. Generally simultaneous increases of gastrin and ghrelin do not occur. Therefore physiological role of this synergistic action of these hormones remain to be clarified. We are supposing this synergistic action may occurs in subjects with Hp infection that induces hypergastrinemia in fasting when ghrelin level rises.

CENTRAL REGULATION OF GASTRIC ACID SECRETION BY GHRELIN

The peripheral vagal nerve and the nuclei of central nerves are thought to be involved in the mechanism of

action of ghrelin[6,12]. Ghrelin administered Ⅳ induced Fos expression only in the neurons of the arcuate nucleus of the hypothalamus in rats[12]. On the other hand, ICV injection induced Fos expression in the neurons of NTS and DMX of the medulla oblongata and other nuclei such as several hypothalamic nuclei, the dentate gyrus, the hippocampus, and the cerebral cortex[6,11]. The hypothalamus is known to be the center for hunger and satiety[36]. In particular, the arcuate nucleus of the hypothalamus is activated by ghrelin administration and this region is known to have important role in controlling food intake relating to the action of leptin[37]. Date *et al*[12] indicated that Ⅳ injection of ghrelin induces Fos expression in neuropeptide Y (NPY)-producing and growth hormone-releasing hormone (GHRH)-producing neurons in the arcuate neucleus. It is known that injection of NPY into cerebral ventricles or directly into the hypothalamus of rats potently stimulates food intake[38]. Therefore, the activation of NPY neuron in the arcuate nucleus of the hypothalamus by ghrelin is thought to relate to the stimulatory effect of ghrelin on food intake. However, it is still unclear whether activation of the arcuate nucleus induces increase in the secretion of gastric acid. It has been shown that ghrelin receptors are synthesized in vagal afferent neurons and transported to the afferent terminals[12]. Date *et al*[12] suggested that the gastric vagal afferent nerve, which is capsaicin sensitive, is the major pathway conveying ghrelin signals for starvation and growth hormone secretion to the brain. It is possible that the same pathway mediates the mechanism for the action on the secretion of gastric acid when ghrelin is administered Ⅳ. On the other hand, as described above, DMX, NTS and several nuclei of the brain are apparently activated by ICV administration of ghrelin[6,11]. As DMX has been demonstrated to relate to the secretion of gastric acid, the activation of DMX may be related to the central nervous system mechanism for the action of ghrelin on acid secretion. Furthermore, vagotomy also abolished the stimulatory effect of ICV administration of ghrelin on acid secretion, thus the vagal efferent may also be involved in the action of cerebral ghrelin[11].

The neuronal pathway mediating the peripheral ghrelin appears to be different from that mediating central ghrelin. Although the vagal afferent nerve was demonstrated to be involved in the action of peripheral ghrelin[10,12], the role of vagal efferent nerve remained to be elucidated. However, as the action of cerebral ghrelin is thought to involve vagal nerve, possibly vagal efferent nerve, and the results of our previous study demonstrated that the actions of ghrelin on acid secretion and HDC mRNA production require the vagal nerve to be intact, it is possible that vagal efferent nerve is also involved in the action of peripheral ghrelin. A likely hypothesis based on the results of our study is that peripheral ghrelin stimulation of gastric acid secretion initiates the activation of central regulatory system that induces the activation of vagal nerve, resulting in possibly release of neurotransmitters and ECL cells stimulation.

Recently, as to the action of ghrelin, involvement of NO synthesis has been indicated[40]. Bilgin *et al* reported that ghrelin stimulates the secretion of gastric acid through NO as a mediator, because acid secretion induced by ghrelin administration was inhibited by applying L-NAME in rats. Previously the gastroprotective effect of ghrelin was reported and this can be attenuated by pretreatment of L-NAME suggesting involvement of NO pathways in the effect of ghrelin[40]. As NO increases mucosal blood flow, the effect of ghrelin on the secretion of gastric acid may partially dependent of an increase of mucosal blood flow.

THE PHYSIOLOGICAL ROLE OF GHRELIN IN THE REGULATION OF ACID SECRETION

The physiological role of ghrelin in the regulation of acid secretion still remains unclear. Comparing the secretion of ghrelin with that of gastrin, the secretion of gastrin is induced by food intake[26], while the secretion of ghrelin is increased during fasting period[33]. As described above, there are many differences between gastrin and ghrelin in the actions, their roles may be different. Gastrin is known to play important roles in the postprandial secretion of gastric acid, while ghrelin may be related to acid secretion during fasting period or at night. To elucidate the physiological role of ghrelin in acid secretion, further studies are required.

Abstract

AIM: To investigate the effect of stable c-Fos overexpression on immortalized human hepatocyte (IHH) proliferation.

METHODS: IHHs stably transfected with c-Fos (IHH-Fos) or an empty vector (IHH-C) were grown in medium supplemented with 1% serum or stimulated with 10% serum. Cell proliferation was assessed by cell counts, 3H-thymidine uptake and flow cytometry analyses. The levels of cell cycle regulatory proteins (Cyclin D1, E, A) cyclin dependent kinases (cdk) cdk2, cdk4, cdk6, and their inhibitors p15, p16, p21, p27, total and phosphorylated GSK-3β and epidermal growth factor receptor (EGF-R) were assayed by Western blotting. Analysis of *Cyclin D1* mRNA levels was performed by reverse transcription-polymerase chain reaction and real-time polymerase chain reaction (PCR) analysis. Stability of Cyclin D1 was studied by cycloheximide blockade experiments.

RESULTS: Stable c-Fos overexpression increased cell proliferation under low serum conditions and resulted in a two-fold increase in [^{3}H]-thymidine incorporation following serum addition. Cell cycle analysis by flow cytometry showed that c-Fos accelerated the cell cycle kinetics. Following serum stimulation, Cyclin D1 was more abundantly expressed in c-Fos overexpressing cells. Cyclin D1 accumulation did not result from increased transcriptional activation, but from nuclear stabilization. Overexpression of c-Fos correlated with higher nuclear levels of inactive phosphorylated GSK-3β, a kinase involved in Cyclin D1 degradation and higher levels of *EGF-R* mRNA, and EGF-R protein compared to IHH-C both in serum starved, and in serum stimulated cells. Abrogation of EGF-R signalling in IHH-Fos by treatment with AG1478, a specific EGF-R tyrosine kinase inhibitor, prevented the phosphorylation of GSK-3β induced by serum stimulation and decreased Cyclin D1 stability in the nucleus.

CONCLUSION: Our results clearly indicate a positive role for c-Fos in cell cycle regulation in hepatocytes. Importantly, we delineate a new mechanism by which c-Fos could contribute to hepatocarcinogenesis through stabilization of Cyclin D1 within the nucleus, evoking a new feature to c-Fos implication in hepatocellular carcinoma.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world, with an increasing number of new cases emerging each year. Etiologically it is linked to chronic viral infections (hepatitis B and C viruses), alcohol-related cirrhosis or aflatoxin B1 exposure, which

all cause disruptions in signal transduction cascades leading to abnormalities in gene expression.

The proto-oncogene *c-fos* is an important member of the activating protein 1 (AP-1) transcription factor involved in major cellular functions such as transformation, proliferation, differentiation and apoptosis[1,2]. Such a large variety of functions is achieved by the combination of different Jun (c-Jun, JunB or JunD) and Fos (c-Fos, FosB, ΔfosB, Fra-1, Fra-2) family members forming various AP-1 homo and heterodimers. *c-fos* is an immediate early gene whose expression is rapidly and transiently induced after mitogenic stimulation[3]. The role of c-Fos in cell proliferation and transformation remains controversial. c-Fos is required during all phases of the cell cycle in exponentially growing cells and is a potent inducer of cell proliferation[4]. However, some studies have suggested that c-Fos poorly contributes to proliferation[5], was totally dispensable for[6], or even down-regulated, cell growth[7,8]. Overexpression of c-Fos leads to morphological transformation of fibroblasts[9,10], and to osteosarcoma formation in transgenic mice[11,12]. Apart from one study describing a negative role for c-Fos in hepatocellular tumorigenesis[8], several reports rather support a potential positive role for c-Fos in this process. High expression levels of c-Fos were determined in tumour tissue compared to the adjacent non-tumour liver in human HCC[13-15], as well as in several models of HCC in rodents[16-18]. A recent study in humans identified a subtype of HCC sharing gene expression patterns with foetal hepatoblasts which can be distinguished from another HCC subtype closer to adult hepatocytes[19]. Interestingly, c-Fos, but not c-Jun expression was higher in the foetal subtype which displayed a poorer prognosis and a greater tendency to invasion than the adult subtype. In addition, the expression of DNA 5-methylcytosine transferase, a c-Fos target gene involved in DNA methylation[20] is increased in human tumour cells and in HCCs[21]. Despite these studies showing that c-Fos overexpression might be an important step towards the development of liver cancer, its precise role in hepatocarcinogenesis remains ill-defined.

In order to clarify c-Fos implication in hepatocarcinogenesis, we examined the effect on proliferation of stable c-Fos overexpression in immortalized human hepatocytes (IHH). We show, for the first time, that a positive role for c-Fos on hepatocyte proliferation can be attained by stabilization of Cyclin D1 in the nuclear compartment, a mechanism which has not been described as a c-Fos related process in any cell type to date.

MATERIALS AND METHODS

Cell culture and reagents

IHH were cultured in Williams' medium E (Invitrogen, Cergy Pontoise, France) supplemented with 100 mL/L fetal calf serum (FCS) (Biochrom AG, Cambridge, UK), 1% penicillin-streptomycin, 1% Glutamax and 1% DMEM sodium pyruvate (Invitrogen). Specific reagents were AG1478 (Calbiochem, San Diego, CA) and cycloheximide (CHX) (Euromedex, Souffelweyersheim, France).

Generation of stably transfected cells

The human *c-fos* cDNA was inserted into the cytomegalovirus driven pCIneo expression vector (Promega, Charbonnières, France) containing a neomycin resistance gene to obtain the pCIneo-*cfos* vector. Cells were stably transfected by electroporation (230V, 960 μF) in PBS-Hepes Buffer 10 mmol/L, pH 7.4 with the empty vector (pCIneo) or with pCIneo-*cfos*. Two days post-transfection, stable clones were selected in media containing 500 μg/mL of G418 (Invitrogen). The resistant clones were pooled after 3 wk of selection, and maintained with G418. c-Fos overexpression was verified by Western blot analysis as shown in Figure 1A.

Growth curve analysis

Cells were plated in triplicate at a density of 1.0×10^5 per well in six-well plates, and cultured in low serum (1% FCS) conditions for 5 d. Triplicate cultures were trypsinized and diluted in an equal volume of trypan blue solution (Invitrogen). Viable cells were counted daily in a haemocytometer counting chamber.

[^{3}H]-thymidine incorporation

DNA synthesis was determined by measuring [^{3}H]-thymidine incorporation. Cells were plated onto 24-well plates at a density of 1.0×10^5 cells/well in quadruplets. Cells were serum deprived for 24 h, and serum stimulated in culture media containing 1.5 μCi/mL tritiated thymidine ([^{3}H]dT) (specific activity of 740 GBq/mmol) (Perkin-Elmer, Waltham, Ma) for 4 h. Cells were fixed and washed in ice-cold 10% trichloroacetic acid. DNA was solubilized in 0.1 mol/L NaOH for 1 h at 37℃. [^{3}H]dT incorporated into the DNA was measured using liquid scintillation counting.

Flow cytometry

DNA cell cycle analysis was measured by 5-bromodeoxyuridine (BrdU) incorporation and propidium iodide staining of the nuclei by flow cytometry (FACScalibur, BD Biosciences, Mansfield, MA) and analyzed with the ProCellQuest software provided by the manufacturer. Cell cycle progression was measured by pulse/chase experiments. Cells plated at a density of 5×10^5 per 6-cm dish were serum starved for 24 h, serum stimulated for 12 h and stained with BrdU (30 μg/mL) for 1 h. Cells were then chased with BrdU free medium for 0, 3, 6, 9, 12 h, stained with propidium iodide and harvested in 70% ethanol. Cells were then treated with 2 N HCl and pepsin (0.2 mg/mL) for 30 min. BrdU content was analyzed using a FITC-labeled monoclonal antibody to BrdU (BD Pharmingen, Le-Pont-de-Claix, France). Labeled cells were washed and resuspended in PBS containing propidium iodide (10 μg/mL) for 30 min prior to flow cytometric analysis.

Western blot analysis

Nuclear proteins were extracted as described[22]. Total proteins were extracted with lysis buffer [1% (v/v) SDS, 1 mmol/L Na_3VO_4, 10 mmol/L Tris pH 7.4, 1% benzonase) for 10 min at room temperature and heated for

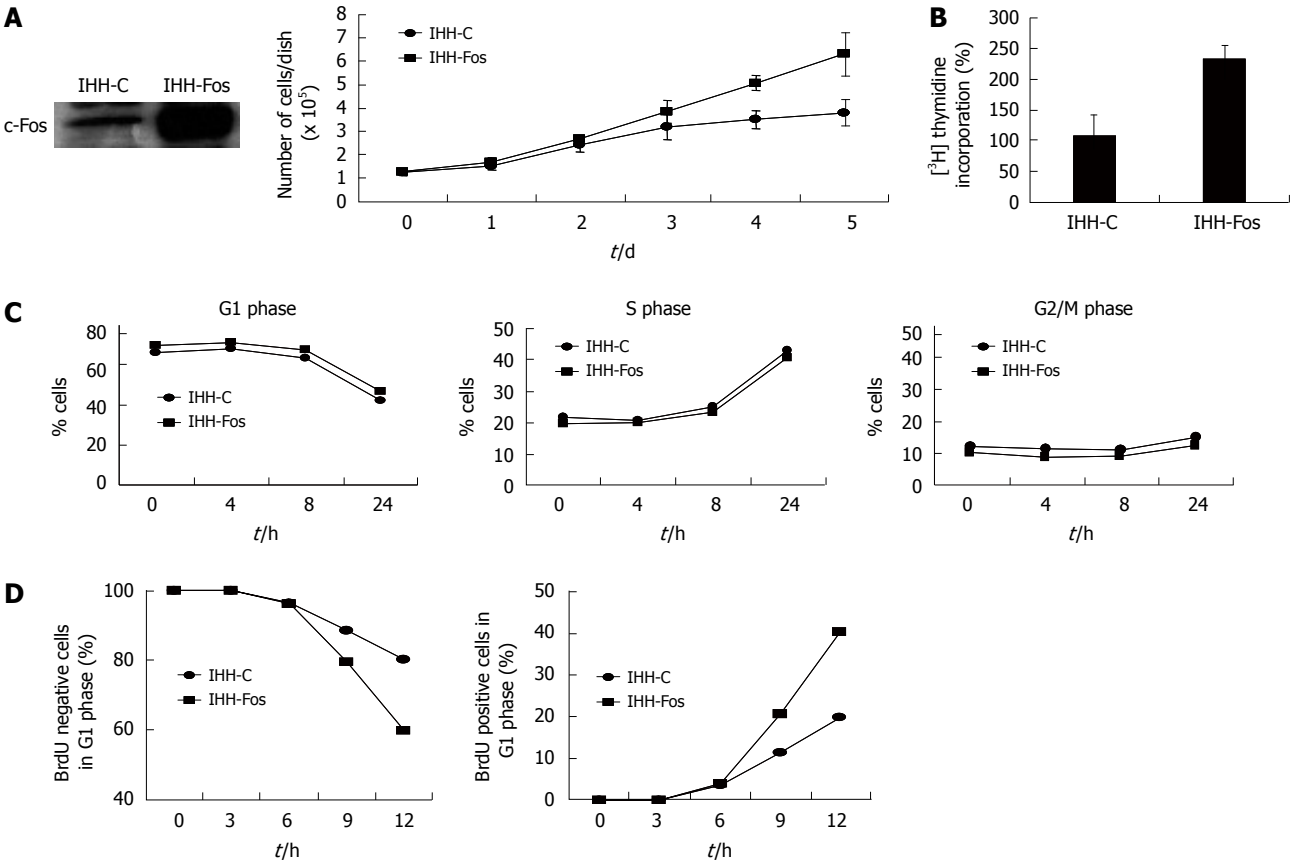

Figure 1 Overexpression of c-Fos accelerates the cell cycle. A: IHH-C and IHH-Fos were grown in 1% FCS, cultured for 5 d and counted daily. Cell growth was determined by counting the number of attached cells every day. Results are the mean ± SE of three independent experiments; B: [^{3}H] thymidine incorporation into DNA. Non-synchronized IHH-C or IHH-Fos serum starved for 24 h then serum stimulated for 4 h were incubated with [^{3}H] thymidine for 4 h. DNA was extracted as described in materials and methods, and [^{3}H] thymidine incorporation into DNA was assessed by scintillation counting. Results are expressed as percentage of increase of [^{3}H] thymidine incorporation in serum-stimulated cells over that of quiescent cells for each cell population. Results are the mean ± SE of six independent experiments; C: Flow cytometry analysis for quantification of cell cycle phase distribution and progression through cell cycle. IHH-C or IHH-Fos serum starved for 24 h were incubated with BrdU for 1 h and stained with propidium iodide 0, 4, 8 and 24 h after serum stimulation. The percentage of cells in each phase is plotted against time. Results of a representative experiment are shown (out of 3); D: IHH-C or IHH-Fos serum starved for 24 h were serum stimulated for 12 h, BrdU pulsed for 1 h, chased with fresh medium for 0, 3, 6, 9, 12 h, and then stained with propidium iodide. The percentage of BrdU-negative cells in the G1 phase (G1 exit) (left panel) and of the BrdU-positive cells in the G1 phase (G1 entry) (right panel) of the cell cycle is plotted against time. Results are representative of four independent experiments.

5 min at 100℃. Equal quantities of nuclear proteins were fractionated on a SDS-polyacrylamide gel and transferred onto nitrocellulose membranes by electroblotting. The antibodies used in this study were as follows: c-Fos, Cyclin D1, Cyclin E, Cyclin A, cdk2, cdk4, cdk6, p15, p16, p21, p27 and EGF-R (Santa Cruz Biotechnology, Santa Cruz, CA), GSK3β (Affinity BioReagents, Golden, CO), Phospho-GSK3β (Serine9) (Abcam, Paris, France). Immunoreactive bands were visualized using the ECL kit (Amersham BioSciences, Saclay, France) according to the manufacturer's instructions.

Reverse transcription-polymerase chain reaction (RT-PCR) and real-time quantitative PCR analysis

mRNA was isolated from cells by Nucleospin RNA II kit (Macherey-Nagel, Hoerdt, France) following the manufacturer's instructions. RNA (1 μg) was reverse transcribed using ThermoScript™ RT-PCR System (Invitrogen, Cergy-Pontoise, France). Real-time quantitative PCR was performed using the following primers: *Cyclin D1*: forward 5'-GCATGTTCGTGGCCTCTAAGA-3'; reverse 5'-CGGTGTAGATGCACAGCTTCTC-3', *EGF-R*: forward 5'-GCGTCTCTTGCCGGAATGT-3' and reverse 5'-GGCTCACCCTCCAGAAGGTT-3'. Real-time quantitative PCR was performed with an ABI PRISM 7700 instrument (Applied Biosystems, Foster City, CA)) using SYBRGreen PCR core reagents (Applied Biosystems). Fold changes in mRNA were calculated by the $\Delta\Delta C_t$ method using *cyclophilin A* (forward: 5'-CAAATGCTGGACCCAACACA-3'; reverse: 5'-TGCCATCCAACCACTCAGTCT-3') as a standard. All PCR reactions were done in triplicate.

Statistical analysis

Data were expressed as means ± SE. Student's *t*-test was performed and statistical significance was considered as $P < 0.05$.

RESULTS

Growth rate and cell cycle regulation by c-Fos overexpression

To determine whether c-Fos could modulate hepatocyte growth, we carried out growth curve assays. While

cell growth was similar in the presence of 10% FCS in IHH-C and IHH-Fos (data not shown), we observed that the growth pattern of the two cell lines differed in low serum conditions (1% FCS). While the number of IHH-Fos increased exponentially over 5 d in culture, IHH-C number increased slowly during the first 3 d of culture, and then reached a plateau, due to the induction of cell death by serum deprivation (Figure 1A and data not shown). Thus, c-Fos overexpression correlated with a more rapid growth in low serum conditions. The effect of c-Fos overexpression on cell proliferation was further established by measuring [^{3}H]dT incorporation following 4 h serum stimulation of cells deprived of serum for 24 h. The increase of [^{3}H]dT incorporation induced by serum was 2.2 times higher in IHH-Fos than in IHH-C (231% and 107%, respectively), and the difference was statistically significant ($P < 0.001$) (Figure 1B). To further analyze the role of c-Fos on the cell cycle, cell cycle phase distribution and cell cycle kinetics were analyzed by flow cytometry. Following serum stimulation, the percentage of cells in the G1 phase decreased, while the percentage of cells in the S-phase increased 24 h after serum stimulation. However, the percentage of cells in the different stages of the cell cycle was comparable in IHH-Fos and IHH-C (Figure 1C). Cell cycle progression was measured by BrdU pulse/chase experiments. The rate at which BrdU positive cells progress into G1 indicates the rate of transit through S, G2 and M phases. Similarly, the rate at which BrdU negative cells become depleted from the G1 pool indicates the transit rate through G1. We show that IHH-Fos quit (Figure 1D, left panel) and enter (Figure 1D, right panel) G1 faster than IHH-C, which reflects a global increase in cell cycle kinetics. The fact that the cell cycle profile was not altered by c-Fos indicates that the acceleration is proportional in all phases of the cycle. These data taken together indicate that c-Fos overexpression increases the growth of exponentially growing cells cultured in low serum medium as well as the proliferation response induced by serum refeeding.

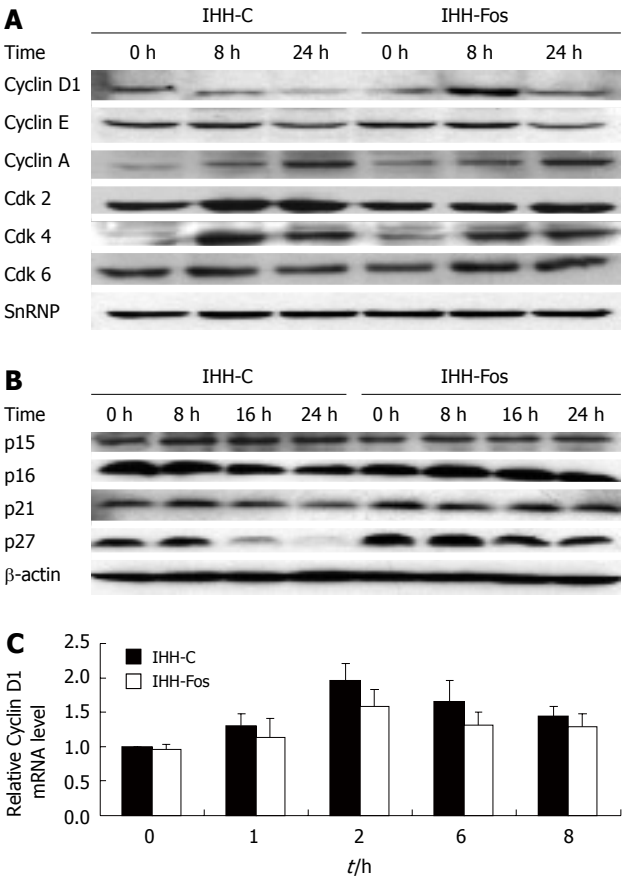

Figure 2 Induction of cell cycle regulatory proteins after serum refeeding. IHH-C or IHH-Fos were serum starved for 24 h. Nuclear (A) or total (B) extracts prepared before or after serum stimulation for 8 h or 24 h were immunoblotted with antibodies, as indicated. Loading of nuclear or total extracts was normalized using a SnRNP or a β-actin antibody, respectively. Results of a representative experiment are shown (out of 3); C: Quantitative real time PCR of Cyclin D1 mRNA levels in quiescent IHH-C or IHH-Fos serum stimulated for the indicated times. Bars indicate mean ± SE of three independent experiments each performed in triplicate.

Induction of cell cycle regulatory proteins by c-Fos

The levels of various cell cycle regulatory proteins before and after serum stimulation of IHH-C and IHH-Fos were analyzed by Western blotting experiments. In both cell lines, serum addition induced an increase in the nuclear levels of Cyclin A, cdk2 and cdk4, but no change in Cyclin E. Of interest, the nuclear levels of Cyclin D1 were increased after 8 h of stimulation in IHH-Fos, but not in IHH-C (Figure 2A). In addition, the levels of p27 were higher in the absence of serum stimulation or following serum stimulation in IHH-Fos than in IHH-C (Figure 2B).

Quantitative RT-PCR analysis was performed to determine whether the increase of Cyclin D1 at 8 h of serum stimulation in IHH-Fos was controlled transcriptionally. Interestingly, a similar 2-fold increase in *Cyclin D1* mRNA 2 h following serum stimulation was observed in IHH-Fos and IHH-C, without any significant differences at any of the time points (Figure 2C), indicating that the higher levels of Cyclin D1 in the nucleus in IHH-Fos are not due to transcriptional mechanisms.

Cyclin D1 stabilization in the nucleus

We next determined whether post-translational regulations could explain the increase of nuclear Cyclin D1 in serum-stimulated IHH-Fos. CHX, a translational inhibitor, was used to block protein synthesis. While in IHH-C, nuclear Cyclin D1 protein levels started to decline as from 1 h, and decreased by 85% after 2 h of CHX treatment, Cyclin D1 nuclear levels were decreased by only 20% upon 2 h of CHX treatment in IHH-Fos (Figure 3), indicating that c-Fos overexpression correlates with increased stability of nuclear Cyclin D1.

Inactivation of GSK-3β in IHH-Fos contributes to Cyclin D1 stabilization

Previous studies have indicated that Cyclin D1 degradation is triggered by GSK-3β-induced phosphorylation on a single threonine residue (Thr-286)[23]. Of note, phosphorylated GSK-3β is the inactive form of the protein[24]. We, therefore, compared the level of

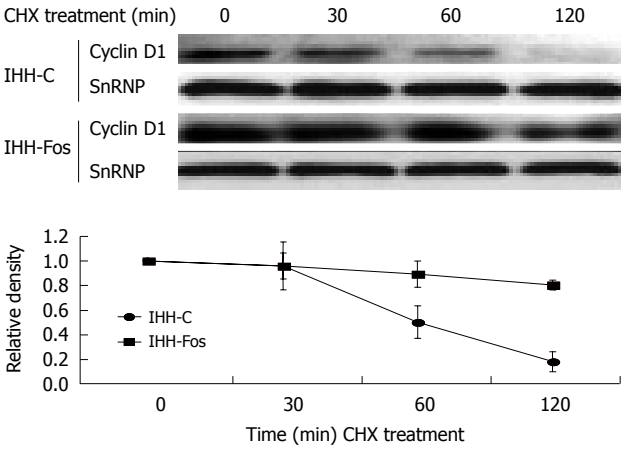

Figure 3 Nuclear Cyclin D1 stability is increased by c-Fos overexpression. IHH-C or IHH-Fos serum starved for 24 h were serum stimulated for 6 h and then treated with CHX (30 μg/mL) for 30 min, 1 h or 2 h. Nuclear extracts were immunoblotted with an antibody against Cyclin D1, and normalized with a SnRNP antibody, as indicated (Upper panels). The Cyclin D1 over SnRNP ratios were quantified by densitometric analysis of the immunoreactive bands (Lower panel). The results are the mean ± SE of three independent experiments.

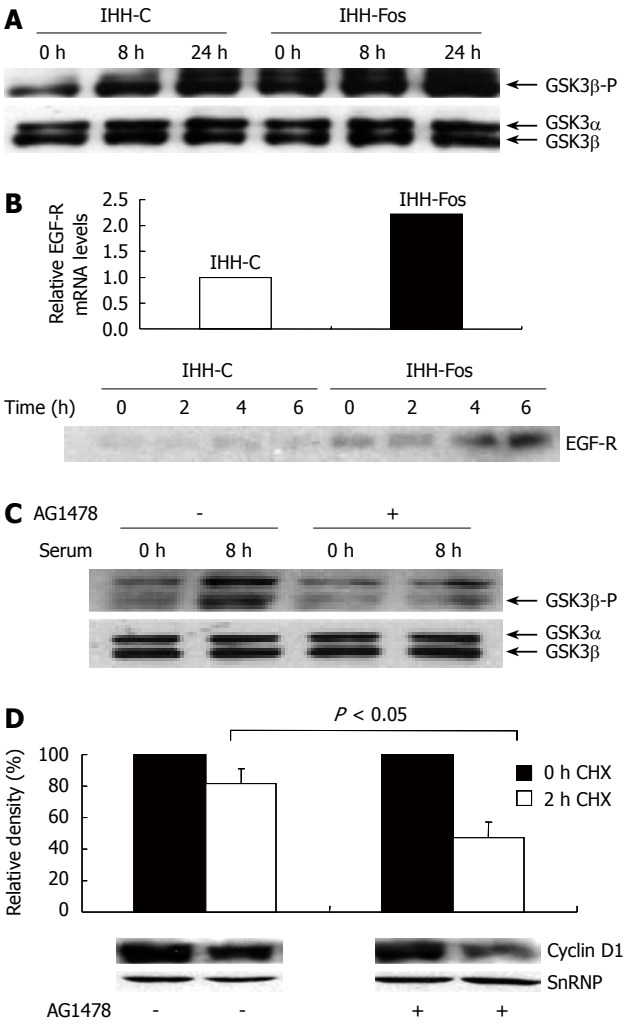

Figure 4 Stimulation of EGF-R signaling by c-Fos overexpression. A: Total and phosphorylated levels of nuclear GSK-β. IHH-C or IHH-Fos were serum starved for 24 h. Nuclear extracts prepared from unstimulated (0 h), 8 h or 24 h serum stimulated IHH-C or IHH-Fos, were immunoblotted with an antibody against phosphorylated or total GSK3β. B: Upper panel, detection of EGF-R mRNA in IHH-C and IHH-Fos by quantitative real time PCR analysis of mRNA isolated from cells grown in the presence of serum. Lower panel, Western blot analysis of EGF-R in total cell extracts from IHH-C and IHH-Fos cells serum starved for 24 h (0) or stimulated with serum for the indicated times; C: Serum deprived IHH-Fos were pre-treated (+) or not (-) with AG1478 (10 μmol/L) for 1 h. Nuclear proteins were prepared from non stimulated and 8 h serum-stimulated cells. Phosphorylated and total GSK3β levels were detected by Western blot; D: Serum-deprived IHH-Fos were pretreated or not with AG1478 (10 μmol/L) for 1 h, then serum-stimulated for 6 h. Nuclear proteins were extracted before (0 h, filled columns) or after 2 h (empty columns) of CHX treatment (30 μg/mL). Cyclin D1 levels were quantified by Western blotting. The immunoreactive bands were quantified by densitometric analysis after loading normalization of the blot using a SnRNP antibody. The results are expressed as the % of Cyclin D1/SnRNP expression and are the mean ± SE of 3 independent experiments. The lower panel illustrates one representative experiment.

phosphorylated GSK-3β between the two cell lines by Western blot analysis. As shown in Figure 4A, the levels of GSK3β phosphorylation were much higher in the nucleus of IHH-Fos than in IHH-C, both in unstimulated and in serum stimulated conditions, indicating higher basal, and induced levels of inactive GSK-3β in IHH-Fos (Figure 4A). Therefore, a decrease in active GSK-3β in IHH-Fos could be responsible for the increased stability of nuclear Cyclin D1 after serum stimulation.

Several signaling pathways are able to induce GSK-3β phosphorylation, including the two main cascades targeted by tyrosine kinase receptors: the phosphatidyl inositol 3-kinase (PI3K) and the Ras/mitogen activated protein kinase pathways[24]. Since the epidermal growth factor receptor (EGF-R) is a known transcriptional target of AP-1[25-27], we tested the hypothesis that overexpression of EGF-R might contribute to high levels of GSK-3β phosphorylation in IHH-Fos. Quantitative RT-PCR analysis revealed a 2.2-fold increase in the basal level of *EGF-R* mRNA in IHH-Fos compared to IHH-C (Figure 4B). Higher levels of EGF-R protein were also observed in serum starved and serum-stimulated IHH-Fos compared to IHH-C (Figure 4B), strongly indicative of increased EGF-R signaling in c-Fos-overexpressing cells. Altogether, these data suggest that increased EGF-R signaling might contribute, at least partly, to increased levels of GSK-3β phosphorylation in IHH-Fos cells.

To demonstrate the implication of EGF-R in GSK-3β-mediated Cyclin D1 stabilization, IHH-Fos cells were treated with AG1478, a specific inhibitor of the EGF-R tyrosine kinase before serum stimulation. Western blot analysis indicated that AG1478 treatment did block the phosphorylation of GSK-3β induced by serum (Figure 4C). Interestingly, the decrease in the nuclear level of Cyclin D1 protein observed after a 2 h-CHX treatment of IHH-Fos cells stimulated by serum was more important in cells treated with AG1478 (50% decrease) than in untreated cells (10% decrease), and the difference was statistically significant ($P < 0.05$, Figure 4D), confirming that blockade of EGF-R induced signaling in IHH-Fos leads to a more rapid nuclear Cyclin D1 degradation.

DISCUSSION

Our results indicate that c-Fos overexpression accelerates

cell growth under reduced serum concentration suggesting that hepatocytes overexpressing c-Fos become relatively independent of the presence of growth factors. We show that c-Fos enhances DNA synthesis after serum stimulation, and accelerates hepatocyte cell cycle progression without altering the overall distribution of cells in each phase due to a proportional acceleration of cell cycle kinetics in all phases.

Our results are at variance with those obtained in immortalized murine hepatocytes[8]. In this model, c-Fos conditional expression for 48 h was shown to decrease cell growth and [^{3}H]dT incorporation of cells grown in serum-supplemented medium. Besides species differences (murine *vs* human cells), the discrepancy in results can be explained by the use of very different cellular models which cannot be compared. The human hepatocytes used in our study were immortalized by SV40 T antigen while murine hepatocytes were immortalized using truncated c-Met[28]. Overexpression of c-Fos in our model was permanently established as the result of stable transfection, while in Mikula's study a c-Fos-estrogen receptor fusion protein was expressed for a limited period (1-3 d) following estradiol treatment of the cultures[8]. Furthermore, the function of the conditionally expressed c-Fos protein may have been modified, since gene fusion has been shown to alter the function of Fos family proteins[29].

We aimed to determine whether the positive role of c-Fos on hepatocyte proliferation depicted in our study was mediated through changes in cell cycle regulation. Different studies have reported an effect of *c-fos* gene deletion or c-Fos protein overexpression on Cyclin D1[9,30,31], Cyclin E[31] or Cyclin A[32] expression, depending on the cell type studied. In our study, while the levels of Cyclin E and A and their associated kinases varied with a similar pattern in both cell types following serum stimulation, nuclear Cyclin D1 levels were higher in IHH-Fos compared to IHH-C 8 h after serum re-feeding. Contrary to previous reports describing c-Fos as a transcriptional activator of Cyclin D1[30], the higher levels of nuclear Cyclin D1 in IHH-Fos than in IHH-C were not due to differences in transcriptional regulation, but to increased protein stability in the nucleus. A similar lack of correlation between Cyclin D1 mRNA and protein expression has been previously described in an *in vivo* experimental model of HCC[33]. Our results strongly suggest a mechanism whereby c-Fos induces nuclear accumulation of Cyclin D1 without affecting the total cellular amount of the protein.

The Cyclin D1 protein is quite unstable, with a half-life of less than 30 min[34]. It accumulates in the nucleus during the G1 phase and exits into the cytoplasm during the S phase. Nuclear export of Cyclin D1, and its subsequent ubiquitination and proteolysis, are dependent on phosphorylation on a single threonine residue (Thr-286) performed mainly by GSK-3β[23], a protein kinase active only when dephosphorylated. In contrast to Cyclin D1, GSK-3β is predominantly cytoplasmic during G1 phase, but a considerable amount becomes nuclear during S phase[23]. We show herein that phosphorylated levels of nuclear GSK-3β are higher in IHH-Fos than in IHH-C. Lower levels of active GSK-3β would consequently lead to a decrease in Cyclin D1 phosphorylation, resulting in its nuclear accumulation in IHH-Fos. Since EGF-R is a known transcriptional target of AP-1[25-27], we tested the possibility that c-Fos overexpression increases the activation of the pathways downstream to EGF signaling. EGF-R activates both the PI3K and the mitogen-activated protein kinase cascades[35], two upstream activators of GSK-3β phosphorylation[24,36]. In support of an involvement of EGF-R signaling in GSK-3β inactivation and nuclear cylin D1 stabilization, we show that IHH-Fos display increased levels of expression of *EGF-R* mRNA and protein than IHH-C. Furthermore, blocking the activation of the EGF-R tyrosine kinase significantly accelerates the rate of Cyclin D1 degradation assessed in CHX experiments. Upregulated expression of EGF-R is a frequent finding in HCC[37-39], and increased EGF-R signaling has been associated with a poorer prognosis[40]. c-Fos is also frequently overexpressed in HCC tumoral tissues[13-15,41]. Our data, therefore, suggest that a causal relationship could exist between c-Fos and EGF-R overexpression in HCC.

Our finding of high levels of nuclear Cyclin D1 associated with c-Fos overexpression adds further support for a contributing effect of c-Fos on HCC development. Indeed, Cyclin D1 exit from the nucleus during S phase is essential for regulated cell division, and its retention in the nucleus is a cancer promoting or predisposing event[42]. Thus, expression of a Cyclin D1 mutant that cannot be phosphorylated by GSK-3β, and remains nuclear throughout the cell cycle is highly transforming and induces tumour growth in nude mice[43].

In accordance with previous reports[32,44], we also found that p27 protein levels were higher in c-Fos overexpressing cells. It is now well recognized that the family of p21/p27 proteins plays a dual role in cell cycle regulation. On one hand, they bind to cdk2 complexes and inhibit their kinase activities. On the other hand, they are able to promote the activation of Cyclin D1/cdk4-6 by complex stabilization, and by facilitating the nuclear import of these complexes, without inhibiting Cyclin D-associated kinase activity[45-48]. In our study, higher levels of p27 in IHH-Fos could, therefore, represent another mechanism contributing to the increase in nuclear levels of Cyclin D1, although the precise mechanisms linking c-Fos and p27 overexpression are currently unknown. Nevertheless, the mechanism is not at the level of transcription, as indicated by our quantitative PCR analysis (data not shown).

To conclude, our results clearly indicate a positive role for c-Fos in cell cycle regulation in hepatocytes. Importantly, we delineate a new mechanism by which c-Fos could contribute to hepatocarcinogenesis through stabilization of Cyclin D1 within the nucleus, evoking a new feature to c-Fos implication in HCC.

ACKNOWLEDGMENTS

COMMENTS

Background

Human hepatocellular carcinoma (HCC) is the fifth most common cancer in the world. Among the numerous genes potentially implicated in hepatocarcinogenesis, the proto-oncogene c-Fos, a member of activating protein 1 (AP-1) transcription factor is a good candidate. Apart from one study reporting a negative role for c-Fos in hepatocellular tumorigenesis, several papers rather support a positive role in this process. High expression levels of c-Fos were determined in tumor tissue compared to the adjacent non-tumor liver in human HCC. However, in different cell types or tissues, the role of c-Fos in cell proliferation and/or transformation remains controversial. This study was designed to determine whether c-Fos could contribute to hepatocarcinogenesis by increasing cell proliferation.

Research frontiers

The role of c-Fos on hepatocyte proliferation has never been studied in human cells, but only in murine hepatocytes. These cells had been immortalized and stably transfected by c-Fos using different techniques than those reported in the present study. The authors showed that c-Fos overexpression led to decreased hepatocyte proliferation. However, these results did not appear consistent with most studies suggesting a positive role for c-Fos in hepatocarcinogenesis.

Innovations and breakthroughs

This study shows for the first time that c-Fos deregulates hepatocyte proliferation by stabilizing Cyclin D1 in the nucleus which is a cancer promoting or predisposing event.

Applications

Strategies designed to suppress c-Fos expression in HCC could contribute reducing hepatocyte proliferation and thereby cancer development.

Terminology

Human immortalized hepatocytes are hepatocytes which have been transfected by SV40 T antigen, allowing them to proliferate when cultured contrary to normal hepatocytes. However these immortalized cells are not tumorigenic *in vitro* and *in vivo*.

Peer review

This is an interesting study. Authors investigated the effect of stable c-Fos overexpression on IHH proliferation.

Abstract

AIM: To explore the mechanism for interactions of leptin with ghrelin and orexin in the arcuate nucleus (ARC) activating neuropeptide Y (NPY) neurons during physiological regulation of feeding.

METHODS: Single neurons from ARC of adult rats with matured feeding function were isolated. $[Ca^{2+}]_i$ was measured to monitore their activities. The time course of leptin effects on ghrelin-induced *versus* orexin-induced $[Ca^{2+}]_i$ increases in NPY neurons was studied.

RESULTS: Administration of ghrelin or orexin-A at 10^{-10} mol/L increased cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) in NPY neurons isolated from the ARC of adult rats. Upon administration of leptin at 10^{-14}-10^{-12} mol/L, ghrelin-induced $[Ca^{2+}]_i$ increases were initially (< 10 min) inhibited but later restored, exhibiting a transient pattern of inhibition. In contrast, orexin-induced $[Ca^{2+}]_i$ increases were inhibited by leptin in a long-lasting manner. Furthermore, a prior administration of leptin inhibited orexin action but not ghrelin action to increase $[Ca^{2+}]_i$.

CONCLUSION: Leptin counteracted ghrelin effects transiently and orexin effects long-lastingly in NPY neurons. The transient property with which leptin counteracts ghrelin action in NPY neurons may allow the fasting-associated increase in ghrelin levels to activate NPY neurons in the presence of physiological leptin and to stimulate feeding.

Leptin transiently antagonizes ghrelin and long-lastingly orexin in regulation of Ca^{2+} signaling in neuropeptide Y neurons of the arcuate nucleus. *World J Gastroenterol* 2008; 14(41): 6347-6354 Available from: URL: http://www.wjgnet.com/1007-9327/14/6347.asp DOI: http://dx.doi.org/10.3748/wjg.14.6347

INTRODUCTION

Food intake is controlled by the feeding regulatory centers, in which the arcuate nucleus (ARC) in the hypothalamus is considered the first order center that senses and integrates a variety of central and peripheral factors[1]. In the ARC, neuropeptide Y (NPY) neurons that coexpress agouti-related peptide (AgRP) are mandatory for feeding[2,3], while proopiomelanocortin (POMC) neurons are essential for satiety[1]. Orexin-A and -B (hypocretin-1 and -2) are orexigenic peptides[4] localized in neurons in the lateral hypothalamus (LH)[5], an area implicated in feeding behavior[6]. Fasting and lowering glucose concentrations increase prepro-orexin mRNA level[4] and cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) in orexin neurons[7], suggesting a possible physiological role of orexins in feeding. Ghrelin is an orexigenic peptide released predominantly from the stomach[8-10] and also from the intestine and pancreas[11-13]. Ghrelin is the only one orexigenic peptide of the peripheral origin known. The plasma concentration of ghrelin increases before meals and rapidly declines upon food intake[14]. Orexin levels might also change during a day,

since this peptide is implicated in regulation of sleep/wakefulness[15]. These rhythmic changes in ghrelin and orexin levels may alter their inputs on the feeding center and thereby regulate feeding. Both ghrelin[9,16-17] and orexin[18] stimulate food intake primarily by activating NPY neurons in the ARC.

Leptin, a powerful anorectic hormone produced and released from the adipocytes, is present constantly in the plasma at the nanomolar range[14] and is considered to enter the brain through the blood-brain barrier[19]. Therefore, leptin is likely to act continuously on the feeding center and thereby modulate the efficacy of orexigenic substances. The primary action of leptin in the feeding center is inhibition of NPY neurons as well as activation of POMC neurons in the ARC. The obesity syndrome in ob/ob mice resulting from lack of functional leptin is attenuated by the loss of neuropeptide Y[20]. Therefore, elucidation of the interaction of leptin with ghrelin and with orexin in the ARC NPY neurons may provide a clue to understand the neuronal mechanisms for physiological regulation of feeding. It has recently been shown that leptin counteracts ghrelin action to increase cytosolic free $[Ca^{2+}]_i$ in NPY neurons in the ARC, and that the PI3-kinase (phosphatidylinositol 3-kinase)-PDE3 (phosphodiesterase 3) signaling plays a key role in the leptin action[17]. In the present study, we isolated single neurons from ARC of adult rats with matured feeding function and monitored their activities by measuring $[Ca^{2+}]_i$. We studied the time course of leptin effects on ghrelin-induced *vs* orexin-induced $[Ca^{2+}]_i$ increases in NPY neurons.

MATERIALS AND METHODS

Animals and preparation of single neurons from the ARC of adult rats

Adult male Sprague-Dawley (SD) rats were maintained on a 12-h light/dark cycle and given conventional food and water ad libitum. The ARC was isolated from the brain of 5-8-wk-old SD rats and single neurons were prepared according to the procedures reported previously[16,21] with slight modifications. Briefly, rats were anaesthetized with an intraperitoneal injection of carbamic acid ethyl ester (900 mg/kg) and decapitated, and their brains were removed. Brain slices containing the ARC were prepared and the whole ARC of the left and right sides was cut out. The dissected tissues were washed with 10 mmol/L HEPES-buffered Krebs-Ringer bicarbonate buffer (HKRB) containing 10 mmol/L glucose. Then they were incubated in HKRB supplemented with 20 U/mL papain (Sigma Chemical Co., St. Louis, MO), 0.015 mg/mL deoxyribonuclease, 0.75 mg/mL bovine serum albumin and 1mmol/L cysteine for 15 min at 36℃ in a shaking water bath, followed by gentle mechanical trituration for 5-10 min. After trituration, the cell suspension was centrifuged at 100 × *g* for 5 min. The pellet was resuspended in HKRB and distributed on coverslips. The cells were kept at 20℃ in moisture-saturated dishes for up to 10 h. The animal protocols were approved by the Jichi Medical School Institute of Animal Care and Use Committee.

Measurements of $[Ca^{2+}]_i$ in single neurons of the ARC

At 2 to 10 h after cell preparation, $[Ca^{2+}]_i$ was measured by ratiometric fura-2 microfluorometry in combination with digital imaging as previously reported[16,21]. Briefly, following incubating with 2 μmol/L fura-2-AM for 30 min at room temperature, the cells were mounted in a chamber and superfused with HKRB at 1 mL/min at 34℃. Fluorescence images due to excitation at 340 nm and 380 nm were detected every 8.0 s with an intensified charge-coupled device (ICCD) camera, and the ratio image was produced by an Argus-50 system (Hamamatsu Photonics Co., Hamamatsu, Japan). Ratio values were converted to $[Ca^{2+}]_i$ according to calibration curves. Data were taken from the cells identified as neurons by the procedures reported previously[16,21].

Post-$[Ca^{2+}]_i$ imaging immunocytochemistry and identification of NPY neurons

Neurochemical identification of the neurons that exhibited $[Ca^{2+}]_i$ responses were performed according to the original method[22] with slight modification[16]. Briefly, the cells were fixed with 4% paraformaldehyde over night. They were blocked in 10% normal goat serum (NGS) and in 0.1 mol/L PBS for 1 h at room temperature. Primary antiserum against NPY (DiaSorin, Stillwater, MN) was diluted 1:1000 in PBS containing 1.5% NGS and was incubated 24 h at 4℃. The antiserum were then rinsed and incubated with biotinylated secondary antibody raised against rabbit IgG (Vector Laboratories Inc., Burlingame, CA; diluted at 1:400) for 1 h at room temperature. The secondary antibody was rinsed, and the sections were labeled with avidin-peroxidase complex (ABC kit, Vector) for 1 h and color-developed with 3,3'-diaminobenzidine (DAB). Control experiments were carried out by omitting the primary antiserum.

To correlate $[Ca^{2+}]_i$ and immunocytochemical data, photographs of all the cells in the microscopic field subjected to $[Ca^{2+}]_i$ measurements were taken at the end of $[Ca^{2+}]_i$ imaging. Based on these photographs, the cells in which $[Ca^{2+}]_i$ was recorded were correlated with their corresponding immunocytochemical results.

Criteria for $[Ca^{2+}]_i$ responses and determination of response amplitude

Ghrelin, orexin-A and leptin were administered to the superfusion solution. Amplitudes of $[Ca^{2+}]_i$ increases in response to agents were calculated by subtracting pre-stimulatory basal $[Ca^{2+}]_i$ levels from peak $[Ca^{2+}]_i$ levels. When increases in $[Ca^{2+}]_i$ took place within 5 min after addition of agents and their amplitudes were 150 nmol/L or larger, they were considered responses. Suppression by leptin was judged by the following criteria. In Figures 1 and 2, when the peak amplitude of ghrelin-induced $[Ca^{2+}]_i$ increase was decreased to a level of 40%

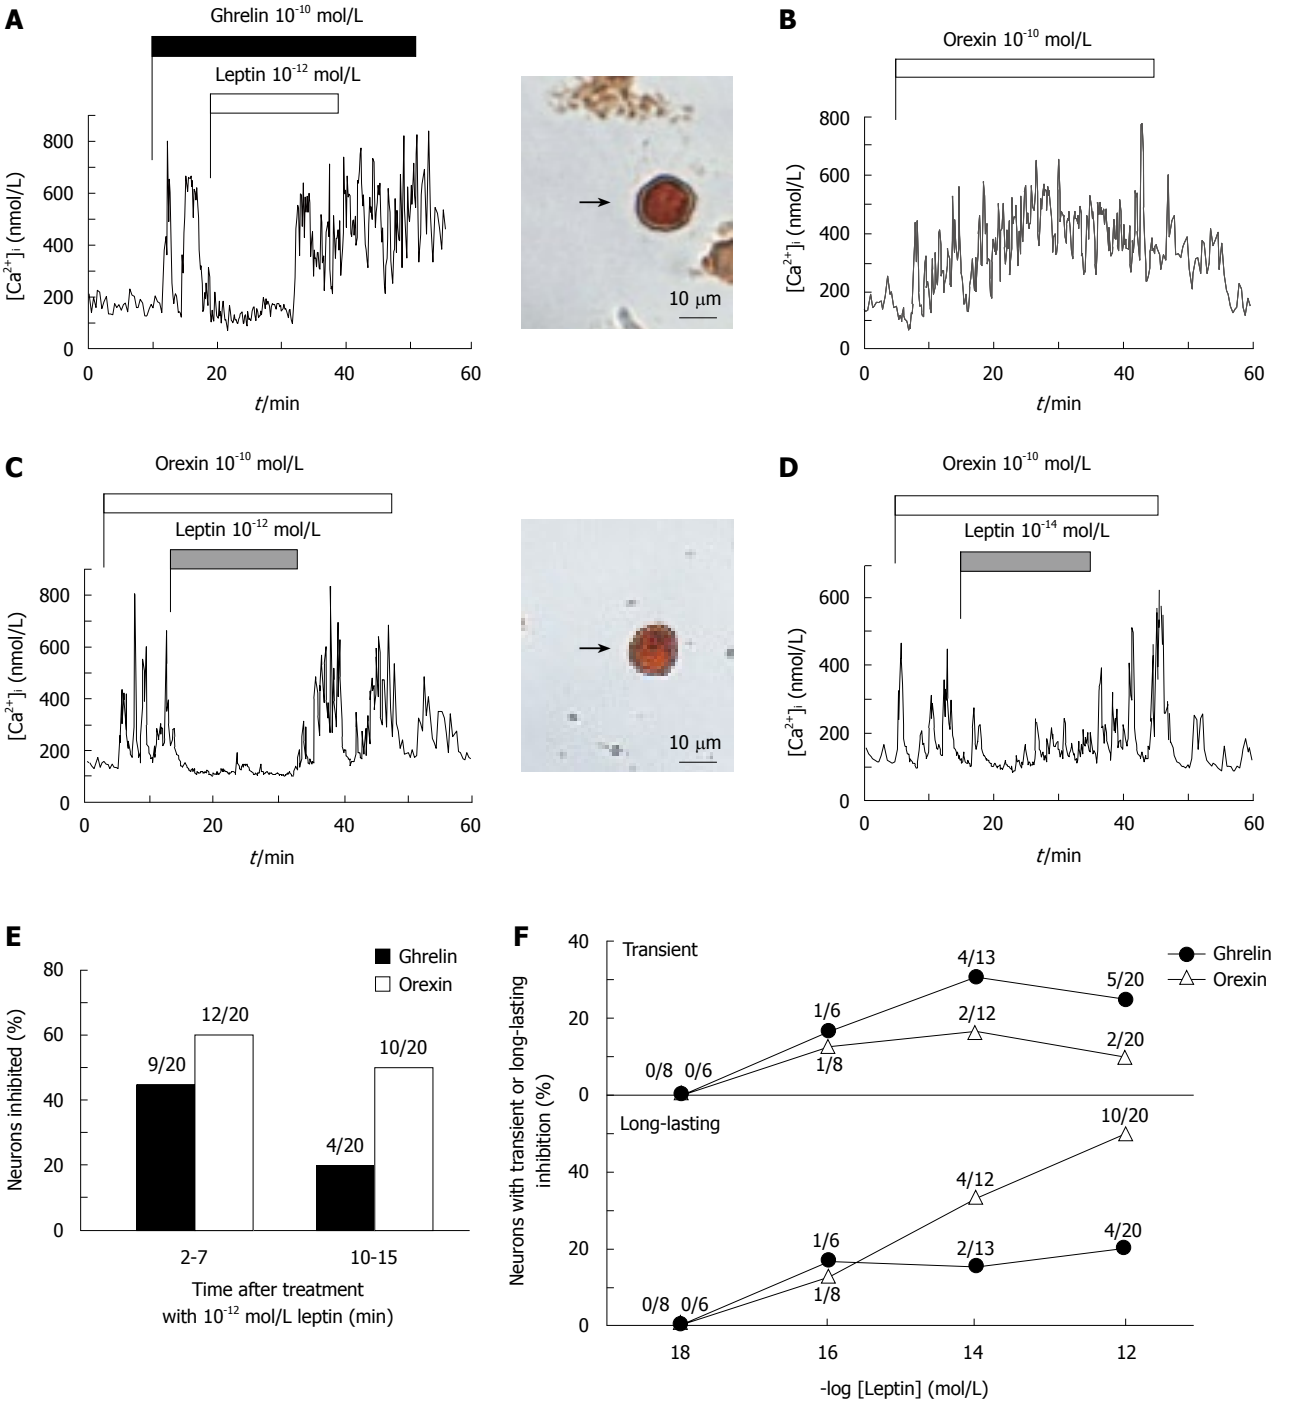

Figure 1 Ghrelin- and orexin-induced $[Ca^{2+}]_i$ increases were suppressed by leptin in a transient or long-lasting manner in NPY neurons. A-D: Ghrelin and orexin-A at 10^{-10} mol/L increased $[Ca^{2+}]_i$ in single neurons isolated from the ARC, and these $[Ca^{2+}]_i$ increases were suppressed by administration of leptin at 10^{-12} mol/L (A, C) and 10^{-14} mol/L (D). Following $[Ca^{2+}]_i$ measurements, the neurons in (A) and (C) were proved to contain NPY by immunocytochemistry using anti-NPY antibody (A, C; right panels). The bars indicate 10 μm. E: Leptin inhibited ghrelin-induced $[Ca^{2+}]_i$ increases in a greater number of neurons in 2-7 min after administration than in 10-15 min. In contrast, leptin inhibited orexin-A-induced $[Ca^{2+}]_i$ increases in the majority of neurons in 2-7 min and 10-15 min after administration. The numbers above the bars indicate the number of neurons inhibited by leptin over that responded to ghrelin or orexin-A. F: The number of neurons whose $[Ca^{2+}]_i$ responses to ghrelin or orexin-A were suppressed by leptin in either a transient or long-lasting manner is expressed by percentage. The numbers above the points indicate the number of neurons inhibited by leptin in the specified manner over that responded to ghrelin or orexin-A.

or smaller for at least 5 min and the recovery of $[Ca^{2+}]_i$ increase was observed after washing out leptin, it was considered inhibition. In Figure 3, repetitive additions of ghrelin or orexin-A twice induced repeated $[Ca^{2+}]_i$ increases, and the second challenge to ghrelin or orexin-A was performed in the presence of leptin. When the amplitude of the $[Ca^{2+}]_i$ response to the second addition was less than 150 nmol/L, it was considered inhibition.

Solutions and chemicals

The measurements were carried out in HKRB solution composed of 129 mmol/L NaCl, 5.0 mmol/L $NaHCO_3$,

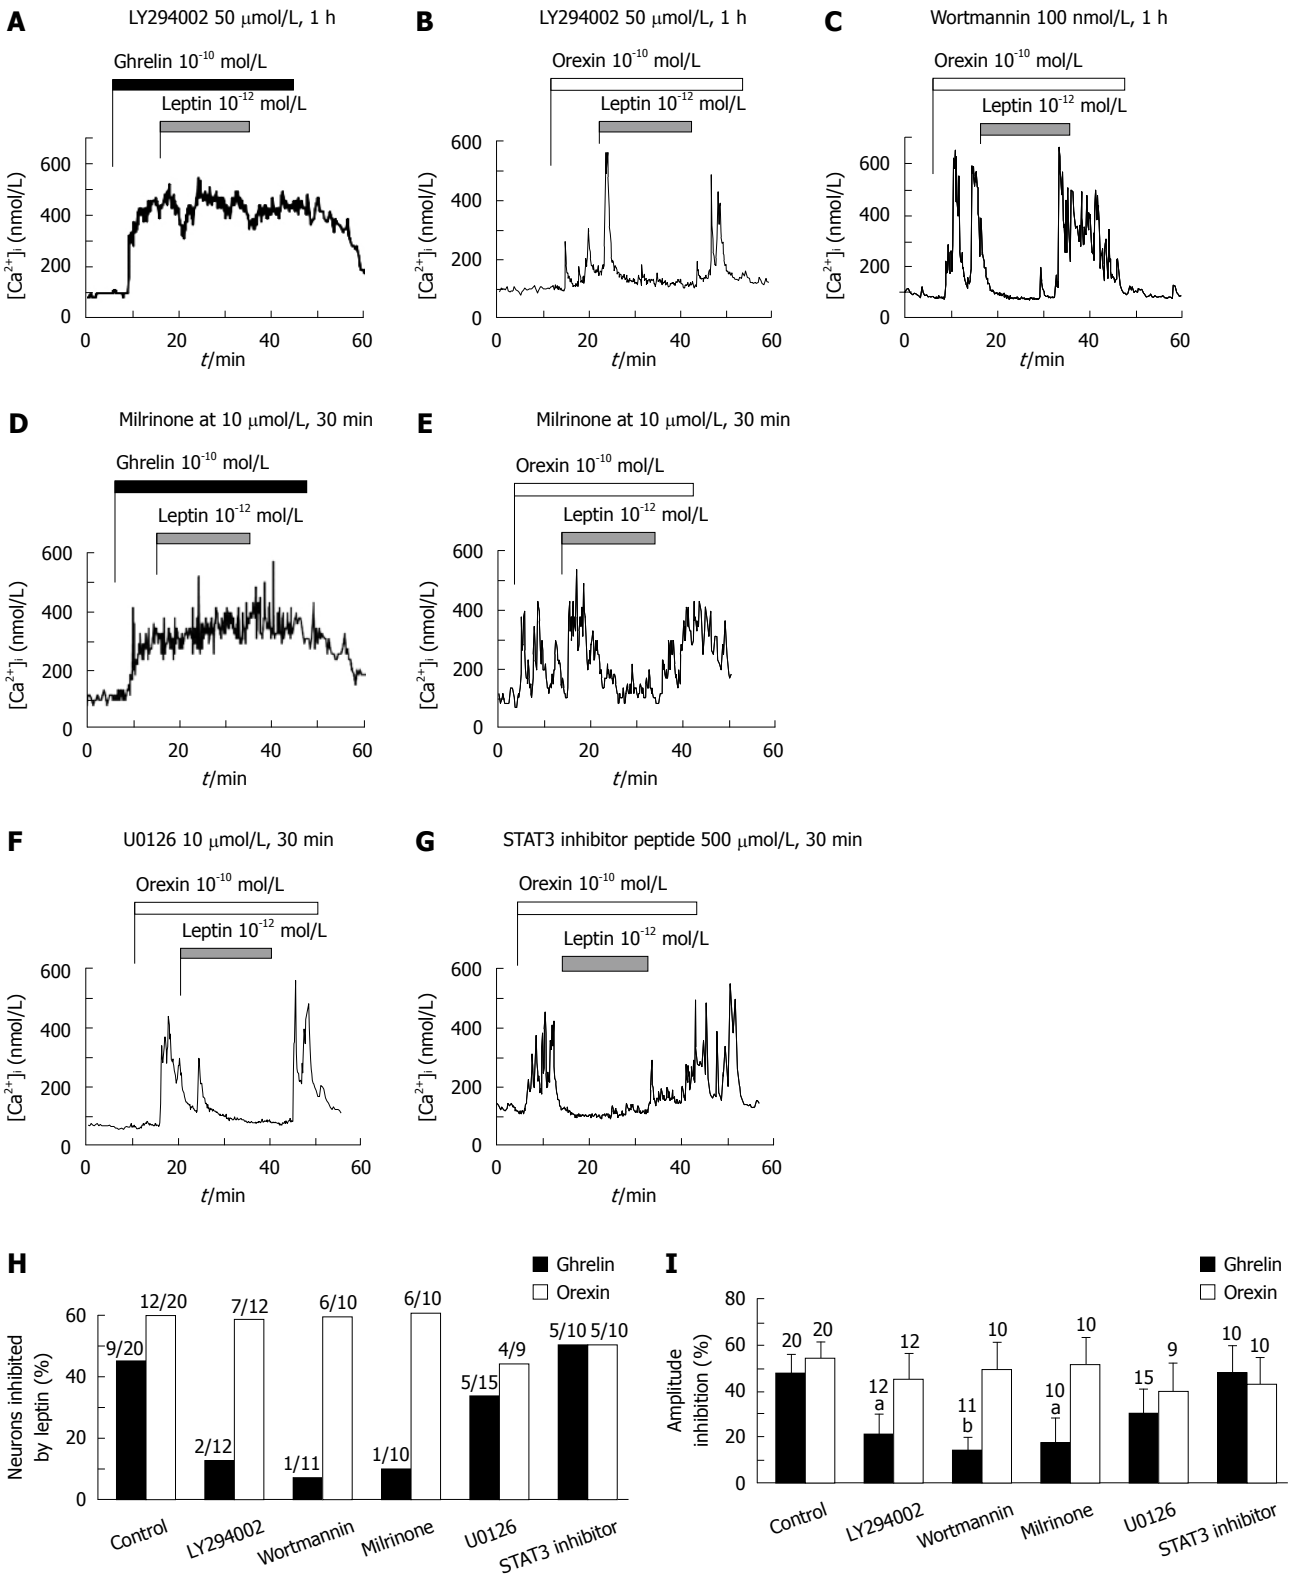

Figure 2 Leptin suppresses ghrelin-induced and orexin-induced $[Ca^{2+}]_i$ increases *via* different signaling pathways in NPY neurons. A-G: Effects of inhibitors for signaling molecules on the leptin action against ghrelin and orexin. Preincubation for 1 h with 50 μmol/L LY294002, an inhibitor for PI3-kinase, interfered with leptin action to suppress $[Ca^{2+}]_i$ responses to ghrelin (A), but not orexin (B). Preincubation for 1 h with 100 nmol/L wortmannin, another PI3-kinase inhibitor, little affected the leptin suppression of orexin-induced $[Ca^{2+}]_i$ increases (C). Preincubation for 30 min with 10 μmol/L milrinone, a PDE3 inhibitor, blocked the leptin action to suppress $[Ca^{2+}]_i$ responses to ghrelin (D), but not orexin (E). Preincubation for 30 min with 10 μmol/L U0126, an inhibitor for MAP-kinase, little affected the leptin action to suppress orexin-induced $[Ca^{2+}]_i$ increases (F). Preincubation for 30 min with a STAT3 inhibitor peptide at 500 μmol/L, did not significantly alter the leptin suppression of orexin-induced $[Ca^{2+}]_i$ increases (G). H: The number of neurons whose $[Ca^{2+}]_i$ responses to ghrelin or orexin were suppressed by leptin in the presence of inhibitors is expressed by percentage. The numbers above the bars indicate the number of neurons inhibited by leptin over that responded to ghrelin or orexin-A. I: Reduction of amplitudes of $[Ca^{2+}]_i$ responses to ghrelin or orexin-A by leptin is expressed by percentage. $^aP < 0.05$, $^bP < 0.01$ *vs* control. The data regarding ghrelin in H and I were in part taken from our previous paper[17].

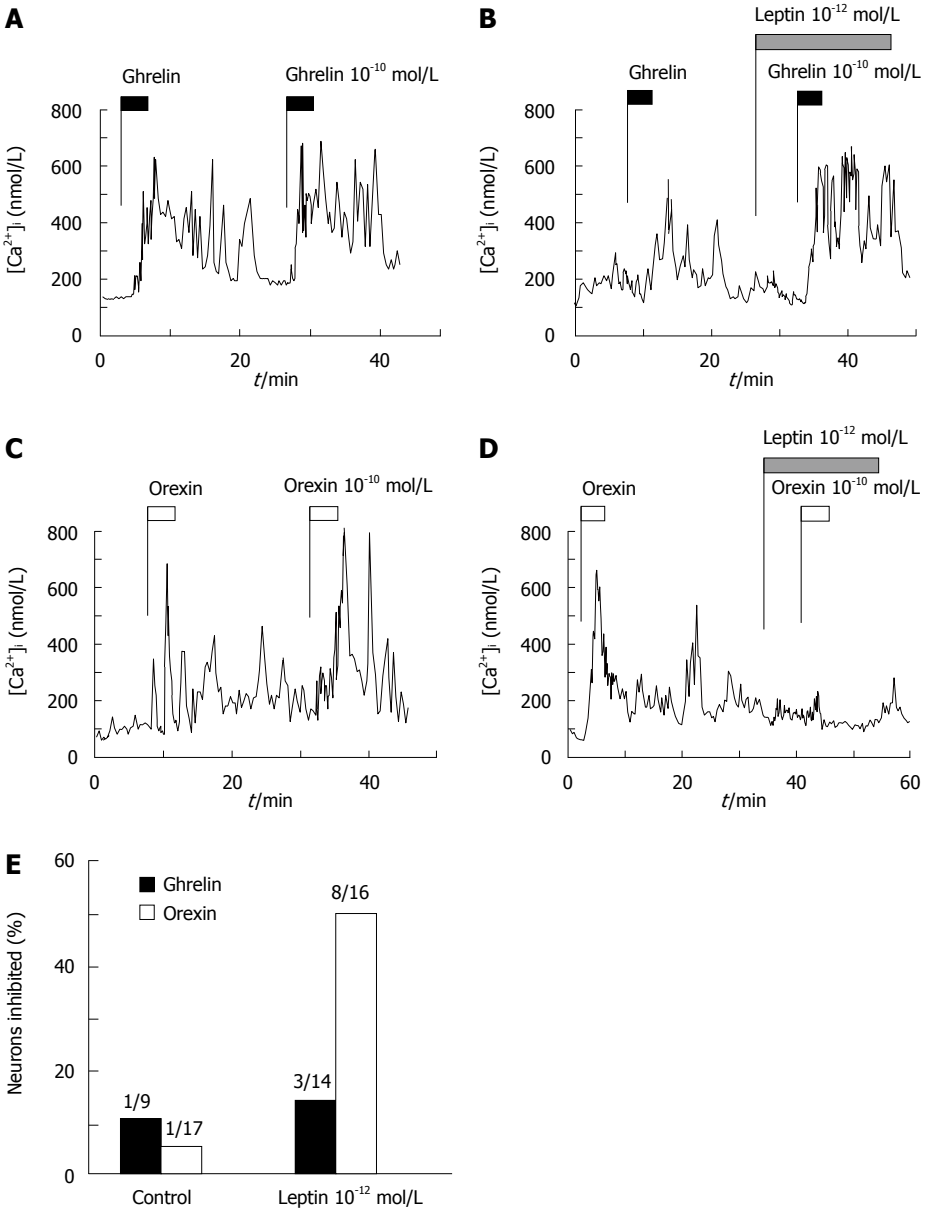

Figure 3 Prior treatment with leptin suppressed $[Ca^{2+}]_i$ responses to subsequent administration of orexin, but not ghrelin, in NPY neurons. A, C: Repeated administrations of ghrelin or orexin-A at 10^{-10} mol/L increased $[Ca^{2+}]_i$ twice in single ARC neurons; B, D: Prior administration of leptin failed to inhibit the effect of ghrelin added subsequently (B), but inhibited the effect of orexin-A (D); E: The number of neurons in which $[Ca^{2+}]_i$ responses to the second ghrelin or orexin addition were suppressed by prior administration of leptin or HKRB (Control) is expressed by percentage. The numbers above the bars indicate the number of neurons whose second responses were inhibited over that exhibited first responses to ghrelin or orexin-A.

4.7 mmol/L KCl, 1.2 mmol/L KH_2PO_4, 1.8 mmol/L $CaCl_2$, 1.2 mmol/L $MgSO_4$, and 10 mmol/L N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES) at pH 7.4. Fura 2-acetoxymethylester was obtained from Dojin Chemical (Kumamoto, Japan). Ghrelin and orexin-A were obtained from Peptide Institute, Inc. (Osaka, Japan), Leptin was from R&D Systems (Mineapolis, MN).

Data presentation and statistical analysis

The data are presented as the mean ± SE (*n*: number of neurons). Each study was based on at least 7 neurons prepared from at least 3 rats. Student's paired or unpaired *t*-test was used to evaluate differences and values of $P < 0.05$ were considered to be significant.

RESULTS

Leptin inhibits ghrelin- and orexin-A-induced $[Ca^{2+}]_i$ increases in NPY neurons

Single neurons isolated from the ARC were superfused with HKRB and subjected to measurements of $[Ca^{2+}]_i$ with fura-2 fluorescence imaging. Administration of ghrelin or orexin-A at 10^{-10} mol/L for 40-50 min into superfusion solutions increased $[Ca^{2+}]_i$ in a continuous manner (Figure 1A and B) as reported previously[16-18]. The $[Ca^{2+}]_i$ increases in response to ghrelin and orexin took place in an oscillatory manner. The peaks of $[Ca^{2+}]_i$ responses to ghrelin [486 ± 49 nmol/L (n = 33)] and orexin-A [433 ± 47 nmol/L (n = 27)] were significantly ($P < 0.001$) higher than the corresponding basal $[Ca^{2+}]_i$ levels prior to administration of the peptides [107 ± 12 nmol/L (n = 33) for ghrelin; 110 ± 10 nmol/L (n = 27) for orexin].

Both ghrelin-induced (Figure 1A) and orexin-induced $[Ca^{2+}]_i$ increases (Figure 1C) were inhibited by administration of 10^{-12} mol/L leptin in the ARC neurons, which were subsequently proven to be immunoreactive to NPY (Figure 1A and C, right panels). The results that leptin counteracts ghrelin and orexin actions on $[Ca^{2+}]_i$ in the ARC NPY neurons confirm previous reports[16-18].

Leptin inhibits ghrelin-induced $[Ca^{2+}]_i$ increases transiently and orexin-A-induced $[Ca^{2+}]_i$ increases long-lastingly in NPY neurons

Typical results of the effects of leptin on $[Ca^{2+}]_i$ responses to ghrelin and orexin-A are shown in Figure 1; leptin at 10^{-12} mol/L inhibited ghrelin-induced $[Ca^{2+}]_i$ increases in a transient manner (Figure 1A) and orexin-induced $[Ca^{2+}]_i$ increases in a longer-lasting manner (Figure 1C) during the 20 min period of leptin administration. Among 20 neurons that exhibited $[Ca^{2+}]_i$ responses to ghrelin, administration of 10^{-12} mol/L leptin inhibited $[Ca^{2+}]_i$ increases in 9 neurons (45%) during the earlier 2-7 min of leptin treatment, but only in 4 neurons (20%) later in the 10-15 min period of treatment (Figure 1E), showing attenuation of the counteracting effect of leptin for ghrelin in the later period (Figure 1F). In contrast, among 20 neurons that exhibited $[Ca^{2+}]_i$ responses to orexin, administration of 10^{-12} mol/L leptin inhibited $[Ca^{2+}]_i$ increases in 12 neurons (60%) during the 2-7 min of leptin treatment, and in 10 neurons (50%) in the 10-15 min period of treatment (Figure 1E), showing a long-lasting counteracting effect of leptin (Figure 1F). The long-lasting effect was also evoked by leptin at a lower concentration of 10^{-14} mol/L (Figure 1D). Leptin at both 10^{-14} mol/L and 10^{-12} mol/L counteracted ghrelin-induced $[Ca^{2+}]_i$ increases predominantly in a transient manner and orexin-induced $[Ca^{2+}]_i$ increases mainly in a long-lasting manner (Figure 1F).

Pretreatment with leptin inhibited orexin-induced, but not ghrelin-induced, $[Ca^{2+}]_i$ increases in NPY neurons

The data that leptin inhibited ghrelin-induced $[Ca^{2+}]_i$ increases transiently prompted us to hypothesize that efficacy of leptin is attenuated by time. Therefore, we examined whether prior administration of leptin is less effective in counteracting ghrelin action. Repetitive additions of ghrelin or orexin-A twice induced repeated $[Ca^{2+}]_i$ increases twice in a similar manner (Figure 3A and C). Following infusion of leptin that had started 8 min in advance, the addition of ghrelin induced $[Ca^{2+}]_i$ increases with amplitudes comparable to those in the control without leptin (Figure 3B), and the similar result was observed in the majority of neurons (Figure 3E). This result indicates a marked attenuation of inhibitory ability of leptin by time. In contrast, infusion of leptin that started 8 min in advance inhibited $[Ca^{2+}]_i$ responses to the addition of orexin-A in 8 of 16 orexin-responsive neurons (50%) (Figure 3D and E). This incidence of the inhibition by leptin administered in prior to orexin was comparable to the inhibition by leptin administered after orexin (12 of 20 neurons, 60%) (Figure 1E). These data indicate that the ability of leptin to counteract orexin action is well preserved without appreciable attenuation.

We next examined whether the difference in the time dependence of leptin action on ghrelin-*vs* orexin-induced $[Ca^{2+}]_i$ increases could involve different leptin signaling mechanisms in NPY neurons. Leptin is linked to several signaling pathways, which include phosphatidylinositol 3 (PI3)-kinase and, its downstream effecter phosphodiesterase 3 (PDE3)[23], signal transducer and activator of transcription 3 (STAT3)[24], and mitogen-activated protein (MAP)-kinase[25]. We have previously shown that leptin suppresses ghrelin-induced $[Ca^{2+}]_i$ increases *via* PI3-kinase- and PDE3-, but not MAP-kinase- and STAT3-, mediated pathway[17]. Therefore, whether these signaling mechanisms could be involved in the leptin action to counteract orexin-induced $[Ca^{2+}]_i$ increases was examined. Pretreatment with inhibitors for PI3-kinase, LY294002 (Figure 2A) or wortmannin (data not shown), blocked the leptin action to suppress $[Ca^{2+}]_i$ responses to ghrelin in both the response incidence (Figure 2H) and response amplitude (Figure 2I). Likewise, pretreatment with an inhibitor for PDE3, milrinone, blocked the leptin action against ghrelin (Figure 2D, H and I). These results confirm previous report[17]. In contrast, LY294002 (Figure 2B), wortmannin (Figure 2C) and milrinone (Figure 2E) failed to significantly affect the leptin suppression of orexin-induced $[Ca^{2+}]_i$ increases in both the response incidence and amplitude (Figure 2H and I). Furthermore, pretreatment with a MAP kinase inhibitor U0126 (Figure 2F) or a STAT3 inhibitor peptide (Figure 2G) little altered the leptin ability to inhibit $[Ca^{2+}]_i$ responses to orexin in both the response incidence and amplitude (Figure 2H and I), the results similar to those reported for ghrelin-induced $[Ca^{2+}]_i$ increases[17].

DISCUSSION

The present data indicate that leptin inhibits ghrelin-induced $[Ca^{2+}]_i$ increases in a transient manner and orexin-induced $[Ca^{2+}]_i$ increases in a long-lasting manner. The transient action of leptin to inhibit ghrelin-induced $[Ca^{2+}]_i$ increases is not due to insufficient concentration of leptin, since leptin at a lower concentration of 10^{-14} mol/L is already maximal in counteracting the ghrelin effect[17] and more specifically in exhibiting the transient inhibitory property (Figure 1F). Furthermore, the transient property for leptin inhibition of ghrelin-induced $[Ca^{2+}]_i$ increases is neither due to excessive concentration of ghrelin, since the ghrelin concentration of 10^{-10} mol/L used in the present study is close to a maximal, but never super-maximal concentration in activating NPY neurons[16]. Therefore, the transient manner with which leptin counteracts ghrelin action reflects the intrinsic property of interaction between leptin and ghrelin.

The present study clearly indicated that the leptin signaling underlying the inhibition of $[Ca^{2+}]_i$ responses to orexin-A in NPY neurons is distinct from that to ghrelin. The transient action of leptin to inhibit ghrelin-induced $[Ca^{2+}]_i$ increases in NPY neurons may be mediated by the leptin signaling *via* PI3-kinase and PDE3, since the inhibitors for these enzymes block the leptin action (Figure 2A and D)[17]. The ghrelin signaling *via* the cAMP system could be the target for this leptin signaling[17]. On the other hand, the long-lasting action of leptin to counteract orexin-induced $[Ca^{2+}]_i$ increases

was not affected by inhibitors for PI3-kinase, PDE3, MAP-kinase and STAT3, well known leptin signaling molecules. This result suggests that the long-lasting counteracting action of leptin for orexin is mediated by a yet unidentified leptin signaling, which may long-lastingly inhibit the orexin-stimulated PLC-PKC-IP3 pathway reported previously[18], though further study is definitely needed to elucidate the signaling interaction between leptin and orexin.

The transient nature with which leptin counteracts the ghrelin action on NPY neurons may serve as the neuronal mechanism that allows fasting-associated increases in ghrelin levels to activate the ARC NPY neurons in the continuous presence of leptin[14] and thereby stimulate feeding.

Both ghrelin and orexin have been suggested to be concerned with obesity and type 2 diabetes[26,27]. Based on the present results, leptin resistance could alter the sensitivity to ghrelin and orexin in the ARC NPY neurons, which may alter the energy metabolism and thereby influence the pathogenesis of obesity and type 2 diabetes.

COMMENTS

Background

Ghrelin and orexins are potent orexigenic peptides working primarily via activating neuropeptide Y (NPY) neurons in the arcuate nucleus (ARC). NPY neurons in the ARC also serve as a major target for the anorexigenic leptin. Therefore, interactions of leptin with ghrelin and orexin in the ARC NPY neurons may play a key role in physiological regulation of feeding.

Research frontiers

The authors study the time course of leptin effects on ghrelin-induced *vs* orexin-induced $[Ca^{2+}]_i$ increases in NPY neurons.

Innovations and breakthroughs

The study clearly indicated that the leptin signaling underlying the inhibition of $[Ca^{2+}]_i$ responses to orexin-A in NPY neurons is distinct from that to ghrelin. The transient action of leptin to inhibit ghrelin-induced $[Ca^{2+}]_i$ increases in NPY neurons may be mediated by the leptin signaling *via* PI3-kinase and PDE3, The ghrelin signaling *via* the cAMP system could be the target for this leptin signaling.

Applications

The transient nature with which leptin counteracts the ghrelin action on NPY neurons may serve as the neuronal mechanism that allows fasting-associated increases in ghrelin levels to activate the ARC NPY neurons in the continuous presence of leptin[14] and thereby stimulate feeding.

Peer review

A well designed, in-depth paper about the time course of leptin effects on ghrelin-induced *vs* orexin-induced $[Ca^{2+}]_i$ increases in NPY neurons.

Abstract

AIM: To elucidate the metabolism and the effect of the cyclosporin A (CyA) as a representative immunosuppressive drug used in transplantation in a partially hepatectomized rat model.

METHODS: CyA was administered to rats that underwent a 70% hepatectomy. These rats were randomly assigned into three groups according to the dose of CyA administration as follows; (group 1) water, (group 2) 5 mg/kg CyA, (group 3) 10 mg/kg CyA. On postoperative days-1, 3, 7 and 14, the rats were killed to analyze the serum concentration of CyA, the liver regeneration ratio, biochemical or histological markers, and mRNA expression using reverse transcriptase-polymerase chain reaction method to determine albumin and cytochrome p450 expression.

RESULTS: The serum concentration of CyA in group 3 was significantly higher than group 2 during liver regeneration. CyA enhanced the liver regeneration in a dose dependent manner. The mRNA expression associated with CyA metabolism was significantly decreased on day 14, while preserving the albumin producing activity.

CONCLUSION: These data indicate that the p-450 activity required to metabolize the CyA may be reduced during regeneration of the remnant liver after a hepatectomy, which may, therefore, be linked to difficulty in controlling the optimal dose of CyA during early period of LDLT.

INTRODUCTION

Orthotopic liver transplantation is an established treatment for patients with end-stage liver disease. However, donor organ shortages remain extremely problematic. To address this issue, living donor liver transplantation (LDLT) was developed[1]. During transplantation, the liver graft is subjected to a variety of potential hepatic injuries including ischemic injury associated with organ harvesting and the obligate storage before revascularization, reperfusion injury following revascularization, immunological attack caused by the immune system of the recipient, toxicity of certain drugs used during the post-transplant period, and certain infections[2,3]. After transplantation the liver graft goes into a regeneration process, which may be important for the overall success of the transplant procedures. Notably, the liver graft must be capable of normal growth, repair, and regeneration in the presence of immunosuppressive drugs such as calcineurin inhibitors. The aim of the present study was, therefore, to investigate the pharmacokinetics of cyclosporin A (CyA)[4] and its effect on liver regeneration and metabolic

activity to elucidate the mechanism of metabolic activity and serum concentration of cyclosporin A as an example of calcineurin inhibitors administered during liver regeneration in a rat model.

MATERIALS AND METHODS

Animals and treatments

Adult male Sprague Dawley rats, weighting 250-320 g (CRJ Charles River Japan, Kanagawa, Japan), were provided with water, and a standard laboratory diet ad libitum. All of the studies were performed according to the rules and regulations of the University of Nagasaki Research Animal Resources Guidelines.

Surgical procedures

A 70% hepatectomy was carried out according to the method described by Higgins and Anderson[5] under light ether anesthesia. Surgery was performed between 9:00 and 12:00 a.m. to avoid diurnal variation in the regenerative responses. The rats were randomly assigned to three groups, and treated daily by gavage beginning immediately after the hepatectomy. Group 1 animals were given water. Group 2 animals received 5 mg/kg CyA (Neoral®, Novartis Pharma, Basel) and group 3 animals received 5 or 10 mg/kg CyA. These CyA doses were selected based on the results reported by Morii *et al*[6].

In each group, five rats were killed before and at day 1, 3, 7 and 14 after the hepatectomy. Immediately before they were sacrifices, blood samples were obtained from the inferior vena cava. The remnant liver was removed to investigate hepatic restoration. The experimental protocol is demonstrated in Figure 1.

Serum concentration of CyA

The serum concentration of CyA was measured in the whole blood by fluorescence polarization according to the manufacturer's protocols (AxSYM® analyzer, Abbott, Tokyo)[7].

Regeneration ratio

The liver regeneration ratio in each experiment was defined as the ratio of the remaining liver weight to the initial body weight.

Serum ALT and T-Bil level

To evaluate liver toxicity of CyA administration, plasma concentrations of alanine aminotransferase (ALT) and total bilirubin (T-Bil) were examined using an automated analyzing system according to the manufacturer's protocol.

RT-PCR analysis

Total hepatic RNA was prepared by the method as described previously[8] and used for the determination of the expression levels of albumin (ALB) and cytochrome-P 3A2 (CYP3A2). In addition, the level of gene expression of glyceral-dehyde-3-phosphate-dehydrogenase (GAPDH) was measured as an internal control. Complementary DNA (c-DNA) was prepared from total RNA by the method described previously[8]. The primers used in the present study are listed in Table 1.

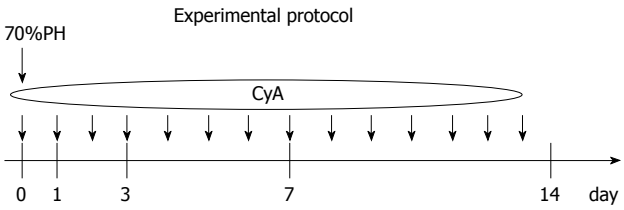

Figure 1 Administration schedule of CyA. Rats underwent a 70% hepatectomy immediately followed by the daily administration of CyA for up to 14 d per os. Blood samples were collected on post operative day 1, 3, 7 and 14.

Statistical analysis

The data are expressed as the mean ± SD (n = 5). Statistical analyses were performed by unpaired, two tailed Student's t-test. A P value less than 0.05 was considered to be significant.

RESULTS

Changes of serum concentration of CyA during liver regeneration

Figure 2 shows that the concentration of CyA reached a maximum during 3 to 7 d, and gradually declined thereafter. The levels of CyA in the PH group were significantly higher than that in control group.

The effect of CyA on liver regeneration ratio

As shown in Figure 3, the lower concentration of CyA (5 mg) did not affect the liver regeneration potential during the observation period; however, the rate of liver regeneration was significantly higher than that in the low CyA group on postoperative day 7.

Changes of hepatocyte specific gene expression during liver regeneration

Alb mRNA expression remained constant during liver regeneration, while hepatocyte specific p450 activity-CYP3A2 was significantly reduced on postoperative day 14 (Figure 4).

The effect of CyA on liver function

Rats were anesthetized and blood samples were collected through the tail vein at the indicated time points. ALT and T-Bil levels were measured as indicators of liver function. On day 1, plasma ALT concentrations increased during the first 24 h after the hepatectomy and then decreased gradually returning to the preoperative values at 72 h. There was no significant difference between the groups (Figure 5).

As shown in Figure 5, the ALT level in control animals were slightly increased, and thereafter gradually reduced. There was no statistically significant difference in any of the groups.

Table 1 Primers used in the present study. The hepatocyte specific gene expression levels were determined by using RT-PCR method. As hepatocyte specific parameters, albumin and CYP3A2 were selected. As an internal control, GAPDH gene expression was also examined. The primer sequences and optimal PCR conditions were summarized

Gene	Sequence (5'-3' sense/antisense)	Reaction condition			Product size	Cycles
		Denaturation	Annealing	Elongation		
GAPDH	TTCAACGGCACAGTCAAG CACACCCATCACAAACAT	95℃, 1 min	60℃, 1 min	72℃, 2 min	240 bp	26
CYP3A2	TACTACAAGGGCTTAGGGAG CTTGCCTGTCTCCGCCTCTT	94℃, 1 min	60℃, 1 min	72℃, 2 min	348 bp	27
ALB	ATACACCCAGAAAGCACCTC CAGAGTGGAAGGTGAAGGTC	94℃, 1 min	60℃, 1 min	72℃, 2 min	305 bp	27

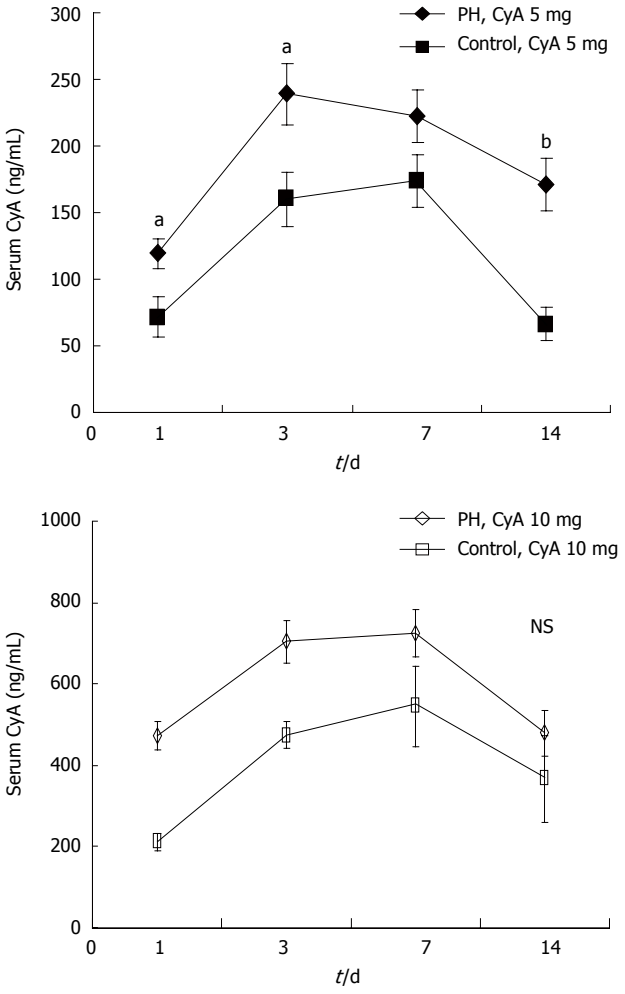

Figure 2 Changes in the serum concentration of CyA during liver regeneration. The values are expressed as the mean ± SD of 5 samples in each group. The concentration of CyA reached a maximum during 3 to 7 d, and gradually declined thereafter. The level of CyA in the PH group was significantly higher than that in control group. $^{a}P < 0.05$, $^{b}P < 0.01$.

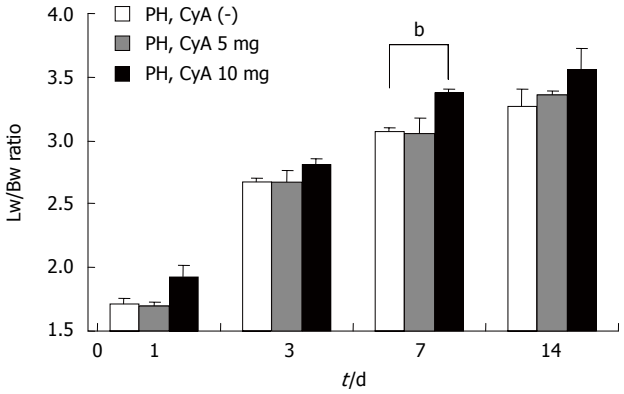

Figure 3 The effect of CyA on the liver regeneration ratio. The values are expressed as the mean ± SE of 5 samples in each group. The low concentration of CyA (5 mg) did not affect the liver regeneration potential during the observation period; however, the rate of liver regeneration was significantly higher than that in the-low CyA group on postoperative day 7. $^{b}P < 0.01$.

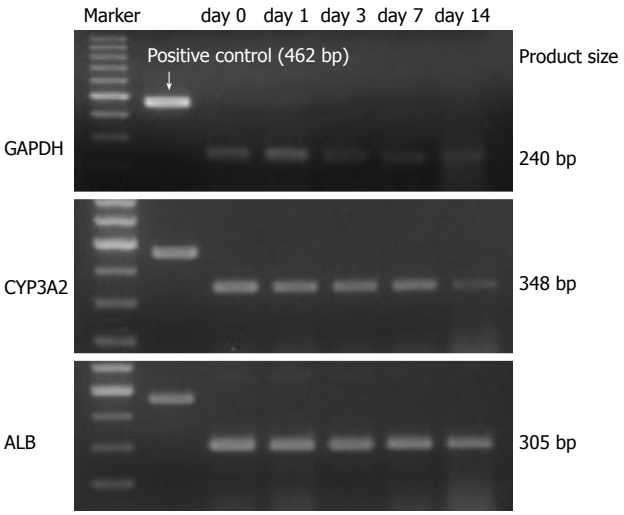

Figure 4 Changes of hepatocyte specific gene expression during liver regeneration. Alb mRNA expression remained constant during liver regeneration, while the hepatocyte specific p450 activity-CYP3A2 significantly decreased on postoperative day 14.

DISCUSSION

The present study, investigated the pharmacokinetics of the CyA in a rat two thirds hepatectomy model, for the first time. The results yielded important information concerning the interrelationship between the CyA and regenerating liver. (1) The metabolism is retarded in a regenerating liver, which is actually seen in clinical partial liver transplantation. (2) CyA has possible hepatotrophic effect on the regenerating liver in a CyA-dose dependent manner. (3) The p450 activity of the regenerating liver was down-regulated after CyA administration.

As expected, the serum concentrations of CyA after

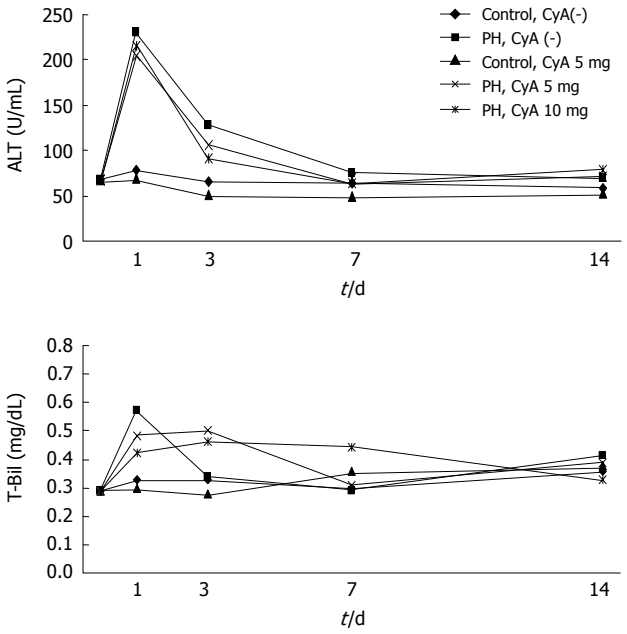

Figure 5 The effect of CyA on liver function. Rats were anesthetized and blood samples were collected through the tail vein at the indicated time points. ALT and T-Bil level were measured as indicators of liver function. On day 1, ALT level were significantly increased and thereafter gradually reduced. There was no statistically significant difference in each group ($P > 0.05$).

a hepatectomy were significantly higher than that seen in the sham operated group as previously reported in clinical settings. There are several possible explanations for this, including increased absorption, decreased volume of distribution, or decreased clearance.

However, an increased absorption is not likely. The CyA used in this study was the microemulsified type, and the absorption is bile independent. Therefore, absorption of the CyA was table in both groups[9]. The volume of distribution should be smaller in the partially hepatectomized rats. In other words, a smaller volume of distribution could increase the relative blood level of an immunosuppressant for a given dose.

Another possibility for the higher levels of CyA after the partial hepatectomy is reduced hepatic immunosuppressive clearance, which may be explained by two possible mechanisms. One is simply because of the reduced hepatic mass available to metabolize the drugs. Another possibility is that immediately after hepatectomy, the hepatic mass is reduced because of the surgical excision of hepatic tissue. As a result, the ability to clear substances through the liver is reduced. For instance, the indocyanine green half-life is increased four-fold after a 60% hepatectomy and by 33% after a 40% hepatectomy[10]. In the rats after a two thirds hepatectomy, the whole-organ reduced form of-cytochrome c reductase and cytochrome p-450 activity are reduced by half. After a 90% hepatectomy, galactose clearance in rats was reduced by 90% within 24 h after surgery. The genetic data regarding the cytochrome p-450 gene suggested that the metabolic activity of specific enzymes responsible for drug metabolism is reduced in the remaining hepatic tissue. Marie *et al* reported that the cytochrome p-450 activity decreased soon after a two-thirds hepatectomy in rats, returning to 90% of the initial activity 2 wk postoperatively. In the present study, the expression analysis of cytochrome p450 activity was performed using RT-PCR method. The results showed the cytochrome p-450 activity remained at the initial stage of liver regeneration, finally declined in the late stages. Although, no other liver specific enzymes were examined, a previous study demonstrated that the levels of mRNA for enzymes responsible for gluconeogenesis and the acute phase proteins are increased up to four fold after a hepatectomy[11]. Therefore, there are adaptive changes in the hepatic tissue after a partial hepatectomy. Collectively, the activity of enzymes that support hepatic regeneration is increased, whereas the activity of the enzymes responsible for drug metabolism is reduced.

The present data also suggest that cyclosporine enhances the hepatic regenerative response without affecting the individual hepatocellular function. Among immunosuppressive drugs currently in clinical use, azathioprine and steroids have been reported to exert an antiproliferative action on the regenerating liver. Azathioprine inhibits the DNA or RNA synthesis of hepatocytes, acting as an antimetabolite, whereas the action of steroids is more complex. Several investigators have suggested a functional linkage between lymphoid tissues and hepatocytes. Craddock *et al* reported that a partial hepatectomy induced proliferation of hepatocytes as well as lymphoid tissues. Another study recently suggested a very close and positive interrelationship between hepatocyte replication and lymphocyte activities[12]. The new potent immunosuppressor, cyclosporin A has been extensively compared with azathioprine and steroids. It primarily inhibits T-lymphocyte responses, and has no functional effects on other hematopoietic cells or phagocytic cells[13-16]. The present study on hepatectomized rats confirmed the antimitotic action of these immunosuppressants on hepatocytes, although the degree of suppression was less than that seen in previous reports.

Notably, there seems to be some discrepancy in these data showing that the statistical difference of the serum concentration of CyA between 5 mg treated and control animals was not observed in the groups treated with 10 mg of CyA treated as demonstrated in Figure 2. However, this is probably a reflection of-the fact that the liver regenerative effect of CyA at a higher dose may improve the impaired metabolic potential for CyA itself.

The limitation of this study is that this model potentially does not require immunosuppresion; therefore, further research will be needed to elucidate the underlining mechanism for these findings in a partial liver transplant model.

In conclusion, these results indicate that CyA levels in hepatectomized rats were significantly higher in control rats without a hepatectomy, probably because of the decreased volume of distribution, and/or decreased clearance by reduced metabolic activity. The possible hepatotrophic effect of CyA on the regenerating liver has also been confirmed.

Abstract

AIM: To investigate the therapeutic potential of an RNA ligand (aptamer) specific for the catalytic ricin A-chain (RTA), the protective effects of a 31-nucleotide RNA aptamer (31RA), which formed a high affinity complex with RTA, against ricin-induced toxicity in cell-based luciferase translation and cell cytotoxicity assays were evaluated.

METHODS: To test the therapeutic potential of anti-RTA aptamers in Chinese hamster ovary (CHO) AA8 cells stably transfected with a tetracycline regulatable promoter, ricin ribotoxicity was measured using luciferase and ricin-induced cytotoxicity was ascertained by MTS cell proliferation assay with tetrazolium compound [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium].

RESULTS: Inhibition of protein synthesis by ricin in CHO AA8 cells resulted in diminished luciferase activity and treatment with polyclonal antibody against deglycosylated RTA (dgA) neutralized the inhibitory effects of ricin on luciferase activity and protected against ricin-induced cytotoxicity as measured by MTS assay. The 31RA anti-RTA aptamer inhibited the translation of luciferase mRNA in cell-free reticulocyte translation assay. 31RA aptamer also partially neutralized the inhibitory effects of ricin on luciferase activity and partially protected against ricin-induced cytotoxicity in CHO AA8 cells.

CONCLUSION: We have shown that anti-RTA RNA aptamer can protect against ricin ribotoxicity in cell-based luciferase and cell cytotoxicity assays. Hence, RNA aptamer that inhibits RTA enzymatic activity represents a novel class of nucleic acid inhibitor that has the potential to be developed as a therapeutic agent for the treatment of ricin intoxication.

INTRODUCTION

Ricin, a lectin from the castor bean plant *R. communis* is considered one of the most potent plant toxins. Ricin poisoning can cause severe tissue damage and inflammation and can result in death. More than 750 cases of accidental or deliberate ricin poisoning have been described in humans. Most accidental exposures occur by ingestion of the seeds of castor beans whereby the toxin is released after the seed coat is damaged. The ingested toxin causes severe gastrointestinal damage with symptoms including nausea, vomiting, diarrhea, and abdominal pain and may progress to hypotension, liver failure, renal dysfunction, and death due to multiorgan failure or cardiovascular collapse[1]. Ricin administered

intragastrically to mice induced villus atrophy and epithelial damage in the proximal small intestine[2]. In experimental exposed animals, intravenous injection of ricin to mice induced severe inflammatory responses and clinical symptoms resembling hemolytic uremic syndrome (HUS), including thrombotic microangiopathy, hemolytic anemia, thrombocytopenia, and acute renal failure[3].

Ricin belongs to a group of toxins referred to as ribosome-inactivating proteins (RIPs)[4,5] and is composed of two glycoproteins, the A-chain (RTA) and the B-chain (RTB), linked by a disulfide bond[6]. RTB binds to galactose residues on cell surface receptors and cell binding is followed by endocytic uptake. A proportion of the ricin moves from early endosomes to the trans-Golgi network and to the endoplasmic reticulum (ER) lumen. In the ER lumen, RTA and RTB dissociate and RTA is retrograde transported across the ER membrane into the cytosol[7]. RTA is a ribotoxin that possesses RNA N-glycosidase activity that disables protein translation by depurinating a single adenine in the 28 S eukaryotic ribosomal RNA[8] which prevents the binding of elongation factor 2, thereby terminating protein synthesis[9,10]. The irreversible poisoning of the ribosome and inhibition of protein synthesis may lead to eventual cell death.

Since currently there is no antidote or specific therapy available for ricin poisoning, the discovery of antitoxins is a high priority. Ricin ribotoxicity can be counteracted by several different types of antitoxins including neutralizing anti-ricin antibodies, small molecule RTA inhibitors, polynucleotide active site inhibitors and polynucleotide substrate analogues[11,12]. *In vitro* selection had been used to generate RNA ligands (aptamers) specific for the catalytic ricin A-chain[13]. An initial 80-nucleotide RNA ligand was minimized to a 31-nucleotide RNA aptamer (31RA) that contained all sequences and structures necessary for forming high affinity complexes with RTA and blocking enzymatic activity of RTA *in vitro*. A transient cell-based luciferase assay had been utilized for quantifying protein synthesis inhibition by bacterial toxins[14]. In this report, we utilized a stable cell-based luciferase assay and showed that 31RA aptamer also neutralized the inhibitory effects of ricin on translation inhibition in cell-free and cell-based luciferase assays and ricin-induced cytotoxicity assay. The use of a stably transfected cell-based luciferase assay will facilitate the development of high throughput screening for inhibitors of ricin as potential antidotes for the treatment of ricin intoxication.

MATERIALS AND METHODS

Cell-free luciferase translation assay

Ricin (*Ricinus communis* agglutinin Ⅱ) and ricin A-chain (RTA) were purchased from Vector Laboratories, Inc. (Burlington, CA). Anti-deglycosylated ricin A-chain (anti-dgA) antibody was IgG purified by protein-A sepharose from pooled polyclonal antisera obtained from mice hyperimmunized with dgA (USAMRIID, Fort Detrick, MD). The anti-RTA RNA aptamer (31RA) (GGCGAAUUCAGGGGACGUAGCAAUGACUGCC)[13] was synthesized by Sigma-Genosys. Rabbit reticulocyte lysate (nuclease treated), amino acid (complete) mixture, luciferase control RNA, RNasin inhibitor, nuclease-free water, and luciferin substrate (CFT luciferase reporter buffer) were purchased from Promega (Madison, WI). 31RA aptamer was diluted and heated for 3 min at 65℃, cooled to 25℃ and incubated at 25℃ for 10 min. After incubation, aptamer and toxin were mixed together and incubated at 25℃ for an additional 10 min. As a standard control, ricin (1.6 to 200 ng/mL) and RTA (0.4 to 50 ng/mL) diluted in PBS buffer were added to a V-shaped 96-well microtiter plate. Rabbit reticulocyte lysate, RNAsin, amino acid complete mixture, nuclease-free deionized water, and luciferase mRNA were mixed together and kept on ice. Five μL of each standard and treatment group were added to microtiter plate, and then 25 μL of the lysate mixture was added to each well. The plate was wrapped in a damp paper towel, placed in a plastic bag and incubated for 90 min at 37℃. After incubation, 5 μL of reaction mixture was transferred to a black microtiter plate and 45 μL of the luciferin reaction buffer was added to each well. Luminescence was measured as counts per second (CPS) using a SpectraMax Luminometer (Molecular Devices). Data were presented as the % of control (PBS only or no treatment) [CPS experimental/CPS PBS control × 100] as previously described[15]. Statistical analyses were calculated using Microsoft Excel 7.0 and SigmaPlot™ V3.01. Three separate assays were performed for each experimental group.

Cell-based luciferase and cytotoxicity assays

Chinese Hamster Ovary AA8 (CHO AA8) cells offered a stably transfected luciferase reporter cell system, whereby expression of the luciferase gene was under the transcriptional control of a tetracycline-repressible promoter system (Tet-Off™ Expression System from Clontech/BD Biosciences). CHO AA8 cells were cultured in Dulbecco's modified Eagle's Medium (DMEM) supplemented with 10% FBS, penicillin and streptomycin and incubated at 37℃ in a humidified 5% CO_2 incubator. Isotype control mouse IgG, anisomycin and doxycycline were obtained from Sigma-Aldrich.

To suppress luciferase expression, CHO AA8 cells were cultured in DMEM containing 10% FBS and doxycycline (Dox) (1 μg/mL). For the kinetics of induction of luciferase activity, cells were trypsinized and seeded at 2×10^5 cells/well in 6-well plate without Dox and 3 h after cell plating, residual and cell-attached Dox was removed by several washes with PBS. Cells were subjected to the indicated treatment and incubated for different lengths of time before cell lysis. As control, cells were treated with anisomycin (10 μg/mL). Equal amounts of protein (20 μg) were assayed for luciferase activity using the Bright-Glo™ Luciferase Assay System (Promega) and luminescence was measured with EG&G Berthold microplate luminometer (MicroLumat Plus LB96V).

To evaluate the protective effects of anti-dgA Ab

and 31RA aptamer, 5000 CHO AA8 cells were plated in 96-well plates in the absence of Dox overnight. Ricin was co-incubated with anti-dgA IgG or control IgG at a ratio of 1 μg ricin to 10 μg antibody for 30 min at 37℃ in 5% CO_2 as previously described[16]. The ricin-antibody mixture was added to CHO AA8 cells in triplicate wells. Prior to use, the 31RA aptamer was heated at 65℃ for 3 min and cool at 25℃ for 10 min. Various dilutions of the 31RA aptamer were added to ricin and incubated at 37℃ for 30-40 min before incubation with cells. Cells were harvested 24 h after treatment for luciferase assay.

For ricin-induced cytotoxicity assay, CHO AA8 cells were seeded in 96-well flat-bottom plates at 5000 cells/well in 100 μL DMEM plus 10% FBS and incubated at 37℃ overnight. Ricin was pre-incubated with anti-ricin Ab or aptamer as described above and cell viability was assayed at 48 h post-treatment. Cytotoxicity of CHO AA8 cells induced by ricin was quantitated in triplicate wells using the CellTiter 96® Aqueous Non-Radioactive Cell Proliferation (MTS) Assay (Promega) and the plate was read using a 492 nm absorbance filter in a Perkin Elmer HTS700 BioAssay plate reader.

RESULTS

Hale ML[15] developed a cell-free *in vitro* translation assay for measuring the ribotoxicity of ribosome-inactivating toxins based on inhibition of protein translation of the luciferase mRNA in a rabbit reticulocyte assay. As shown in Figure 1 (upper panels), the amount of luciferase translated, as measured by luminescence, was inversely proportional to the concentration of RTA and ricin holoenzyme. The protective effects of 31RA aptamer were first evaluated using the cell-free translation assay. Preincubation of RTA (5 ng/mL) with 31RA aptamer at both 1 and 5 ng/mL protected equally against RTA-induced translation inhibition while dose-dependent protection was observed with a higher dose of RTA (10 ng/mL) (Figure 1A, lower panel). When preincubated with the ricin holoenzyme, 31RA aptamer partially neutralized protein synthesis inhibition by ricin (Figure 1B, lower panel).

To evaluate the protective effects of 31RA aptamer against ricin ribotoxicity in cells, we utilized a cell-based luciferase assay to complement the cell-free luciferase translation assay. For the cell-based luciferase assay, CHO AA8 cells stably transfected with a luciferase reporter gene under a tetracycline-repressible promoter were used to measure the ribotoxicity of ricin. In the presence of ATP, the luciferase enzyme catalyzes the oxidation of D-luciferin to produce light and the light output corresponds to the concentration of the luciferase enzyme and activity. The light output (Relative light unit, RLU) was used to measure the dose-dependent inhibition of luciferase activity by ricin compared to anisomycin, a small molecule protein synthesis inhibitor known to target ribosomal RNA (rRNA) at an adjacent site distinct from that targeted by ricin[10]. First, the kinetics of induction of expression of the luciferase reporter gene after removal of doxycycline

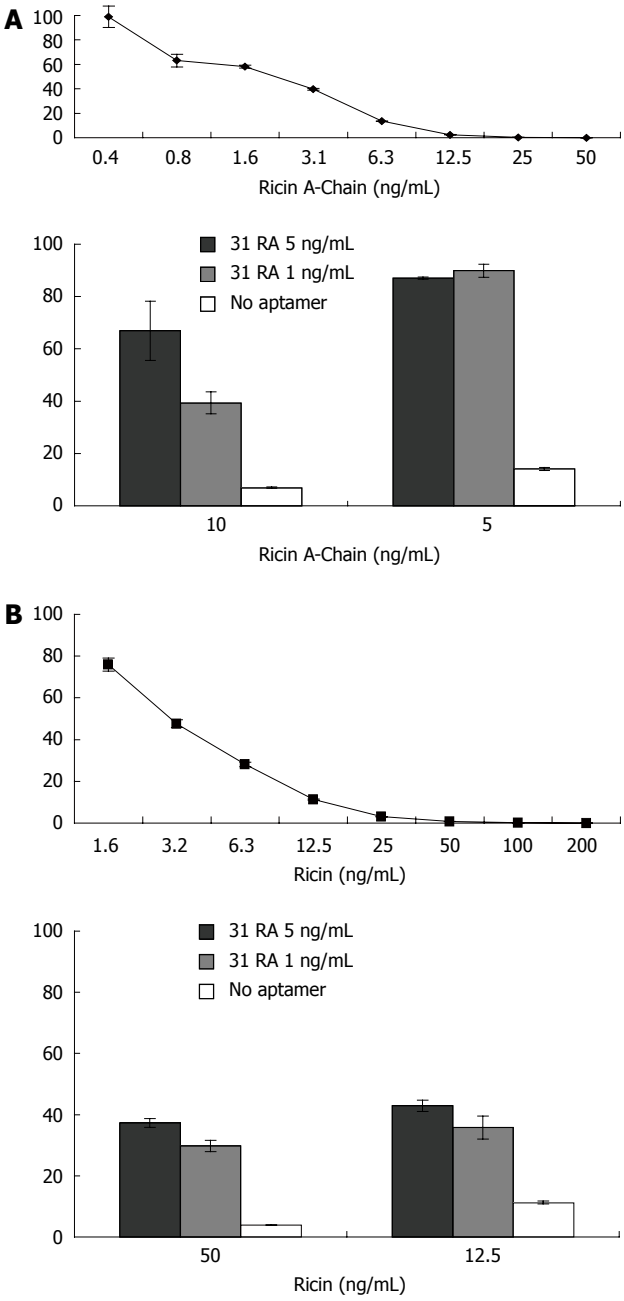

Figure 1 Cell-free luciferase translation assay for biological activity of ricin and protective effects of anti-RTA 31RA aptamer. A: Effects of increasing concentrations of RTA on luciferase activity in cell-free translation assay (upper panel) and neutralization by 31RA aptamer (lower panel); B: Effects of increasing concentrations of ricin holoenzyme on luciferase activity in cell-free translation assay (upper panel) and neutralization by 31RA aptamer (lower panel).

was determined by measuring luciferase activity over a 24-h period in the absence and presence of ricin or anisomycin (Figure 2A) The increase in luciferase activity was observed at 3 h after induction and ricin (1 μg/mL) and anisomycin (10 μg/mL) completely inhibited the increase in luciferase activity. Treatment of CHO AA8 cells with increasing concentrations of ricin resulted in increased inhibition of luciferase activity in a dose-dependent manner compared to untreated control and maximal inhibition was obtained with > 0.5 μg/mL ricin (Figure 2B).

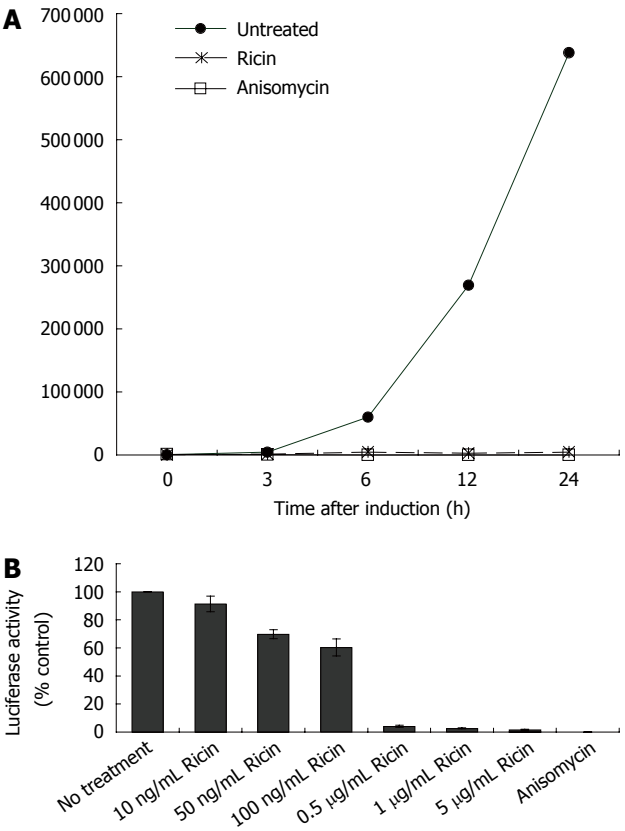

Figure 2 Cell-based luciferase assay for biological activity of ricin in CHO AA8 cells. A: Kinetics of induction of luciferase activity in CHO AA8 cells and inhibition by ricin and anisomycin. CHO AA8 cells were cultured in medium containing doxycycline (Dox) to suppress luciferase expression. For induction of luciferase expression, medium containing Dox was removed and replaced with medium (untreated) or medium containing ricin (1 μg/mL) or anisomycin (10 μg/mL). At various timepoints (0, 3, 6, 12, 24 h) after treatment, luciferase activity was measured. Light output is expressed as RLU; B: Dose-dependent inhibition of luciferase activity by increasing concentrations of ricin or anisomycin as control.

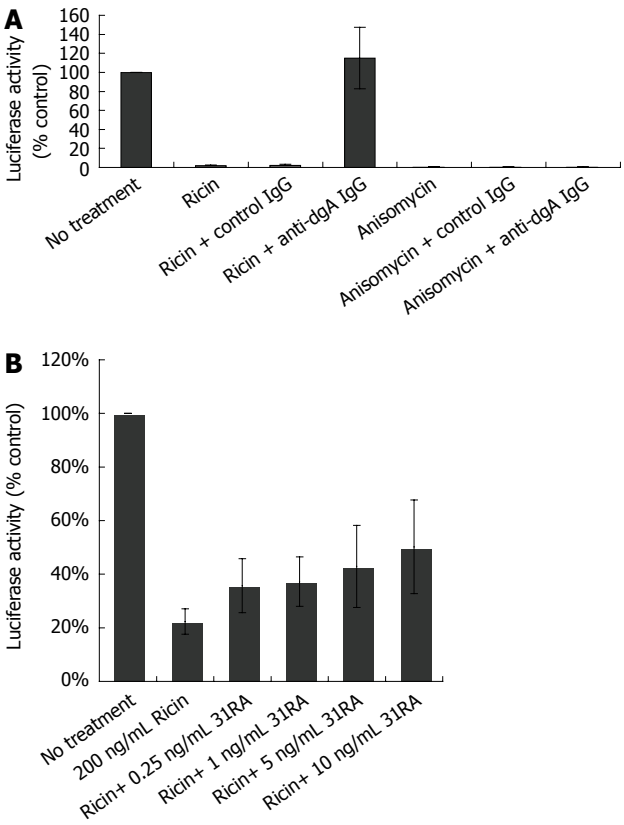

Figure 3 Protective effects of polyclonal anti-dgA IgG and anti-RTA 31RA aptamer on ricin-inhibited luciferase activity. A: Protective effects of anti-dgA IgG against ricin-inhibited luciferase activity, but not anisomycin-inhibited luciferase activity; B: Protective effects of various concentrations of 31RA aptamer against ricin-inhibited luciferase activity.

To determine the utility of this cell-based assay for testing specificity of antitoxins against ricin toxicity, the effects of polyclonal anti-deglycosylated ricin A chain (dgA) antibody in neutralizing the inhibitory effects of ricin on luciferase activity were determined. We have previously shown that anti-dgA Ab protected against ricin-induced cytotoxicity of RAW 264.7 mouse macrophage cells and ricin-induced lung injury and lethality[17]. CHO AA8 cells were treated with ricin or anisomycin in the presence of control IgG or IgG purified from the sera from dgA-immunized mice (anti-dgA IgG) and luciferase activity was measured 24 h later. As depicted in Figure 3A, anti-dgA IgG specifically neutralized the inhibitory effects of ricin on luciferase activity, but not that of anisomycin. Compared to anti-dgA IgG, 31RA aptamer partially protected against ricin-induced ribotoxicity as assessed by luciferase assay (Figure 3B).

To examine the effects of increasing doses of ricin on viability of CHO AA8 cells using the MTS assay. As shown in Figure 4A, treatment of CHO AA8 cells with increasing concentrations of ricin resulted in decreased cell survival. Interestingly, similar to the dose-dependent inhibition of luciferase activity (Figure 2B), ricin (100 ng/mL) induced ~50% cell death while > 0.5 μg/mL induced > 80% cell death (Figure 4A). Treatment with anti-dgA IgG, but not control IgG protected against cytotoxicity induced by ricin, and not anisomycin in CHO AA8 cells (Figure 4A). Pretreatment of ricin with 31RA aptamer also neutralized ricin-induced cytotoxicity in CHO AA8 cells (Figure 4B) and RAW264.7 mouse macrophage cells (data not shown).

DISCUSSION

In vitro selection is a powerful molecular tool for the generation of ligands for a wide variety of targets for therapeutic purposes. RNA aptamers that bind to human immunodeficiency virus type I Rev also inhibit viral replication[18]. Therefore, aptamers that recognize and inhibit ricin might be useful therapeutic agents. Interestingly, although the 31RA aptamer specific for the catalytic RTA bore no resemblance to the normal RTA substrate, i.e. the sarcin-ricin loop (SRL) and was not depurinated by RTA[13], it contained all sequences and structures necessary for interacting with RTA. This minimal 31-nucleotide RNA formed high affinity complexes with RTA (K_d = 7.3 nmol/L) which could compete with SRL for binding to RTA and inhibited RTA depurination of the SRL and could partially protect protein translation from RTA inhibition in *in vitro* translation assay. The IC_{50} of the aptamer for

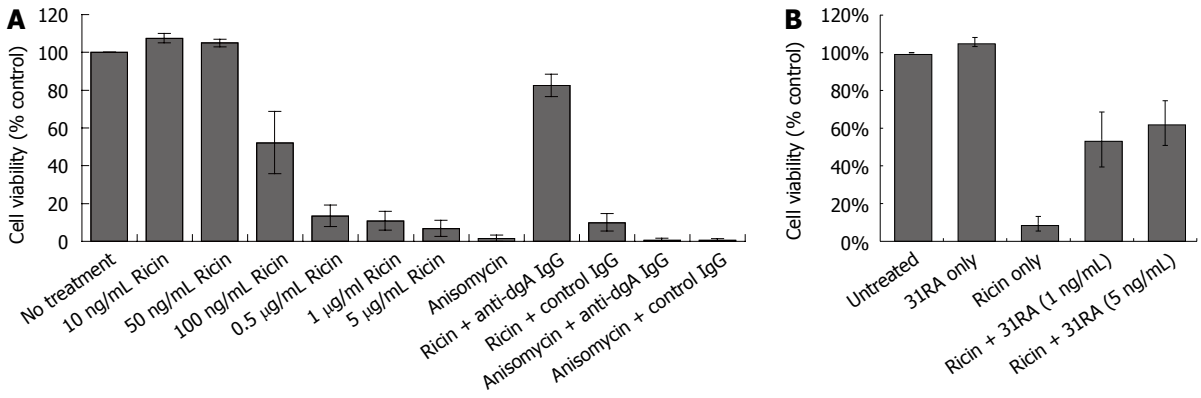

Figure 4 Protective effects of polyclonal anti-dgA IgG and anti-RTA 31RA aptamer on ricin-induced cell cytotoxicity as measured by MTS assay. A: Protective effects of anti-dgA IgG against ricin-induced cytotoxicity, but not anisomycin-induced cytotoxicity; B: Protective effects of 31RA aptamer against ricin-induced cytotoxicity.

RTA in the latter assay was 100 nmol/L, roughly 3 orders of magnitude lower than a small molecule inhibitor of ricin, pteroic acid[19]. Here we showed that 31RA aptamer can inhibit ricin ribotoxicity in cell-free and cell-based luciferase translation assays and cell cytotoxicity assay. It will also be interesting to determine if the 31RA aptamer will be effective against ricin after cell internalization which will be relevant for post-exposure treatment. We are currently testing various methods for intracellular delivery of the 31RA aptamer to determine if internalized aptamer can block toxicity of intracellular ricin A-chain. Hence, anti-RTA aptamers have the potential to be developed as ricin inhibitors and the therapeutic effects of aptamers *in vivo* in animal models of ricin intoxication remain to be determined.

Luciferase and luminescence assays, commonly used readouts for small molecule screens because of high sensitivity and linear signal response, can readily be adapted for high throughput screening of large libraries of compounds[20]. We have utilized a CHO Tet-Off luciferase system for measuring the biological activity of ricin based on protein synthesis inhibition and have shown that this assay can be used for measuring the protective effects of ricin inhibitors including anti-RTA neutralizing antibodies and an anti-RTA RNA aptamer. Compared to the transient luciferase-based assay described by Zhao *et al*[14] which utilized adenoviral transduction to deliver the luciferase gene, our cell-based assay is a stable cell system whereby the luciferase gene is stably integrated and its expression can be regulated by removal of tetracycline or doxycycline. Another advantage of using a stable cell system compared to adenoviral transduction is that the variability due to batch-to-batch variations of viral titers and infection efficiency are avoided. The conventional assays for protein synthesis utilize radioactive amino acids, but these assays suffer from significant sample-to-sample variability and insufficient sensitivity for high throughput assays. Hence, the adaptation of the stable luciferase-based assay in combination with cell cytotoxicity assay will be useful for high throughput screening of compounds for inhibitors of ricin and other related ribotoxins.

COMMENTS

Background

Ricin, a lectin from the castor bean plant *Ricinus communis* is considered one of the most potent plant toxins. Ricin poisoning can cause severe tissue damage and inflammation and can result in death. More than 750 cases of accidental or deliberate ricin poisoning have been described in humans. Most accidental exposures occur by ingestion of the seeds of castor beans whereby the toxin is released after the seed coat is damaged. The ingested toxin causes severe gastrointestinal damage with symptoms including nausea, vomiting, diarrhea, and abdominal pain and may progress to hypotension, liver failure, renal dysfunction, and death due to multiorgan failure or cardiovascular collapse.

Research frontiers

Since currently there is no antidote or specific therapy available for ricin poisoning, the discovery of antitoxins is a high priority. Ricin ribotoxicity can be counteracted by several different types of antitoxins including neutralizing anti-ricin antibodies, small molecule RTA inhibitors, polynucleotide active site inhibitors and polynucleotide substrate analogues. The development of specific inhibitors of RTA will offer novel insights into the development of effective therapeutics against ricin poisoning.

Innovations and breakthroughs

In vitro selection had been used to generate RNA ligands (aptamers) specific for the catalytic ricin A-chain. An initial 80-nucleotide RNA ligand was minimized to a 31-nucleotide RNA aptamer (31RA) that contained all sequences and structures necessary for forming high affinity complexes with RTA and blocking enzymatic activity of RTA *in vitro*. In this report, authors utilized a stable cell-based luciferase assay and showed that 31RA aptamer also neutralized the inhibitory effects of ricin on translation inhibition in cell-free and cell-based luciferase assays and ricin-induced cytotoxicity assay.

Applications

The use of a stably transfected cell-based luciferase assay will facilitate the development of high throughput screening for inhibitors of ricin as potential antidotes for the treatment of ricin intoxication.

Peer review

The manuscript deals with the inhibitory effects of a previously described aptamer against ricin toxicity. The authors employ an *in vitro* translation and a cell-based luciferase assay. This is an interesting paper.

Abstract

AIM: To determine the most frequent etiologies of hepatic epithelioid granulomas, and whether there was an association with chronic hepatitis C virus (HCV).

METHODS: Both a retrospective review of the pathology database of liver biopsies at our institution from 1996 through 2006 as well as data from a prospective study of hepatic fibrosis markers and liver biopsies from 2003 to 2006 were reviewed to identify cases of hepatic epithelioid granulomas. Appropriate charts, liver biopsy slides, and laboratory data were reviewed to determine all possible associations. The diagnosis of HCV was based on a positive HCV RNA.

RESULTS: There were 4578 liver biopsies and 36 (0.79%) had at least one epithelioid granuloma. HCV was the most common association. Fourteen patients had HCV, and in nine, there were no concurrent conditions known to be associated with hepatic granulomas. Prior interferon therapy and crystalloid substances from illicit intravenous injections did not account for the finding. There were hepatic epithelioid granulomas in 3 of 241 patients (1.24%) with known chronic HCV enrolled in the prospective study of hepatic fibrosis markers.

CONCLUSION: Although uncommon, hepatic granulomas may be part of the histological spectrum of chronic HCV. When epithelioid granulomas are found on the liver biopsy of someone with HCV, other clinically appropriate studies should be done, but if nothing else is found, the clinician can be comfortable with an HCV association.

INTRODUCTION

Epithelioid granulomas are found in 1%-10% of liver biopsy specimens[1-3]. They tend to fall into three broad categories which are systemic granulomatous disease, primary liver disease, or miscellaneous conditions that fit neither category. Hepatic granulomas are sometimes a surprise finding that may trigger an extensive search for an etiology. In some cases the granulomas are associated with a clinical picture which includes a high alkaline phosphatase and hepatomegaly; but these features are frequently absent. A significant percentage of liver biopsies performed today are for the staging of chronic hepatitis C. Granulomas have been reported with possible increased frequency in patients with hepatitis C with both mild disease as well as in explants[4-8]. It has been postulated that hepatitis C virus (HCV) may have a role in granuloma formation[9]. We decided to undertake a retrospective review of cases of hepatic granulomas at our institution during the last decade in order to determine the most frequent etiologies, and also to determine if there was an association with HCV.

MATERIALS AND METHODS

Patients studied

Following approval by our institutional review board, we used the data information system in our surgical pathology information system to identify all patients

Table 1 Patients with hepatic granuloma by diagnosis

Diagnosis	Number of patients
HCV	9
Histoplasmosis	4
Sarcoidosis	3
HIV alone	2
HCV/HBV	2
HCV/HIV	2
Mycobacterium avium	2
Primary biliary cirrhosis	2
Unknown	2
Tuberculosis	1
Coccidiomycosis	1
Cryptococcus	1
HBV	1
Hodgkin's lymphoma	1
Q Fever	1
Mucormycosis	1
Drug induced	1

from 1995 through 2005 that had a percutaneous or surgical liver biopsy, and also had the word granuloma or granulomatous in the final diagnosis or in the pathologists description. This data base includes all liver biopsies that are performed at our institution. The University of Texas Medical Branch is a tertiary care institution that consists of 5 hospitals and an outpatient center in Galveston, Texas, USA. Each year it serves patients from most of the counties in Texas, although two thirds of the patients are residents of the Texas Upper Gulf of Mexico Coast. One of the hospitals provides out patient and hospital care to a majority of the inmates in the Texas prison system. No explanted livers were included. We also excluded cases where the biopsy was performed at another institution, but slides were reviewed for a second opinion, and we also excluded several cases where biopsy of ossified nodules at surgery revealed old burned out or inactive granulomas. Autopsies were also excluded. Patients that had only lipogranulomas or small, poorly organized granulomas on their original pathology report were excluded from the study.

Since March 2003, the hepatology service at our institution has been in the midst of a prospective study of hepatic fibrosis markers in patients undergoing pre-treatment liver biopsies in chronic HCV. Some of the results of this study have been published[10,11]. This data base was searched as well for patients with evidence of hepatic granulomas on liver biopsy.

Parameters assessed

When appropriate, charts, reports, and the liver biopsy slides were reviewed. We tabulated information on special stains and cultures that were obtained on the specimens. All patients with hepatic granulomas had their biopsies examined with polarized light for crystalloid particles[12]. Clinical data was assessed to determine HCV, hepatitis B virus (HBV), and human immunodeficiency virus (HIV) status. The diagnosis of HCV was based on the presence of serum HCV RNA[13]. Information was also recorded regarding the patient's HCV genotype and routine liver tests. The stage of fibrosis based on the Batts Ludwig (F0-F4) staging system[14] was also noted.

Table 2 Patients with HCV only

Age (yr)	Gender	Fibrosis stage	Granuloma location	Comments
46	Female	F3	Portal tract	Multiple
54	Male	F2	Lobule	Multiple
46	Male	F2	Portal tract	Single
52	Female	F1	Diffuse	↑ alkaline phos
51	Female	F1	Portal tract	Single
45	Male	F1	Lobule	Multiple
67	Male	F1	Portal tract	Multiple, refractile Crystals
47	Male	F1	Portal tract	Multiple
37	Female	F2	Portal tract	Single

RESULTS

There were a total of 4578 liver biopsies performed at our institution during this time. There were 36 (0.79%) patients identified from the surgical pathology review that had at least one hepatic epithelioid granuloma (Table 1). Special stains were performed in 26 f and tissue cultures in five. The associated diagnoses are listed in Table 1. The most common association was HCV. Fourteen (36.1%) had HCV, and nine of these had no other clinical associations to explain the granulomas. Five of the HCV patients had other confounding associations including chronic hepatitis B, sarcoidosis, histoplasmosis, and HIV (2 patients). The etiologies with more than one case in the non HCV patients were sarcoidosis (3), histoplasmosis (4), primary biliary cirrhosis (3), HIV only (2), mycobacterium avis complex (2), and primary biliary cirrhosis (2), and unidentifiable (2).

There were 241 patients with chronic HCV that had liver biopsies while enrolled in the prospective hepatic fibrosis study during 2003-2006. Three (1.24%) had granulomas, and all of these had been identified in the above database search.

Patients with HCV and granulomas

Table 2 summarizes the results of the 9 patients with HCV, hepatic granulomas, and no other identifiable associations. All of the patients had special stains performed on their liver biopsies, and only one had a crystalloid substance noted on polarizing light. Eight of the patients had genotype 1, and the fibrosis stages F1, F2, and F3 were all present in at least one patient. None of the patients had cirrhosis. One patient with diffuse granulomas had an alkaline phosphatase consistently twice normal. Otherwise the liver function tests were typical of chronic HCV.

Characteristics of granulomas in HCV

The histologic findings in the patients with HCV only were variable. Figure 1 shows a large granuloma in an asymptomatic patient with mild elevation of ALT that had a staging liver biopsy. The granulomas were present in the

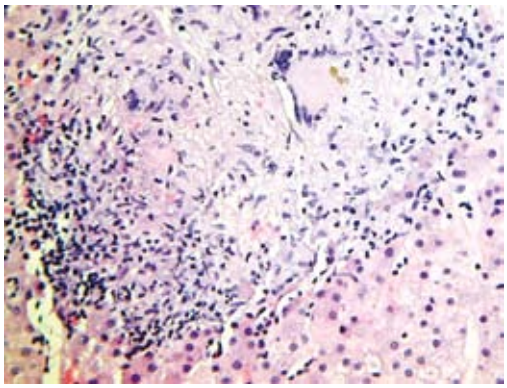

Figure 1 Large granuloma in the hepatic lobule noted in an asymptomatic patient with chronic HCV and mildly elevated ALT (HE, × 40).

portal area in 6 patients, the hepatic lobule in 2 patients, and diffusely in both the portal tract and lobule in one patient. In three patients, there was only a solitary granuloma in the portal tract, while in the others there were multiple granulomas. The case that had crystalloid substance on polarized light had multiple portal granulomas.

DISCUSSION

We found granulomas in less than 1% of our liver biopsies. Other reports have found granulomas in up to 10% of liver biopsies[1-3]. The frequency of detection as well as the frequency of various diagnoses can depend upon the geographic location of the center and the diseases endemic in that area as well as the diligence of the histopathology laboratory and the pathologists that prepare and examine the slides. Previous studies of hepatic granulomas have primarily been from eras before HIV and widespread organ transplantation, and before HCV became prominent. Although the percentages varied, sarcoidosis and tuberculosis tended to be most common associated diseases reported. A study from our institution from another era found that tuberculosis accounted for 53% and sarcoidosis 12% of the cases of hepatic epithelioid granulomas while in 20% no etiology could be determined[1]. In a large series of 565 cases of epithelioid hepatic granulomas in over 6000 biopsies accumulated over 4 decades, Klatskin[2] found that 36% had sarcoidosis, 12% had tuberculosis and 7% were undiagnosed. While our study indeed found 3 patients with sarcoidosis and another with *M. tuberculosis*, most cases were associated with HCV or HIV with associated infections.

There have been several reports of granulomas in the liver biopsies of patients with HCV and no other known systemic or hepatic diseases. This may not be unexpected since the most common reason for liver biopsies at most institutions today is staging of chronic HCV, and some unexplained granulomas have long been found on liver biopsies. On the other hand, the concurrence of HCV and granulomas may be frequent enough to not be simply explained by chance. A large recent retrospective review found epithelioid granulomas in 63 of 1662 liver biopsies[5]. While primary biliary cirrhosis (23.8%), sarcoidosis (11.1%), and unknown (11.1%) were the most common associations, HCV was associated with 9.5% of the cases. Emile *et al*[9] found that the explants of 5 of 52 patients undergoing liver transplantation for cirrhosis from HCV had epithelioid granulomas, and none of these patients had evidence of any other diseases such as tuberculosis or sarcoidosis. Goldin *et al*[4] found in a retrospective study that there were granulomas in the liver biopsy specimens of 14/155 patients with HCV compared with only 3/151 with HBV and 3/129 with alcoholic liver disease. Yamamoto *et al*[6] found unexplained granulomas in 2/273 (0.73%) liver biopsies of patients with chronic HCV. In a more recent study from Turkey, 8/605 (1.3%) of patients with chronic hepatitis C had unexplained granulomas on liver biopsy[7]. This is the same percentage that we found among chronic HCV patients in our prospective study of hepatic fibrosis markers that underwent liver biopsies over a three year period. Consequently, it has been postulated that hepatic granulomas may themselves be part of the histologic picture of chronic HCV, albeit uncommonly. Our finding that 9 of 36 patients with hepatic epithelioid granulomas had HCV as their only disease association would support this. We cannot rule out that some of these patients could have had other undiagnosed disorders such as sarcoidosis; but in follow up, none of them have manifested pulmonary or systemic findings to support another diagnosis.

Alpha interferon in regular or pegylated form has been used in the therapy of chronic HCV since the discovery of the virus[13]. It has been speculated that interferon itself can stimulate granuloma production, and there are several reported cases of the development of sarcoidosis in patients receiving interferon therapy[15-19]. This is thought to be related to the ability of interferon to stimulate a Th 1 immune response which is felt to be responsible for the granulomas in sarcoidosis[20]. Both the sarcoidosis and granulomas have usually regressed when interferon was stopped. It is unlikely that interferon usage played a major factor in our patients since only one subject with chronic HCV and granulomas had received interferon prior to liver biopsy.

Intravenous drug use is the most common route of transmission of chronic hepatitis C[21]. Since granulomas can be induced by foreign substances that might be used in a "street prepared" illicit drug mixture, we examined all the slides of patients with HCV and granulomas with polarized light, and a crystalloid substance was found in only one patient. Therefore, foreign body induced granulomas do not appear to be an explanation for most of the granulomas found in our patients with HCV.

We realize that there are problems interpreting the results of a retrospective study such as ours. The majority of the liver biopsies that we perform are on patients that are being staged prior to proposed treatment for chronic HCV. Therefore, the finding of otherwise unexplained granulomas in multiple patients with chronic HCV may not be that unusual or surprising. Nevertheless, in this study the most common association of hepatic granulomas was chronic HCV.

We would recommend if a patient with chronic HCV should have granulomas on liver biopsy that a search

for another disease should be made by utilizing special stains and other clinically appropriate tests such as a chest X-ray. However, if no other abnormality is found, the clinician should be comfortable associating the granuloma(s) with the chronic HCV.

COMMENTS

Background

Granulomas have long been curious findings on liver biopsies, and sometimes can trigger exhaustive searches for the etiology. Although there are many causes, sarcoidosis and tuberculosis have been the most frequent associations in previous series.

Research frontiers

Recent papers have reported finding granulomas in chronic hepatitis C virus (HCV) patients, and it has been speculated that granulomas may be an uncommon part of the immune response in chronic HCV. This study looked retrospectively at a decade of liver biopsies at the large institution to see what the most common disease associations with hepatic granulomas were. Authors also looked prospectively at the prevalence of granulomas in a series of chronic HCV patients undergoing staging liver biopsies.

Innovations and breakthroughs

The most common association of hepatic granulomas at the institution is chronic hepatitis C. The granulomas were both in the portal area and the lobule, and they were both single and multiple. Although present in only about 1% of liver biopsies of patients with hepatitis C, they should be considered as part of the histologic spectrum of the disease.

Applications

The finding of hepatic granulomas on the liver biopsy of someone with chronic HCV does not necessitate an extensive workup. Special stains and pertinent tests such as a chest x-ray should be done, but the clinician should be comfortable with the association if nothing is found.

Terminology

An epithelioid granuloma is a complex of transformed macrophages together with inflammatory cells and often multinucleated giant cells. It is a manifestation of delayed hypersensitivity.

Peer review

This is a very good retrospective examination of characteristics associated with hepatogranulomas, with the added strength of the prospective surveillance.

Abstract

AIM: To study the small bowel (SB) mucosa on biopsy in cirrhotic patients with portal hypertension and in non-cirrhotic controls and grade findings according to the Marsh criteria.

METHODS: We prospectively enrolled 51 consecutive patients undergoing an upper endoscopy for their routine medical care. Twenty five patients with cirrhosis and portal hypertension were compared to 26 controls. We obtained coeliac serology and multiple upper small bowel biopsies on all 51 patients. A GI pathologist interpreted biopsies and graded findings according to the Marsh criteria. We assessed equivalence in Marsh grade between cirrhotic and non-cirrhotic controls using the Mann-Whitney test for equivalence.

RESULTS: Gender, ethnicity and age were similar between both groups. Marsh grades were equivalent between the groups. Grade of 0 was present in 96% and grade of 1 was present in 4% of both groups and there was no villus atrophy or decrease in villus/crypt ratio in patients with portal hypertension.

CONCLUSION: This study provides evidence for the lack of villus atrophy in patients with cirrhosis and portal hypertension, and supports the continuous reliance on the Marsh criteria when the diagnosis of coeliac disease is to be made in the presence of cirrhosis.

INTRODUCTION

Studies of small bowel (SB) mucosa in cirrhosis and portal hypertension report a diverse spectrum of histological abnormalities[1-5]. These include increased capillary angiogenesis, mucosal edema, decreased villus to crypt ratio, villus atrophy and decreased total absorptive surface. Villus abnormalities resemble the abnormalities of coeliac disease (CD) and this may affect the interpretation of small bowel biopsy, and lead to confusion when CD is to be excluded in patients with cirrhosis and portal hypertension.

The diagnosis of CD is increasingly considered and work up recommended during the evaluation of abnormal liver enzymes[6-7]. This is in part due to the heightened awareness of the association of CD with a variety of liver disorders. Most commonly described associated liver disorders include autoimmune hepatitis, primary biliary cirrhosis, non-alcoholic fatty liver disease, unexplained abnormal liver tests and cirrhosis[8-15]. The mechanisms of this association are not clear and the prevalence of CD in patients with liver disease is variable depending on the associated liver disease. For example, while CD affects 1% of the general population, one study reports that about 4% of 185 cirrhotic patients who had undergone liver transplantation were found to have CD, and 3 of 4 pa-

tients presenting with severe liver disease were diagnosed with CD and were remitted as possible candidates for liver transplantation when placed on a gluten free diet[16]. Approximately 40% of patients with CD have abnormal liver enzymes, and these return to normal in 75% to 95% when a gluten free diet is instituted[16,17]. Based on these and other studies, it is recommended that clinicians should have a low threshold for testing for CD in patients with abnormal liver blood tests[6].

The diagnosis of CD is based on initial screening with coeliac serological tests (endomysial EMA and human tissue transglutaminase hTTG antibodies); but histological examination of SB biopsy is required for establishing a definite diagnosis[6,10]. However, in patients with cirrhosis, the diagnosis of coexisting CD is a challenge because of the reported similar changes on SB mucosa in both cirrhosis and CD. CD may, therefore, be underdiagnosed in cirrhosis. Studies of SB biopsy in cirrhosis[1-5], have thus shed doubt on the validity of biopsy in the diagnosis of CD in cirrhotic patients; but reported findings are poorly characterized, lack standardized grading, and of unclear significance. The current study was undertaken to determine if SB biopsies in cirrhosis show features that might mimic CD. Findings would determine if SB biopsy should be used in the diagnosis of CD in patients with cirrhosis and portal hypertension.

The aim of the study was to prospectively assess the histological abnormalities of the SB mucosa in patients with and without cirrhosis and portal hypertension by grading findings according to the grading system defined by Marsh[6].

MATERIALS AND METHODS

Selection of patients and data collection

This is a prospective case control study approved by the Institutional Board Review at the Cleveland Clinic. Eighty consecutive patients scheduled for an upper endoscopy EGD at the Cleveland Clinic between 9/1/2005 to 11/30/2005 were identified. Medical records were reviewed. Of 80 patients, 25 with cirrhosis and portal hypertension and 26 without cirrhosis, portal hypertension or liver disease fulfilled inclusion and exclusion criteria and were enrolled in the study.

Records reviewed included age, ethnicity, gender, indications for upper endoscopy EGD, imaging studies and laboratory tests. Laboratory tests obtained within the preceding 6 mo of the date of enrollment were reviewed for liver transaminases, alkaline phosphatase, protime/INR, celiac serology panel, complete blood count and differential, iron saturation and ferritin, and viral hepatitis panel.

Patients were included if they were older than 18 years old and able to give informed consent. Patients with cirrhosis and undergoing EGD were included regardless of the etiology of cirrhosis. Patients without cirrhosis and undergoing EGD for acid reflux, abdominal pain, dysphagia or vomiting were included.

Cirrhosis was defined histologically according to Batts and Ludwig staging system[18]. In patients without a liver biopsy, diagnosis of cirrhosis and portal hypertension was based on a combination of clinical data (jaundice, cutaneous spider angiomas, muscle wasting, ascites, and palmar erythema), biochemical data (decreased serum albumin and prolonged protime), imaging study (nodular surface on ultrasound or CT scan), and manifestations of portal hypertension (low platelets, splenomegaly, esophageal varices, hepatic encephalopathy or ascites) in the setting of chronic liver disease.

Patients were excluded if they were pregnant, on dialysis, had a bleeding disorder or were actively bleeding at the time of endoscopy, taking anticoagulants or had INR greater than > 1.5 or platelet count less than $30 \times 10^3/mm^3$. Patients with a diagnosis of malabsorption, coeliac disease, patients taking corticosteroids or immunosuppressant drugs, patients with a history of Crohn's disease, organ transplant, graft versus host disease, food allergies, iron deficiency anemia, osteoporosis, ataxia, and autoimmune disorders that could potentially be associated with CD such as thyroid disorders, dermatitis herpetiformis and type 1diabetes were excluded. In the control group, additional exclusions encompass individuals with a history of chronic liver disease or a history of abnormal liver tests.

Informed consent for SB biopsy and for blood draw for coeliac serology panel was obtained on all 51 patients. Severity of cirrhosis was assessed by calculating Child Turcotte Pugh (CTP) and Model for End-Stage Liver Disease (MELD) scores for all cirrhotic patients.

Laboratory assessment

Coeliac serology panel included antibodies to human tissue transglutaminase (IgG and IgA for hTTG, QUANTA lite™ ELISA, Inova diagnostics, San Diego CA), endomysial antibodies (IgA EMA, Immunofluorescence Inova diagnostics San Diego CA), and total IgA levels by nephelometry (Beckman Coulter Immage/image 800 Immunochemistry system and Calibrator 1, Fullerton CA). Tests were consecutively analyzed in the immunology laboratory at the Cleveland Clinic. These tests are reported to be highly sensitive and specific in the diagnosis of CD in the general population with sensitivities and specificities above 85%, and they supplant the use of gliadin antibody testing as the preferred mean of serological detection[6]. Abnormal serology panel is any value for IgA EMA above 1:10 dilution, or any value for either IgG hTTG or IgA hTTG above 20 U.

Histological assessment

Upper endoscopies were performed by gastroenterologists at the Cleveland Clinic. The gastroenterologists were not blinded to the study, and they were asked to obtain at least 3 biopsies from the second part of the duodenum or beyond on all subjects. Biopsy specimens were placed in vials containing 10% of buffered formalin solution for fixation. Paraffin sections were prepared and stained by hematoxylin and eosin (HE) stain. Pathology slides were interpreted by a Cleveland Clinic pathologist (A.B.) experienced with the spectrum of mucosal changes in CD. The pathologist was blinded to names

and diagnosis. All slides were batched and read after samples from all 51 subjects collected and processed. The pathologist graded findings according to the Marsh grading system[6]. Marsh 0 is defined by normal mucosal and villus architecture, Marsh I is defined by normal villus architecture, but increased numbers of intraepithelial lymphocytes, Marsh Ⅱ shows increased intraepithelial lymphocytes, enlarged crypts and increased crypt cell division, Marsh Ⅲ is defined by villus atrophy, shortened blunt villi and enlarged hyperplastic crypts. Marsh Ⅳ demonstrates hypoplastic mucosa.

Statistical analysis

The sample size estimation was based on the inference that the standard deviation of the Marsh grade would be equal to 1 for both groups. The study was designed to establish equivalence in small bowel mucosa (defined as a difference in mean Marsh grades no greater than1) between cirrhotics and non-cirrhotics with a significance level of 0.05 and a power of at least 90%. Therefore, it was estimated that a total of 25 subjects would be required in each group.

Descriptive statistics, such as frequencies for categorical factors and mean (SD) for continuous factors, were computed for all variables. A Student's *t*-test was used to assess differences in age between cirrhotics with portal hypertension and non-cirrhotic controls. In addition, Pearson's χ^2 and Fisher's exact test were used to compare gender and race between the groups.

In order to assess whether the SB mucosal architecture in cirrhotic patients with portal hypertension was indistinguishable from the mucosal architecture in non-cirrhotic controls, the Mann-Whitney test for equivalence was used[19]. It tests the null hypothesis (H_0) of difference in SB mucosal architecture between groups versus the research hypothesis (H_a) of equivalent SB mucosal architecture between groups. A *P*-value < 0.05 was considered statistically significant. SAS version 9.1 software (SAS institute, Carey, NC) was used to carry out all analyses.

RESULTS

Study populations

A total of 51 patients were enrolled. Twenty five had cirrhosis and portal hypertension and 26 controls had no evidence of liver disease or portal hypertension. Fifty patients had normal coeliac serology and one patient in each group had abnormal biopsy.

Baseline demographic characteristics of patients who fulfilled inclusion criteria are shown in Table 1. The mean age was 57 (± 10) years in the portal hypertension with cirrhosis group and 52 (± 15) years in the control group. Fifty two percent were males and 92% were Caucasians in the former group *versus* 42% and 84% respectively in the control group. There was no evidence to suggest statistically significant differences in the demographic characteristics between the groups ($P > 0.05$).

The most common indications for upper endoscopy in cirrhotic patients with portal hypertension were screening for or banding of esophageal varices (100%). In the control group, the most common indications were acid reflux (30.8%), dysphagia (23.1%), epigastric pain (23.1%), and nausea and vomiting in (15.4%).

Table 1 Demographic characteristics of study subjects (mean ± SD) *n* (%)

	Cirrhotic	Non-cirrhotic	*P* value
n	25	26	-
Age	57.5 ± 9.7	51.9 ± 15.3	0.12
Gender			0.49
Male	13 (52)	11 (42.3)	
Female	12 (48)	15 (57.7)	
Ethnicity			0.67
Caucasian	23 (92)	22 (84.6)	
Other	2 (8)	4 (15.4)	

All 25 patients with cirrhosis had evidence of portal hypertension, esophageal varices, thrombocytopenia and an imaging study showing cirrhotic liver. Fifteen patients had a liver biopsy. Twelve patients had CTP score A, 11 had CTP score B and 2 had CTP score C. The mean platelet count was $89.76 \times 10^3/mm^3$, with a range between 45 and $148 \times 10^3/mm^3$. The mean MELD score was 10 with a range between 5 and 17. The most common etiologies for cirrhosis were nonalcoholic steatohepatitis (24%), hepatitis C (24%) and cryptogenic cirrhosis (24%).

Histological findings in patients with and without cirrhosis

There was strong evidence to suggest that based on Marsh grade, cirrhotics and non-cirrhotics have indistinguishable SB mucosa (Mann-Whitney test of equivalence: $P < 0.01$). One patient in each group (4%) had an abnormal small bowel biopsy and 96% of patients from each group had a normal small bowel biopsy (Figures 1 and 2). Both patients with abnormal biopsy were females with normal coeliac serology. The two women had Marsh grade I based on 3 SB biopsies obtained for each. One of these women was 57 years old, and had a liver biopsy that was consistent with nonalcoholic steatohepatitis and cirrhosis. Her platelet level was $130 \times 10^3/mm^3$, her MELD score was 10 and her CTP score was B. The other woman with Marsh grade I on SB biopsy did not have cirrhosis. She was 51 years old and was scheduled for EGD for epigastric pain and bloating.

DISCUSSION

Portal hypertension and cirrhosis due to a variety of parenchymal liver diseases are associated with malnutrition[20,21]. The pathophysiologic mechanisms are not totally understood and several factors may be involved. Malabsorption has been implicated and this was presumed to be related to changes in the SB villi[2,4,5]. For example, Such *et al*[4] investigated 6 patients with cirrhosis using jejunal biopsies, and studied the mucosa under electron microscopy. The authors observed that "the microvilli were reduced in number and appeared shorter

Figure 1 Percentage of patients with Marsh grade 0 and Marsh grade 1 in cirrhosis and no cirrhosis.

and thicker when compared to controls", and their conclusion was that "the total absorptive surface may be reduced in cirrhotic patients". Misra[2] found a significant decrease in villus/crypt ratio in cirrhotic patients when compared to healthy volunteers. On the other hand, Nagral[22] reports a significant number of patients with large vessels in duodenal mucosa of patients with portal hypertension in comparison with controls, but did not find a statistical difference in severity and type of infiltrate, edema of lamina propria or villus/crypt ratio between the groups. In the study of Barakat[5], abnormal villus changes were present in 11.4% of portal hypertensive patients. These were described as "shortened villi, decreased or even reversed villus to crypt ratio down to total villus atrophy". The authors implied that these changes might have an effect on the intestinal absorptive functions, and in turn, might have a share in the pathogenesis of nutritional derangements in portal hypertensive patients.

Results of these studies implicate SB villus shortening and atrophy as underlying factors in the malabsorption and malnutrition observed in cirrhosis. Such conclusions need further validation and other diseases that may affect the SB mucosa should be considered in the differential diagnosis. Furthermore, histological abnormalities were reported descriptively and without systematic classification. Lack of a proper classification of abnormalities was once described by Marsh[23] as follows: "The system of qualitative terminology is not only inappropriate but also seems to have paralyzed any new intellectual activity that might elucidate afresh the immunopathogenic basis of mucosal response". And in 1992, Marsh described the mucosal abnormalities of the SB by establishing a classification system that utilized inflammatory and atrophic grades. This grading system has since been adopted by clinicians and pathology researchers in the diagnosis and study of CD, and is the only available system to systematically grade mucosal abnormalities of the SB. In this unprecedented study, we prospectively analyzed and graded changes of SB mucosa on biopsy according to the unified and accepted grading system characterized by Marsh[6,10].

We found no difference in Marsh grade between the study groups. Our patients had either a grade of 0 or a grade of I . One patient in each group had a Marsh grade of I , but neither had abnormal coeliac serology. The presence of Marsh grade I or intraepithelial lymphocytes is a non-specific finding especially in the absence of coexistent abnormal serology. We did not find

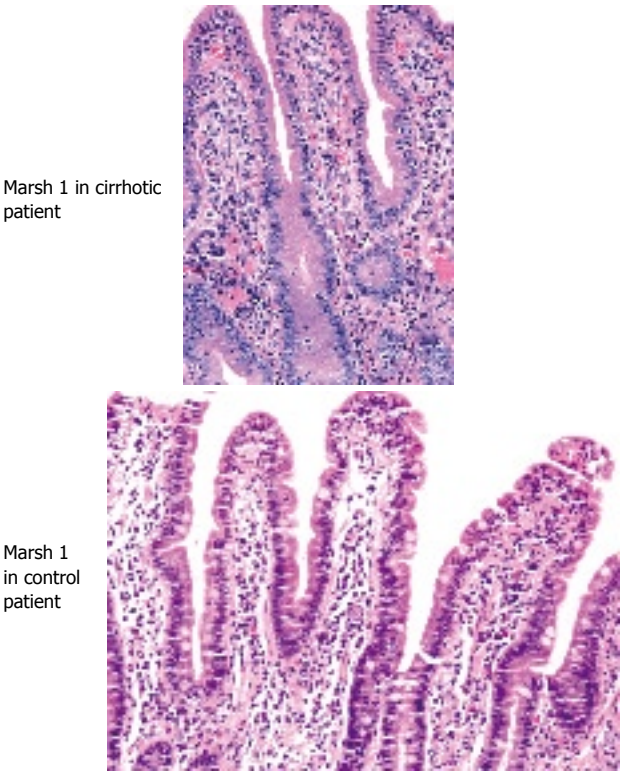

Figure 2 Small bowel mucosa in the cirrhotic and in the control patient, respectively.

any Marsh grades Ⅱ, Ⅲ or villus/crypt changes of CD among patients in either group. This provides evidence that histological abnormalities of the SB mucosa are equivalent between cirrhotic patients with portal hypertension and non-cirrhotic controls.

Since the etiology of cirrhosis has not been shown to influence the changes in mucosal architecture of the SB, we included all eligible cirrhotic patients regardless of the etiology of their cirrhosis. We excluded patients with clinical and laboratory evidence of malabsorption, patients with known SB mucosal disease and/or on therapy that included corticosteroids and immunosuppressants, and patients with autoimmune diseases that have the potential to be associated with CD or induce changes in the SB mucosa, because such cases may not necessarily yield the direct effects of cirrhosis on the SB mucosa.

We calculated the MELD and CTP scores on all cirrhotic patients. Although our study did not aim to examine whether the severity of liver disease would further exacerbate villus damage, we did not observe any correlation between Marsh grade and the degree of MELD and CTP scores. This has been reported previously[22].

An exact quantitative count for the intraepithelial lymphocytes IEL and immunohistochemical typing were not obtained because such stains are not utilized in routine clinical practice, and because one observer (pathologist A.B.) interpreted and analyzed all biopsy specimens.

Portal hypertensive enteropathy is receiving increased recognition in research studies of recent years. Studies have aimed at characterizing abnormalities on endoscopy, wireless capsule imaging, and SB biopsy. Small

bowel biopsy findings describe villus changes and villus atrophy. Contrary to previously reported studies, our study did not show shortened villi, reversal of villus to crypt ratio, villus atrophy, crypt hyperplasia or changes suggestive of CD in patients with portal hypertension. This concurs with the study of Nagral[22].

Our study is unique and different from other studies of the effects of cirrhosis and portal hypertension on the SB mucosa because we used the validated Marsh grading system to grade for abnormalities and we excluded subjects with CD and other diseases that would potentially affect the SB mucosa such as Crohn's and lymphoma *etc*, because we intended to study the sole effect of cirrhosis on the SB. SB villus changes and atrophy are characteristic, but are not specific for coeliac disease[24,25].

Coeliac serological tests have low sensitivities and specificities in chronic liver disease and cirrhosis[15,26-29] which emphasizes the importance of validating SB biopsy as the most important tool for the diagnosis of CD in this group of patients. Results of this study support the use of SB biopsy in patients with cirrhosis and portal hypertension when the diagnosis of CD is suspected. Furthermore, and since cirrhosis is not associated with significant inflammatory or atrophic changes of SB villi, we can extrapolate that there is a low probability that different results would be seen in the earlier stages of liver disease when cirrhosis has not yet developed.

Due to the estimated high prevalence of CD in patients with cirrhosis that is higher than in the general population[8,16,29,30], and the potential reversibility of liver dysfunction on a gluten free diet, we recommend prompt consideration and exclusion of SB mucosal diseases and CD (by using a combination of laboratory, clinical, pathologic and genetic examinations, and response to a gluten free diet), when shortened villi, reversal of villus to crypt ratio or villus atrophy are seen in patients with cirrhosis.

As to the mechanisms of malabsorption reported in patients with cirrhosis and portal hypertension, factors other than cirrhosis- related- villus changes should be considered. These may include bile salt deficiencies, motility disorders, protein losing enteropathy and other concomitant diseases of the SB. Further studies are needed.

In conclusion, our study provides evidence for the lack of villus atrophy in patients with cirrhosis and portal hypertension. Hence, small bowel biopsies can be interpreted reliably to exclude coeliac disease in these patients. Furthermore, findings of shortened villi and villus atrophy should trigger the exclusion of coeliac disease and other diseases of the small bowel in this group of patients.

We thank Cathy Means, Donald Wachsberger, Melanie Panhorst and Sue Bradney for their excellent help and technical support.

COMMENTS

Background

Cirrhosis affects the small bowel mucosa in ways not totally elucidated. Villus shortening and atrophy are described. But these findings are reported descriptively and without proper classification, which may affect the interpretation of small bowel biopsy when the diagnosis of coeliac disease is to be excluded in patients with cirrhosis. We aimed to study the small bowel mucosa on biopsy in cirrhotic patients with portal hypertension and in non-cirrhotic controls and grade findings according to the standardized grading system described by Marsh.

Research frontiers

Studies of recent years have shown that coeliac disease is increasingly recognized in association with chronic liver disease and cirrhosis, and coeliac disease is more common than previously thought but is under diagnosed. It is, therefore, recommended to exclude coeliac disease in patients who have cirrhosis and cryptogenic abnormality of liver tests, and the diagnostic tool of choice is a small bowel biopsy.

Innovations and breakthroughs

This study is different from other studies of the small bowel mucosa in cirrhosis and portal hypertension because we graded findings according to the standardized Marsh grading system and excluded subjects with diseases that could potentially affect the small bowel in order to assess the sole effect of portal hypertension on the small bowel mucosa. Additionally, we used the Mann-Whitney test of equivalence to support the equality of mucosal abnormalities in both study groups, and we estimated a sample size of 25 individuals in each group in order to confer a statistical power of at least 90%.

Applications

Today's medical practice emphasizes evidence based medicine. Our study provides evidence for the lack of villus atrophy in cirrhosis and portal hypertension; hence SB biopsies can be interpreted reliably to exclude coeliac disease in these patients and in future studies of the mechanisms of liver disease in patients with coeliac disease. Additionally, small bowel mucosal diseases should be excluded when villus shortening and atrophy are seen in patients with cirrhosis and portal hypertension

Peer review

This is a well designed study, and the data looks sound. Patients with liver disease of unknown etiology can have small bowel biopsies that reliably exclude coeliac disease as an association or cause of their hepatic disease.

Abstract

AIM: To evaluate the relation of cluster of differentiation 44 (CD44) expression with clinicopathological features of gastric adenocarcinoma, and also its effect on prognosis with an emphasis on the differences between intestinal and diffuse types.

METHODS: From 2000 to 2006, 100 patients with gastric adenocarcinoma, who had undergone total or subtotal gastrectomy without any prior treatment, were studied. Haematoxylin & eosin (HE) staining was used for histological evaluation, including the type (Lauren's classification) and grading of the tumor. The expression of CD44 in the gastric adenocarcinoma mucosa and the adjacent mucosa were determined by immunohistochemistry. The survival analysis was obtained using the Kaplan-Meier test.

RESULTS: Of 100 patients, 74 (74%) patients were male. The tumors were categorized as intestinal type (78%) or diffuse type (22%). Sixty-five percent of patients were CD44-positive. CD44 expression was not detected in normal gastric mucosa. Rather, CD44 was more commonly expressed in the intestinal subtype (P = 0.002). A significant relation was seen between the grade of tumor and the expression of CD44 (P = 0.014). The survival analysis showed a poor prognosis of patients with CD44-positive tumors (P = 0.008); and this was more prominent in the intestinal (P = 0.001) rather than diffuse type.

CONCLUSION: Cell adhesion molecule CD44 is highly expressed in gastric adenocarcinoma. CD44 expression is correlated with a poor prognosis in patients with the intestinal type of gastric adenocarcinoma. CD44 can, therefore, be utilized as a prognostic marker for this group of patients.

INTRODUCTION

Gastric malignancy is one of the leading types of cancer

and is the second most common cause of cancer-related death in the world[1,2]. According to reports from Iran's Ministry of Health, gastric cancer is the most common fatal gastrointestinal malignancy, while cancer is the third most common cause of mortality in this country[3,4]. Adenocarcinoma is the most prevalent type of gastric cancer. According to Lauren's histological classification, it is subdivided into diffuse and intestinal pathologic subtypes, each having different epidemiological and prognostic features[5,6]. Multiple genetic and epigenetic alterations in oncogenes, tumor-suppressor genes, cell-cycle regulators, cell adhesion molecules and DNA repair genes are implicated in the multistep process of human stomach carcinogenesis[6,7], and different genetic pathways have been proposed for these two subtypes of gastric carcinoma[2]. Depth of invasion and lymph node metastasis result from the polygene, and their protein expression in gastric carcinoma. The key step of the basic and clinical research of gastric carcinoma is to discover the related etiological biomarkers.

The loss of normal cellular adhesion is a significant event in human cancer development. Metastasis is characterized by a loss of adhesion that allows cancer cells to invade, and leave the site of origin, subsequently adhering to other sites, such as lymph nodes, liver, or peritoneum[8]. Cluster of differentiation 44 (CD44) is a transmembrane glycoprotein involved in cellular adhesion. This polymorphic integral membrane glycoprotein, which is expressed by many cell types, serves as the principal transmembrane hyaluronate receptor. It is considered a determinant of metastatic and invasive behavior in different malignancies, such as lung carcinoma, malignant melanoma, leukemia, breast cancer, as well as gastrointestinal carcinomas[2,9,10]. On the other hand, contradictory reports concerning the biological role of CD44 in tumorigenesis and its clinical value in prognosis have also been presented[9]. The expression of CD44 potentiates tumor cells to adhere to the extracellular matrix through ligands such as hyaluronan and facilitates the efficient formation of cell colonies[11,12].

The reported frequency of CD44 expression in human gastric carcinoma specimens varies widely from 31% to 72%, most likely reflecting the differences in the study population[13,14]. The intensity of CD44 expression has been reported to correlate with an increased depth of invasion[13], although different correlations have been reported in the two histological types of this cancer.

In this study, the expression of CD44 in patients with gastric carcinoma was measured by immunohistochemical method, with an aim to evaluate the relation of CD44 expression with clinicopathological features and also its effect on prognosis with an emphasis on the differences between intestinal and diffuse types.

MATERIALS AND METHODS

From 2000 through 2006, 100 gastric adenocarcinoma patients, who underwent total or sub-total gastrectomy without any prior treatment such as chemotherapy or radiation therapy at Omid Oncology Hospital (Mashhad, Iran), were enrolled in this study. All patients had been residing in the north-eastern provinces of Iran at the time of surgery. Demographic data of all patients were recorded and TNM staging was performed according to AJCC (American Joint Committee on Cancer) staging by supra- and infra-diaphragmatic imaging studies. Follow-up data were also gathered from patients, including local and distant recurrence and metastasis. The study protocol was approved by the Clinical Research Ethics Committee of the Mashhad University of Medical Sciences.

Formalin-fixed and paraffin wax-embedded gastric adenocarcinoma specimens from these patients were selected from the pathology archive. Specimen blocks were stained with HE and histological typing was determined according to the Lauren's classification and tumor grade (well-differentiated, moderately-differentiated and poorly-differentiated). The pathologist reviewed all the blocks and chose one block with more tumoral tissue and less necrotic tissue for immunostaining. Specimens were cut into 4-μm thick sections, and the sections were dewaxed and processed for immunohistochemical (IHC) staining. The sections were stained using the streptavidin-biotin-peroxidase complex method (Dako LSAB2 system, Denmark). Mouse anti-CD44 monoclonal antibody (1:50 dilution; clone DF1485, Dakocytomation, Denmark) which is able to detect all isoforms of CD44, was employed as the primary antibody for 30 min. Internal lymphocytes were used as positive control, and normal gastric tissue as negative control. Also, for negative control, the primary antibody was omitted.

All sections were evaluated by the pathologist who was unaware of the clinical outcome of the patients. Tumors with more than 5% of CD44-positive cancer cells were regarded as positive. The results were reported as positive (cytoplasmic and/or membranous staining) or negative with the percentage of positive cells for each section.

Statistical analysis

The correlation between the CD44 expression status and clinicopathological variables was analyzed using parametric and non-parametric tests run by the statistical software SPSS version 13. Also a log-linear model by the statistical software SAS was used for more detailed analysis of the data. The survival analysis was performed by the Kaplan-Meier test. A P value less than 0.05 was considered statistically significant.

RESULTS

This study included 100 gastric adenocarcinoma cases (74 males and 26 females; male/female ratio: 2.8), with a mean age of 63.3 years (range 26-82 years). Data about stage, grade, histological types and location of tumors are summarized in Table 1. Forty-seven percent of patients were less than 65 years old. The mean age of patients with poorly differentiated tumors was

significantly lower than other patients (55 years *vs* 65 years, $P = 0.019$). Stage Ⅳ disease was significantly more common among patients younger than 65 years ($P = 0.02$). All stage I cases were observed among patients older than 65 years. The diffuse-type cancer was two times higher among the patients younger than 65 years ($P = 0.021$).

Sixty-five percent of patients were CD44-positive and 35% were CD44-negative. CD44 staining was not detected in any adjacent normal gastric mucosa (Figure 1). Of 65 CD44-positive cases, 52 showed CD44 staining only on tumor cell surface membrane, while 13 showed both in cytoplasm and membrane.

In addition, a significant difference in CD44 expression was seen between the two histological subtypes: intestinal-type showed a significantly higher CD44 positivity (71%) compared to diffuse-type (42%) ($P = 0.002$). Moreover, poorly differentiated carcinomas showed a significantly less CD44 positivity, indicating a significant relation between CD44 expression, and the grade of tumor ($P = 0.014$; log linear, $P = 0.004$). Patients with stage 4 cancer expressed CD44 more than other stages, although this was not statistically significant. Other studied variables (sex, age and location of tumor) did not show any significant correlation with the expression of CD44.

Follow-up data were gathered for 71 patients. The median follow-up time was 6 mo. The overall survival was 16 mo. Regarding the results of survival analysis, there was no correlation between sex, age, location, type and the grade of tumor with prognosis. Poor outcome was seen among the patients with higher stage tumors (stages Ⅲ and Ⅳ, $P = 0.034$) compared to those with lower stages. In addition, the patients with CD44-positive tumors showed a poor prognosis (Log Rank, $P = 0.008$,

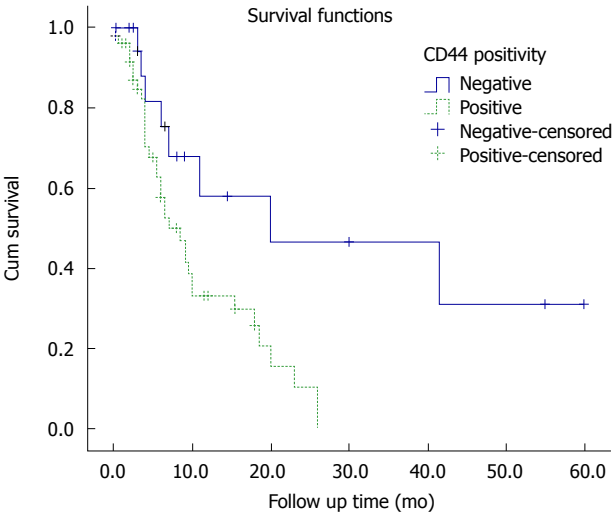

Figure 2 Kaplan-Meier curves of overall survival for CD44-positive and -negative gastric cancer cases.

Figure 2). Among patients with lower stage tumors, CD44 expression affected the prognosis regardless of tumor stage ($P = 0.040$). When analyzing the correlation of CD44 positivity, and intestinal/diffuse-type tumors separately, the results showed that CD44 only affected survival time in intestinal-type ($P = 0.001$), but not the diffuse-type tumors ($P = 0.7$).

DISCUSSION

The present study examined the expression of CD44 as an adhesion molecule in primary tumors by utilizing the IHC technique in 100 patients with gastric adenocarcinoma who had undergone surgery as the first step of management. The results showed that the expression rate of CD44 in tumoral tissue reached 65% in contrast to no expression of this molecule in the adjacent normal mucosa. CD44 was more commonly expressed in the intestinal-type tumor than in diffuse-type tumor, indicating that CD44 expression was related to the histological subtype of tumor, which is in agreement with previous studies[15,16]. In addition, a correlation was found between CD44 expression and tumor grade. But, no correlations between CD44 and other clinicopathological parameters were observed. Survival analysis showed that the grade and the histological type of gastric adenocarcinoma did not significantly affect survival. On the other hand, patients with higher stage adenocarcinoma showed a poor prognosis. CD44 was shown to affect survival, even more significantly than, and independently from the stage of the tumor. Moreover, CD44 positivity appeared to provide a poor prognosis only in patients with the intestinal-type gastric adenocarcinoma.

Since 1993 when Hieder *et al*[17] reported the expression of CD44 variants in gastric cancer, this adhesive molecule was recognized as a molecular marker related to the clinicopathological aspects of gastric cancer. CD44 is a member of a widely expressed family of adhesion receptors. This molecule was first described as a lymphocyte-homing receptor; however, it is expressed on a wide variety of cell types including mature T and B-cells[9,18-20]. Metastasizing tumor cells and recirculating (activated) lymphocytes share several properties, including motility and invasive behavior, an analogy which prompted the hypothesis that malignant cells might use molecules like CD44 for metastasizing[9]. *CD44* gene is located on chromosome 11p12-13, having at least 20 exons, of which ten are expressed in hematopoietic cells or the standard form of the gene. Other exons can be alternatively spliced to make up a wide variety of CD44 splice variants which have been found in various types of human malignancies, and have been considered markers in tumor progression and metastasis[15].

It has been supposed that the evaluation of the CD44 isoforms expression by the IHC method in cases of non-Hodgkin lymphoma, colon and renal cell carcinomas, as well as neuroblastomas may be a useful diagnostic parameter indicating invasive processes[21]. In 1994, Yokozaki *et al*[22] indicated that the detection of CD44 transcription variants can serve as a powerful tool for the diagnosis of gastric cancer. Many studies have indicated that the generation of CD44 splice variants, like V5 and V6, might be linked closely to gastric carcinoma tumorigenesis and differentiation, suggesting that these isoforms can be used as an indicator of tumor progression in the biopsies of patients with gastric carcinoma[23-28]. Moreover, it has been shown that patients with an over-expression of CD44 have a higher lymph node metastatic rate and invasion[27].

It is possible that different results among studies reflect the use of diverse antibodies having subtle variations in specificity. The problem is complicated more by the existence of numerous CD44 isoforms, which may have remarkable homology in their antigenic repertoire, thus increasing the possibility of cross-reactivity between the antibodies. Another reason for such discrepancies is probably the comparison of results having different techniques[9].

The correlation between clinicopathological parameters and CD44 expression in the tumor is known to be different between intestinal and diffuse types of gastric carcinoma[29,30]. A study showed that the intestinal-type was more frequently CD44s- and CD44v6-positive than the diffuse-type tumor[15], although the reactivity to these two antibodies did not correlate with histopathological and clinical prognostic factors in intestinal-type carcinoma[31]. More recently, Yamaguchi *et al*[16] found that the expression of CD44v6 protein was significantly higher in differentiated adenocarcinoma than in diffuse-type carcinoma. On the other hand, Saito *et al*[29] observed that CD44v6 appeared to play an important role in the invasion and metastasis of diffuse-type gastric carcinoma, but not in that of intestinal-type gastric carcinoma, and also demonstrated a significant correlation between CD44v6 expression and poor prognosis of diffuse-type gastric carcinoma.

The results of this study are consistent with previous findings, demonstrating that CD44 is mostly expressed

in the intestinal-type gastric cancer, and its expression is associated with poor prognosis. Thus, it can be concluded that the expression of CD44 is related to the phenotype of gastric malignancy, and may serve as a useful indicator of tumor metastasis, and may have a potential significance in diagnosing gastric cancer.

The mortality associated with gastric carcinoma is almost entirely caused by a subsequent metastatic disease. In fact, the prognostic assessment of gastric carcinoma still relies mainly on TNM staging, but the wide individual variability in prognosis is observed even in the same stages. The accurate prediction of the metastatic potential of the primary tumor, and hence the probable existence of undetected metastases, would be a critical factor in the management of patients with gastric carcinoma[14]. Our results emphasize that expression of CD44 is related to the prognosis of intestinal-type gastric cancer.

In conclusion, this study demonstrated that detection of CD44 protein in routinely fixed gastric carcinoma tissue by the IHC method can be used, along with other established parameters, to assess prognostic outcome, and particularly, to identify patients with a poor short-term prognosis. Furthermore, this suggests that, in the future, assessment of CD44 expression may guide the clinician in delineating a subset of patients with biologically unfavorable tumors who may profit from more intense post-operative adjuvant therapy.

We would like to thank our colleagues in the Gastric Cancer Research Group, and especially thank Mrs. Nahid As'adi for her efforts in IHC staining in the Pathology Laboratory of Omid Oncology Hospital.

COMMENTS

Background

Gastric cancer is the 2nd most common cause of cancer-related death in the world. The mortality associated with gastric carcinoma is almost entirely caused by a subsequent metastatic disease. The accurate prediction of the metastatic potential of the primary tumor would be a critical factor in the management of patients with gastric carcinoma. Metastasis is characterized by a loss of adhesion that allows cancer cells to invade and leave the site of origin, subsequently adhering to other sites such as lymph nodes, liver, or peritoneum. Cluster of differentiation 44 (CD44), as an important glycoprotein involved in cellular adhesion, is considered a determinant of metastatic and invasive potential in different malignancies. There are different and even contradictory reports considering the role of this adhesive molecule in gastric carcinogenesis and metastasis.

Research frontiers

While there was no expression in surrounding normal tissue, CD44 expression rate in gastric adenocarcinoma was up to 65%, considering that the intestinal-type tumor expressed this marker, more common than diffuse-type tumor. Beside the prognostic effect of stage, CD44 was shown to affect survival, even more significantly than and independently from the stage of the tumor and this was more pronounced in intestinal-type.

Innovations and breakthroughs

For the first time in Iranian patients, this study demonstrated that detection of the CD44 protein in routinely fixed gastric carcinoma tissue by the IHC method can be used, along with other established parameters, to assess prognostic outcome, and particularly, to identify patients with a poor short-term prognosis.

Applications

In the future, assessment of CD44 expression may guide the clinician in delineating a subset of patients with biologically unfavorable tumors who may benefit from more intense postoperative adjuvant therapy.

Peer review

The results showed that the over-expression of cell adhesion molecule CD44 is correlated with a poor prognosis in patients with the intestinal-type gastric adenocarcinoma. CD44 can, therefore, be utilized as a prognostic marker for this group of patients.

Abstract

AIM: To evaluate the efficacy of continuous regional arterial infusion therapy (CRAI) with gabexate mesilate and antibiotics for severe acute pancreatitis (SAP).

METHODS: We conducted a prospective study on patients who developed SAP with or without CRAI. Out of 18 patients fulfilled clinical diagnostic criteria for SAP in Japan, 9 patients underwent CRAI, while 9 patients underwent conventional systemic protease inhibitor and antibiotics therapy (non-CRAI). CRAI was initiated within 72 h of the onset of pancreatitis. Gabexate mesilate (2400 mg/d) was continuously administered for 3 to 5 d. The clinical outcome including serum inflammation-related parameters were examined.

RESULTS: The duration of abdominal pain in the CRAI group was 1.9 ± 0.26 d, whereas that in the non-CRAI group was 4.3 ± 0.50. The duration of SIRS in the CRAI group was 2.2 ± 0.22 d, whereas that in the non-CRAI group was 3.2 ± 0.28. Abdominal pain and SIRS disappeared significantly in a short period of time after the initiation of CRAI using gabexate mesilate. The average length of hospitalization significantly differed between the CRAI and non-CRAI groups, 53.3 ± 7.9 d and 87.4 ± 13.9 d, respectively. During the first two weeks, levels of serum CRP and the IL6/IL10 ratio in the CRAI group tended to have a rapid decrease compared to those in the non-CRAI group.

CONCLUSION: The present results suggest that CRAI using gabexate mesilate was effective against SAP.

INTRODUCTION

Severe acute pancreatitis (SAP) remains a lethal disease. It is defined as an inflammatory process of the pancreas with possible peripancreatic tissue, and multi-organ involvement inducing multi-organ dysfunction syndrome (MODS) with an increased mortality rate[1,2]. Continuous regional arterial infusion (CRAI) with protease inhibitor nafamostat mesilate and antibiotics has been proven to be effective as an initial therapy in Japan[2]. However, evidence supporting the benefit of CRAI in treating acute pancreatitis is insufficient, and its advisability according to the JPN guidelines for the management

of acute pancreatitis is classed as "Recommendation C"[3]. In the statement, it was described that CRAI with protease inhibitors and antibiotics may possibly reduce the mortality rate and incidence of infectious complications in necrotizing pancreatitis. Actually, until now, most cases have been treated with the protease inhibitor nafamostat mesilate. Here, we performed CRAI using gabexate mesilate to treat SAP, and investigated the clinical benefits including serum inflammation-related parameters such as cytokines and chemokines.

MATERIALS AND METHODS

Patients

The severity of acute pancreatitis was assessed within 48 h of admission according to the diagnostic criteria for the diagnosis of acute pancreatitis by the Research Committee for Intractable Diseases of the Pancreas in Japan by Ministry of Health, Labour and Welfare Japan (Tables 1 and 2)[4-6]. A total of 18 patients fulfilling clinical diagnostic criteria for SAP at six participating institutions were selected for the present study. Nine patients underwent CRAI (CRAI group), while 9 patients underwent conventional systemic protease inhibitor and antibiotics therapy (non-CRAI group). Each institution made the decision to perform CRAI or non-CRAI therapy, so the present study was not a randomized controlled trial. Clinical features of both groups were shown in Table 3. All 9 patients in the CRAI group were men, average age 48.0 ± 13.4 years (mean ± SD). The cause of SAP was alcohol (n = 5), gallstone (n = 1), hyperlipidemia (n = 1), post-endoscopic retrograde cholangiopancreatography (ERCP, n = 1), or unknown (n = 1). On the other hand, 4 of the 9 patients in the non-CRAI group were male and 5 were female (average age of group, 59.9 ± 15.1 years; mean ± SD). Regarding age at onset, no significant difference was observed between CRAI group and non-CRAI group (P = 0.0979). The causes of SAP patients in the non-CRAI group were gallstones (n = 4), alcohol (n = 3), post-ERCP (n = 1), or unknown (n = 1). All patients in both groups were diagnosed as stage 2 SAP. CRAI was initiated within 72 h of the onset of pancreatitis. A 5-Fr shepherd's catheter was placed in either the celiac artery (including the splenic and gastro-duodenal arteries) or in the supra-mesenteric artery, and gabexate mesilate (2400 mg/d) was continuously administered for 3-5 d. Antibiotics were administered every 12 h (panipenem in 5 patients, meropenem in 2 patients, imipenem in 1 patient, and piperacillin in 1 patient). Catheters were placed in the superior mesenteric, celiac, splenic, and gastroduodenal arteries of 3, 3, 2, and 1 patient, respectively. Complications in one patient comprised thrombosis of the superior mesenteric artery, and warfarin was administered. Carbapenem antibiotics were administered to all patients in the non-CRAI group.

Measured parameters

The duration of abdominal pain and of systemic inflammatory response syndrome (SIRS) as well as the length of hospitalization were recorded. As biochemical markers of pancreatitis, the levels of serum pancreatic amylase (P-amylase), the white blood counts (WBC), and C-reactive protein (CRP) were examined on day 0 (onset of pancreatitis), day 1, day 3, day 7, and day 14. ELISAs were performed to determine serum IL-6, IL-8, IL-10, TNF-α, and MCP-1 concentrations on day 0 (onset of pancreatitis), day 1, day 3, day 7, and 14. Samples were

Table 1 Criteria for grading the severity of acute pancreatitis in Japan[4]

Prognostic factors	Clinical signs	Laboratory data
Prognostic factor Ⅰ (2 points for each positive factor)	Shock Respiratory failure Mental disturbance Severe infection Hemorrhagic diathesis	BE ⩽ -3 mmol/L Ht ⩽ 30% (after hydration) BUN ⩾ 40 mg/dL or creatinine ⩾ 2.0 mg/dL
Prognostic factor Ⅱ (1 points for each positive factor)		PaO_2 ⩽ 60 mmHg (room air) FBS ⩾ 200 mg/dL Total protein ⩽ 60 g/L LDH ⩾ 700 IU/L Ca ⩽ 7.5 mg/dL Prothrombin time ⩾ 15 s Platelet count ⩽ $1 \times 10^5/mm^3$ CT grade Ⅳ or Ⅴ
Prognostic factor Ⅲ	SIRS score ⩾ 3 (2 points) Age ⩾ 70 yr (1 point)	

BE: Base excess; Ht: Hematocrit; BUN: Blood urea nitrogen; FBS: Fasting blood sugar; LDH: Lactate dehydrogenase; SIRS: Systemic inflammatory response syndrome. CT grade Ⅳ or Ⅴ: Presence of diffuse and uneven density in the pancreatic parenchyma or the presence of inflammatory changes extending beyond the border of the pancreas. Severity score: Sum of the points for the positive prognostic factors is defined as the severity score. Standardized criteria: Severe, presence of more than one prognostic factor Ⅰ, and/or the presence of more than two prognostic factor Ⅱ (severity score ⩾ 2 points); Moderate, presence of one prognostic factor Ⅱ (severity score = 1 point); Mild, acute pancreatitis without prognostic factor Ⅰ or Ⅱ (severity = 0 point).

Table 2 Stage classification of acute pancreatitis and mortality rate in 2003 in Japan[4]

Stage	Severity score	Severity	No. of patients (%)	Died	Mortality rate (%)
Stage 0	0 point	Mild	943 (53.3)	1	0.1
Stage 1	1 point	Moderate	280 (15.8)	2	0.7
Stage 2	2-8 points	Severe Ⅰ	455 (25.7)	17	3.7
Stage 3	9-14 points	Severe Ⅱ	63 (3.6)	16	25.4
Stage 4	⩾ 15 points	Most severe	27 (1.5)	16	59.3
Total			1786 (100)	52	2.9

In 2004, nationwide survey of patients with acute pancreatitis in Japan who visited the hospitals in the year 2003 (from January 1 to December 31) was performed by stratified random sampling method. From the first survey, the total number of patients treated for acute pancreatitis in Japan in the year 2003 was estimated as 35300 (95% confidence interval, 30500-40000). Clinical records of 1768 patients with acute pancreatitis were obtained in the second survey for analysis of etiology and outcome. Number of patients who died of acute pancreatitis or related complications.

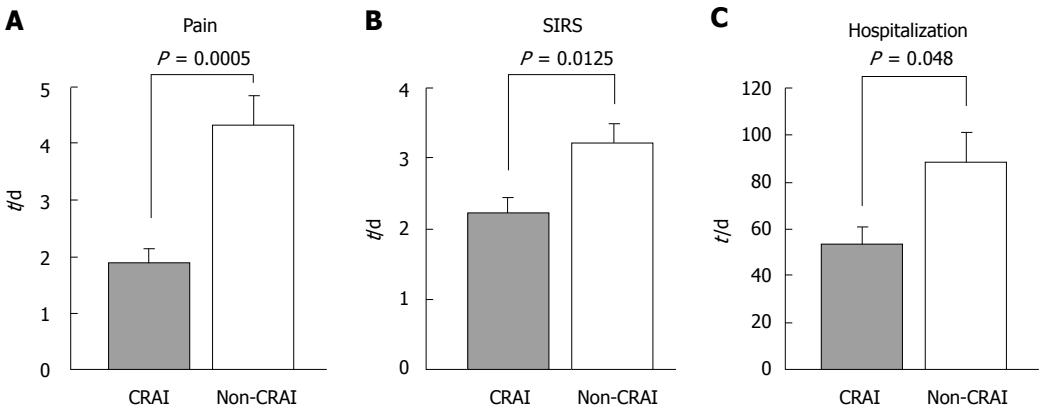

Figure 1 Changes in clinical parameters. The duration of abdominal pain (A) and of systemic inflammatory response syndrome (SIRS) (B) as well as the length of hospitalization (C) were investigated. Grey columns represent data for continuous regional arterial infusion using gabexate mesilate with antibiotics (CRAI-group) and white columns for non-CRAI group. Values are expressed as mean ± SE.

determined with commercially available kits according to the manufacturer's instructions for human IL-6, human IL-8, human IL-10, human TNF-α, and human MCP-1 (Biosource, Camarillo, CA, USA).

Statistical analysis

Results are expressed as mean ± SE. We analyzed the duration of abdominal pain, SIRS as well as the length of hospitalization using the proportional hazard model. Serum pancreatic enzymes, inflammation-related parameters, cytokines and chemokines were analyzed using the non-parametric Mann-Whitney U test. P values < 0.05 were considered significant. Pearson's correlation analysis was used to calculate correlations between the data.

RESULTS

Duration of abdominal pain, SIRS, and hospitalization

The duration of abdominal pain in the CRAI group was 1.9 ± 0.26 d (range, 1-3), whereas the duration in the non-CRAI group was 4.3 ± 0.50 (range, 3-8). Abdominal pain disappeared significantly in a short period of time after the initiation of CRAI with the protease inhibitor (P = 0.0005, Figure 1A). Similarly, SIRS disappeared significantly and shortly after the initiation of CRAI (P = 0.0125, Figure 1B). The duration of SIRS in the CRAI group was 2.2 ± 0.22 d (range, 1-3), whereas the duration in the non-CRAI group was 3.2 ± 0.28 (range, 2-4). The average length of hospitalization significantly differed between both groups, 53.3 ± 7.9 and 87.4 ± 13.9 d for the CRAI and non-CRAI, respectively. Patients in the CRAI group discharged significantly in a short period of time after the initiation of CRAI with gabexate mesilate (P = 0.048, Figure 1C).

Changes in serum inflammation-related parameters

P-amylase and WBC quickly decreased, with no significant differences between the groups (Figure 2A and B). During the first two weeks of therapy, levels of serum CRP in the CRAI group rapidly decreased (Figure 2C). IL-6 and IL-10 in the CRAI group rapidly decreased in the same manner as the IL-6/IL-10 ratio (Figure 2D). On the other hand, both CRP and IL-6/IL-10 in the non-CRAI group tended to decrease slowly with a 2-d delay in peak values compared to those in the CRAI group, with no significant differences between the groups. Levels of serum IL-8, TNF-α, and MCP-1 over time did not significantly differ between the two groups (data not shown).

DISCUSSION

Protease inhibitors are widely applied to treat acute pancreatitis in Japan; but since randomized controlled trials (RCTs) are difficult to conduct on patients with acute pancreatitis, only five RCTs have been examined gabexate mesilate[7-11]. The results of a meta-analysis of 4 among 5 trials were negative, and indicated that gabexate mesilate does not lower rates of surgical intervention or mortality. One of the reason was considered as follows; the protease inhibitors used to treat acute necrotizing pancreatitis cannot easily reach the pancreas when administered intravenously, and, because of ischemia or impaired microcirculation, they hardly penetrate into pancreatic tissue[12,13]. However, Chen *et al*[11] conducted an RCT and reported that continuous intravenous administration of high doses of gabexate mesilate (2400 mg/d) decreased the incidence of complications and mortality. On the other hand, since Takeda *et al*

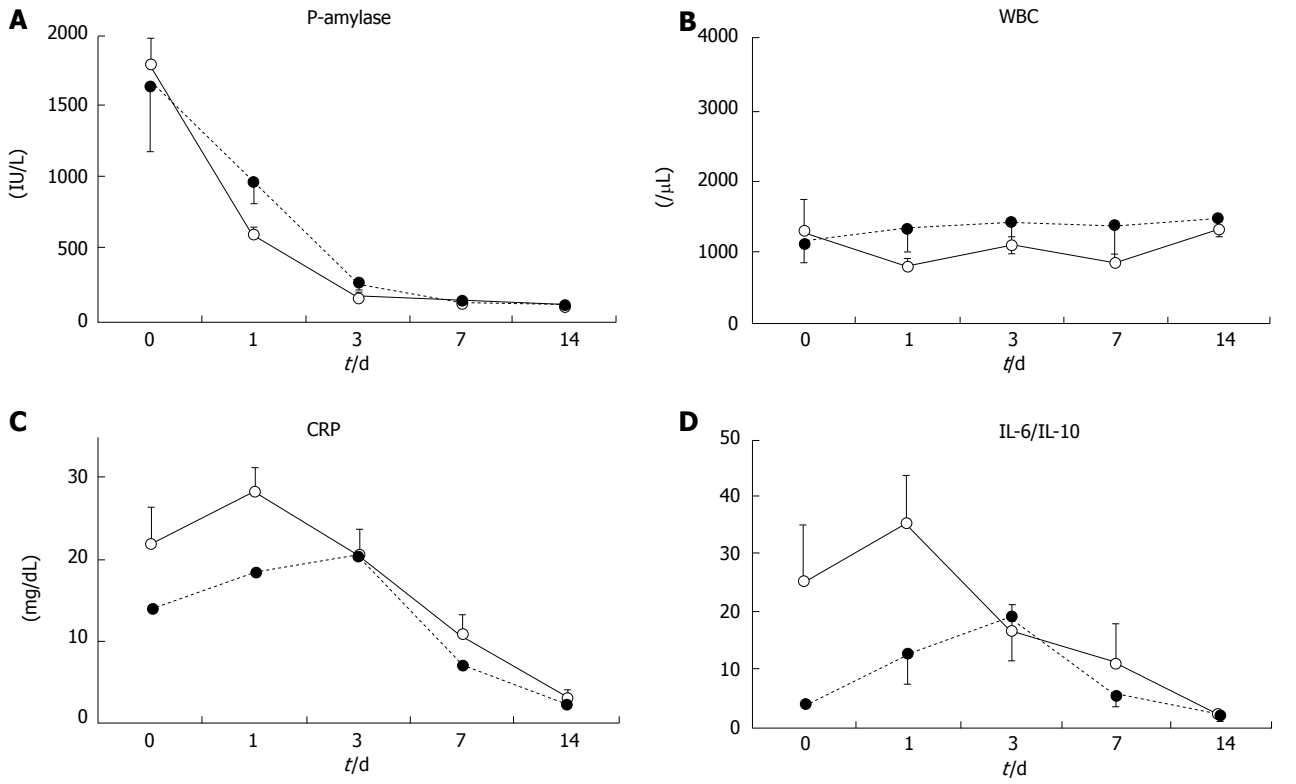

Figure 2 Changes in serum inflammation-related parameters. The levels of serum pancreatic amylase (P-amylase) (**A**), the white blood counts (WBC) (**B**), C-reactive protein (CRP) (**C**, and IL-6/IL-10 ratio **D**) were examined on days 0 (onset of pancreatitis), 1, 3, 7, and 14. Straight lines give data for continuous regional arterial infusion using gabexate mesilate with antibiotics (CRAI-group) and dotted lines for non-CRAI group. Values are expressed as mean ± SE. No significant differences between the groups were observed.

described arterial infusion with a protease inhibitor together with an antibiotic in Japan, severe acute pancreatitis has been treated by CRAI with nafamostat mesilate, and whereas an RCT has not been conducted, the usefulness of CRAI has been documented[14-17]. This strategy suppresses early inflammation and infection in pancreatic tissue, which controls subsequent systemic inflammation. The level of protease inhibitor in pancreatic tissues after CRAI using nafamostat was 5-fold higher than that delivered by intravenous injection, and trypsin activities in pancreatic tissues are significantly suppressed by CRAI[18]. On the other hand, the level of protease inhibitor in pancreatic tissues after CRAI using gabexate mesilate was 32-fold higher than that delivered by intravenous injection[19]. However, until now, CRAI using gabexate mesilate has not been examined sufficiently. In the present study, therefore, we investigated the usefulness of CRAI using gabexate mesilate for patients with SAP. The reasons for using gabexate mesilate were as follows: (1) Gabexate mesilate is the only intravenous protease inhibitor that has been proven effective in an RCT[11,20]. (2) Gabexate mesilate has a higher anticoagulant capacity than nafamostat mesilate[21]. (3) Gabexate mesilate induces less hyperkalemia even at high doses compared to nafamostat mesilate[22]. (4) In Japan, most studies on CRAI have used nafamostat mesilate, and more needs to be understood about gabexate mesilate.

All patients in this study had stage 2 pancreatitis, and since the severity was relatively mild, the patients were discharged in good health without requiring surgical intervention. The duration of pain, SIRS, and hospitalization was shorter for the CRAI group than the non-CRAI group. Previous studies of CRAI evaluated the mortality rates and surgical intervention in lethal SAP; but the present study suggested that CRAI is also effective against relatively milder forms of non-lethal SAP.

Blood cytokines and chemokines play important roles in the progression of severe acute pancreatitis. Local release of the proinflammatory cytokines, IL-18, TNF-α, and IL-1 upregulates IL-6. Levels of anti-inflammatory cytokines such as IL-10 also increase to maintain homeostasis. Excessive proinflammatory responses advance SIRS, and activated neutrophils and endothelial cells damage multiple organs. Ohmoto *et al*[23] reported that, during the healing process of acute pancreatitis, the IL-10/IL-6 ratio initially decreased, but increased as the pancreatitis improved. Put another way, IL-6/IL-10 ratio reveals an increase in a more severe stage of acute pancreatitis. We found here that IL-6 and IL-10 levels quickly increased and then decreased with therapy. The changes in the IL-6/IL-10 ratio were the same as those in CRP, but the ratio tended to decrease 2 d earlier in the CRAI group than in the non-CRAI group. These findings suggested that CRAI using gabexate mesilate effectively treats acute pancreatitis regarding biochemical features. On the other hand, changes in other

proinflammatory cytokines such as IL-8 and TNF-α were not significant. However, among patients with relatively mild stage 2 SAP in the present study, the release of these cytokines in tissues was insufficient to increase and reflect in their blood concentrations.

Essentially, a large-scale RCT should be necessary to verify the effects of CRAI; but to conduct such a study on patients with highly lethal SAP seems to be unethical in Japan. A future RCT might consider enrolling patients with stage 2 pancreatitis that is relatively mild and less fatal than in the present study. In conclusion, the present results suggest that CRAI using gabexate mesilate was effective against SAP in terms of yielding clinical benefits for patients with SAP.

The authors thank Mr. Rife SE and Mr. Matsuo H for their contribution to this article.

COMMENTS

Background

Severe acute pancreatitis (SAP) remains a lethal disease. Protease inhibitors are widely applied to treat acute pancreatitis in Japan; but the protease inhibitors used to treat acute necrotizing pancreatitis cannot easily reach the pancreas when administered intravenously, and, because of ischemia or impaired microcirculation, they hardly penetrate into pancreatic tissue. Recently, continuous regional arterial infusion (CRAI) with the protease inhibitor nafamostat mesilate and antibiotics has proven effective as an initial therapy. CRAI has been applied to treat SAP, but the evidence of its value is still scarce.

Research frontiers

The article focuses on the efficacy of CRAI using gabexate mesilate and antibodies for SAP.

Innovations and breakthroughs

The present study shows the efficacy of CRAI using gabexate mesilate for SAP, and the clinical benefits and sequential changes in serum inflammation-related parameters such as cytokines and chemokines. Abdominal pain and SIRS disappeared significantly in a short period of time after the initiation of CRAI with a protease inhibitor compared to non-CRAI. The average length of hospitalization significantly decreased with CRAI and patients discharged significantly in a shorter period of time after the initiation of CRAI with gabexate mesilate compared to non-CRAI.

Applications

CRAI using gabexate mesilate was shown to be effective against SAP in terms of clinical benefits for patients with SAP, and thus may provide a new strategy of treatment for SAP.

Peer review

Effect of continuous regional arterial infusion therapy with gabexate and antibiotics for SAP is very interesting clinical research. Known that SAP may have high mortality, some new modalities of therapy which improve prognosis of patients are welcome.

Abstract

AIM: To evaluate the prevalence of chronic gastrointestinal symptoms and their impact on health-related quality of life (HRQOL) in the Korean population.

METHODS: A cross-sectional survey, using a reliable and valid Rome Ⅱ based questionnaire, was performed on randomly selected residents, between 18 and 69 years in age. All respondents were interviewed at their homes or offices by a team of interviewers. The impact of chronic gastrointestinal symptoms on HRQOL was assessed using the Korean version of the 36-item Short-Form general health survey (SF-36).

RESULTS: Of the 1807 eligible subjects, 1417 (78.4%: male 762; female 655) were surveyed. Out of the respondents, 18.6% exhibited at least one chronic gastrointestinal symptom. The prevalence of gastroesophageal reflux disease (GERD), defined as heartburn and/or acid regurgitation experienced at least weekly, was 3.5% (95% CI, 2.6-4.5). The prevalence of uninvestigated dyspepsia, irritable bowel syndrome (IBS) and chronic constipation based on Rome Ⅱ criteria were 11.7% (95% CI, 10.1-13.5), 2.2% (95% CI, 1.5-3.1), and 2.6% (95% CI, 1.8-3.5) respectively. Compared with subjects without chronic gastrointestinal symptoms (n = 1153), those with GERD (n = 50), uninvestigated dyspepsia (n = 166) and IBS (n = 31) had significantly worse scores on most domains of the SF-36 scales.

CONCLUSION: The prevalence of GERD, uninvestigated dyspepsia and IBS were 3.5%, 11.7% and 2.2% respectively, in the Korean population. The health-related quality of life was significantly impaired in subjects with GERD, uninvestigated dyspepsia and IBS in this community.

INTRODUCTION

Functional gastrointestinal disorders (FGIDs) are highly prevalent in different geographic populations and cause a variety of gastrointestinal symptoms that greatly inconvenience the affected individuals[1,2]. According to a household survey in the United States, 69% of those questioned reported as having at least one of twenty functional gastrointestinal symptoms in the preceding three months[1]. In other population-based surveys, the prevalence of non-ulcer dyspepsia was approximately 30% and irritable bowel syndrome was 15%[2,3]. The prevalence of functional gastrointestinal disorders has been reported to differ based on the geographical region and race. Although the prevalence of such disorders in

Koreans is thought to be different from that in the Westerners, there has been no randomly sampled population-based study on the prevalence of chronic gastrointestinal symptoms in the Korean population.

The health-related quality of life (HRQOL) is a patient-focused concept, referring to an impairment of functional status (physical or mental) and the sense of well-being. As such, it is an important measure of the impact of chronic diseases. Several studies have shown that the HRQOL is significantly reduced in patients with chronic gastrointestinal symptoms in referral settings, compared with the general population, as well as in patients with other chronic conditions, such as GERD and asthma. However, there is a lack of evidence to support a decrease in the HRQOL in the general population having chronic GI symptoms[4,5].

The aims of the present study were to evaluate the prevalence of chronic gastrointestinal symptoms according to the Rome Ⅱ criteria, and to determine whether the HRQOL is impaired in subjects having chronic gastrointestinal symptoms in the Korean community.

MATERIALS AND METHODS

Subjects

The study was carried out in Asan-si, Chungchungnam-do Province from January 3, 2000 to February 28, 2001. Asan-Si is a small city located in the middle of South Korea. The population comprises approximately 180 000 people, and is a combination of urban and farming community. Sociodemographic factors including age, sex, educational background and economic level of Asan-si are similar to the overall Korean population, based on the information obtained from the Korean National Statistical Office (http://www.nso.go.kr). We assumed a symptom prevalence of 40%; thus at least 1024 interviews were required to achieve the required precision of ± 3% with 95% confidence. Therefore, the target sample size was 1400. A cross-sectional survey was performed on randomly selected Asan-si residents, between 18 and 69 years of age. A lengthy consultation was made with the regional health office (RHO) to prepare the survey. For instance, the general regional information provided by the RHO helped to organize visits and complete other administrative activities. Ten out of Asan-si's 17 districts, with population size over 500 were randomly selected. Within each of these districts, a total of 200 households from every third street were chosen. The size, gender and age of all household members were obtained from the RHO database before the visit. Gender and age were used to stratify the households and one person in each household was selected by random sampling, before a list of selected individuals was compiled in each stratum. The regional health office checked the eligibility of the selected individuals by examining their medical records, followed by a telephone interview. Exclusion criteria included pregnant or lactating women, history of surgery of the GI tract including partial resection of the stomach and/or resection of the small/large intestine (subjects with an appendectomy were included), major psychosis, mental retardation or dementia, significant illness that may render them unable to complete the questionnaire, or had other nationalities. The revised list was used for actual household visit after excluding the ineligible individuals. Since only housewives and elderly individuals would be available during the day, we pre-scheduled the time and order of the house visits with the help of the regional health office.

Questionnaire

We developed a bowel symptom questionnaire to identify chronic gastrointestinal symptoms in adults, based on the Rome Ⅱ criteria. The complete questionnaire was 22 pages long and included 130 questions, of which 103 were used to diagnose gastroesophageal reflux and chronic gastrointestinal symptoms. The bowel symptoms questionnaire was modified from the Mayo version of Bowel Symptoms Questionnaire[6] and several items were adopted from the Rome Ⅱ criteria. The validation process consisted of forward and backward translation as well as confirming the patient's ability to understand. However, we did not perform test-retest reliability, because this was not a self-reported questionnaire, and trained interviewers visited homes and helped the subjects to complete the questionnaire. During the survey, a face-to-face interview was conducted to help describe certain parts of the Bowel Symptoms Questionnaire. Specifically, heartburn is not a term in the Korean language; therefore the symptoms had to be verbally described and a diagram indicating the location of the burning sensation was added to the questionnaire in order to help ensure that the subjects fully comprehended the medical conditions under investigation. The remaining 27 questions enquired about the sociodemographic characteristics, self-reported height and weight, physician visits, past illnesses, social habits (smoking, alcohol, and medication use), impact on everyday life, possible anxiety induced by the problem, as well as lifestyle changes that may have been relevant.

HRQOL was assessed by the Korean version of SF-36 (SF-36-K). We previously assessed the reliability, discriminant validity and concurrent validity of the SF-36-K before conducting this study. The SF-36-K was fully applicable and well understood by Korean patients, as well as healthy subjects. The reliability was assessed by using the test-retest method, and the internal consistency method. The test-retest method showed high correlation between the two tests. Cronbach's correlation alpha of all 8 subscales of the SF-36-K was > 0.73 (range, 0.73-0.96). Discriminant validity was supported by comparing the SF-36 score in 179 healthy subjects and 44 patients with gastrointestinal disorders. All 8 domains of the SF-36 were well correlated with subscores of the WHO Quality of Life Scale-K and the Psychological Well-Being Index. The SF-36 is a widely used general health profile questionnaire with 36 questions comprising eight scales: physical functioning (e.g. walking, lifting), role functioning-physical (limitations in ability to perform usual activities), role functioning-emotional (impact of emotional problems on work or

daily activities), social functioning (impact of health or emotional problems on social activities), bodily pain (level of bodily pain or discomfort), mental health (anxiety, depression, sense of psychological well-being), vitality (energy level or fatigue), and general health perceptions (global evaluations of health). The SF-36 is scored from 0 to 100 with higher scores indicating a better HRQOL.

Survey design

We conducted a cross-sectional survey of gastrointestinal symptoms and their impact on the quality of life (QOL) in Korean subjects in cooperation with the public health center. Before the survey, the questionnaire was explained to the health-care personnel of the Public Health Center to outline the purpose of the study and to request their participation. All subjects were interviewed in person at their homes or offices by a team of interviewers, all trained by the same physician (C.M.G.). The consistency and completeness of the completed questionnaire was checked after each interview.

Statistics

The 1807 eligible individuals interviewed can be considered as a representative sample of the Asan-si population. We calculated the prevalence of GERD and chronic gastrointestinal symptoms according to the Rome Ⅱ criteria. The prevalence is presented in percentages with 95% exact confidence intervals (CI). Comparisons among groups were performed by the χ^2 test or Fisher's exact test for categorical data and *t*-test for continuous data. The association between prevalence rate and age in each group was tested by logistic regression model. Differences of SF-36 sub-scale scores between groups were estimated by ANCOVA model with adjustment of covariates. Pair-wise differences between groups without chronic GI symptoms and groups with chronic GI symptoms (GERD, UD and IBS) were tested by Bonferroni adjusted *t*-test. Gender, age, economic level and education variables were used for adjustment. A multiple regression model was performed for SF-36 sub-scale scores for individuals who had chronic GI symptoms. Gender, age, smoking, religion, education, economic level, physician visit and overlapping symptom variables were used as predictors. Statistical analyses were performed using SAS (SAS, Cary, NC, USA).

RESULTS

Response rate and subject characteristics

Among the randomly selected 2024 subjects, a total of 217 were not eligible to participate in the study. One hundred and twenty individuals were no longer living in Asan-si and 97 could not be interviewed due to physical or mental disorders. Out of the 1807 eligible subjects, 314 could not be contacted after three attempts, and 76 refused to participate. A total of 1417 (78.4%) of the 1807 eligible subjects returned the completed survey. Of these respondents, 762 were male (53.8%) and 655 were female (46.2%), with a mean age of 44 years. The demographic and socioeconomic features of the respondents are shown in Table 1.

Table 1 Characteristics of the study population *n* (%)

Variable	Male (*n* = 762)	Female (*n* = 655)	Total (*n* = 1417)
Age			
18-29	163 (11.5)	151 (10.7)	314 (22.2)
30-39	132 (9.3)	110 (7.8)	242 (17.1)
40-49	169 (11.9)	146 (10.3)	315 (22.2)
50-59	150 (10.6)	116 (8.2)	266 (18.8)
60-69	148 (10.4)	132 (9.3)	280 (19.7)
Median age (yr)	45	44	44
Mean age (yr)	44.1 ± 14.4	43.7 ± 15.1	43.9 ±14.8
BMI (kg/m^2)	22.8	22.0	22.4
Ever tobacco smoker (%)	67.8[a]	4.0	38.3
Alcohol use (> 75 g/wk) (%)	36.4[a]	2.6	20.7
Marital status (single)[1] (%)	26.5	28.7	27.5
Employed (%)	85.4[a]	45.6	67.0
Presence of religion (%)	50.5[b]	65.0	57.2
High school graduate (%)	57.0[a]	49.2	53.4
Economic status (%)			
High	6.4	6.3	6.4
Middle	76.1	79.8	77.8
Low	17.5	13.9	15.8

[1]Marital status was divided into single or married/living as a couple. Single status was extended to include unmarried persons, divorced individuals and those with a deceased spouse [a]$P < 0.01$, [b]$P < 0.001$ compared to female.

Prevalence of chronic gastrointestinal symptoms

The prevalence of weekly episodes of heartburn and acid regurgitation was 2.0% (95% CI, 1.2-2.7) and 2.0% (95% CI, 1.3-2.8) respectively. The prevalence of GERD, defined as heartburn and/or acid regurgitation experienced at least weekly, was 3.5% (95% CI, 2.6-4.5). The prevalence of specific chronic gastrointestinal symptoms, according to the Rome Ⅱ criteria is summarized in Table 2. At least one chronic gastrointestinal symptom was present in 18.6% of the 1417 respondents. The most prevalent chronic gastrointestinal symptom was uninvestigated dyspepsia (11.7%; 95% CI, 10.1-13.5). According to the subtypes of dyspepsia, dysmotility-like dyspepsia was the most prevalent (69.9%), followed by ulcer-like dyspepsia (28.3%) and non-specific dyspepsia (1.8%). Thirty one subjects (2.2%) fulfilled the Rome Ⅱ criteria for the diagnosis of IBS (Table 2). Of these, 13 subjects (42%) were classified as diarrhea-predominant, and 12 (39%) constipation-predominant IBS. The remaining 6 subjects (19%) fell into the alternating IBS subgroup. There were no differences in the overall prevalence of IBS based on gender; however, compared to male subjects, females reported more frequent constipation-predominant IBS (IBS-C). Females also reported more frequent chronic constipation. There were no gender-based differences in the prevalence of the other chronic gastrointestinal symptoms (Table 2).

Age-specific prevalence of GERD, uninvestigated dyspepsia, and IBS are shown in Figure 1, and the odds ratio with 95% confidence interval are shown in Table 3. The prevalence of GERD and dyspepsia showed significant differences between different age groups (logistic regression, $P < 0.01$).

Physician visit and medication use

In the present population-based study, 50.5% of the

Table 2 Prevalence of chronic gastrointestinal symptoms, according to the Rome Ⅱ criteria

Chronic gastrointestinal symptoms	Respondent (*n* = 1417) *n*	% (95% exact CI)	Male (*n* = 762) %	Female (*n* = 655) %
Globus	7	0.5 (0.2-1.0)	0.4	0.7
Chronic dysphagia	7	0.5 (0.2-1.0)	0.3	0.7
Rumination	0	0.0 (0.0-0.3)	0	0
Chronic chest pain	21	1.5 (0.9-2.3)	1.6	1.4
Chronic heartburn	24	1.7 (1.1-2.5)	1.8	1.6
Uninvestigated dyspepsia	166	11.7 (10.1-13.5)	10.8	12.8
IBS	31	2.2 (1.5-3.1)	1.8	2.6
IBS-D	13	0.9 (0.5-1.6)	1	0.8
IBS-C	12	0.8 (0.4-1.5)	0.1	1.7[a]
IBS-A	6	0.4 (0.2-0.9)	0.7	0.2

Chronic constipation	37	2.6 (1.8-3.6)	0.5	5.0[a]
Chronic diarrhea	11	0.8 (0.4-1.4)	0.8	0.8
Chronic incontinence	18	1.3 (0.8-2.0)	1.6	1.1

IBS: Irritable bowel syndrome; IBD-D: Diarrhea-predominant IBS; IBS-C: Constipation- predominant IBS; IBS-A: Alternating constipation and diarrhea IBS. [a]$P < 0.05$ (Fisher's exact test) compared to male.

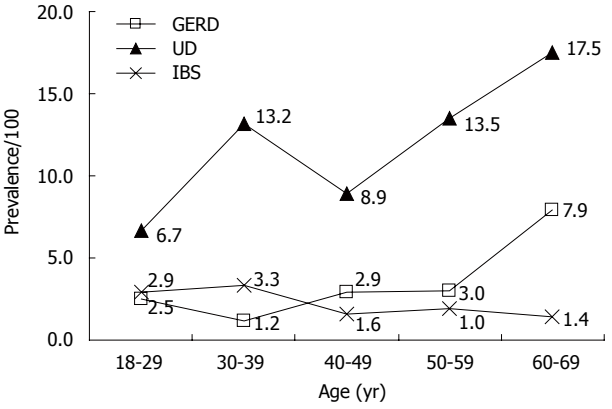

Figure 1 Age specific prevalence rate (per 100) of GERD, UD and IBS in Asan-si, Korea. GERD: Gastroesophageal reflux disease; UD: Uninvestigated dyspepsia; IBS: Irritable bowel syndrome.

subjects surveyed had experienced at least one gastrointestinal symptom in the previous year, and 10.9% had reported visiting a physician due to their gastrointestinal symptoms. With regard to the use of medications, 5.7% of the respondents took non-steroidal anti-inflammatory drugs (NSAIDs), and 5.5% had taken anti-acid agents or antacids in the past year. More women took NSAIDs and constipation medications (Table 4).

Impact of chronic gastrointestinal symptoms on health-related quality of life

Of the 1417 respondents, 1153 individuals did not experience any chronic GI symptoms, while 198 subjects had features suggestive of GERD, UD or IBS, or a combination of these symptoms. There was no significant difference between the two groups with respect to gender, smoking, martial status and BMI ($P > 0.05$). However, age, education level and the number of physician visits were statistically different ($P < 0.001$). The mean age of subjects with chronic GI symptoms and subjects without chronic GI symptoms was 47.8 ± 14.9 and 43.0 ± 14.6, respectively. Subjects with chronic GI symptoms had a lower education level, and also visited a physician more frequently for gastrointestinal symptoms than subjects without chronic GI symptoms. SF-36 subscale scores were calculated for four groups: (1) subjects without chronic gastrointestinal symptoms, (2) subjects with GERD, (3) subjects with uninvestigated dyspepsia, and (4) subjects with IBS. The adjusted mean scores for gender, age, education and economic level, as well as the accompanying *P*-values for the eight domains of the SF-36 are summarized in Table 5. Compared with those not experiencing chronic gastrointestinal symptom, subjects with GERD exhibited significantly worse scores on all except two domains (social-functioning and role-emotional). Subjects with uninvestigated dyspepsia and IBS had significantly worse scores on all domains compared with those not having chronic gastrointestinal symptoms (Table 5). Multiple regression analysis of the association between the HRQOL and covariates was performed on subjects with chronic GI symptoms (n = 198) (Table 6). All covariates shows VIF smaller than 10, thus no covariates were excluded as the cause of multi-

Table 3 Association between age and chronic gastrointestinal symptoms

Age	GERD	UD	IBS
18-29	1.0 (Reference)	1.0 (Reference)	1.0 (Reference)
30-39	0.48 (0.13-1.82)	2.12 (1.19-3.77)	1.15 (0.44-3.04)

collinearity. The results of overall *F*-test were significant for all models ($P < 0.05$). Female gender, old age, a low level of education (< high school education), a low economic class, number of physician visits within the past year, and overlapping chronic gastrointestinal symptoms were associated with reduction in the SF-36 scales.

DISCUSSION

The present population-based study describes the prevalence of chronic gastrointestinal symptoms and their impact on the HRQOL in the Korean population.

Heartburn and acid regurgitation are specific symptoms of GERD, and a diagnosis of GERD can be made on the basis of these symptoms alone without further diagnostic tests[7]. When defined as "at least weekly heartburn and/or acid regurgitation", the prevalence of GERD in the West ranges between 10% and 20%, whereas in Asia the prevalence is reported to be < 5%[8]. In the present study, the prevalence of GERD was found to be 3.5% which is much lower than that in Western countries. According to two previous population studies in Korea, the prevalence of GERD was 5% and 7.1%, respectively[9,10]. It is unclear why the prevalence of GERD is lower in Korea compared to the West. Differences in the intake of dietary fat, body build, genetic factors, and the prevalence of *H pylori* infection are possible contributing factors[11]. The prevalence of dyspepsia has been shown to vary considerably between different populations. Although our data may represent the presence of valid epidemiological differences, it is also possible that the varying definitions used in different population-based studies may have contributed to this discrepancy. In the present study, the prevalence of uninvestigated dyspepsia by Rome Ⅱ criteria was 11.7%. These results are similar to a study from Taiwan, which reported prevalence of functional dyspepsia (FD) by the Rome Ⅱ criteria as 11.8%[12]. Population-based studies in Australia and Mexico have reported prevalence rates of dyspepsia by Rome Ⅱ criteria of 24.4%[13] and 8.0%[14], respectively. Based on Rome Ⅱ criteria, a patient presenting with upper abdominal pain or discomfort that is exclusively relieved by defecation and/or is associated with a change in the bowel pattern is defined as IBS rather than dyspepsia plus IBS[15]. Accordingly, many of the previously Rome I-defined dyspepsia subjects should be reclassified as IBS, rather than IBS with dyspepsia. Furthermore, patients with predominant heartburn should be excluded. Although, the present study could not demonstrate the prevalence of dyspepsia defined by Rome I criteria, the prevalence of dyspepsia by Rome Ⅱ criteria was lower compared to our previous study using the Rome I criteria (11.7% *vs* 15.5%)[9]. Reduction in prevalence has also been reported in other studies that directly compared the prevalence of dyspepsia using Rome I and Rome Ⅱ criteria[12,13,16]. Several individuals who did not meet Rome Ⅱ criteria for dyspepsia were taking medications such as antacids, prokinetic agents and digestives for a long time. If medication alone was indicative of dyspepsia, our study indicates that its prevalence would be 16%. It is also possible that some subjects had GERD and not dyspepsia, or there was an overlap. One of these factors may also account for the low prevalence of GERD in the Korean population. Over-the-counter medications may explain the underestimation of the prevalence of other functional GI disorders. Conversely, a number of drugs can theoretically induce bowel symptoms. However, data supporting the role of drugs, aside from NSAIDs, in the development of bowel symptoms in the general population are lacking[17,18].

The prevalence of IBS in Asian population-based studies has generally been lower compared to in the

West, regardless of the criteria applied. The prevalence of IBS by Rome Ⅱ criteria has been reported to vary from 4.7% to 25% in the West and from 3.7% to 19.1% in Asia[19]. In the present study, the prevalence of IBS by Rome Ⅱ criteria was 2.2%. In addition, the overall prevalence of IBS was similar among men and women; however, the prevalence of constipation-predominant IBS was higher in women. There is typically a significant female predominance with respect to hospital visits by IBS patients in Western countries, but this trend is not consistent with community studies and has been attributed to gender differences in health care utilization[19]. In a recent systematic review of 13 studies on IBS, based on Rome Ⅱ criteria, 7 studies found a higher prevalence of IBS in females and 4 studies found no gender difference, as in the present study[19]. A possible explanation for the lower female to male ratio in IBS in Koreans may be that men encounter more socioeconomic problems, causing increased stress and, as a consequence, an increased level of IBS[20].

In the present study, we also examined the impact of GERD, and two common chronic gastrointestinal symptoms (uninvestigated dyspepsia and IBS) on the HRQOL. Although a number of studies suggest that the HRQOL is significantly reduced in patients with chronic gastrointestinal symptoms in a referral setting, the data are conflicting[21], and very few studies have evaluated the impact of chronic gastrointestinal symptoms on HRQOL in the general population. In the present study, we observed that the quality of life was significantly impaired in subjects with GERD, uninvestigated dyspepsia and IBS. These findings are consistent with previous studies[5,22-24].

The present study showed that old age, female gender, the number of physician visits per year and presence of overlapping symptoms were associated with a negative impact on several domains of the SF-36. In general, old age was associated with a less favorable assessment of their personal health, pessimistic health appraisal, social isolation and unemployment[25]. Few studies have investigated whether women and men with chronic gastrointestinal symptoms differ with respect to the HRQOL measures. In a study based on referral center and primary care patients, Simren *et al*[26] observed that women with IBS had lower HRQOL compared to men with IBS. In another study, Lee *et al*[27] also found that women with IBS reported lower HRQOL scores. In the present study, a greater number of hospital visits was associated with a poorer HRQOL, which is in agreement with a US population-based study[28]. Fifty five percents of subjects with IBS had sought health care in the past year, and subjects with IBS had significantly lower IBS-QOL scores in the mental health and social functioning domains[28].

The strengths of the present study were inclusion of a random population sample, and the use of personal interviews with the subjects. As a result, we obtained a high response rate (78.4%), avoided a significant response bias, and had a negligible number of missing values. Since the interviewers associated with this study were trained before the commencement of contact with the subjects, a uniform survey was possible due to the fact that the interviewers could explain each aspect of the questionnaire fully, especially to subjects who were old, had low education level, or those who could not understand certain items. Sociodemographic factors including age, gender, educational background and economic level of the individuals in Asan-si were similar to the Korean population, based on the information obtained from the Korean National Statistical Office. Asan-si is a combined urban and farming community. We selected 10 out of the 17 districts of Asan-si. Five districts were randomly chosen in urban areas and the remaining five were selected in rural areas, which may have limited the generalization of the study. However, no differences were found between the demographic factors and the prevalence of GI symptoms in the 10 districts, and between rural and urban areas.

In summary, we evaluated the prevalence of chronic gastrointestinal symptoms in the Korean general population and demonstrated a significant impact of chronic gastrointestinal symptoms on the HRQOL. Dyspepsia was found to be the most common chronic gastrointestinal symptom, and the prevalence of GERD and IBS was lower compared to in the West. The presence of chronic gastrointestinal symptoms was found to have a negative impact on the HRQOL. This negative impact was greater in females, the elderly, individuals of lower economic class, and in subjects with higher number of physician visits, and overlapping symptoms.

Abstract

AIM: To investigate the efficacy and safety of n-3 polyunsaturated fatty acids (PUFA) from seal oils for patients with nonalcoholic fatty liver disease (NAFLD) associated with hyperlipidemia.

METHODS: One hundred and forty-four patients with NAFLD associated with hyperlipidemia were included in the 24-wk, randomized, controlled trial. The patients were randomized into two groups. Group A (n = 72) received recommended diet and 2 g n-3 PUFA from seal oils, three times a day. Group B (n = 72) received recommended diet and 2 g placebo, three times a day. Primary endpoints were fatty liver assessed by symptom scores, liver alanine aminotransferase (ALT) and serum lipid levels after 8, 12, 16, and 24 wk. Hepatic fat infiltration was detected by ultrasonography at weeks 12 and 24 after treatment.

RESULTS: A total of 134 patients (66 in group A, 68 in group B) were included in the study except for 10 patients who were excluded from the study. After 24 wk of treatment, no change was observed in body weight, fasting blood glucose (FBG), renal function and blood cells of these patients. Total symptom scores, ALT and triglyceride (TG) levels decreased more significantly in group A than in group B ($P < 0.05$). As expected, there was a tendency toward improvement in aspartate aminotransferase (AST), γ-glutamyltranspeptidase (GGT), and total cholesterol (TCHO) and high-density lipoprotein (HDL) cholesterol levels ($P < 0.05$) after administration in the two groups. However, no significant differences were found between the two groups. The values of low-density lipoprotein (LDL) were significantly improved in group A ($P < 0.05$), but no significant change was found in group B at different time points and after a 24-wk treatment. After treatment, complete fatty liver regression was observed in 19.70% (13/66) of the patients, and an overall reduction was found in 53.03% (35/66) of the patients in group A. In contrast, in group B, only five patients (7.35%, 5/68) achieved complete fatty liver regression (P = 0.04), whereas 24 patients (35.29%, 24/68) had a certain improvement in fatty liver (P = 0.04). No serious adverse events occurred in all the patients who completed the treatment.

CONCLUSION: Our results indicate that n-3 PUFA from seal oils is safe and efficacious for patients with NAFLD associated with hyperlipidemia and can improve their total symptom scores, ALT, serum lipid levels and normalization of ultrasonographic evidence. Further study is needed to confirm these results.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) represents a

spectrum of conditions characterized by an excessive accumulation of hepatic fat in the absence of alcohol consumption[1]. In Western countries and some regions of China, the prevalence of nonalcoholic steatohepatitis (NASH) and NAFLD is 1%-5% and 15%-39%, respectively[2]. In most of patients, NAFLD follows a relatively benign course and remains stable for years[1]. However, it was recently reported that many cases of cryptogenic liver cirrhosis may be related to unrecognized NASH[3]. Thus, treatment should be reserved for patients at risk of developing severe liver diseases. Medical therapy for NAFLD and NASH has been disappointing to date[4]. Although a number of treatment modalities are available, they cannot prevent the progression of early liver disease to its advanced stage, and the only recommended therapies are dietary modification and weight loss[1,5]. It has been shown that n-3 polyunsaturated fatty acids (PUFA) is effective on NAFLD[6-8]. In this study, we evaluated the efficacy and safety of n-3 PUFA from seal oils in ameliorating serum lipids and liver enzymes in patients with NAFLD associated with hyperlipidemia.

MATERIALS AND METHODS

Patients

One hundred and forty-four patients with NAFLD associated with mixed dyslipidemia were studied as outpatients in the Tonggji Hospital, Tongji University, from September 2006 to June 2008. Written informed consent was obtained from all patients and the study was approved by the Ethics Committee in Tonggji Hospital of Tongji University.

The inclusion criteria were as follows: age between 18 and 65 years, lack of excessive alcohol ingestion confirmed by careful questioning by the primary physician and dietitians (consumption of less than 70 g alcohol in female and 140 g in male per week), elevated serum alanine aminotransferase (ALT) and/or aspartate aminotransferase (AST) above the normal limit, but under 5 times the upper limit of the normal range for $\geqslant$ 6 mo before the study. Diagnosis of dyslipidemia was based on the presence of one or more of the following findings: fasting serum total cholesterol (TCHO) > 5.7 mmol/L, serum triglyceride (TG) > 1.8 mmol/L and high-density lipoprotein cholesterol (HDL-C) < 0.8 mmol/L, fatty liver diagnosed by abdominal ultrasonography, and ability to give informed consent. Exclusion criteria included overuse of alcohol, viral hepatitis, hemochromatosis, Wilson's disease, autoimmune hepatitis, α-1 antitrypsin deficiency, primary sclerosing cholangitis or primary biliary cirrhosis; history of any other hepatic, gastrointestinal, renal, cardiovascular, neurological or hematological disorders, psychiatric disorder which might impair the ability of patients to provide written informed consent; as well as pregnancy, breastfeeding, or lack of effective birth control in women at child-bearing age. In addition, patients were excluded if they were on any medications that could influence liver function during the observation period or involved in any clinical trial before the study.

Study design

All the patients meeting the criteria for enrollment agreed to participate in the study. The patients were randomized into two groups to receive a 24-wk treatment. Group A (n = 72) received recommended diet and 2 g n-3 PUFA from seal oils (Shanghai Hengsheng Biology & Medicine CO. Ltd, Shanghai, China), three times a day. Group B (n = 72) received recommended diet and 2 g placebo (Shanghai Hengsheng Biology & Medicine CO. Ltd, Shanghai, China), three times a day. Recommended diet was composed of 50% carbohydrates, 20% protein and 30% fat in accordance with the American Heart Association diet[9]. All obese and overweight patients were advised to lose their weight with a restriction of daily caloric intake to 25-30 kcal/kg per day[9]. All medications the patients received during the 24-wk treatment period were recorded. At the time of enrolment and when the study was completed, body temperature, body mass index (BMI), blood pressure and heart rate were detected and liver ultrasonography was performed. Laboratory tests included serum ALT, AST, γ-glutamyltranspeptidase (GGT), TG, TCHO, HDL-C, LDL-C, FBS, and complete blood cell counts.

During the 24-wk treatment period, total symptom scores, liver enzymes and fasting lipids were monitored at weeks 8, 12, 16, and 24. Hepatic fat infiltration was detected by upper abdominal ultrasonography at weeks 12 and 24. Symptoms included liver discomfort or pain, weakness, abdominal distention, and nausea. The severity of each clinical symptom was scored using a 4-point scale as follows: 0 score = asymptomatic, 1 score = mild, 2 scores = moderate, 3 scores = severe. All patients were investigated after 12 h fasting and underwent ultrasonography for liver steatosis. Ultrasound scans were performed by a trained operator who was blind to the treatment of participants. The severity of steatosis was also scored using a 4-point scale as follows[10]: grade 0 = normal echogenicity, grade 1 = slight, grade 2 = moderate, grade 3 = severe.

Statistical analysis

The data were presented as mean ± SD and analyzed using SPSS11.5 for Windows (SPSS, Chicago, IL, USA). Statistical analysis for baseline characteristics of the study groups was performed using χ^2 test and t-test. Student's t-test and Wilcoxon signed rank test were used to evaluate the changes in biochemical parameters before and after treatment. $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of the patients

Of the 144 patients enrolled in this study, 134 completed the protocol and were included in the analysis. The baseline clinical and demographic data about the two

Table 1 Baseline characteristics of groups A and B (mean ± SD)

	Group A (n = 66)	Group B (n = 68)	P vaule
Age (yr)	45.00 ± 10.91	44.03 ± 11.30	0.74
Sex ratio (male/female)	47/19	50/18	0.76
Body height (cm)	169.07 ± 7.96	169.71 ± 7.89	0.88

BMI: Body mass index; HR: Heart rate; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; HB: Haematoglobin; RBC: Red blood cells; WBC: White blood cells; BUN: Blood urea nitrogen; FBG: Fasting blood glucose.

groups are shown in Table 1. Patients in the two groups were matched for age, sex, body height and weight, BMI, HR, course of disease, blood pressure, and blood tests including transaminase and lipid concentrations. The ultrasound stages of steatosis were also paired (P = 0.63). No patient was classified as grade 0. In group A, 37% of the patients were classified as grade1, 48% as grade 2, and 15% as grade 3, respectively. In group B, 30% of the patients were classified as grade 1, 56% as grade 2, and 14% as grade 3, respectively.

Findings in the two groups before and after treatment

No significant difference was observed in dietary compliance, BMI, blood pressure, HR, HB, RBC, WBC, platelet, serum BUN and creatinine(Cr) between the two groups. At the end of a 24-wk treatment period, a significant improvement in several liver and lipid parameters was observed between the two groups. In particular, total symptom scores, ALT and TG levels decreased more significantly (P < 0.01) in Group A (total symptom score = 1.87 ± 1.18 to 0.42 ± 0.72, ALT = 62.79 ± 35.92 U/L to 39.27 ± 18.94 U/L, TG= 3.94 ± 2.69 mmol/L to 2.08 ± 1.03 mmol/L) than in Group B (total symptom score = 1.87 ± 1.18 to 0.42 ± 0.72, ALT = 79.76 ± 50.59U/L to 42.32 ± 22.23U/L, TG = 3.80 ± 2.85 mmol/L to 2.33 ± 1.42 mmol/L) (Table 2). As compared to the pretreatment values, total symptom score, ALT and TG levels at weeks 8, 12, and 16 decreased significantly in the two groups after treatment (P < 0.01).

As expected, there was a tendency toward improvement in AST, GGT, TCHO, and HDL levels (P < 0.05) in the two groups after treatment. However, no significant difference was observed in the two groups.

Table 2 Liver enzymes, lipid parameters and ultrasound findings before and after treatment in groups A and B (mean ± SD)

Variables	Group A (n = 66)	Group B (n = 68)
At baseline		
Total symptom scores	1.87 ± 1.18	1.79 ± 1.45

TCHO: Total cholesterol; TG: Triglycerides; HDL-C: High density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol. ^aP < 0.05, ^bP < 0.01 *vs* baseline; ^cP < 0.05, ^dP < 0.01 *vs* group B.

Significant improvements were found in serum LDL-C levels of group A (P < 0.05), but not found in group B after treatment.

Ultrasonography showed a normal liver echopattern at the end of treatment in 19.70% (13/66) of the patients, and an overall reduction in 53.03% (35/66) of the patients in group A. In contrast, only five patients (7.35%, 5/68) achieved complete regression (P = 0.04), whereas 24 patients (35.29%, 24/68) had a certain reduction (P = 0.04) in group B. No change was

observed in the remaining 64.71% of patients.

Gastrointestinal complaints of increased fecal frequency, epigastria, and defecation were occasionally noted in 8 of the 134 patients; but these adverse effects were not significantly different in the two groups. The patients recovered when they completed the treatment. Most of the patients who completed the treatment had no adverse events, indicating that they can tolerate the treatment. No severe adverse event was observed.

DISCUSSION

NAFLD is a chronic disease with multiple consequences. The spectrum of this disease ranges from simple steatosis to NASH, which may lead to liver fibrosis and cirrhosis[11-13]. It has also been well established that NAFLD is intimately related to various clinical and biological markers of the insulin resistance syndrome[14-16]. The pathogenesis of NASH is multifactorial, including insulin resistance, excessive intracellular fatty acids, oxidant stress, mitochondrial dysfunction and innate immunity[17]. However, the pathogenesis of NAFLD/NASH is yet to be clearly elucidated. Since the most prevailing general theory is the "two-hit" hypothesis proposed by Day and James in 1998[16], most treatment modalities should be focused on improving the "two-hit" hypothesis or insulin resistance[18].

Currently, therapeutic options are limited. The present "gold standard" for NAFLD is weight reduction, or more precisely, a reduction in central obesity so as to reverse insulin resistance[19-21]. Standard practice advocates weight loss and exercise. Such "lifestyle adjustment" or anti-obesity measures (including bariatric surgery when required) can improve insulin sensitivity with only a modest weight loss (2-8 kg)[22-24], which is difficult for most patients to achieve.

It was reported that dietary supplementation with fatty acids, such as fish and fish oils, can improve NAFLD associated with hyperlipidemia by modifying the function of platelets and leukocytes[25-26]. Suggested modes of action are through their modulation of eicosanoid synthesis and reduction in plasma TG concentration. The fat composition of seal oils differs significantly from that of fish. In marine mammals, eicosapentaenoic acid (EPA, 20:5 n-3) and docosahexaenoic acid (DHA, 22:6 n-3) are found mainly at the sn-1 and sn-3 positions of TG, whereas in fish, these fatty acids are positioned in sn-2, which may display the better effects on NAFLD associated with hyperlipidemia than fish oils.

Increased fat intake with an excessive amount of n-6 fatty acids can promote NAFLD. However, n-3 PUFA can ameliorate experimental NAFLD[27]. It was reported that n-3 PUFA from different animals is effective against NAFLD[28-30]. In this study, we evaluated the efficacy and safety of n-3 fatty acids from seal oils in 144 patients with NAFLD associated with hyperlipidemia. The results showed that treatment of NAFLD patients with hyperlipidemia with n-3 PUFA from seal oils significantly reduced their total symptom score, ALT and lipid levels, and normalized ultrasonographic evidence compared to treatment with the recommended diet alone.

As expected, there was a tendency toward improvement in AST, GGT, TC, and HDL levels ($P < 0.05$) in the two groups after treatment. However, no significant difference was seen in the two groups. Spadaro *et al*[29] also reported that serum GGT, HDL, ALT, and lipid levels are decreased after treatment. In the present study, the values of LDL were significantly improved in group A ($P < 0.05$), but not in group B at different time points and after a 24-wk treatment period. Ultrasonography showed complete fatty liver regression in 19.70% (13/66) of the patients, and an overall reduction in 53.03% (35/66) of the patients in group A. In contrast, only five patients (7.35%, 5/68) achieved complete regression ($P = 0.04$), whereas 24 patients (35.29%, 24/68) had a certain reduction ($P = 0.04$) in group B. No change was observed in the remaining 64.71% of patients.

Tanaka *et al*[31] reported that treatment with EPA, one of the major components of n-3 PUFA, seems to be safe and efficacious for patients with NASH, largely due to its anti-inflammatory and anti-oxidative properties. On the other hand, n-3 PUFA could reduce VLDL production, resulting in decreased serum triglyceride levels[32-34]. These findings are consistent with our findings, such as improvement in total symptom score, ALT and lipid levels and normalization of ultrasonographic evidence in patients with NAFLD associated with hyperlipidemia. Improvement in serum biochemistry parameters was also observed in group B, indicating that restricted diet and exercise can reverse insulin resistance at a certain extent[35-37]. In the present study, the two drugs (placebo and seal oils) appeared to be safe and effective in patients with NAFLD associated with hyperlipidemia and no severe side effects were observed during treatment.

The gold standard for diagnosis of NAFLD is liver biopsy, but it is not frequently performed in NAFLD patients due to its low acceptance rate[38]. In our study, ultrasonography was performed to detect and monitor changes in the liver since it is sensitive, cheap, invasive and easy to perform. However, lack of histological findings is a major drawback of this investigation.

In conclusion, treatment of NAFLD associated with hyperlipidemia with PUFA from seal oils seems to be safe and efficacious, and can improve the total symptom score, ALT and lipid levels and normalization of ultrasonographic evidence. Further study is needed to confirm these results.

COMMENTS

Background

Recent reports suggest that many cases of cryptogenic liver cirrhosis may be related to unrecognized nonalcoholic steatohepatitis (NASH); however, medical therapy for nonalcoholic fatty liver disease (NAFLD) and NASH has been disappointing to date. The only recommended therapies are dietary modification and weight loss. N-3 polyunsaturated fatty acids (PUFA) seems to be efficacious on treating NAFLD from animal and some small samples human studies.

Research frontiers

The present "gold standard" for treatment of NAFLD is a reduction in central obesity so as to reverse insulin resistance. Several small samples randomized trails have suggested n-3 PUFA from different animals were effective in the treatment of NAFLD; we explored whether seal oil is efficacious and safe in large samples NAFLD patients.

Innovations and breakthroughs

Total symptom scores in NAFLD patients, and large samples were observed besides biochemical indicators and ultrasonography in this study. Seal oils n-3 PUFA can improve liver enzyme, serum lipid levels and normalization of ultrasonographic evidence.

Applications

Seal oils PUFA administration seems to be safe and efficacious for patients with NAFLD associated with hyperlipidemia as well as the "lifestyle adjustment" or anti-obesity measures.

Terminology

NAFLD refers to the presence of hepatic steatosis not associated with a significant intake of ethanol. Insulin resistance is central to the pathogenesis of NAFLD; thus obesity, diabetes, and the metabolic syndrome are frequently associated with the disease.

Peer review

This is an interesting study. Further details need to be given as to the precise ultrasound scoring system that was used to assess the resolution of hepatic steatosis. Was there an objective scoring system used or was this all subjective? The paper is otherwise well written and merits publication.

Abstract

AIM: To determine the influence of excision repair cross complementing group 1 (*ERCC1*) codon 118 polymorphism and mRNA level on the clinical outcome of gastric cancer patients treated with oxaliplatin-based adjuvant chemotherapy.

METHODS: Eighty-nine gastric cancer patients treated with oxalipatin-based adjuvant chemotherapy were included in this study. *ERCC1* codon 118 C/T polymorphism was tested by polymerase chain reaction-ligation detection reaction (PCR-LDR) method in peripheral blood lymphocytes of those patients; and the intratumoral *ERCC1* mRNA expression was measured using reverse transcription PCR in 62 patients whose tumor tissue specimens were available.

RESULTS: No significant relationship was found between *ERCC1* codon 118 polymorphism and *ERCC1* mRNA level. The median relapse-free and overall survival period was 20.1 mo and 28.4 mo, respectively. The relapse-free and overall survivals in patients with low levels of *ERCC1* mRNA were significantly longer than those in patients with high levels ($P < 0.05$), while there was no significant association found between *ERCC1* 118 genotypes and the disease prognosis. Multivariate analysis also showed that *ERCC1* mRNA level was a potential predictor for relapse and survival in gastric cancer patients treated with oxaliplatin-based adjuvant chemotherapy ($P < 0.05$).

CONCLUSION: *ERCC1* codon 118 polymorphism has no significant impact on *ERCC1* mRNA expression, and the intratumoral *ERCC1* mRNA level but not codon 118 polymorphism may be a useful predictive parameter for the relapse and survival of gastric cancer patients receiving oxaliplatin-based adjuvant chemotherapy.

INTRODUCTION

In China, gastric cancer is the leading cause of cancer deaths, accounting for nearly one-fourth of all cancer deaths. Surgery is the primary modality for managing early-stage and locally-advanced disease. However, even after gastrectomy, the majority of patients develop local or distant recurrence[1]. Adjuvant chemotherapy for gastric cancer has been under clinical investigation for more than four decades. Fluoropyrimidines, platinum-drugs and taxanes were shown to be effective in the treatment of gastric cancer. However, the response rates of these drugs or their combinations were less than 50%[2,3]. There is no standard regimen for postoperative treatment at the moment. Having an effective assay to predict the response to a given chemotherapeutic protocol beforehand would greatly enhance the success rate as well as the life quality of the patients.

The nucleotide excision repair (NER) system plays a significant role in repairing a variety of distorting

lesions, including platinum-drug induced DNA adducts. Oxaliplatin is a platinum-based therapeutic agent that has shown anti-tumor activities in gastric cancer. Resistance to oxaliplatin has been attributed to enhanced tolerance and repair of DNA damage through the NER pathway. As an excision nuclease within the NER pathway, excision repair cross complementing group 1 (*ERCC1*) has been reported to play a major role in the response to platinum-based chemotherapy. Studies have shown that the higher the *ERCC1* expression levels, the less sensitive the tumors to platinum therapies[4-7]. Recently, a single nucleotide polymorphism at codon 118 (C→T) was reported to be associated with altered *ERCC1* mRNA levels[8] and clinical outcome in cancer patients treated with platinum-based chemotherapy[9-12]. However, the results about the relationship among *ERCC1* codon 118 polymorphism, *ERCC1* mRNA level and platinum sensitivity are controversial. In this study, we investigated whether the *ERCC1* codon 118 polymorphism could influence *ERCC1* mRNA expression, and whether the polymorphism, and the intratumoral *ERCC1* mRNA expression have the prognostic value for the gastric cancer patients receiving oxaliplatin-based adjuvant treatment.

MATERIALS AND METHODS

Patients

From June 2001 to March 2006, 89 patients with histologically confirmed gastric cancer were enrolled in this study at the 4th Affiliated Hospital of Suzhou University. Inclusion criteria included: (1) patients without early recurrence or incurable resection, (2) patients receiving no other adjuvant treatment, such as radiotherapy or immunotherapy, and (3) patients with their performance status score of 0-1 and a life expectancy over 6 mo. All those patients received radical surgery, and then were treated with at least four cycles of oxaliplatin-based adjuvant treatment, including 70 with 5-FU/leucovorin/oxaliplatin (FOLFOX4: oxaliplatin 85 mg/m^2 and leucovorin 400 mg/m^2 followed on days 1 and 2 by 5-FU 400 mg/m^2 intravenous (IV) bolus, then 600 mg/m^2 IV over 22-h continuous infusion, and repeated every 2 wk), 9 with 5-FU/leucovorin/oxaliplatin/other regimens (taxanes or hydroxycamptothecin) (paclitaxel 135 mg/m^2 or docetaxol 75 mg/m^2 on day 1, hydroxycamptothecin 8 mg/m^2 on days 1-5; and the usage of 5-FU and leucovorin was the same as that in FOLFOX4). If patients had hematologic toxic effects of -grade 3 or grade 4 or nonhematologic toxic effects of grades 2-4, their daily dose was reduced properly.

Blood samples were collected in EDTA-containing tubes from gastric cancer patients before surgery or chemotherapy, and tumor tissue samples were obtained during surgery, and stored in liquid nitrogen until preparation of RNA extracts. Follow-up of those patients was made at 3-mo intervals after chemotherapy at outpatient clinics or by routine phone calls. This study was approved by the ethics and research committee of our hospital.

Genotyping of ERCC1 codon 118 polymorphism

Genomic DNA was isolated from peripheral blood lymphocytes using Axygene genomic DNA purification kit (Axygen Biotechnology, China). The primers and probes are listed in Table 1. Genotyping of *ERCC1* codon 118 was performed using polymerase chain reaction-ligation detection reaction (PCR-LDR) method as described previously[13].

Relative quantitative analysis of ERCC1 mRNA using reverse transcription-polymerase chain reaction (RT-PCR)

Total RNA was extracted from 62 tumor tissues using Trizol (Invitrogen Corporation, CA) according to the manufacturer's instructions. The amount of total RNA was estimated by ultraviolet absorbance at 260 nm, and the quality was determined by agarose gel electrophoresis in the presence of formaldehyde. cDNA strand synthesis was performed using a reverse transcription system (Promega Corporation, US).

ERCC1 and an internal reference gene (β-*actin*) cDNA fragments were amplified separately by PCR in triplicates. The PCRs were carried out in a total volume of 25 μL including 2 μL cDNA, 1× PCR buffer, 1.5 mmol/L $MgCl_2$, 0.2 mmol/L dNTPs, 0.5 μmol/L each primer, 1 U hot-start Taq DNA polymerase (QIAgen). Cycling parameters were as follows: 95℃ for 15 min; 35 cycles of 94℃ for 40 s, 52℃ for 30 s, and 72℃ for 30 s; and a final extension step at 72℃ for 10 min. PCR products were analyzed by 2% agarose gel electrophoresis, and ethidium bromide staining following by visualization with ultraviolet illumination using a gel imaging analyzing system. *ERCC1* amplification products were calculated as a ratio of the gray scale of *ERCC1* to that of β-*actin*.

Statistical analysis

Data analysis was performed using SPSS 13.0 for Windows. *ERCC1* levels were categorized into a low and high value using the median concentration as a cut-off point. The relationship between the genotype frequencies, mRNA, levels and clinical characteristics were assessed by χ^2 or Fisher's exact probability tests. The Mann-Whitney *U* test was used to assess the correlation between *ERCC1* genotypes and mRNA levels. Relapse-free survival (RFS) was defined as the

Table 2 Relationship among *ERCC1* genotypes, mRNA expression and clinical characteristics of gastric cancer

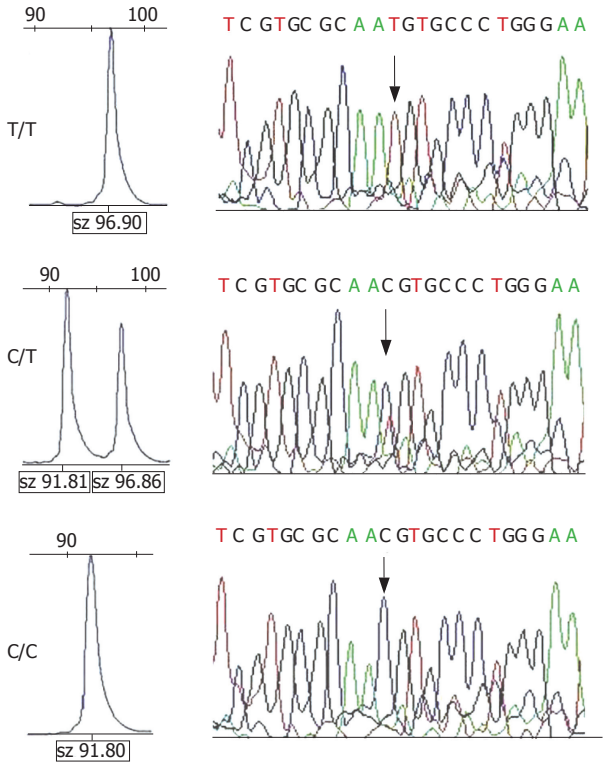

Figure 1 Genotyping results of *ERCC1* codon 118 polymorphism electrophoresis results of PCR-LDR products with different genotypes and its sequencing results. LDR products of *ERCC1* 118 C/C and T/T were 92 and 97 base pairs. The SNP sites are indicated by the arrowhead. The results were completely matched to the corresponding results derived from PCR-LDR.

time interval between the date of surgery and the date of confirmed relapse or the date of last follow-up. Overall survival (OS) was defined as the time between surgery and death. Survival curves were generated by the Kaplan-Meier method, and verified by the log-rank test. Cox proportional hazards regression analysis was used to estimate odds ratios (ORs) and their 95% confidence intervals (CIs), representing the overall relative risk of relapse and death associated with *ERCC1* polymorphism or expression, and to adjust for potential confounding variables. All of the values were two-sided and statistical significance was defined as $P < 0.05$.

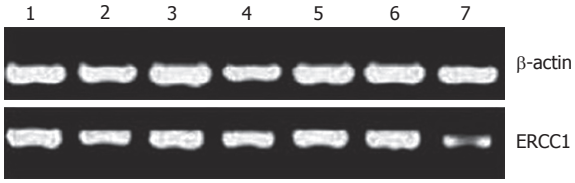

Figure 2 RT-PCR results of *ERCC1* mRNA in gastric cancer tissues.

RESULTS

ERCC1 genotypes and mRNA expression

A total of 89 patients were analyzed. Their demographic and disease characteristics are shown in Table 2. The allelic discrimination data from PCR-LDR assay were confirmed by direct sequencing of representative PCR products (Figure 1). Of the 89 patients, the frequencies of *ERCC1* codon 118 C/C, C/T and T/T were 50.6% (45/89), 42.7% (38/89) and 6.7% (6/89); and the allele frequencies of A and T were 71.9% and 28.1%, respectively. Genotype distribution of *ERCC1* codon 118 was consistent with the Hardy-Weinberg equilibrium among patients ($\chi^2 = 0.288$, $P > 0.05$).

Gastric cancer tissue samples were available in 62 patients. The intratumoral expression of *ERCC1* mRNA in those tissues was tested by semi-quantitative RT-PCR (Figure 2). A marked inter-individual variation in *ERCC1* mRNA expression in the 62 samples was observed: *ERCC1*/β-*actin* ratios ranged from 0.087 to 1.006 with a median value of 0.672. The median value was assigned as the cut-off value to divide those 62 patients into two groups with high or low *ERCC1* mRNA values.

No significant relationship was found between *ERCC1* expression and *ERCC1* codon 118 genotypes (the median *ERCC1* expression was 0.680 for C/C and 0.665 for C/T + T/T; $Z = -0.592$, $P = 0.554$) (Figure 3).

No significant association was found between age, gender, stage or grading and *ERCC1* codon 118 polymorphism or mRNA levels, except that a trend was found between the polymorphism and stage ($P = 0.079$) (Table 2).

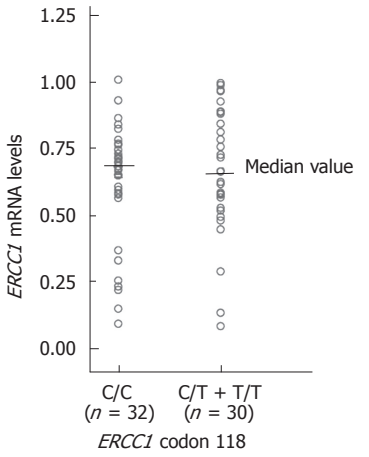

Figure 3 Relationship between *ERCC1* mRNA levels and codon 118 polymorphism.

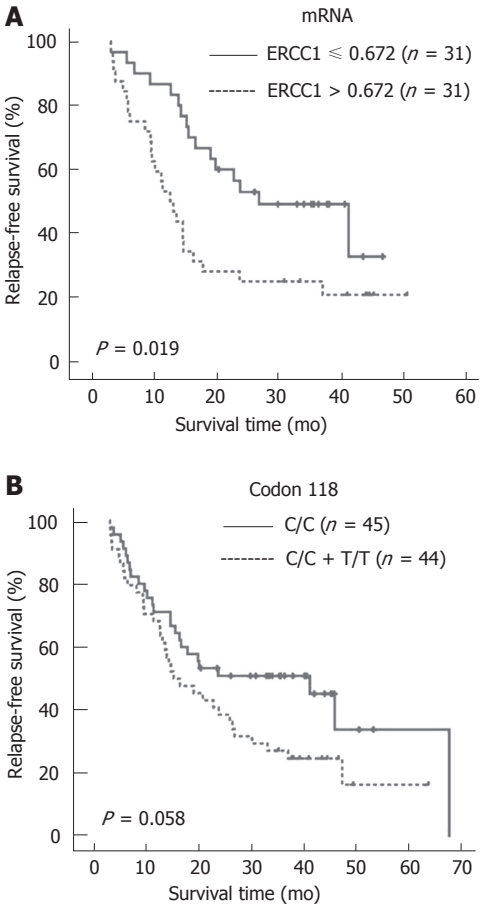

Figure 4 Relapse-free survival curves of gastric cancer patients according to *ERCC1* mRNA expression and *ERCC1* 118 C/T polymorphism relapse-free survival curves according to *ERCC1* mRNA expression (A) or *ERCC1* 118 polymorphism (B). The relapse-free survival in patients with high levels of *ERCC1* mRNA (> 0.672) was significantly poorer than that in patients with low levels (⩽ 0.672) ($P < 0.05$), while there was no significant difference between patients with *ERCC1* 118 C/C and variant genotypes (T/T or C/T).

Associations between ERCC1 polymorphism, mRNA levels and clinical outcome

Patients with the C/C genotype showed a trend towards correlation with prolonged RFS when compared to those with the C/T + T/T genotypes (22.0 mo *vs* 16.5 mo, χ^2 = 3.602, $P = 0.058$, Figure 4A). The median OS was 29.8 (95% CI = 20.9-83.1) mo for the patients with the C/C genotype, and 26.4 (95% CI = 22.1-34.7) mo in those with the C/T or T/T genotype ($\chi^2 = 1.548$, $P = 0.214$) (Figure 5A). The median RFS was 23.8 mo in patients with low *ERCC1* values, but only 13.2 mo in patients with high *ERCC1* levels ($\chi^2 = 5.464$, $P = 0.019$) (Figure 4B). A significant difference in OS also was found between the groups with low *ERCC1* levels and high *ERCC1* levels (29.6 mo *vs* 18.7 mo, $\chi^2 = 4.546$, $P = 0.033$) (Figure 5B).

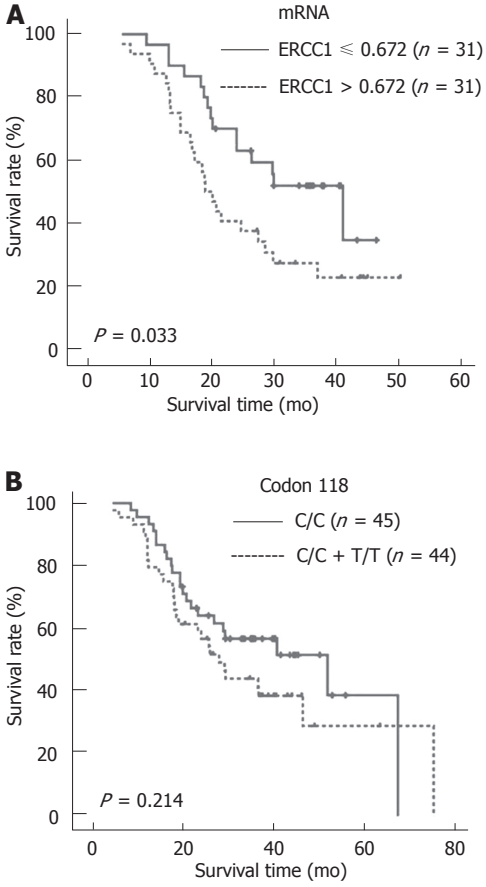

Figure 5 Overall survival curves of gastric cancer patients according to *ERCC1* mRNA expression and *ERCC1* 118 C/T polymorphism survival curves according to *ERCC1* mRNA levels (A) or *ERCC1* 118 polymorphism (B). The overall survival in patients with low level of *ERCC1* mRNA was significantly longer than that in patients with high levels ($P < 0.05$), while there was no significant difference found between patients with *ERCC1* 118 C/C and variant genotypes (T/T or C/T).

Cox multivariate analysis showed that, after adjustment for age, gender, stage and grading, a high *ERCC1* mRNA level appeared to be an independent risk factor for RFS (adjusted OR = 2.493, 95% CI: 1.291-4.814, $P = 0.006$) and OS (adjusted OR = 2.449, 95% CI: 1.264-4.743, $P = 0.008$). No significant association was found between *ERCC1* codon 118 genotypes and RFS (adjusted OR = 1.644, 95% CI = 0.954-2.833, $P = 0.074$) or OS (adjusted OR = 1.310, 95% CI = 0.727-2.358, $P = 0.369$).

DISCUSSION

Optimal chemotherapeutic treatment would allow clinicians to maximize the benefits of cancer

chemotherapy. Successful adjuvant chemotherapy following gastrectomy is crucial for a favorable outcome in gastric cancer. However, few prognostic and predictive markers have been identified to individualize treatment, maximize therapeutic effect. The *ERCC1* expression and codon 118 polymorphism have been reported to influence platinum-based drug sensitivity in advanced or metastatic cancers. The aim of this study was to determine whether *ERCC1* codon 118 polymorphism could influence the intratumoral *ERCC1* mRNA level and predict the clinical outcome of gastric cancer patients treated with oxaliplatin-based adjuvant chemotherapy.

Some studies suggested that impaired DNA repair within the tumor could lead to the decreased removal of platinum-DNA adducts and, therefore, increased clinical response to platinum chemotherapy. *ERCC1* mRNA level has been shown to correlate with nucleotide excision repair capacity. Chinese hamster ovary cells, which do not express a functional ERCC1 protein, are more susceptible to platinum-drugs than the parental cell line with normal ERCC1[4]. So it is naturally expected that the higher the levels of *ERCC1* expression, the less susceptible the tumors to platinum agents. Recently, a synonymous polymorphism at codon 118 converting a common codon usage (AAC) to an infrequent one (AAT), both coding for asparagine, has been associated with reduced mRNA and protein levels[8]. However, the assumed relationship between *ERCC1* codon 118 polymorphism and expression was not always observed[14]. In this study, the *ERCC1* mRNA levels in patients with C/C genotype was higher than that in patients with C/T or T/T genotype; but the difference failed to reach statistical significance ($P > 0.05$), which suggested that the polymorphism may have limited impact on *ERCC1* mRNA levels. In addition, the possibility that *ERCC1* codon 118 polymorphism is in linkage disequilibrium with other *ERCC1* mutations or polymorphisms that directly affect its expression also cannot be ruled out. Other possible reasons may be the relatively small sample size of the present study, and the quantitative method for *ERCC1* mRNA expression used in this study. In the future, using more accurate real-time quantitative RT-PCR assay on the large number of patients may help us to give more persuasive data on the putative association.

Although *ERCC1* codon 118 polymorphism has been extensively studied for its involvement in carcinogenesis[15,16], the predictive value of the polymorphism on platinum chemotherapy has not been studied thoroughly. The functional importance of this polymorphism is still under debate. A limited number of studies suggest that the favorable prognosis seems associated with the T allele[12,17-19]; but controversial results also exist[9-11,20,21]. Viguier *et al*[12] and Martinez-Balibrea *et al*[19] found that colorectal cancer patients with the *ERCC1* 118 T/T genotype were more likely to respond to oxaliplatin-based chemotherapy than carriers of the other genotypes. The favorable effect of T/T genotype also was found in lung cancer[22], pancreatic cancer[23], and ovarian cancer[18] patients treated with platinum-based chemotherapy. However, other studies on lung cancer[10] and colorectal cancer[9,11,20,21] showed opposite results. In addition, several studies demonstrated that no clear association was found between *ERCC1* codon 118 polymorphism and platinum sensitivity[24-26]. In a recent study on advanced gastric cancer treated with fluorouracil/cisplatin palliative chemotherapy, a tendency to higher response rate was found in patients with C allele ($P = 0.09$). In this study, patients with the C/C genotype also showed a trend to prolonged RFS when compared to those with the other genotypes, while no significant relationship was found between *ERCC1* codon 118 genotypes and OS. The small sample size ($n = 89$) of the present study might remain a limitation to clarify the exact role of *ERCC1* codon 118 polymorphism. Other possible reasons for controversial results may include genotyping in normal or tumor tissues, variable doses and schedules of platinum-based therapy, different ethnic populations, variable tumor stage and different kind of cancers.

A limitation of the presented study is that we only analyzed germline genotype. The germline genotypes offer better clinical accessibility and applicability, compared to tumor tissue, which presents difficulties in obtaining and handling samples. To analyze somatic genotype from tumor tissues was not easy. It is difficult to purify malignant cells from miscellaneous normal cells in clinical tumor tissue even using laser microdissection. The classification of a certain gene polymorphism may be hampered in a mixture of normal and malignant cells, which has been clearly illustrated by loss of heterozygosity. The correlation between germline genotype from peripheral blood and tumor tissue should be considered. To the best of our knowledge, there are no related reports on the impact of LOH on *ERCC1* polymorphism in gastric cancer. Hence, the possible influence of LOH on *ERCC1* genotyping should be discussed in the future.

Relative consensus conclusions were obtained regarding the effect of *ERCC1* expression on platinum-drug sensitivity. A multi-centers study on non–small-cell lung cancer found that cisplatin-based adjuvant chemotherapy significantly prolonged survival among patients with ERCC1-negative tumors, but not among patients with ERCC1-positive tumors[5]. In advanced gastric cancer patients treated with 5-FU and oxaliplatin, favorable response rate and survival were also found in patients without ERCC1 protein expression[7]. Other studies showed that the low intratumoral *ERCC1* mRNA expression was associated with favorable clinical outcomes after treatment with platinum-based chemotherapy in lung cancer[27,28], colorectal cancer[29], gastric cancer[30-32], ovarian cancer[33], bladder cancer[34], head and neck cancer[35]. A recent phase Ⅲ trial in non-small-cell lung cancer also demonstrated that assessment of intratumoral *ERCC1* mRNA expression is feasible in the clinical setting and predicts response to cisplatin[36]. However, most of those studies focused on the influence of *ERCC1* expression on the effect of platinum-drug in advanced or metastatic diseases, little was known about its effect on platinum-drug adjuvant chemotherapy. Our

results suggested that low *ERCC1* mRNA level appeared to be an independent prognostic factor for better prognosis, which is consistent with the results observed in advanced gastric cancer[30-32].

In conclusion, *ERCC1* codon 118 polymorphism has no significant effect on *ERCC1* mRNA expression; and the intratumoral *ERCC1* mRNA level, but not *ERCC1* codon 118 polymorphism may be an important prognostic marker for the clinical outcome of gastric cancer patients treated with oxaliplatin-based adjuvant chemotherapy. Detection of the intratumoral *ERCC1* mRNA expression may give meaningful clinical information with respect to the rational choice platinum compound in the treatment of gastric cancer.

COMMENTS

Background

Oxaliplatin is one of the most effective agents against gastric cancer; its efficacy rate differs greatly among patients. Resistance to oxaliplatin has been attributed to enhanced tolerance and repair of DNA damage. Excision repair cross complementing group 1 (ERCC1) has been reported to play a major role in the response to platinum chemotherapy, but little is know about the effect of *ERCC1* codon 118 polymorphism and expression on clinical outcome of oxaliplatin-based adjuvant chemotherapy in gastric cancer.

Research frontiers

ERCC1 has been reported to play a major role in the response to platinum chemotherapy. Studies have shown that the higher the *ERCC1* expression levels, the less sensitive the tumors to platinum therapies. Recently, a single nucleotide polymorphism at codon 118 (C→T) was reported to be associated with altered *ERCC1* mRNA levels and clinical outcome in cancer patients treated with platinum-based chemotherapy. However, the results about the relationship among *ERCC1* codon 118 polymorphism, *ERCC1* mRNA level and platinum sensitivity are controversial.

Innovations and breakthroughs

No significant relationship was found between *ERCC1* codon 118 polymorphism and *ERCC1* mRNA levels. It is found that *ERCC1* mRNA level but not codon 118 polymorphism was a potential indicator in predicting the relapse and survival of gastric cancer patients treated with oxaliplatin-based adjuvant chemotherapy. To our knowledge, it is the first report to study the effect of intratumoral *ERCC1* expression and *ERCC1* codon 118 polymorphism on clinical outcome of oxaliplatin-based adjuvant chemotherapy in Chinese patients with gastric cancer.

Applications

Controlled, prospective clinical trials are required to confirm our results and to establish the advantage of pre-treatment tumor biopsy for *ERCC1* screening, which permits a more rational decision on whether to precede an oxaliplatin-based adjuvant chemotherapy. So patients who are unlikely to respond may spare unnecessary toxicity and can be treated with alternative drugs.

Terminology

Oxaliplatin is a widely applied medicine for chemotherapy of gastrointestinal cancer. ERCC1 is an important enzyme for DNA repair.

Peer review

This is a good study. Over all the study has clinical relevance for LDLT programmes.

INTRODUCTION

Acute acalculous cholecystitis (AAC) is defined as an acute inflammation of the gallbladder in the absence of stones. Traditionally, it was considered a fatal disease almost exclusively of critical ill patients; however, there are recent reports of cases of AAC affecting less severe patients with good prognosis treated with antibiotics, in the absence of cholecystectomy.

We herein report a case of a young man who developed AAC after a *Salmonella enteritidis* gastrointestinal infection.

CASE REPORT

A 27-year-old man was admitted to hospital with abdominal pain, diarrhoea, persistent vomiting and 38℃ temperature. On physical examination, he was febrile, but in a good state of health. His abdomen was mildly tender to palpation with guarding in his lower right area. Laboratory tests disclosed a white cell count of 5300 × 1000/μL with 50% neutrophils and 32% lymphocytes, and haemoglobin and platelets were normal. The biochemical studies including liver and renal tests, electrolyte panel and coagulation profile, were normal. An abdominal X-ray film showed gas in several loops of a moderately dilated small bowel, and an abdominal sonography disclosed marked mucosal thickening in the right quadrant affecting ileon loops, cecum and ascending colon with small lymph node enlargement; the remainder of the abdominal contents, including the gallbladder were normal. Serology for *Salmonella typhi* H and O, Yersinia and Shigella were negative, as were blood cultures. The coproculture obtained on admission was positive for *Salmonella enteritidis*.

The patient was treated with intravenous fluids, analgesics and antipyretics and became afebrile on the second day; in a week time, the abdominal pain subsided and he was able to restart oral diet so he was discharged from hospital.

The following day he returned to the Emergency Department due to epigastric and right hypochondria pain, nausea and fever. He had no diarrhoea. On physical examination, he presented a temperature of 38℃, a tender upper abdomen, and Murphy's sign. The laboratory tests showed mild normocytic-normochromic anaemia with 7900 × 1000/μL white cells. The biochemical tests were normal. A new abdominal sonography disclosed normal intestinal loops, but his gallbladder was distended and presented a markedly thick wall (7 mm) with no stones, and was surrounded by a little fluid collection.

He was then administered intravenous antibiotics

(ciprofloxacine and metronidazole) and showed no signs of fever on the second day. The abdominal pain slowly subsided. Blood, urine and faeces cultures taken on admission showed negative results. He was discharged 10 d later on oral antibiotics and controlled as an outpatient. A new abdominal ultrasound disclosed a normal gallbladder without lithiasis or sludge.

DISCUSSION

AAC accounts for 5%-14% of all cases of acute cholecystitis[1,2]. Patients tend to be predominantly male and older than 50 years of age.

The pathogenesis of AAC is not well defined as the precise mechanism is unknown to date. It seems that several factors such as ischemia, infection and bile changes are involved. Ryu *et al*[1] found that patients with visceral atherosclerosis may be at increased risk for acute acalculous cholecystitis due to an impaired mucosal resistance. Systemic sepsis with release of mediators and bile stasis with alterations in the chemical composition of bile are another implicated potential pathogenic mechanisms involved. Multiple risk factors such as previous surgery and trauma or burn injury have been associated, but none of them were present in our patient.

However, as in our patient, AAC may also occur from secondary infection of the gallbladder following a systemic infection by bacteria[3], virus[4], parasites[5] or fungi.

AAC due to primary bacterial infection is rare. Several cases have been reported complicating *Salmonella typhi* infection[3,6] and after non-typhoidal salmonellosis[7,8] as well.

During the past two decades, an increase in the number of *Salmonella enteritidis* isolates has been observed even in developed countries[9], and there are also rare complications of this common disease described in medical literature[10] Some of these complications are extra-intestinal such as septic arthritis[11] or meningitis[12], but most of them are intra-abdominal[13] due to blood or lymphatic spread of the gbacteria.

Among the latter, AAC is infrequent and can occur even weeks after the diarrhoea has stopped[13] (our patient was discharged from hospital asymptomatic and developed symptoms 24 h later). The diagnosis is based on clinical symptoms, and ultrasound provides the definite diagnosis.

Salmonella enteritidis can be absent in blood cultures and be cultivated in faeces and bile[8,14]. The bacterium, like any other intestinal pathogen, can not only reach the gallbladder through blood drainage but also directly from the bowel along the bile ducts, as could have been the case in our patient.

Most cases described in literature experienced a bad outcome due to gallbladder gangrene, and perforation[2]. Even with early cholecystectomy in good surgical candidates[2], or cholecystostomy or endoscopy nasobiliary drainage in bad ones[15], the outcomes were bad. However, this has changed as the disease is now described in less severely ill patients with no adverse prognosis factors. In this setting, a 4-6 wk course of broad spectrum antibiotics, as indicated in our patient, is recommended. If symptoms cease and a control ultrasound shows a non-dilated gallbladder with a thin wall, cholecystectomy is not needed.

In conclusion, this case shows that AAC, a rare complication of *Salmonella enteritidis*, can also be present in non-critically ill patients. In this setting, the prognosis is better, cholecystectomy is not always needed and patients treated with a long course of wide spectrum antibiotics can obtain a good prognosis.

Abstract

Colonoscopy is a safe and routinely performed diagnostic and therapeutic procedure for different colorectal diseases. Although the most common complications are bleeding and perforation, extracolonic or visceral injuries have also been described. Splenic rupture is a rare complication following colonoscopy, with few cases reported. We report a 60-year-old female who presented to surgical consultation 8 h after a diagnostic colonoscopy. Clinical, laboratory and imaging findings were suggestive for a massive hemoperitoneum. At surgery, an almost complete splenic disruption was evident, and an urgent splenectomy was performed. After an uneventful postoperative period, she was discharged home. Splenic injury following colonoscopy is considered infrequent. Direct trauma and excessive traction of the splenocolic ligament can explain the occurrence of this complication. Many times the diagnosis is delayed because the symptoms are due to colonic insufflation, so the most frequent treatment is an urgent splenectomy. A high index of suspicion needs an early diagnosis and adequate therapy.

INTRODUCTION

Colonoscopy is a safe and routinely performed diagnostic and therapeutic procedure for different large bowel diseases. The most common complications include bleeding (1%) and perforation (0.1%-0.2%), and the chance of complication increases if any therapeutic actions are added, such as polypectomy or dilation[1,2]. Extracolonic or visceral injuries, including pneumothorax, pneumomediastinum, acute appendicitis, retroperitoneal abscess and others, are far less common[3]. Splenic injury is a rare complication of colonoscopy with few cases described; the first one was reported in 1974[4]. Even when some patients with late presentation have been mentioned[5,6], most of them developed symptoms a few hours after colonoscopy, and the majority of them underwent emergency surgery. We report a case of splenic rupture following colonoscopy, treated with urgent splenectomy.

CASE REPORT

A 60-year old female, with no significant medical history, underwent a diagnostic colonoscopy in another center. During the procedure, two rectal polyps (5 mm each) were resected. It was not difficult to reach the ileocecal valve. Endoscopy was performed under intravenous sedation (midazolam, 5 mg iv). She was observed in the recovery room for 2 h and then discharged home. Eight hours later, the patient came to our institution, complaining of diffuse abdominal pain and distension. On examination, she was pale, with a pulse rate of 100 beats per minute and her blood pressure was 103/52 mmHg. She had nonspecific abdominal tenderness, but no peritoneal signs. A colonic perforation after colonoscopy was suspected. The patient was resuscitated with vigorous intravenous fluid administration at the intermediate care unit. Her chest and abdominal X-ray showed no free air (Figure 1). Blood tests showed a hematocrit of 18% (hemoglobin, 6 g/dL). After an adequate haemodynamic stabilization and transfusion of 3 units of packed red cells, an abdominal

Figure 1 Abdominal X-ray showing no free air.

Figure 2 Hemoperitoneum and perisplenic hematoma.

CT scan demonstrated free fluid with a density suggesting blood, and a 12.5 cm × 9.6 cm left subphrenic perisplenic hematoma (Figure 2). No pneumoperitoneum was evident. At laparotomy, about three liters of intraperitoneal blood, and an almost complete splenic disruption were evident, so a splenectomy was performed. There were no perisplenic adhesions. No colon wounds or tears were seen. The postoperative course was uneventful, and she was discharged home on postoperative day 4. Specimen histologic examination revealed nothing but haemorragic parenchyma and inflammatory response, without any underlying splenic disease.

DISCUSSION

Splenic injury following colonoscopy is considered very infrequent. Only 40 cases have been reported[3-15]. To our knowledge, our case is the first case coming from South America. We believe that this is a rare but, most of the times, an under published complication of colonoscopy, so the real incidence might be higher. Although no specific causes have been established, the mechanism of injury may be related to direct trauma or preferently, excessive traction on the splenocolic ligament, which results in evulsion of the splenic capsule and different grades of parenchymal disruption[3,5,7]. A polypectomy or a biopsy was performed in most of reported cases[8]. Splenomegaly, inflammatory bowel disease, pancreatitis and intrabdominal post-surgical adhesions have been mentioned as predisposing factors, due to a suspected decreased mobility between the spleen and colon[8-10]. However, these are not constant findings at surgery[9]. The addition of external abdominal pressure during colonoscopy has also been proposed as a risk factor for the development of this complication[7,8]. Usually, the clinical presentation occurs within the first 24 h after colonoscopy[7,8]; but many times the diagnosis is delayed because the symptoms are attributed to colonic insufflation[3]. Finally, the diagnosis is made in a critically ill patient, with the onset of hypotension and acute anemia. There are also some reported cases with a late presentation (from more than 24 h to 10 d) and mild symptoms[5,6]. CT scan is the imaging modality of choice[11,12], which determines the extent of splenic damage, and demonstration of hemoperitoneum. This information, added to the clinical setting, may help decide on the therapeutic option. In most series, splenectomy is the most frequent treatment of choice[3-9]. Very few cases have been treated with transfusion of hemocomponents, broad spectrum antibiotics and close hemodynamic monitoring[10,13,14]. Another therapeutic action successfully described is splenic artery embolization[15]. The use of this "conservative" treatment must be in direct relation with the hemodynamic status of each case, and in the expertise of a multidisciplinary medical team. In our case, the patient was treated with an urgent splenectomy, and had an uneventful postoperative period.

We believe that this is an unusual and probably under reported complication of colonoscopy. As colonoscopy is performed widely in different centers, the medical team should be aware of the possibility of a splenic injury after colonoscopy and a high level of suspicion needs an early diagnosis and adequate treatment.

Abstract

The prevalence of diverticular diseases of the colon, including severe and persistent bleeding in Eastern countries, has increased in the last decades. The bleeding from colonic diverticula is the most common cause of acute lower gastrointestinal bleeding. Herein, we report four cases of severe and persistent bleeding of colonic diverticular disease that could be treated with a high concentration barium enema. These four cases showed a similar pattern of bleeding whose source could not be identified. Colonoscopy revealed fresh blood in the entire colon and many diverticula were noted throughout the colon. No active bleeding source was identified, but large adherent clots in some diverticula were noted. After endoscopic and angiographic therapies failed, therapeutic barium enema stopped the severe bleeding. These patients remained free of re-bleeding in the follow-up period (range 17-35 mo) after the therapy. We report the four case series of therapeutic barium enema and reviewed the literature pertinent to this procedure.

INTRODUCTION

Diverticular hemorrhage is a common cause of lower gastrointestinal bleeding[1-3]. Most colonic diverticula are asymptomatic and remain uncomplicated. However, it was reported that severe diverticular hemorrhage occurs in 3%-5% of patients with diverticula[4,5]. Most cases of diverticular bleeding resolve themselves. However, massive bleeding of diverticula often requires endoscopic or angiographic therapy. As in some cases, the source of bleeding cannot be identified or multiple sites of bleeding are found, endoscopic or angiographic treatment is not so effective for bleeding. Although surgical treatment has been performed for persistent bleeding, the patients are often elderly and, therefore, at a high risk for surgery.

Most of the reported series of therapeutic barium enema are from Western countries. However, the prevalence of diverticular diseases of the colon, including severe and persistent bleeding in the Eastern countries, has increased in the last decades. We present herein four patients with severe and persist bleeding due to colonic diverticular disease that were treated with high concentration barium enemas, and have reviewed the literature pertinent to this procedure.

CASE SERIES

Case 1

A 63-year-old man was hospitalized for a several-day history of painless passage of bright red blood per rectum. He had hypertension and diabetes mellitus, and had been taking medication for hypertension for ten years. He had no history of receiving non-steroidal anti-inflammatory drugs, low-dose aspirin, and anticoagulants. His past history revealed two bleeding episodes from colonic diverticula that resolved on their own. Physical examination revealed no abdominal tenderness. Laboratory tests showed severe anemia.

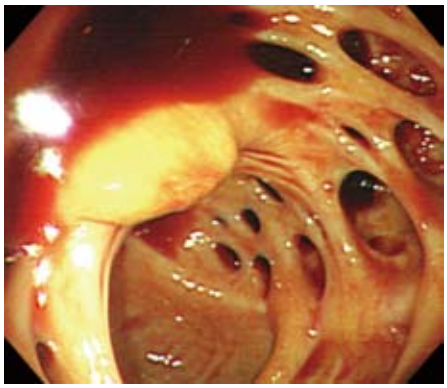

Figure 1 Endoscopic appearance of bleeding diverticula with adherent clots in the ascending colon.

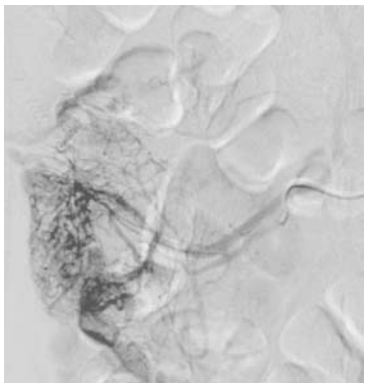

Figure 2 Superior mesenteric arteriogram showing hypervascularity in the ascending colon.

Colonoscopy revealed fresh blood in the entire colon and many diverticula with adherent clots were noted throughout the colon (Figure 1). No active bleeding source was identified; but large adherent clots in some diverticula were noted. Endoscopic placement of metallic clips was done for some diverticula with large adherent clots suspicious of being a bleeding source. On the next day, the patient had severe hematochezia again and required additional transfusion of 4 units of packed red cells. Scintigraphic examination failed to identify the bleeding site. Emergency angiography was performed. Although superior mesenteric arteriography could not reveal any extravasation, hypervascularity was noted on the right side of the colon (Figure 2). Vasopressin infusion was administered; but the patient continued to bleed, and required 4 units of blood. We discussed the situation with the patient and his family, and explained the subsequent treatment modalities, including surgical treatment or optional therapeutic barium enema. After obtaining informed consent, we performed therapeutic barium enema. Barium (concentration: 200%, volume: about 400 mL) including 50 000 units of thrombin was administered per rectum, and the leading edge of the contrast medium was followed up to the ascending colon by fluoroscopy. The enema tip was withdrawn one hour after confirming that the diverticula in the ascending colon were filled with barium (Figure 3). On the next day, we confirmed that multiple diverticula were filled with barium by abdominal X-ray examination. Ten days after the therapy, we also confirmed that the multiple diverticula at the right side of the colon were filled with barium. The patient was discharged without any further bleeding or complications, and surgical treatment was avoided. The patient remained free of re-bleeding more than 3 years after the therapy.

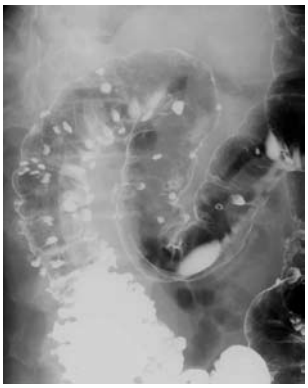

Figure 3 X-ray revealing diverticula in the ascending colon filled with barium.

Case 2

A-67-year old man with diverticula, noted on prior screening colonoscopy, was transferred to our hospital with sudden painless massive rectal bleeding. While in hospital, he developed painless hematochezia and severe anemia requiring transfusion of 2 units of packed red cells. He had hypertension, and had been taking medication for hypertension for five years. He had a history of receiving non-steroidal anti-inflammatory drugs for lumbago. Colonoscopy revealed fresh blood in the entire colon and many diverticula throughout the colon. Endoscopic placement of metallic clips was done for some diverticula suspicious of being a bleeding source. Two days later, the patient had severe hematochezia again and required additional transfusion of 2 units of packed red cells. Emergency angiography could not reveal any extravasation. Therapeutic barium enema was performed and the patient remained free of re-bleeding two years after the therapy.

Case 3

A-76-year old man visited the Emergency Department for a three-day history of diarrhea and painless hematochezia. He had hypertension and had been taking medication for hypertension. Colonoscopy revealed fresh blood throughout the colon and many diverticula in the ascending and sigmoid colon. Endoscopic placement of metallic clips was done for some diverticula suspicious of being a bleeding source. Three days later, the patient began bleeding again, and required transfusion of 2 units of packed red cells. The patient and his family wished to avoid intervention, and agreed to the therapeutic barium enema. Active bleeding was stopped after the therapeutic barium enema. He remained free of re-bleeding 20 mo after the therapy.

Case 4

A-63-year old man was hospitalized for a two-day history

of painless passage of bright red blood per rectum. Colonoscopy revealed fresh blood in the entire colon and many diverticula with adherent clots in the ascending colon. Endoscopic placement of metallic clips was done for some diverticula suspicious of being a bleeding source. During the following hospitalization days, the patient experienced 3 further episodes of bleeding and received 3 units of packed red cells. The patient wished to avoid intervention and agreed to receive therapeutic barium enema. There was no evidence of re-bleeding 17 mo after the therapy.

DISCUSSION

The prevalence of diverticular diseases of the colon in the Eastern countries has increased in the last decades, and the increasing prevalence reflects changes in the life-style and eating habits. A previous study on 6849 patients undergoing barium enema examination during an 8-year period (from 1985 to 1992) revealed an increase in the frequency from 10.7% in 1985 to 17.8% in 1992[6] Another study concluded that diverticular diseases of the right colon have increased steadily in Japan, suggesting that diverticulitis and bleeding may continue to increase[7]. As many reports stated, the prevalence of colonic diverticula and their related severe bleeding have increased recently in the Eastern countries including Japan[6-8].

Colonic diverticula are usually asymptomatic. However, in some cases, acute and chronic inflammation, hemorrhage, and perforation develop as complications of this disease. Bleeding from colonic diverticula is the most common cause of acute lower gastrointestinal bleeding[1-3]. It was reported that acute lower intestinal bleeding occurs in up to 3%-5% of colonic diverticula[4,5]. Most cases of diverticular bleeding resolve themselves and diverticular bleeding stops spontaneously in 70%-80% of cases[9]. However, some patients require evaluation by colonoscopy and angiography, or surgical treatment to stop their bleeding. There are some case reports on various techniques of treatment with colonoscopy for diverticular bleeding including heater probes, epinephrine injection therapy, argon plasma coagulation, and endo-clip application[10-16]. Endoscopic treatment can be useful when a source of lower gastrointestinal bleeding is identified. However, when the source of bleeding cannot be identified or multiple sites of bleeding are found, endoscopic treatment is not effective for stopping bleeding. The specific location of bleeding points is very important for therapeutic colonoscopy of bleeding diverticula. Intermittent diverticular hemorrhage can also lead to incomplete endoscopic therapy.

Angiography is recognized as an accurate diagnostic modality for detecting the site of active gastrointestinal bleeding. Mesenteric angiography is indicated when the flow is estimated to be greater than 0.5-1 mL/min, and offers a potential for selective vasopressin infusion or arterial embolization if the bleeding site is identified[16]. However, angiography frequently fails to reveal the source of gastrointestinal hemorrhage. In addition, in p patients with multiple sites of bleeding or intermittent and quiescent bleeding, it is difficult to treat diverticular hemorrhage by angiographic intervention. Furthermore, angiography is an invasive modality with complications such as arterial dissection and occlusion, bowel infarction, myocardial infarction with vasopressin infusion, and renal failure due to contrast medium[1,17].

In our four cases, colonoscopy demonstrated large amounts of fresh blood throughout the colon and many diverticula with adherent blood clots; but it was difficult to identify the active bleeding site, and the specific bleeding points. Endoscopic and angiographic therapies failed to identify the bleeding points, and could not stop bleeding. As an optional therapy, therapeutic barium enema was performed for severe bleeding to avoid surgical treatment. Table 1 summarizes the four cases of persistent and severe diverticular bleeding in whom the active bleeding sites could not be identified and therapeutic barium enema was effective and no re-bleeding was detected. Each case had one or two persistent bleeding episodes previously and underwent repeated endoscopic treatment. However, these patients remained well and had no re-bleeding after barium enema treatment for 17-35 mo. In all cases, the concentration of barium was 200%, the volume was 400 mL, and the enema tip was withdrawn one hour after the therapy (Table 1). In our four cases, although no severe complications of therapeutic barium enema (such as perforation) occurred, we have to take into account the

possibility of perforation in patients with diverticulitis.

Some case reports and clinical studies of therapeutic barium enema for diverticular hemorrhage have been reported (Table 2)[8,18-20]. A previous case report[8] presented successful treatment with a high concentration of barium with 1 mg of epinephrine. In that case, epinephrine was added to the solution for vasoconstriction; but the possible adverse effects of epinephrine such as sudden hypertension were not ruled out. Another case report[18] presented successful treatment with a 20% barium sulphate solution at a height of 0.9 m for 5 min. In 1970, Adams *et al*[19] demonstrated that 26 of 28 acute bleeding episodes were arrested by therapeutic barium enema with a 20% concentration of barium. That study also stated that the only single complication was laceration of the rectal mucosa by the enema tube[19]. A previous clinical study[20] evaluated the efficacy of barium enema therapy for severe diverticular bleeding and concluded that therapeutic barium enema is the treatment of choice for the first bleeding episode, while surgical resection should be performed if re-bleeding occurs. In that report, the failure rate of conservative treatment and therapeutic barium enema with consequent re-bleeding was 43.4% and 15.9%, respectively[20]. Furthermore, an investigation suggested that complications develop more often in patients after colonic resection than in those after barium enema therapy, and that the mortality after surgery is significantly higher than that following therapeutic barium enema[20].

Most of the reported cases of therapeutic barium enema were from the Western countries. However, the prevalence of diverticular diseases of the colon in the Eastern countries including Japan has increased recently. From our present experiences, therapeutic barium enema is also effective for right side diverticula which are typically located in the Eastern countries.

It is difficult to clarify the mechanism underlying the effect of therapeutic barium enema. Adams *et al*[19] mentioned two potential factors, namely the pressure by the barium solution producing tamponade of the bleeding vessel, and the direct hemostatic action by the barium sulfate. The effect of barium on bleeding in the gastrointestinal tract is also described in a previous report[21]. That report mentioned that tap-water enema is better, as it contains no anticoagulants, and is more effective in producing clot formation than most barium suspensions.

A clinical study on surgery for complicated colonic diverticula concluded that in patients with multiple bleeding sites or severe ongoing hemorrhage from a source that cannot be localized despite endoscopic and angiographic assessment, subtotal or total colectomy may be imperative[22]. However, in view of the mortality of surgical therapy, optional and non-invasive therapies such as therapeutic barium enema are needed in the cases that require colonic resection.

In conclusion, the prevalence of diverticular diseases of the colon has increased in the last decades not only in the Western countries, but also in the Eastern countries. Barium enema therapy is effective for diverticular hemorrhage when the active bleeding site could not be identified by colonoscopy. When no other therapeutic techniques are available, barium enema therapy may be useful as an optional therapy which may avoid surgical therapy. As far as we know, there are few reports on randomized trials of treatment of colonic diverticular bleeding. Because of the limited number of clinical case series, further randomized controlled trials of treatment are required to clarify the role of therapeutic barium enema in bleeding diverticula.

Abstract

Polysplenia syndrome, defined as the presence of multiple spleens of almost equal volume, is a rare condition involving congenital anomalies in multiple organ systems. We report this anomaly in a 41-year-old female who underwent a left lateral sectionectomy due to recurrent cholangitis and impacted left lateral duct stones. Polysplenia syndrome with preduodenal vein was diagnosed preoperatively by computed tomography (CT) and surgery was done safely. Although the polysplenia syndrome with preduodenal portal vein (PDPV) in adult is rarely encountered, surgeons need to understand the course of the portal vein and exercise caution in approaching the biliary tract.

INTRODUCTION

Polysplenia syndrome is a rare disease that occurs in patients with two or more spleens of identical sizes and various organ anomalies[1]. Reports indicate that most patients with polysplenia syndrome die before 5 years of age because the disease is often associated with congenital anomalies, such as cardiovascular anomalies[2]. Severe cardiovascular anomalies include interruption of the suprarenal inferior vena cava, atrioventricular septal defects, ipsilateral pulmonary venous drainage, ventricular outflow tract obstruction, dextrocardia and abnormal great vessel relationships[3]. Some patients with polysplenia syndrome have a normal heart or only minor cardiac defects, are often diagnosed incidentally in patients being treated for other disease[4]. However, they may harbor anomalies in abdominal organs or the gastrointestinal tract, one example of which is a preduodenal portal vein (PDPV)[5]. A PDPV can be diagnosed early as duodenal obstruction in infants, but is often found incidentally or during surgery when there are no symptoms[6].

One of the ways to prevent injuries to the hepatic portal system during surgery is to diagnosis polyspenia syndrome accompanied by a PDPV prior to surgery. We treated a patient with polysplenia syndrome, which was diagnosed during a left lateral sectionectomy to treat intrahepatic duct stones, and we report our findings along with related studies.

CASE REPORT

A 41-year-old female presented for evaluation of right upper quadrant pain of 1 mo duration. At a local hospital, she was noted to have polysplenia and left lateral intrahepatic duct stones without intrahepatic duct dilatation of segment 4. She was referred to our institution for further evaluation and treatment. The physical examination revealed no abnormalities. An abdominal computed tomography (CT) showed intrahepatic duct stones with polysplenia and the portal vein was located anteriorly to the duodenum (Figure 1). Laboratory findings revealed

Figure 1 Abdominal computed tomography scan. Polysplenia (asterisks) are present in the left upper quadrant and it shows the left lateral intrahepatic duct stones with atrophy (arrow).

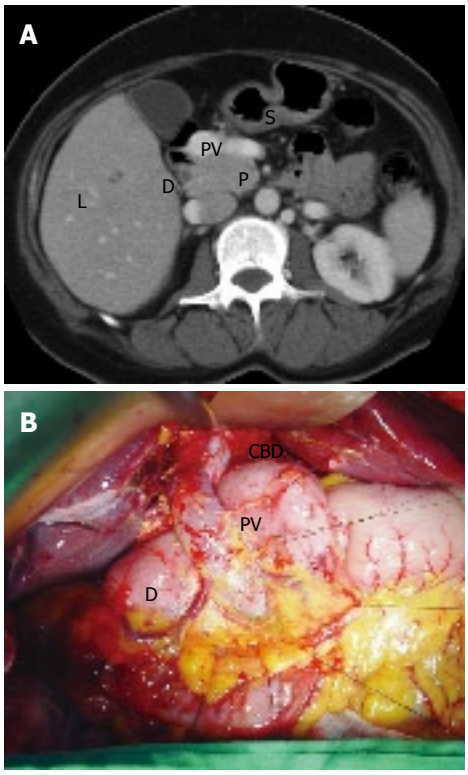

Figure 2 The location and presentation in surgery of the portal vein. A: The portal vein (PV) was located ventrally to the duodenum (D) and pancreas (P), liver (L) and stomach (S) are in the normal position; B: At surgery, the portal vein (PV) was seen running anteriorly across the duodenal first portion (D), the common bile duct (C) was identified left to the portal vein.

elevated levels of aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase and lactate dehydrogenase. Echocardiography and chest radiography were normal. The diagnosis of intraheptic duct stones with polyspenia syndrome was established.

The surgical procedure for intrahepatic duct stones began with a thorough exploration of the abdomen. The portal vein was detected in front of the first part of the duodenum. The portal vein passed upward, right to the common bile duct, and bifurcated into the left and right portal branches in the porta hepatis (Figure 2). Both the common bile duct and the right hepatic artery were identified to the left of the portal vein. The left hepatic artery originated from the left gastric artery. The presence of two spleens was confirmed on the left side of the upper abdomen, along with the greater curvature of the stomach. A nasogastric tube passed through duodenum without any difficulty. We could not locate the stenotic duodenal region posterior to the portal vein. The shape of the liver and pancreas were normal; the small bowel and colon were normally positioned.

Figure 3 T-tube cholangiography shows variations of right intrahepatic bile duct.

A left lateral sectionectomy with a cholecystectomy was performed safely. An intraoperative choledochoscopy through the segment 3 bile duct was done for removal of the right intrahepatic duct stone, and we confirmed no residual stones existed in the bile duct based on T-tube cholangiography (Figure 3). The postoperative course was uneventful, and the patient was discharged 12 d postoperatively.

DISCUSSION

As the name of the condition implies, polysplenia syndrome refers to patients with two or more spleens. Studies also include descriptions of cases that involve a number of very small spleens, a multilobular spleen with tiny accessory spleen, and an undivided spleen[2,7].

The spleen develops during the 5th embryonic week from the splenic primordia, originating from the dorsal mesogastrium. The initial splenic primordia are then created as incisures on the left side of the dorsal mesogastrium. When the incisures fail to fuse, they create two or more spleens[8]. The blood flow of an embryo makes a transition from symmetric to asymmetric around the 25th d to determine the visceral sidedness, and it has been suggested that this is when cono-truncal anomalies and anomalies of atrioventricular canal occur[9]. At the same time, PDPV also develop. Venous blood is drained from the primitive gut, consisting of two vitelline veins of the yolk sac. The veins implement communication in the liver (cranial communication), behind (middle communication) and in front of (caudal communication) the duodenum. When the caudal and cranial communications are lost during the 9-mm embryo stage, the S-shape portal vein is created. It is believed that the PDPV anomaly is developed during this stage if cranial

and middle communications are lost[10].

Although the exact cause of polysplenia is unknown, studies have suggested that it is caused by various factors including embryogenic, genetic, and teratogenic components[11]. Since splenic anomalies (splenic agenesis, hypogenesis and polysplenia) are often accompanied by anomalies in the cardiovascular tract and other abdominal organs, it can be inferred that the spleen plays a significant role during the early embryonic stage[12].

Reports indicate that polysplenia syndrome occurs in both genders with an identical frequency[5]. Known cardiovascular anomalies include absence or hypoplasia of the suprarenal inferior vena cava (with or without azygos or hemiazygos continuation), levoisomerism of the right bronchial tree, dextrocardia, ventricular septal defects, and the absence of the coronary sinuses, most patients die before 5 years of age due to the accompanying cardiovascular anomalies. Patients without cardiac anomalies may reach adulthood, accounting for 10%-15% of cases of polysplenia. Since most adult patients do not exhibit any symptoms, polysplenia syndrome is often diagnosed incidentally during other procedures[5]. Even adult patients can have anomalies in abdominal organs including visceral heterotaxia with a right-sided stomach, a left-sided or large midline liver, right-sided spleen, malrotation of the intestine, a short pancreas, and anomalies of the inferior vena cava. Cases with only PDPV, as with our patient, are recognized as very minor anomalous cases. Even though intestinal obstruction is often displayed in such cases, there were no anomalies of the digestion system for our patient. First described by Knight HO in 1921, PDPV is a congenital anomaly that involves the portal vein passing in front of the duodenum[13]. A PDPV can be associated with duodenal atresia, stenosis, web, annular pancreas and malrotation, and surgery may be required for treatment[14]. However, since the portal vein is a thin-walled, low-pressure vessel, it is highly unlikely that PDPV alone can cause duodenal obstruction. Patients can survive to reach adulthood without any symptoms, and the anomaly is often found during examinations or surgeries to treat other diseases.

Polysplenia syndrome can be detected relatively easily with diagnostic imaging including abdominal CT and magnetic resonance imaging (MRI)[15]. In our case, polysplenia syndrome was diagnosed incidentally while examining the patient who was complaining of pain in the right upper abdomen and fever. Known causes of atrophy of the lateral segment of the liver in PDPV include selective portal vein obstruction, biliary duct obstruction, partial obstruction of the portal vein associated with distention of the hepatic bile duct, long-standing malnutrition and cachexia, or toxic and vascular influences[14]. However, in the case of our patient, it is likely that the atrophy was caused by intrahepatic duct stones. Reports indicate that most cases of PDPV in adults involve surgery for cholelithiasis, making us believe that PDPV could be a cause for cholelithiasis[14]. When surgery is required, care must be exercised, especially for procedures involving the upper abdomen. If PDPV is not detected prior to surgery, it can cause severe complications, such as hemorrhage and vascular ligation. Such accidents can be prevented by performing careful diagnostic imaging in advance, such as CT, and especially noting the possibility of PDPV in cases of polysplenia syndrome.

Abstract

Splenic tumors are rare. Differentiation of the tumors before operation is of great value regarding the outcome. A case of a 32-year-old man with a splenic inflammatory pseudotumor (IPT) mimicking splenic angiosarcoma is described. The tumor was highly suspected of being splenic angiosarcoma based on radiological findings preoperatively. However, after splenectomy, histopathological examinations revealed splenic IPT. Splenic IPT and angiosarcoma are rare and often pose diagnostic difficulties because the clinical and radiological findings are obscure. Due to large differences in prognosis, we briefly reviewed the clinical, radiological, and pathological features of both of the tumors.

INTRODUCTION

Although splenic tumors are rare, differentiation of the tumors before operation is of great value. Among them, splenic inflammatory pseudotumor (IPT) is a benign tumor characterized microscopically by a proliferation of inflammatory cells[1]; but splenic angiosarcoma is a dismal malignancy of vascular origin[2]. We usually differentiate them before operation by imaging studies. In this report, we present a case of splenic IPT mimicking angiosarcoma on radiological findings.

CASE REPORT

A 32-year-old man was a carrier of hepatitis B virus for years with regular follow-up at outpatient clinics. A splenic mass was incidentally detected by sonography. Physical examinations were unremarkable. The patient had no systemic complaints except mild vague discomfort over the epigastric region. Biochemical and hematological investigations were all within normal ranges except for slightly elevated serum glutamate-oxaloacetate transaminase (SGOT). Tumor markers including CEA, AFP, CA-199, and CA-125 were all negative. Sonography of the spleen showed a well-defined encapsulated tumor, 6.3 × 6.1 cm in diameter, with hyperechoic density in the central portion (Figure 1). Non-contrast and contrast abdominal computed tomography (CT) showed a mass over the spleen with high density in the central portion and multiple diffuse low-attenuation nodules in liver parenchyma (Figure 2A and B). Magnetic resonance imaging (MRI) was done for differentiation and revealed a mass lesion around 6 cm in the spleen, which showed partially dense intensity in T2-weighted image (Figure 3A) and peripheral nodule enhancement with gadolinium-contrast filling and pooling in T1 contrast-enhancement dynamic study (Figure 3B-D).

Overall, there were two parts of different signal

Figure 1 Sonography showed a well-defined encapsulated tumor, 6.3 cm x 6.1 cm in size, over the spleen with hyperechoic density in the central portion (arrow) of the tumor.

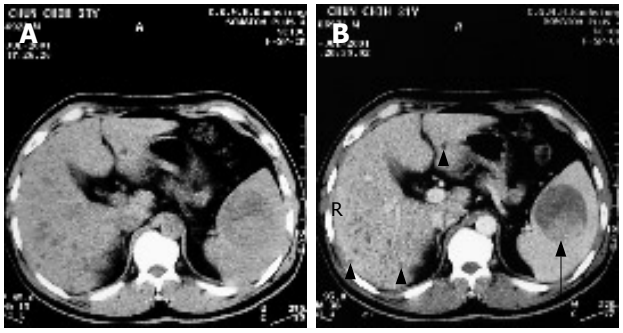

Figure 2 Abdominal CT. A: Non-contrast CT showed a well-defined tumor over the spleen; B:Contrast CT showed partial enhancement of the tumor with high density in the dorsal portion of the tumor (arrow) and multiple diffuse low-attenuation nodules in liver parenchyma (arrowhead).

intensity comprising the tumor at the spleen. The major part of the circumscribed lesion showed persistent low-signal intensity with some stippling enhancement from MRI dynamic contrast-enhanced series, while the minor portion located at the dorsal aspect showed similar signal-intensity change as the normal spleen parenchyma either at pre- or post-contrast phases, which is suggestive of hypervascular lesion, such as angiosarcoma.

Diffuse multiple tiny cystic lesions were noted in bilateral lobes of the liver. Biliary hamartoma was first considered. However, differential diagnosis should have included multiple hepatic cysts, micro-abscesses or even metastases. Therefore, primary splenic angiosarcoma with the possibility of multiple liver metastasis was the first consideration.

Surgical intervention was indicated, and exploratory laparotomy was performed thereafter. During the operation, the spleen was removed smoothly and liver hypertrophy with multiple tiny cystic lesions over the liver surface was noted. There was no evidence of malignancy in the frozen sections examined.

The specimen of spleen measured 11 × 8.5 × 6 cm in size and weighed 240 g (Figure 4A). Grossly, there was a well-circumscribed tumor inside the spleen, measuring 5.5 × 5.0 × 4.0 cm in size (Figure 4B). There were two parts of different appearances comprising the tumor. The major part of the circumscribed lesion showed yellowish appearance with some stippling red spots scattered over the cut surface, while the minor portion located at the dorsal aspect showed similar appearance as the normal spleen parenchyma.

Microscopically, the sections of the specimen were

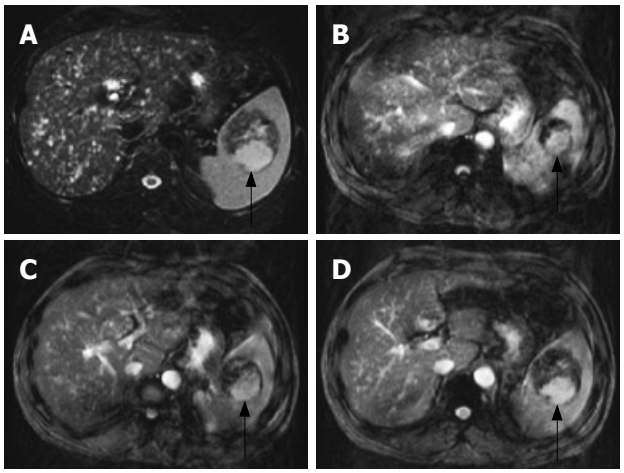

Figure 3 MRI. A: In T2-weighted image, a well-circumscribed tumor (arrow) in the spleen, which showed partially dense intensity; B-D: In T1 contrast-enhancement dynamic study, peripheral nodule enhancement with gadolinium-contrast filling and pooling were noted in the tumor.

composed of fibrosis, focal sclerosis, plump spindle cells and vascular proliferation (Figure 5). An admixture of inflammatory cells included lymphocytes, plasma cells and neutrophils, in which lymphocytes were predominant. The major part of the tumor consisted of more fibrosis and focally sclerotic change, while the minor part consisted of more vascular proliferation and more inflammatory cell infiltration. The sections of the specimen were compatible with the picture of IPT.

The patient's postoperative course was uneventful, and he has been well for 3 years following surgery.

DISCUSSION

The term "inflammatory pseudotumor" was first proposed in 1954, since these lesions are composed of inflammatory cells. Inflammatory pseudotumors have been reported in several anatomic locations, such as orbit, respiratory tract, gastrointestinal tract, and liver[3]. However, splenic involvement is extremely rare. The first 2 cases of splenic inflammatory pseudotumor were reported in 1984. About one-half of the lesions are discovered incidentally during work-up for other malignancies after splenectomy for other conditions such as idiopathic thrombocytopenic purpura, or at autopsy[4]. Clinical symptoms are not specific to the disease, with left upper quadrant or epigastric pain. Splenomegaly is usually present. Laboratory investigations may reveal fever, anemia, hypergammaglobulinemia, thrombocytosis, or hypersplenism; however, more than one-third of the cases reported showed no evidence of any abnormality in laboratory investigations[1]. Other patients have signs of immune thrombocytopenic purpura[4]. However, our patient only had history of hepatitis B with mild vague abdominal discomfort.

There are several radiological modalities suggested for diagnosing splenic IPT, including ultrasonography, CT, and MRI. Ultrasonography usually shows a low echoic mass in most cases[5]. CT is the radiological

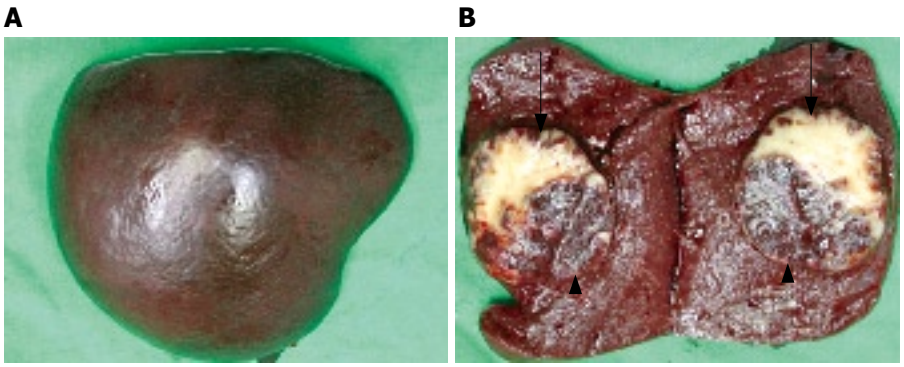

Figure 4 The specimen of spleen. The removed spleen (A) was 11 cm x 8.5 cm x 6 cm in size. A well-circumscribed tumor (B), measuring 5.5 cm x 5 cm x 4 cm, over the central portion of the spleen was noted. There were two parts of different appearances comprising the tumor. The major part of the circumscribed lesion (arrow) showed yellowish appearance with some stippling red spots scattered over the cut surface. While the minor portion (arrowhead) located at dorsal aspect showed similar appearance as the normal spleen parenchyma.

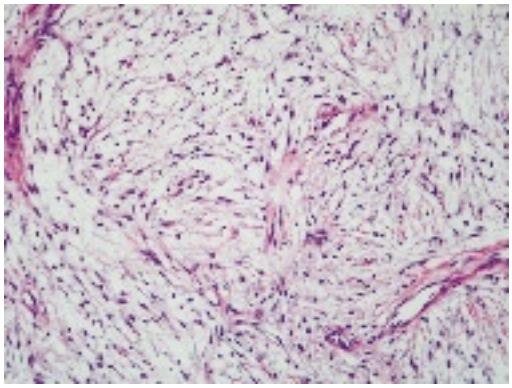

Figure 5 Histologic findings (hematoxylin and eosin stain, original magnification x 200). The sections of the specimen are composed of fibrosis, focal sclerosis, plump spindle cells and vascular proliferation.

test that most often demonstrates the presence of a splenic lesion and usually demonstrates a low-density mass in both the non-enhanced and enhanced modes. Although CT is quite sensitive, this modality is not specific in differentiating between splenic IPT and other malignancies[3]. MRI findings usually show an iso- or low-intensity mass on the T1-weighted images and a low-intensity mass on the T2-weighted images, while also demonstrating a low-intensity in the early phase and a high-intensity mass in the delayed phase of a dynamic study. However, the same criticism can be said about MRI with T1- and T2-weighted imaging for the poor specificity in differentiating pseudotumors from other malignancies[3].

Gross features in all reported cases of splenic IPT are described as a solitary well-circumscribed lesion with a white or tan cut surface that compresses the adjacent splenic parenchyma. Histological examinations of specimens are composed of acute and chronic inflammatory cells infiltrating a stroma of mesenchymal myofibroblastic spindle cells. The inflammatory cells are predominantly plasma cells, mature lymphocytes, and rarely eosinophils.

Etiology and pathogenesis of IPT remain unknown. Some characteristics described support an immunologic disorder[4]. Pathologic features of pseudotumor may be related to the production of mediators in inflammation, and note that interleukin-1 can produce local lesions and systemic manifestations with IPT. In addition, granulomatous inflammation process, focal parenchymal necrosis with hemorrhage, disturbance of blood supply or bacterial or viral infection have all been speculated in the pathogenesis of splenic IPT[6].

If a primary splenic tumor is suspected, splenectomy is required for diagnostic purposes and for therapy. Laparoscopic surgery for benign splenic tumors is considered to be a valid procedure. However, if the splenic lesions have a malignant potential, laparoscopic surgery elevates the risk of either intra-abdominal dissemination or skin metastasis. Therefore, if malignant splenic tumor can not be ruled out, laparoscopic surgery is not suggested[7].

Angiosarcoma is a malignancy of vascular origin, and is characterized by masses of endothelial cells with cellular atypia and anaplasia[2]. Angiosarcoma may occur anywhere in the body, but most often in the skin, soft tissues, breast and liver. Splenic involvement is exceedingly rare. Clinical manifestations include abdominal discomforts, splenomegaly and signs of immune thrombocytopenic purpura[2], which were not specific to the disease. Pathogenesis remains obscure. Prognosis is extremely poor, with a 6-month survival rate of 20%[8]. The tumor commonly metastasizes to the liver, lung, bone, lymph nodes, omentum, or peritoneum.

There are also several radiological modalities suggested for diagnosing splenic angiosarcoma including sonography, CT, MRI and angiography. Unlike splenic pseudotumor, sonographic findings in splenic angiosarcoma show a heterogeneous mass or multiple reflective areas[8,9]. CT may demonstrate hypoattenuating lesions on nonenhanced scans. Areas of high attenuation on noncontrast CT may represent acute hemorrhage or hemosiderin deposits. Contrast enhancement of angiosarcoma may show some enhancements similar to that of hepatic hemangioma[2]. The MRI appearance of splenic hemangioma is similar to that of hemangioma of the liver. The lesion will be hypo- or isointense on T1-weighted MR images and hypertense on T2-weighted MR images. T1-weighted images obtained after contrast administration may demonstrate a difference between the cystic and solid components[2]. The most specific modality to differentiate splenic IPT from angiosarcoma is angiography. Angiographic findings of angiosarcoma show a hypervascular tumor with contrast pooling, and that of splenic IPT usually show avascular or hypovascular tumor[10].

In the present case, sonography showed hyperechoic density in the central portion of the tumor. CT also

showed a high density area and partial enhancement in the central portion of splenic tumor with multiple diffuse low-attenuation nodules in liver. MRI revealed a mass, which showed partial dense intensity in T2-weighted image. In T1 mode with gadolinium-enhancement, peripheral nodule with contrast filling and pooling, which was compatible with a picture of angiosarcoma, was noted. Therefore, the first impression of angiosarcoma with suspected liver metastasis was reasonable preoperatively. The reason why splenic IPT could mimic the picture of angiosarcoma could be explained by the hypervascular component within the minor part of the tumor, which absorbed the contrast medium in radiological examination. Accordingly, the ITP should be kept in mind in the differential diagnosis of splenic space-occupying lesions even if the imaging modality does not favor it.

Abstract

We report a rare case of acute pulmonary and cerebral complication after transarterial chemoembolization (TACE) for inoperable hepatocellular carcinoma. The case involved a large tumor and hepatic vein invasion. Nonspecific pulmonary and cerebral symptoms such as acute dyspnoea and transient consciousness loss developed in the patient, a 49-year-old woman, following the TACE due to pulmonary and cerebral oil embolism. The chest and brain conditions of this patient improved after some supportive therapies and nursing interventions. She also subsequently completed the other three procedures of TACE.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the leading causes of cancer-related death in China where the majority of HCC patients have underlying hepatic B virus (HBV) infection and cirrhosis, and most cases are unresectable due to late stage and multifocali. Transarterial chemoembolization (TACE) is one of the most common treatment modalities as a palliative and preoperative method for patients with advanced HCC, which can improve the resection rate of HCC and prolong the survival time of patients. HCC has a tendency to invade the portal and hepatic veins, which may result in formation of hepatic arterio-venous shunts. Some rare complications such as remote ectopic embolism can be caused by this kind of abnormal shunts. In this paper, we report a rare pulmonary and cerebral complication of HCC, which is probably associated with hepatic vein invasion.

CASE REPORT

A 49-year-old woman was admitted to the Department of Radiology of the Second Affiliated Hospital of Zhejiang University in October 2004 with right upper quadrant pain and weight loss. She was a hepatitis B virus carrier. Her α-fetoprotein level was 1185.3 ng/mL. Ultrasonography and computed tomography (CT) revealed a 10-cm mass in the posterior segments of the right liver lobe. A 1.5-cm mass was also found in the left lateral segment. These clinical signs indicated that the patient had inoperable HCC and Child-Pugh class A cirrhosis. TACE was offered to the patient. Angiogram demonstrated no obvious hepatic arterio-venous shunt, but multiple smaller masses in both lobes of the liver. An emulsion of oxaliplatin, pirarubicin, hydroxycamptothecin and lipiodol were prepared, 35 mL and 3 mL of the mixture were administered intra-arterially to the right and left hepatic artery, respectively. The patient experienced right upper quadrant pain after TACE and had an uneventful recovery. One month later, a second TACE procedure was performed *via* the right hepatic artery and 40 mL of the mixture was administered. On the next day, she experienced sudden acute dyspnoea and the peripheral oxygen saturation decreased to 90%. The chest X-ray showed some

Figure 1 Chest CT scan revealing multiple iodized oil-like high-density materials in parenchyma of the lung.

Figure 2 Non-contrast enhanced CT scanning showing multiple disseminated hyper-intense lesions in the brain, consistent with deposition of iodized oil.

increased reticular shadows in the left lung, especially in the lower zones, and a chest CT scan revealed multiple iodized oil-like high-density materials in parenchyma of the lung (Figure 1). After 10 mg dexamethasone i.v. and other supportive therapies were administered, the respiratory symptom was attenuated. Two days later, the patient suffered from a serious headache and transient consciousness loss, accompanying nausea and vomiting followed by confusion, lower extremity weakness. Non-contrast enhanced CT scanning showed multiple disseminated hyper-intense lesions in the brain, consistent with deposition of iodized oil (Figure 2). One week later, her respiratory and neurologic symptoms disappeared completely, and she was discharged. The patient also consequently completed the other three TACE procedures, during which no similar symptoms occurred.

DISCUSSION

TACE has various severe complications, including acute hepatic failure, intrahepatic biloma, pseudoaneurysm formation, and ectopic infarction, which occur in less than 1% of patients. Pulmonary embolism is a rare complication of TACE. Xia *et al*[1] reported a total of 2012 TACE procedures in 1348 patients, but pulmonary embolism occurred only in case. Sporadic cases of cerebral embolism after TACE have also been reported[2-5]. No reports are available on pulmonary embolism accompanying cerebral embolism after TACE. We encountered a rare pulmonary and cerebral complication of HCC, which was probably associated with hepatic vein invasion. The patient had nonspecific respiratory and neurological symptoms, including cough, dyspnoea, headache, transient loss of consciousness, confusion, and weak extremities. Chest X-ray and CT scanning showed some positive findings, indicating deposition of iodized oil, and the diagnosis of pulmonary and cerebral embolism was confirmed clinically.

The underlying mechanisms of pulmonary and cerebral embolism after TACE are still obscure. Hepatic arterio-venous shunt, which is associated with hepatic vein invasion of HCC, may be the reasonable explanation for pulmonary embolism. Vascular abnormalities, referred to as pulmonary arterio-venous shunt, can be found in patients with advanced liver disease[6]. If patients have pulmonary embolism after TACE, the oil emboli may also pass through the pulmonary arterio-venous shunt and enter the systemic circulation. In this case, the patient suffered from pulmonary and cerebral embolism subsequently. Thus, we hypothesize that iodized oil passed through the hepatic arterio-venous shunt, and then traveled to the cerebral artery through intrapulmonary arterio-venous shunt There are also some other hypotheses including intracardiac right-to-left shunt (e.g. patent foramen ovale) and right-to-left shunt *via* the arteriovenous anastomosis between the right inferior phrenic artery (IPA) and the intrapulmonary vasculature. However, there is no evidence to support the theory of intracardiac or IPA shunts in this patient.

Although pulmonary and cerebral embolism or infarctions are rare complications of TACE in patients with HCC, we should be aware of this kind of situations when we observe complications of TACE. When angiogram shows any hepatic arterio-venous shunts, we should decrease the dose of lipiodol during the procedure and pay great attentions to the respiratory and neurological symptoms post-operatively, which may be caused by ectopic embolism. The manifestations caused by lipiodol are different from those caused by thrombus, because lipiodol diffuses to peripheral blood vessels while thrombus usually obstructs the main branch of arteries.

A thorough patient assessment should be performed by nurses before the procedure. Some risk factors including a large size of HCC, hepatic vein invasion of HCC, live cirrhosis, congenital cardiovascular disease, and chronic pulmonary disease should be noticed before the procedure. If the patients have risk factors for pulmonary and cerebral complications of TACE, nurses should give a reassessment, extra education, psychological support.

In addition to post-embolization syndrome (PES), with its symptoms manifested as fever, pain, nausea, and vomiting, there are also some severe or rare complications of TACE, including acute hepatic failure,

intrahepatic biloma, pseudoaneurysm formation, ectopic infarction, *etc*. Nurses should keep in mind that a small number of patients after TACE will suffer from some severe or rare complications. Our patient developed a dry cough and dyspnea in the first day after TACE, followed by severe headache, nausea, vomiting, weak extremities and lost consciousness transiently in the third day. Nurses immediately provided nursing interventions such as semi-reclining position, inhaling oxygen, administration of steroids and dehydrating agents, and intensive monitoring of the patient's vital signs. She had a good recovery and was discharged. If some symptoms such as cough, chest pain, chest distress, headache, nausea, and vomiting occur in patients after TACE, nurses should make physical examination and notify the physician to exclude pulmonary and cerebral complications.

When the diagnosis of pulmonary embolism is confirmed, some nursing actions must be taken immediately. Nurses should keep the patient's airway open, and have oxygen inhaled to maintain the patient's basic respiratory function. Vital signs, blood oxygen saturation, mental status, and some laboratory values must be monitored and documented. If the patient has signs of respiratory failure, intensive care and mechanical ventilation must be provided promptly. Tiny lipiodol particles usually diffuse and stay in the peripheral bronchus and alveoli, which can damage gas exchange and cause special inflammations. Steroids, bronchodiators and prophylactic antibiotics should also be given.

The aim of nursing care during an acute phase of cerebral embolism after TACE is to minimize cerebral damage. Nurses should frequently observe the level of consciousness, pupil size and reaction to light, patient's response to commands, movement and strength, patient's vital signs, *etc*. To reduce the intracranial pressure, some nursing routines must be given such as keeping the head of bed above 30º, restriction of fluids, oxygen inhaling and administration of steroids and dehydrating agents. Sedatives and tranquilizers, which can depress the respiratory center and obscure neurological observations, should not be given except for some specific situations such as epileptic seizure attack.

In summary, even though pulmonary embolism and cerebral embolism are rare complications of TACE, we should be aware of these rare complications in patients with high risk factors and reduce the dose of iodized oil or stop the procedure.

Abstract

We report port site and distant metastases of unsuspected gallbladder cancer after laparoscopic cholecystectomy diagnosed by positron emission tomography (PET) in two patients. Patient 1, a 72-year-old woman was diagnosed as cholelithiasis and cholecystitis and received laparoscopic cholecystectomy. Unsuspected gallbladder cancer was discovered with histological result of well-differentiated squamous cell carcinoma of the gallbladder infiltrating the entire wall. A PET scan using F-18-fluorodeoxyglucose (FDG-PET) before radical resection revealed residual tumor in the gallbladder fossa and recurrence at port site and metastases in bilateral hilar lymph nodes. Patient 2, a 69-year-old woman underwent laparoscopic cholecystectomy more than one year ago with pathologically confirmed unsuspected adenosquamous carcinoma of stage pT1b. At 7-mo follow-up after surgery, the patient presented with nodules in the periumbilical incision. Excisional biopsy of the nodule revealed adenosquamous carcinoma. The patient was examined by FDG-PET, demonstrating increased FDG uptake in the right lobe of the liver and mediastinal lymph nodes consistent with metastatic disease. This report is followed by a discussion about the utility of FDG-PET in the gallbladder cancer.

INTRODUCTION

The vast majority of cholecystectomies are currently performed laparoscopically, and unsuspected gallbladder cancer can be discovered incidentally following 1% of routine cholecystectomies[1]. There is a suspicion that recurrence of the tumor in the abdominal incision is more common after laparoscopic operations. Several possible factors probably involved in the development of such metastases have been proposed[2,3]. Resection of the recurrent malignancy developed in the port sites is warranted, and may lead to survival benefit only when the port site metastases is the only manifestation of recurrent disease. The preoperative accurate evaluation of recurrent gallbladder cancer is essential for reasonable treatment. We report two cases of port site and distant metastases of unsuspected gallbladder cancer after laparoscopic cholecystectomy diagnosed by FDG-PET.

CASE REPORT

Patient 1

A 72-year-old woman presented with right upper quadrant pain and fever. She had a history of cholelithiasis documented by ultrasound, and intermittent attacks of biliary colic over 2 years. She was diagnosed with cholelithiasis and cholecystitis. She received laparoscopic

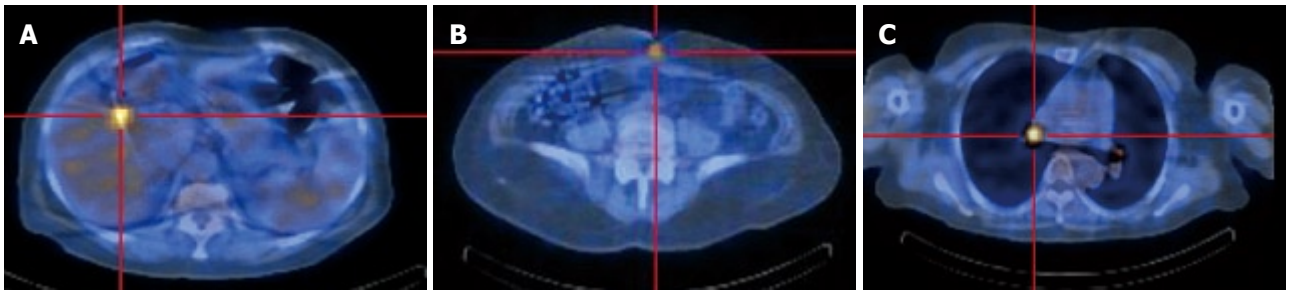

Figure 1 Increased uptake of the radiopharmaceutical in patient 1 (FDG-PET). A:Gallbladder fossa; B: Periumbilical area; C: Bilateral hilar lymph nodes.

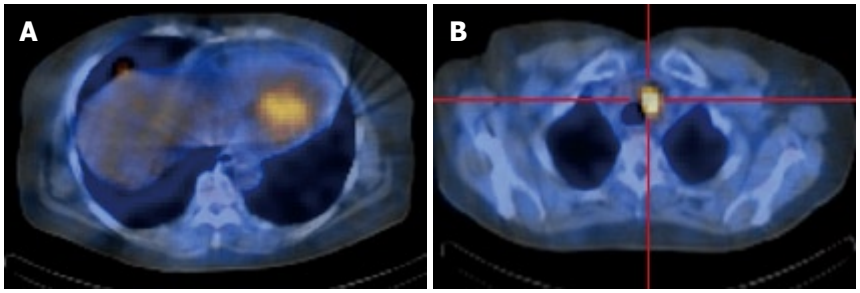

Figure 2 Increased uptake of the radiopharmaceutical in patient 2 (FDG-PET). A:Right lobe of the liver; B: Mediastinal lymph nodes.

cholecystectomy and the gallbladder was noted to be edematous and thick-walled, with multiple stones. Histological evaluation revealed an unsuspected well differentiated squamous cell carcinoma of the gallbladder infiltrating the entire wall. More than one month after surgery, she visited our hospital for further radical surgery. Palpable nodules in the periumbilical incision were found by physical examination during admission. A FDG-PET scan was performed, demonstrating increased uptake of the radiopharmaceutical in the gallbladder fossa and periumbilical area as well as bilateral hilar lymph nodes (Figure 1). The lesions were interpreted as residual tumor in the gallbladder fossa and recurrence at port site and metastases in bilateral hilar lymph nodes. Tru-cut biopsy confirmed metastatic squamous cell carcinoma similar to the previous histology. The patient refused further treatment and was discharged.

Patient 2

A 69-year-old woman with a history of intermittent right upper quadrant pain over 11 years underwent laparoscopic cholecystectomy more than 1 year ago. The histological examination revealed an unsuspected adenosquamous carcinoma of stage pT1b (tumor invades into muscularis). At 7-mo follow-up after surgery, the patient presented with nodules in the periumbilical incision interpreted as inflammation or postoperative change. The nodule enlarged progressively, and she visited our hospital 19 mo after surgery. Abdominal CT scan revealed a small nodule in the right lobe of the liver, which was difficult to interpret. Excisional biopsy of the nodule in the periumbilical incision was performed and histological examination revealed adenosquamous carcinoma. The patient was examined by FDG-PET, demonstrating increased FDG uptake in the right lobe of the liver and mediastinal lymph nodes consistent with metastatic disease (Figure 2). Chest computed tomography demonstrated enlarged mediastinal lymph nodes consistent with metastases. The patient has subsequently been treated with Gemzar and oxaliplatin with regression of tumor. She died of a non-cancer related cause 4 mo after the second operation.

DISSCUSSION

PET is a noninvasive scanning method to assess metabolism *in vivo* by means of positron-emitting radiolabeled tracers. This is in contrast with conventional imaging modalities, including ultrasonography (US), computed tomography (CT) and magnetic resonance imaging (MRI) which evaluate structural or anatomical changes[3]. The tracer to measure cellular metabolism commonly used in PET is FDG. FDG is a glucose analogue that is phosphorylated in the cells, but not further metabolized. Most malignant tumors show increased uptake of FDG because malignant transformation and growth of tumor cells is associated with overexpression of glucose transporters and increased hexokinase activity[4].

FDG-PET imaging has been increasingly used to identify and stage various tumors. The majority of these studies show FDG-PET to be superior to traditional imaging in the differential diagnosis of malignancy. This has been particularly notable in the evaluation of recurrent or metastatic disease[5-7]. A few studies have evaluated the use of FDG-PET in the assessment of biliary system tumors or gallbladder carcinoma[4,8-10]. In the study of Anderson *et al*, nine of 14 gallbladder cancer patients had residual carcinoma at the time of PET[9]. FDG-PET was useful in our cases to delineate recurrent gallbladder cancer, and its extent and had an important clinical impact on the selection of proper treatment. In both cases, FDG-PET detected residual tumor or port site and distant metastatic diseases and

changed the surgical plan of radical resection with intent for cure. This report emphasizes that FDG-PET may play an important role in the posttherapy follow-up of gallbladder cancer. Taking the accumulation of FDG in the malignant gallbladder cancer cells into consideration, FDG-PET can be considered as a complementary preoperative staging method. In cases in which it is easy to understaging gallbladder cancer before surgery such as peritoneal seeding, small hepatic metastases, and small regional lymph nodes involvement, FDG-PET may be able to provide important diagnostic information to obtain a correct presurgical staging, and sometimes lead to the change of treatment.

Gallbladder cancer is a relatively rare disease that has no specific symptoms or signs, and the clinical presentations of gallbladder cancer, and gallstone disease are commonly difficult to distinguish. The only effective treatment for carcinoma of the gallbladder is operative resection, and an open technique is preferred. Unfortunately, as is often the case, the lack of presurgical differential diagnosis hampers the planning of surgery. Recently, a few published articles have studied the utility of FDG-PET in gallbladder cancer focusing on not only posttherapy follow-up and preoperative staging, but also the establishment of the benign or malignant natures of gallbladder lesions. Koh *et al*[10] reported that FDG- PET provided reliable differential diagnoses, identifying gallbladder carcinoma with 75% sensitivity, 87.5% specificity, and 81.3% accuracy. Anderson *et al*[9] report that the sensitivity of this modality was 78% in their series of 14 gallbladder cancer cases. In the study of Antonio *et al*, which comprises a series of 16 patients, FDG-PET showed a sensitivity of 0.80, a specificity of 0.82 in diagnosing gallbladder cancer[4]. These studies revealed that FDG-PET can provide important information for establishing the nature of gallbladder lesions especially when in conjunction with conventional modalities.

Because FDG is taken up not only by malignant tumor cells, but also by activated inflammatory cells, benign inflammatory or infectious lesions typically without obvious increase of FDG uptake under some circumstances can produce false positive results[11,12]. The most common reason for false positive FDG-PETs is an inflammatory lesion. Xanthogranulomatous cholecystitis and polypoid lesion with adenomyomatosis are also the common reasons caused false positive result[4,10,11]. PET imaging must be interpreted with caution in patients with known severe inflammatory or granulomatous disease. Nishiyama *et al*[12] illustrated the relationship between the severity of inflammation and the specificity of PET, and proposed that patients with signs of acute inflammation should be excluded from examination. If the PET scans are performed under conditions with no or low-grade inflammation, an accurate diagnosis of acute or chronic cholecystitis as a benign lesion may be possible.

Although PET was sensitive for the detection of gallbladder cancer, some false negative findings also occurred. The limited sensitivity of FDG-PET for small lesions may have several causes[10,12]. Some factors illustrate the intrinsic limitations of PET resolution for small lesions: activity in small lesions may be underestimated because of the partial-volume effect, movement artifacts caused by nongated breath holding, or physiologic liver FDG uptake. PET scanning performed under suboptimal conditions can also decrease the sensitivity: patient fasting may be too short, and lead to an unnecessarily high liver FDG uptake; the duration of FDG administration and data acquisition may be too short. In diabetic patients, the rate of FDG accumulation in the tumor is decreased, impaired the sensitivity of FDG-PET[10]. In patients with mucinous adenocarcinoma of the gallbladder, a false-negative result has also been reported, probably secondary to poor cellular density[4]. To increase the sensitivity for small lesions, the underestimation due to the partial-volume effect may be reduced by improving the spatial resolution of PET; movement artifacts may be reduced by breath gating of the measurement, and by avoiding reintroduction of the patient to the scanner; PET scanning can be well performed under optimal conditions. Nishiyama *et al* adopted dual-time-point FDG-PET to evaluate the nature of gallbladder lesions, and demonstrated that delayed FDG-PET was more helpful than early FDG-PET in the evaluation of malignancy, because of the increased uptake by lesions, and the increased lesion-to-background contrast[12]. Recent hybrid PET-CT systems provide structural and functional information simultaneously, and may offer early and accurate staging with an improved specificity[13,14].

In conclusion, despite the relatively small number of gallbladder cancer patients, received FDG-PET scan, this imaging may play an important role in the differential diagnosis, staging, restaging, and posttherapy follow-up of gallbladder cancer.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

WJG publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidermiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialities, and thus eventually improving the clinical practice and healthcare for patients.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Hepatocellular carcinoma (HCC) commonly occurs in hepatitis B endemic areas, especially in Asian countries. HCC is highly refractory to cytotoxic chemotherapy. This resistance is partly related to its tumor biology, pharmacokinetic properties, and both intrinsic and acquired drug resistance. There is no convincing evidence thus far that systemic chemotherapy improves overall survival in advanced HCC patients. Other systemic approaches, such as hormonal therapy and immunotherapy, have also disappointing results. Recently, encouraging results have been shown in using sorafenib in the treatment of advanced HCC patients. In this review, we concisely summarize the evolution of developments in the systemic therapy of advanced HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth ranking cancer in the world, with more than 80% of cases occurring in Asia[1]. The most common causes of HCC are hepatitis B and C viral infections. Chronic hepatitis B viral infection is prevalent in Asian countries and accounts for most cases of HCC. In contrast, chronic hepatitis C viral infection is more common in Western countries. In recent years, there is an increasing incidence of HCC in Western countries, primarily due to increase in prevalence of hepatitis C viral infection.

Current effective treatments for HCC include liver resection, transplantation, various local ablative and trans-arterial therapies. Surgical resection and liver transplantation are the main curative treatments. Unfortunately, only around 20% patients, mostly diagnosed by regular screening, may benefit from these surgical therapies. Most other patients either present late with advanced tumor or have severe underlying cirrhosis, precluding any surgical or even loco-regional therapies. Previously, these patients can only be palliated by chemotherapy or best supportive treatment alone.

CHEMOTHERAPY TREATMENT OF HCC

HCC is a relatively chemo-resistant tumor and is highly refractory to cytotoxic chemotherapy. This resistance is partly related to its tumor biology, pharmacokinetic properties, and both intrinsic and acquired drug resistance.

In terms of HCC tumor biology, the liver is a defensive organ that responds to the damages in a unique manner. Non-hepatic epithelial cells progress through the cell cycle until they either die or arrest/repair; whereas growth-arrested (i.e. G0) hepatocytes proliferate in response to damage[2,3]. In fact, HCC cells show a higher apoptotic capacity in earlier stages of carcinogenesis. Nonetheless, in advanced stages, they gradually develop the resistance to apoptosis. This anti-apoptotic phenotype is associated with the development and progression of HCC[4]. More importantly, it also partly explains why HCC cells are resistant to cytotoxic chemotherapy. Moreover, p53 mutation is the most commonly encountered alternations in HCC. Both hepatitis viruses and chemicals are implicated in the etiology of p53 mutations during the molecular

Table 1 Pivotal chemotherapy trials in advanced HCC

pathogenesis of HCC[5]. As chemotherapeutic agents require p53 to induce apoptosis, tumors with a disruption in p53 pathway are thus resistant to chemotherapy. Furthermore, DNA topoisomerase Ⅱ alpha is over-expressed and up-regulated in HCC cell lines. Since doxorubicin targets DNA topoisomerase Ⅱ, over-expression of the protein in HCC may account for HCC resistance to doxorubicin-based therapy[6]. Regarding its pharmacokinetic properties, the liver plays a pivotal role in the metabolism of both endogenous and exogenous substances inside the body *via* the CYP450 enzyme system[7]. In cirrhotic patients, the total liver mass is reduced, and distortion of the liver architecture leads to significant intra-hepatic shunting and reduced extraction of protein-bound substances. Moreover, cirrhosis also affects the absorption, plasma protein binding, distribution and renal excretion of drugs. Therefore, cirrhosis has a significant impact on the pharmacokinetics of systemic therapy for HCC. Lastly, HCC cells have intrinsic drug resistance mediated by an enhanced cellular drug efflux mechanism, which is usually enacted through the drug transporter family of the ATP-binding cassette proteins that include MDR1, p-glycoprotein and the multidrug resistance protein[8,9]. Moreover, co-expression of p53 and p-glycoprotein also contribute to HCC drug resistance[9].

There is no convincing evidence, thus far, that systemic chemotherapy improves overall survival in advanced HCC patients[10]. Table 1 summarizes the results of pivotal chemotherapy studies of HCC. Single-agent doxorubicin has been shown to produce a response rate of about 10%-15%, but with no proven survival benefit[11]. It has been widely used and regarded as the standard systemic treatment for advanced HCC until recently. Significant grade 3 or 4 toxicities, especially neutropenia, are encountered in patients treated with doxorubicin[12]. Other chemotherapeutic agents, such as epirubicin, cisplatin, 5-fluorouracil, etoposide, and their combinations, have been studied with low response rates and no survival benefit[13]. Similarly, the newer generation of chemotherapeutic agents, such as gemcitabine, irinotecan and pegylated liposomal doxorubicin, also show disappointing results[14,15]. Combination chemotherapy has been employed in the treatment of advanced HCC. Although some of the combination regimes have shown promising activity in phase Ⅱ studies, most of them fail to demonstrate any survival advantage in randomized phase Ⅲ studies[16,17]. Especially, the combination of cisplatin, interferon-alpha-2b, doxorubicin and fluorouracil (PIAF) was under intense investigation at one time. In the phase Ⅱ study, Leung *et al*[18] showed on average 26% partial response, with 4 patients achieving a complete pathological response. Nevertheless, in the phase Ⅲ study, although this combination had achieved higher response rates than other combinations, there was no demonstrable survival benefit and there were considerable toxicities[19]. Recently, a phase Ⅱ study using a combination of gemcitabine and oxaliplatin demonstrated an 18% response rate and 76% of patients had the disease under control[20]. Similarly, another phase Ⅱ study showed a 6% response rate and a 72% disease control rate by employing a 3-wk cycle of capecitabine and oxaliplatin in the treatment of advanced HCC patients[21]. However, as with the results from the PIAF study, these 'promising' data need to be further validated in the ongoing randomized phase Ⅲ trials before they can be employed in routine clinical practice.

HORMONAL THERAPY

Estrogen receptor, progesterone receptor and androgen receptor are expressed in HCC[22,23]. Thus, hormonal agents were used to treat advanced HCC. Among various hormonal agents used for the treatment of advanced HCC patients, tamoxifen was frequently employed in the past, due to its good tolerability and oral administration. However, several prospective randomized controlled trials failed to demonstrate overall survival benefit in treating advanced HCC patients with tamoxifen[24-26]. Moreover, a recent meta-analysis conducted by Nowak *et al*[27] also showed no survival advantage.

IMMUNOTHERAPY OF HCC

Interferon is frequently employed in the treatment of viral hepatitis. However, its role in the treatment of HCC remains controversial. Studies conducted by Lai

et al[28,29] had shown encouraging efficacy with a 30% response rate and overall survival benefit from using a high dose of interferon (2.5×10^7-5.0×10^8 IU/m^2, three times weekly) to treat advanced HCC patients. However, there were significant treatment-related toxicities in patients who received high-dose interferon. On the other hand, when a lower dosage (3×10^6 IU/m^2, three times weekly) of interferon was used instead, there was no demonstrable clinical benefit[30].

SOMATOSTATIN ANALOG TREATMENT

The somatostatin analog octreotide and the long-acting form lanreotide are used in treating HCC, due to the presence of somatostatin receptors in HCC cells[31]. A randomized study, conducted by Kouroumalis *et al*[32], showed survival benefits in employing subcutaneous octreotide in the treatment of advanced HCC patients. Nevertheless, the study conducted by Becker *et al*[33] and Yuen *et al*[34] did not show any survival benefit in using lanreotide in the treatment of advanced HCC patients'.

THALIDOMIDE

Thalidomide was originally introduced in the 1960s as a sedative[35]. It was later re-evaluated for its anti-neoplastic effect in the 1990s. Its mechanism of action is poorly understood and complex, including anti-angiogenesis *via* the inhibition of VEGF, tumor necrosis factor-alpha and modulation of other inflammatory cytokines[36]. It was used in treating advanced HCC patients, mainly due to its anti-angiogenic property. However, single-agent thalidomide[37,38] and its combinations with epirubicin or interferon[39,40] only produced a response rate of 3.1%-6.3% with a median survival of 2.7-6.8 mo. In view of its limited activity and frequent association with treatment-related toxicities, it is now seldom included in the treatment algorithm for advanced HCC patients.

SORAFENIB FOR ADVANCED HCC

Growth factors and related receptors are often overexpressed and/or dysregulated in HCC. Clinical trials indicate that growth factor receptors and their related signalling pathways play important roles in HCC cancer etiology and progression, thus providing rational targets for innovative cancer therapies[41]. Among various growth factor pathways, the activation of the Raf/mitogen-activated protein kinase-extracellular signal-regulated kinase (MAPK) pathway[42,43] plays a pivotal role in promoting the tumor growth. Sorafenib is an oral multi-kinase inhibitor that blocks tumor proliferation by targeting the Raf/MAPK/ERK signaling pathway; it also has anti-angiogenic properties attained by targeting the tyrosine kinase VEGR-2, VEGFR-3 and PDGF receptor β[44]. Recently a large randomized phase Ⅲ study, the SHARP trial[45], was conducted and in this study, 602 patients with biopsy-proven advanced HCC were randomized to receive either sorafenib (400 mg twice daily, $n = 299$) or a placebo ($n = 303$). The results demonstrated a significant improvement in both OS (median 10.7 mo *versus* 7.9 mo) and TTP (median 5.5 mo *versus* 2.8 mo) in the sorafenib group *versus* the placebo group. These results represented a 44% increase in OS (hazards ratio, 0.69; $P = 0.00058$) and 73% prolongation in the TTP (hazards ratio, 0.58; $P = 0.000007$). Sorafenib was generally well-tolerated and serious adverse events only occurred in 13% of patients. This trial represents the first randomized systemic therapy trial that demonstrates the overall survival benefit of systemic treatment in patients with advanced HCC thus far. Similar to the study design of SHARP study, an Oriental sorafenib study was conducted to investigate the efficacy and tolerability of using single agent sorafenib in treating advanced HCC patients in hepatitis-B endemic Asian population[46]. In this study, the median OS of patient on sorafenib was 6.2 mo which was significantly better than 4.1 mo achieved in patients on placebo ($P = 0.0155$). Again, sorafenib was well-tolerated in Asian patient population. However, the commonest toxicities encountered in Asian patient population were hand-foot skin reactions (10.1%) instead of diarrhea (39%) in the SHARP trial.

CONCLUSION

The management of patients with advanced HCC has been a disappointing issue for decades. The recent development of single agent sorafenib, in the treatment of advanced HCC patients, indeed represents an important advance in this challenging disease. Although these two pivotal studies have demonstrated good activity and tolerability in treating advanced HCC patients with sorafenib, there are still many unresolved issues regarding the optimal use of sorafenib. In particular, most patients enrolled in these two pivotal trials had Child-Pugh A cirrhosis with favorable clinical parameters. Therefore, the benefits and safety profile of sorafenib in unselected advanced HCC patients, especially those with Child-Pugh B/C patients or other poor prognostic factors, are still unknown. Moreover, there are currently no reliable clinical parameters or biomarkers which may predict the response to sorafenib. In view of the high cost of sorafenib and potential toxicities associated with sorafenib, reliable biomarkers that can potentially guide the use of sorafenib in the treatment of advanced HCC patients is desperately needed.

Moreover, in the era of targeted therapy, proper patient selection, treatment assessment and endpoints are vital to the success of the clinical trials. This is especially true in HCC, where radiological assessment is difficult, because of poor delineation of the tumor in the liver. Recently, the HCC expert panel meeting recommended adopting a modification of RECIST criteria to assess tumor response[47]. Also, the time to progression was recommended by the panel as the primary endpoint in phase two trials testing targeted therapy in HCC.

The modest improvement, as demonstrated in these two pivotal trials; is still not optimal, as most patients

still have relatively short survival times when compared to patients with other solid tumors, such as colorectal cancer. Therefore, there is a need for researchers to unravel more of the underlying hepato-carcinogenesis mechanism and key molecular targets for therapeutic intervention. Moreover, another future focus will be on how to best combine the other targeting agents or chemotherapeutic agents in order to incrementally improve the survival of advanced HCC patients.

Abstract

An inflammatory process that involves the sigmoid colonic segment associated with diverticular disease (SCAD) appears to be a distinct clinical and pathological disorder. It has been described in older adults, often presenting with rectal bleeding. Most of the patients seem to respond to treatment only with a 5-aminosalicylate, but some spontaneously resolve with no treatment. Endoscopic evaluation usually shows a non-specific inflammatory process localized in the sigmoid colon alone that may resolve completely with histologically normal colonic mucosa. Repeated symptomatic events with discrete episodes of segmental colitis may occur, but most patients have an entirely benign clinical course. Definition of the underlying molecular events that occur with SCAD may be critically important in understanding the critical elements present in a colonic inflammatory process that can completely resolve without pharmacological or biological treatment.

INTRODUCTION

Segmental colonic involvement with a well circumscribed inflammatory process may occur in different forms of infectious colitis or inflammatory bowel disease. In infectious disease, multiple different sites within the colon are likely to be involved, sometimes with small bowel changes. In ulcerative colitis, the rectum or rectosigmoid segment is generally involved with disease extending in a continuous pattern proximally within the colon for a variable distance. During colonoscopic examination in ulcerative colitis, this inflammatory process seems to be well demarcated, while in others, less so. In Crohn's disease, any segment of the colon may be involved, most often cecum and/or ascending colon. Concomitant small intestinal disease is also present. In recent years, other less common, but distinct types of inflammatory disease have become better recognized. One segmental form associated with diverticulosis, usually involving only the sigmoid colon, is the so-called "SCAD syndrome", or more precisely, segmental colitis associated with diverticulosis (SCAD)[1-5].

CLINICAL FEATURES OF SCAD

This form of segmental involvement, especially if only the sigmoid colon is affected, frequently presents with bloody stools. In some, but not all, abdominal pain, cramping discomfort, or diarrhea may occur. Males are generally affected more often than females[6], and usually, most suffer from the initial onset of symptoms after 40 or 50 years of age, somewhat different from the usual female predominant distribution of Crohn's disease, including Crohn's disease of the colon[6]. In Crohn's disease, as well, studies have shown that over 80% of adults are usually diagnosed well before age 40[6-8]. Like other forms of idiopathic inflammatory bowel diseases, the cause and pathogenesis needs to be better characterized and elucidated[1,5,9]. Endoscopic examination reveals a localized sigmoid inflammatory process with normal rectal and proximal colonic mucosa. Detailed biopsy examination of the entire colonic mucosa shows a localized non-specific mucosal inflammatory process only in the sigmoid colon[6,10].

SELECTION BIAS

In some, an earlier diagnosis of a resected colonic neoplasm (i.e. adenoma) is not infrequent[6]. As a

result, a form of selection bias may be present as this subgroup of older patients may be simply more aware of the significance of rectal bleeding and their particular increased risk for recurrent adenomas or colon cancer. Therefore, many often seek expedient medical investigation to define their symptoms and alleviate their anxiety. The good news of detection of inflammatory mucosal disease, rather than colonic cancer, is the virtually immediate relief of their concerns.

LONG-TERM NATURAL HISTORY

Even better news is that most diagnosed with this segmental form of colitis, if followed over several years, remain well, usually resolving completely within a few weeks or months without recurrence[6]. Repeat endoscopic studies, including biopsies, reveal no evidence of residual inflammatory change. Some may have been initially treated with oral 5-aminosalicylates or other symptomatic agents. However, it is not certain that these medications are really necessary since some have spontaneously resolved with no traditional pharmacologic measures. Occasionally, other drugs have been used, including steroids, suggesting that there may be a spectrum of disease severity observed over time. In some cases, discrete episodes of recurrent symptoms and endoscopic changes have been defined and resection of the sigmoid colon was very rarely done. To date, no particular predisposition to colonic neoplastic disease, including invasive carcinoma, has been documented.

CLINICAL SIGNIFICANCE

This entity has special significance. First and most important, this inflammatory process is most often self-limited. Typically, the clinical course of SCAD is benign and it resolves without further recurrence or need for treatment. Due to similarities with other forms of inflammatory bowel disease, particularly Crohn's disease, the implications of an inaccurate diagnosis are evident. A case of segmental colitis involving the sigmoid colon, labeled as Crohn's colitis, might lead the treating physician or clinical trial investigator (in the case of new agents) to conclude that a positive outcome was due to the treatment provided rather than the natural history of an otherwise clinically benign inflammatory process. Anecdotal treatment success, including open label treatment trials of new agents for Crohn's disease, may be quite difficult to evaluate, especially if there are claims of "complete mucosal healing". Second, utilization of modern classification methods used for entities, such as Crohn's disease, that define age of diagnosis, location within the intestinal tract and clinical behavior may lead to further recognition of such entities so as to permit more precise treatment[7,8]. Finally, a "new" or distinct colonic inflammatory process that usually spontaneously resolves, such as SCAD, raises a critical need to better understand the molecular events that might be present allowing a long-term benign disease course. More precise treatments for other inflammatory colonic diseases aimed at cure, rather than remission, might then emerge.

Abstract

Optical coherence tomography (OCT) is an optical imaging modality that performs high-resolution, cross-sectional, subsurface tomographic imaging of the microstructure of tissues. The physical principle of OCT is similar to that of B-mode ultrasound imaging, except that it uses infrared light waves rather than acoustic waves. The *in vivo* resolution is 10-25 times better (about 10 μm) than with high-frequency ultrasound imaging, but the depth of penetration is limited to 1-3 mm, depending upon tissue structure, depth of focus of the probe used, and pressure applied to the tissue surface. In the last decade, OCT technology has evolved from an experimental laboratory tool to a new diagnostic imaging modality with a wide spectrum of clinical applications in medical practice, including the gastrointestinal (GI) tract and pancreatic-biliary ductal system. OCT imaging from the GI tract can be done in humans by using narrow-diameter, catheter-based probes that can be inserted through the accessory channel of either a conventional front-view endoscope, for investigating the epithelial structure of the GI tract, or a side-view endoscope, inside a standard transparent ERCP catheter, for investigating the pancreatico-biliary ductal system. Esophagus and the esophago-gastric junction has been the most widely investigated organ so far; more recently, also duodenum, colon and pancreatico-biliary ductal system have been extensively investigated. OCT imaging of the gastrointestinal wall structure is characterized by a multiple-layer architecture that permits an accurate evaluation of the mucosa, lamina propria, muscularis mucosae, and part of the submucosa. The technique may be, therefore, used to identify pre-neoplastic conditions of the GI tract, such as Barrett's epithelium and dysplasia, and evaluate the depth of penetration of early-stage neoplastic lesions. OCT imaging of the pancreatic and biliary ductal system could improve the diagnostic accuracy for ductal epithelial changes and the differential diagnosis between neoplastic and non-neoplastic lesions.

INTRODUCTION

Optical coherence tomography (OCT) is an optical imaging modality, introduced in 1991[1], that performs high-resolution, cross-sectional, subsurface tomographic imaging of the microstructure in materials and biologic systems by measuring backscattered or backreflected infrared light.

The physical principle of OCT is similar to that of B-mode ultrasound imaging, except that the intensity of infrared light, rather than sound waves, is measured. OCT devices use a low-power infrared light with a wavelength ranging from 750 to 1300 nm in which the only limiting factor is the scattering of light. Scattering occurs when the light interacts with tissue surface and the image formation depends upon the difference in optical backscattering properties of the tissue. OCT images are generated from measuring the echo time delay and the intensity of back-scattered light[2,3]. Wavelengths of

the infrared light used in OCT are one to two orders of magnitude higher than ultrasound wavelength, so OCT technology can yield a lateral and axial spatial resolution of about 10 μm, which is 10 to 25 fold better than that of available high-frequency ultrasound imaging[4]. The spatial resolution of OCT images is nearly equivalent to that of histologic sections. The depth of penetration of OCT imaging is approximately 1-3 mm, depending upon tissue structure, depth of focus of the probe used, and pressure applied to the tissue surface. Although the progressive increase in ultrasound resolution is accompanied by a corresponding decrease in depth of penetration, a similar trade-off between resolution and depth of penetration does not occur in OCT imaging.

In OCT, two-dimensional cross-sectional images of tissue microstructure are constructed by scanning the optical beam and performing multiple axial measurements of backscattered light at different transverse positions. The resulting data set is a two-dimensional array that represents the displayed as a grey-scale or false-color image.

Three types of scanning patterns are available for OCT imaging: radial[5,6], longitudinal[7,8], and transverse[9]. The radial-scan probe directs the OCT beam radially, giving images that are displayed in a "radar-like", circular plot. Radial scanning can easily image large areas of tissue by moving the probe back over the tissue surface and has the highest definition when the probe is inserted within a small diameter lumen, because the OCT images become progressively coarser when a large-diameter lumen is scanned, due to the progressive increase of pixel spacing with increasing the distance between the probe and the tissue. The linear and transverse probes scan the longitudinal and transverse positions of the OCT beam at a fixed angle, generating rectangular images of longitudinal and transverse planes at a given angle with respect to the probe. Linear scanning has the advantage that pixel spacing in the transverse direction is uniform and can better image a definite area of the scanned tissue, especially in presence of large-diameter and non-circular lumens, where maintaining constant distance from the probe to the surface over the entire circumferential scan may be impossible. Transverse scanning modality provides a better depth of field. Depth of field is the range of distances from the probe over which optimal resolution of scanning can be obtained; current OCT scans permit imaging depths of up to 2-3 mm in tissues, by using probes with different focuses.

In the last decade, OCT technology has evolved from an experimental laboratory tool to a new diagnostic imaging modality with a wide spectrum of clinical applications in medical practice, including the gastrointestinal (GI) tract and pancreatico-biliary ductal system.

OCT TECHNIQUE FOR GI TRACT AND PANCREATICO-BILIARY DUCTAL SYSTEM IMAGING

OCT imaging from the GI tract can be done in humans by using narrow-diameter, catheter-based probes. The probe can be inserted through the accessory channel of either a conventional front-view endoscope, for investigating the epithelial structure of the GI tract, or a side-view endoscope, inside a standard transparent ERCP catheter, for investigating the pancreatico-biliary ductal system.

OCT scanning can be done by maintaining the probe placed lightly or firmly on the wall of the GI tract. When the probe is placed lightly on the mucosal surface, the depth of penetration is limited mainly to the superficial submucosa; by this way superficial epithelium, lamina propria, and the upper part of submucosa are clearly visualized. When the probe is placed firmly against the mucosal surface, submucosa and muscularis propria can be clearly visualized, but details of the superficial layers of the mucosa are lost. When the OCT probe is held in strict contact with the tissue surface, as occurs when it is inserted across strictures of the pancreatico-biliary ductal system, the superficial epithelium may appear compressed and difficult to evaluate.

Several *in vitro* studies demonstrated the feasibility of OCT in the GI tract: In these studies the GI tract wall was identified as a multiple layer structure characterized by a sequence of hyper- and hypo-reflective layers, with a variable homogenicity of the back-scattered signal[8-10]. Neoplastic and normal tissue also showed different light backscattering patterns[11-13].

Subsequent studies were, therefore, performed in *ex vivo* tissue specimens and aimed at comparing OCT imaging with histology, to assess the reliability of the OCT technique to identify and recognize the GI and pancreatico-biliary wall structure. OCT was shown to clearly differentiate the layer structure of the wall[14].

In vivo studies confirmed the possibility of OCT to recognize the multiple-layer structure of the GI wall[15,16]; the possibility to introduce the OCT probe into a standard transparent catheter for cannulation during an ERCCP procedure permits the epithelial layers of the pancreato-biliary ductal system and sphincter of Oddi to be investigated. From a clinical point of view, OCT imaging of the pancreatic and biliary ductal system could improve the diagnostic accuracy for ductal epithelial changes and the differential diagnosis between neoplastic and non-neoplastic lesions, since in several conditions, X-ray morphology obtained by ERCP and other imaging techniques may be non-diagnostic, and the sensitivity of intraductal brush cytology during ERCP procedures is highly variable.

In our studies, a near-focus OCT probe (Pentax, Lightlab Imaging, Westford, MA, USA) was used, with a penetration depth of about 1 mm and a resolution of approximately 10 μm. The probe operates at 1.2-1.4 μm center wavelength (nominal value: 1.3 μm), with a scan frequency ranging from 1000 to 4000 kHz (nominal value: 3125 kHz). Radial and longitudinal scanning resolutions have an operating range in tissue of 15-20 μm (nominal value: 18 μm), and 21-27 μm (nominal value: 24 μm), respectively. Infrared light is delivered to the imaging site through a single optical fiber 0.006 diameter. OCT probe is assembled in a catheter with an outer

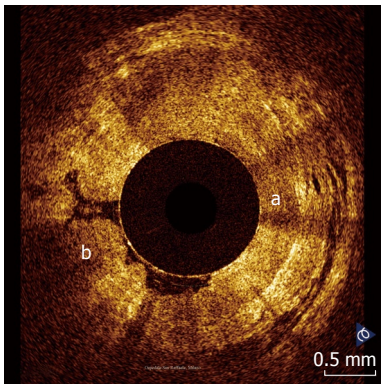

Figure 1 OCT pattern of squamo-columnar junction. The horizontal, layered architecture of the esophageal wall (a) appears clearly distinguishable from the vertical crypt-and-pit architecture of the gastric wall (b).

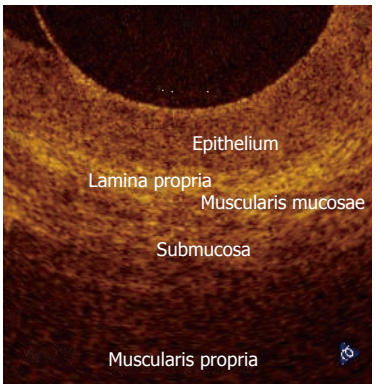

Figure 2 Magnification of a OCT image showing normal esophageal wall. The OCT image shows a multiple-layer structure characterized by a superficial weakly scattering (hypo-reflective) layer, corresponding to the squamous epithelium, a highly scattering (hyper-reflective) layer corresponding to the lamina propria, a weakly scattering layer corresponding to the muscularis mucosae, difficult to recognize, a moderately scattering layer corresponding to the submucosa, and a weakly scattering, deep layer corresponding to muscolaris propria.

diameter of 1.2 mm; the catheter-based probe consists of a rotating probe encased in a transparent outer sheath, which remains stationary while the rotating probe has a pullback movement of 1 mm/s, with an acquisition rate of 10 frames per second. Using this technique, a segment of tissue 5.5 cm long can be filmed over a 55-s period.

OCT RECOGNITION OF GI TRACT AND PANCREATICO-BILIARY WALL STRUCTURE IN NORMAL CONDITIONS

GI tract

The esophagus and the esophago-gastric junction has been the most widely investigated organ so far. Esophago-gastric junction appears at OCT investigation clearly recognizable because the stomach wall shows a different OCT pattern, characterized by the presence of a vertical crypt-and-pit architecture of the mucosa that changes abruptly to the horizontal, layered tissue architecture of the esophageal squamous epithelium (Figure 1).

In normal conditions, OCT imaging of esophageal wall recognizes a multiple-layer structure characterized by a superficial weakly scattering (hypo-reflective) layer, corresponding to the squamous epithelium, a highly scattering (hyper-reflective) layer corresponding to the lamina propria, a weakly scattering layer corresponding to the muscularis mucosae, a moderately scattering layer corresponding to the submucosa, and a weakly scattering, deep layer corresponding to muscularis propria (Figure 2). The latter layer is not even recognizable *in vivo*, depending on the depth of penetration of the OCT probe used. Submucosal glands and vessels have also been identified[5-8]. In a recent *ex vivo* study the muscularis mucosae was distinctly recognized during OCT investigation by using a Ti: Sapphire laser light source[16].

Overall, the normal esophageal wall architecture shows at OCT imaging a clearly recognizable horizontal, layered structure.

OCT images of the gastric mucosa are characterized by less contrast, depending upon the crypt-and-pit architecture of the glandular epithelium[2,8,12]. Four layers can be identified from the surface: The glandular epithelium, muscularis mucosae, submucosa with blood vessels, and muscularis propria[9]. Inflammation, as occurs in gastritis, has been reported to produce greater backscattering of the signal and a more pronounced crypt-and-pit pattern architecture, compared with normal tissue[17].

In the duodenum and small intestine OCT clearly recognizes the mucosa and submucosa with the vascular structure[5,15]. OCT identified intestinal villous morphology and the degree of atrophy with 100% agreement compared to histology in a study by Hsiung *et al*[18], who analyzed OCT images *ex vivo* on fresh surgical specimens from the small intestine compared with histology. The ability of OCT imaging to recognize the villous pattern and its alterations could be used to identify celiac disease in real time during standard upper GI endoscopy in patients undergoing endoscopy for conditions often related to a misdiagnosed celiac disease, such iron deficiency anemia, osteoporosis, diabetes mellitus, or autoimmune disorders, and select dyspeptic patients who need biopsies for detecting the disease[19,20].

In the colon, mucosa and submucosa can also be seen with strong correlation with histology. Mucosa appears as a hyper-reflective layer; submucosa as a hypo-reflective layer with horizontal striations, and the OCT appearance is related to its composition, which could be of assistance in the diagnosis of chronic inflammatory conditions involving the submucosa. Dynamic application of pressure of the OCT probe on the tissue reveals compressibility of both mucosa and submucosa, that may be another criteria for identifying chronic inflammation and fibrosis[19]. The detection of transmural inflammation serves to distinguish patients with Crohn's disease from those with ulcerative colitis; the detection of dysplasia may help in the follow-up of long-standing chronic inflammatory diseases[21]. In presence of dysplasia, the detection of lower boundary of the mucosa may help in identifying the extension of dysplastic changes.

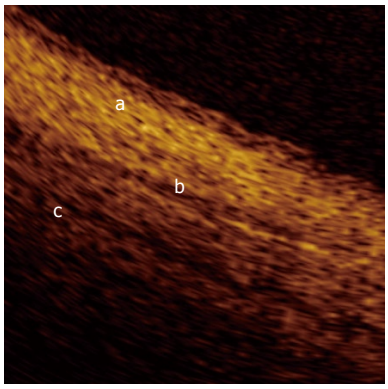

Figure 3 Magnification of an OCT image from the normal common bile duct wall. From the surface of the duct, up to a depth of 1 mm, the following layers are recognizable: the single layer of epithelial cells, approximately 0.04-0.06 mm thick, visible as a superficial, hypo-reflective band (a); the connective-muscular layer surrounding the epithelium, visible as a hyper-reflective layer approximately 0.34-0.48 mm thick (b); the connective layer visible as a hypo-reflective layer with longitudinal relatively hyper-reflective strips (smooth muscle fibers) (c).

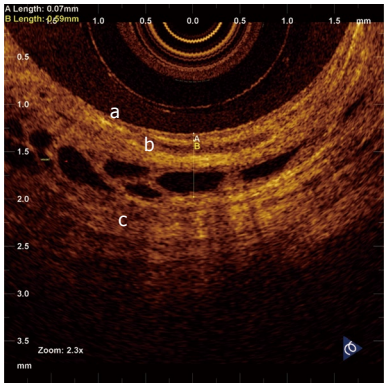

Figure 4 Magnification of an OCT image from the normal sphincter of Oddi wall. From the surface of the duct, up to a depth of 1 mm, the following layers are recognizable: The single layer of epithelial cells, approximately 0.04-0.08 mm thick, visible as a superficial, hypo-reflective band (a); the connective-muscular layer surrounding the epithelium, visible as a hyper-reflective layer approximately 0.23-0.37 mm thick (b); the connective layer visible as a hypo-reflective layer with longitudinal relatively hyper-reflective strips (smooth muscle fibers) (c). Within the intermediate and outer layer vessels are also recognizable, visualized as non-reflecting areas surrounded by a hypo-reflective endothelium. Margins between the intermediate and outer layer are poorly recognizable, due to the irregular distribution of connective and muscular structure.

Pancreatico-biliary ductal system

To date, visualization of the epithelium of the main pancreatic duct has been obtained mainly post-mortem[22] and *ex vivo* in humans[23,24], while *in vivo* it comes from one study in animals[25] and another in humans[26]. Normal biliary ductal system has been investigated in humans, *ex vivo* in a study[23] and *in vivo*, in two ERCP-based studies[27,28]. Sphincter of Oddi structure has also been investigated in normal and pathological conditions either in *ex vivo* or *in vivo* studies[23,27].

In a recent study by our group[26], OCT imaging of main pancreatic duct, common bile duct and sphincter of Oddi normal structure has been shown to be able to provide features that were similar to those observed

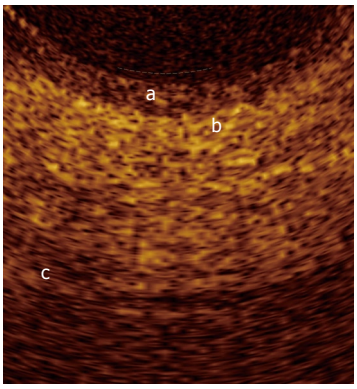

Figure 5 Magnification of an OCT image from the normal main pancreatic duct wall. From the surface of the duct, up to a depth of 1 mm, the following layers are recognizable: The single layer of epithelial cells, approximately 0.04-0.08 mm thick, visible as a superficial, hypo-reflective band (a); the connective-fibro-muscular layer surrounding the epithelium, visible as a hyper-reflective layer approximately 0.36-0.56 mm thick (b); the connective and acinar structure close to the ductal wall epithelium, visible as a hypo-reflective layer (c).

in the corresponding histological specimens in 80% of sections; the agreement between OCT and histology in the definition of normal wall was good (81.8%). OCT images identified three differentiated layers up to a depth of about 1 mm. From the surface of the duct, it was possible to recognize an inner hypo-reflective layer corresponding to the single layer of epithelial cells close to the lumen, an intermediate homogeneous hyper-reflective layer corresponding to the fibro-muscular layer surrounding the epithelium, and an outer, less definite, hypo-reflective layer corresponding to the smooth muscular structure within a connective tissue in the common bile duct and at the level of the sphincter of Oddi, and connective-acinar structure in the main pancreatic duct (Figures 3-5).

The three different layers showed a linear, regular surface and each layer had a homogeneous back-scattered signal in every frame; however, the differentiation between the intermediate and outer layer appeared more difficult than between the inner and intermediate layer. The thickness of the inner and intermediate layers measured by OCT was similar to those measured by histology; the muscular and connective-acinar structure was visible until the working depth of penetration into the tissue of the near-focus probe (about 1 mm).

Smooth muscle structure appeared at OCT scanning as hyper-reflective, longitudinal strips within a context of hypo-reflective tissue and was particularly recognizable at the level of sphincter of Oddi. Veins, arteries and secondary pancreatic ducts were also identifiable by OCT, characterized by hypo- or non-reflective, well delimited areas.

The images acquired in this study provided information on tissue architectural morphology that could have only previously be obtained with conventional biopsy. These results suggest that OCT could become a powerful imaging technology, enabling high-resolution diagnostic images to be obtained from the pancreato-biliary system during a diagnostic ERCP procedure.

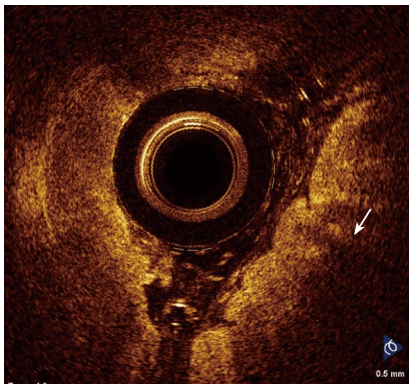

Figure 6 Barrett's esophagus (arrow). OCT features predictive for the presence of intestinal metaplasia are: The absence of the layered structure of the normal squamous epithelium and the presence of the vertical crypt-and-pit morphology of normal gastric mucosa; a disorganized architecture with inhomogeneous backscattering of the signal and an irregular mucosal surface; the presence of submucosal glands characterized by a markedly hypo-reflective tissue below the epithelial surface.

OCT RECOGNITION OF GI TRACT AND PANCREATICO-BILIARY WALL STRUCTURE IN DYSPLASTIC AND NEOPLASTIC CONDITIONS

At present, the exact cause of the disorganized architecture and altered light-scattering associated with dysplastic tissue by OCT imaging is unknown. A number of factors have been suggested, including subcellular morphological changes, altered fibrovascular stroma and abnormal mucin content associated with neoplastic tissue change, proliferation of cells leading to a loss of epithelial and stromal orientation, and altered cytological features such as an increased nuclear-to-cytoplasm ratio that may alter infrared light back-scattering[9,29].

In its current form and resolution, OCT will likely localize areas displaying architectural distortion to guide biopsy.

GI tract

Most of the so far published studies used OCT imaging to detect dysplasia and early cancer within Barrett's epithelium. Since the penetration depth of OCT does not exceed 1-2 mm, the technique could be useful, not only in detecting dysplasia, but also in staging superficial cancers that are difficult to stage accurately with ultrasound endoscopy. The technique appears, therefore, of crucial importance in the management of the disease.

Barrett's epithelium is characterized by the presence of specialized intestinal metaplasia within the esophageal mucosa. The hallmark histologic feature of specialized intestinal metaplasia is the presence of goblet cells. Identification of Barrett's epithelium is of clinical relevance since the lesion requires endoscopic follow-up, being a recognized precancerous condition. In clinical practice Barrett's epithelium is generally identified by performing multiple biopsies within the areas of gastric metaplasia, either in a random manner or after a previous vital staining with methylene blue (MB).

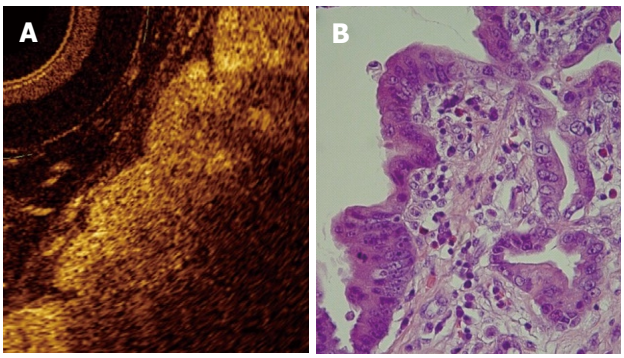

Figure 7 OCT image showing high-grade dysplasia (A) compared to histology (B). Because the degree of reflectivity depends upon nuclear size, a markedly inhomogenous and hypo-reflective back-scattering of the signal should indicate the presence of high-grade dysplasia.

Although the inter-subject variability of OCT imaging of normal squamous epithelium and gastric mucosa appears to be low, the OCT imaging of Barrett's epithelium demonstrated a greater variability in the previous published studies. OCT features predictive for the presence of intestinal metaplasia are: (1) the absence of the layered structure of the normal squamous epithelium and the presence of the vertical crypt-and-pit morphology of normal gastric mucosa; (2) a disorganized architecture with inhomogeneous back-scattering of the signal and an irregular mucosal surface; and (3) the presence of submucosal glands characterized at the OCT imaging as pockets of low reflectance below the epithelial surface[30-32] (Figure 6). When these OCT criteria were applied to images acquired prospectively, the criteria were found to be 97% sensitive and 92% specific for specialized intestinal metaplasia, with a PPV of 84%. The presence of the crypt-and-pit architecture may render difficult to discriminate between intestinal metaplasia and normal or inflamed gastric mucosa[9].

Unfortunately, up to now, attempts to identify OCT patterns characteristic for dysplasia, mainly the high-grade type, have been substantially disappointing. The increased nuclear-to-cytoplasmic ratio occurring in dysplasia may alter the light reflection characteristics, giving a more inhomogeneous back-scattering of the signal (Figure 7). Because the degree of reflectivity depends upon nuclear size, a markedly homogenous and hypo-reflective back-scattering of the signal should indicate the presence of high-grade dysplasia; moreover, it is possible that by quantitating the OCT signal as a function of depth, OCT would be able to characterize high-grade dysplasia within intestinal metaplasia tissue. Poneros *et al*[17], by using two parameters of tissue reflectivity as an indicator of dysplasia, retrospectively diagnosed high-grade dysplasia with 100% sensitivity and 85% specificity. Such an accurate analysis of the degree of signal reflectivity requires to avoid areas with incorrect artifact signal properties: This may be obtained by the identification of a precisely defined area with homogeneous signal reflectance, an adequate catheter-tissue contact, and a reduction of motion

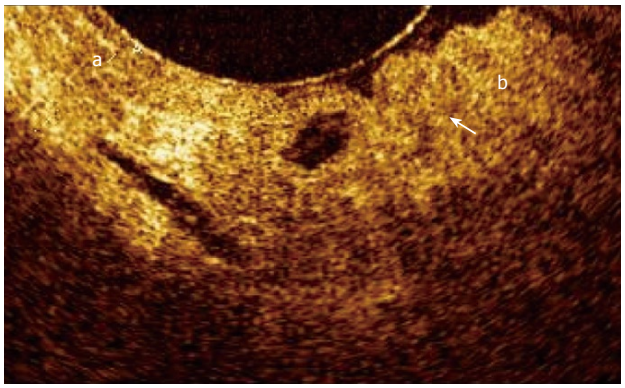

Figure 8 OCT image showing normal oesophageal mucosa (a) and Barrett's epithelium (b) with focal high-grade dysplasia (arrow).

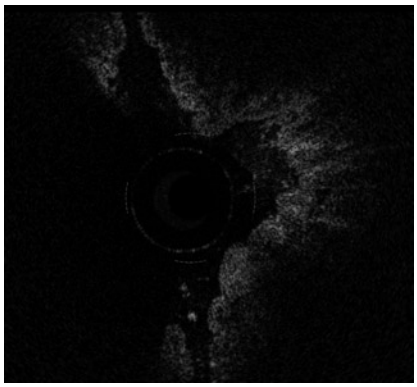

Figure 9 Magnified OCT imaging of early stage adenocarcinoma raised within Barrett's epithelium. The lack of the regular esophageal wall layered morphology and a markedly heterogeneous back-reflectance of the signal characterize the neoplastic lesion, which is confined within the epithelium.

artifacts. More recently, the morphological appearance of the OCT images, rather than the quantitative analysis of the OCT signal in the image, were used for the diagnosis and grading of dysplasia; for this purpose an endoscope fitted with an EMR standard cap was used, to stabilize the mucosal surface and avoid movement from esophageal peristalsis and transmitted cardiac and respiratory motion. In this study sensitivity, specificity, positive predictive value, negative predictive value, and diagnostic accuracy for dysplasia were respectively, 68%, 82%, 53%, 89%, and 78%[33].

However, with the current available OCT devices, the recognition of dysplasia within intestinal metaplasia and mainly the differentiation between low- and high-grade dysplasia appears difficult[34] (Figure 8).

OCT features characteristic for adenocarcinoma arising from Barrett's epithelium are the lack of the regular esophageal wall layered morphology and a markedly heterogeneous back-reflectance of the signal[35,36] (Figure 9). These features permit to clearly identify the lesion and differentiate between the neoplastic and non-neoplastic tissue in advanced disease.

Figure 10 shows and compares OCT findings of normal esophageal mucosa, Barrett's epithelium, dysplasia, and adenocarcinoma.

Despite some studies were conducted about the use

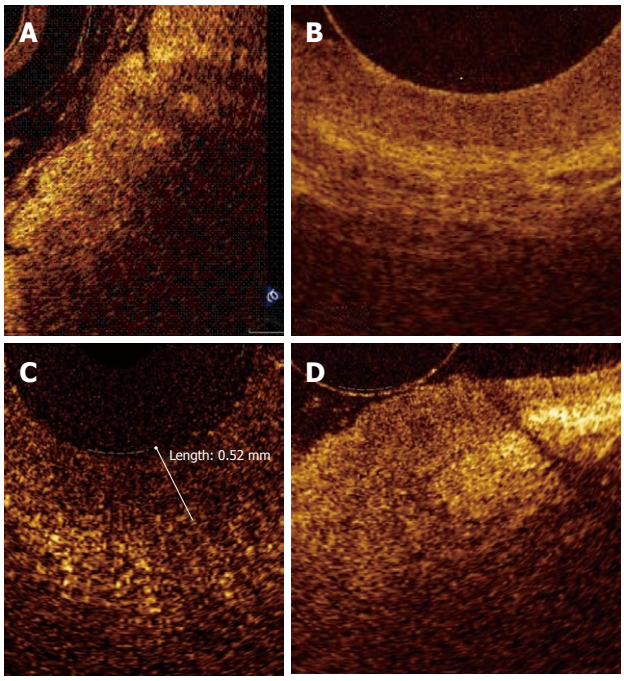

Figure 10 Comparison of OCT findings of normal esophageal mucosa (A), Barrett's epithelium (B), dysplasia (C), and adenocarcinoma (D).

of the OCT in the stomach and small intestine, no data are actually available about its use in detecting dysplasia.

Only few data are present in literature concerning the use of the OCT to detect dysplasia or cancer in the colon[37-39]. In a study by Pfau *et al*[39] on 24 patients, 30 dysplastic adenomas and 14 hyperplastic polyps were studied; the real-time OCT investigation showed that adenomas were more disorganized than the hyperplastic polyps, with a significantly more disorganized structure ($P = 0.0005$). Moreover, the infrared-light back-scattering of the adenomatous polyps appeared more hypo-reflective than hyperplastic ($P = 0.0007$). By using a computer-generated method to quantify the degree of scattering of individual pixels within a specified area in each image (60 × 60 pixels), it was found that the mean differences in light scattering were significantly greater between adenomatous and normal tissue (mean difference = 45.81), than between hyperplastic polyps and normal tissue (mean difference = 14.86). The real-time OCT infra-red light back-scattering score of polyps was also demonstrated to be a significant predictor of an adenomatous status. However, differently from the dysplasia occurring within Barrett's epithelium, in the study done by these authors defined OCT parameters histologically proven to detect colonic dysplasia were not found.

Pancreatico-biliary ductal system

Pathological pancreatic ductal system has been investigated by our group in humans in two *ex vivo* studies[14,24] performed on multiple surgical pancreatic specimens obtained from patients with pancreatic head adenocarcinoma.

In chronic inflammatory changes involving the main pancreatic duct, OCT still showed conserved three-layer

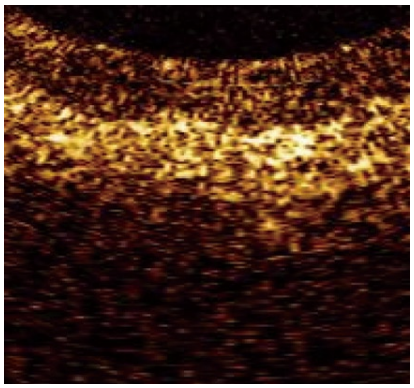

Figure 11 Magnified OCT images from section of main pancreatic duct showing low-grade dysplasia. The surface between the inner and intermediate layers appeared irregular. Dysplasia presents strong hyper-reflectance of the intermediate layer, particularly in the part closest to the inner layer. The outer layer did not differ from other non-malignant conditions and appeared homogeneously hypo-reflective.

architecture. However, the inner, hypo-reflective layer appeared slightly larger than normal and the intermediate layer appeared more hyper-reflective than in normal tissue; this is probably because of the dense mononuclear cell infiltrate. The back-scattered signal was heterogeneous with marked hypo- or hyper-reflectance in some sections. The agreement between OCT and histology in the definition of MPD chronic inflammatory changes was poor (27.7%).

The OCT pattern in presence of dysplasia of the main pancreatic duct epithelium was characterized by an inner layer markedly thickened, strongly hypo-reflective and heterogeneous; this OCT finding is probably due to the initial structural disorganization (increased mitosis and altered nucleus/cytoplasm ratio). The surface between the inner and intermediate layers appeared irregular. As in chronic inflammatory tissue, dysplasia too gave strong hyper-reflectance of the intermediate layer, particularly in the part closest to the inner layer. The outer layer did not differ from other non-malignant conditions and appeared homogeneously hypo-reflective (Figure 11). However, in chronic pancreatitis and dysplasia, only 62% of cases OCT and histology were concordant. The K statistic used to assess agreement between the two procedures was equal to 0.059 for non-neoplastic MPD wall appearance.

Overall, normal wall structure and chronic inflammatory or low-grade dysplastic changes cannot be distinguished in 38% of the sections because the architecture of the layers and surface light reflection did not show a characteristic OCT pattern.

In all sections with histologically proven adenocarcinoma, OCT showed a totally subverted MPD wall architecture. The three layers of the ductal wall and their linear, regular surface, normally giving a homogeneous back-scattered signal, were not recognizable. The margins between the connective-fibromuscular layer and acinar tissue were unidentifiable. The back-scattering of the signal appeared strongly heterogeneous, with minute, multiple, non-reflective

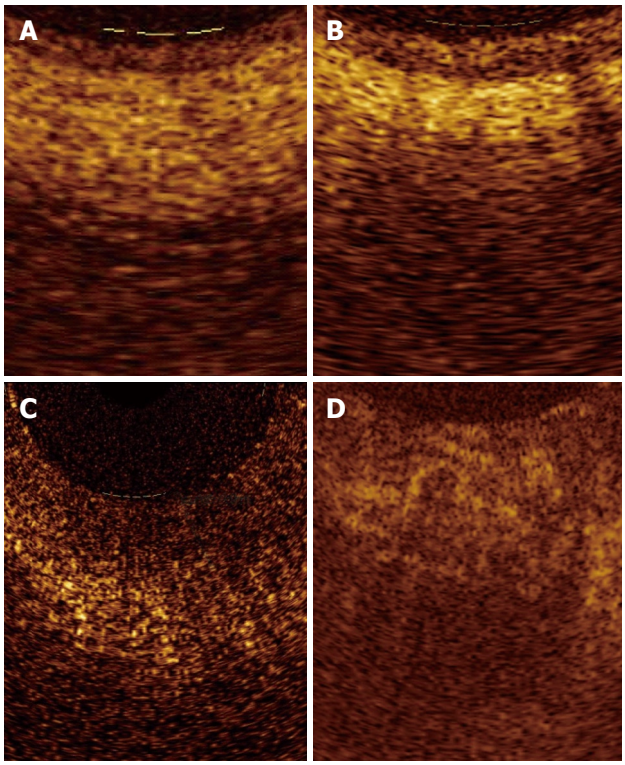

Figure 12 Magnified OCT images from sections with either normal (A), tumor-associated chronic inflammation (B), low-grade dysplasia (C), and adenocarcinoma (D) tissue.

areas in the disorganized pancreatic microstructure. Of sections with adenocarcinoma, OCT and histology were 100% concordant.

Figure 12 shows magnified OCT images from sections of main pancreatic duct with normal tissue, chronic pancreatitis, low-grade dysplasia, and adenocarcinoma.

Totally subverted wall architecture was also observed by OCT in presence of neoplastic tissue within the common bile duct[40] (Figure 13).

Studies *in vivo* were performed in animals[25] and humans[27]. We evaluated the diagnostic accuracy of OCT for the diagnosis of carcinoma, during ERCP, in a series of patients with MPD strictures of unknown etiology. In this study, the accuracy of OCT for detection of neoplastic tissue was 100%, compared with 66.7 % for intraductal brush cytology. The study showed that OCT is feasible during an ERCP procedure and was superior to brush cytology in distinguishing non-neoplastic from neoplastic lesions[26].

In conclusion, OCT appears a promising technique for real-time, high-resolution, cross-sectional imaging of the inner layer of the wall of the GI and pancreatobiliary tract, during the routine endoscopy. The technique recognizes with high definition the mucosa, muscularis mucosae and submucosa, and seems particularly useful in the study of the esophageal mucosa; given its superior resolution compared with other imaging modalities such as endoscopic ultrasonography (EUS) or catheter-probe EUS (CPEUS), OCT has great potential as a powerful adjunct to standard endoscopy in identification and

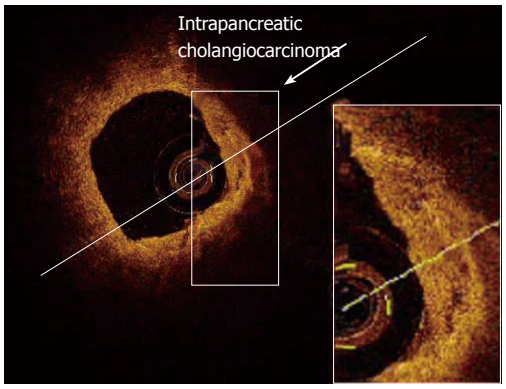

Figure 13 Magnified OCT images of neoplastic tissue within the intrapancreatic portion of the common bile duct.

surveillance of Barrett's epithelium, in order to detect high-grade dysplasia and adenocarcinoma at early stage and identify cases in whom mucosectomy becomes a curative procedure.

In the pancreatico-biliary ductal system, OCT can be used to discriminate between non-neoplastic and neoplastic tissue when strictures of unknown etiology are identified during an ERCP procedure, being its diagnostic accuracy higher than reported for intraductal brush cytology.

However, despite the promising studies reported in literature, with the current available OCT devices the recognition of dysplasia within intestinal metaplasia and mainly the differentiation between low- and high-grade dysplasia appears difficult.

On the other hand, since OCT has a penetration depth that does not exceed the 2 mm, it has a greater capability of diagnosing adenocarcinoma confined within mucosa and submucosa and could, therefore, be useful in staging superficial cancers that are difficult to stage accurately by EUS.

Features characteristic for adenocarcinoma within Barrett's epithelium are the lack of the regular layered morphology of the esophageal wall and a markedly heterogeneous back-reflectance of the signal. However, further studies are needed to evaluate whether OCT can identify and stage the lesion at an early stage.

OCT appears more promising in the differential diagnosis between non-neoplastic and neoplastic lesions arising within the pancreatico-biliary ductal system, since the ductal wall layered structure can be recognized easier and clearer.

At present, it seems to be fairly premature to affirm that OCT plays a role in the real-time diagnosis of dysplasia *in vivo*. However, improvements in both axial and lateral resolutions to the subcellular level (< 5 μm) together with the development of better light sources and optics, may allow dysplastic cells to be better identified in the future. Doppler OCT could also offer a unique ability to provide detailed subsurface imaging of mucosal microvascular networks.

Abstract

Colorectal cancer is the third most common form of cancer. Current treatments are all associated with a high risk of complications and a low success rate. Recently, synbiotics have been proposed as a new preventive and therapeutic option. There is no direct experimental evidence for cancer suppression in humans as a result of the consumption of pro-, pre- or synbiotics. However, there is a wealth of evidence emerging from laboratory studies. The mechanisms by which pro-, pre- and synbiotics may inhibit colon cancer are now beginning to be understood and will be addressed in the present review.

INTRODUCTION

Over the past years yogurt and the lactic acid producing bacteria that it contains, have received much attention as potential cancer prevention agents in the diet. Prebiotics, such as non-digestible oligosaccharides, appear to have similar effects, while some studies indicate that combinations of pro and probiotics (synbiotics) are more effective.

Colorectal cancer (CRC) is the third most prevalent form of cancer in men and women, with a 5-year survival rate of 63%, decreasing to 10% in patients with metastatic disease[1]. More than 80% of colorectal neoplasms occur sporadically, arising from adenomatous polyps *via* the long-term accumulation of mutations in genes including *APC*, *K-ras* and *TP53*[2]. Mortality and incidence of CRC is the third only to that of prostate and lung cancer in men, breast and lung cancer in women and has shown little sign of decreasing in the last 20-30 years. Diet makes an important contribution to CRC risk[3], implying that the risks of CRC are potentially reducible. Evidence also supports the view that the colonic microflora are involved in the etiology of CRC[3]. This has led to an intense interest in factors that can modulate the gut microflora and their metabolism, such as probiotics and prebiotics.

The original definition of a probiotic was "a live microbial feed supplement which beneficially affects the host animal by improving its intestinal microbial balance"[4]. Recent definitions are more general, omitting the aspect of intestinal balance. The most acceptable definition is "a living microorganism which upon ingestion in certain numbers, exert health benefits beyond inherent general nutrition"[5]. A probiotic should be non-pathogenic and non-toxic and also resistant to low pH and bile salts to improve its chances of survival in the gastrointestinal tract[6]. Most probiotics are members of two genera of lactic acid bacteria (LAB), Lactobacillus and Bifidobacterium, but Saccharomyces and Enterococcus are also used. The list of beneficial

effects attributed to probiotics bacteria is extensive and includes alleviation of lactose-intolerance symptoms, serum cholesterol reduction, alleviating constipation, prevention of drug-induced colitis, while they also demonstrate efficacy in a number of conditions including ulcerative colitis, pouchitis, radiation colitis, atopic eczema and diarrhea.

A prebiotic, as defined by Gibson and Roberfroid, is "a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth and activity of one or a limited number of bacteria in the colon that have the potential to improve host health"[7]. A number of poorly digested carbohydrates fall into the category of prebiotics, including certain fibers and resistant starches, but the most widely described prebiotics are non-digestible oligosaccharides. Combinations of probiotics and prebiotics can result in additive or synergistic effects on gastrointestinal function. The term synbiotic has been proposed for such combinations. A synbiotic has been defined as "a mixture of prebiotics and probiotics that beneficially affects the host by improving the survival and implantation of live microbial dietary supplements in the gastrointestinal tract, by selectively stimulating the growth and activating the metabolism of one or a limited number of health-promoting bacteria, and thus improving host welfare" (Gibson *et al*[7], 1995).

MECHANISMS BY WHICH PROBIOTIC BACTERIA MAY INHIBIT COLON CANCER

There is accumulating evidence describing the ability of probiotic strains to prevent CRC. Some epidemiological studies have indicated that consumption of large quantities of fermented milk products containing lactobacillus or bifidobacteria are associated with a lower incidence of colon cancer[8], although, other studies have suggested that consumption of fermented dairy products imparts little, or no, protection[9]. The mechanisms by which probiotics may inhibit colon cancer are not yet fully characterized. However, there is evidence for: Alteration of the metabolic activities of intestinal microflora, alteration of physicochemical conditions in the colon, binding of potential carcinogens, short chain fatty acid production, production of anti-tumorigenic or anti-mutagenic compounds, elevating the hosts' immune response and altering the hosts' physiology.

Alteration of the metabolic activities of intestinal microflora

The bacterial enzyme β-glucuronidase has the ability to hydrolyse many glucuronides. Many foreign compounds are detoxified by glucuronide formation in the liver. In that way, many carcinogenic aglycones are liberated in the intestinal lumen. Several more bacterial enzymes have been implicated in the carcinogenic process, releasing carcinogens in the intestinal tract. Lactic acid bacteria reduced the specific activities of fecal enzymes in human volunteer studies[10]. Goldin and Gorbach also studied the effect of feeding L.acidophilus strains NCFM and N-2 on the activity of three bacterial enzymes (β-glucuronidase, nitroreductase and azoreductase) in 21 healthy volunteers[11]. Both strains had similar effects and caused a significant decline in the specific activity of the three enzymes in all subjects after 10 d of feeding. A reversal of the effect was observed within 10-30 d of stopping Lactobacillus feeding; suggesting that continuous consumption of these bacteria was necessary to maintain the effect. Human studies have demonstrated that the capacity for probiotics to decrease the activity of bacterial enzymes is strain specific. To this end, *L. plantarum* 299V, *L. rhamnosus* DR20 and *L. acidophilus* A1 were unable to decrease β-glucuronidase activity in healthy subjects[12,13,14], while *L. casei Shirota* and *L. acidophilus* significantly decreased enzymatic activity[15,16]. Reports published to date do not always find reductions in the same enzymes, although findings with β-glucuronidase and nitroteductase are most consistently positive. However, we do not know how or whether a reduction in these enzyme activities affect cancer rates in man.

Alteration of physicochemical conditions in the colon

It has been suggested that large bowel cancer could be influenced directly by reducing intestinal pH[17], thereby preventing the growth of putrefactive bacteria. In rats given inulin containing diets with or without *B. longum*, an increase in caecal weight and β-glucosidase and a decrease in caecal pH were observed[18], though some other studies did not detect a significant change in intestinal pH[19].

One hypothesis regarding colon carcinogenesis involves a cytotoxic effect on the colonic epithelium, exerted by bile acids in the aqueous phase of faeces, followed by an increased proliferation of cells in the intestine[20]. Dietary fat has also been considered a risk factor for colon cancer. This phenomenon may be mediated by increased levels of secondary bile acids in the colon, produced by the action of bacterial 7a-dehydroxylase on primary bile acids. It has been demonstrated that a 6-wk administration of *L. acsidophilus* fermented milk supplements to colon cancer patients resulted in lower concentrations of soluble bile acids in faeces[21]. In another study, patients with colonic adenomas participated in a 3-mo study, where *L. acidophilus* was administered together with *B. bifidum*[22]. During this period, the faecal pH was reduced significantly, and patients having a higher proliferative activity in the upper colonic crypts than that calculated for subjects at low risk for colon cancer showed a significant decrease after therapy with the lactic acid bacteria.

Binding and degrading potential carcinogens

Mutagenic compounds, commonly found in the western meat-rich diet, can be bound to the intestinal and lactic acid bacteria *in vitro* and binding has been found to be correlated well with the reduction in the

mutagenicity observed after exposure to the bacterial strains. In a study, the ability of 22 strains of intestinal bacteria to bind the mutagenic pyrolyzates was investigated and compared their ability to that of some dietary fibres[23]. Some indoles, including 3-amino-1-methyl-5H-pyrido (4, 3-β) indole (Trp-P-2) were effectively bound to all gram-positive and some gram-negative bacterial cells, maize bran, and apple pulp and soybean fiber. The mutagenicity of Trp-P-2 for *Salmonella typhimurium* TA98 in the presence of S9 mix was inhibited by the addition of *L. casei* to the reaction mixture, indicating that bound Trp-P-2 did not cause mutation under the assay conditions. A more recent study demonstrated a reduced uptake of Trp-P-2 and its metabolites in various tissues of mice supplemented with dietary lactic acid bacteria[24]. In addition to that, the consumption of lactobacilli by human volunteers has been shown to reduce the mutagenicity of urine and feces associated with the ingestion of carcinogens in cooked meat[25]. It is possible that the lactic acid bacteria supplements are influencing the uptake and excretion of mutagens by simply binding them in the intestine. Lactobacilli have also been shown to degrade nitrosamines[26]. Nitrosamines have been shown to be carcinogenic in animal models and these compounds have been detected in human faeces.

Short chain fatty acid (SCFA) production

The production of SCFAs, such as butyrate, is one key mechanism by which probiotics and prebiotics may impart beneficial effects. Butyrate has been shown to inhibit cancer cell proliferation and promote apoptosis *in vitro*[27]. Butyrate administration in animal models of CRC has produced varying results[28]. Laminar delivery of butyrate reduced aberrant crypt foci (ACF) by 45% compared to untreated rats[29], while other studies have shown butyrate to be ineffective. The bacterial strain *Butyrivibrio fibrisolvens* MDT-1 has been investigated in the context of CRC treatment as it produces high amounts of butyrate[30]. In a mouse model of colon cancer, administration of MDT-1 led to a significant decrease in ACF, and the number of mice with an increased proportion of ACF was also reduced, indicating an inhibited progression of tumour development. MDT-1 also reduced β-glucuronidase activity and increased the immune response, indicated by an increase in NK cell numbers. Similar effects have been observed in the propionate and acetate producing probiotic, *Propionibacterium acidipropionici*[31]. It has been suggested that short chain fatty acid delivery *via* probiotic ingestion may be an exciting new treatment option for CRC[32].

Production of anti-tumorigenic or anti-mutagenic compounds

It has been suggested that lactic acid bacteria or a soluble compound produced by the bacteria may interact directly with tumor cells in culture and inhibit their growth[33]. In a study, lactic acid bacteria significantly reduced the growth and viability of the human colon cancer cell line HT-29 in culture and dipeptyl peptidase Ⅳ and brush-border enzymes were increased[34], suggesting that these cells might have entered a differentiation process. In another study, milk fermented with *B. infantis*, *B. bifidum*, *B. animalis*, *L. acidophilus* and *L. paracasei* inhibited the growth of the MCF7 breast cancer cell line, with their anti-proliferative effect not being related to the presence of the bacteria[35]. On these grounds, the presence of a soluble compounds produced by lactic acid bacteria during milk fermentation has been suggested.

Elevation of the host's immune response

One explanation for tumor suppression by probiotics is the enhancement of the host's immune response. In 1985 it was suggested by Sekine *et al*[36] that *B. infantis* stimulates the host-mediated response, leading to tumor suppression or regression. There are many studies that suggest that lactic acid bacteria play an important role and function in the host's immunoprotective system by increasing various mechanisms to have an anti-tumor effect. *L. casei Shirota* has been shown to have anti-tumor and anti-metastatic effects on transplantable tumor cells, to suppress chemically induced carcinogenesis in rodents and to induce the production of several cytokines, such as interferon-γ, IL-1β and TNF-α which resulted in the inhibition of tumor growth and the increased survival of tumor bearing mice[37]. Similar results have been reported recently for strains of *L. acidophilus SNUL*, *L. casei* YIT9029 and *B. longum* HY8001[38]. Sun *et al*[39] demonstrated *in vivo* that peptidoglycan from a lactobacillus species was able to dose-dependently reduce the growth of CT26 colon cancer cells in BALB/c mice *via* an increased level of apoptosis. Interestingly, peptidoglycan had no effect on tumor cell apoptosis *in vitro*, implying that the *in vivo* anti-tumorigenic effect may have been mediated by the immune response. In addition to that, recent studies have shown probiotics to be effective against Caco-2 colonic adenocarcinoma[40], but also against a breast cancer cell line[41], suggesting that probiotic therapeutic interventions may not necessarily be restricted to cancers affecting the gastrointestinal system.

Effects on the host's physiology

The ileal mucosa as well as the colonic mucosa has the capacity to absorb mutagenic compounds from the intestinal lumen, which are then passed into the bloodstream. Lactic acid bacteria have been shown to increase colonic NADPH-cytochrome P-450 reductase activity[42] and glutathione S-transferase levels[43] and to reduce hepatic uridine diphosphoglucuronyl-transferase activity[19], enzymes which are involved in the metabolism of carcinogens in rats.

PREBIOTICS AND COLORECTAL CANCER

Prebiotics have also been linked to the reduction of CRC. Friedenreich *et al*[44] concluded in a meta-analysis that the consumption of over 27 g of fiber per day

resulted in a 50% reduction in CRC compared to consumption of less than 11 g. Inulin-type fructans present in foods such as garlic, onion, artichoke and asparagus have been demonstrated to elevate the levels of bifidobacteria and to increase SCFA concentrations in the intestinal lumen. Inulin and oligofructose have been demonstrated to reduce the severity of 1,2-dimethylhydrazine induced colon cancer in rats[45]. A further study demonstrated the capacity for the prebiotic resistant starch type-3 Novelose 330, to reduce the incidence of colon carcinogenesis *via* induced apoptosis of damaged cells in rats[46]. This effect was attributed to the increased production of butyrate. In another study, the consumption of modified arabinoxylan rice bran was able to enhance the activity of NK cells and the binding of NK cells to tumor cells[47]. This demonstrates the ability of prebiotics to enhance the hosts' immune response.

SYNBIOTICS AND COLORECTAL CANCER

The combinations of pro- and prebiotics have a synergistic effect, greater than that of either the pro- or prebiotic administered individually. Rowland *et al*[48] reported that the combination of inulin and *B. longum* was more successful at decreasing azoxymethane-induced ACF than either treatment alone. Another study demonstrated that the consumption of *B. lactis* and resistant starch was able to increase the apoptotic response to azoxymethane in rats, and this was suggested to be due to the resistant starch acting as a metabolic substrate to provide optimal activity of the probiotic species[49]. Roller *et al*[50], demonstrated that synbiotic treatment prevented azoxymethane-induced suppression of NK-cell activity in Peyer's patches, an effect not observed in the individual pro- and prebiotic treatments. These studies suggest that synbiotics may have a role in CRC treatment.

CONCLUSION

Overall, studies *in vitro* systems and in a wide range of animal models provide considerable evidence that probiotics, prebiotics and synbiotics exert anti-neoplastic effects. Their consumption may be beneficial in preventing the onset of cancer, but also in the treatment of existing tumors. However, evidence from human studies is still limited. Many researchers have pointed out the need for carefully designed human clinical trials. Furthermore, research is required to identify the probiotic, prebiotic or synbiotic combination that will be more effective for humans. It is very likely that there will not be an ideal treatment for all cases, but the treatment will depend on the individuals' unique intestinal flora composition. New options are given through the genetic manipulation of probiotics, designed to act as a delivery system for anti-neoplastic factors in the colon. Although this field of study is promising and exciting, this enthusiasm should be tempered by the fact that we are likely many years away from determining how to use these agents and their ultimate role may remain quite limited. However, it is safe to conclude that pro-, pre- and synbiotics hold great potential as a new strategy for the prevention and treatment of colorectal cancer.

Abstract

Cholangiocarcinoma (CC) is a devastating cancer arising from biliary epithelia. Unfortunately, the incidence of this disease is increasing in Western countries. These tumors progress insidiously, and liver failure, biliary sepsis, malnutrition and cancer cachexia are general modes of death associated with this disease. To date, no established therapy for advanced disease has been established or validated. However, our knowledge in tumor biology is increasing dramatically and new drugs are under investigation for treatment of this notorious tumor. In clinical practice, there are better diagnostic tools in use to facilitate an earlier diagnosis of CC, at least in those patients with known risk factors. CC is resectable for cure in only a small percentage of patients. Preoperative staging for vascular and biliary extension of CC is very important in this tumor. Laparoscopy and recently endosonography seem to protect against unnecessary laparotomies in these patients. During the last 15 years, aggressive surgical approaches, including combined liver resections and vascular reconstructive surgical expertise, have improved survival in patients with CC. Surgery is contraindicated in CC cases having primary sclerosing cholangitis (PSC). Although CC was previously considered a contraindication to liver transplantation, new cautious protocols, including neo-adjuvant chemoradiation therapies and staging procedures before the transplantation, have made it possible to achieve long-term survival after liver transplantation in this disease. New ablative therapies with photodynamic therapy, intraductal high-intensity ultrasonography and chemotherapy-impregnated plastic biliary endoprosthesis are important steps in the palliative management of extrahepatic CCs. Radiofrequency and chemo-embolization methods are also applicable for intra-hepatic CCs as palliative modes of treatment. We need more prospective randomized controlled trials to evaluate the role of the new emerging therapies for CC patients.

INTRODUCTION

Cholangiocarcinoma (CC) is a malignant epithelial tumor of the biliary tree that accounts for approximately 10% to 15% of all hepatobiliary malignancies. CC mostly arises from the extra-hepatic biliary tree (50%-60% hilar CC, "Klatskin" tumors), spreads slowly and infiltrates periductal tissues. Hilar lesions are further subdivided based on location as indicated by Bismuth-Corlette classification (Figure 1). This form of CC characteristically presents with signs of ductal and vascular obliteration. Biliary tract sepsis, liver failure and/or cancer cachexia and malnutrition are the most important causes of death associated with these tumors[1]. The intra-hepatic form of CC appears as a mass lesion in the liver, which is mostly confused with metastatic tumor. These tumors usually progress insidiously, are difficult to diagnose and have grave prognosis. Unfortunately, the treatment alternatives are few. Effective surgery and other non-surgical treatment modalities for these patients with CC often fail due to characteristically late clinical presentation of this tumor.

Although our current understanding of tumor biology has far exceeded our past knowledge, the overall survival (including the resected patients) over the past 30 years is poor, with less than 5% of cases surviving for five years[1].

EPIDEMIOLOGY

Generally, CC is the second most common primary liver cancer after hepatocellular carcinoma (HCC) in most parts of the world. However, in some populations where HCC is uncommon, such as in Danish women, the prevalence of CC surpasses that of HCC[2]. Presentation is usually in the seventh decade in patients with CC, and it demonstrates slight male preponderance[3,4]. Fortunately, this tumor is a relatively rare kind of malignancy. In autopsy series, its prevalence is reported as around 0.01%-0.5%[5]. It represents 3% of all gastrointestinal system (GIS) cancers[6]. Of concern, some reports indicate that the incidence and mortality of intra-hepatic CC are increasing worldwide[7-9], while those of extra-hepatic CC are decreasing[7,8,10]. However, the increase in intra-hepatic CC is higher than the rate of decline in extra-hepatic CC. Whether this represents a real increase in this tumor or whether it can be attributed to better detection rates or changes in classification strategies is debatable. However, no increase has been noted in early stage or smaller-sized intra-hepatic CCs, perhaps indicating that these tumors are not better detected at present[11]. Thus, the underlying reason for the increasing incidence of intra-hepatic CC remains ambiguous.

RISK FACTORS AND PATHOPHYSIOLOGY

There are well-recognized risk factors for this tumor, such as congenital biliary anomalies, primary sclerosing cholangitis (PSC), hepatolithiasis, parasitic infections, chronic typhoid carriage, bile duct adenoma, biliary papillomatosis, drug exposure and genetic risks[12,13]. Chronic biliary inflammation is the common denominator in these conditions. An inflammatory milieu is believed to dysregulate or change the expression patterns of growth factors, pro-inflammatory cytokines and their receptors. Cytokines produced by cholangiocytes and activated macrophages can modulate gene expression and lead to activation of carcinogen metabolism. For example, interleukin (IL) -6 is a potent mitogen for cholangiocytes[14]. This cytokine can also induce nitric oxide (NO) synthase expression in cholangiocytes. NO can also directly injure the cellular DNA. Consumption of cellular detoxification and dysregulation of DNA repair and apoptosis are final steps of biliary carcinogenesis[5]. Bile acids also have been shown to activate inducible cyclo-oxygenase 2 and an anti-apoptotic molecule, myeloid cell leukemia protein 1 in cholangiocytes[15]. Thus, an inflammatory milieu and toxic bile constituents act together to promote carcinogenesis in the biliary tree. Histomorphological aspects in biliary carcinogenesis indicate that the intestinal metaplasia-dysplasia-carcinoma sequence can also be valid for CC[5].

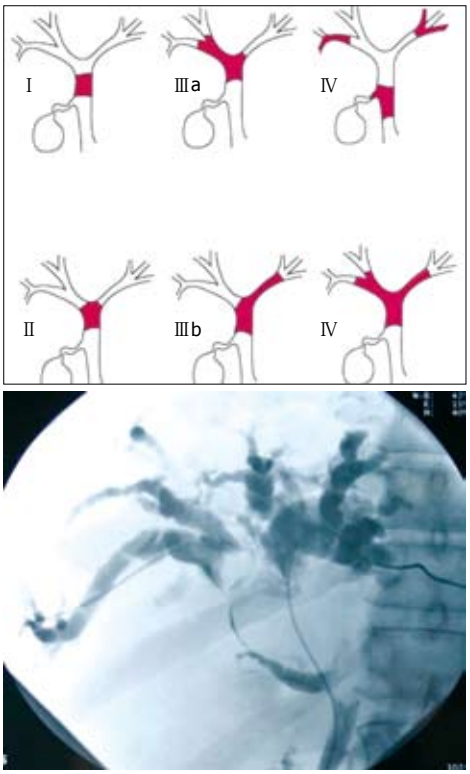

Figure 1 Hilar lesions are further subdivided based on location as indicated by Bismuth-Corlette classification. A: Bismuth-Corlette classification of hilar CC. Type Ⅰ involves the common hepatic duct, distal to the bifurcation of the biliary tree. Type Ⅱ affects the bifurcation. Type Ⅲa affects the right hepatic duct in addition to the bifurcation. Type IIIb affects the left hepatic duct in addition to the bifurcation. Type Ⅳ involves the bifurcation and both right and left hepatic ducts or indicates multifocal CC; B: Endoscopic retrograde cholangiography reveals hilar cholangiocarcinoma (Klatskin type 2) in one of our cases.

Congenital biliary cysts and pancreaticobiliary malfunction together have been obviously linked to biliary carcinogenesis, as both were present in 90% of cases in a reported clinical series[16]. Mixture of bile and pancreatic fluid due to impaired function of the Oddi sphincter induces chronic inflammation in the biliary tree with possible activation of carcinogenesis cascades.

PSC is one of the most common causes of CC in the Western world. As much as 42% of patients with PSC were reported to have CC in autopsy series[17]. Interestingly, the duration of PSC is not a risk factor for developing CC. Chronic inflammation and increased proliferation of biliary epithelium, along with increased production of endogenous mutagens in the bile, seemed to be related to carcinogenesis associated with PSC. Moreover, k-ras mutations were known to be common both in colon and biliary tree cancers in association with PSC[17].

Parasites such as *Opisthorchis viverrini* and *Clonorchis sinensis* have both direct strong carcinogenic effects and increase the susceptibility of cholangiocytes to endogenous and exogenous carcinogens. This is *via* chronic irritation and increased cellular turnover[18].

Hepatolithiasis leads to chronic proliferative cholangitis near to stone-bearing ducts and it has been reported in around 17.5% of patients with CC in some East Asian countries[19].

Chronic typhoid carriage and chronic cholangitis are representatives of chronic inflammatory conditions in the biliary tree and these conditions are accepted risk factors for developing CC.

Environmental toxins such as dioxin, and vinyl chloride, are known to be responsible for some cases of CC[20,21]. Thorotrast, which was used as a radiocontrast agent in the 1930s, is a potent carcinogenic agent for CC[22]. Nitrosamines, either taken exogenously or with tobacco use, or endogenously by nitrosation of nitrogenous compounds *via* NO, are potent carcinogens for biliary cancer[23,24].

Biliary papillomatosis, although a benign disease, has a moderately high malignant transformation rate[25]. Bile duct adenomas also carry appreciable risk for CC development[26].

Genetic polymorphisms in CYP1A2 and glutathione-S-transferase omega 1 and 2 have been related with this tumor[27]. These polymorphisms are believed to influence environmentally toxic substances, such as asbestos or dioxin.

A follow-up study of more than 1000 patients indicated late development of CC after biliary enteric diversion operations for benign biliary diseases[28,29].

Indeed, the majority of CC cases do not have these classic risk factors. Recently, a report from the United States included chronic viral hepatitis, cirrhosis and alcohol use among the risk factors for development of CC in elderly patients[30].

Obesity, moreover, was implicated as a risk factor for CC in a Korean study[1].

ROLE OF CLINICS AND LABORATORY TESTS IN DIAGNOSTIC EVALUATION

Extra-hepatic CC presents with classic signs of cholestasis including jaundice, dark urine, pale stools, pruritus, malaise and weight loss. Laboratory investigations reveal increased alkaline phosphatase, gamma-glutamyl transpeptidase and bilirubin. Prolonged obstruction of the main bile ducts can cause increased prothrombin time and a reduction in fat soluble vitamins. As the disease advances further, albumin, hemoglobin and lactate dehydrogenase can decrease. A glycoprotein tumor marker, CA 19-9, can be found elevated in 85% of such cases. A value of > 100 U/mL in PSC patients has a sensitivity of 89% and specificity of 86% for the diagnosis of CC. CC should not be diagnosed only on the basis of elevated CA 19-9. However, in patients without PSC, the sensitivity of CA 19-9 > 100 U/mL is 53%[31,32]. CEA is elevated in 30% of cases, while CA 125 is elevated in 40%-50% of patients with CC. CEA and CA 125 are also non-specific markers. A high index of suspicion is necessary to diagnose perihilar and extra-hepatic CCs because of other possible alternatives, including benign strictures, metastatic lymph nodes and/or gall bladder cancer. This is also true for PSC patients having dominant strictures. The confirmation of CC in these patients is quite challenging. Nevertheless, recent advances, especially in cytodiagnostic techniques, have contributed to establishing a correct diagnosis in nearly 80% of such cases.

Intra-hepatic CCs present mostly with non-specific symptoms, such as abdominal pain, weight loss, malaise and decreased appetite. Occasionally, an incidental abdominal mass detected during physical examination or radiologic evaluation is the single finding. Mildly elevated alkaline phosphatase and normal bilirubin levels are noticed on laboratory testing. CA 19-9 can also be found increased. These tumors are generally confused with metastatic adenocarcinomas. Indeed, a liver mass with adenocarcinoma histology, without an obvious primary source, should be seriously considered as intra-hepatic CC. A needle biopsy of the dominant liver mass is a straightforward diagnostic approach in these patients. Exclusion of another primary source can usually be accomplished by systemic physical examinations, chest X-ray, and tomography of the abdomen and pelvis.

Ultrasound is usually the first choice during investigation to visualize the location and extent of disease. Sonography can classify intra-hepatic CC as mass lesions. Contrast enhanced helical computerized tomography (CT) is very sensitive for detecting intra-hepatic CC larger than 1 cm. CT can also locate the site of obstruction and the presence of lymphadenopathy[33,34]. CT angiography can also detect vascular encasement[35]. Helical CT is only 60% correct in determining resectability. Although the experience with CT cholangiography is limited, this technique has been reported to be superior to conventional spiral CT examination. Ninety-four percent diagnostic accuracy has been noted for the diagnosis of malignant biliary lesions with CT cholangiography[36]. Magnetic resonance imaging (MRI) with MR Cholangiopancreatography (MRCP) has mostly replaced CT in diagnosis and staging evaluation of CC[37-39]. MR investigations can detect the site and extent of tumor involvement in the absence of PSC. MR angiography can show vascular involvement in these cases[40]. Thus, MRI studies have the advantage of showing vascular anatomy, cross-sectional imaging of the liver and cholangiography with a single technique and may exemplify an optimal imaging technique for this disease. However, in one study, MR cholangiography was reported to under-stage malignant hilar strictures in as high as 20% of patients[41]. Endosonography (EUS) is the most recent addition to the list of imaging modalities in diagnosis and staging of CCs[42]. EUS-guided fine needle aspiration (FNA) of hilar lymph nodes can be very important for staging procedure in CCs. EUS with FNA can diagnose Klatskin cases with 89% diagnostic accuracy even in the presence of negative brush cytology[43]. This technique does not induce contamination of the biliary tree, which can easily occur with endoscopic retrograde cholangiography (ERC). However, the hazard with this technique has been indicated as peritoneal tumor seeding[43]. Though a normal positron emission tomography (PET) scan with (18F)-fluorodeoxyglucose (FDG) can not exclude cancer and false-positives are highly common due to inflammatory conditions, PET may be useful for detecting metastatic disease[44]. FDG-PET/CT combination in detecting

Table 1 Memorial Sloan Kettering T stage for hilar CC

Stage	Criteria
T1	Tumor involving biliary confluence ± unilateral extension to second-order biliary radicals
T2	T1 ± ipsilateral portal vein involvement ± ipsilateral hepatic lobar atrophy
T3	Tumor involving biliary confluence + bilateral extension to second-order biliary radicals; or unilateral extension to second-order biliary radicals with contralateral portal vein involvement; or unilateral extension to second-order radicals with contralateral hepatic lobar atrophy; or main or bilateral portal vein involvement

Klatskin tumors was highly recommended in such patients[45].

Other methods to depict the biliary tree are ERC and percutaneous transhepatic cholangiography. These techniques allow visualization of a very detailed topography of the biliary tree. ERC is one of the main tools in the diagnosis of CCs. It can easily detect a stenosing tumor along the bile ducts. Unfortunately, both techniques carry a risk of bacterial cholangitis, a rather common complication after ERC. Using these techniques, brush cytology can provide cell samples to analyze and diagnose the biliary tract malignancy. Unfortunately, brush cytology has been reported to carry a very low diagnostic yield, ranging from 9%-24%. This was reported to be independent of the quantity of the specimen cellularity[46]. New technologies, such as the use of fluorescence *in situ* hybridization and digital image analysis methods, were reported to be more sensitive than the routine cytology. In one study, these technologies doubled the diagnostic accuracy of brush cytology[47]. The combined use of cholangioscopy improved the diagnostic yield of ERC for CCs. Cholangioscopy can detect the tumor vessel and improve diagnostic potential of direct cholangiographic examination[48]. Intraductal ultrasonography has also been reported to increase diagnostic accuracy of direct cholangiography[49].

OTHER POSSIBLE DIAGNOSES

Most patients with hilar stenosis and jaundice have CC. On the other hand, 10%-15% of cases had alternative diagnoses, including gall bladder carcinoma, Mirizzi syndrome and benign focal stenosis. The thickened and irregular gall bladder wall, infiltration to the right portal vein origin and liver segments 4 and 5, and occlusion of the common hepatic and cystic ducts suggest the presence of gall bladder cancer. Mirizzi syndrome results from periductal inflammation and fibrosis due to a large gall stone impacted at the neck of the gall bladder. Benign focal strictures involving the hilar region are uncommon. Other causes of the strictures affecting the whole biliary tree and benign in nature are postoperative strictures, chronic infectious cholangitis due to gall stones and flukes, ischemic cholangiopathy, chemoradiotherapy, vasculitis, human immunodeficiency virus cholangiopathy, infections such as tuberculosis and histoplasmosis, bile duct varices, papillary stenosis, and sphincter of Oddi dysfunction[50]. These strictures, though benign in nature, can masquerade malignancy on ERC as they may give a "pseudocholangiocarcinoma sign", which is sometimes difficult to differentiate from a true sign of CC. This sign was first reported by some authors in a patient with bile duct varices due to portal vein thrombosis and portal cavernomatous transformation[51].

STAGING AND TREATMENT MODALITIES

Resection and/or liver transplantation are the only curative options for CC. Accurate preoperative staging will determine the treatment approach in these patients. Although a pathologic staging system has been developed for ductal CC, it has a limited value in clinically assessing extra-hepatic CC. TNM classification does not correlate with resectability in patients with extra-hepatic CC. Conversely, the Memorial Sloan-Kettering staging system evaluates the biliary and vascular involvement of these tumors and clearly correlates with resectability and survival (Table 1). Indeed, clinical staging has three important points in presurgical evaluation of these cases. The first is the determination of proximal and distal extent of the disease. The second and third goals are to assess vascular involvement and the presence of metastasis, which can be done by Doppler ultrasound or MRI, CT and EUS examinations. FDG-PET scanning changes the surgical management in a third of patients, with an overall sensitivity for metastasis in 65%. FDG-PET has high false positivity in PSC patients and patients with biliary stents[52]. Laparoscopy for staging improved overall accuracy in choosing the optimal management formula in these cases. In one study, laparoscopy prevented unnecessary laparotomies in 42% of cases[53].

Surgery is the most suitable option for patients with intra-hepatic CC. With curative surgery, three-year survival rates have been reported to be approximately 40%-60%[54]. Surgery performed with curative intents is the best option for hilar and other extra-hepatic ductal CC cases without PSC. Surgery in patients with positive margins show no better results than with palliative therapies[54]. To obtain tumor-free margins, partial liver resections are often necessary. The liver resection has a great impact on obtaining negative margins in patients undergoing a potentially curative resection for hilar CC (Table 2)[55-60]. A combined data from United States and European experiences proved that five-year survival is higher in patients undergoing liver resection than in those not[61]. An analysis of recent surgical series indicated that five-year survival data is around 40% (Table 3)[62-66]. Most surgeons advocate caudate lobe resections, as the drainage of hilar biliary structures is directly

into the caudate lobe bile ducts. In cases with involvement of the distal common bile duct, pancreatoduodenectomy is performed additionally to obtain negative margins. In patients with tumor-free margins after surgery, five-year survival is around 20%-40% and operative mortality 10%[54]. The presence of one of the following indicates unresectability: Bilateral involvement of secondary biliary radicals, invasion of the main portal vein proximal to its bifurcation, unilateral hepatic lobar atrophy together with invasion of contralateral portal vein and/or contralateral secondary biliary radicals, and metastatic involvement of N2 lymph nodes, liver, lung or peritoneum. Indeed, the invasion of the main portal vein may not be an absolute contraindication to surgery as surgeons can prefer to extend their surgical expertise by portal vein resection and its reconstruction in such cases. Though the significance of biliary drainage before surgery is controversial, preoperative biliary drainage of the obstructed lobe *via* percutaneous or endoscopic methods in hilar CCs is generally not indicated. Postoperative morbidity in such cases mostly arises from the introduction of bacteria into the biliary tree *via* preoperatively placed stents. Usually, drainage of the contralateral lobe, free of tumor, is preferred by most surgeons if the involved liver lobe is to be resected and there is deep jaundice. Some authors have shown that lack of intestinal bile delays liver regeneration associated with cyclin E-associated kinase inactivation after surgery[67].

In patients with PSC and CCs, surgery has the worst results. Five-year postoperative survival in these cases has been reported as low as 10%[17,68]. Postoperative recurrent cholangitis attacks, intolerance of partial hepatectomy, due to concomitant advanced fibrosis and high risks of *de nova* CC elsewhere in the biliary tree, are the main obstacles precluding surgery in PSC cases with CCs[69,70]. Thus, liver transplantation can be an alternative option in these cases.

Previously, CC was considered a contraindication for liver transplantation. However, three centers from the United States reported long-term survival following liver transplantation[71-73]. The Mayo Clinic reports five-year survival rates of more than 80% for patients with TNM stage 1 and 2 disease after liver transplantation[72]. The liver transplant protocols in these cases include preoperative chemo-irradiation therapy and exploratory laparotomy. Thus, longer survival expectations for CC cases can be possible with these new fastidious liver transplantation protocols. A recent study compared two treatment modalities, liver transplantation with neoadjuvant protocols and resection surgery, in extrahepatic CC cases. Five-year survival rates were 82% for 38 patients who underwent liver transplantation and 21% for 26 cases who were resected[74]. Adjuvant treatment modalities such as external beam and intraluminal radiation therapies showed no benefit in two separate reports from Johns Hopkins[75,76]. There is currently no role for adjuvant chemotherapy. However, another study revealed positive effects of radiation therapy on survival in histologically positive tumor margin[76]. Similarly, one study demonstrated higher resectability in patients given neoadjuvant radiation therapy before exploration[76]. However, these studies were non-randomized and most consisted of small patient groups.

In patients with unresectable disease, the initial approach is to provide the patient with supportive care and, if necessary, to plan some form of biliary drainage. Palliative therapies provide less than 18 mo of survival. Intractable pruritus, cholangitis, and need for intraluminal radiotherapy and chemotherapy make it necessary to decompress the biliary tree. The patients with unresectable hilar tumors may not be suitable for an endoscopic approach, due to high failure rates and subsequent cholangitis with this technique. However, there are new metal stent designs for the biliary tree that can provide high success rates of endoscopic insertion without complications. For example, a newly designed Y-shaped metal stent with central wide-open mesh provided 80% technical success in bilateral stent insertion for advanced hilar CCs[77]. Percutaneous biliary drainage and subsequent placement of a self-expandable metallic stent can also be easily and successfully applied in patients with hilar tumors. The patency rates of metallic endoprosthesis at the hilus is approximately 6 mo, which is significantly lower than that reported for similar stents placed in the

distal bile duct. A small pilot study investigated the role of a new percutaneous drainage tube coated with carboplatin[78]. The carboplatin-coated tube continuously released a fixed amount of carboplatin for 4 wk in five patients. Partial response was reported in three (60%) of the cases. Operative segment Ⅲ bypass provides excellent biliary drainage and is less prone to occlusion than metal stents. In one study, the one-year patency of segment 3 bypass was reported to be 80%[79].

Palliative external radiation therapy and percutaneous intraluminal iridium-192 for patients with unresectable locally advanced tumors, but without evidence of widespread disease, did not improve survival compared with biliary decompression[75,80-84]. In a group of 12 patients treated with this regimen, the median survival was around 14.5 mo[80]. Another report indicated improved survival in irradiated compared to non-irradiated patients. However, both groups had less than one-year survival[75]. A group of authors reported a beneficial effect of radiotherapy only in patients with aneuploid Klatskin tumors[85]. Radiation therapy is clearly not indicated in widespread disease. Successful ablation of intra-hepatic CC cases with radiofrequency ablative therapy was reported previously[86]. Photodynamic therapy is another palliative approach. This therapy is accomplished by the systemic administration of a photosensitizer that accumulates in the malignant cells. Red laser light-induced photoactivation at the time of ERC destroys the malignant cells. This therapy facilitates biliary decompression, and pilot studies have suggested a survival benefit and improvement in cholestasis, performance status and quality of life with this approach[87-90]. Another palliative treatment option is endoscopic administration of high-intensity ultrasound to induce coagulative necrosis of tumoral tissue. Local tumor destruction, with a high-intensity ultrasound probe during ERC, has been reported to induce complete regression of extra-hepatic CC in a pilot study[91]. For mass-forming tumors, transarterial chemoembolization or radiofrequency ablation may be useful. However, these therapies have been tested in small patient groups. Results with chemotherapy appear to be disappointing. Gemcitabine appears to be the most effective single agent[92]. Systemic chemotherapy combined with regional chemoembolization was proven feasible in a small group of patients[93]. New promising drugs are under investigation for their anti-tumoral effects on CCs. A very recent *in vitro* study clearly indicated a high apoptotic effect of proteasome inhibitors on CC cell lines[94].

CONCLUSION

CC is a devastating tumor with a high mortality rate. Its incidence is increasing and there is no new proven medical treatment modality. It is notorious as being difficult to diagnose as well as treat. Strategies are needed to detect these tumors at an early stage to apply radical curative therapy modalities. EUS-guided FNA is the most promising approach in this respect. Liver transplantation protocols must be supported, as necessitated by the recent reports of success using these protocols. Investigations of neoadjuvant and adjuvant treatment alternatives should continue and new *in vitro* effective anti-tumoral agents should be investigated in *in vivo* studies.

Abstract

The main goals of treating cirrhotic patients with antiviral therapy are to attain sustained viral clearance (SVR), halt disease progression, and prevent re-infection of the liver graft. However, while the medical need is great, the use of interferon and ribavirin might expose these patients to severe treated-related side effects as a large proportion of them have pre-existing hematological cytopenias. We have reviewed potential benefits and risks associated with antiviral drugs in patients with liver cirrhosis, due to hepatitis C virus (HCV) infection. In cases presenting with bridging fibrosis or cirrhosis, current regimens of antiviral therapy have attained a 44%-48% rate of SVR. In cirrhotic patients with portal hypertension, the SVR rate was 22% overall, 12.5% in patients with genotype 1, and 66.7% in those with genotypes 2 and 3 following therapy with low doses of either Peg-IFN alpha-2b and of ribavirin. In patients with decompensated cirrhosis, full dosages of Peg-IFN alpha-2b and of ribavirin produced a SVR rate of 35% overall, 16% in patients with genotype 1 and 4, and 59% in those with genotype 2 and 3. Use of hematological cytokines will either ensure full course of treatment to be accomplished with and prevent development of treatment-associated side effects. Major benefits after HCV eradication were partial recovery of liver metabolic activity, prevention of hepatitis C recurrence after transplantation, and removal of some patients from the waiting list for liver transplant. Several observations highlighted that therapy is inadvisable for individuals with poor hepatic reserve (Child-Pugh-Turcotte score $\geqslant$ 10). Although SVR rates are low in decompensated cirrhotics due to hepatitis C, these patients have the most to gain as successful antiviral therapy is potentially lifesaving.

INTRODUCTION

Extensive fibrotic deposition in advanced hepatitis C virus (HCV) liver disease is the histopathological hallmark of a chronic necro-inflammatory process that involves parenchymal cells. Progressive derangement of normal liver architecture correlates with a reduction in liver synthetic function and brings to its late clinical expressions of decompensation, such as intractable ascites, hepatic synthetic failure, encephalopathy, jaundice, variceal bleeding, and hepatocellular carcinoma. Once cirrhosis is present, the process is generally considered as irreversible and predisposing to high mortality risk with a survival rate of 50% at 5 years[1]. A mathematical model of the natural history of chronic hepatitis C projected number of cases with cirrhosis to increase by more than 50% by 2010[2]. As a result, there will be a dramatic increase in the number of cases with complications of liver failure throughout the next three decades.

Once decompensation complicates liver cirrhosis, liver transplantation is the only successful therapeutic option. However, the limited number of organ donors as well as impairment in age-related cardiovascular, renal, and pulmonary functions, renders this option unlikely for the majority of patients. In addition, age over 65 years is commonly considered as an exclusion criterion

to enlist patients for liver transplant. Exploring new therapeutic options to offer patients with HCV end-stage liver cirrhosis is a critical need, as cirrhotics who are never listed for liver transplant could still potentially benefit from non-surgical therapy.

In advanced liver cirrhosis, antiviral therapy is currently not recommended despite the fact that theoretical benefits of treating HCV-related patients with or without decompensated cirrhosis would be an improvement in liver histology, reversal of established cirrhosis, and prevention of life-threatening complications. Despite this, a large proportion of these patients have pre-existing neutropenia, thrombocytopenia, and anemia that will tend to worsen with the use of interferon and ribavirin, exposing them to potentially severe side effects. We will review this topic with the intent to highlight potential benefits and risks associated with antiviral therapy in patients with compensated and decompensated cirrhosis due to HCV infection.

HCV CIRRHOSIS IN COMPENSATED PHASE

Compensated cirrhosis is defined by the absence of clinical complications and presence of both preserved hepatic synthetic function and adequate bone marrow reserve. Post-hoc analyses of patients with bridging fibrosis or compensated cirrhosis included in two international, registrative trials on the efficacy of Peg-IFN and ribavirin, produced a 43% rate of sustained viral clearance (SVR) by 48 wk administration of once weekly Peg-IFN alpha 2a 180 μg plus ribavirin 1000-1200 mg/d[3]: a similar rate of 44% was seen in those treated with Peg-IFN alpha-2b 1.5 μg/kg weekly plus ribavirin 800 mg/d for 48 wk[4]. From previous trials, data on cirrhotic patients could not be retrieved separately from those with bridging fibrosis, so that exact figures of SVR rate in cirrhotics remain to be determined. Moreover, cirrhotics enrolled in these studies were commonly in a Child-Pugh-Turcotte (CPT) class A, had as a rule a compensated disease, and slightly abnormal hematological parameters; moreover, no information was usually given on the degree of portal hypertension.

The first study proving the benefits of antiviral therapy in cirrhotics with signs of portal hypertension, a subset of patients with more advanced cirrhosis than the cohort of cirrhotics enrolled in registrative trials, was the one published by Di Marco *et al*[5]. In the study, a branch of 51 cirrhotics received 1 μg/kg per week of Pegylated-interferon alpha-2b plus oral ribavirin at a fixed dose of 800 mg/d for 52 wk. By intention-to-treat analysis, a sustained virologic response (SVR) was achieved by 11 patients (21.6%), with a therapeutical efficacy poorest in those infected with genotype 1 and 4 (6 of 45, 13.3%) than in those with genotypes 2 and 3 (5 of 6, 83.3%). All responders achieved negative HCV-RNA during the first 12 wk of treatment, and no subject still positive at this time evaluation became negative later despite continued treatment. The median WBC count decreased from baseline, particularly during the first two months of treatment. Five patients stopped PEG-IFN due to neutrophil counts $< 0.75 \times 10^3$/dL, but none of them developed infections. Cumulative incidence of events was significantly higher in patients without an SVR: disease deterioration occurred only in 6% of patients with SVR as compared to 38% of non-responders. This study established the effectiveness of antiviral therapy in the subgroup of patients with severe portal hypertension, although it must be emphasized that entry criteria for the trial excluded patients with clinical, biochemical, or hematological decompensation of the liver disease.

Safety of combination therapy in cirrhotics is a major concern. Bone marrow suppression by administration of both standard or Peg-IFN-alpha leads to significant decrease in all 3 lineages of the hematopoietic system, whereas anemia through haemolysis is more a sequela of ribavirin therapy[6]. Absolute neutrophil and lymphocyte counts typically decrease by 30% to 50% of baseline values during therapy[7]. In a recent analysis of patients treated at a single referral center, where basal neutropenia was not an exclusion criterion, therapy was safely accomplished despite decreases in neutrophils below the usual levels that lead to dose reduction or drug interruption[8]. No patients who developed infections had a pre-existing neutropenia (below 1500 cells/mL), and none developed neutropenia of less than 750 cells/mL at any point during treatment. Although the use of interferon in cirrhotics with neutropenia is usually not recommended, there is no evidence, up to now, of a significantly higher risk of severe infections or death correlated with interferon therapy in cirrhotics, a concern supported by the studies of Heathcote and Di Marco, where none of the cirrhotics with interferon-induced neutropenia of less than 750 cells/mL developed serious infection or sepsis[4,5].

It is currently recommended that development of leucopenia during antiviral therapy, an event that develops in 15%-20% of cases[9], to be managed by modification or withdrawal of drugs. This recommendation may potentially affect achieving an SVR, being the therapeutic outcome dependent on both dose and duration of currently administered drugs[10]. Hematopoietic cytokines, such as granulocyte colony-stimulating factor (G-CSF), at the weekly dosage of 300 μg, can reverse neutropenia, enabling patients to remain on full dosage and duration of therapy[11,12]. However, G-CSF is prescribed less frequently than erythropoietin, likely for two reasons: First, ribavirin-induced anaemia is more common than IFN-induced neutropenia and, secondly, practitioners are probably less responsive to neutropenia than to anaemia being the latter more often symptomatic than neutropenia. As regards to chronic hepatitis C, no official guidelines have been set for the use of G-CSF, probably because of the absence of firm data of the benefit of the cytokine administration in increasing SVR while reducing infections.

Treatment of HCV-infected patients induces hemoglobin drop in the majority of patients[13]. The anemia is of "mixed" type: Ribavirin induces a dose-dependent hemolytic anaemia, whereas IFN alpha suppresses eryth-

roid progenitor cell and red blood cell production[7]. The mean maximal hemoglobin decrease, reached within the first 12 wk of therapy, is a relevant point as a reduction in ribavirin dosage in the initial 12 wk of therapy below 80% of the starting dose lowers the chance of early virologic response (EVR)[14] and compromise treatment success[15,16]. The management of anemia recommends ribavirin dose reduction untill 600 mg/d if hemoglobin decreases to < 10 g/dL in a patient without cardiac risk factors, and discontinuation of ribavirin if hemoglobin becomes < 8.5 g/dL[17]. A decrease in hemoglobin levels is normally accompanied by an increase in the serum erythropoietin (sEPO) level, an endogenous hormone that acts in the bone marrow to increase the number of erythroid progenitor cells[18], which will ultimately normalize the hemoglobin level[19]. In HCV-infected patients treated with PEG-IFN/RBV, although increased levels of sEPO, the hemoglobin level did not return to normal, suggesting that the physiological increase in sEPO is not sufficient to fully compensate for the degree of anemia. Administration of recombinant human erythropoietin at a dosage of 40 to 60 U once weekly, may constitute an alternative: 88% of patients receiving erythropoietin *versus* 60% of controls could maintain the assigned ribavirin doses[20].

Several lines of evidence have supported the hypothesis that the fibrotic component of cirrhosis is a reversible process[21-26]. SVR is the "sine qua non" to pursue histological benefits[27] and has been associated with a mean reduction in fibrosis score of -0.88 ± 0.08 U/year at 3 years of follow up[22]. Resolution of cirrhosis, defined as a decrease of the fibrotic score from 4 to 1 by Knodell index, was observed in 9 of 109 cirrhotic patients (8.2%), with a delay between pre- and post-therapy biopsies of 4.0 ± 2.3 years[21]. The most striking result of a post hoc analysis[25] of 4 major clinical trials involving 3010 patients randomized to various treatment regimens was the reversal of fibrosis at different extent after therapy in 75 out of 153 patients with cirrhosis (49%). These observations provide evidence for major beneficial effects of antiviral therapy on cumulative probabilities of disease progression, development of HCC, and death or liver transplantation in patients attaining an SVR[28].

HCV CIRRHOSIS IN DECOMPENSATED PHASE

Antiviral therapy is commonly deferred in cirrhotics with signs of liver decompensation, due to even more compelling concerns over treatment-induced side effects. Along with the progression of liver disease, a reduction in the capability to remove endotoxin and bacteria from the bloodstream, due an acquired immunodeficiency state, is observed in these patients[29]. However, the majority of cirrhotics with HCV infection have reasonably stable hepatic function after a successful treatment of a decompensated event and, therefore, might be suitable candidates for antiviral therapy. It seems conceivable that tolerance of antiviral therapy in this particular setting of patients might be extremely poor due to their advanced age, as adherence to combination therapy is negatively influenced by increasing patient's age[30]. In addition, impaired age-related cardiovascular and pulmonary functions may reduce tolerance of ribavirin-induced anemia, while impaired renal function by increasing blood levels of ribavirin (primarily cleared by kidney) may worsen anemia. Finally, insulin resistance secondary to HCV infection may further impair response to combination therapy[31].

Several reports on antiviral therapy in HCV-infected cirrhotic patients who sustained one or more episodes of liver decompensation are available in the literature[32-36] (Table 1): The results indicate that these patients might tolerate current antiviral regimens. However, unstandardized dosages of antiviral drugs that have been administered for a variable and different treatment length may have underestimated and differentiated outcomes and virologic response rates in previous reports. After reviewing existing experience, the International Liver Transplantation Society Expert

Table 2 Suggested guidelines for the use of interferon-based therapy in patients with cirrhosis (International liver transplantation society expert panel, 2003)

Consider treatment	CTP score	MELD score
Strongly consider	⩽ 7	⩽ 18
Possibly consider	8-11	18-25
No, avoid treatment	> 11	> 25

Panel issued guidelines, in 2003, for the use of interferon-based therapy in patients with cirrhosis, strongly considering therapy in those with a CTP score ⩽ 7, and possibly in those with a score of 8 to 11 (Table 2). In the low-accelerating dosage regimen, starting doses were 1.5 MU thrice weekly for conventional interferon, 0.5 μg/kg per week for Peg-IFN alpha 2b, or 90 μg/wk for Peg-IFN alpha 2a, given alone or in combination with a ribavirin dose of 400 mg/dL[32]. Dose adjustments for each of the two drugs were made every 2 wk as tolerated to achieve optimal effective doses. Using an initially low, accelerating regimen of non-pegylated interferon plus ribavirin, 39% of 102 patients experienced clearance of HCV-RNA on treatment, and 21% attained an SVR, 11% with genotype 1, and 50% with genotypes 2 and 3[36]. Moreover, of patients with SVR, none relapsed after liver transplantation[37]. By including Peg-IFNs, further improvement in efficacy can be expected. In our initial investigation, Peg-IFN alpha 2b (1.0 μg/kg) plus standard dose of ribavirin were administered for a short treatment duration (24 wk for all genotypes) to decompensated cirrhotic patients[33]: The overall SVR rate attained with this suboptimal regimen of therapy amounted to 19.7% (13 of 66 treated cases), higher efficacy (43.5% of SVR) being found in genotype 2 and 3 infection than in genotype 1 and 4 (7%). Therapy was tolerated by patients, at a remarkable exception of individuals with very advanced liver disease (CTP score > 10) who experienced severe life-threatening side effects.

Based on our initial investigation, we went further to determine whether currently recommended dosages of Peg-IFN and ribavirin for the standard length of treatment could be safely tolerated in decompensated cirrhotic patients. An ongoing protocol has been set up at our institution where all cirrhotic patients with a CTP score ⩽ 9 and a decompensated event that abated with common management are offered therapy with Peg-IFN alpha-2b (1.5 μg/kg) and ribavirin (800-1000 mg for genotypes 2 and 3, and 1000-1200 mg for genotypes 1 and 4) for the recommended treatment duration (48 and 24 wk for genotype 1 and non-1, respectively) (submitted, unpublished data). In this program, at the end of the 24 wk follow-up period off therapy, 35% of our end-staged cirrhotics cleared the HCV infection, 16% of patients with genotype 1 and 4, and 59% of patients with genotype 2 and 3. Almost 60% of patients tolerated full dosage and duration of treatment, whilst 18 (19.1%) patients discontinued treatment and among these 4 developed severe infections.

All previous reports have outlighted the feasibility of antiviral treatment of patients with a decompensated cirrhosis, allowed to further refine selection of these patients (treatment unsafe for CTP ⩾ 10), and established the relative safety of current schedules of treatment, providing that administration of cytokines could maintain safe levels of hemoglobin (> 10 g/dL) and of neutrophils (> 750/dL). Scant data are available on the impact of therapy on "long term" disease progression, avoidance of transplantation, and improvement of life expectancy. These hard clinical end points are particularly applicable to patients with advanced disease, as liver function is more likely to deteriorate within a few years in these subjects. Achieving HCV clearance has been clearly correlated with improved liver function, as apparent from significant reductions in CTP and MELD scores after treatment[33]. A standardized mortality rate analysis reported a lower liver-related mortality among cirrhotics with SVR (0.6: CI: 0.0-3.1) than in untreated patients[26]. Further benefits after HCV eradication and partial recovery of liver metabolic activity were no more allograft failure secondary to recurrence of viral infection[34], and eventually long term removal of those patients who cleared HCV-RNA from the waiting list for liver transplant. We have reported a significant improvement in overall and event-free survivals as well as in clinical status and laboratory profile of patients who eventually cleared HCV after treatment with Peg-IFN alpha-2b and ribavirin administered for 24 wk. During the follow-up, the total number of decompensated events was significantly higher in controls and non-responders as compared with patients who achieved a SVR.

CONCLUSION

The main goals of treating cirrhotic patients are to attain SVR, halt disease progression, and prevent re-infection of the liver graft. Antiviral therapy for patients with chronic hepatitis C and an advanced stage of compensated or decompensated liver cirrhosis, is evolving: If left untreated, cirrhosis due to chronic HCV infection, is associated with decreased survival, whereas current data from existing trials suggest a reduction in the complication for those with an SVR. As in patients with milder liver disease, standard schedules of treatment may be efficacious particularly for those harboring HCV genotype 2 and 3 infection, in which HCV-RNA is rendered negative during treatment in more than half of individuals. Conversely, the risk-benefit ratio of treating patients with genotype 1 infection remains to be defined. Liberal use of hematopoietic cytokines will either enable the recipient to tolerate full dosage and course of treatment and prevent development of treatment-associated infections. Therapy is inadvisable for individuals with poor hepatic reserve. Although response rates appear to be lower in cirrhotic patients with and without complications of liver disease, successful antiviral therapy is potentially lifesaving.

Abstract

AIM: To investigate the causal relationship between hypoadiponectinemia and colorectal carcinogenesis in *in vivo* experimental model, and to determine the contribution of adiponectin deficiency to colorectal cancer development and proliferation.

METHODS: We examined the influence of adiponectin deficiency on colorectal carcinogenesis induced by the administration of azoxymethane (AOM) (7.5 mg/kg, intraperitoneal injection once a week for 8 wk), by using adiponectin-knockout (KO) mice.

RESULTS: At 53 wk after the first AOM treatment, KO mice developed larger and histologically more progressive colorectal tumors with greater frequency compared with wild-type (WT) mice, although the tumor incidence was not different between WT and KO mice. KO mice showed increased cell proliferation of colorectal tumor cells, which correlated with the expression levels of cyclooxygenase-2 (COX-2) in the colorectal tumors. In addition, KO mice showed higher incidence and frequency of liver tumors after AOM treatment. Thirteen percent of WT mice developed liver tumors, and these WT mice had only a single tumor. In contrast, 50% of KO mice developed liver tumors, and 58% of these KO mice had multiple tumors.

CONCLUSION: Adiponectin deficiency enhances colorectal carcinogenesis and liver tumor formation induced by AOM in mice. This study strongly suggests that hypoadiponectinemia could be involved in the pathogenesis for colorectal cancer and liver tumor in human subjects.

INTRODUCTION

Obesity is a global medical problem because of its association with the development of various disorders such as diabetes, cardiovascular diseases, and several

cancers[1,2]. Recent studies have indicated that obesity is a significant risk factor for colorectal cancer[3], but the relationship between obesity and colorectal carcinogenesis is poorly understood at the molecular level.

Adipose tissue is currently recognized as an important endocrine organ that secretes various bioactive substances, conceptualized as adipokines or adipocytokines[1,2,4,5]. We and others identified adiponectin as an adipose-specific secretory factor[6-8]. Adiponectin exists abundantly in the circulation[9], and its plasma levels are reduced in obesity, type-2 diabetes, and coronary artery disease[9-11]. Recently, adiponectin has attracted much attention because of its potential role in the development and progression of various obesity-related malignancies[12]. Several clinical studies have shown that plasma adiponectin level is inversely associated with the risk of obesity-related cancers, including uterine, breast, gastric, and prostate cancers[13-16]. It has been reported that treatment with recombinant adiponectin significantly suppresses the growth of several types of cancer cells in cultured cells and/or in xenograft models by inhibiting cell proliferation[17-20].

Recent clinical studies have shown that low plasma adiponectin levels is an independent risk factor for colorectal cancer and its precursory adenoma[21-23]. Moreover, colorectal adenomas in patients with low plasma adiponectin levels tend to be larger and histologically more progressive[23]. However, the causal relationship between low plasma adiponectin levels and colorectal carcinogenesis has not been fully elucidated in *in vivo* experimental model.

Azoxymethane (AOM) is a well-characterized colon carcinogen, and AOM-induced colorectal cancer in rodents is similar to human colorectal cancer with respect to morphology, proliferation characteristics and involvement of gene mutation[24,25]. The present study was designed to explore the mechanisms of hypoadiponectinemia and colorectal carcinogenesis. For this purpose, we used AOM to induce colorectal cancer in adiponectin-knockout (KO) mice.

MATERIALS AND METHODS

Mice and experimental procedures

The animal care and use procedures were approved by the Animal Care Committee of Osaka Medical Center for Cancer and Cardiovascular Diseases. The generation of KO mice has been described previously[26]. We mated wild-type (WT) littermate mice produced by backcrossing to the C57BL/6J strain for five generations and used their offspring as WT controls in this study. Mice were maintained on a 12-h light/dark cycle with free access to drinking water and a standard diet. We injected 10-wk-old male mice with AOM (Sigma Chemical Co., St. Louis, MO) at a dose of 7.5 mg/kg body weight intraperitoneally once a week for 8 wk, and control mice received equal volume of saline injection (WT + saline, $n = 9$; WT + AOM, $n = 23$; KO + saline, $n = 13$; and KO + AOM, $n = 24$). The mice were sacrificed 53 wk after the first AOM injection, and the colons and small intestines were removed immediately. The harvested specimens were opened longitudinally, and the number and size of tumors were recorded. Using calipers, we measured the length (L), width (W), and depth (D) of each intestinal tumor and calculated the tumor volume using the formula $V = L \times W \times D \times \pi/6$, as described previously[27]. We also noted the development of liver tumors.

Histopathology and immunohistochemistry

Tumors were fixed in 10% buffered formalin, embedded in paraffin blocks, and sectioned at 3.0-μm thickness. Some sections of the colon tumors were subjected to hematoxylin and eosin (HE) staining for histopathology, and others were used for immunohistochemistry. proliferating cell nuclear antigen (PCNA) was visualized by staining with rat anti-mouse PCNA monoclonal antibody (Dakocytomation, Glostrup, Denmark). To determine the PCNA labeling index, we selected five representative PCNA-positive fields in each section, counted more than 200 tumor cells in each field, and then calculated the percentage of PCNA-positive cells. cyclooxygenase-2 (COX-2) was visualized by staining with rabbit anti-mouse COX-2 polyclonal antibody (Cayman, Ann Arbor, MI). We observed immunoreactive COX-2 expression in the periluminal stromal cells and epithelium of the colorectal tumors. Therefore, we evaluated COX-2 expression; both the intensity of immunoreactivity and the percentages of positively-stained areas in relation to the circumference of the tumor. We graded COX-2 expression of each immunostained section on a 0 to 4+ scale; no immunoreactivity (0), weak immunoreactivity and 1% to 25% positive regions (1+), mild immunoreactivity and 26% to 50% positive regions (2+), moderate immunoreactivity and 51% to 75% positive regions (3+), strong immunoreactivity and 76% to 100% positive regions (4+). We regarded a case displaying very weak immunoreactivity, or less than 1% positive regions, as negative. Sections of the liver tumors were subjected to HE staining for histopathology.

Statistical analysis

Results are expressed as mean ± SE. Statistical analyses of data were performed using the Student's t-test, the chi-square test, Fisher's exact probability test, Wilcoxon rank sum test, or the Spearman's rank correlation. Statistical significance was defined as $P < 0.05$.

RESULTS

Enhanced colorectal carcinogenesis induced by AOM in KO mice

We treated WT and KO mice with AOM at a dose of 7.5 mg/kg or with saline vehicle once a week for 8 wk. At 53 wk after the first AOM treatment, the mice were sacrificed to evaluate the development of colorectal tumors. Body weight changes did not differ between WT and KO

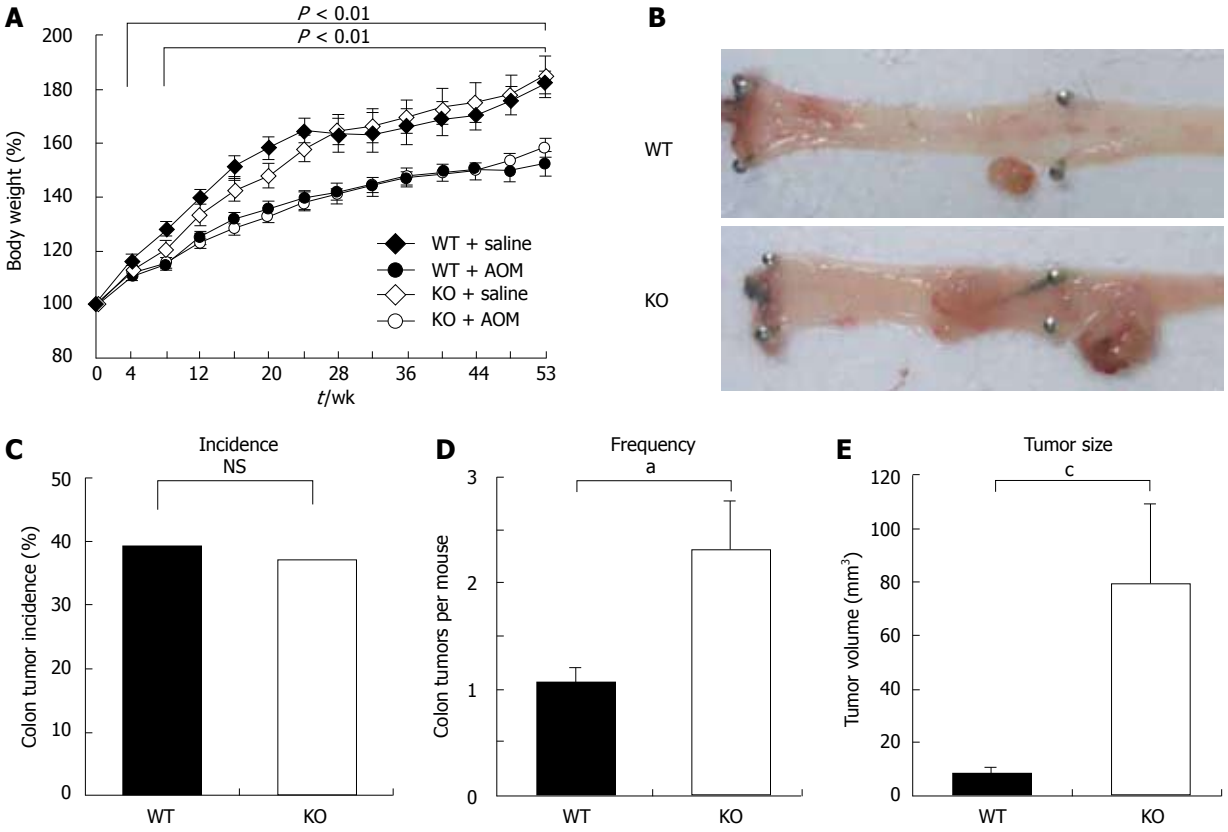

Figure 1 Enhanced AOM-induced colorectal carcinogenesis in KO mice. A: Changes in percentage of body weight. $P < 0.01$, between WT + saline ($n = 9$) and WT + AOM ($n = 23$). $P < 0.001$, between KO + saline ($n = 13$) and KO + AOM ($n = 24$); B: Representative pictures of the colorectal tumors arising in WT and KO mice after AOM treatment; C: Tumor incidence is expressed as the ratio of mice with tumor/total number of mice (NS: Not statistically significant; χ^2 test); D: Tumor frequency. WT, $n = 9$; KO, $n = 9$ ($^aP < 0.05$, Student's *t*-test); E: Tumor size. WT, $n = 9$; KO, $n = 19$ ($^cP < 0.05$, Student's *t*-test). Results are presented as mean ± SE.

mice after AOM treatment, although AOM treatment resulted in a significant reduction in body weight gain of both WT and KO mice (16.4% *vs* 14.4% reduction at sacrifice, Figure 1A). We observed no colorectal tumors in either WT or KO mice treated with only saline (data not shown). Figure 1B shows representative pictures of the colorectal tumors arising in WT and KO mice treated with AOM. There was no difference in the incidence of colorectal tumor formation between WT and KO mice (39.1% *vs* 37.5%, Figure 1C). However, the number of colorectal tumors per mouse was significantly greater in KO mice (2.33 ± 0.47, range: 1-4) than in WT mice (1.11 ± 0.11, 1-2) ($P < 0.05$; Figure 1D), and the average volume of colorectal tumors was markedly larger in KO mice (79.2 ± 29.2 mm^3) than in WT mice (9.02 ± 1.46 mm^3) ($P < 0.05$; Figure 1E). Histological analysis revealed that KO mice developed more progressive tumors in the colon than WT mice (Figure 2). We observed one adenoma (1 of 9, 11%), three carcinomas *in situ*, as assessed by the findings of high-grade dysplasia (3 of 9, 33%) and five adenocarcinomas (5 of 9, 56%) of the colorectal tumors arising in WT mice (Figure 2A). In contrast, of the colorectal tumors in KO mice examined, all tumors (14 of 14) were classified as adenocarcinomas (2 well- and 12 moderately-differentiated adenocarcinomas) (Figure 2B). These findings suggest that adiponectin deficiency enhances AOM-induced colorectal carcinogenesis. One KO mouse developed a small intestinal tumor, classified as a moderately-differentiated adenocarcinoma, in the duodenum (data not shown), whereas none of WT mice developed small intestinal tumors.

High expression of PCNA and COX-2 in colorectal tumors of KO mice

To characterize the influence of adiponectin deficiency on colorectal tumor growth, we evaluated cell proliferation of colorectal tumor cells using the PCNA labeling index assessed by immunohistochemistry. Figure 3A shows representative sections of PCNA-labeled nuclei in colorectal tumors from WT and KO mice. Expression of PCNA was identified by cell nuclei that stained brown to PCNA. For quantitative analysis, we determined the PCNA labeling index by calculating the percentage of PCNA-positive cells. The PCNA-labeling index of KO mice (68.5% ± 2.3%) was greater than that of WT mice (44.8% ± 6.3%) ($P < 0.01$; Figure 3B), suggesting that adiponectin deficiency increased cell proliferation of colorectal tumor cells. To investigate the mechanisms by which adiponectin deficiency increased cell proliferation, we first examined the expression of cyclin-dependent kinase inhibitors (CDKIs), $p21^{CIP}$ and $p27^{KIP}$, in colorectal tumors by immunohistochemistry. However, WT and KO mice showed absence or only focal positivity of both proteins in the colorectal tumors, and there was no significant difference (data not shown).

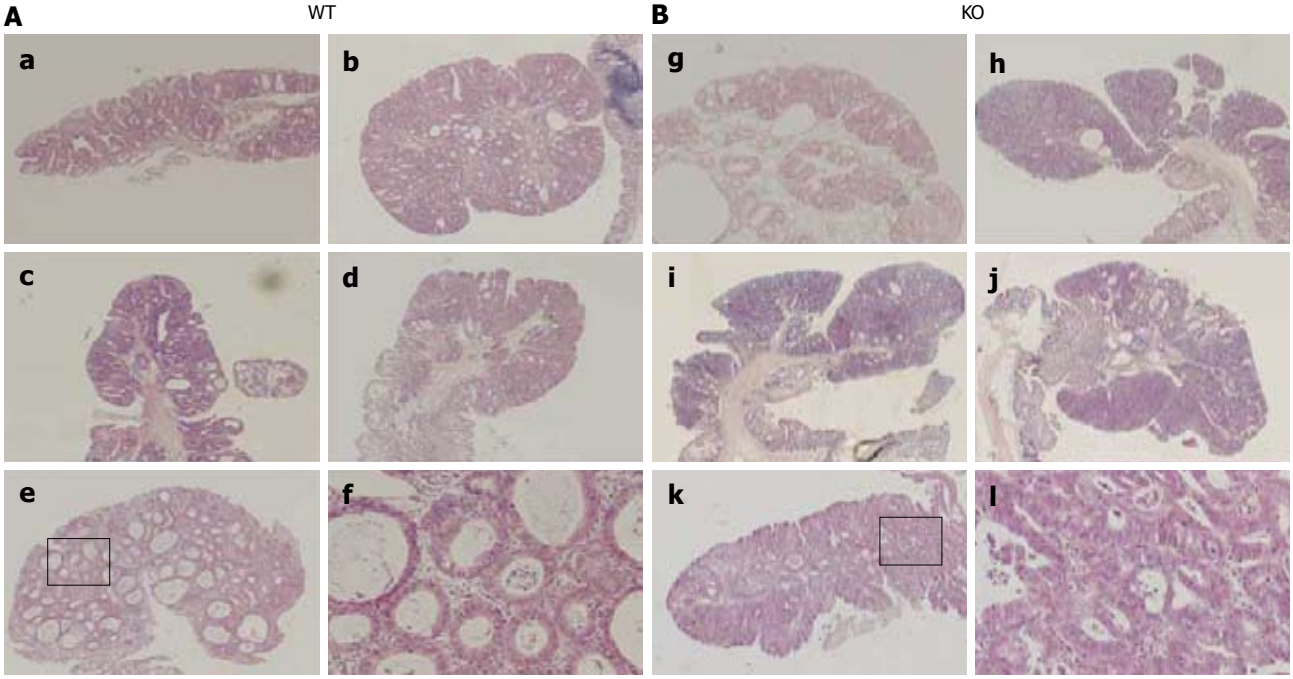

Figure 2 Histological analysis of colorectal tumors induced by AOM. Original magnification: × 20 for b, c, d, h, i, j; × 40 for a, e, g, k; and × 200 for f and l.

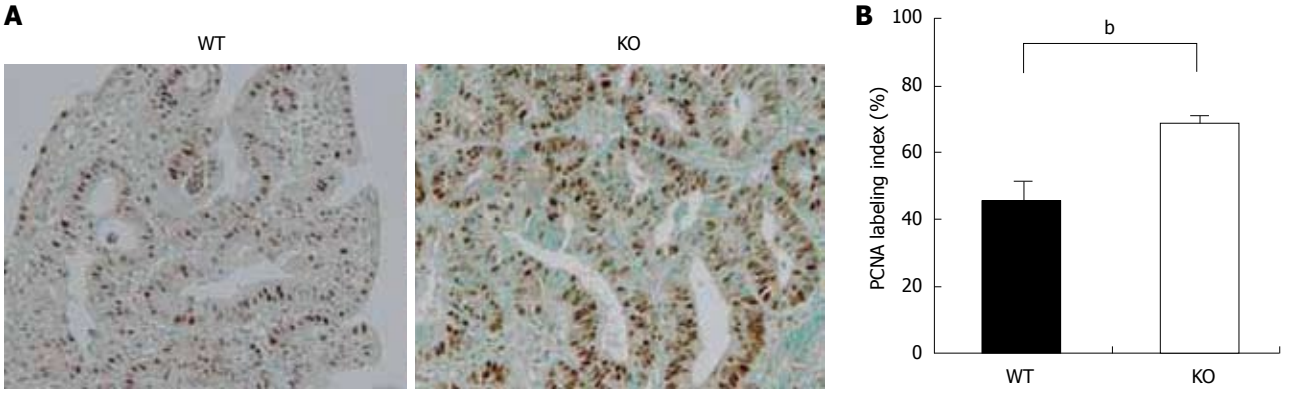

Figure 3 PCNA overexpression in colorectal tumor cells of KO mice. Immunohistochemical staining for PCNA in colorectal tumors using rat anti-mouse PCNA monoclonal antibody. Cells with strongly stained nuclei were considered positive for PCNA. A: Representative section of a colorectal tumor in a WT mouse and a KO mouse (× 200); B: PCNA labeling index in colorectal tumors. WT mice (n = 9), KO mice (n = 11) ($^bP < 0.01$, Student's t-test). Results are mean ± SE.

Next, we examined the expression of COX-2, a well-established pathogenic factor in colorectal carcinogenesis[28,29], by immunohistochemistry. Figure 4 depicts representative sections stained for COX-2. We found no COX-2 positive staining in normal colonic tissues of WT and KO mice. In the colorectal tumor tissues, we observed immunoreactive COX-2 expression in the epithelium and periluminal stromal cells, predominantly in the myofibroblasts. We detected very weak COX-2 staining in 22% (2 of 9) and only local COX-2 staining in 56% (5 of 9) of the colorectal tumors in WT mice (Figure 4A), whereas colorectal tumors in KO mice showed higher levels of COX-2 staining (Figure 4B). In 36% (4 of 11) of the colorectal tumors in KO mice, we detected marked COX-2 staining almost all over the surface of the tumor. Statistical analysis revealed that the expression of COX-2 in colorectal tumors of KO mice was higher than in WT mice (Figure 4C, $P < 0.05$; Wilcoxon rank sum test). Moreover, we found a significant correlation ($r = 0.89$, $P < 0.001$; Spearman's rank correlation) between the PCNA-labeling index and COX-2 expression level (Figure 4D). These results suggest that adiponectin deficiency may promote proliferation of colorectal tumor cells, which may be associated with overexpression of COX-2 in the periluminal stromal cells.

Enhanced liver tumor formation induced by AOM in KO mice

AOM is primarily metabolized by the liver and induces DNA damage in both the colon and the liver[30]. While AOM can induce tumor formation in the liver[31,32], tu-

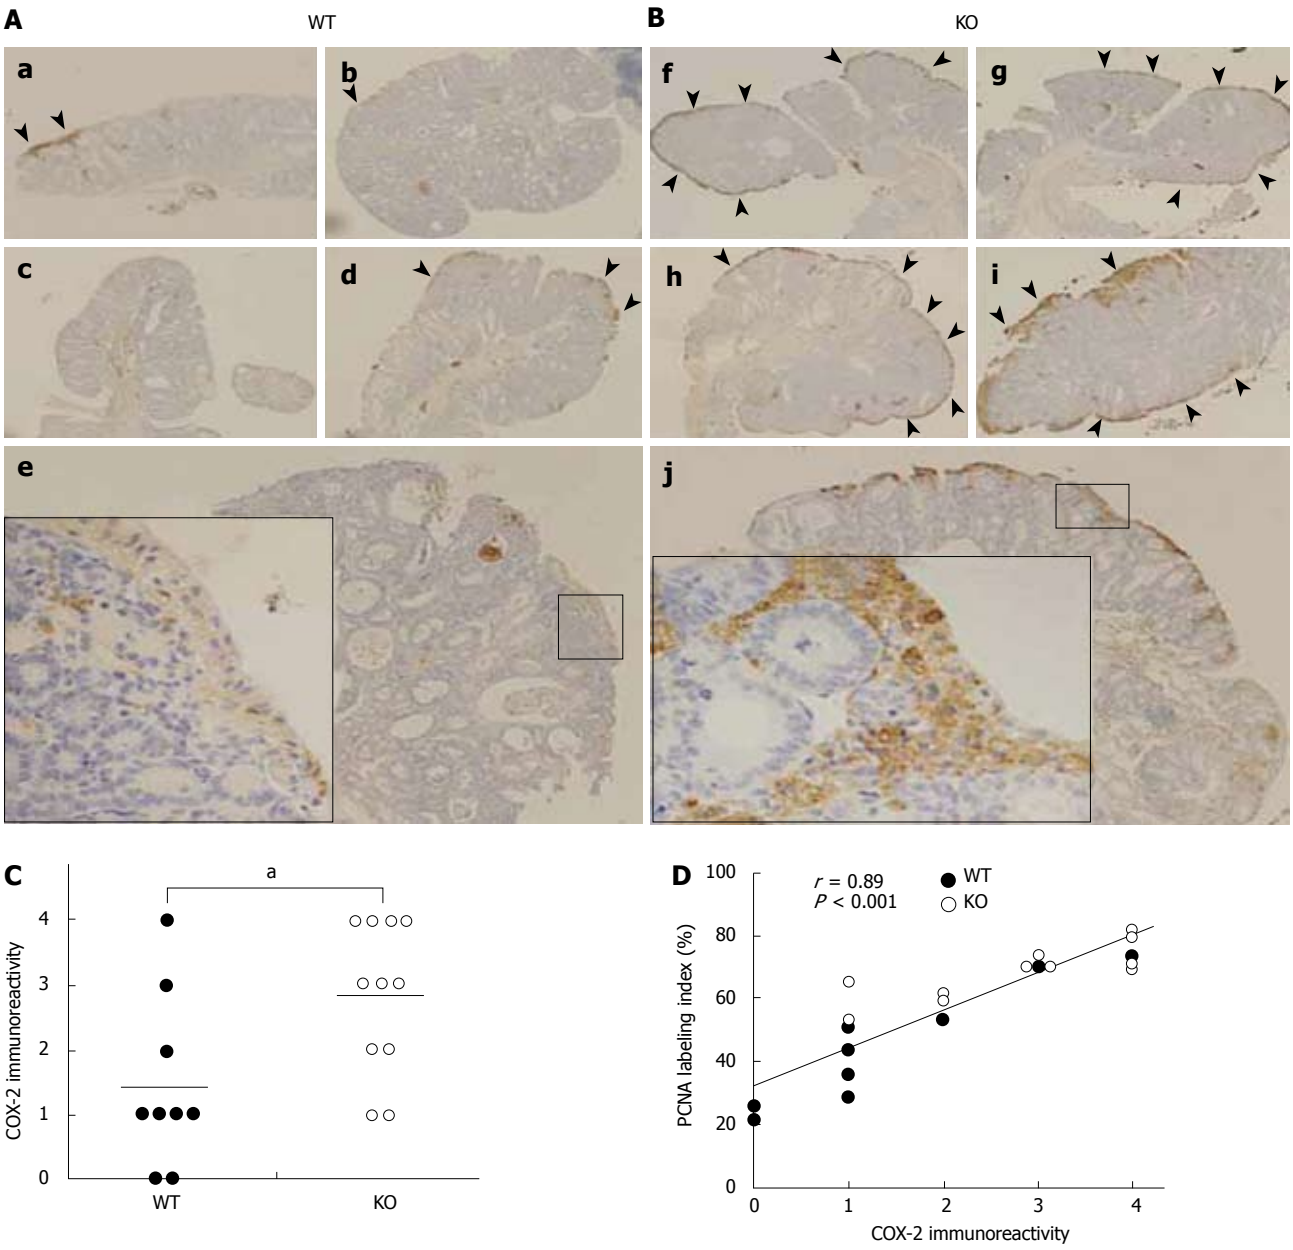

Figure 4 COX-2 overexpression in colorectal tumors of KO mice. Immunohistochemical staining for COX-2 in colorectal tumors using rabbit anti-mouse COX-2 polyclonal antibody. Immunoreactive COX-2 expression is observed in the epithelium and periluminal stromal cells of the tumors (Arrowheads). A: Representative sections of colorectal tumors in WT mice: e: Boxed area is shown at a higher magnification; B: Representative sections of colorectal tumors in KO mice: j: Boxed area is shown at a higher magnification. Original magnification: × 20 for b, c, d, f, g, h; × 40 for a, e, i, j; × 200 for the boxed area in e and j. C: Statistical analysis of immunoreactive COX-2 expression in colorectal tumors. COX-2 expression was higher in colorectal tumors of KO mice (n = 11) compared with WT mice (n = 9; $^{a}P < 0.05$, Wilcoxon rank sum test). Horizontal lines: mean value of COX-2 immunoreactivity in colorectal tumors of WT or KO mice. D: Significant correlation between COX-2 immunoreactivity and PCNA-labeling index in colorectal tumors (r = 0.89, $P < 0.001$, Spearman's rank correlation). WT mice (n = 9), KO mice (n = 11).

mors are reported to be formed almost exclusively in the colon[30]. Consistent with the previous observation[32], the incidence of liver tumor formation after AOM treatment was only 13% (3 of 23) in WT mice (Figure 5A), and all three WT mice had only a single tumor (Figure 5B). In contrast, the incidence of liver tumor formation was 50% (12 of 24) in KO mice (Figure 5A); 5 mice with a single tumor (42%), 2 mice with two tumors (16%), and 5 mice with more than three tumors (42%) (Figure 5B). Figure 5C and D show representative HE-stained sections of the liver tumors in KO mice. The majority of the liver tumors were identified as hepatocellular neoplastic nodules (Figure 5C), and one was a hepatocellular carcinoma (Figure 5D). We also observed that WT mice developed 2 hepatocellular neoplastic nodules and one hepatocellular carcinoma (data not shown). These results suggest that adiponectin deficiency may promote AOM-induced liver tumor formation.

DISCUSSION

Recent epidemiological studies have shown an inverse association between plasma adiponectin levels and the risk of colorectal cancer and its precursor adenoma[21-23]. In the present study, KO mice developed larger and more advanced colorectal tumors compared with WT

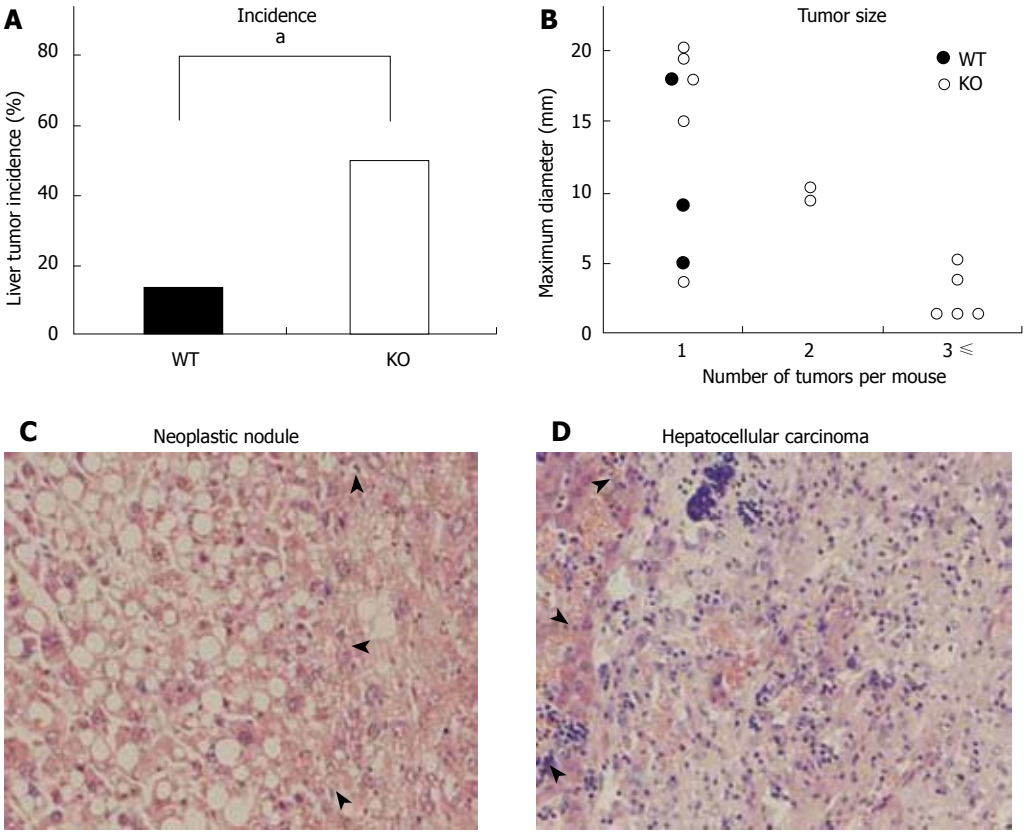

Figure 5 Enhanced AOM-induced liver tumor formations in KO mice. A: Tumor incidence is expressed as the ratio of mice with tumor/total number of mice ($^aP < 0.05$; Fisher's exact probability test); B: Tumor size is evaluated by its maximum diameter. Mice were divided into three groups according to the number of tumors per mouse. Maximum diameter of the tumors is plotted individually in each group. WT mice ($n = 3$), KO mice ($n = 12$). C and D: Representative HE-stained sections liver tumors in KO mice (× 200). Arrowheads indicate liver tumors. C: Neoplastic nodule; D: Hepatocellular carcinoma.

mice, although there was no difference in the tumor incidence between WT and KO mice. These findings suggest that adiponectin deficiency may influence colorectal tumor growth. Indeed, we found that cell proliferation of the colorectal tumor cells was significantly increased in KO mice compared with WT mice, as evaluated by the PCNA labeling index. The anti-proliferative effect of adiponectin on several types of cancer cells has been well documented in cultured cells and/or xenograft models[17-20]. Here we examined whether adiponectin deficiency directly influences colorectal tumor cells. AMP-activated protein kinase (AMPK), which is traditionally thought of as a regulator of cellular energy balance[33], has been reported to suppress cell proliferation in a variety of cell types including several cancer cells[34,35]. These effects of AMPK may be mediated partly through the cell cycle regulation by augmenting the p53-p21 axis[34,35]. Since adiponectin is known to stimulate AMPK[36], the molecular pathways regulated by AMPK could be the potential mechanisms through which adiponectin regulates carcinogenesis[12]. However, immunohistochemical analysis of the CDKIs such as $p21^{CIP}$ and $p27^{KIP}$, as downstream targets of AMPK, showed a negative or only focal immunopositivity of these CDKIs in colorectal tumors of both WT and KO mice, and there was no significant difference between the two strains (data not shown). Further studies are required to elucidate the involvement of this AMPK-CDKIs pathway in the anti-proliferative effect of endogenous adiponectin on colorectal tumors.

Next, to investigate other mechanisms by which adiponectin deficiency promoted colorectal tumor growth in KO mice, we determined the levels of COX-2 expression in the colorectal tumor tissues by immunohistochemistry. COX-2, the inducible enzyme involved in prostaglandins production, plays a crucial role in colorectal carcinogenesis[28,29]. It has been shown that inactivation of COX-2, by disruption of the COX-2 gene or the use of selective COX-2 inhibitors, markedly reduces intestinal tumor formation in the *Apc*$^{\Delta 716}$ mice[29]. Treatment with selective COX-2 inhibitors also suppressed AOM-induced colorectal carcinogenesis in rodents[37]. Moreover, clinical trials of selective COX-2 inhibitors reported a successful reduction in intestinal tumors of patients with familial adenomatous polyposis[38] and sporadic colorectal adenomas[39,40]. Here, we found that adiponectin deficiency enhanced COX-2 expression in the epithelium and periluminal stromal cells of the colorectal tumors, predominantly in the myofibroblasts. We also found that adiponectin deficiency promoted tumor cell proliferation in proportion to COX-2 expression levels. Intestinal myofibroblasts, a family of α-smooth muscle actin-positive fibroblast-like cells, play a pivotal role in the carcinogenic process[41]. The tumor cell-derived cytokines such as transforming growth factor-β provoke the transdifferentiation of fibroblasts

into myofibroblasts, which promote adjacent tumor cell proliferation through paracrine secretion of various mediators including cytokines, chemokines, growth factors, and extracellular matrix molecules[41]. Moreover, it has been shown that COX-2-expressing myofibroblasts synthesize and release prostaglandin E_2 into the tumor microenvironment, which is reported to promote epithelial cell proliferation[42]. Based on these reports, the influence of adiponectin deficiency on cell proliferation of colorectal tumor cells observed in this study could be explained, at least in part, by COX-2 overexpression in the stromal myofibroblasts.

KO mice treated with AOM had greater incidence and frequency of liver tumors, compared with WT mice. AOM is metabolically activated in the liver mainly by cytochrome P450 2E1 (CYP2E1)[43], and can induce tumor formation also in the liver[31]. The increased hepatic CYP2E1 level is considered as one possible mechanism that ethanol treatment may enhance DNA adduct formation by AOM metabolites and may potentiate dysplasia of the liver[44]. In a mouse model of nonalcoholic steatohepatitis induced by choline-deficient *L*-amino acid-defined diet, KO mice showed increased expression of hepatic CYP2E1, which might lead to the progression of liver tumor formation through the enhancement of oxidative stress[45]. On the basis of these reports, adiponectin deficiency might increase hepatic CYP2E1 activity, due to AOM exposure and, therefore, contribute to enhanced liver tumor formation. Further studies are required to clarify these points.

In conclusion, adiponectin deficiency in mice was directly associated with enhanced colorectal carcinogenesis and liver tumor formation induced by AOM. This is the first evidence that adiponectin deficiency a more caused severer and increased frequent carcinogenesis in *in vivo* model. Our results strongly suggest that hypoadiponectinemia could be involved in the pathogenesis for colorectal cancer and liver tumor in human subjects.

COMMENTS

Background

Adiponectin has attracted much attention because of its potential role in the development and progression of obesity-related malignancies. It has been reported that hypoadiponectinemia is an independent risk factor for colorectal cancer and its precursory adenoma.

Research frontiers

The anti-proliferative effect of adiponectin on several types of cancer cells has been well documented in cultured cells and/or xenograft models. The molecular pathways regulated by AMP-activated protein kinase (AMPK) have been reported to be the potential mechanisms through which adiponectin regulate carcinogenesis.

Innovations and breakthroughs

This study represented the causal relationship between hypoadiponectinemia and colorectal carcinogenesis in an *in vivo* model. Adiponectin deficient (KO) mice developed more advanced colorectal tumors, and showed enhanced liver tumor formation after azoxymethane (AOM) treatment.

Applications

This study demonstrated overexpression of cyclooxygenase-2 (COX-2) in the stromal myofiroblasts of the colorectal tumors in knockout (KO) mice. COX-2 overexpression might be a potential mechanism through which adiponectin deficiency was involved in the colorectal carcinogenesis.

Terminology

Adiponectin is one of the major adipocytokines, and its plasma levels are reduced in obesity, type-2 diabetes, and coronary artery disease.

Peer review

The present paper shows highest growth and progression of AOM-induced colon cancer in KO mice, with respect to wild type (WT) control mice. The results are of certain interest. Nevertheless, some points need to be further clarified and considered in depth to increase the interest of the paper.

Abstract

AIM: To determine the association of *Helicobacter pylori* (*H pylori*) CagA$^+$ infection and pro-inflammatory polymorphisms of the genes interleukin (IL)-1RN and IL-1B with the risk of gastric atrophy and peptic ulcers in a dyspeptic population in Costa Rica, a country with high incidence and mortality of gastric cancer.

METHODS: Seven biopsy specimens, a fasting blood sample and a questionnaire concerning nutritional and sociodemographic factors were obtained from 501 consecutive patients who had undergone endoscopy for dyspeptic symptoms. A histopathological diagnosis was made. Pepsinogen concentrations were analyzed by enzyme linked immunosorbent assay (ELISA). Infection with *H pylori* CagA$^+$ was determined by serology and polymerase chain reaction (PCR). IL-1B and IL-1RN polymorphisms genotyping was performed by PCR-restriction fragment length polymorphism (PCR-RFLP) and PCR respectively.

RESULTS: In this dyspeptic population, 86% were *H pylori* positive and of these, 67.8% were positive for CagA. Atrophic antral gastritis (AAG) was associated with CagA$^+$ status [odd ratio (OR) = 4.1; $P < 0.000$] and fruit consumption (OR = 0.3; $P < 0.00$). Atrophic body gastritis (ABG) was associated with pepsinogen PGI/PGII < 3.4 (OR = 4.9; $P < 0.04$) and alcohol consumption (OR = 7.3; $P < 0.02$). Duodenal ulcer was associated with CagA$^+$ (OR = 2.9; $P < 0.04$) and smoking (OR = 2.4; $P < 0.04$). PGI < 60 μg/L as well as PGI/PGII < 3.4 were associated with CagA$^+$.

CONCLUSION: In a dyspeptic population in Costa Rica, *H pylori* CagA$^+$ is not associated with ABG, but it is a risk factor for AAG. The pro-inflammatory cytokine polymorphisms IL-1B + 3945 and IL-1RN are not associated with the atrophic lesions of this dyspeptic population.

INTRODUCTION

Colonization with *Helicobacter pylori* (*H pylori*) is associated with atrophic gastritis, peptic ulcer and distal gastric cancer[1,2]. Nevertheless, many colonized individuals never develop these pathologies. Genetic characteristics of the host and the bacteria as well as environmental factors may be involved in the final clinical outcome[3]. The pathogenicity and virulence of *H pylori* increases when the infecting strain expresses the *cagA* gene that codes for a highly immunogenic protein CagA, which is a marker

for the presence of the *cag* pathogenicity island (PAI)[4,5]. Moreover, the immune response of the host is considered a key event in the pathogenic process that leads to gastric cancer. A number of studies have reported that carriers of certain alleles in genes encoding proinflammatory and anti-inflammatory cytokines exhibit a stronger inflammatory response against *H pylori* and a marked inhibition of acid secretion resulting in an increased risk of gastric cancer and its precursors, atrophic gastritis and intestinal metaplasia[6,7]. However, this association has not been found in all studied populations[8].

The development of atrophic gastritis is central in the multi-step process which leads to gastric cancer, and the risk increases with the severity and physical extension of the atrophic lesion[9,10]. Serum levels of pepsinogen I (PGI) and the ratio of PGI/PGII serum levels decrease significantly with increased extension and severity of atrophic gastritis and the presence of gastric cancer. Therefore, these parameters have been proposed as serological markers for those histopathological changes[11-13]. Costa Rica is one of the countries with the highest incidence and mortality rates of gastric cancer worldwide. The prevalence of *H pylori* associated gastritis is high from an early age[14].

Recently, we found an association between the PGI/PGII ratio and atrophic body gastritis in dyspeptic patients[15]. In the present study, the same population was analyzed for associations of atrophic body and antral gastritis and presence of peptic ulcers with *H pylori* *CagA*$^+$ infection and pro-inflammatory interleukin-1 (*IL-1*) gene polymorphisms.

MATERIALS AND METHODS

Patients

As previously described[15], between January and July, 2000, 800 consecutive patients referred to the endoscopy service at the Calderón Guardia Hospital in San José for dyspeptic symptoms were interviewed. This hospital is a tertiary hospital that, however, also provides gastroenterology service at primary and secondary levels. Patients were excluded if they were under 18 years of age, had not resided in Costa Rica for the previous two years, had received *H pylori* eradication therapy, had taken antibiotics during the 3 mo preceding endoscopy, had taken bismuth compounds at the time of endoscopy, had a history of gastric surgery, suffered from diseases associated with coagulation, or presented digestive bleeding. A total of 501 patients fulfilled the inclusion criteria and signed an informed consent form before 25 mL of fasting blood was obtained. The project had been previously approved by the ethic committees of the University of Costa Rica and the Hospital. A questionnaire with information concerning sociodemographic factors, family history, general health status, consumption of salt, coffee, alcohol, fruit, vegetables, and smoking habits was filled out[15]. Blood pressure and height and weight were recorded to calculate the body mass index.

Endoscopy procedure

Seven biopsies were obtained: Two biopsies from the middle part of the antrum were taken from the major and minor curvatures and two from the gastric body at the anterior and posterior walls of the central body for histopathological diagnosis. One biopsy from the antrum and one from the body were taken for culture and one from the antrum for rapid urease test[15].

Histological diagnosis

Sections of formaline-fixed and paraffin-embedded biopsies, stained with hematoxylin and eosin, were used for the histopathological diagnosis according to the Sydney Classification[16]. All slides were independently read by two specialists in gastric pathology (JA Ramírez in San José, Costa Rica, and A De Mascarel in Bordeaux, France). Cases with discrepant diagnoses were reviewed by both pathologists until a consensus was reached. A patient was considered to have: (1) atrophic body gastritis (ABG), if atrophy or metaplasia was present in any of the biopsies from the body; (2) atrophic antral gastritis (AAG), when atrophy was found in any of the biopsies from the antrum and not in the body; (3) non-atrophic gastritis (NAG), in the case of gastritis without atrophy, and (4) Normal mucosa, when no pathology was found in the antrum or the body and no granulocytic activity or lymphoid follicles were observed. In 22 of the patients, there was no histopathological diagnosis due to insufficient tissue in the biopsies[15].

H pylori status

Infection with *H pylori* was determined by histology, culture and serology. For histological detection, the slides were stained with toluidine blue. One biopsy from the antrum and one from the body were cultured for *H pylori*. Biopsies from the antrum and corpus were ground in brucella broth with an electric homogenizer. The suspensions were plated on two in-house media: A Wilkins Chalgren agar containing 10% human blood and antibiotics and a Columbia blood agar without antibiotics incubated for 10 d in a microaerobic atmosphere at 37℃. Standard identification was performed. Serum antibodies to *H pylori* were measured by an in-house enzyme linked immunosorbent assay (ELISA) developed in our laboratory and based on a modification of a previously described ELISA[17]. The antigen preparation and determination of cutoff points was previously reported[15]. A patient was considered positive for *H pylori* when positive by any of the three methods: culture or histology or serology and negative when none of the methods were positive.

CagA status

The *cagA* status was determined by polymerase chain reaction (PCR) on isolated strains using primers *cag*A_1-A_2 and, if negative, a second set of primers, *cag*A_3-A_4, were used[18]. Serum antibodies to CagA were measured by ELISA as described by Blaser *et al*, 1995[19]. A patient was considered positive for *H pylori* CagA$^+$ infection when positive by PCR and/or serology.

Serum pepsinogen concentrations

The concentrations of PGI and PGII in sera were

measured by an enzyme immunosorbent assay (EIA) (Eiken Chemical Company, Tokyo, Japan) according to the manufacturers' recommendations. The validation of pepsinogen levels for this population was described previously[15]. In order to detect as many patients as possible with ABG, a cut-off point that favored sensitivity was selected. The optimal cut-off point for this population had been set at a PGI/PGII ratio of 3.4, which gave a sensitivity of 91.2% and a specificity of 38.5%[15]. The predictive value for a positive sample was 11.2% and for a negative 98.1%. Pepsinogen levels could not be measured in 51 patients, because insufficient amounts of blood were obtained or because the patients did not accept being bled.

IL-1B and IL-1RN genotyping

IL-1B polymorphism analysis was performed by PCR-restriction fragment length polymorphism (PCR-RFLP). 100 ng of genomic DNA were amplified with the primers and PCR conditions previously reported[20]. The PCR products for IL-1B + 3954 were digested with the restriction enzyme *Taq*I and the allele designation for this polymorphism was the same as previously reported[21].

Genomic DNA (100 ng) was amplified using the same primers and PCR conditions as previously reported for *IL-1RN*[20]. For statistical analysis purposes and because of the low frequency of alleles 3, 4 and 5, this polymorphism was treated as biallelic by dividing alleles into short and long categories, in which the short allele has two repeats (allele 2) and long allele has more than two repeats (allele L). For 110 (22%) patients genotyping was not done because of insufficient leukocyte samples or problems in the isolation or analysis of the DNA.

Statistical analysis

χ^2 statistics were used for comparing genotype frequencies among the groups studied and to assess Hardy-Weinberg equilibrium for each of the loci studied. Allelic frequencies were assessed using Estimating Haplotype Frequencies (EH) (available at ftp://linkage.rockefeller.edu/software/eh/). Politomic logistic regression was used to compare genotypic frequencies among the groups studied here using STATA/SE 8.0 (STATA Corporation, College Station, TX).

A logistic regression model was used to calculate the odd ratios (ORs) for (dependent variable): (1) ABG compared to dyspepsia without atrophic gastritis; (2) AAG compared to dyspepsia without atrophic gastritis; (3) Gastric ulcer compared to all of the others; (4) Duodenal ulcer compared to the rest; (5) Levels of PGI < 60 μg/L compared to levels of PGI > 60 μg/L; and 6) Values of PGI/PGII < 3.4 compared to values of PGI/PGII > 3.4. The systematic independent variables were *H pylori* CagA infection, IL-1B + 3954 allele T carriers, IL-1RN allele 2 carriers, and those that had been associated with the dependent variables in a previous study of the same population: Age, sex, overweight, frequency of alcohol and fruit consumption and the PGI/PGII ratio for atrophic gastritis and age; gender and cigarette smoking for peptic ulcers[15]. The logistic regression analyses were performed including either, only *H pylori* infected individuals or, all of the participants. The association was determined as an OR at a confidence interval of 95%. Statistical significance was set at $P < 0.05$. The software STATA/SE 8.0 (STATA Corporation, College Station, TX) was used for the statistical analysis.

Table 1 Sex, age and pepsinogen levels according to histopathological diagnosis

	Sex (M/F) (*n* = 155/324)	Age (yr), mean (95% CI)	PGI (mg/L), mean (95% CI)	PGI/PGII, mean (95% CI)
Normal	9/12	38 (30.7-45.7)	39.7 (27.9-51.5)	4.3 (3.3-5.4)
NAG	104/225	45 (43.2-46.6)	53.1 (49.4-56.9)	3.3 (3.1-3.6)
AAG	26/67	50 (47.0-52.8)	60.2 (52.9-67.5)	3.3 (2.9-3.7)
ABG	16/20	53 (48.2-57.6)	36.1 (26.6-45.5)[1]	1.9 (1.5-2.4)[1]

[1]$P \leq 0.001$, ABG *vs* the rest.

RESULTS

In this study, 501 patients were included, 338 women with an average age of 46.3 years, and 163 men with an average age of 46 years. The mean age was higher in groups with the most severe pathologies (Table 1).

Pepsinogen

PGI y PGII concentrations could be measured in 450 patients. Serum concentrations of PGI as well as the PGI/PGII ratio were lower in patients with ABG as compared to other dyspeptic patients (Table 1). Dyspeptic patients with a ratio below 3.4 were at increased risk of having ABG compared to those with a ratio higher than 3.4 (Table 2).

H pylori CagA$^+$

The frequency of *H pylori* infection was 86%, out of which 67.8% were CagA$^+$, however, the prevalence varied according to the pathology. Patients with a normal histopathological diagnosis, although few, showed a lower incidence of infection with *H pylori* and *H pylori* CagA$^+$ (15.0% and 5.3%, respectively) as compared to the rest, NAG (88.9% and 55.5%), AAG (93.3% and 81.6%) or ABG (82.9% and 58.8%). The prevalence of infection with *H pylori* and *H pylori* CagA$^+$ for gastric ulcer was 100% and 52.2%, respectively, and for duodenal ulcer 98% and 85%, respectively. Among patients with PGI/PGII < 3.4, the prevalence of infection with *H pylori* was 87.7% and with *H pylori* CagA$^+$ 61.3% while that of patients with ratios > 3.4 were at 82.1% and 50.0%. *H pylori* CagA+ was associated with a PGI/PGII ratio < 3.4 and PGI < 60 μg/L (Table 3).

Polymorphisms: IL-1RN and IL-1B + 3954

Genotyping of the cytokine polymorphisms was successfully performed in 371 patients (74%). Genotypic distributions of IL-1RN and IL-1B + 3954 polymorphisms were not significantly different among the studied groups (Table 4). There was Hardy-Weinberg

equilibrium for the IL-1RN locus in the groups used here as controls (dyspepsia without atrophic gastritis and all of the groups together excluding ABG). However, in the case of the IL-1B + 3954 polymorphism, there was no equilibrium for any of the control groups (data not shown). The frequency of the allele 2 for IL-1RN polymorphism was not significantly different in normal patients, compared to those with some type of gastritis (Table 4).

Logistic regression atrophic gastritis

An increased risk of ABG was observed among patients older than 50 years, those consuming alcohol and those with a PGI/PGII ratio < 3.4. Patients infected with CagA$^+$ strains of *H pylori* and those with lower consumption of fruit were at higher risk of developing AAG, (Table 2). The presence of pro-inflammatory alleles, IL-1B + 3954T and IL-RN*2, did not confer an enhanced risk of any type of atrophy (Table 2).

[1]Logistic regression, Peptic ulcer *vs* no peptic ulcer.

Peptic ulcers

Duodenal ulcer was more frequent than gastric ulcer (52/24) in both genders. However, it was twice as common in males and the average age of patients with duodenal ulcer (average 46; 95% IC, 42.5-50.2) was lower than that of those with gastric ulcer (average 58; 95% CI, 52.2-63.6). Males, smokers and patients infected with *H pylori* CagA$^+$ were at increased risk of duodenal ulcer (Table 5).

DISCUSSION

While NAG associated with *H pylori* is more prevalent in industrialized countries, atrophic gastritis is more common in the developing world. The reason for this is probably a combination of effects caused by *H pylori* and other infections in early childhood, as well as other environmental factors and genetic composition[4,22]. Atrophic gastritis initiates in the antrum and may extend upwards towards the gastric body, often resulting in more severe atrophic gastritis with increased age[9]. It has been reported in sev-

eral studies that infection with *H pylori* CagA$^+$ increases the risk of atrophic gastritis and gastric cancer[4,23]. In the present study, infection with *H pylori* CagA$^+$ is associated with atrophic gastritis of the antrum, but not of the body, results which are in accordance with those reported by Oksanen *et al*, 2000[24]. Indeed, in a stomach affected by ABG, the microenvironment is more hostile for the survival and growth of *H pylori* promoting spontaneous eradication of the bacteria and a progressive decline in concentrations of serum antibodies to *H pylori*[25-27]. Atrophic gastritis has been considered as a consequence of prolonged gastritis caused by *H pylori* and the association between *H pylori infection* and gastric cancer appears stronger when the infection is recorded several years before the onset of cancer[28]. Therefore, in our study, the association of *H pylori* CagA$^+$ with ABG may be underestimated, taking into account that patients belong to a population in which *H pylori*-associated gastritis is prevalent from childhood[14]. *H pylori* and its virulence factor CagA may be involved in processes during the early stages of inflammation of the antrum that lead to extension of atrophic gastritis towards the gastric body[29].

In concordance with other studies, infection with *H pylori*-CagA$^+$ is associated with low PGI/PGII ratios[24]. Several studies have reported an association of low PGI concentrations and low PGI/PGII ratios with precancerous lesions as well as with gastric cancer[30-32]. In the study population, PGI/PGII values below 3.4 were previously shown to be associated with ABG but not with AAG[15]. The studies performed in Costa Rica to date indicate low specificities of the pepsinogen test for the detection of gastric cancer and ABG (64% and 38.5%, respectively). Nevertheless, its high negative predictive values (99.5% and 98%) could make the PG test useful to eliminate, from subsequent steps of screening programs, persons that are unlikely to develop gastric cancer[15,33].

Our results fail to demonstrate an association between AAG, ABG and pro-inflammatory polymorphisms IL-1B + 3945 or IL-1RN. The control group consisted of dyspeptic patients of which a large majority suffered from some inflammatory condition (NAG). In a previous study, performed by our group, among participants in a program at the Center for Early Detection of Gastric Cancer in Costa Rica, it was found that IL-1B + 3945T and IL-1RN*2 were associated with an increased risk of gastric cancer: OR = 3.7 $P = 0.007$ and OR = 2.9; $P = 0.03$ respectively[34]. In this study, the control groups were normal individuals as judged by X-ray (double contrast, gastric study).

The combination of IL-1B + 3954 and IL-1RN proinflammatory genotypes, or that of proinflammatory alleles and CagA, did not reveal any association with any particular pathology when included in the logistic regression analysis (data not shown).

Recent reports concerning the association of polymorphisms enhancing the expression of the gene IL-1B with atrophic gastritis, gastric cancer and peptic ulcer, diverge in their results[35]. Several studies link these polymorphisms to a reduction in acid secretion, gastric inflammation, atrophy, and gastric cancer[6,20,36-38], whereas others do not[39-42]. These contradictory results may be related to the characteristics of the studied population, the methodology used, regional differences with regard to the frequencies of pro- or anti-inflammatory polymorphisms, the prevalence and time of infection with *H pylori* and the characteristics of the infecting strain, as well as diet and other environmental factors that interact with and influence the final result of the pathological process initiated by the infection[43-45].

The results of the present study show that consumption of fruit, even in modest quantities, diminishes the risk of AAG, but has no effect on more advanced atrophy, ABG. It has been suggested that the protective properties of fruit are due to its content of antioxidants that would counteract the oxidative stress induced by *H pylori*[46].

The data presented here are in accordance with reports from other laboratories stating that CagA$^+$ individuals are at higher risk of developing duodenal ulcers[47,48]. Although patients with duodenal ulcer have reduced risk of gastric cancer, *H pylori* predisposes to both conditions[49]. These different consequences may be a result of the host response to the infection. It has been reported that an increase in acidity predisposes for duodenal ulceration whereas hypochlorhydria is associated with a higher risk of developing gastric cancer[50].

In summary, this study does not permit the conclusion that there exists no association between infection with CagA$^+$ *H pylori* and ABG, because *H pylori* is spontaneously eradicated with the severity and extension of atrophic lesions. Future epidemiologic investigations should eliminate the inherent biases of sub-detection of *H pylori* and specially *H pylori* CagA$^+$. The true relationships between *H pylori* and diseases of the upper gastrointestinal tract are highly complex. It is of crucial importance to identify the factors that direct the initial inflammatory reactions to different gastric pathologies and decipher the mechanisms involved those processes, not only for the understanding of carcinogenesis, but also for the prevention and detection of diseases related to *H pylori*.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Drs. Ricardo Barahona, Rigoberto Salas-Aguilar, Alessia Ávalos, Gerardo Avendaño and Rolando Páez, at the Calderón Guardia Hospital for performing the gastroscopic examinations and providing the biopsies used in the study. We also thank Victor Castillo for excellent technical assistance and Anne Chinnock for revising the manuscript.

COMMENTS

Background

Costa Rica has a high incidence of and mortality from gastric cancer. Infection with *H pylori* and proinflammatory interleukin (IL) gene polymorphisms have been associated with precancerous gastric lesions and gastric adenocarcinoma. Atrophic gastritis may lead to the development of cancer. This study addresses the association of atrophic antral and body gastritis with infection with

H pylori-CagA+ strains and IL-1 gene polymorphisms in a dyspeptic population in an area at high risk of gastric cancer in Costa Rica.

Research frontiers

In a dyspeptic population in Costa Rica, *H pylori* CagA$^+$ is not associated with atrophic body gastritis, but it is a risk factor for atrophic antral gastritis (AAG). The pro-inflammatory cytokine polymorphisms IL-1B + 3945 and IL-1RN are not associated with the atrophic lesions.

Innovations and breakthroughs

Studies of various populations have indicated an association between gastric cancer and *H pylori*-CagA as well as proinflammatory gene variants. The etiology of gastric cancer varies among populations. The present study shows that *H pylori*-CagA is related to active AAG, but not to more advanced atrophy of the gastric body in a high-risk population. It is speculated that the bacteria may have disappeared at this stage. Furthermore, the study demonstrates no relation between two proinflammatory IL-1 gene polymorphisms and atrophy of the stomach in dyspeptic patients.

Applications

In developing countries with high incidence of *H pylori* infection and dyspepsia it is not feasible to screen large populations with endoscopy. The information generated here may be used to create a battery of markers to detect risk factors for gastric cancer from a blood sample. Screening and intervention may then be concentrated on people with a high-risk profile.

Peer review

The report is interesting. It could be useful in clinical settings. It indicated that in a dyspeptic population in Costa Rica, *H pylori* CagA$^+$ is a risk factor for AAG.

Abstract

AIM: To clarify whether serum chemokine and cytokine levels can become useful biological and functional markers to assess the severity of chronic pancreatitis (CP). This study aimed at clarifying whether serum chemokine and cytokine levels can become useful biological and functional markers to assess the severity of CP.

METHODS: Serum monocyte chemoattractant protein-1 (MCP-1), transforming growth factor beta-1 (TGF-β1), and soluble type fractalkine (s-fractalkine) concentrations were examined in patients with CP (n = 109) and healthy controls (n = 116). Severity of disease was classified in patients with CP by a staging system. Relationships between stage-specific various clinical factors and serum MCP-1, TGF-β1, and s-fractalkine levels were investigated. Furthermore, 57 patients with non-alcoholic CP were similarly evaluated in order to exclude influence of alcohol intake.

RESULTS: Patients with CP showed significant higher levels of serum TGF-β1 and s-fractalkine, but not MCP-1, compared to the controls. Serum TGF-β1 in the severe stage and s-fractalkine in the mild and the severe stage of CP significantly increased compared to those of controls. However, it was observed that both TGF-β1 and s-fractalkine levels were affected by alcohol intake. In patients with non-alcoholic CP, serum TGF-β1 showed significant increase in the moderate stage of CP, and serum s-fractalkine revealed significant increase in the early stage of CP.

CONCLUSION: It is suggested that the measurement of serum F-fractalkine is useful to diagnose early-stage CP. Moreover, the combined determination of both, s-fractalkine and TGF-β1, in human sera may be helpful in evaluating the severity status of CP.

INTRODUCTION

Chronic pancreatitis (CP) is a chronic clinical disorder characterized by irreversible damage to the pancreas, the development of histologic evidence of inflammation and fibrosis, and eventually the destruction and permanent loss of exocrine and endocrine tissue[1-4]. Furthermore, patients with long-standing CP are also at a markedly increased risk of developing pancreatic cancer[3]. Unfortunately, simple, indirect measurements of decreased pancreatic function do not show abnormality until CP is considerably advanced. Imaging or function tests may not reveal early CP, and the results of these tests do not necessarily correlate with each other[5-9]. The quest continues for useful biological and functional markers of early-stage CP. Recently, chemokines and

cytokines have been recognized to be important factors in the progression of CP[10,11]. A preliminary study by us in a small number of CP patients showed the possibility that measurement of serum soluble type fractalkine (s-fractalkine) may be useful for diagnosing early-stage of CP[7]. Thus, in the current study, using a large number of CP patients classified by severity with a staging system, we investigated whether chemokine and cytokine levels can become useful biological and functional markers of early-stage CP, focusing particularly on monocyte chemoattractant protein-1 (MCP-1), transforming growth factor beta-1 (TGF-β1), and s-fractalkine, which are supposed to be involved in chronic inflammation.

MATERIALS AND METHODS

Patients

One hundred nine patients with CP (63 males and 46 females; age range, 25-81 years; mean, 56.8 years) who fulfilled clinical diagnostic criteria for CP by the Japan Pancreas Society[12] and 116 healthy controls (69 males and 47 females; age range, 26–93 years; mean, 56.5 years) were selected for this study. Patients and healthy controls with recent inflammatory diseases, e.g. infectious diseases, chronic hepatitis, or substantial alcohol consumption were excluded. The study protocol was approved by the ethics committee at Kyushu University.

CP patients were classified according to a staging system reported previously (Table 1)[12-14]. The staging system comprises 6 parameters: exocrine pancreatic function (scored 0-3), pancreatic imaging tests by endoscopic retrograde cholangiopancreatography (ERCP; scored 0-4), glucose metabolism (scored 0-4), pain (scored 0-4), alcohol intake (scored 0-2), and complications associated with CP (scored 0-2). The CP is then subclassified, according to a total score from these 6 grading factors, into mild (total score, 0-3), moderate (total score, 4-7), and severe (total score, ⩾ 8). The number of patients with mild, moderate, or severe disease was 36 (33.0%), 49 (45.0%), and 24 (22.0%), respectively (Table 2). We analyzed whether each grading factors and severity of CP are related with serum MCP-1, TGF-β1 and s-fractalkine.

Table 1 CP staging system (partial modification of reference 12, 16, 17)

Exocrine pancreatic function (score, 0-3)
Each of the following abnormalities is scored as 1: Decreased serum level of pancreatic amylase or trypsin, abnormal bentiromide-para amino benzoic acid (BT-PABA) test result, and low fecal chymotrypsin.
0 No abnormalities in the above examination
1 Total score 1 in the above examinations
2 Total score 2 in the above examinations
3 Total score 3 in the above examinations
Pancreatography by endoscopic retrograde cholangiopancreatography (ERCP; score, 0-4)
0 Normal
1 Slightly abnormal (simple dilatation of the main pancreatic duct or localized and irregular dilation of two to three branches)
2 Mild pancreatitis (diffuse and irregular mild dilatation of the main pancreatic duct or branches, or moderate dilatation of the main pancreatic duct localized in the body and/or tail of the pancreas)
3 Moderate pancreatitis (diffuse and irregular moderate dilatation of the main pancreatic duct or branches, or advanced dilation of the main pancreatic duct localized in the body and/or tail of the pancreas)
4 Severe pancreatitis (diffuse and irregular advanced dilatation of the main pancreatic duct and branches)
Glucose metabolism (score, 0-4)
0 Normal glucose tolerance (urine glucose negative; postprandial glucose < 160 mg/dL)
1 Slightly impaired glucose tolerance (impaired glucose tolerance after oral glucose loading test; postprandial glucose, > 160 mg/dL, < 200 mg/dL)
2 Mild diabetes mellitus (urine glucose positive after meal; postprandial glucose, > 200 mg/dL; < 300mg/dL; HbA1c < 7%)
3 Moderate diabetes mellitus (postprandial glucose, > 300 mg/dL; HbA1c 7%-11%)
4 Severe diabetes mellitus (HbA1c > 11%, diabetic retinopathy, or diabetic nephropathy)
Pain (evaluated in the previous 1 yr, score 0-4)
0 No or only slight pain (requires no analgesics)
1 Mild pain (occasional pain but requires no analgesics)
2 Moderate pain (frequent pain attacks, often requires analgesics)
3 Severe (always requires analgesics)
4 Most severe (requires frequent injections of analgesics, and, often, hospitalization)
Alcohol intake (score, 0-2)
0 Less than 180 mL sake[1], not every day
1 Less than 540 mL sake, almost every day
2 More than 540 mL sake, almost every day
Complications associated with chronic pancreatitis (score, 0-2)
0 No complications such as pseudocyst and stenosis of the biliary tract
1 Complications that require no treatment
2 Complications that require treatment

Total score	Severity of chronic pancreatitis
0-3	Mild
4-7	Moderate
> 8	Severe

[1]Sake and shochu are typical Japanese alcoholic beverages, with an ethanol content of about 16% and 25%, respectively. One unit of sake, which contains 29 g of ethanol, represents one Japanese drink.

Laboratory methods

Enzyme-linked immunosorbent assays (ELISAs) were used to determine serum MCP-1, TGF-β1, and s-fractalkine concentrations. Samples were examined with commercial kits according to the manufacturers' instructions; human MCP-1, human TGF-β1 (Biosource, Camarillo, CA), and s-fractalkine (R&D systems, Minneapolis, MN). MCP-1 and TGF-β1 assays were run according to the protocol that was recommended in the kit. S-fractalkine was measured according to the protocol mentioned below. S-fractalkine was assessed using the basic components required by the manufacturer, and briefly, for the plate preparation, 4 μg/mL of mouse antibody to human fractalkine was used as the capture antibody with 96 well low-cell-binding EIA plates (Nunc, Roskilde, Denmark) in an overnight incubation at 25℃. Next, the plate was blocked with phosphate buffer saline (PBS) containing 10% fetal bovine serum (Invitrogen, Auckland, New Zealand), biotinylated mouse antibody to human fractalkine (500 μg/mL) was added after serum samples and standard, and were incubated for two hours at 25℃. Recombinant human fractalkine (R&D systems) was used as a standard. After that, the plate was incubated with streptavidin conjugated to horseradish peroxidase (HRP) for 20 min at 25℃ in the

Table 2 Number of each classification in patients with CP

N/A: Not applicable.

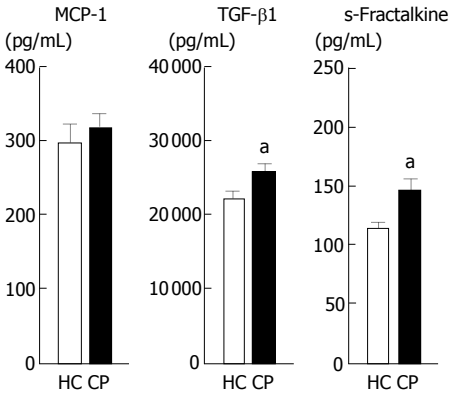

Figure 1 Serum MCP-1, TGF-β1, and s-fractalkine concentrations in patients with CP. Serum MCP-1, TGF-β1, and s-fractalkine concentrations were measured by ELISA for each pancreatic disease. Healthy control (HC, $n = 116$) and chronic pancreatitis (CP, $n = 109$). Bars represent the mean ± SD. [a]$P < 0.05$ *vs* healthy control.

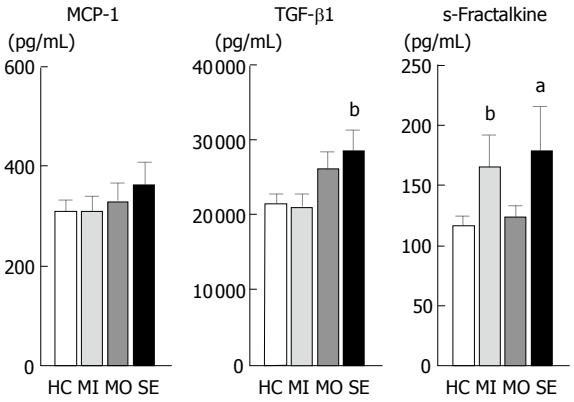

Figure 2 Serum MCP-1, TGF-β1, and s-fractalkine concentrations with regard to severity of CP. Serum MCP-1, TGF-β1, and s-fractalkine concentrations were measured by ELISA for each stage of severity. Healthy control (HC, $n = 116$), mild severity (MI, $n = 36$), moderate severity (MO, $n = 49$), and severe (SE, $n = 24$). Bars represent the mean ± SD. [a]$P < 0.05$ *vs* healthy control, [b]$P < 0.01$ *vs* healthy control.

dark. Finally, antibody complex was detected by base on the formation of the avidin-biotin complex, and the color was developed with tetramethylbenzidine (TMB) solution by incubating for 30 min at 25℃ in the dark. Absorbance was read at 450 nm/570 nm.

Statistical analysis

Statistical analysis was performed using the non-parametric Mann-Whitney *U* test. *P* values less than 0.05 were considered significant. Pearson's correlation analysis was used to calculate correlations between the data.

RESULTS

Serum MCP-1, TGF-β1, and s-fractalkine concentrations in patients with CP (Figure 1)

Serum MCP-1 levels in patients with CP were not significantly elevated. On the other hand, serum TGF-β1 levels in patients with CP were significantly higher than those of healthy controls ($P = 0.029$). Furthermore, s-fractalkine levels in CP were also significantly increased when compared to those of healthy controls ($P = 0.011$). Thus, we next analyzed whether specific grading factors as pancreatic imaging tests, exocrine function, glucose metabolism, pain, alcohol intake, or complications and severity of CP are related to serum MCP-1, TGF-β1, and s-fractalkine concentrations.

Serum MCP-1, TGF-β1, and s-fractalkine concentrations in relation to the severity stage of CP (Figure 2)

First, we examined the MCP-1, TGF-β1, and s-fractalkine levels in each stage of severity. Serum TGF-β1 levels in the severe stage of CP were significantly higher than in healthy controls ($P = 0.008$). On the contrary, serum s-fractalkine levels in the mild and in the severe stage of CP were significantly elevated compared to healthy controls ($P = 0.004$ and $P = 0.046$, respectively). However, the serum MCP-1 level didn't significantly increase for each stage of severity.

Serum MCP-1, TGF-β1, and s-fractalkine concentrations in relation to imaging test scores in patients with CP (Figure 3)

Serum of MCP-1, TGF-β1, and s-fractalkine levels were analyzed regarding imaging scores. Serum TGF-β1 levels in patients with CP revealed a score of > 3 in pancreatic imaging tests and was found to be significantly enhanced when compared to healthy controls ($P = 0.0001$). On the other hand, serum s-fractalkine levels in patients with a score of 1 and a score of $\geqslant 3$ were significantly elevated when compared to healthy controls ($P = 0.010$ and $P = 0.041$, respectively). However, no relationship was found between serum MCP-1 levels and any level of the imaging tests.

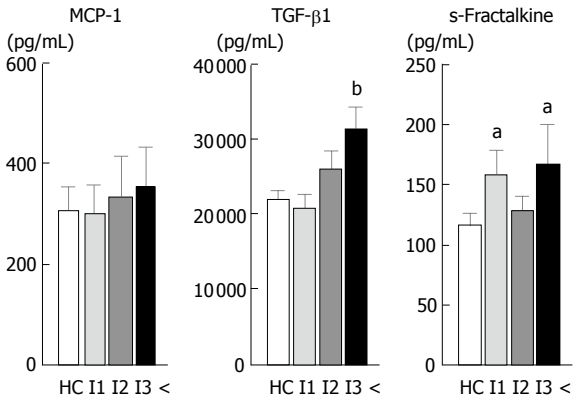

Figure 3 Serum MCP-1, TGF-β1, and s-fractalkine concentrations for each score of imaging tests in CP patients. Serum MCP-1, TGF-β1, and s-fractalkine concentrations were measured by ELISA for each score for pancreatic imaging tests. Healthy control (HC, *n* = 116), score 1 on pancreatic imaging tests (I1, *n* = 47), score 2 on pancreatic imaging tests (I2, *n* = 33) and score ≥ 3 on pancreatic imaging tests (> I3, *n* = 29). Bars represent the mean ± SD. [a]*P* < 0.05 *vs* healthy control, [b]*P* < 0.01 *vs* healthy control.

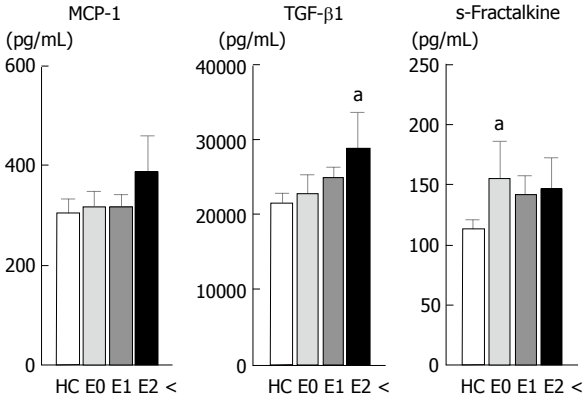

Figure 4 Serum MCP-1, TGF-β1, and s-fractalkine concentrations for each score for the exocrine function tests in CP patients. Serum MCP-1, TGF-β1, and s-fractalkine concentrations were measured by ELISA for each score for the exocrine function. Healthy control (HC, *n* = 116), score 0 for exocrine function (E0, *n* = 31), score 1 for exocrine function (E1, *n* = 66) and score > 2 for exocrine function (> E2, *n* = 12). Bars represent the mean ± SD. [a]*P* < 0.05 *vs* healthy control.

Serum MCP-1, TGF-β1, and s-fractalkine concentrations in relation to exocrine function test scores in patients with CP (Figure 4)

Serum TGF-β1 levels in patients with an exocrine function score ≥ 2 were significantly higher than in healthy controls ($P = 0.042$). In contrast, serum s-fractalkine was significantly elevated in patients with an exocrine function score of 0 compared to healthy controls ($P = 0.030$). However, no significant relationship was observed between serum MCP-1 levels and the exocrine function test.

Serum MCP-1, TGF-β1, and s-fractalkine concentrations for each score of alcohol intake in patients with CP (Figure 5)

Serum TGF-β1 and s-fractalkine levels in patients with an alcohol intake score of ≥ 1 were significantly higher than in healthy controls ($P = 0.018$ and $P = 0.010$, respectively). Serum MCP-1 levels, in contrast, appeared not to be related to alcohol consumption.

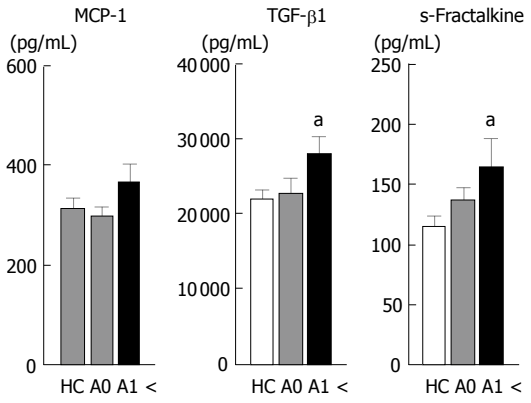

Figure 5 Serum MCP-1, TGF-β1, and s-fractalkine concentrations in relation to alcohol intake in CP patients. Serum MCP-1, TGF-β1, and s-fractalkine concentrations were measured by ELISA for each score for alcohol intake. Healthy control (HC, *n* = 116), score 0 for score of alcohol intake (A0, *n* = 57) and score > 1 for score of alcohol intake (> A1, *n* = 52). Bars represent the mean ± SD. [a]*P* < 0.05 *vs* healthy control.

Analysis of serum MCP-1, TGF-β1, and s-fractalkine concentrations on other factors in patients with CP

Finally, serum MCP-1, TGF-β1, and s-fractalkine concentrations were analyzed in relationship to other grading factors. However, we did not observe any significant relation among them. Furthermore, serum MCP-1, TGF-β1, and s-fractalkine levels did not correlate with each other. Moreover, MCP-1, TGF-β1, and s-fractalkine levels also did not correlate with age, sex, or serum pancreatic enzymes (p-amylase and lipase).

Serum TGF-β1 concentrations in non-alcoholic CP

In order to assess the influence of alcohol intake, we next focused on 57 patients with non-alcoholic CP. In the classification of severity for CP, patients with CP in the moderate stage alone showed a significant increase in serum TGF-β1 compared to healthy controls ($P = 0.039$, Figure 6A). In the classification of imaging tests and exocrine function tests, patients with CP revealing a moderate progressive stage tended to have an increase in serum TGF-β1 (Figure 6B and C).

Serum s-fractalkine concentrations in non-alcoholic CP

Similarly, we examined serum s-fractalkine in patients with non-alcoholic CP. In the classification of severity and pancreatic imaging tests, patients with CP in a mild stage alone and with a score of 1 alone showed a significant increase in serum s-fractalkine compared to healthy controls ($P = 0.026$ and $P = 0.025$, respectively; Figure 7A and B). Serum s-fractalkine didn't have a tendency for the exocrine function test (Figure 7C).

DISCUSSION

Recently, the impact of chemokines and cytokines have been recognized in the progression of chronic inflammatory diseases[15]. However, until now, there are

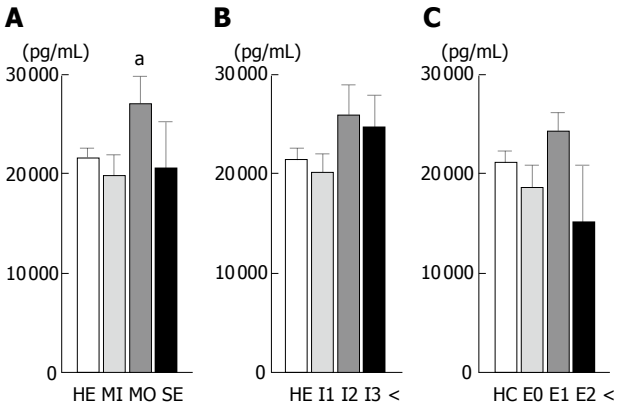

Figure 6 Serum TGF-β1 concentrations in non-alcoholic CP for each factor. Serum TGF-β1 concentrations were measured in patients with non-alcoholic CP (n = 57) by ELISA. A: Serum TGF-β1 concentrations for each stage of severity: Healthy control (HE, n = 116), mild severity (MI, n = 33), moderate severity (MO, n = 19) and severe (SE, n = 5); B: Serum TGF-β1 concentrations for each imaging test score: Healthy control (HE, n = 116), score 1 for imaging tests score (I1, n = 33), score 2 for imaging tests score (I2, n = 15) and score < 3 for imaging tests score (< I3, n = 9); C: Serum TGF-β1 concentrations for each score for exocrine function. Healthy control (HC, n = 116), score 0 for exocrine function (E0, n = 16), score 1 for exocrine function (E1, n = 37) and score > 2 for exocrine function (> E2, n = 4). Bars represent the mean ± SD. $^aP < 0.05$ *vs* healthy control.

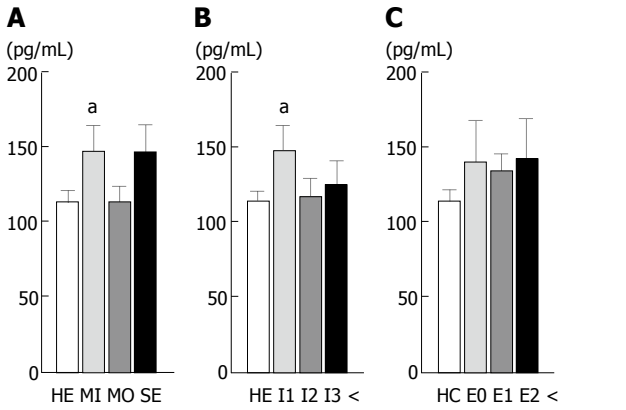

Figure 7 Serum s-fractalkine concentrations in non-alcoholic CP for each factor. Serum s-fractalkine concentrations were measured for patients with non-alcoholic CP (n = 57) by ELISA. A: Serum s-fractalkine concentrations were measured by ELISA for each stage of severity: Healthy control (HE, n = 116), mild severity (MI, n = 33), moderate severity (MO, n = 19) and severe (SE, n = 5); B: Serum s-fractalkine concentrations were measured by ELISA for each imaging tests score. Healthy control (HE, n = 116), score 1 for imaging tests score (I1, n = 33), score 2 for imaging tests score (I2, n = 15), and score < 3 for imaging tests score (< I3, n = 9); C: Serum s-fractalkine concentrations for each score of exocrine function. Healthy control (HC, n=116), score 0 for exocrine function (E0, n = 16), score 1 for exocrine function (E1, n = 37) and score > 2 for exocrine function (> E2, n = 4). Bars represent the mean ± SD. $^aP < 0.05$ *vs* healthy control.

only few reports related to the serum chemokines and cytokines levels in patients with pancreatic diseases, especially CP. Therefore, in the present study, we examined serum MCP-1, TGF-β1, and s-fractalkine concentrations that are supposed to be involved in the progression of chronic inflammatory diseases in patients with CP. In patients with CP, TGF-β1 and s-fractalkine levels, but not MCP-1 levels, were significantly increased compared to healthy controls. CP patients were classified according to severity of disease using a staging system which is based on clinical symptoms and pancreatic functions[12-14] and analyzed for the relationship with those chemokines and cytokines in order to assess the usefulness of these mediators as biological or functional markers of CP.

MCP-1, a family member of C-C chemokines, is known to play an important role in the development of the pancreatic fibrosis in CP. Previously, we reported that MCP-1 is expressed strongly in mild to moderate stages of pancreatic fibrosis in CP model rats, and suggested MCP-1 to be a pro-fibrogenic factor for CP[16,17]. Furthermore, we showed fibrosis of CP is inhibited by blocking MCP-1[18,19]. In the present study, we thus examined whether MCP-1 might be a useful marker in CP. MCP-1 levels in patients with CP, however, were not significantly higher than in healthy controls. Also in previous reports, serum MCP-1 didn't increase in patients with CP[20]. Consequently, it is thought that serum MCP-1 doesn't become a useful marker in the diagnosis of CP.

TGF-β1 is a homodimeric, multifunctional cytokine[21]. Until now, it has been generally well understood that TGF-β1 plays an important role in the development of the pancreatic fibrosis in CP[22]. TGF-β1 is thought to be expressed in pancreatic stellate cells (PSC) and acinar cells closer to pancreatic fibrosis, and to regulate the synthesis of collagen from PSC[23-25]. In our results, serum TGF-β1 levels of the patients with CP elevated significantly in the more severe stages of CP, especially in the group with more advanced scores in pancreatic imaging and exocrine function tests. These findings suggest that serum TGF-β1 levels tended to increase significantly in patients with more advanced CP. Previously, Su *et al*[26] reported the expression of TGF-β1 in pancreatic tissue in WBN/Kob rats which is considered as a CP model, and demonstrated that expression of TGF-β1 and fibronectin showed a peak at 12 wk, whereas pancreatic fibrosis peaked at 16 wk. It was concluded that TGF-β1 may trigger fibrogenesis. Furthermore, Detlefsen *et al*[27] classified the pancreatic tissue from CP patients into histological staging by an inflammatory process, and showed that TGF-β1 receptors had expressed predominantly in the early to moderate stage of pancreatic fibrosis. Given these data, we had expected that TGF-β1 levels might increase in the progressive process of pancreatic fibrosis for the present study. However, our results showed that TGF-β1 levels are elevated in patients with most advanced CP. On the other hand, interestingly, CP patients with high alcohol consumption showed a significant increase in levels of TGF-β1 (Figure 5). Concerning other organs, such as the liver and lungs, it is well known that the expression of TGF-β1 increases in the tissue of local organs from the effects of alcohol[28,29]. Therefore, in the present study, in order to clarify whether serum TGF-β1 levels might increase by TGF-β1 originated from various organs under the influence of alcohol, we focused on 57 patients with non-alcoholic CP who are not influenced by alcohol, and analyzed similarly the

relationship between TGF-β1 and each factor (Figure 6). For the classification of severity of CP, patients with CP in the moderate stage alone showed a significant increase in serum TGF-β1 compared to healthy controls. Furthermore, in the classification of imaging tests and exocrine function tests, CP patients revealing a moderate progressive stage tended to have higher serum TGF-β1 levels. These results are in accordance with previous reports[26,27]. That is to say, our results support the idea that serum TGF-β1 levels might increase because the expression of TGF-β1 was elevated in the moderate stage in which fibrosis had been proceeding in a broad range of pancreatic tissue. On the other hand, serum TGF-β1 levels might decrease in severe stages because pancreatic tissue had been already replaced with fibrosis. Taken together, it is suggested that the determination of serum TGF-β1 levels might be useful to diagnose moderate stages in patients with non-alcoholic CP.

Fractalkine/CX3CL1, a family member of CX3C chemokines, has recently been reported to be expressed as a membrane-spanning adhesion molecule that can be cleaved from the cell surface to produce a soluble chemoattractant[30-33]. The expression of fractalkine has been observed on various cells such as epithelial cells or endothelial cells of several organs. Membrane-bound fractalkine (m-fractalkine) is shed by metalloproteinase, and releases s-fractalkine[34]. M-fractalkine functions as an adhesion molecule, whereas s-fractalkine acts as a chemoattractant and recruits inflammatory cells expressing fractalkine receptors such as monocytes[33]. In inflamed local organs, such as the liver, lungs, and the kidneys, the participation of fractalkine has been recently noted[35-40]. Furthermore, increased s-fractalkine serum levels have been reported for patients with various chronic inflammatory diseases[40-44]. However, until now, there are no reports related to fractalkine in pancreatic inflammatory diseases. In the present study, we measured s-fractalkine in the serum of patients with CP. We found serum s-fractalkine levels to be significantly elevated in patients with CP. In classification of severity and pancreatic imaging tests, serum s-fractalkine levels showed significant bisferious increase in mild and severe stages. In classification of the exocrine function tests, serum s-fractalkine levels increased in mild stages alone. On the other hand, CP patients with high alcohol consumption showed a significant increase in s-fractalkine levels, similar to those of TGF-β1 (Figure 5). Since the relationship between alcohol and fractalkine was still unclear in organs, including the pancreas, we focused on 57 patients with non-alcoholic CP, and analyzed the relationship between s-fractalkine and each factors, similar to TGF-β1 (Figure 7). In classification of severity and pancreatic imaging tests, only patients with CP in the mild stage alone showed a significant increase in serum s-fractalkine compared to healthy controls. Thus, in patients with non-alcoholic CP, the measurement of serum s-fractalkine may be useful biological and functional markers to diagnose early-stage CP.

In conclusion, it is suggested that the measurement of serum TGF-β1 may be available to diagnose moderate stage of non-alcoholic CP, and that the measurement of serum s-fractalkine may be useful to diagnose early stages of non-alcoholic CP. Therefore, the measurement of a combination of TGF-β1 and s-fractalkine may be helpful to evaluate the status of CP.

COMMENTS

Background

Chronic pancreatitis (CP) is a chronic clinical disorder characterized by irreversible damage to the pancreas. Unfortunately, simple, indirect measurements of decreased pancreatic function have not shown abnormality until CP is advanced. The quest continues for useful biological and functional markers of early-stage CP. Recently, the roles of chemokines and cytokines have been made clear in the progression of chronic inflammatory diseases. Similarly, chemokines and cytokines have been recognized as important factors in the progression of CP. However, until now, there are only few reports addressing serum chemokine and cytokine levels in patients with pancreatic diseases, especially CP.

Research frontiers

Recently, it is widely accepted that pancreatic stellate cells are responsible for the progression of pancreatic fibrosis production of an extracellular matrix, chemokines and cytokines. Especially, the expression of transforming growth factor beta-1 (TGF-β1) is, prior to pancreatic fibrosis in WBN/Kob rats, supposed to be a trigger for the fibrogenic process. Monocyte chemoattractant protein-1 (MCP-1) is related to the pancreatic fibrosis in di-n-butyl tin dichloride (DBTC)-induced rats. Next, it has been reported that soluble type fractalkine (s-fractalkine) increased in the serum of patients with various chronic inflammatory diseases: Atopic dermatitis, the nervous system, lupus erythematosus, rheumatoid vasculitis, and pityriasis rosea. Therefore, the purpose is to investigate whether the determination of serum MCP-1, TGF-β1, and s-fractalkine concentration can become a useful biological and functional marker of CP using large number of CP patients classified by severity with a staging system.

Innovations and breakthroughs

Serum TGF-β1 levels of the patients with CP tended to increase in the patients with more advanced CP, whereas serum s-fractalkine levels showed bimodal increase in mild and severe stages. However, it was observed that both TGF-β1 and s-fractalkine levels were affected by alcohol intake. Thus, serum TGF-β1 showed significant increase in the moderate stage of CP, and serum s-fractalkine revealed significant increase in the early stage of CP, when removed alcoholic CP. Therefore, the measurement of serum TGF-β1 may be available to diagnose moderate stage of non-alcoholic CP, and that the measurement of serum s-fractalkine may be useful to diagnose early stages of non-alcoholic CP. The measurement of a combination of TGF-β1 and s-fractalkine may be helpful to evaluate the severity status of CP.

Applications

Patients with CP fulfilled clinical diagnostic criteria for CP by the Japan Pancreas Society and healthy control patients excluded with recent inflammatory diseases such as infectious diseases and chronic hepatitis, and a large scale of drinking were selected. We classified the CP patients into stages of severity by the modified staging system which consists of 6 grading factors. Then, we analyzed whether each grading factor (pancreatic imaging tests, exocrine function, glucose metabolism, pain, alcohol intake, complications) and severity of CP are related with serum MCP-1, TGF-β1 or s-fractalkine levels. Enzyme-linked immunosorbent assays (ELISA) were performed to quantify serum MCP-1, TGF-β1, and s-fractalkine concentrations.

Peer review

The conclusion of the study is that serum s-fractalkine determination is useful at the early stage of the disease. First, the classification of severity of chronic pancreatitis seems complicated since involving 6 grading factors. Apart from the clinical course and histological stage, the staging system for CP, based on

clinical symptoms and pancreatic functions has been proposed in Japan. Next, to analyze a third group, a group of "healthy" but alcoholic controls without liver or other organic disease would be interesting although they are excluded in this study. An interesting perspective of this work should be the longitudinal evolution of this maker during progression of the disease.

Abstract

AIM: To observe the effect of electroacupuncture (EA) of "Neiguan" (PC6) and "Gongsun" (SP4) on pathological changes of the heart and stomach in rats with acute myocardial ischemia (AMI), and to explore its underlying mechanism.

METHODS: Fifty Wistar rats were randomized into control, model, PC6, SP4 and PC6 + SP4 groups (n = 8 each group). An AMI model was established by occlusion of the descending anterior branch (DAB) of the left coronary artery. ECG-ST of cervico-thoracic lead and electrogastrogram (EGG) were recorded. EA was applied to PC6, SP4 and PC6 + SP4 groups, respectively. At the end of experiments, the rats were transcardically perfused with 4% paraformaldehyde, and the heart base myocardium, gastric antrum and duodenum tissues were sampled, sectioned and stained with a reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH)-diaphorase histochemical method for displaying nitric oxide synthase (NOS) activity.

RESULTS: After AMI, ECG-ST values elevated. After EA, the elevated ECG-ST values at 20 min in PC6 group, at 30 min in PC6 + SP4 and SP4 groups had no significant differences in comparison with their respective basal values before AMI. Following AMI, the amplitude and frequency of slow waves of EGG decreased remarkably ($P < 0.05$). At 30 min after EA, the mean amplitude and frequency of slow waves of EGG in the three EA groups had no marked differences compared with their individual basal levels and those in the control group. After AMI, the mean integral grey values of NOS-positive product in myocardium, gastric antrum and duodenum tissues in the model group increased remarkably in comparison with the control group, while those in three EA groups were lower than those in the model group. No significant differences were found in ECG-ST and EGG improvement among the three EA groups. However, EA of PC6 had a better effect on ECG-ST and EA of PC4 had a better effect on EGG, respectively.

CONCLUSION: EA of PC6, SP4 and PC6 + SP4 can significantly promote the recovery of cardiac and gastric electrical activities after AMI, and up-regulate NOS expression in myocardium, gastric antrum and duodenum tissues.

INTRODUCTION

It has been well documented that acupuncture of Neiguan (PC6) can effectively improve symptoms of angina, palpitation, *etc* and the left cardiac function in coronary heart disease (CHD) patients[1-4]. Experimental studies in rabbits, rats, and cats also showed that acupuncture improves myocardial ischemia (MI), hemodynamics, microcirculation and energy metabolism of ischemic heart, decreases susceptibility to ventricular

tachycardia, and protects myocardiocytes from injury[5-12]. PC6 combined with other acupoints often functions well in relieving pregnancy or MI-induced vomiting, alimentary canal ulceration, abdominal pain, *etc* and regulating secretion activities of various hormones in the gastrointestinal tract[13-15]. PC6 combined with Gongsun (SP4) can improve electrocardiogram (ECG) of CHD patients[16], and lessen gastrointestinal reactions in cancer patients undergoing chemotherapy[17,18]. It was reported that after injection of choleratoxin B coupled horseradish peroxidase (HRP) in PC6 and simultaneous electroacupuncture (EA) stimulation of SP4, the number of the labeled neurons in C6-C8 spinal ganglia and dorsal horns increases significantly and the distribution segments are expended[19], displaying a synergistic action. However, majority of these studies only explored the effect of acupuncture of a single acupoint on one internal organ and fewer studies have been conducted to explore its effect of one or more acupoints on two-visceral activities. For this reason, the present study was designed to observe the characteristics and regularities of EA of PC6 and/or SP4 in regulating the cardiac and gastric functional activities in acute myocardial ischemia (AMI) rats, and to analyze its underlying mechanisms.

MATERIALS AND METHODS

Animals and grouping

Forty male Wistar rats (weighing 250-320 g), supplied by the Experimental Animal Center of Chinese Academy of Medical Sciences, were used in the present study. All the rats fasted for about 24 h before each experiment (with free access to water) and were randomized into control, model, PC6, SP4 and PC6 + SP4 groups (n = 8 in each group). All procedures were approved by the Administrative Committee of Laboratory Animal Care and Use of Chinese Academy of Medical Sciences.

Main instruments and reagents

Instruments used in this study included multi-channel physiological recorder (RM-6000 Nihon Kohden, Japan), PowerLab data acquisition system (Australia, AD/ instruments), mini-animal respirator (Jiangwan Type-Ⅱ), HANS EA apparatus (LH202H), DRB-2D electrical blanket, cryostat freezing microtome (Leica, Leitz1720), light microscope (OLYMPUS), image analyzer (MSP UV-VIS 2000, USA).

Reagents used in this study were a reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH), nitroblue tetrazolium (NBT, Sigma), paraformaldehyde (Sigma).

Experimental protocols

Surgical operation: After anesthesia with a mixture solution (0.5 mL/100 g, ip) of 1.5% chloralose (5 mg/100 g) and 25% urethane (42 mg/100 g), the rat was fixed on an animal table for performing trachea cannula, thoracotomy between the 3rd and 4th intercostal spaces on the left side of the chest along the sternum, and laparotomy below the xiphoid-process.

Establishment of AMI model: After turning on artificial respirator (60 cycles/min), a surgical suture (gauge-0) was put through the myocardium beneath the root part of the descending anterior branch (DAB) of the left coronary artery for inducing AMI.

Electrogastrogram (EGG) recording electrode resettlement: For EGG recording, a pair of stainless steel electrodes was implanted beneath the subserosa about 0.5 cm apart from the pylorus of gastric antrum and a reference electrode was placed subcutaneously in the adjoining incision.

Electrocardiogram (ECG) recording electrode resettlement: For recording ECG of the cervico-thorax lead, two stainless steel electrodes were placed beneath the skin close and left to the xiphoid-process, and the neck back, respectively, and the reference electrode was placed beneath the skin of the right hindlimb.

EA: Bilateral PC6 and SP4 were located as previously described[20]. Two acupuncture needles (Gauge-28, 0.5 cm) were separately inserted into each acupoint, and connected to the HANS EA apparatus to stimulate the acupoint for 30 min with parameters of 2/15 Hz and 1-3 mA (increased gradually).

Procedure of management: After settlement of all the electrodes, ECG and EGG were recorded using polygraph, Power-Lab/8S-Chart 6.0 and computer before and during occlusion of DAB (30 min) and reperfusion (AMI/R, 30 min). EA was given just before the occlusion.

Sampling: After physiological experiments were finished, the animals were subjected to transcardial perfusion with normal saline (300 mL), and 4% polyoxymethylene in a phosphate buffer (4℃, 400 mL, 0.1 mol/L, pH 7.4), respectively. The left-atria tissue of the cardiac base (between the aorta and the pulmonary artery, containing nerve plexus controlling cardiac functional activities), gastric antrum and annectant duodenum tissues were taken and equilibrated in 20% sucrose overnight, and stored at 4℃.

Staining and observation of tissue samples: Tissue samples were cut into 20-μm thick sections and mounted onto gel-treated glass slides. The sections were washed twice with PBS and incubated to demonstrate NADPH-diaphorase activity in the following medium: 0.1 mol/L phosphate buffer solution (pH 7.4, 10 mL) containing 5 mg of NBT, 10 mg of beta-NADPH, and 0.1 mol/L Tris-HCL for 30 min at 37℃. The sections were then incubated in 0.1 mol/L PBS (pH 7.4) containing 0.2% Triton X-100 (1.0 mL) for 120 min, dehydrated in a graded series of alcohol, and sealed with neutral gum.

Under a light microscope, cells containing NADPH-

diaphorase, a marker for the presence of inducible nitric oxide synthase (NOS), were observed and the integral grey value was detected using an image analyzer.

Statistical analysis

Data were expressed as mean ± SD and analyzed with one-way ANOVA using SPSS11.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of EA on ischemic ECG-ST

After occlusion of DAB, ECG-ST elevated significantly in model, PC6, SP4, PC6 + SP4 groups ($P < 0.05$, Figure 1A). Following AMI/R, ECG-ST elevated in the model group and declined in the three EA groups (PC6, SP4, PC6 + SP4). The ECG-ST values were significantly lower in PC6, SP4 and PC6 + SP4 groups than those in the model group at 10, 20 and 30 min after EA ($P < 0.05$). No significant difference was found among the three EA groups ($P > 0.05$). The ECG-ST values were still markedly higher in the SP4 and model groups than those in control group 30 min after EA ($P < 0.05$), and no significant difference was found between the PC6 and control groups or between the PC6 + SP4 and control groups.

Effect of EA on the amplitude of slow waves of EGG

After AMI, the slow wave amplitude of EGG declined remarkably ($P < 0.05$, Figure 1B), the slow wave amplitude of EGG in the model group decreased further, while those in the PC6, SP4 and PC6 + SP4 groups had an apparent recovery. The slow wave amplitude of the model group was significantly lower than that in the control group after AMI and AMI/R ($P < 0.05$). The slow wave amplitudes of the SP4, PC6 and PC6 + SP4 groups were comparable after AMI/R, and significantly higher in the SP4 group than that in the control group ($P < 0.05$). The effect of EA of SP4 was slightly stronger on increasing the slow wave amplitude of EGG.

Effect of EA on the frequency of slow waves of EGG

Following AMI, the frequency of slow waves of ischemic EGG decreased significantly in comparison with the basal values in each group ($P < 0.05$, Figure 1C). After AMI/R, the mean frequency of slow waves of ischemic EGG in the model group decreased further, and was still markedly lower than its basal value 30 min post-EA ($P < 0.05$). The mean frequencies of slow waves were significantly higher in the three EA groups than that in model group after AMI/R ($P < 0.05$). At 20 min after EA, the mean frequency of slow waves of ischemic EGG in the SP4 group was not significantly different from that in the control group ($P > 0.05$). At 10 min after AMI/R and EA, the mean frequencies of slow waves of ischemic EGG in the PC6 + SP4 and PC6 groups were obviously higher than that in the model group ($P < 0.05$, Figure 1C) and did not return to their basal values 30 min after EA

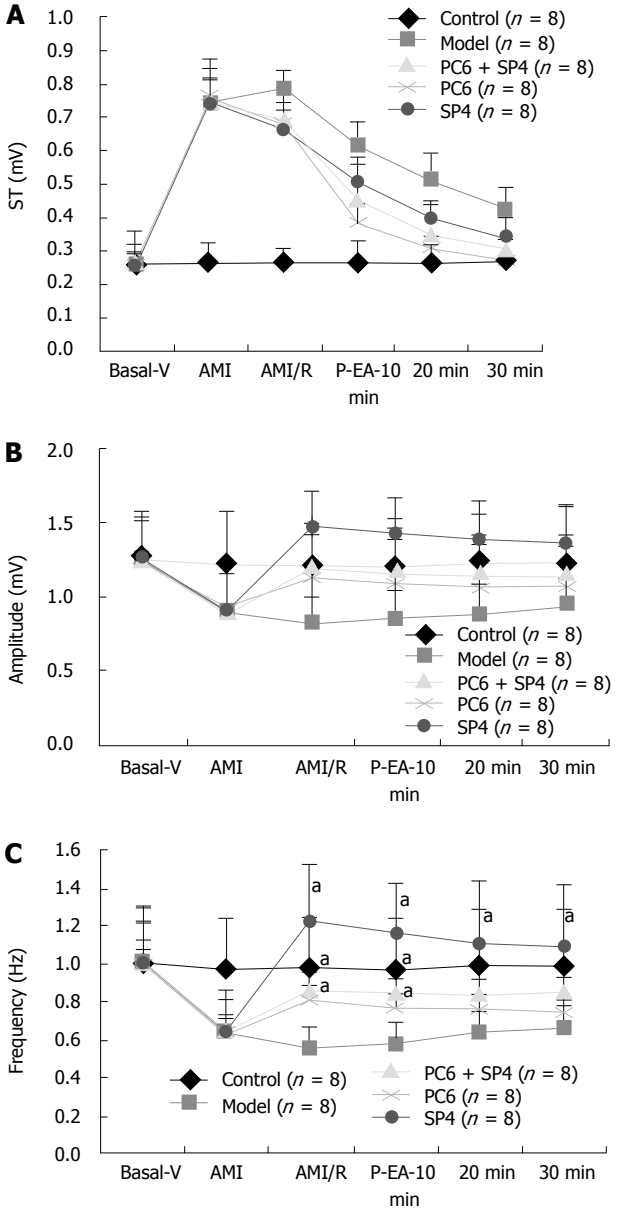

Figure 1 Changes in rabbit ECG-ST (mV, A), amplitude (mV, B) and frequency (pulses/s, C) of slow waves of electrogastrogram (EGG) in control, model, PC6, SP4 and PC6 + SP4 groups ($n = 8$ in each group) at different courses after acute myocardial ischemia and reperfusion (AMI/R). [a]$P < 0.05$ *vs* model group; Basal-V: Basal value; P-EA: Post-EA.

($P < 0.05$). The effect of EA of SP4 was slightly better on increasing the frequency of slow waves of ischemic EGG.

Effect of EA on the frequency of fast waves of ischemic EGG

During experiments, burst (fast) of waves ischemic of EGG appeared only in some animals, particularly after AMI/R. We randomly chose three rats in each group and analyzed the effect of EA (Table 1). The frequency of fast waves of ischemic EGG increased significantly from the beginning of AMI/R after EA in the SP4 group, while the frequencies of fast waves of ischemic EGG in the model, PC6 and PC6 + SP4 groups were close to that in the control group.

Table 1 Changes in mean frequency of EGG fast waves in rabbits at different time-courses after AMI/R and EA (mean ± SD, pulses/s, *n* = 3/group)

Groups	Basal values	AMI	AMI/R	P-EA 10 min	P-EA-20	P-EA-30 min
Control	1.90 ± 1.91	1.84 ± 1.82	1.89 ± 1.87	1.84 ± 1.82	1.90 ± 1.84	1.85 ± 1.83

Effect of EA on the NOS activity of myocardium, gastric antrum and duodenum muscle

NADPH-diaphorase staining of myocardium, gastric antrum and duodenum (Figure 2A-C) showed that NADPH-diaphorase/NOS-expressed positive fibers, neurons and their processes had a purple/blue color, which was denser in the control group, moderate in the three EA groups and lightest in the model group.

In myocardium tissue (Figure 2A), NOS positive reaction product (in nerve fibers) presented a string-of-beads-like distribution (dark blue color) on the wall of larger blood vessels along the longitudinal axis of the smooth muscle fibers, and was denser in the control group, moderate in the PC6 group, milder in the PC6 + SP4 and SP4 groups, and lightest in the model group. In gastric antrum tissue (Figure 2B), most NOS-expressed neurons were round and oval in shape. Fewer irregular polygons and their cytoplasm were uniformly dark blue and their nuclei were relatively lighter in color. NOS-positive reaction product was denser in the control group, moderate in the SP4 group, milder in the PC6 and PC6 + SP4 groups, lightest in the model group. In the duodenum tissue (Figure 2C), the shape and color of NOS-expressed positive neurons in the control, model, PC6, PC6 + SP4 and SP4 groups were similar to those in the gastric antrum.

The integral grey values for myocardium, gastric antrum and duodenum increased in the model and PC6, PC6 + SP4 and SP4 groups compared with the control group after AMI/R (Table 2). Following EA, the integral grey values for myocardium and duodenum in the PC6 and SP4 group were closer to that in the control group, suggesting that EA could suppress AMI/R- induced down-regulation of NOS.

DISCUSSION

In the light of the theory of Chinese medicine, PC6 and SP4 are two convergent acupoints of the eight Meridians. PC6, the Luo-point of the Pericardium Meridian, is often used to treat palpitation, chest distress and thoracalgia in the upper energizer, gastralgia and vomiting of the middle energizer, and irregular menstruation of the lower energizer, *etc*. SP4, the Luo-point of the Spleen Meridian of Foot-Taiyin, is frequently employed to treat gastralgia, vomiting, abdominal pain, diarrhea, *etc*. These two acupoints, used in combination, can function well in relieving disorders of the heart and gastrointestinal tract, but related experimental investigations are fewer, in spite of being frequently used in clinic practice.

Results of the present study show that ECG-ST elevated significantly after occlusion of DAB, meaning occurrence of AMI. After release of the ligature (AMI/R), ECG-ST in the model group elevated further, while decreased significantly in the PC6, SP4 and PC6 + SP4 groups. At 20 min after EA in the PC6 group, and 30 min in the PC6 + SP4 group after EA, ECG-ST values returned to their basal levels before occlusion of DAB, and those in the SP4 and model groups were still higher than their respective basal levels. No significant differences were found in ECG-ST values at different time courses among the three EA groups, indicating that EA of PC6, SP4 and PC6 + SP4 can effectively promote the recovery of ischemic myocardial injury. Unfortunately, no synergistic action of EA of PC6 + SP4 on AMI was found in the present study. The results of EA of PC6 and PC6 + SP4 are similar to the reported findings[5,7,8,16].

After AMI, the cardiac blood-pumping function was weakened, leading to decrease in cardiac output and in perfusion volume in many organs, and disturbance of blood circulation, thus an abnormal change occurred in EGG.

The results of this study show that after AMI, the amplitude and frequency of slow waves of EGG decreased considerably, and decreased further in the model group, and did not return to their pre-AMI levels at 30 min after ligation of DAB, suggesting a remarkable suppression of the basal electrical activity of the gastric smooth muscle due to insufficient blood supply. In the three EA groups, both the amplitude and frequency of slow waves of EGG increased after EA stimulation. The amplitude of slow waves of EGG in the three EA groups returned to their pre-AMI basal levels at 30 min after EA. No significant difference was found in the amplitude of slow waves of EGG among the three EA groups. Twenty minutes after EA, the mean frequency in the SP4 group was not markedly different from that in the control group. Ten minutes

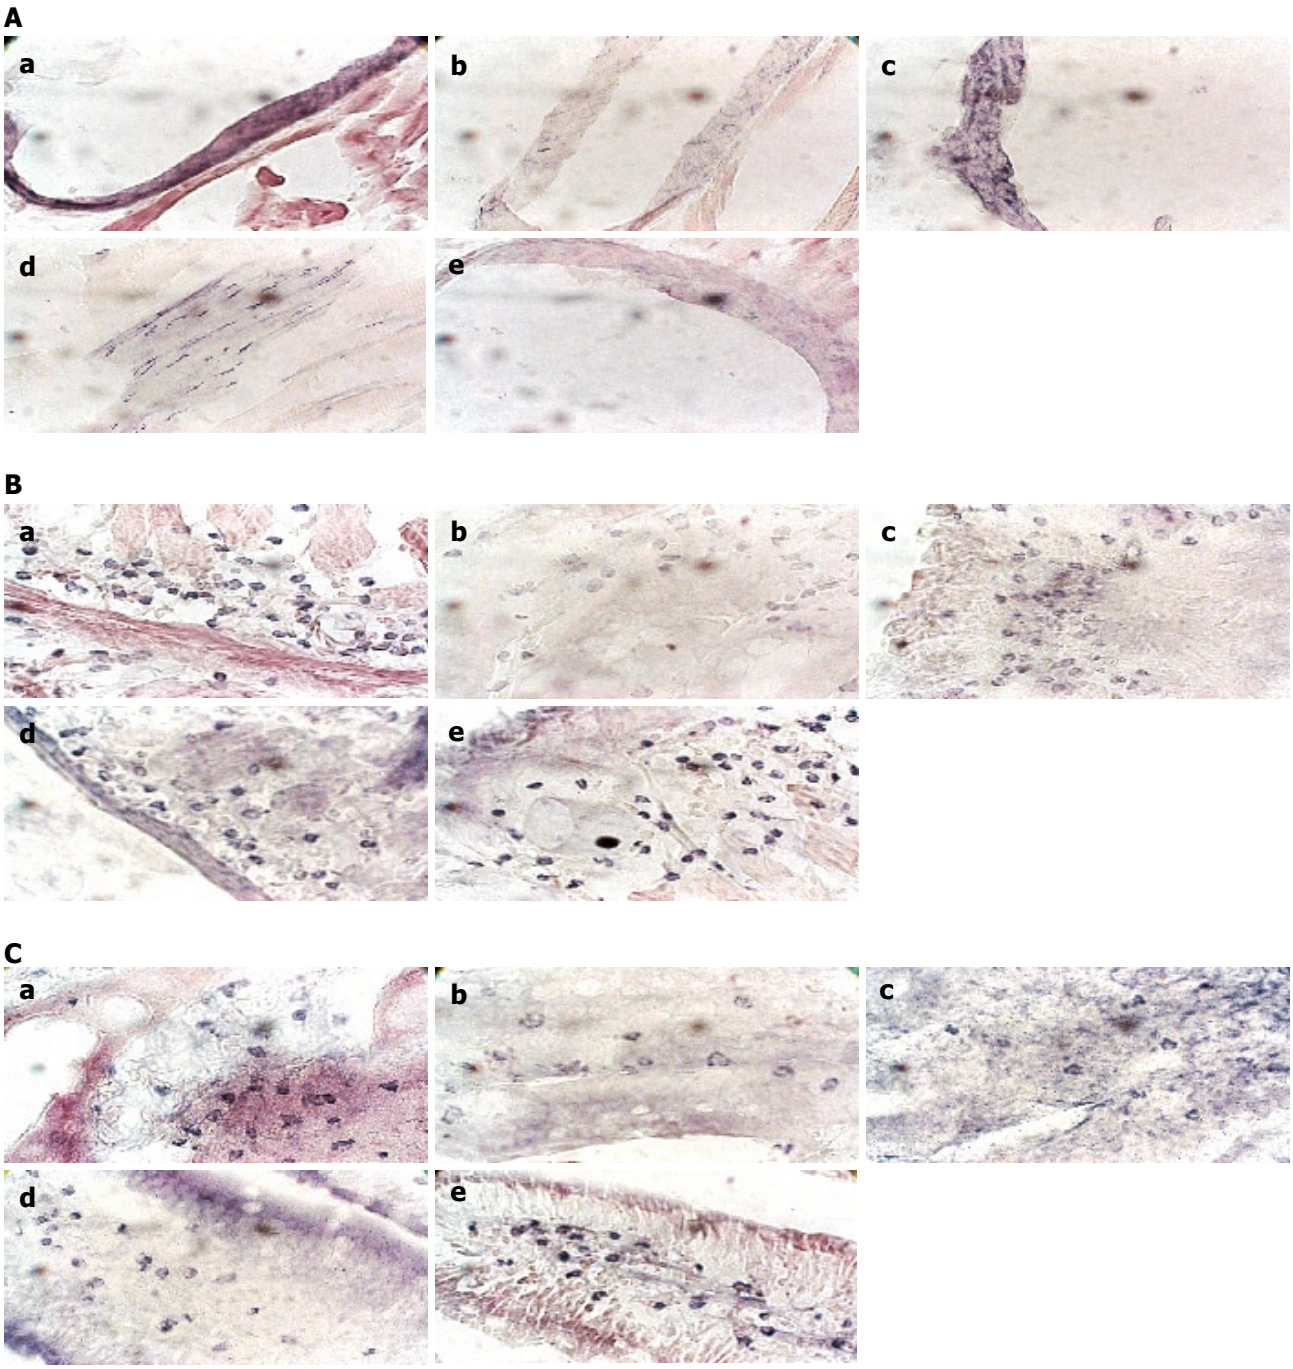

Figure 2 Photographs showing NOS expression in the myocardium of the rabbit heart base (left atrium, A), gastric antrum (B) and duodenum (C) in control (a), model (b), PC6 (c), PC6 + SP4 (d) and SP4 (e) groups. A: NOS positive reaction product (in nerve fibers) presented string-of-beads-like distribution (dark blue color) on the wall of larger blood vessels along the longitudinal axis of the smooth muscle fibers. NOS-positive product was denser in control group (a), moderate in PC6 group (c), milder in PC6 + SP4 (d) and SP4 (e) groups, lightest in model group (b); B: NOS positive reaction neurons distributing in the mucous layer and underlayer of the rabbit gastric antrum; C: NOS positive reaction neurons distributing in the mucous layer and underlayer of the rabbit duodenum tissues. Most of them were round and oval, and fewer irregular polygon, and their kytoplasm was uniformly dark blue and their nuclei were relatively lighter in color. NOS-positive reaction product was denser in control group (a), moderate in SP4 group (e), milder in PC6 (c) and PC6 + SP4 (d) groups, lightest in model group (b). (X 400).

after AMI/R and EA, the mean frequency in PC6 + SP4 and PC6 groups was obviously higher than that in the model group and did not return to their basal values 30 min after EA, indicating that the effect of EA of SP4 on the frequency of slow waves of EGG is stronger. It has been demonstrated that EA of PC6 and SP4 can ameliorate symptoms of abdominal pain, vomiting, *etc*, and the ratio of the main frequency of EGG between pre- and post-meal in functional dyspepsia patients[13,14,21,22].

It has been well-documented that the effect of acupuncture on regulating cardiac and gastrointestinal activities involves the nervous system, endocrine system, and multi-targets[1,4,12,14]. Improved microcirculation and appropriate amount of NO production may be one of the important factors. NO, a micromolecule gas, is

synthesized from *l*-arginine under the catalysis of NO synthase, and can activate guanylate cyclase of the cells and exert biological effects *via* the resultant cGMP. Continuous basal release of NO is very important for maintaining stable diastole state and base tension of the coronary artery and regulating blood pressure and myocardial blood perfusion[23]. Myocardial ischemia decreases myocardial NO concentration and NOS expression[24]. In our experiments, the blue positive reaction product in the myocardium, gastric antrum and duodenum was the densest in the control group, moderate in the three EA groups, and the lightest in the model group. The integral grey values for myocardium in the PC6 group, gastric duodenum in the PC6 + SP4 group were relatively denser, suggesting that NOS expression decreases apparently after AMI, while increases after EA, which may contribute to its effect on improving cardiac and gastric electrical activities in AMI/R rats. Our results are basically identical to other reported findings[25-29]. For example, Li *et al*[25] observed that EA of PC6 could up-regulate plasma NO and blood platelet α granule membrane protein-140 contents and reduce myocardial injury in myocardial ischemia rabbits. Luo *et al*[26] reported that acupuncture of PC6, SP4, *etc*, could relieve symptoms of peptic ulcer and elevate plasma NO level. In rats with alcohol-induced mucous membrane injury, EA of Zusanli (ST36) plus PC6 or SP4, or simple PC6, could effectively raise the contents of NO and epidemic growth factor in gastric mucosa tissue, and promote the synthesis and release of NO, thus protecting gastric mucosa from injury[27-29]. These results suggest that NO is able to mediate the effects of EA on improving cardiac and gastrointestinal functional activities. Our study did not show a synergistic action of EA of both PC6 and SP4 as reported[30].

In conclusion, EA of PC6 and SP4 can exert similar effects on cardiac and gastric activities. EA of one acupoint may simultaneously regulate the activities of multiple viscerae. Hence, in clinical practice, PC6 and SP4 used in combination are applicable to the treatment of both cardiac and gastric disorders.

COMMENTS

Background

Neiguan (PC6) and Gongsun (SP4), two convergent acupoints of the eight Meridians, are indicated for disorders of the stomach, heart and chest. In fact, the two acupoints are frequently used in combination to treat gastrointestinal disorders as nausea, vomiting, *etc*, in clinical practice. When used individually, PC6 mainly functions well in regulating problems of the heart, while SP4 is chiefly indicated for gastralgia, acute and chronic enteritis, vomiting, menstrual disorder, *etc*. The present study observed the effect of electroacupuncture (EA) of PC6 and/or SP4 on the activities of the heart and gastrointestine under pathological state (acute myocardial ischemia) from electrophysiological and histochemical aspects so as to analyze their action regularities.

Research frontiers

The correlation between acupoints and internal organs is a key theoretical basis of Chinese acupuncturology and acupuncture in clinical practice. The present study was undertaken to observe the relative specificity of EA of acupoints in regulating activities of the corresponding internal organs. In addition, joint application of two or more acupoints may have a synthetic effect or a counter action under certain circumstances. Since the related regularities and the underlying mechanism remain unknown, the present study observed the effects of EA of PC6 and /or SP4 on activities of the heart and gastrointestine simultaneously.

Innovations and breakthroughs

Fewer experimental studies have been conducted to observe the effect of EA of one or two acupoints on two internal organs at the same time. The present study demonstrated that EA of PC6, SP4 or PC6 + SP4 on myocardial ischemia-reperfusion (MI-R)-induced elevation of ECG-ST and decreased mean amplitude and frequency of slow waves of electrogastrogram (EGG), as well as reduced nitric oxide synthase (NOS) expression in the myocardium, gastric antrum and duodenum were all corrected significantly sooner or later. Moreover, EA of PC6 and SP4 could improve ECG-ST, and regulate NOS activity of myocardium and mucous membrane of duodenum.

Applications

The results of the present study provided certain new experimental evidence for treating disorders of the heart and gastrointestine by acupuncture of PC6 and SP4 and verified the theory of Chinese acupuncturology about the relatively specific effects of acupoints on their corresponding internal organs.

Terminology

According to Chinese medicine theory, there are 12 regular meridians distributed regularly in the human body, each meridian pertains to a certain Zang- or Fu-organ (internal organ). When a certain acupoint is stimulated with an acupuncture needle, the corresponding internal organ can be regulated effectively in functional activities by way of meridian, particularly under pathological state. However, the regulatied effect of the stimulated acupoint on the internal organ is definitely not absolute, some related organs may be influenced at the same time. Thus, when mentioning the acupoint specificity, it mainly refers to its relative specificity in function.

Peer review

The paper describes the characteristics, values and significance of electroacupuncture, as well as the effects of electroacupuncture on cardiac and gastric activities of rats with ischemia, which may be of some values for clinicians in their clinical practice.

RAPID COMMUNICATION

Routine rectal retroflexion during colonoscopy has a low yield for neoplasia

Abstract

AIM: To investigate the value of retroflexion in detecting neoplasia in the distal rectum.

METHODS: This was a prospective observational study performed in an academic endoscopy unit. Consecutive patients undergoing colonoscopy had careful forward viewing of the distal rectum by retroflexion. Of 1502 procedures, 1076 (72%) procedures were performed with a 140° angle of view colonoscope and 426 (28%) were performed with a 170° angle of view colonoscope. The outcome measurement was the yield of neoplasia in the distal rectum detected by forward viewing *vs* retroflexion.

RESULTS: A total of 1502 patients, including 767 (51%) females and 735 (49%) males, with mean age of 58.8 ± 12.5 years were enrolled. Retroflexion was successful in 1411 (93.9%) patients, unsuccessful or not performed because the rectum appeared narrow in 91 (6.1%). Forty patients had a polyp detected in the distal rectal mucosa. Thirty-three were visible in both the forward and retroflexed view (25 hyperplastic, 8 adenomatous). Seven polyps were visualized only by retroflexion (6 hyperplastic sessile polyps, one 4 mm sessile tubular adenoma). There was no significant difference in information added by retroflexion with 140° *vs* 170° angle of view instrument.

CONCLUSION: To our knowledge, this is the largest reported evaluation of retroflexion in the rectum. Routine rectal retroflexion did not detect clinically important neoplasia after a careful forward examination of the rectum to the dentate line. Since retroflexion has risks and may cause discomfort, the use of routine retroflexion should be at the discretion of the endoscopist.

INTRODUCTION

Retroflexion is a commonly performed maneuver during colonoscopy[1], and has been strongly endorsed as an essential component of colonoscopy by experts, and specifically for the purpose of detecting neoplasia[1]. However, whether retroflexion substantially or significantly increases the detection of neoplasia during sigmoidoscopy and colonoscopy is controversial[2-5]. Among the four previously published reports of retroflexion, two failed to detect a single adenoma in retroflexion[2,3] and two detected lesions of such substantial size that the care with which the forward viewing of the distal rectum was performed is suspect[4,5]. Further, rectal retroflexion may be uncomfortable for patients and may result in perforation[6-9]. Retroflexion can be a useful therapeutic maneuver in the colon or rectum for polypectomy[10,11] and in the rectum for treatment of hemorrhoids[12,13]. However, two prospective studies found that anoscopy was superior to retroflexion for detection of hemorrhoids[14,15], and experts have opined that anoscopy provides more clinically useful information about hemorrhoids than can be detected by retroflexion[16]. Regardless of the contribution of retroflexion to the detection of non-neoplastic disease, the apparent mandate for performance of retroflexion during colonoscopy is the detection of neoplasia[1].

Given that the literature on the value of rectal

retroflexion during routine procedures is mixed[2-5], we prospectively assessed the detection of neoplasia during rectal retroflexion in 1502 consecutive patients.

MATERIALS AND METHODS

As part of our continuous quality improvement program, one of us (Douglas Kevin Rex) prospectively recorded the findings of retroflexion during colonoscopy from June 20, 2005 to August 15, 2006. Patients with poorly prepared colons, known history of rectal cancer or rectal resection, active Crohn's disease or ulcerative colitis, and patients referred for resection of known rectal polyps or for other therapeutic interventions in the rectum were excluded. Permission to review the data for publication was granted by the Institutional Review Board at Indiana University/Purdue University Indianapolis. The colonoscope used was prospectively recorded with regard to its angle of view (140º or 170º). Colonoscopes without cap-fitting were used as they were available and not otherwise selected.

The rectum was initially examined on forward view with withdrawal of the colonoscope to the dentate line with reflection of the tip in all directions using torque and up-down and right-left deviation as possible and appropriate. The endoscope was reinserted and retroflexed using the method of Grobe *et al*[2]. Manual rotation of the instrument was performed to inspect in a circumferential manner the anorectal area. The maneuver was considered successful if a complete 360º visualization of the distal rectum was obtained. Cases where retroflexion was successful, unsuccessful, or not attempted were documented. Whether polyps in the distal rectum were visible on forward or retroflexed views or both was prospectively recorded.

RESULTS

There were 1502 eligible patients, including 767 (51%) females and 735 (49%) males, with the mean age of 58.8 ± 12.5 years (range 17-95 years). Retroflexion was successfully performed in 1411 (93.9%) patients, unsuccessful in 1 patient because of a narrow rectum, and not attempted in 90 (6.0%) because the endoscopist judged that the rectum was too narrow. One thousand and seventy six (72%) procedures were performed with a 140º angle of view colonoscope while the rest 426 (28%) were performed with a 170º angle of view colonoscope.

We found that 40 of 1411 (2.8%) patients had a polyp detected in the distal rectum, of which 33 were visible in both the forward and retroflexed view (25 hyperplastic, 8 adenomatous), and 7 were visible only during retroflexion (6 hyperplastic and 1 adenomatous). Of the 8 adenomas in the distal rectum detected on both the forward and retroflexed view, the mean size was 7.3 mm (range 3-15 mm), 3 were pedunculated, 5 were sessile, 7 were tubular and 1 was tubulovillous. Each adenoma was detected in a separate patient and none had high-grade dysplasia. The adenoma detected only on retroflexion was a 4 mm tubular adenoma with low-grade dysplasia. Thus, 1 of 1411 patients had an adenoma detected only by retroflexion and none had an advanced adenoma or cancer.

Using 140º angle of view colonoscopes, 6 of 1076 (0.56%) patients had a polyp detected only by retroflexion, including the patient with the adenoma. Using 170º angle of view instruments, 1 of 426 patients (0.23%) had a polyp detected only by retroflexion (P = 0.41; Chi-square test).

DISCUSSION

In this prospective series, we found that routine performance of retroflexion during colonoscopy added little to the diagnostic yield of neoplasia. Importantly, retroflexion was performed only following a detailed forward-viewing examination of the entire rectum to the dentate line with a concerted attempt to view the entire rectal wall, including the distal rectum, on forward view. We also perform a careful digital rectal examination prior to colonoscope insertion, and none of the distal rectal polyps reported here were appreciated by palpation. Given that perforation has been reported to result from retroflexion[6-9], and that we are anecdotally aware of medical-legal actions against endoscopists for perforations occurring from retroflexion, we believe our data support a perspective that retroflexion during lower endoscopy is not mandated and must be left to the discretion of the endoscopist.

Previous studies have drawn varied conclusions with regard to the value of routine retroflexion during lower bowel endoscopy. Cutler and Pop[3] reported no adenomas detected only by retroflexion in 453 patients and questioned the value of routine retroflexion. Grobe *et al*[2] deemed retroflexion valuable in 75 patients, but did not document a single adenoma detected only by retroflexion. Hanson *et al*[4] detected four adenomas in 526 patients that were visible only on rectal retroflexion, and one was a 15 mm tubulovillous adenoma. Varadarajulu *et al*[5] reported the highest yield of routine retroflexion. Among 590 patients (91% male), 6 had adenomas detected only on retroflexion, of which all were > 1 cm in size and 2 were pedunculated. They stated that 50% of the distal rectal lesions were visible only on retroflexion. For unclear reasons, we did not encounter this prevalence of advanced pathology in the distal rectum either with forward or retroflexed views. Although the polyps we encountered were generally smaller, we could still visualize a high percentage (83%) on forward view. Thus, perhaps the value of routine retroflexion could be greater than we encountered when performed in different populations or if a different technique from the one that we used was employed to perform the forward examination that precedes retroflexion.

From an imaging perspective, the goal in exposing colorectal mucosa during colonoscopy is to expose and examine all of it. Based upon the senior authors' experience, knowledge of rectal anatomy, and logic, the need for retroflexion to complete exposure of the rectal mucosa is likely to vary based on each patients' unique

rectal anatomy. Thus, in some patients with narrow rectum, the rectal walls are visible circumferentially in a continuous fashion as they extend proximally when viewed from the internal anal verge in the forward view. Logically, retroflexion has little to add in such patients. In patients with a larger rectum, the posterior rectal wall may not be visible continuously when the instrument is looking forward from the anal verge. In this instance, retroflexion is logically more likely to add information, to be easier to perform, safer to perform, and more comfortable for the patient. In the senior authors' experience, the distal rectal walls are more likely to be continuously visible when viewed in the forward view from the anal verge using a 170º angle of view colonoscopy, as compared to a 140º angle of view instrument. In this study, the fraction of patients with a polyp detected only on retroflexion was lower with the 170º angle of view instrument compared to the 140º instrument, but the difference was not significant. Additional study of the impact of 170º angle of view instruments on the value of routine rectal retroflexion seems warranted.

Limitations of the current study include the relatively low yield of neoplasia in the distal rectum. However, the endoscopist of this study reported the highest adenoma detection rates in the literature[17], so there is no reason to believe that the study population had a low prevalence of adenomas. Indeed, the low prevalence of distal rectal adenomas may reflect the progressive shift of neoplasia toward the proximal colon in recent decades. A second limitation is that the procedures were performed by a single endoscopist. Endoscopists with less effective forward viewing technique could logically expect a higher yield from retroflexion.

Retroflexion in the rectum is unquestionably a useful diagnostic or therapeutic maneuver during colonoscopy in some patients and should be mastered by all colonoscopists. Retroflexion may provide useful information about benign anal disease and can provide a critical advantage for completion of polypectomy in some cases. Our study, however, supports the conclusion of Cutler that routine rectal retroflexion adds little to the detection of rectal neoplasia after careful forward viewing. Given the low yield of retroflexion when careful forward viewing has been completed, as well as the discomfort and risk of retroflexion, performance of retroflexion in routine cases should be at the discretion of the endoscopist. Anecdotally, we recommend that the appropriateness of retroflexion be considered after reaching the anal verge in the forward view and assessing whether the rectal walls are continuously visible as they extend proximally, as well as the size and anatomy of the patient's rectum.

COMMENTS

Background

Some experts believe that retroflexion or performance of a U-turn must be performed routinely during colonoscopy to rule out neoplasia in the distal rectum However, the available literature is mixed with regard to the value of routine retroflexion.

Applications

The study found that routine performance of retroflexion has a very low yield for neoplasia. Since retroflexion has a low but real risk, the results suggest that retroflexion is not routinely required to achieve a highly effective colonoscopy.

Terminology

Rectal retroflexion refers to a maneuver during colonoscopy in which the instrument tip is deflected in U-turn so that the imaging system is directed backward, allowing clear visualization of the distal rectum.

Peer review

Every year many patients experience complications associated with the practice of retroflexion. Prospectively collected data on whether or not retroflexion is essential is very much needed.

Abstract

AIM: To investigate the frequency of gastroenterological diseases in the etiology and the efficacy of proton pump inhibitors (PPIs) in the treatment of cardiac syndrome X (CSX) as a subform of non-cardiac chest pain (NCCP).

METHODS: We investigated 114 patients with CSX using symptom questionnaires. A subgroup of these patients were investigated regarding upper gastrointestinal disorders (GIs) and treated with PPI. Patients not willing to participate in investigation and treatment served as control group.

RESULTS: Thirty-six patients denied any residual symptoms and were not further evaluated. After informed consent in 27 of the remaining 78 patients, we determined the prevalence of disorders of the upper GI tract and quantified the effect of treatment with pantoprazole. We found a high prevalence of gastroenterological pathologies (26/27 patients, 97%) with gastritis, gastroesophageal reflux disease (GERD) and acid reflux as the most common associated disorders. If treated according to the study protocol, these patients showed a significant improvement in the symptom score. Patients treated by primary care physicians, not according to the study protocol had a minor response to treatment (n = 19, -43%), while patients not treated at all (n = 26) had no improvement of symptoms (-0%).

CONCLUSION: Disorders of the upper GI tract are a frequent origin of CSX in a German population and can be treated with pantoprazole if given for a longer period.

INTRODUCTION

Cardiac syndrome X (CSX) is a specific subform of non-cardiac chest pain (NCCP), defined as recurrent episodes of substernal chest pain or discomfort (exercise-related or not) with pathologic electrocardiographic (ECG) changes, but without significant cardiac abnormalities[1]. As relatively specific symptom complex involving ECG abnormalities, it often leads to cardiac catheterization after non-invasive cardiac diagnostic procedures, including treadmill exercise. Several studies indicate that about 15%-20% of all invasive cardiac diagnostic

procedures can not detect any significant coronary abnormalities, reliably ruling out cardiac origin of the symptoms, supporting the assumption that the prevalence of NCCP (including CSX) is approximately 25% in the general population[2]. Several studies have contributed in elucidation of the origin and possible therapeutic approaches of NCCP with partially quite heterogenous results[2]. However, there are very limited data for the subgroup of CSX patients.

Interestingly, many patients with NCCP are not forwarded to gastroenterologists for further diagnostic work-up after exclusion of cardiac origin for chest pain[3]. Thus, they remain with their symptoms, which may cause significant economic and psychological burden because of frequent work absenteeism, frequent consultation of healthcare providers and reduced quality of life[4]. NCCP represents an important determinant of resource utilization and health care costs[5]. A defined further diagnostic work-up and targeted therapy of NCCP, therefore, is not only useful for patients, but also for the society as a whole.

Previous studies have shown that NCCP originates mostly from GERD and other gastrointestinal diseases, including motility disorders, often combined with visceral hypersensitivity or abnormal cerebral processing of visceral stimuli[6]. Musculoskeletal diseases may be a minor origin of NCCP. Additionally, psychological abnormalities play an important role in causing or modulating NCCP[7]. Published mechanistic hypotheses involve the presence of an esophagocardiac reflex, leading to coronary spasms when the distal esophageal mucosa is exposed to hypochloric acid[8]. This mechanism is also called "linked angina" and would serve as an explanation for NCCP in patients with clear pathologic ECG signs despite normal coronary angiography, which has frequently been termed as CSX[9,10].

Treatment studies of general NCCP focus on proton pump inhibitors (PPIs), and there are clear data that omeprazole, rabeprazole and lansoprazole are effective in symptom relieve of NCCP[10].

To investigate prevalence of disorders of the upper gastrointestinal tract and treatment in CSX, we designed a study enrolling patients with abnormal treadmill exercise results, but angiographic exclusion of coronary abnormalities. Firstly, these patients were investigated thoroughly regarding gastrointestinal disorders (GIs). In a second step, they were included into a therapeutic trial with pantoprazole, initially intended as a randomized, double-blind study, to test the efficacy of the drug in this subgroup of NCCP.

MATERIALS AND METHODS

Inclusion and exclusion criteria

Patients at least 18 years of age with recurrent chest pain, a pathological treadmill exercise and a normal coronary angiogram fulfilled the inclusion criteria of the study. Patients were excluded from the study if they had medications lowering the pressure of the lower esophageal sphincter (calcium antagonists, nitrates), were already on acid-suppressive drugs during cardiologic work-up (PPI or histamine blockers) or had clearly identifiable and established musculoskeletal pain in the thoracic spine or the chest. The study protocol was approved by the Local Ethics Committee.

Table 1 Mean age and proportion of female patients in all patient groups

Patient group	Age (yr, mean ± SD)	Female gender (%)
Study protocol group	59 ± 10	56
External PPI group	63 ± 8	63
Control group	62 ± 9	73

Patients

In the period between May, 2003 and November, 2004, all patients with chest pain, a pathological treadmill exercise and with a normal coronary angiogram were identified in the Cardiology Center of Aachen University, Germany. All patients were contacted by phone and, after testing the eligibility, were asked whether they still suffered from chest pain. Patients without any symptoms immediately after the angiography and without any specific medication were considered to have chest pain at least modulated by psychological diseases and were excluded from further questioning. Patients with ongoing chest pain, but treated with PPI after the normal angiography by their primary care physicians (PPI test approach[10]), were included into an external PPI group. Patients with ongoing chest pain and no specific medication were asked to join the study.

In total, 78 patients were eligible for the study, but only 72 agreed to participate in data collection. Twenty-seven patients gave written informed consent to participate in the PITFALL study protocol including diagnostic work up and therapy with pantoprazole. The initial study design is depicted in Figure 1A. The planned study randomization arms A and B were closed shortly after beginning of the study, due to low patient recruitment. Ninety seven percent (26/27) of the study patients had to be included into study arm C because of pathological findings during the diagnostic work-up. In order to establish an external control group, we included patients with ongoing chest pain who were not willing to participate in the diagnostic and therapeutic study in another group. These patients and the patients in the external PPI group received questionnaires regarding symptoms and treatment at study entry and 8 wk after study entry. The adapted study design is shown in Figure 1B. Characteristics of study patients from each group are given in Table 1.

Quantitation of symptoms

All patients (study group, both external groups) ranked the symptoms using a visual analogue scale (VAS) ranging from 0 to 10 each for intensity, duration and frequency of chest pain. Characteristics of each scale are given in Table 2. The three parameters were added (maximum score: 30 points) and used as symptom score

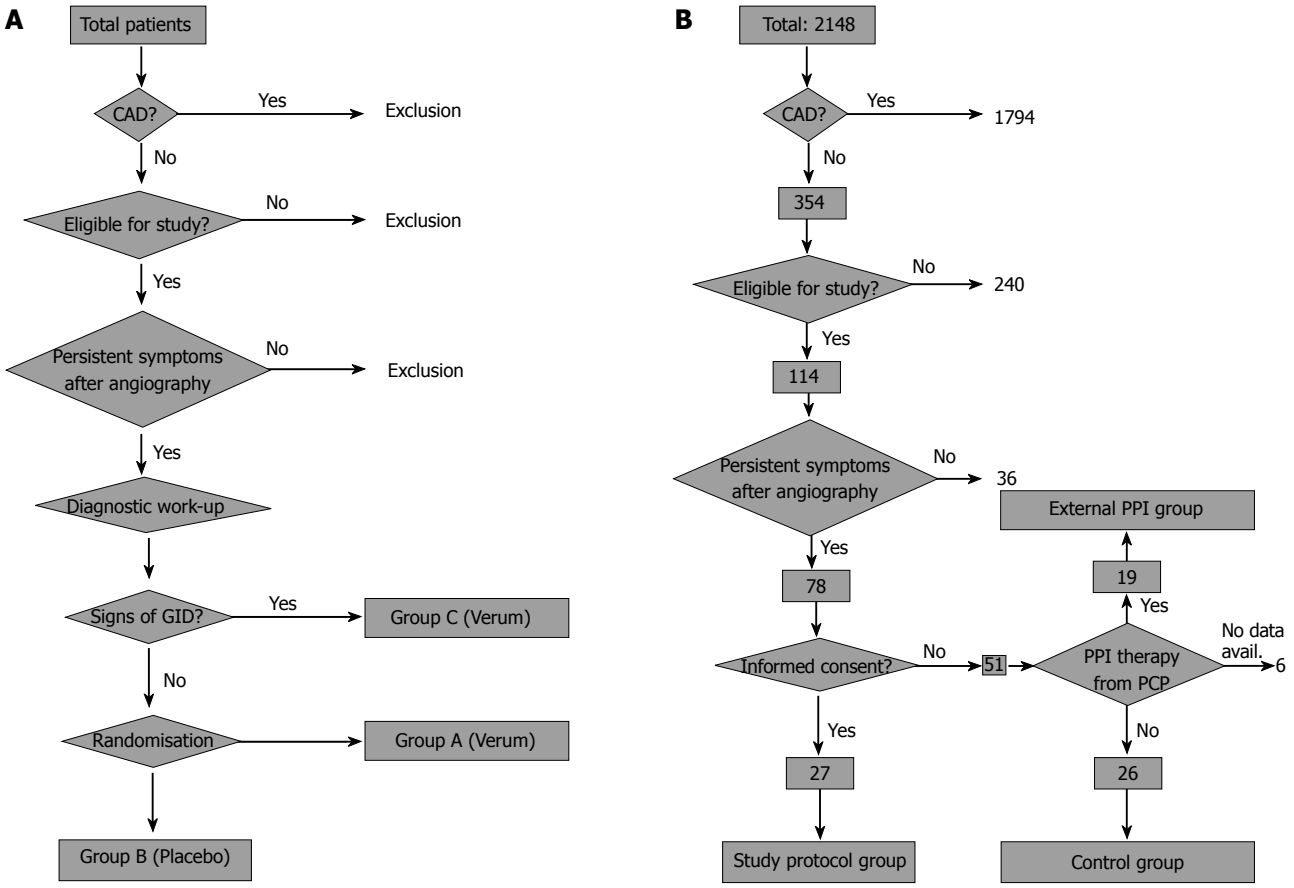

Figure 1 Study design. A: Original study design with 3 patient groups. Randomization was planned after the diagnostic procedures in order to randomize only patients without overt signs of gastrointestinal disease. After recruitment of the first 10 patients only for patient group C, the other two patient groups were closed and the study design was adapted as depicted in B (CAD: Coronary artery disease; GID: Gastrointestinal disease); B: Adapted study design without randomization. To compare the results of per protocol treatment to patients treated in a non-standardized fashion or untreated patients, an external PPI group and a control group were built by recruiting patients who were treated by their primary care physicians (external PPI group, 19 patients) or were not willing to undergo treatment at all (control group, 26 patients). These patients were not matched to the study protocol group and most of them did not receive diagnostic procedure regarding gastrointestinal diseases (CAD: Coronary artery disease; PCP: Primary care physician).

Table 2 Definitions of ranks in visual analogue scale (characteristics of symptoms)

Grade	Frequency	Duration	Intensity
10	Permanent	Permanent	
9	Several times daily	Almost whole day	
8	Daily	More than 6 h	
7	Almost daily	More than 2 h	
6	Several times weekly	About 1 h	Grading by patients
5	Up to 3 times weekly	10-30 min	on a scale from 0 to 10
4	Once weekly	5-10 min	
3	Several times in 1 mo	1-5 min	
2	Up to 3 times in 1 mo	Less than 1 min	
1	Once per month	A few seconds	
0	Never or very seldom	Never	

Patients were asked for symptoms and were helped to grade the frequency, duration and intensity using the characteristics below.

(VAS total score). These four different VAS scores were evaluated before and after therapy (in the external placebo group in a time difference of 8 wk). Patients in both external groups were also asked regarding their co-medication during the 8-wk period.

Diagnostic work-up

All patients in the study group received gastroscopy, 24-h esophageal pH-monitoring and concurrent impedancometry and manometry (CIM) in the gastroenterological endoscopy unit of Aachen University Medical Center. The latter procedure (CIM) was conducted using a custom-made catheter consisting of 11 impedance segments (each 2 cm long) and 4 semiconductor pressure transducers. The solid-state pressure transducers are located between the impedance channels 1-2, 4-5, 7-8 and 10-11 with an intertransducer distance of 6 cm. The configuration of the catheter allows a simultaneous registration of bolus transport and esophageal peristalsis (details in reference by Nguyen *et al*[11]). The catheter was passed through the nose into the esophagus with the most distal pressure sensor placed at the level of the lower esophageal sphincter.

If the diagnosis of acid-related disorders such as gastritis, ulcer disease or GERD was established, the patients were enrolled into study arm C. This led to closure of study arms A and B as described above.

Diagnostic findings from patients in the external groups were not used for study purposes.

Therapeutic study protocol

Patients in study arm C received pantoprazole 40 mg bid for 8 wk. After this period, treatment strategy was

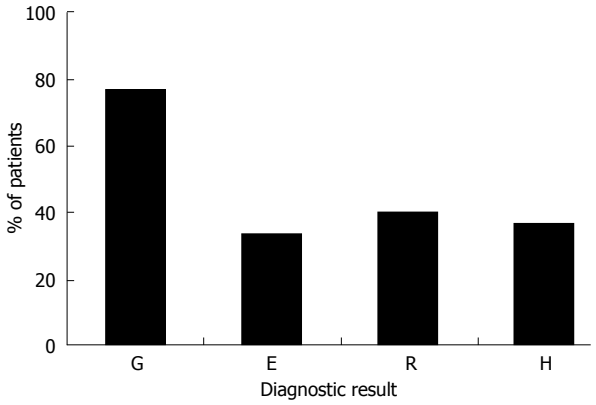

Figure 2 Percentage of study protocol patients with gastritis (G, partially erosive or ulcerative), esophagitis (E), reflux as diagnosed by pH monitoring (R) and/or hiatal hernia (H). Multiple diagnoses in a patient were possible so that the total percentage is above 100.

open and depending on symptoms. If tested positive for *H pylori*, eradication treatment was initiated. Intolerance of pantoprazole led to prescription of omeprazole 20 mg bid. After completion of the therapeutic study arm, patients gave information about their symptoms using the same VAS scores as described above and most patients underwent control investigations of gastroscopy and 24-h esophageal pH-monitoring.

Statistical analysis

Categorical data were summarized as absolute and corresponding relative frequencies. Observed VAS scores were condensed by minimum, maximum, median and corresponding interquartile range, separately for the two different time points (before therapy, after therapy) in each of the three study groups. Parallel boxplots were used for graphical comparison of the obtained VAS scores between the time points before and after therapy within each study group.

In each group, paired Wilcoxon tests were conducted for comparison of the different VAS scores before and after therapy. A global significance level of $\alpha = 5\%$ was chosen. Only the results (*P*-values) of the tests carried out with respect to the VAS total scores were interpreted in a confirmatory fashion, while results for the scores of intensity, duration and frequency were meant solely exploratively. Thus, $P \leqslant 0.05$ was considered statistically significant. All statistical analyses were performed with the statistical analysis software package R (http://www.R-project.org).

RESULTS

Large subgroup of patients without symptoms after angiography

Only patients with normal coronary angiography performed for chest pain, with abnormal treadmill exercise and without any further diagnostic procedures or therapy after angiography were included into the study. In telephone interviews, 114 eligible patients were asked for persisting symptoms following the diagnostic procedure. Thirty-six (31%) of the 114 interviewed patients without further therapy denied any residual symptoms. It is likely that a substantial subset of these patients had chest pain due to psychosomatic reasons. These patients were excluded from further investigations of this study.

Further stratification of study population

Only 27 of the 78 patients meeting the inclusion criteria of the study group agreed to join the diagnostic and therapeutic study according to the PITFALL study protocol. Of the remaining 51 patients, 19 discussed the possibility of gastrointestinal diseases with their primary care physicians and received diagnostic work-up and therapy from them, mostly in the form of a PPI test. They agreed to give information about their symptoms during and after the primary care physician-guided therapy. The gained information was included in the study and the patients were grouped as "external PPI group". The prescribed therapy did not follow the study protocol in most cases regarding dose and length of treatment (data not shown) and involved prescription of several different proton-pump inhibitors, as well as different length and follow-up of therapy.

Twenty-six of 51 patients denied any diagnostic procedure and therapy and explained that they were not interested in any further work-up of persisting symptoms. These patients, however, agreed to give information about their symptoms in certain intervals and were grouped as "external control group"; the gained information (i.e. different VAS scores at different time points) of these patients was included into statistical evaluation of the study as well. Age and gender distribution of all patient groups are given in Table 1.

Six of 51 patients refused any cooperation or data collection and were excluded from further questioning.

Prevalence of GIs in NCCP patients

Fifty-seven percent of the study patients had signs of acid reflux consistent with GERD (De Meester Score > 14, pH time < 4 more than 5% and/or gastroscopic evidence of esophagitis). Relevant gastritis with or without erosive changes of the mucosa was present in 78% of the patients (histologically proven), from which 27% had no signs of GERD. *H pylori* was detected in 11% and eradicated using the French triple therapy with amoxicillin and clarithromycin. In total, 97% (26/27) patients showed a relevant acid-related disorder (GERD or histologically proven gastritis) of the upper gastrointestinal tract (Figure 2).

Symptomatic improvement in the study protocol group

Results of the total symptom score before and after PPI therapy are given in Figure 3A. The study patients experienced a statistically significant improvement in symptoms after 8 wk of PPI therapy in doubled standard dose ($P < 0.0001$). If analyzed in an explorative fashion for all subscores, this improvement turned out

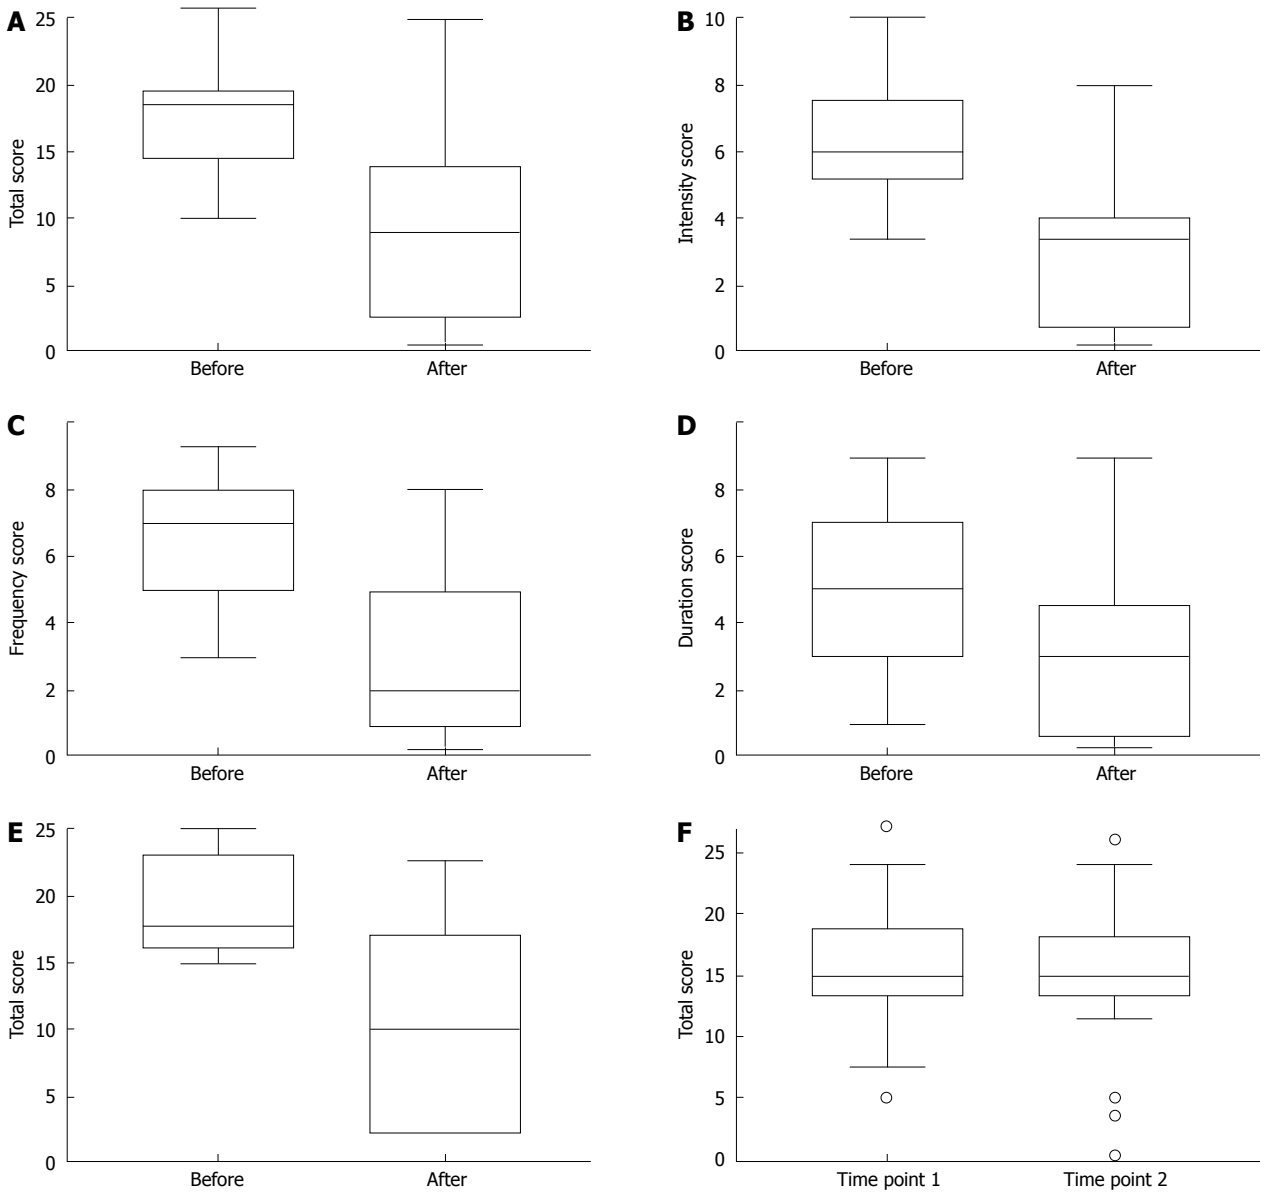

Figure 3 Results of the different group by graphical representation (parallel boxplot). A: Total score; B: Intensity score; C: Frequency score; D: Duration score. The three symptom scores (B-D) are before and after treatment with pantoprazole in the study protocol group. There was statistically significant difference between the scores before and after therapy ($P < 0.001$ for all four scores). E: Graphical representation (parallel boxplot) of the total score before and after treatment in the external PPI group. The total score after treatment was significantly different compared to the total score before treatment ($P = 0.0011$); F: Graphical representation (parallel boxplot) of the total score before and after an observation period of 8 wk in the control group. There was no significant difference between the scores before and after the observation period ($P = 0.2448$).

to be valid for all three quantities (intensity, frequency and duration of symptoms, Figure 3B-D, $P < 0.001$ for all quantities).

Symptomatic improvement in the external PPI group

Similar to the study group, patients in the external PPI group reported statistically significant improvement in symptoms after a variable PPI therapy ($P = 0.0011$).

The improvement was not as large as in the study group (Figure 3E). Explorative analysis of the subscores showed a benefit for all three symptom quantities (similar to the study group, data not shown).

No symptomatic improvement in the external control group

In contrast to the first two groups, we observed no improvement of the total VAS score for the patients in the external control group. Scores at start and 8 wk later without any specific treatment were not statistically significant different ($P = 0.2448$, Figure 3F).

Identification of specific risk factors for gastrointestinal causes of NCCP or treatment success

In the original study protocol, a multivariate analysis was planned to identify specific risk factors for stratifying NCCP patients with gastrointestinal causes. Furthermore, we wanted to identify specific parameters to predict the extent of treatment success in the study group. Due to the changed study design and the low patient volume in all groups, especially in the study protocol therapy group, we did not conduct such data analysis.

DISCUSSION

Patients with a special subgroup of NCCP, the so-called CSX, were investigated in the present study. This syndrome is defined as recurrent chest pain with pathological electrocardiography, but normal coronary angiography. Given the results of pathophysiological studies and the common efferent and afferent nerve supply of the upper gastrointestinal tract and the heart[8,9], our results confirm that symptoms of CSX patients are almost invariably caused by acid-related disorders of the upper gastrointestinal tract. The described symptoms consequently could be treated very well using the doubled standard dose of pantoprazole.

Interestingly, there is a large group of patients with CSX, which presents with much improved or absent symptoms after coronary angiography. This seems to indicate that many patients probably exhibit stress-induced symptoms of psychosomatic character. Recent studies show a prevalence of psychological abnormalities between 17% and 43% in NCCP patients[7], which is in line with our results (31%) in patients with CSX. Additionally, stress can provoke gastrointestinal acid-related disorders as well. However, many patients with psychosomatic origin of NCCP still have persistent symptoms after cardiac diagnostic procedures and they often do not respond to PPI therapy. In our study protocol group, 2/27 patients (7%, but 30% in the external PPI group) showed no or only little benefit of PPI therapy (defined as improvement < 10%), so that these patients may have psychosomatic disorders as well. Very recently, it was shown that hypnosis might contribute to symptom improvement in this patient group[12].

The referral rate of patients with chest pain, after exclusion of cardiac abnormalities, was low in our study. Only 8 of 78 (10%) patients were already in diagnostic work-up for or in treatment of GIs. This result is in agreement with previous studies indicating a low interest or strain in further diagnostic work-up after cardiologic examination[2]. Whether this low referral rate is due to the patients or their primary care physicians is not completely clear and deserves further studies. Nevertheless, this finding clearly demonstrates the need for a closer follow-up of NCCP patients in every day practice.

All but one patient in the treatment group had evidence of upper gastrointestinal tract disease of different degrees. The most important diagnostic tool in this setting was gastroscopy, followed by 24-h esophageal pH-monitoring. Interestingly, we could not find one relevant motility disorder using a highly sensitive method with measurement of impedance and motility in the esophagus (CIM). This indicates that motility disorders are rare in causing the investigated subform of NCCP/CSX. Though dysmotility has often been demonstrated in NCCP[13], its impact on chest pain is unclear. There is no specific treatment for dysmotility and PPI therapy has no influence on the motility disorder. Data observing an effect of PPI therapy on chest pain associated with motility disorders[14] showed only a very minor effect on the respective motility disorder itself. These data indicate that dysmotility only is a facet or associated symptom of NCCP, not the main origin[15].

Interestingly, a large subgroup of patients presented with different degrees of histologically proven gastritis. These patients did not complain about epigastric pain, but exhibited chest pain. GERD has been the central investigated acid-related disorder in causing NCCP[6]. Gastritis may play a more important role in the etiology of CSX or has been underestimated up till now for causing NCCP. It is also possible that gastritis is, in our study, simply an expression for esophageal acid reflux, which could not be detected by 24-h esophageal pH-monitoring. It has been shown that extending the recording time of pH measurement to 48 h increases the sensitivity of the procedure[16]. Further studies with larger patient groups and improved pH measurement are necessary to solve this issue.

Treatment with pantoprazole, in the treatment group, led to a significant improvement in the symptom score. This supports our assumption that the symptoms were caused by the diagnosed GIs including gastritis, and indicates the value of the tested substance in treating NCCP patients. Seven of 27 patients were completely asymptomatic after 8 wk of treatment with pantoprazole and 54% of the patients showed an improvement of at least 50% in the symptom score. In the external PPI group, the improvement of symptoms was lower, mostly owing to shorter treatment periods and lower dosages of PPI. This clearly indicates that treatment of gastrointestinal NCCP causes requires a clear protocol with initial high doses (double the standard dose per day) and long treatment periods. Several recent studies, especially those using a "test therapy approach", treated for only 7 d which may have led to underestimation of the PPI benefit[10]. In the external control group, we observed no improvement in the symptom score. This is in line with our expectations and underlines, though we were not able to randomize these patients, the treatment effect of pantoprazole in our study group.

Unfortunately, we were not able to identify any significant predictor (other than the diagnosis of an acid-related disorder) for treatment response in our patient group. Additionally, our sample size was too small to identify predictors for NCCP before cardiac catheterization in order to reduce normal coronary angiographic results and induce a PPI test treatment in such patients which may benefit from this approach. It has been shown in the past that the "PPI-test" is cost-effective in terms of avoiding the traditional invasive gastroenterological diagnostic strategy[17]. However, we consider an approach to identify patients with NCCP before they receive invasive cardiological diagnostic procedures much more important, because these diagnostic procedures are more expensive and more prone to side effects than gastroscopy and 24-h esophageal pH-monitoring.

In conclusion, we have shown that in patients with CSX, acid-related disorders are frequent and respond very well to a long-term therapy with pantoprazole.

Motility disorders obviously are extremely rare, as shown by a very sensitive diagnostic tool (CIM) in our study. The rate of gastroenterological referral after exclusion of cardiac abnormalities is still too low. It is useful to conduct additional studies with more patients, which should lead to criteria to identify patients having a benefit from a PPI therapy before coronary angiography is done.

ACKNOWLEDGMENTS

We thank Rüdiger Hoffmann and Karin Lung, Department of Cardiology at Aachen University, for valuable assistance and help in identifying potential study patients. We also thank Wolfgang Fischbach for critical reading of the manuscript and helpful comments.

COMMENTS

Background

Non-cardiac chest pain (NCCP) and its subform cardiac syndrome X (CSX) have a high incidence in Western countries and represent a significant health burden.

Research frontiers

In this study, authors investigated, for the first time, the pathogenesis and possible treatment of the specific NCCP subform CSX in a German population.

Innovations and breakthroughs

The authors established that gastrointestinal disorder (GI)-tract-associated disorders in a high percentage are responsible for CSX and that the symptoms can be treated by proton pump inhibitor (PPI).

Applications

The results of this study are important for primary care physicians, cardiologists and gastroenterologists in the medical care of chest pain patients.

Terminology

NCCP denotes angina-like typical chest pain which could not be linked to the heart by specific investigations (including angiography). CSX is a subform of NCCP and means that these patients showed typical electrocardiographic (ECG) abnormalities despite a normal angiogram.

Peer review

This is an interesting paper. It investigated the frequency of gastroenterological diseases in the etiology and the efficacy of PPIs in the treatment of CSX as a subform of NCCP. It provided useful information to the readers.

Abstract

AIM: To compare the liver stiffness (LS) measurement by transient elastography (TE) to the liver biopsy (LB)-considered the "gold standard" in the evaluation of patients with chronic hepatitis C.

METHODS: During a period of 12 mo, we evaluated 199 consecutive patients with chronic hepatitis due to hepatitis C virus (HCV), in which LB and LS assessments (by means of TE) were performed during the same session.

RESULTS: Out of 199 patients, a valid measurement of the LS could not be obtained in 8. The mean value of LS in the cohort of 191 valid measurements was 8.45 ± 4.96 kPa, ranging from 2.3 to 38 kPa. The mean value of LS in patients with significant fibrosis at biopsy (161 patients with F ⩾ 2 according to Metavir) was 9.02 ± 5.15 kPa, significantly higher than in patients with no or mild fibrosis (30 patients with F < 2 Metavir): 5.39 ± 1.81 kPa (P < 0.0001). For a cut-off value of 6.8 kPa, the LS had a PPV of 98%, a NPV of 30.1%, a sensitivity of 59.6% and a specificity of 93.3% for the presence of significant fibrosis (at least F2 Metavir), with a diagnostic performance of 77.3% (AUROC 0.773). Using this cut-off value, we reached the best discrimination between absence of fibrosis/mild fibrosis (F < 2 Metavir) and the presence of moderate to severe fibrosis (F ⩾ 2 Metavir).

CONCLUSION: In patients with chronic hepatitis due to HCV, a cut-off value of 6.8 kPa measured by TE can differentiate between significant fibrosis and absent or mild fibrosis, with a PPV of 98%, a NPV of 30.1%, a sensitivity of 59.6%, a specificity of 93.3%, and a diagnostic performance of 77.3%.

INTRODUCTION

In the evolution of chronic viral and non-viral hepatitis, liver fibrosis is a very important factor associated with prognosis. Hence, it is necessary to evaluate precisely the severity of fibrosis in those patients, in order to perform a correct staging and, eventually, to take a decision regarding the treatment.

Currently, the biopsy examination of the liver is considered the optimal method to evaluate changes in fibrosis over time[1]. Nevertheless, the liver biopsy (LB) has its shortcomings: the intra- and interobserver variability[2,3], the sampling variability (as proven in a study by Ratziu *et al*[4]), and, last but not least, the fact that LB is an invasive method, with morbidity and mortality greater than zero.

Based on these premises, noninvasive methods for the evaluation of liver fibrosis have been developed during the last few years in order to replace the LB. The most promising noninvasive methods are, currently, the FibroTest-ActiTest[5] and the transient elastography (TE) measured with the FibroScan device[6,7].

TE is an ultrasound-based method. By using an ultrasound transducer probe mounted on the axis of a vibrator, the transmission of low-frequency vibrations from the right intercostal space creates an elastic shear wave that propagates into the liver. A pulse-echo ultrasound acquisition is then used to detect the velocity of wave propagation. This velocity is proportional to the liver stiffness, with faster wave progression occurring through stiffer tissues. Measurement of liver stiffness (LS) is then performed and measured in kPa[6].

The FibroScan assessment of LS was validated as method of evaluation in chronic hepatitis C. Also, there are some articles that proved the value of this method in other chronic hepatopathies, like chronic hepatitis due to the hepatitis B virus (HBV) infection, hemochromatosis, primary billiary cirrhosis or non-alcoholic steato-hepatitis[8-11].

MATERIALS AND METHODS

During a 12 mo period (June, 2007 to June, 2008), all patients with chronic hepatitis C from the Departments of Gastroenterology and Hepatology and Infectious Diseases of Timisoara were investigated in the same session by means of two methods: LS measurement by means of TE and LB, in order to compare the value of that noninvasive method for the assessment of liver fibrosis. Patients with proven liver cirrhosis (ascites, jaundice, esophageal varices) were excluded from the study, as were patients who had another cause of chronic hepatitis, apart from hepatitis C virus (HCV) (HBV, alcoholic hepatitis, *etc*).

The LS was evaluated by means of TE with a FibroScan device (Echosens-Paris, France) by three experienced physicians. Measurements were performed in the right lobe of the liver through the intercostal spaces while the patients were lying in dorsal decubitus position with the right arm in maximal abduction. The tip of the transducer was covered with coupling gel and placed on the skin, between the ribs, aiming at the right lobe of the liver. The operator, assisted by ultrasound A-mode images provided by the system, located a portion of the liver that was at least 6 cm thick, free of large vascular structures. Once the area of measurement had been located, the operator pressed the probe button to begin an acquisition. Acquisitions that did not have a correct vibration shape or a correct follow-up of the vibration propagation were automatically rejected by the software.

Ten successful acquisitions were performed on each patient. The success rate was calculated as the ratio of the number of successful acquisitions over the total number of acquisitions. The median value of the 10 valid measurements was then calculated by the device and considered to be the value of LS in that patient.

Only patients in which LS measurements had a success rate of at least 60%, with interquartile range (IQR) of all validated measurements less than 30% of the median values (IQR < 30%), were considered for further analysis.

We performed echoguided LB, with Menghini type modified needles, 1.4 and 1.6 mm in diameter. Only LB fragments of at least 2 cm, including at least 8 portal tracts were considered adequate for pathological interpretation. The LB was assessed according to the Metavir score by a senior pathologist. Fibrosis was staged on a 0-4 scale: F0-no fibrosis; F1-portal fibrosis without septa; F2-portal fibrosis and few septa extending into lobules; F3-numerous septa extending to adjacent portal tracts or terminal hepatic venules and F4-cirrhosis

The statistical analysis was performed using Microsoft Excel and GraphPad Prism programs. For the statistical study of quantitative variables, the mean and standard variation were calculated. The diagnostic performance of LS measurements was assessed by using receiver operating characteristics (ROCs) curves. Connected with any cutoff value is the probability of a true positive (sensitivity, Se) and the probability of a true negative (specificity, Sp). The ROC curve is a plot of Se *vs* 1-Sp for all possible cutoff values. The most commonly used accuracy index is the area under the ROC curve, when values close to 1.0 indicate high diagnostic accuracy. ROC curves were thus built for the detection of significant fibrosis (F $\geqslant$ 2 Metavir) and severe fibrosis (F $\geqslant$ 3 Metavir). Optimal cutoff values for LS measurements were chosen to maximize the sum of Se and Sp.

RESULTS

The study group included 199 patients with chronic hepatitis C, 138 women and 61 men, with a mean age of 49.79 ± 10.98 years. In 8 cases we could not obtain valid measurements, as we did in the remaining 191 patients (96%).

The mean value of LS in the subgroup of 191 patients with valid measurements was 8.45 ± 4.96 kPa, ranging from 2.3 to 38 kPa.

We divided patients according to the degree of fibrosis, i.e. into a subgroup with significant fibrosis (F $\geqslant$ 2 Metavir, patients who should receive antiviral therapy) and another one with no or mild fibrosis (F < 2 Metavir, in which antiviral treatment is currently not recommended).

The mean value of LS in patients with significant fibrosis (161 patients with F $\geqslant$ 2 Metavir) was 9.02 ± 5.15 kPa, significantly higher than in patients with no or mild fibrosis (30 patients with F < 2 Metavir): 5.39 ± 1.81 kPa ($P < 0.0001$) (Figure 1A).

The values of LS in various subgroups of patients, divided according to fibrosis stage, were (Figure 1B): 5.27 ± 0.83 kPa in 4 patients with F0; 5.41 ± 1.92 kPa in 26 cases with F1; 7.18 ± 2.62 kPa in 97 patients with F2; 9.75 ± 4.63 kPa in 45 cases with F3; and 16.68 ± 8.10 kPa in 19 cases with F4.

The statistical significance of the differences between the LS in these subgroups was: F0 *vs* F1 $P = 0.8081$; F0 *vs* F2 $P = 0.1117$; F0 *vs* F3 $P < 0.0001$; F0 *vs* F4 $P < 0.0001$; F1 *vs* F2 $P = 0.0048$; F1 *vs* F3 $P < 0.0001$; F1 *vs* F4 $P < 0.0001$; F2 *vs* F3 $P = 0.0011$; F2 *vs* F4 $P < 0.0001$; F3 *vs* F4 $P = 0.0002$.

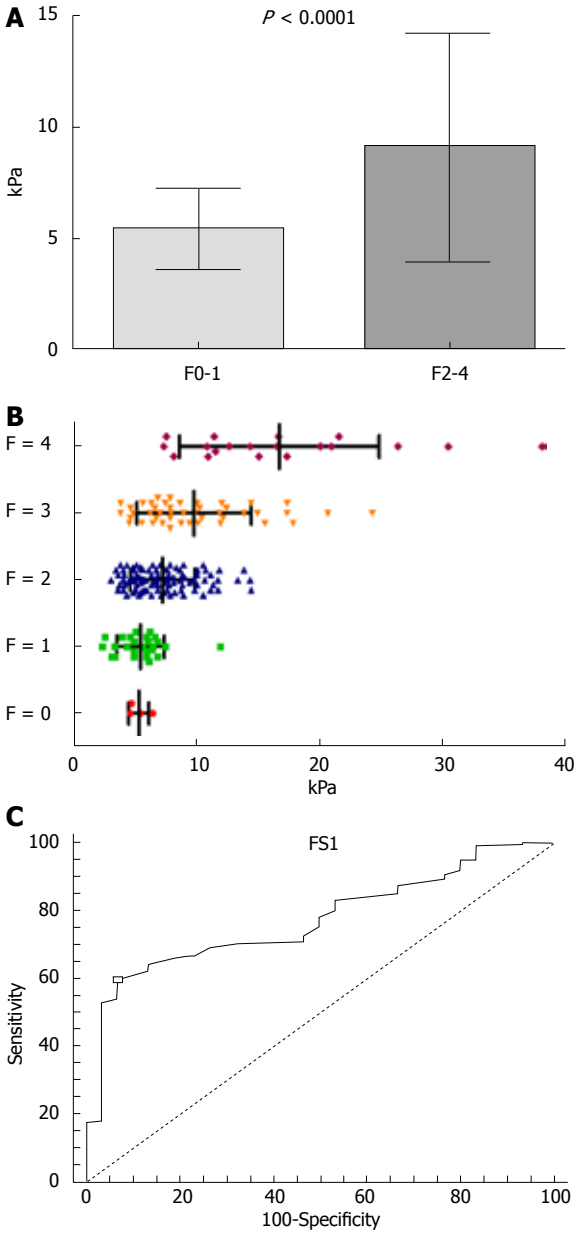

Figure 1 The mean value of LS and AUROC for LS predictive value. A: Mean value of LS in patients with significant fibrosis (F ⩾ 2 Metavir) as compared to those with no or mild fibrosis (F < 2 Metavir); B: Mean value of LS according to fibrosis; C: The AUROC for LS predictive value of the presence of significant fibrosis (at least F2 Metavir).

The statistical analysis of these subgroups showed that there were no significant differences between the mean values of LS in the F0 *vs* F1 subgroup (so that the cases with mild and no fibrosis cannot be differentiated by means of FibroScan evaluation of LS). The comparison of the mean values of LS between the other subgroups showed significant (S) or very significant (ES) differences.

The mean value of LS in patients with severe fibrosis (64 patients with F ⩾ 3 Metavir) was 11.81 ± 6.62 kPa, significantly higher than in patients with at most moderate fibrosis (127 patients with F < 3 Metavir) 6.76 ± 2.56 kPa ($P < 0.0001$).

We tried to establish the value of LS measured by means of FibroScan, which best predicts the presence of significant fibrosis (F ⩾ 2 Metavir) in patients with chronic hepatitis C.

For a cut-off value of 6.8 kPa, the LS had a PPV of 98%, a NPV of 30.1%, a sensitivity of 59.6%, a specificity of 93.3% for the presence of significant fibrosis (at least F2 Metavir), and a diagnostic performance of 77.3% (AUROC 0.773) (Figure 1C).

For a cut-off value of 7.2 kPa, the PPV was 97.8%, the NPV was 28.6%, the sensitivity was 56.5% and the specificity was 93.3% for the presence of significant fibrosis (at least F2 Metavir).

For a cut-off of value of 7.5 kPa, the PPV was 98.8%, the NPV was 27.4%, the sensitivity was 52.2% and the specificity was 96.7%.

DISCUSSION

We compared our results with data from the literature (Table 1). In a multicentric study coordinated by Beaugrand[12] on 494 patients chronically infected with HCV, who were evaluated in the same session by means of percutaneous LB and valid FibroScan, a significant correlation was found ($r = 0.57$, $P < 0.0001$) between the LS and histological fibrosis, with AUROC [confidence interval (CI) 95%] 0.84, 0.93 and 0.96 for F ⩾ 2, F ⩾ 3 and F = 4, respectively. This study tried to establish cut-off values in order to differentiate among various histological stages. Thus, a cut-off value of 7.5 kPa differentiates F01/F234 with a sensitivity of 67%, a specificity of 87%, a PPV of 86% and a NPV of 68%, with 76% diagnostic accuracy.

In a study performed by Foucher *et al*[13] that compared LB with LS evaluation by means of FibroScan in 354 patients with chronic hepatitis C, the cut-off value was 7.2 kPa, for moderate and severe fibrosis (F234), 12.5 kPa for F34 and 17.6 kPa for cirrhosis.

In a Korean study[14], the cut-off values were 7.3 kPa for F ⩾ 2, 8.8 kPa for F ⩾ 3 and 15.1 kPa for F = 4. In a study performed in the Netherlands[15], using a cut-off value of 7.1 kPa, 88% of the patients who did not have significant fibrosis (F < 2 Metavir) were correctly identified.

In a study performed in Romania[16], on 324 consecutive patients chronically infected with HCV, evaluated both by TE and LB in the same session, the LS values were strongly correlated with fibrosis ($r = 0.759$, $P < 0.0005$), but also with steatosis ($r = 0.255$, $P < 0.005$), necroinflammatory activity ($r = 0.378$, $P < 0.0005$) and hepatic iron deposition ($r = 0.143$, $P = 0.03$). The univariable regression analysis of this study demonstrated that fibrosis ($R^2 = 0.610$, $P < 0.0005$), activity ($R^2 = 0.145$, $P < 0.0005$) and steatosis ($R^2 = 0.037$, $P < 0.002$) were correlated with LS. In multiple regression analysis, all three variable independently influenced LS: fibrosis ($P < 0.0005$), activity ($P = 0.039$) and steatosis ($P = 0.025$). The conclusions of this study showed that fibrosis is the main predictor of LS, but also that the latter bis influenced by activity and steatosis.

In a study performed by Coco and co-workers[17], the value of LS was evaluated considering the level of

Table 1 Cut-off values for significant fibrosis (at least F2 Metavir) in various studies

Study	No. of cases	Cut-off value for F2 (kPa)
Ziol *et al*[12]	494	7.5
Foucher *et al*[13]	354	7.2
Kim *et al*[14]	47	7.3
Berends *et al*[15]	24	7.1
Lupşor *et al*[16]	324	7.4
Present study	199	6.8

aminotransferases. The LS dynamics profiles paralleled those of ALT, increasing 1.3 to 3 fold during ALT flares. This study showed that the LS remained unchanged in patients with stable biochemical activity.

All these studies, coming from different regions of the world, completed previous studies from France[18-22], demonstrating the value of non-invasive, FibroScan evaluation of LS for the fibrosis assessment in chronic hepatitis C. This method is not accurate enough to differentiate among contiguous stages of fibrosis (especially 0, 1 and 2), but is sensitive enough to differentiate between the absence and/or mild fibrosis from significant fibrosis, an essential step for the decision regarding treatment. In the future, we shall still find exactly whether histological activity, steatosis or biological activity (ALT) have an important role in the assessment of LS by means of FibroScan.

Considering the data presented from our study, the cut-off value of 6.8 kPa is the most accurate for the discrimination between absence or mild fibrosis (F < 2 Metavir) and the presence of moderate and severe fibrosis (F ⩾ 2 Metavir), thus allowing us to select the patients with chronic hepatitis C who should be treated (knowing that patients with F < 2 Metavir are not candidates for treatment, since they have mild disease). In our study, using a cut-off value of 6.8 kPa, the sum of sensitivity and specificity was the highest.

Based on our results, we may use the FibroScan to evaluate LS in patients with chronic hepatitis C prior therapy. By using a cut-off value of 6.8 kPa, we can differentiate patients who needed to be treated (F ⩾ 2 Metavir) from those who, according to most current guidelines, should not receive treatment (F < 2 Metavir).

The cut-off value of 6.8 kPa in our study had a PPV of 98%, meaning that we can identify quite accurately the patients who should be treated (F ⩾ 2 Metavir). For patients with values of LS smaller than 6.8 kPa, we think appropriate to perform LB, because the NVP is low (30.1%), and otherwise we could miss patients with significant fibrosis using only TE. In our cohort of 191 patients with valid measurements of LS, using a cut-off value of 6.8 kPa, we could avoid LB in 160 patients who had a LS greater than 6.8 kPa and who could directly receive treatment, without LB. On the other hand, a LB should have been performed only in 31 patients (a 83.8% reduction in the number of LB performed in our Department during this same interval of time).

Considering the data from the literature and looking to our own, we could use the TE evaluation of LS in patients with chronic hepatitis C in order to decide about therapy. All studies show that, by using a cut-off value of 6.8-7.5 kPa, we could identify accurately enough the patients who need to be treated (F ⩾ 2 Metavir) *vs* those who should not be treated (F < 2 Metavir), and this without performing a LB[13-15]. The PPV of 98% obtained in our study for a cut-off value of 6.8 kPa suggests that we can quite accurately identify patients who must be treated (F ⩾ 2 Metavir). For patients with LS smaller than 6.8 kPa, we think appropriate to perform a LB, because the NPV is low (30.1%) and therefore we may miss patients with significant fibrosis if only based on LS measurement.

CONCLUSION

The FibroScan evaluation of LS is a method in which valid measurements can be obtained in the great majority of scanned patients (96% of the cases). In patients with chronic hepatitis C, when compared to the LB considered to be the "gold standard", LS measurement by means of TE can differentiate between significant fibrosis and absent or mild fibrosis. We found that a cut-off value of 6.8 kPa is the one that best differentiates absence or mild fibrosis (F < 2 Metavir) from significant fibrosis (F ⩾ 2 Metavir), with PPV of 98%, NPV of 30.1%, sensitivity of 59.6%, specificity of 93.3% and a diagnostic performance of 77.3%. In our cohort of patients, if the cut-off value of 6.8 kPa had been used for the presence of significant fibrosis, more than 80% of the LB would have been avoided.

Considering all these facts, the FibroScan evaluation of LS is a useful non-invasive method for the evaluation of patients with chronic hepatitis C in clinical practice, and can replace in many cases the LB for the decision of therapy.

COMMENTS

Background

In the evolution of chronic viral and non-viral hepatitis, liver fibrosis is a very important factor associated with prognosis. Hence, it is necessary to evaluate precisely the severity of fibrosis in those patients, in order to perform a correct staging and, eventually, to take a decision regarding the treatment. Fibrosis can be assessed through invasive [liver biopsy (LB)] and non-invasive methods such as transient elastography (TE) assessment of liver stiffness (LS), developed in the last few years in order to replace LB.

Research frontiers

The aim of the study was to assess the value of LS measurement by TE as compared to the LB-considered to be the "gold standard", in the evaluation of patients with chronic hepatitis C.

Innovations and breakthroughs

This study concluded that LS measurement by TE can predict the presence of significant fibrosis (at least F2 Metavir, that requires treatment) in patients with chronic hepatitis C, confirming previously published studies.

Applications

Transient evaluation of LS could replace in many cases the LB for the decision of therapy in patients with chronic hepatitis C, if the values of LS are higher than the established cut-off values for significant fibrosis (6.8-7.5 kPa according to various studies). The LB should be performed only if the LS is lower than the cut-off, in order to avoid "missing" patients with significant fibrosis.

Terminology

TE is an ultrasound-based method that assesses the LS as a marker of fibrosis.

By using an ultrasound transducer probe mounted on the axis of a vibrator, the transmission of low-frequency vibrations from the right intercostal space creates an elastic shear wave that propagates into the liver. A pulse-echo ultrasound acquisition then is used to detect the velocity of wave propagation. This velocity is proportional to the tissue stiffness, with faster wave progression occurring through stiffer material. The stiffer the liver, the higher the degree of fibrosis.

Peer review

This paper investigated the usefulness of elastography in assessing the stage of biopsy-proven fibrosis in patients with chronic hepatitis C. This is a straightforward study and the authors concluded that this new technique can predict the presence of severe fibrosis that require treatment.

Abstract

AIM: To investigate the effect of ascorbic acid (AA) dietary supplementation on myenteric neurons and epithelial cell proliferation of the jejunum of adult rats with chronic diabetes mellitus.

METHODS: Thirty rats at 90 d of age were divided into three groups: Non-diabetic, diabetic and diabetic treated with AA (DA) (1 g/L). After 120 d of treatment with AA the animals were killed. The myenteric neurons were stained for myosin-V and analyzed quantitatively in an area of 11.2 mm²/animal. We further measured the cellular area of 500 neurons per group. We also determined the metaphasic index (MI) of the jejunum mucosa layer of about 2500 cells in the intestinal crypts, as well as the dimensions of 30 villi and 30 crypts/animal. The data area was analyzed using the Olympus BX40 microscope.

RESULTS: There was an increase of 14% in the neuronal density (792.6 ± 46.52 *vs* 680.6 ± 30.27) and 4.4% in the cellular area (303.4 ± 5.19 *vs* 291.1 ± 6.0) respectively of the diabetic group treated with AA when compared to control diabetic animals. There were no significant differences in MI parameters, villi height or crypt depths among the groups.

CONCLUSION: Supplementation with AA in the diabetic animal promoted moderate neuroprotection. There was no observation of alteration of the cellular proliferation of the jejunum mucosa layer of rats with chronic diabetes mellitus with or without supplementation with AA.

INTRODUCTION

The disease diabetes mellitus is characterized by abnormally high plasma glucose concentrations. Chronic hyperglycemia and the associated metabolic abnormalities are responsible for many disease complications, including damage to the blood vessels, eyes, kidneys and nervous system[1].

In diabetes mellitus, the mucosa of the small intestine undergoes morphological changes[2,3]. This impairs passage of food along the intestine, secretion of enteric juices and the absorption of the digestion products, all of which depend on the integrity of the epithelial lining. Intestinal epithelium is characterized by fast cellular renewal with continuous proliferation of stem cells inside Lieberkühn crypts, cellular migration along the crypt-villi axis, cellular differentiation, polarization, apical apoptosis and luminal loss[4].

It has been shown that the autonomic nervous system has a role in intestinal epithelium renewal, which can be assessed through the elimination of the parasympathetic[5], sympathetic[6] or myenteric innervation[7]. The enteric nervous system is a division

of the autonomic nervous system in the gastrointestinal tract; it can mediate independent reflexes (motility, absorption and secretion) and is made up of sensory neurons, interneurons and interconnected motor neurons[8]. Diabetes mellitus causes a decrease in enteric innervation with a consequent onset of the diabetic neuropathy[9-11].

Several theories have been proposed to explain the neuropathy in diabetes mellitus. They include: impaired metabolism of fatty acids, reduction in the blood supply to the nerves, advanced products of non enzymatic glycation, oxidative stress, inadequate trophic support and the activation of the polyol pathway[12,13]. Aldose reductase converts glucose excess into sorbitol[14,15] which is responsible for edema, neuronal lesions[14,16,17]. The sorbitol concentration can be reduced in the diabetes mellitus through the use of ascorbic acid (AA), an inhibitor of the enzyme aldose reductase[18,19].

Another factor that can be related to the paper neuroprotector of the AA is the antioxidant activity exercised by this vitamin, being of some importance in the diabetes mellitus seen that in this pathology the oxidative stress is intensified and the defense antioxidants are diminished. In this way, our aim was to verify the effect of supplementation with AA on the myosin-V immunoreactive myenteric neurons and on the intestinal mucosa of the jejunum of diabetic rats.

MATERIALS AND METHODS

Animal procedure

Albino male rats (*Rattus norvegicus*), Wistar strain weighing about 300 g and aged 90 d were used in this study. The rats were submitted to a 14-h-fast and then injected with streptozotocin (35 mg/kg of body weight) dissolved in citrate buffer (10 mmol/L, pH 4.5) in the penial vein to induce diabetes mellitus. The onset of diabetes mellitus was verified by the glycosuria and polyuria.

Thirty rats, divided into three groups of ten animals each, were used as follows: Non diabetic rats (ND), diabetic rats (D) and diabetic treated with AA (DA). The AA was given orally for 16 wk (from the 90 d of age) in water (1 g/L prepared daily)[20]. The rats were kept in individual cages with a photoperiod of 12 h (6:00 am-6:00 pm) and at room temperature (RT) (24 ± 2℃) with water and food (Nuvital® lab chow) *ad libitum*.

At 210 d of age, the rats were anesthetized intraperitoneally with sodium thiopental-Thionembutal® (40 mg/kg of body weight). The blood was collected by heart puncture for measuring the levels of glycated hemoglobin[21], glucose[22] and AA[23]. The animals used in this study were treated under the ethical principles adopted by the Brazilian College of Animal Experimentation (COBEA) and approved by the Ethics Committee in Animal Experimentation of the State University of Maringá.

Myosin-V neuronal staining[24]

Fifteen animals were perfused with 1 mL/body weight of saline solution followed by perfusion with 1 mL/g per body weight of fixation solution containing sodium periodate (10 mmol/L), lysine (75 mmol/L), paraformaldehyde (1%) in phosphate buffer (PB) (37 mmol/L, pH 7.4)[25]. Immediately after perfusion, each treated fragment of jejunum was removed, rinsed with saline solution, flushed with fixative solution and tied in its extremities (balloons). Thirty minutes after immersion in fixative solution, the jejunum was opened and left in this solution for an additional 30 min. Subsequently, the segments were opened along the mesenteric border and dehydrated in alcohols (50%, 70%, 80%, 90%, 95% and 100%), remained in each solution 10 min, cleared in xylol (10 min), rehydrated back through the ethanol 100%, 95%, 90%, 80%, 70%, and stored in 70% ethanol. Afterwards, the segments were dissected under stereomicroscopy with trans-illumination, through the removal of the mucosa and submucosa layer, obtaining muscular layer whole mounts. These mixtures were washed four times in phosphate buffered saline (PBS) (0.1 mol/L, pH 7.4) and blocked for 2 h with PBS containing bovine serum albumin (2%), goat serum (2%) and Triton X-100 (0.5%) at room temperature. Later, the segments were incubated in eppendorfs in a solution containing 0.86 μg/mL of the myosin-V primary antibody (extracted from rabbits) (1:750) diluted in PBS, BSA (1%), Triton X-100 (0.1%) and goat serum (2%) at room temperature under agitation (48:00). After incubation, the tissues were rinsed twice in PBS (0.1 mol/L), Triton X-100 (0.1%) and twice in a solution of PBS (0.1 mol/L) + Tween-20 (0.05%). Then, the tissues were incubated in peroxidase-conjugated secondary antibodies (1 μg/mL) (1:1000) at room temperature under shaking (24 h). Finally, they were rinsed four times for 15 min in PBS (0.1 mol/L) + Tween-20 (0.05%). The staining with peroxidase-conjugated antibody was developed by incubation with 0.75 mg/mL diaminebenzidine and 0.03% of H_2O_2 in water (1 mL) and PBS 0.1 mol/L (1 mL) for 15 min at room temperature under shaking. Samples were mounted in glycerol gel, containing glycerol (50%), gelatin in water (0.07 g/mL) and phenol (2 μL/mL). The negative control was performed with the omission of the primary antibody.

Quantitative and morphometric analyses of myosin-V stained myenteric neurons

Quantitative analysis: Measurements were made in the intermediate area of the jejunum intestinal circumference (60º-120º; 240º-300º), considering the mesenteric intersection as 0º[26]. Myenteric neurons were counted in 50 random fields, under a light microscope (Olympus BX40) with a 40× lens. The area of each microscope field was 0.224 mm^2.

Morphometric analysis: The images were taken with a high-resolution camera, transmitted to a microcomputer and recorded to a compact disk. The area (μm^2) of 100 cell bodies of the jejunum, in a total of 500 neurons per group, was measured through an image analysis system,

the Image-Pro-Plus 4.0. The neurons were distributed in intervals of 100 μm^2.

Morphometric analysis of the intestinal mucosa: An additional 15 animals were injected with vincristine, a blocking agent of the mitotic fuse, at a dose of 1 mg/kg of body weight, in the penial vein 2 h before segment collection.

The jejunum was collected, open along the mesenteric border and washed with saline solution, fixed in buffered paraformaldehyde (10%) for 6 h. After fixation, they were dehydrated and immersed in resin 2-hydroxyethyl-methacrylate. Later, 2 μm transverse semi-serial sections were made (a section for each five discarded), using a Leica RM 2145 microtome, with a glass razor. The resin sections were stained by HE.

Metaphasic index (MI): MI shows the number of metaphasic cells/total number of cells (%) that was obtained from the interphasic and metaphasic epithelial cells in the crypts of the jejunum. Twenty five thousand cells per animal were quantified under a light microscope.

Villi and crypts: We measured the height of 30 villi and the depth of 30 crypts per animal, in a total of 900 measurements (300 measurements/treatment), under a light microscope with an ocular micrometer. The heights of the villi were measured from the crypt-villus junction to its apex. The depth of the crypts was measured considering the extension between the crypt-villus junctions to its base.

Chemical products

AA, serum albumin bovine (BSA), diaminebenzidine (DAB), streptozotocin (STZ), Tween-20, paraformaldehyde and Triton X-100 were obtained at Sigma Chemical Company, USA); Vincristine sulfate (Eli Lilly of Brazil, Brazil); Historesin kit (Leica); secondary antibody conjugated with peroxidase serum anti-rabbit IgG (Pierce, Rockford, USES). The polyclonal antibody anti myosin-V was characterized by Espreafico *et al*[27].

Statistical analysis

The data were submitted to analysis of variance (ANOVA) and the test of Tukey as a post-test to compare the means. Since the areas of the cell bodies of the neurons did not have an even distribution, we used the Kruskal-Wallis test to compare the means. The analyses were accomplished with the prism 3.0 software. The data are shown as mean ± SE as an indicator of the observation number (*n*). The level of significance was $P < 0.05$.

RESULTS

Streptozotocin promoted the onset of the diabetic syndrome with accentuated hyperglycemia. The diabetic rats and the diabetic-treated with AA had similar levels of glycated hemoglobin ($P > 0.05$). There was a reduction of 48.7% in the plasmatic level of AA in the diabetic animals when compared to the non-diabetics ($P < 0.05$). The supplementation in group DA increased their level of AA in 25.7% when compared to the non-diabetics ($P > 0.05$), and 61.9% when compared to the diabetic group ($P > 0.05$) (Table 1).

601-700	6	2	7
> 700	2	1	1
Total of neurons	500	500	500

Quantitative analysis of the myosin-V stained myenteric neurons

Experimental diabetes mellitus caused a reduction in the myenteric neuronal density in an area of 11.2 mm^2 in the jejunum, as shown in Figure 1A ($P < 0.001$). The AA supplementation in the diabetic animals caused a 14% increase in the density of the myosin-V stained neurons when compared to the non-treated diabetic animals ($P > 0.05$).

Cellular area of myenteric neurons stained with myosin-V

The results regarding the neuronal area means (μm^2) were 289.41 ± 5.19 for the non-diabetic group, 290.1 ± 6.02 for the diabetic group and 303.4 ± 5.19 for group DA (Figure 1B). The means of the cellular areas were similar for the three studied groups ($P > 0.05$). The 201-300 μm^2 interval was the predominant cellular area for all groups (Table 2).

Morphometric analysis of the intestinal mucosa

The intestinal mucosa, assessed through the determination of the MI and measurements of the height of the villus and depth of crypts, did not show statistically significant differences among the groups.

MI of the diabetic group was 1.5% higher when compared with the non-diabetic group ($P > 0.05$). The MI obtained for group DA was 1.77% smaller than the one observed in the diabetic group ($P > 0.05$). The quantification data are presented in Figure 1C.

The villus height (μm) of the diabetic animals was 7% inferior in relation to the non-diabetic group. The

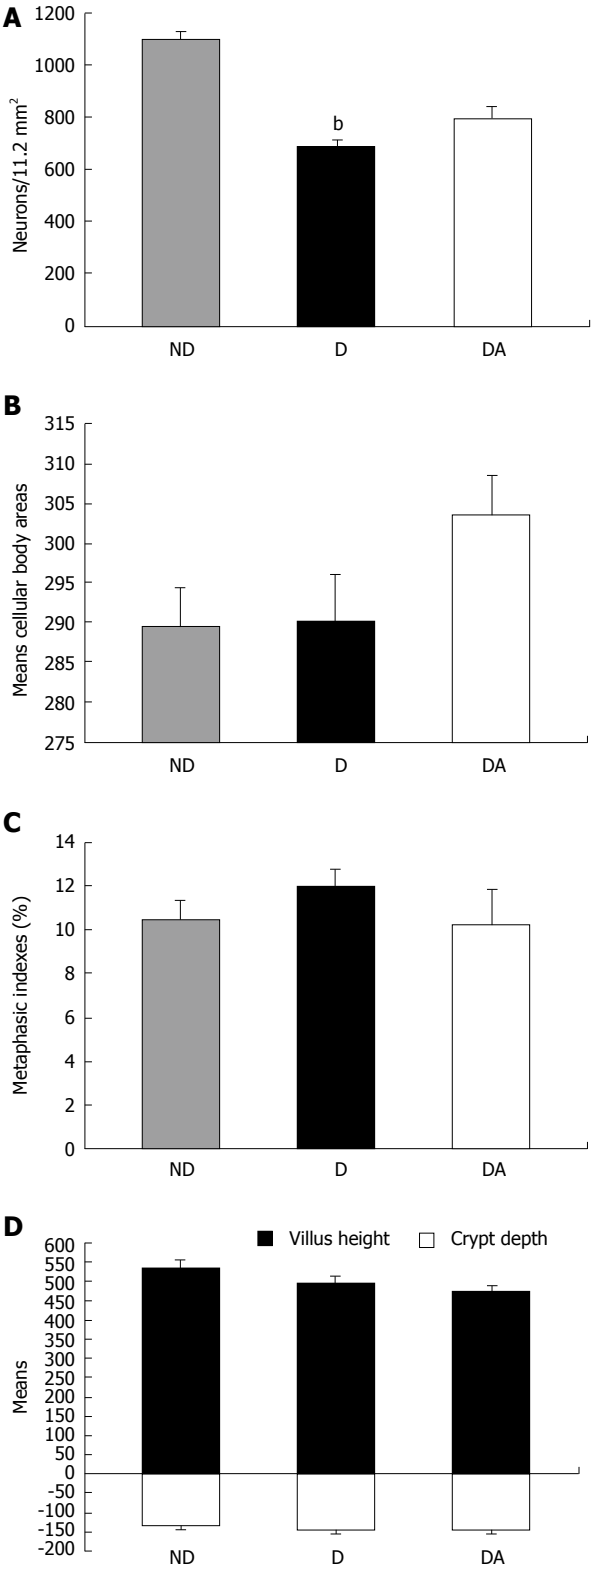

Figure 1 Quantitative and morphometric neurons meyenteric stained of myosin-V analyses. A: Number of myenteric neurons myosin-V stained quantified in 11.2 mm^2 in the jejunum of rats from groups: ND, D and DA, mean ± SE (*n* = 5). $^bP < 0.001$, *vs* the corresponding values in group ND; B: Means (μm^2) of neuronal area of myosin-V-stained myenteric neurons in animals from groups: ND, D and DA, mean ± SE (*n* = 5). There were no significant differences when comparing the three groups by Kruskal-Wallis test; C: IMs (%) of animals from groups: ND, D and DA, mean ± SE (*n* = 5). There were no significative differences when comparing the three groups by test of Tukey; D: Villus height (μm) and crypt depth (μm) in the jejunal mucosa of animals from groups: ND, D and DA, mean ± SE (*n* = 5). There were no significant differences when comparing the three groups by test of Tukey.

animals from the DA group had villi with lower heights than the non-diabetic and diabetic groups (11% and 4% lower, respectively) ($P > 0.05$).

The crypts of the diabetic group were 10% deeper than the crypts observed in the non-diabetic group. The animals from group DA showed a 17% reduction in the depth of their crypts when compared to the diabetic group, and an 8% reduction when compared to the non-diabetic group ($P > 0.05$). The data are shown in Figure 1D.

DISCUSSION

We observed the onset of diabetes mellitus in the diabetic animals and the DA group, characterized by polyuria, polydipsia and polyphagia, thus, validating this experimental model of streptozotocin-induced diabetes mellitus. The onset occurred in the first days of the induction and is associated with the elevation of glucose levels observed by the glucose oxidase and glycated hemoglobin test.

We also verified a sharp reduction of the plasma level of AA due to the diabetes mellitus, in agreement with Young *et al*[28], Garg *et al*[29] and Lindsay *et al*[30]. This reduction might be associated with the increased consumption of the AA due to the increase of the oxidative stress caused by the diabetes mellitus[20,31]. The supplementation with AA allowed the rats from the DA group an increase of 61.9% in their plasmatic level when compared to the diabetic rats, maintaining the glycemia and typical state of diabetes mellitus for these animals.

In order to examine the possible neuroprotector action of the AA in the population of myenteric neurons, we used the immunohistochemical technique for staining the neurons that had myosin-V, since these neurons have a high concentration of this protein, similar to the central nervous system[24].

The loss of neurons suffered by the diabetic animals (680.6 ± 30.27 neurons/11.2 mm^2, group D), resulting in the pathology, was 37.9% in relation to the non diabetic rats (1097 ± 29.79 neurons/11.2 mm^2) ($P < 0.001$) while in the DA group (792.6 ± 46.52 neurons/11.2 mm^2) the loss of neurons was 27.7% in relation to the same group. Treatment of the DA group with AA, resulted in an upper number of myosin-V neurons at 14% in relation to group D ($P > 0.05$). The AA acts by reducing the activity of the aldose reductase. It is the first rate-limiting enzyme of the polyol pathway[32]. Under euglycemic conditions, aldose reductase plays a minor role in glucose metabolism; however, during diabetes, its contribution is significantly enhanced[33,34] leading to a conversion of excess glucose to sorbitol in insulin independent tissues like myenteric neurons. The hyperglycemia, increases sorbitol accumulation and osmotic stress because of the slower oxidation of sorbitol to fructose by sorbitol dehydrogenase. The importance of the AA is also related to its antioxidant activity; therefore, in diabetes mellitus there is an increase of the oxidative stress and a reduction of the levels of antioxidants, endogenous

and exogenous[35]. Cotter *et al*[36], using vitamin C (150 mg/kg per day), demonstrated a 36% prevention in the reduction of the speed of motor nervous conduction provoked by the DM ($P < 0.001$). According to the author, the levels of glycemia observed in experimental diabetes and the consequent increase of free radicals, are excessively higher than the relatively controlled observed one in patients with diabetes. This would explain the statistically significant neuroprotection exerted for the vitamin, which was not observed in our animals of group DA ($P > 0.05$). Due to the fact of a differential effect of streptozotocin-diabetes on different regions of the rat intestine[9], our research group carried out experiments in different intestinal segments. Our work developed in the Department of Morphophysiological Sciences of the State University of Maringá, Paraná, Brasil in whole mounts of diabetic rats supplemented with AA (1 g/L). Zanoni *et al*[37] and Zanoni *et al*[10] verified a reduction of the area of the cellular body from enteric neurons VIP-immunoreactives and NADPH-d positives of the ileum, respectively. Also it was verified 74.3% and 33.4% of neuroprotection in NADH-d myenteric neurons of the duodenum[38] and of the proximal colon[39], respectively. This percentage supports the neuroprotection in the number of myenteric neurons in animals of group DA, when compared to group D.

When analyzing the results obtained through the mean cellular area, we verified there were no significant differences when the three groups were compared. When considering specifically the diabetic condition with the non-diabetic group, we noticed some divergences in our results. Hernandes *et al*[7] and Fregonesi *et al*[40] observed an increase in the cellular area. They attributed as a possible cause the increase on the sorbitol concentration that would lead to changes of the intracellular osmolality, increasing it and resulting in edema and neuronal lesion. Similar to our results, Zanoni *et al*[37] also did not observe differences when they compared the cellular area of the myosin-v-stained myenteric neurons of the ileum of diabetic rats with the acid ascorbic diabetic-treated rats. On the other hand, VIP-ergic neurons of the ileum showed an increase in their cellular area in the diabetic rats and the supplementation with AA prevented this increase[37]. We believe that AA supplementation has an effect on the neuronal population. However, this happens in a specific way, depending on the subpopulation studied: for example, it is evident that it affords neuroprotection Vip-ergic neurons.

The onset of the experimental diabetes mellitus in the jejunum of rats did not cause alterations in the MI or in the morphometry of the intestinal mucosa (villi height and depth of crypts) of our animals. The literature data reveal that the small intestine of the rat responds to the experimental with hyperplasia and hypertrophy of the mucosa[41,42] and an increase of the thickness of the submucosa layer and total wall[42]. These results cannot be considered contradictory to ours, since these authors maintained acute diabetes. They also agree partially with the data of Zoubi *et al*[3], who did not detect alterations in the morphometry of the intestinal crypts in the small intestine of rats after 84 d of inducing the diabetes mellitus. However, they observed an increase in the mitotic index.

As the intrinsic enteric nervous system mediates signals of the autonomic nervous system that regulate the dynamics of the intestinal epithelium carrying out an inhibitory control about the same one. Zucoloto *et al*[43] and Hernandes *et al*[44] carried out denervation of the myenteric plexus with benzalkonium chloride in rats. Zucoloto *et al*[43] did not observe differences in the cellular growth of crypts after 5 mo and Hernandes *et al*[44] observed an increase in cellular proliferation of the mucosa 15 d after denervation, but not after 23 d. We believe that the results found for the cellular proliferation of the intestinal mucosa may be related to an adaptation of the mucosa layer to the chronic pathogenesis of diabetes mellitus (if we consider the long period, 120 d, of maintaining diabetes mellitus).

Despite maintaining the morphometry of the mucosa layer, we presume that the diabetes mellitus did not lead to functional damage of the jejunum revealing an important mechanism of intestinal adaptation to chronic diabetes mellitus. On the other hand, the absence of morphometric variations on the intestinal mucosa of the diabetic rats supplemented with AA is explained by the effect of this antioxidant on the myenteric neurons being too little to promote significant changes.

The conclusion was that supplementation with AA in the diabetic animal promoted a moderate neuroprotection. Alteration of the cellular proliferation of the jejunum mucosa layer of rats was not observed, with chronic diabetes mellitus with or without supplementation with AA.

COMMENTS

Background

Diabetes mellitus (DM) is caused by inadequacy of insulin production in the pancreas, when this organ either totally stops producing insulin or does not produce enough of the hormone. When badly controlled, the glucose level increases abnormally and causes harm, such as dysfunction and failure of several organs, especially nerves, kidneys, eyes, heart and blood vessels. In DM, the concentration of free radicals and/or the oxidative stress increases in an uncontrolled way, causing lesions on the neurons. The oxidative stress in DM is intensified due to the reduction of antioxidant levels, an increase of non-enzymatic glycation, and also frequent inflammations. Drugs that reduce the oxidative stress may have a relevant role in the treatment of the neurological complications of DM. Ascorbic acid (AA) is one of these substances, and it seems to be a promising one, not in the sense of curing diabetes, but of contributing to the maintenance of better conditions of neural conduction.

Research frontiers

The repercussions of the DM on the longevity and quality of life of individuals

in this condition, and their economic implications affect the productive potential and overburden the health system, has acted as motivation for many searches that seek to assess substances which might collaborate in the reduction of degenerative processes arising from DM. Results with AA have been promising, not to cure diabetes, but at least contribute to maintenance of better neural conditions, and reduction of oxidative stress common to this pathology.

Innovations and breakthroughs

Due to the fact of a differential effect of streptozotocin-diabetes on different regions of the rat intestine, our group carried out experiments in different intestinal segment in whole mounts of jejunum of diabetic rats supplemented with AA (1 g/L) and found that supplementation with AA in the diabetic animal promoted moderate neuroprotection.

Applications

The authors understand that the confirmation of the real benefits of AA will be consolidated or discarded based on new research, but will also be of some importance to the disclosure of reports of cases where this product was administered to treat patients, thus contributing to publication of a history containing comments on its use.

Peer review

The present study shows the myenteric neurons and intestinal mucosa of diabetic rats after AA supplementation. This present study is an interesting trial.

Abstract

AIM: To study the results for the treatment of symptomatic hemorrhoids using rubber band ligation (RBL) method.

METHODS: A retrospective study for 750 patients who came to the colorectal unit from June, 1998 to September, 2006, data was retrieved from archived files. RBL was performed using the Mc Gown applicator on an outpatient basis. The patients were asked to return to out-patient clinic for follow up at 2 wk, 1 mo, 6 mo and through telephone call every 6 mo for 2 years).

RESULTS: After RBL, 696 patients (92.8%) were cured with no difference in outcome for second or third degree hemorrhoids (P = 0.31). Symptomatic recurrence was detected in 11.04% after 2 years. A total of 52 patients (6.93%) had 77 complications from RBL which required no hospitalization. Complications were pain, rectal bleeding and vaso-vagal symptoms (4.13%, 4.13% and 1.33% of patients, respectively). At 1 mo there were a significant improvement in mean SF-36 scores over baseline in five items, while after 2 years there were improvement in all items over baseline, but not significant. No significant manometric changes after band ligation.

CONCLUSION: RBL is a simple, safe and effective method for treating symptomatic second and third degree hemorrhoids as an out patient procedure with significant improvement in quality of life. RBL doesn't alter ano-rectal functions.

INTRODUCTION

Hemorrhoids are the clinical manifestation of the downward disruption of normal functional structures known as the anal cushions[1]. Hemorrhoids are considered one of the most frequent diseases of the anal region with high prevalence (nearly 50% of proctological visits in a colorectal unit)[2], involving any age and affecting both males and females equally[3,4]. They commonly occur in patients with chronic increased intra-abdominal pressure as well as in pregnancy[5].

Numerous modalities and techniques have been

developed to treat symptomatic hemorrhoids ranging from simple dietary measures and bowel habit regulation, through a number of non-operative procedures, to different techniques of excision of diseased anal cushions. The vast amount of treatment options means none are close to perfection[6]. While many non-operative procedures are effective in controlling symptoms, at least from the patients' perspective, they all share the common problem of recurrence[7]. Although, surgical hemorrhoidectomy is more definitive in symptom control, it has a reputation for being a painful procedure for a relatively benign disorder[8]. First, second and third degree hemorrhoids can be treated by non surgical methods in outpatient clinics while severe prolapsed or circumferential hemorrhoids can be treated using a variety of surgical techniques, e.g. Milligan Morgan, Longo and others[9,10].

Nonsurgical methods aim at tissue fixation (sclerotherapy, cryotherapy, photocoagulation, laser), or fixation with tissue excision [rubber band ligation (RBL)][11]. RBL is considered the most widely used procedure, and it offers the possibility to resolve hemorrhoidal disease without the need for hospitalization or anaesthesia, and with lower incidence of complications[12,13].

In this retrospective study, we analyze the effectiveness, safety, quality of life and results (early and long term) of RBL in the management of symptomatic hemorrhoids as outpatient procedure.

MATERIALS AND METHODS

This is a retrospective analysis of data of patients diagnosed with hemorrhoids who were managed by RBL at the outpatient clinic of colorectal surgery unit, Mansoura university hospitals from June, 1998 to September, 2006. Data, from 750 patients who had symptomatic hemorrhoids and treated by RBL, were retrieved from archived files of our colorectal surgery unit out of 2200 cases of hemorrhoids. The mean age was 39.13 ± 14.75 years (ranging from 15 to 90 years old). Six hundreds and twenty seven patients (82.8%) were males, while 123 patients (17.2%) were females. Sixty four patients (8%) had chronic liver disease. Supplemental information was obtained from telephone follow up.

The policy of our colorectal unit stated for the following inclusion and exclusion criteria: Patients at any age with first, second or third degree internal piles were included. While, patients with: Previous ano-rectal surgery, associated ano-rectal pathology "fissure, fistula …*etc*", fourth degree hemorrhoids and complicated piles (infection, ulceration or strangulation) were excluded.

Patients who fulfilled inclusion criteria were subjected to: Thorough history taking including the following items; age, sex, occupation and residence, presentation (bleeding, prolapse, anal pain, discharge, and pruritus). For local examination, the patient was examined when relaxed in the left lateral position and the local examination to anal region is carried out by inspection, palpation, P.R. examination, proctoscopic examination and sigmoidoscopic examination for patients above 50 years.

Ano-rectal manometery was performed using a standard low compliance water perfusion system and eight-channels catheters with pressure transducer connected to 5.5 mm manometric probe with spirally located ports at 0.5 cm interval. The protocol of performance is a stationary pull through technique with recording the functional length of the anal canal (FL), mean maximum resting pressure, mean squeeze pressure.

All patients received a cleansing rectal enema before the procedure to avoid bowel movement in first 24 h so ligatures would not be expelled. The procedure was done in left lateral position. No anaesthesia was used; no antibiotics were administered, except to patients with valvular heart diseases or chronic liver disease.

The procedure was performed through the proctoscope, which was inserted and placed about 1-2 cm. above the dentate line using K-Y gel as a lubricant. The hemorrhoidal cushion was allowed to prolapse into the lumen of proctoscope, after that it was sucked into the Mc Gown ligator. It was important that the patient experienced no pain when the cushion was sucked; if pain was experienced, the cup was placed in a more proximal position. The tissue was drawn into the drum until it was taut, and the trigger was released, expelling rubber O-ring with an inner diameter of about 1 mm around the base of the haemorrhoid. The policy of our unit is that all piles are ligated in the same session.

By the end of the procedure, each patient treated by RBL was kept in the outpatient clinic and observed for 1-2 h following the procedure, in order to detect any early complication as hemorrhage and pain. The patients were informed about the progress of the treatment (fall of the necrosed hemorrhoidal nodule). We recommended high residue diet, mild laxative to softening the stool, local anal hygiene, avoidance of straining, and information concerning early and late complications.

The patients were asked to return to out-patient clinic for follow up at 2 wk, 1 mo, 6 mo and then through telephone call every 6 mo for 2 years. Subsequent ligations were performed at 1 mo after the prior one, if the patients still had symptoms.

Results were classified as following; cure if the patient was asymptomatic after the end of treatment, improvement if the symptoms had been minimized, and as failure of the method if no improvement whatsoever occurred.

Post ligation complications include: pain, Vaso-vagal symptoms (dizziness or fainting), retention of urine, bleeding per rectum whether primary, secondary or reactionary and post ligation infection were recorded. Also, the patient was asked about continence and anal stricture during scheduled P.R examinations

Functional status was assessed with the medical outcomes study 36-item short-form general health survey (SF-36) questionnaire, version 2[14] (pre procedure,

1 mo post procedure and after 2 years). The SF 36 consists of eight multi-item dimensions, each of which generates a score of between 0 and 100; higher scores indicate higher levels of perceived health.

Statistical analysis

The statistical analysis of data was done by using SPSS (Statistical Package for Social Science) version 10 under Microsoft Windows XP. The description of data was done in form of mean ± SD for quantitative data; while frequency and proportion for qualitative data. The analysis of data was done to test the statistical significant difference between groups. For quantitative data, to compare between 2 groups Student *t*-test was used and for qualitative data χ^2 test was used. $P < 0.05$ was considered significant.

RESULTS

Our study includes 750 patients with hemorrhoidal disease with a mean age was 39.13 ± 14.75 years (ranging from 15 to 90 years old). Six hundred and twenty seven patients (82.8%) were males, while 123 patients (17.2%) were females. Male to female ratio was 5.09:1.

Demographic data, clinical presentation and severity of hemorrhoids for all patients are shown in Table 1.

In 473 patients (63.06%), one session ligation was performed while in the remaining patients, multiple hemorrhoidal ligations were performed in two sessions for 259 patients (34.53%), and three sessions for 18 patients (2.4%) with 1 mo interval.

The total of 2122 ligations in 1045 sessions were carried out, with a mean of 2.35 (± 0.49) per patient and 2.03 (± 0.54) per session.

Successful results were achieved in 696 patients (92.8%), 650 patients (86.66%) were cured after the end of treatment, whereas, 46 patients (6.13%) improvement was reported. Fifty four patients (7.2%) failed to get any benefit from RBL. There was no significant difference in the outcome of RBL between second and third degree hemorrhoids ($P = 0.31$) Table 2.

Two years after the end of treatment, 643 patients 85.73% came for follow up. Symptomatic recurrence was detected in 71 out of 643 patients (11.04%), with repeated treatment by RBL in 23 cases and additional surgical treatment was required in another 48 patients due to severe symptoms in 30 patients, associated anal fissure in 6 patients, and patient desire in 12 patients Tables 3 and 4.

Seventy seven complications from RBL were encountered in 52 patients (6.93%) as shown in Table 5. Pain was occurred in 31 patients (4.13), 22 cases (3.78%) had second degree hemorrhoids and 9 cases (5.35%) had third degree hemorrhoids with no statistical significance ($P = 0.8$) (Table 5). Patients with multiple hemorrhoidal banding, when compared with patients with single banding had great discomfort and pain (19/277, 6.85% *vs* 12/473, 2.53% respectively). Pain was treated conservatively with analgesic and warm baths in all patients and no patient forced to remove the band.

Role limitation due to emotional problem (RE)	60.4 ± 3.2	58.5 ± 5.6	0.08	65.2 ± 4.5	0.09
Mental heath (MH)	71.9 ± 2.8	73.5 ± 2.3	0.01	73.6 ± 5.2	0.04

blood transfusion or hospitalization in any of these cases. Post banding bleeding occurred in 21 cases (2.8%) with second degree hemorrhoids and in third degree hemorrhoids only 10 cases (5.95%) complicated with mild bleeding after RBL with no statistical significance ($P = 0.35$) (Table 5).

Post-banding vaso-vagal symptoms were reported in 10 cases (1.33%). There were no cases of urine retention that necessitate catheterization, fecal incontinence did not occur after RBL in this study, also no cases were complicated by anal stenosis (Table 5).

Perianal abscess occurred in one case (0.13%) after RBL. It was drained, but 2 mo later the patient developed low anal fistula which was treated by fistulectomy. Three patients (0.4%) complicated with anal fissure after RBL.

There was no significant difference in pre banding and post banding manometric study (pre banding and post banding mean resting pressure were 87.29 ± 17.44 and 86.45 ± 15.46, respectively, $P = 0.065$) and (pre banding and post banding mean squeeze pressure were 227.82 ± 43.82 and 227.04 ± 44.12, $P = 0.193$).

The SF-36 questionnaires were completed by 730 patients pre banding, 720 patients at 1 mo and 630 patients at 2 years for assessment of quality of life. At 1 mo after banding there was greater improvement in mean score over baseline, the difference observed were significant for five dimensions in physical, social activity, vitality, freedom of pain and mental health. At 2 years after banding there were greater improvement in mean scores over baseline for all items, but only mental health showed significant difference Table 6.

DISCUSSION

The need to treat hemorrhoids is based primarily on the severity of symptoms, but the type of treatment is based on the traditional classification of hemorrhoids, which may have little to do with symptom severity[15]. The best treatment remains unanswered despite of the wide variety of treatment options in use. Safety is of paramount importance, especially when treating a benign disease such as hemorrhoids[16,17]. Although surgical hemorrhoidectomy is more definitive in symptom control, it has a reputation of having a significant postoperative pain and an extended recovery time for a relatively benign disorder[7]. Nowadays, rubber-band ligation is the most widely used procedure, and it offers the possibility to resolve hemorrhoids disease without the need for hospitalization or anaesthesia, and with a lower incidence of complications when compared to conventional surgery[15].

The success rates of the method range between 79% and 91.8%[11,16,18]. Wrobleski *et al*[19] reported that 80% of their patients improved and 69% were symptom-free at a mean follow-up of 5 years. There was no difference in success rates of RBL in 1st, 2nd and 3rd degree hemorrhoids[11]. In our study, successful results were achieved in 696 patients (92.8%), 650 patients (86.66%) were cured or presented great improvement after the end of treatment and 2 years later, 572 patients were cured out of 643 patients who attended follow-up. Johanson *et al*[20] showed that 6.6%-14% of the patients undergoing RBL will require additional treatment, due to the recurrence of symptoms. Many authors reported that recurrence rate may be as high as 68% at 4 or 5 years of follow-up and symptoms usually respond to repeated ligation, but only 10% of such patients require excisional hemorrhoidectomy[21,22]. Vassillios *et al*[11] reported that symptomatic recurrence was 11.9% (53/445) 2 years after RBL, with repeat RBL or surgery in (41/445) 9.2% cases. Bayer *et al*[23] found that 18% of their patients required one or more additional sessions of RBL while 2.1% failed to be cured by RBL and were referred for conventional hemorrhoidectomy. In our study, symptomatic recurrence was detected in 11.04% (71/643) after 2 years follow up, with repeated treatment by RBL in 23 cases while additional surgical treatment was required in 48 patients.

A review of 39 studies incorporating 8 060 patients undergoing RBL revealed post banding complications in the form of severe pain in 5.8%, hemorrhage in 1.7%, infection in 0.05% anal fissure and fistula in 0.4%[24]. Bat *et al*[16] showed that the complications rate after RBL was relatively low (4.2%), most of the complications were minor and self limiting. only 2.5% of his patients had severe complications that required hospitalization. Vassillios *et al*[11] reported that in 94 patients (18.8%), complications were occurred. In our series, seventy seven complications from RBL encountered in 52 patients (6.93%) were mostly minor and no hospitalization was needed. Many authors reported that post banding pain was frequently observed even during careful placement

above the dentate line[25]. Furthermore, pain and anal discomfort were reported to be greater, ranging from 28% to 79%, when multiple bandings were performed per session[26]. Gupta[18] found that out of 44 patients underwent RBL; seven patients (15.9%) reported pain and Oueidat and Jurjus[27] noted that out of 148 patients underwent RBL; twenty patients (13.5%) reported pain. We found that, pain occurred in 31 patients (4.13%), in all cases the pain appeared immediately or few hours after the ligation and lasted less than 2-3 d. Patients with multiple hemorrhoidal banding in one session had greater discomfort and pain. These results are in accordance with those of Vassillios *et al*[11], who reported that patients with multiple hemorrhoidal banding in a single session compared with patients with single banding had greater discomfort and pain (9.35% *vs* 1.96%). Also, Lee *et al*[28] and Gehmy *et al*[29] reported the same results. On the contrary, Hardwick *et al*[30] failed to show any relationship between the number of bands applied and the degree of pain. Moreover, Khubchandani[31], in a prospective randomized study, compared the results of single, double and triple hemorrhoidal ligation, but did not notice any difference even if they were forced to remove the elastic band in many cases in the third group.

Bleeding is a significant complication of RBL and it cannot be prevented. It is the result of the fall of the hemorrhoidal nodule and local inflammation, bleeding in our series occurred in 31 cases (4.13%). It was mild and treated conservatively in all cases without hospitalization or blood transfusion. Band ligation is safe in patients with cirrhosis and portal hypertension as reported by Vassillios *et al*[11]. Bat *et al*[16] and Bayer *et al*[23] reported that only 2.2% of his patients complicated by rectal bleeding.

Watson *et al*[32], in their study of 183 cases of band ligation, found that 41 patients (30%) of patients had vaso-vagal symptoms. Kumar *et al*[33] reported that 15.3% of their studied group (98 patients) had vaso-vagal symptoms. In our study, Post-banding vaso-vagal symptoms occurred in 10 cases (1.33%). There were no cases of urine retention that necessitate catheterization, fecal incontinence or cases complicated by anal stenosis after band ligation. This also reported by Benzoni *et al*[34] and Watson *et al*[32].

Bursics *et al*[35] reported that maximum resting pressure and squeeze pressure remained unchanged after RBL, as found in our study.

Our conclusion is that RBL is a simple, safe and effective method for treating symptomatic second and third degree hemorrhoids as an out patient procedure with significant improvement in quality of life. RBL can be used to treat grade 2 and 3 hemorrhoids with similar effectiveness. RBL doesn't alter ano-rectal functions.

COMMENTS

Background

Numerous modalities and techniques have been developed to treat symptomatic hemorrhoids ranging from simple dietary measures and bowel habit regulation, through a number of non-operative procedures, to different techniques of excision of diseased anal cushions. The vast amount of treatment options means none are close to perfection. Nonsurgical methods aim at tissue fixation (sclerotherapy, cryotherapy, photocoagulation, laser), or fixation with tissue excision [rubber band ligation (RBL)].

Research frontiers

RBL is a simple, safe and effective method for treating symptomatic second and third degree hemorrhoids as out patient procedure with significant improvement in quality of life. RBL doesn't alter ano-rectal functions.

Innovations and breakthroughs

RBL is effective method for treating symptomatic hemorrhoids as an out patient procedure with significant improvement in quality of life. RBL doesn't alter ano-rectal functions.

Applications

After RBL, 696 patients (92.8%) were cured with no difference in outcome for second or third degree hemorrhoids (P = 0.31). Symptomatic recurrence was detected in 11.04% after 2 years. A total of 52 patients (6.93%) had 77 complications from RBL which required no hospitalization. Complications were pain, rectal bleeding and vaso-vagal symptoms (4.13%, 4.13% and 1.33% of patients respectively). At 1 mo there were a significant improvement in mean SF-36 scores over baseline in five items while after 2 years there were improvement in all items over baseline but not significant. No significant manometric changes after band ligation.

Peer review

This is an interesting study of a large series of patients with RBL and their results. Authors retrospectively analyzed the effectiveness, safety, quality of life and results of RBL in the management of symptomatic hemorrhoids. The paper is well written.

Abstract

AIM: To study the frequency, gender and age distribution as well as pathological characteristics of colorectal carcinoma (CRC) in Lagos and Sagamu in SW Nigeria.

METHODS: This is a retrospective pathological review of histologically diagnosed CRC from 5 laboratories in Lagos & Sagamu. The clinical data, such as age, sex and clinical summary were extracted from demographic information. Cases of anal cancer were excluded from this study.

RESULTS: There were 420 cases (237 males and 183 females) of CRC. It peaked in the 60-69 year age group (mean: 50.7; SD: 16.2), M:F ratio 1.3:1 and 23% occurred below 40 years. The majority was well to moderately differentiated adenocarcinoma 321 (76.4%), mucinous carcinoma 45 (10.7%) and signet ring carcinoma 5 (1.2%), and more common in patients under 40 years compared to well differentiated tumors. The recto-sigmoid colon was the most common site (58.6%). About 51% and 34% of cases presented at TNM stages Ⅱ and Ⅲ, respectively.

CONCLUSION: CRC is the commonest malignant gastrointestinal (GIT) tumor most commonly located in the recto-sigmoid region. The age and sex prevalence and histopathological features concur with reports from other parts of the world.

INTRODUCTION

Colorectal carcinoma (CRC) is an important cause of cancer death worldwide, but has variable geographical distribution. In developed countries, it is among the 3 most common cancers with an estimated worldwide incidence of 570 000 new cases per annum[1]. Previous

studies have shown it to be a rare disease in Africans representing 3%-6% of all malignant tumors in most African studies[2-5]. It accounts for 10%-50% of all gastrointestinal (GIT) malignancies in Nigeria[6-8]. Incidences from various parts of the country range between 3.75-6 cases per annum in South South/South-East Nigeria[9,10], 12.5-14.4 cases per annum in the North[11,12] and 26.3 cases per annum in SW regions, respectively[13]. An 81% increase in incidence over a period of two decades was reported from Ibadan SW Nigeria[13]. Several reasons have been adduced for this increase, including an increase in hospital attendance by the populace due to an increasing awareness about cancer and change in dietary habit among others[13]. Major predisposing factors in the etiopathogenesis of CRC include the presence of pre-malignant conditions, such as familial polyposis syndrome, inflammatory bowel disease (IBD) and dietary factors, such as diet rich in refined carbohydrate, diet low in fibre content and fresh vegetables, all of which increase fecal transit time[14]. The low incidence in Africans was attributed to fiber rich diet which is common practice and rarity of the familial polyposis syndrome and IBD[2]. Recent urbanization/civilization has resulted in upsurge of confectionary food outlets in major cities resulting in many Nigerians changing their dietary habit from a fiber rich diet, which was common practice to a highly refined carbohydrate and fat diet.

Molecular studies have characterized 5 subtypes of CRC which have different etio-pathogenetic pathways that correlate with the morphologic and prognostic features[15]. These subtypes are based on DNA microsatellite instability status (MMR) and CpG island methylator phenotype[15]. Hameed, in South Africa using immunohistochemistry to detect expression of hMLH1 & hMSH2 (MMR status) in CRC, found that while 60% had normal expression of both gene products, 40% showed negative expression of either of the two genes[16]. He further observed that CRC with absence MMR (hMLH1 or hMSH2) tended to be right sided, mucinous and poorly differentiated when compared with the tumors that express the gene product. Also, Lanza *et al*, in Italy studying MMR status in CRC reported that 15.9% of CRC studied had abnormal expression of hMLH1 and hMSH2. They also observed that patients whose tumor was MMR negative had better clinical outcome particularly in Stage Ⅱ and Ⅲ tumors[17]. This advantage was more evident in patients with surgery alone than those who had adjuvant chemotherapy.

The present study is aimed at documenting the frequency pattern, age and sex distribution, as well as histopathologic characteristics of CRC in Lagos and Sagamu in SW Nigeria, as a preliminary to immunophenotypic subtyping; which we are currently carrying out in collaboration with the Department of Histopathology & Molecular Biology, Leeds General infirmary, Leeds United Kingdom.

MATERIALS AND METHODS

The paraffin embedded blocks and slides as well as pathology reports of malignant colorectal tumors collected from five laboratories (Morbid Anatomy Departments of the Lagos University Teaching Hospital 1995-2007, Olabisi Onabanjo University Teaching Hospital in Sagamu, Ogun State, as well as the three private histolopathology laboratories in Lagos State between 2002-2007 viz: The Specialist Laboratory, Histolab Diagnostics and Seramoses Laboratory) constituted the materials utilized for this study.

The slides were reviewed to confirm the diagnosis, type and grade of the tumor. The resection samples were further staged using Tumor-Node-Metastases staging system of International Union against Cancer (TNM) and Duke's staging system.

A proforma was used to extract the bio data such as age, sex, clinical symptoms and signs as well as the endoscopic findings when available from the histopathology request forms; some of the patient's case files where available in their various clinics or hospitals.

The clinical biodata and histopathological characteristics were analyzed using Microsoft Excel software and presented as tables.

RESULTS

There were a total of 420 cases of CRC with 237 males and 183 females and a male to female ratio of 1.3:1. CRC was the most common malignant GIT tumor accounting for 59% of all GIT malignancies and representing 87% of all malignant tumors of the colorectal and anal regions. It accounted for 5.8% of all the 7225 malignant lesions diagnosed from the five laboratories during the period.

The youngest patient was 10 years while the oldest was 95 years with a mean age of 50.7 (SD-16.2). CRC peaked in the 60-69 years age group (mode 60 years). About 12% (12.4%) occurred in patients 30 years and below, 23% occurred below 40 years and 16.8% above the age of 60 years.

Left-sided (distal colon) tumor 261 (62%) was more common than right-sided (proximal) ones 58 (14%). More than half of the cases were located in the recto-sigmoid region 246 cases (58.6%) followed by caecum 34 cases (9%), ascending colon 24 cases (6%), transverse 19 cases (4.5%) and descending colon 15 cases (3.6%) each. In 82 cases (19.5%), the specific site was not indicated.

Macroscopically, the right sided tumors were fungating nodular lesions with surface ulcerations while the left sided tumors were flat and infiltrating or constricting. Microscopically, the tumors were adenocarcinoma of varying grades. Majority were well-differentiated adenocarcinoma in 233 (55.5%), 88 (21%) were moderately differentiated and 34 (8%) were poorly differentiated carcinoma. Mucinous and signet ring carcinomas accounted for 45 cases (10.7%) and 5 cases (1.2%), respectively. Fifteen cases (3.6%) were anaplastic (undifferentiated) tumors (Table 1).

Mucinous carcinoma (19%) and signet ring carcinoma (3%) were more common in patients under 40 years; compared to 4% & 0.6% record in patients

Table 1 Site and gender distribution and histological types of CRC in patients 40 yr and above compared with those below 40 yr *n* (%)

	40 yr and above	Below 40 yr
Site		
Cecum	23 (7.14)	11 (11)
Ascending colon	20 (6.21)	4 (4)
Transverse colon	13 (4.04)	6 (6)
Descending colon	13 (4.04)	2 (2)
Recto sigmoid	194 (60.25)	52 (53)
Unspecified	59 (18.32)	23 (23)
Total	322 (100)	98 (100)
Histological grade		
Well differentiated adenocarcinoma	191 (59.3)	42 (43)
Moderately differentiated adenocarcinoma	63 (19.6)	25 (26)
Poorly differentiated adenocarcinoma	38 (11.8)	7 (7)
Mucinous carcinoma	15 (4.7)	19 (19)
Signet Ring carcinoma	2 (0.6)	3 (3)
Undifferentiated	13 (4)	2 (2)
Total	322 (100)	98 (100)
M:F ratio	1.3:1	1.2:1

Table 2 Pathological staging of 123 cases of CRC

Duke's stage	*n* (%)	TNM staging	*n* (%)
A	17 (14)	Stage Ⅰ	17 (14)
B	64 (52)	Stage ⅡA	54 (43)
C	41 (33)	Stage ⅡB	10 (8)
D	1 (1)	Stage ⅢA	13 (11)
		Stage ⅢB	28 (23)
		Stage Ⅳ	1 (1)

above 40 years (Table 1). On the other hand, well differentiated adenocarcinoma was more common in patients above (59%) than those below 40 years (43%). The male to female ratio is also less for younger patients. The cases less than 40 years also tended to be located in the cecum (11%) compared to older patients (7%) (Table 1).

Pathological staging was carried out for 123 cases with colectomy samples using Duke's and TNM staging systems. Of the 123 cases, 14%, 51%, 34% and 1% presented at TNM stages Ⅰ, Ⅱ, Ⅲ and Ⅳ, respectively (Table 2).

The clinical presentation was varied including abdominal pain, abdominal mass, bloody mucoid stool, change in bowel habit, weight loss, anaemia, and/or features of intestinal obstruction.

DISCUSSION

In this study, CRC accounted for 5.8% of all malignancies diagnosed in the five laboratories. This concurs with figures of 3.7%-10% that have been reported from various parts of Nigeria and Africa[2-5,18]. In Libya, it was the 2nd most common malignant tumor accounting for 10% and 9% in males and females, respectively [18]. Ohanaka & Ofoegbu in Benin, South West Nigeria reported CRC to be the 3rd most common cancer[7]. From the surgical biopsy register of Morbid Anatomy Lagos University Teaching Hospital, CRC is the third most common cancer diagnosed after breast and cervix. The annual frequency of this cancer in Lagos as documented in this study, was 32.3, a figure which is higher than 3.76 cases/annum in the South-South, 14.4 in the North-Central and 26.3 recorded in Ibadan South West Nigeria, respectively[9,11,13]. The higher number in this study could be attributed to the wider coverage of all the histopathology laboratories servicing both Lagos and Ogun states in South West, Nigeria.

CRC was the most common malignant GIT tumors, accounting for 59% of all GIT malignancies in this study. This is similar to studies from other parts of Nigeria where it was found to represent between 53%-67% of all malignant GIT tumors[3,7,8]. An earlier study from this center also recorded 56%[19]. Even in the United States of America, it was reported to be the most common GIT cancer and the second leading cause of cancer death[20].

Rising incidence has been reported from various parts of Africa which were considered low incidence areas. Iliyasu reported 81% increase in Ibadan over two decades; a 2.7 fold increase has also been reported from Kenya[13,21]. In the present study, we have also noticed an increase in the number of colorectal cases recorded over the years. Although there has been an increasing awareness resulting in an increased hospital attendance, change in dietary habit of Nigerians is a possible reason for this observation and needs to be further investigated to ascertain its relationship with CRC. A South African study has demonstrated 3-fold higher incidence of MSI-H tumors in African-American patients compared with Caucasian Americans; a difference which the authors suggested may reflect dietary differences or genetic polymorphisms that may be common in the African-American population[22].

African Americans have the highest incidence and mortality rates for colon cancer among ethnic populations in the United States, the incidence being 15% higher and the mortality 40% higher in African-Americans than in Caucasian Americans[20]. The relatively low incidence of CRC in native Africans was associated with high fiber diet. Recent workers have however, affirmed that low prevalence of CRC in black African can no longer be explained by high fiber diet because dietary patterns of Africans has changed and even protective anti-oxidants, such as Vitamins C, E, A and calcium, are low in African diet[23,24]. The most incriminating risk factors for CRC in most studies are the high intake of animal protein and fat[24,25]. O'Keefe *et al*[25] earlier showed that CRC risk is determined by interactions between the external (dietary) and internal (bacterial) environments.

The mean age in this study is 50.7 years which corroborates 44.3, 49.7, 51, and 52.3 years reported from Jos in North-Central Nigeria, Kenya, Egypt and Iran, respectively[12,21,26,27]. The age incidence of CRC in Nigeria is lower compared to developed countries;

about 10 years difference has been reported in many studies[9,28,29]. Peak age reported from Nigeria ranged between 42.9 years to 53 years with a mean of 46[11,12].

There appears to be an increasing number of CRC cases occurring in the young as 23% occurred below age 40 years while 12.4% occurred in patients 30 years and below in this study. Reports from other parts of Nigeria showed that 35%-42% of patients with CRC are below age 40 years[28,30,31]. CRC in younger age has been shown to present a diagnostic and therapeutic problem and prognosis tends to be less favorable[32]. In one study, CRC in young females was reported to have more tendencies to present with a late stage disease and anemia[33]. The reason for increasing incidence may be genetic, thus underscoring the need to study the prevalence of HNPCC associated CRC in our environment. On the other hand, it may be related to dietary factors since the young Africans tend to be more civilized and more likely take Westernized diet. In Nigeria, there has been a shift from the traditional African diet, due to upsurge in the number of fast food outlets, and it has become fashionable particularly among the youths to eat these Westernized food which are high in animal protein and fat.

Similar to previous studies, the sex prevalence is in favor of males with M:F ratio of 1.3:1. Except for the studies from Ife[28] which showed higher ratio of 2:1, other studies from Nigeria had reported ratio ranging between 1.1:1 and 1.6:1[6,9,11-13]. In the Middle East, M:F ratio of 1.1:1 was reported in Iran[27].

In terms of location within the colon, our study concurs with previous studies which have indicated that majority of CRC are located in the distal part of the colon; the rectosigmoid[8-13,28,29,32]. The reason for this may partly be due to the endoscopic practice in Nigeria in which the majority do sigmoidoscopy rather than colonoscopy. For example, in Lagos and Sagamu, only three of the eight endoscopic centers do colonoscopy. This limitation might have caused under-reporting of CRC cases, thus underscoring the need for prospective studies and provision of colonoscopy facilities as well as skilled specialists.

All the CRC cases studied were adenocarcinoma of varying grades. The present study also showed that patients < 40 years tended to have poor prognostic tumors such as mucinous and signet ring carcinoma. This concurs with the finding of Fazeli *et al*[27] in Iran who reported that 22% of patients < 40 years had poorly differentiated tumor compared to 5.9% in patients above 40 years. Mucinous carcinomas have been associated with poor prognosis with poor response to chemotherapy, tend to be located in the proximal colon and associated with micro satellite instability[22]. The majority of CRC in this study presented at TNM stages Ⅱ and Ⅲ or (Duke's Stage B and C), which concurs with most reports from Africa[6,13,21,26,27].

In conclusion, CRC in Lagos and Sagamu is the commonest malignant GIT tumor. The age and sex prevalence, as well as histopathological characteristics, are similar to findings from other parts of the world. However, very little is known about the etio-pathogenetic mechanisms. We have therefore commenced follow-up immunohistochemical study, in Collaboration with the Department of Histopathology & Pathology, St. James University Hospital, Leeds, United Kingdom, to identify the molecular subtypes with a view to ascertaining the specific pathogenetic and prognostic features.

ACKNOWLEDGMENTS

We acknowledge with thanks the grant received from the Central Research Committee of the University of Lagos to conduct this study. We also appreciate the cooperation of the management and staff of the Specialist laboratory, Histolab diagnostics, and Seramoses Laboratory and Morbid Anatomy department of Olabisi Onabanjo College of Health sciences.

COMMENTS

Background

Colorectal carcinoma (CRC), the most common gastrointestinal (GIT) cancer, is an important cause of cancer death worldwide, but incidence is lower in Africans representing 3%-6% of all malignant tumors in most African studies.

Research frontiers

Differences exist between the incidence of CRC in Africans and that in developed countries; CRC carcinogenesis is related to development of genetic instability.

Innovations and breakthroughs

The age and sex prevalence, as well as histopathological characteristics of CRC in Lagos & Sagamu SW Nigeria, are similar to findings from other parts of the world. However the incidence is still low compared to Europe and America and very little is known about the immunophenotypic subtypes.

Applications

This study thus underscores the importance of epidemiological study to investigate the immunophenotypic subtypes of CRC in Nigeria respect to the role of dietary factors and genetic factors in the aetiopathogenesis.

Terminology

CRC is a malignant tumor arising from the epithelium of the large bowel; Histopathological characteristics refers to tumor characteristics as seen under the light microscope; Pathological staging means extent of tumor growth and spread based on the size of the primary tumor and extent of lymph node involvement, as well as spread to distant sites (metastasis); Familial Adenomatous Polyposis syndrome is the prototype of polyposis syndrome caused by mutation of adenomatous polyposis coli gene on chromosome 5q21 and characterized by presence of multiple polyps in the GIT tract; Immunophenotypes mean subtypes of CRC based on DNA microsatellite instability status (MMR) and cpG island methylator phenotype.

Peer review

This report on the histopathological characteristics of colorectal cancer in Lagos, Sagamu and southwest Nigeria is of interest as this is a region considered historically to be a low prevalence region for CRC and reports regarding the characteristics of CRC in the region are not great in number. The data reported here are reasonably novel and the presentation is fairly clear and concise.

Abstract

AIM: To assess the prevalence of clinically significant lesions in patients with minimal bright red bleeding per rectum (BRBPR).

METHODS: Consecutive outpatients prospectively underwent colonoscopy at Loghman Hakim Hospital, Tehran. Minimal BRBPR was defined as small amounts of red blood after wiping or in the toilet bowl. Patients with the following alarm signs were excluded: Positive personal history of colorectal neoplasms or inflammatory bowel disease (IBD), positive first degree family history of colorectal neoplasms, history of altered bowel habits, recent significant weight loss, and presence of iron deficiency anemia. Neoplastic polyps, colorectal carcinoma, and IBD were defined as significant lesions.

RESULTS: A total of 402 patients (183 female and 219 male, aged 43.6 ± 15.7 years) were studied. Hemorrhoids (54.2%), anal fissures (14.2%) and ulcerative colitis (14.2%) were the most common lesions and colonoscopy was normal in 8.0%. Significant lesions were found in 121 (30.1%) patients, including 26 patients (6.5%) with adenocarcinoma and 30 (7.5%) with adenomatous polyps. Almost all patients with significant lesions had at least one lesion in the distal colon; an adenocarcinoma and an adenomatous polyp in the proximal colon were found in 2 patients with hemorrhoids.

CONCLUSION: Flexible sigmoidoscopy appears to be sufficient for the evaluation of average risk patients with minimal BRBPR. Rigid sigmoidoscopy may be used as an alternative in patients less than 40 years of age in settings where the former is not available. The choice of colonoscopy over flexible sigmoidoscopy in patients aged over 50 years should be individualized.

INTRODUCTION

Minimal bright red bleeding per rectum (BRBPR) is a clinical problem frequently found in adults of all ages. The problem may be even more common in younger adults because of under-reporting to physicians[1]. For example, a community-based study of 1643 adults ages 20 to 64 found that 13 percent reported blood on wiping. The prevalence of any rectal bleeding was significantly higher in younger people. Only 14 percent of those with any rectal bleeding had seen a physician for bowel problems in the prior year[2].

The etiology of bleeding is highly variable and depends upon the nature of the population studied. The etiology of minimal BRBPR is often difficult to determine because individual patients may have multiple potentially culpable lesions found at endoscopy[3]. In addition, colorectal neoplasms (mostly adenomas) have been found in 16 percent of patients who were concurrently diagnosed with an anorectal source of bleeding[4]. Benign anorectal pathologies appear to account for 90 percent or more of all episodes of minimal BRBPR[3]. The true proportion of benign etiologies may be even higher since many young people with minimal BRBPR never present for care. The appropriate evaluation of a patient presenting with minimal BRBPR must be guided by the risk of underlying serious pathology.

There are relatively few studies that have addressed issues relevant to the appropriate evaluation of patients

with minimal BRBPR and most studies have not been performed in patients with strictly minimal BRBPR. It is a source of controversy as to whether minimal BRBPR necessitates total colonoscopy as a first-line procedure or a 60 cm flexible sigmoidoscopy[5]. Some authors have recommended colonoscopy in all patients with rectal bleeding[4,6,7], while others prefer colonoscopy for patients over 50 years of age and recommend sigmoidoscopy only if a potential source of bleeding is not identified on physical examination or anoscopy/proctoscopy[3].

Medical resources are limited in developing countries and a total colonoscopy may not be easily accessible for all patients with minimal BRBPR in Iran. Our aim was to determine the type and prevalence of colonoscopic findings in patients with minimal BRBPR in order to establish which patients need total colonoscopy.

MATERIALS AND METHODS

The study was performed prospectively on consecutive out-patients undergoing colonoscopy during a three-year period (October, 2004-August, 2007) at the "open access" Unit of Gastrointestinal Endoscopy at Loghman Hakim Hospital of Shaheed Beheshti University of medical sciences, in Tehran-Iran.

Minimal BRBPR was defined as small amounts of red blood after wiping or a few drops of blood in the toilet bowl after defecation. Small amounts of blood on the surface of the stool were also considered minimal BRBPR, but red blood intermixed with stool was not. Exclusion criteria were age below 12 years, positive personal history of colorectal neoplasms or inflammatory bowel disease (IBD), positive first degree family history of colorectal neoplasms, history of altered bowel habits, recent significant weight loss, presence of iron deficiency anemia, those who had already had a colonoscopy within the previous year, and those who did not consent or refused colonoscopy. Patients less than 40 years of age who refused to participate in the study underwent flexible sigmoidoscopy according to the current recommendations[3]. These patients are excluded from the main data analysis, but their results are presented as a separate group.

All patients were interviewed and examined by a gastroenterologist. Informed written consent was obtained from each patient before interview according to the guidelines of the institute. After clinical evaluation, all patients underwent anal inspection and digital rectal examination. Regardless of any anal pathologies detected, all patients underwent total colonoscopy.

Endoscopy was performed by an expert endoscopist in patients after the ingestion of 4 to 6 liters of polyethylene glycol solution. Any abnormal lesion was biopsied and sent for histology. IBD was diagnosed based on colonoscopy features and histopathological findings. Patients with poor bowel preparation were scheduled for repeat colonoscopy and the results of a satisfactory examination are reported. Colonoscopy was supplemented with double contrast barium enema if the colon was examined to at least the hepatic flexure, but the cecum could not be reached.

Patients less than 40 years of age are referred to as 'young' patients. The part of colon, situated between the rectum and the splenic flexure, was defined as distal colon. Neoplastic polyps, colorectal carcinoma, and IBD were defined as "significant lesions".

The study was approved by the institutional review board of the Loghman Hakim research unit of Shaheed Beheshti University of Medical Sciences, according to the declaration of Helsinki. Informed written consent was obtained from each patient before interview and procedures according to the guidelines of the institute.

Quantitative variables are presented with mean ± SD. The qualitative variables are expressed with number and percent. The two groups of values were compared using the chi-square test and the Fisher's exact test, a value of $P < 0.05$ was considered statistically significant.

RESULTS

Patient population

During the study period, 402 patients with minimal BRBPR were enrolled. This study group was composed of 219 males (54.5%) and 183 females (45.5%). Their ages ranged from 13 to 86 years (mean 43.6 ± 15.7 years). Of these, 177 (44.0%) were in the young age group.

There were another 94 young patients (41 male, 53 female; aged 27.6 ± 5.8 years), who met the eligibility criteria, but did not agree to participate and undergo colonoscopy.

Endoscopic lesions

Endoscopy was performed up to the cecum in 389 patients (96.8%). There were no complications attributed to the procedure. The 13 (3.2%) incomplete examinations showed distal lesions in 11 patients and 2 normal results. All barium enemas were normal.

Endoscopic findings are presented in Table 1. Hemorrhoids, anal fissures and IBD were the most common diagnoses.

Location of lesions in patients with abnormal findings

At least one distal lesion was found in all patients with abnormal findings (370 patients), but a concomitant proximal significant lesion was found in 15 patients (4.1%). The concomitant proximal lesion was in the same diagnostic category (e.g. distal and proximal polyps) in 13 patients; a 53 year-old woman with hemorrhoids was found to have adenocarcinoma in the transverse colon and one adenomatous polyp was found in the transverse colon of a 62 year-old woman with hemorrhoids.

At least one anorectal lesion was found in 359 patients (97.0%). In patients with anorectal source of bleeding, a different distal lesion was found in 31 (8.6%). A statistically significant difference in the frequency of concomitant lesions could not be found between young and older patients (5.8% *vs* 10.2%, $P = 0.14$).

Table 1 Colonoscopic findings in 402 patients with minimal bright red bleeding per rectum at Loghman Hakim hospital by age group[1]

		Total		Age < 40 yr		Age ⩾ 40 yr		*P*
		Number	Percent	Number	Percent	Number	Percent	
Significant lesions	Carcinomas	26	6.5	4	2.3	22	9.8	0.002
	Polyps	30	7.5	8	4.5	22	9.8	0.046
	UC	57	14.2	37	20.9	20	8.9	0.001
	CD	10	2.5	5	2.8	5	2.2	0.700

	Normal	32	8.0	23	13.0	9	4.0	0.001

UC: Ulcerative colitis; CD: Crohn's disease; SRUS: Solitary rectal ulcer syndrome; AD: Angiodysplasia. [1]Some patients with more than one lesion were presented in more than one diagnostic category.

Table 2 Location of significant lesions according to the reach of different diagnostic procedures[1] in patients with minimal bright red bleeding per rectum at Loghman Hakim hospital

Distance from anal verge[2]	Carcinomas	Polyps	UC	CD
Age < 40 yr				
10 cm	3/4	2/8	36/37	3/5
30 cm	4/4	8/8	37/37	5/5
60 cm	4/4	8/8	37/37	5/5
Entire colon	4/4	8/8	37/37	5/5
Age ⩾ 40 yr				
10 cm	12/22	10/22	20/20	0/5
30 cm	17/22	13/22	20/20	4/5
60 cm	21/22	21/22	20/20	5/5
Entire colon	22/22	22/22	20/20	5/5

UC: Ulcerative colitis; CD: Crohn's disease. [1]The length of evaluation was considered 10 cm for anoscopy/rectoscopy, 30 cm for rigid sigmoidoscopy and 60 cm for flexible sigmoidoscopy; [2]In patients with multiple lesions of the same type, the nearest lesion to the anal verge has been considered.

Significant lesions

Significant lesions were found in 54 young patients (30.5%) and 67 patients (29.8%) in the older group ($P > 0.5$). The potential diagnostic yields of different approaches (based on the location of the lesions) for the diagnosis of significant lesions are compared in Table 2.

Findings in young patients who underwent flexible sigmoidoscopy

There were 94 young patients (41 male, 53 female; aged 27.6 ± 5.8 years), who met the eligibility criteria, but did not agree to undergo colonoscopy. Evaluation of these patients revealed hemorrhoids in 46 (48.9%), anal fissures in 20 (21.3%), IBD in 7 (7.4%), solitary rectal ulcer syndrome in 6 (6.4%), and diverticulosis in 1 (1.1%). There were no cases of carcinoma, polyps or angiodysplasia. Normal results were found in 21 patients (22.3%).

DISCUSSION

Our study showed that significant lesions in the proximal colon are infrequent in patients with minimal BRBPR. Colonoscopy is recommended for the evaluation of rectal bleeding in patients who are at increased risk for colorectal neoplasms ('red flags')[3], but there are no specific recommendations for the appropriate evaluation of the majority of patients who lack these risk factors. The decision about the extent of the evaluation of these patients should be based on the prevalence of clinically significant lesions, potential need for a repeat procedure, costs and availability of the facility. Some experts recommend that young patients do not require further evaluation, if the presentation and history do not suggest an increased risk of cancer and a potential source of bleeding (such as hemorrhoids or an anal fissure) is identified in the clinical evaluation[3]. Several studies have concluded that flexible sigmoidoscopy is initially appropriate[5,8-10], while others have recommended colonoscopy in this age group[7]. Contrasting opinions are also expressed in the guidelines prepared by the American Society for Gastrointestinal Endoscopy (ASGE) and the European Panel for Appropriateness of Gastrointestinal Endoscopy (EPAGE): While the former specify that middle-aged or older individuals must always undergo a total colonoscopy, even in the presence of an anal lesion that could justify the hematochezia[11], the latter consider total colonoscopy inappropriate when the source of bleeding has been ascertained by ano- or sigmoidoscopy[12].

IBD was found in 16.4% of our patients. Other studies have reported lower rates of IBD in their patients[5,7,9-10]. Detection of ulcerative colitis is not a problem, because the rectum is almost always involved. Our 10 patients with Crohn's disease also had distal colonic involvement (less than 30 cm from the anal verge). Thus, our results show that IBD can be readily diagnosed in patients with minimal BRBPR with any of the available procedures.

Colorectal cancer has been reported as low as 0%-4% and adenomatous polyps in 9.9%-30% in patients with minimal BRBPR from Western countries[5,7-10]. Some of the differences in these results may be explained by the differences in their study populations. In a recent study from Iran, Sotoudehmanesh *et al*[13] found no cancer and

4 adenomatous polyps (3%) in 134 average-risk patients with minimal bright red bleeding from midline anal fissures. We found colorectal carcinoma in 6.5% of our patients and adenomatous polyps in 7.5%. Our findings may be overestimated, because we excluded 94 patients from analysis who underwent only flexible sigmoidoscopy and there were no neoplastic lesions in this group. Nevertheless, minimal BRBPR should be regarded as an 'alarm symptom' for neoplastic colorectal lesions.

Patients with minimal BRBPR from colorectal cancer are likely to have left-sided lesions[3]. Almost all of neoplastic lesions in our patients were located in the distal colon. There was one patient with hemorrhoids and an adenocarcinoma in the transverse colon, but we believe that the bleeding may have been caused by the hemorrhoids and the tumor was incidentally found during colonoscopy. The distribution of polyps was similar to colorectal cancer in our patients. Thus, we conclude that average risk patients with minimal BRBPR of any age may not be at an increased risk for proximal neoplastic colonic lesions.

The choice of the appropriate diagnostic evaluation depends mainly on the age of the patient. According to our results in Table 2, young patients should at least be evaluated up to the distal 30 cm of the colon. Physical examination (including digital rectal examination), anoscopy and rectoscopy are simple and low cost maneuvers that do not require bowel preparation. In fact, anoscopy has a higher sensitivity for the detection of hemorrhoids than flexible video endoscopy[9]. However, these approaches would fail to diagnose most neoplastic lesions in our young patients, even if a potential anorectal source of bleeding was identified. Rigid sigmoidoscopy is a widely used modality as a preliminary investigation to exclude colorectal pathology and is usually done in outpatient clinics on unprepared bowel[14]. All significant lesions of our young patients were in the reach of rigid sigmoidoscopy; however, flexible sigmoidoscopy has been shown to be superior in terms of diagnostic value and patient discomfort[14]. Thus, we suggest flexible sigmoidoscopy for young patients with minimal BRBPR regardless of identified anorectal pathologies and rigid sigmoidoscopy may be an appropriate alternative in settings, where flexible sigmoidoscopy is not accessible.

Colorectal cancer screening recommendations should be considered, when deciding about the evaluation of middle-aged or older individuals with minimal BRBPR. Both flexible sigmoidoscopy and colonoscopy have been recommended for this purpose and the decision about which option to select should be made between the patient and physician[15]. Although, clinically significant lesions of 97% of our older patients were in the reach of flexible sigmoidoscopy; colonoscopy is also an appropriate option for patients over 50 years willing to undergo screening for colorectal cancer simultaneously. Therefore, patients should be informed that minimal BRBPR does not place them at an increased risk for proximal neoplastic colonic lesions and the costs and availability of the facility should also be considered. Another important factor is the need for a repeat procedure. About 30% of patients who undergo initial flexible sigmoidoscopy will eventually require colonoscopy.

Our findings should be interpreted in the context of the limitations of our study. First, not all patients with minimal BRBPR are referred to gastroenterologists for evaluation, and this is particularly true for younger patients[10]. Second, any recommendation about the appropriate extent of evaluation of patients with minimal BRBPR should be made from randomized clinical trials with follow-up data.

We suggest flexible sigmoidoscopy for the evaluation of average risk patients for colorectal cancer with minimal BRBPR. Rigid sigmoidoscopy may be used as an alternative in patients less than 40 years of age in settings where the former is not available. The choice of colonoscopy over flexible sigmoidoscopy in patients aged over 50 years should be individualized.

The authors gratefully acknowledge the assistance of Professor Sadegh Massarrat and Dr. Rasoul Sotoudehmanesh for their comments on the manuscript.

COMMENTS

Background

Minimal bright red bleeding per rectum (BRBPR) is a clinical problem frequently found in adults of all ages. The etiology of bleeding is highly variable and depends upon the nature of the population studied.

Research frontiers

It is a source of controversy as to whether minimal BRBPR necessitates total colonoscopy as a first-line procedure or a 60 cm flexible sigmoidoscopy. We performed this study to investigate the prevalence of clinically significant lesions in patients with minimal BRBPR.

Innovations and breakthroughs

Hemorrhoids, anal fissures and ulcerative colitis were the most common lesions. Almost all patients with clinically significant lesions had at least one lesion in the distal colon, which can be examined by flexible sigmoidoscopy.

Applications

We suggest flexible sigmoidoscopy for the evaluation of patients with minimal BRBPR who are at average risk for colorectal cancer. Rigid sigmoidoscopy may be used as an alternative in patients less than 40 years of age in settings where the former is not available. The choice of colonoscopy over flexible sigmoidoscopy in patients aged over 50 years should be individualized.

Terminology

Patients less than 40 years of age are referred to as 'young' patients. The part of colon situated between the rectum and the splenic flexure was defined as distal colon. Neoplastic polyps, colorectal carcinoma, and inflammatory bowel disease were defined as "significant lesions".

Peer review

They assess the prevalence of clinically significant lesions in patients with minimal bright red bleeding per rectum. It is a very interested topic for the readers of WJG, it is written in correct English, with valuable results and conclusions.

Abstract

AIM: To examine the associations between objective health indicators and high need for recovery (NFR) after work, one of the subjective presentations of work related-fatigue, among apparently healthy workers in modern workplaces.

METHODS: From October to December, 2007, an annual health examination was performed for the workers from an electronics manufacturing factory in Taiwan. Health records of 1216 workers with a relatively homogeneous socioeconomic status were used for analysis. The health checkups included personal and NFR scale questionnaires, physical examinations, blood tests for biochemistry and hematology. The workers within the top tertile NFR score were defined as high-NFR workers.

RESULTS: After adjusted for potential confounders, the workers with elevated alanine aminotransferase (ALT) and central obesity had a significantly higher NFR after work, with increased risks of 1.4-fold [95% confidence interval (CI) = 1.01-2.0] and 1.8-fold (95% CI = 1.2-2.7), respectively. Shiftworkers had a 2.0-fold (95% CI = 1.5-2.6) increased risk for high-NFR. The associations between high-NFR and lipid profiles, blood sugar, hematology indexes or blood pressure were insignificant after controlling for confounders.

CONCLUSION: For apparently healthy workers, high NFR after work is not simply a subjective experience. Objective health measures, such as elevated ALT and increased waist circumference, should be carefully evaluated for the apparently healthy workers having a higher NFR after work.

Key words: Liver enzyme; Need for recovery after work; Obesity; Work-related fatigue

INTRODUCTION

Work-related fatigue is a common complaint encountered by the occupational physician in the industrialized societies[1-3]. Most past investigations of work-related fatigue focused on age[4], subjective discomforts, social-economical factors[3,5] or on work styles[6]. However, the associations between work-related fatigue and general objective health measures, such as liver function tests, metabolic syndrome components (waist circumference, blood pressure, sugar and lipids profile) or hematology test results are yet to be declared among the modern workplaces in Taiwan. Since most factories in Taiwan provide routine health check-ups for their workers, we had the opportunity to examine the association between work-related fatigue and the objective health measures.

The need for recovery (NFR) scale questionnaire is a validation tool used for the evaluation of work-related fatigue[4,7,8]. In the present study, we surveyed the potential risk factors for work-related fatigue by utilizing NFR scale questionnaire and health examination records. The records were collected from the workers of an electronics manufacturing factory. All the participants had similar salary and educational levels. Our focus was put on the association between the NFR after

work and the objective health measures. Data analyses were controlled for the confounders of gender, age, working years, smoking status, shiftwork, liver function, hematology tests and metabolic syndrome components.

MATERIALS AND METHODS

Participants

Most of the blue collar workers in this electronics manufacturing factory were residents of north Taiwan, aged from 23 to 56 years. These workers took periodic health checkups according to the Labor Health Protection Regulation of the Labor Safety and Health Act. The exclusion criteria of our analysis were workers' records with a past medical history of malignancy, uncompleted questionnaire or any illness on the day of health checkups. This periodic health examination was performed at the healthcare unit in the workplace between October and December, 2007. All the health examinees were suggested to avoid drastic physical exercises, such as long-distance (marathon or endurance) running, heavy weight lifting training, within 3 d before the health checkups. The records of 1216 eligible apparently healthy workers were collected for the final analysis.

Methods

The 11-item NFR scale questionnaire containing yes/no questions representing short-term effects of a day of work[8] was translated into Chinese and then conducted by three trained nurses at the start of health examinations. The NFR scale score was calculated by adding the individual's scores on the 11 recoded items, and transformed into a scale ranging 0-100[9]. A higher scale score indicates a higher degree of NFR after work (high-NFR). For calculating relative risks, the scale scores were divided into tertiles. Workers within the top tertile NFR scale score were defined as high-NFR workers or as suffering from work-related fatigue. A questionnaire about personal history, including current smoking (recent one year and more than one pack consumed a day: Yes *vs* no), shiftwork involving night duty (yes *vs* no) was completed by the examinees.

The physical examination records used for analysis included measurements of waist circumference, weight, height and blood pressure. The definition of central obesity was waist circumference > 90 cm for males and > 80 cm for females, based on the Taiwanese criteria[10]. Elevated blood pressure was defined as systolic blood pressure (SBP) ≥ 130 mmHg or diastolic blood pressure (DBP) ≥ 85 mmHg[11]. The biochemistry blood tests for analysis included: Aspartate aminotransferase (AST), alanine aminotransferase (ALT), fasting plasma glucose, levels of triglyceride, and high-density lipoprotein (HDL) cholesterol. Elevated ALT was defined as > 40 U/mL, according to the standard reference limits used at the Tao-Yuan General Hospital and other studies[12,13]. The definitions of hyperglycemia, hypo-HDL cholesterolemia and hypertriglyceridemia were fasting sugar ≥ 100 mg/dL, HDL < 40 mg/dL for males or HDL < 50 mg/dL for females and triglyceride ≥ 150 mg/dL based on the modified ATPIII criteria[11]. Significant anemia was defined as hemoglobin (Hb) < 11 for females or < 12 for males[14].

Student's *t*-test was used to analyze the continuous variables. Cochran-Armitage trend test was used for analyzing the categorical variables among NFR score tertiles. Multivariate logistic regression was utilized to examine the association between high-NFR and potential risk factors. SAS version 8.0 (SAS Institute, Cary, NC, USA) was used for all statistical analyses.

Table 1 Baseline data and distribution of characteristics

Characteristic/Potential risk factor	Total (n = 1216)
NFR score	27.8 (21.6)
Age (yr)	34.6 (7.1)
Working year (yr)	9.1 (6.5)
Blood tests	
ALT (U/dL)	31.5 (31.8)
AST (U/dL)	23.4 (16.1)
HDL-cholesterol (mg/dL)	56.2 (12.4)
Triglyceride (mg/dL)	122.3 (81.8)
Fasting blood sugar (mg/dL)	91.6 (22.1)
Hemoglobin (mg/dL)	14.7 (1.6)
White blood count (× 10^3/mL)	6.3 (1.7)
Anthropometric measures	
Waist (cm)	81.0 (11.1)
Body mass index (kg/m^2)	24.3 (3.8)
Systolic blood pressure (mmHg)	124.9 (15.8)
Diastolic blood pressure (mmHg)	80.5 (11.5)
Male gender *n* (%)	852 (70)
Shiftwork *n* (%)	400 (33)
Smoking[1] *n* (%)	126 (11)
Blood tests	
Abnormal ALT *n* (%)	249 (21)
Hypo-HDL[2] *n* (%)	134 (11)
Hypertriglyceridemia[2] *n* (%)	309 (25)
Elevated fasting blood sugar[2] *n* (%)	167 (14)
Anemia[3] *n* (%)	29 (2)
Anthropometric measures	
Central obesity[2] *n* (%)	274 (23)
Elevated blood pressure[2] *n* (%)	543 (45)

Abnormal ALT: > 40 mg/dL. [1]Recent one year and more than one pack a day: Yes *vs* no; [2]Taiwanese metabolic syndrome criteria; [3]Significant anemia: Hb < 11 for females or < 12 mg/dL for males.

RESULTS

The records of a total of 1216 workers (852 males, 364 females) were used for the final analysis. Thirty-three percent of participants in this study were shiftworkers. The overall characteristics and abnormal prevalence rates are summarized in Table 1. The mean age, working years and NFR score for this population were 34.6 years, 9.1 years and 27.8, respectively. The prevalence of elevated ALT, hypo-HDL cholesterolemia, elevated triglyceride, elevated fasting sugar, significant anemia, central obesity, elevated blood pressure and current smoking were 21%, 19%, 25%, 14%, 2%, 23%, 45% and 11%, respectively.

The objective health measures were compared according to the NFR scale score tertiles (Table 2). From the bottom to the top tertile NFR scale scores (means, 6.8, 22.4 and 52.6), ALT (29.2, 31.2 and 34.0 U/dL) and HDL cholesterol (57.6, 56.0 and 55.1 mg/dL) were significantly

Table 2 Distribution of potential risk factors according to the NFR after work score

Potential risk factor	NFR Tertiles			P^1
	1st tertile (n = 409)	2nd tertile (n = 379)	3rd tertile (n = 428)	
NFR score	6.8 (3.9)	22.4 (4.5)	52.6 (15.4)	-
AGE (yr)	34.6 (7.2)	34.3 (7.1)	34.8 (6.9)	0.571
Working year (yr)	8.9 (6.9)	8.7 (6.3)	9.5 (6.4)	0.251
Blood tests				
ALT (U/dL)	29.2 (22.4)	31.2 (27.3)	34.0 (41.6)	0.035
AST (U/dL)	22.4 (8.9)	23.3 (14.2)	24.4 (21.9)	0.092
HDL-cholesterol (mg/dL)	57.6 (12.9)	56 (12.4)	55.1 (11.8)	0.004
Triglyceride (mg/dL)	120.6 (76.9)	121.7 (82.7)	124.5 (85.5)	0.489
Fasting blood sugar (mg/dL)	92.3 (28.1)	90.8 (14.1)	91.7 (21.3)	0.725
Hemoglobin (mg/dL)	14.7 (1.6)	14.6 (1.6)	14.7 (1.5)	0.898
White blood count (× 10^3/mL)	6.3 (1.9)	6.4 (1.6)	6.3 (1.6)	0.566
Anthropometric measures				
Waist (cm)	80.7 (10.8)	80.9 (11.2)	81.4 (11.6)	0.394

Systolic blood pressure (mmHg)	124.8 (15.3)	125.6 (16.3)	124.3 (15.9)	0.678
Diastolic blood pressure (mmHg)	80.1 (11.6)	80.9 (11.5)	80.4 (11.4)	0.725
Male gender n (%)	300 (73)	258 (68)	294 (69)	0.072
Shiftwork n (%)	87 (22)	125 (33)	188 (44)	< 0.001
Smoking[2] n (%)	32 (8)	38 (10)	56 (13)	0.007
Blood tests				
Abnormal ALT n (%)	70 (17)	78 (21)	101 (24)	0.010
Hypo-HDL[3] n (%)	44 (11)	39 (10)	51 (12)	0.294
Hypertriglyceridemia[3] n (%)	103 (25)	91 (24)	115 (27)	0.285
Elevated fasting blood sugar[3] n (%)	58 (14)	51 (14)	58 (14)	0.397
Anemia[4] n (%)	11 (3)	10 (3)	8 (2)	0.217
Anthropometric measures				
Central obesity[3] n (%)	84 (21)	76 (20)	114 (27)	0.017
Elevated blood pressure[3] n (%)	169 (41)	186 (49)	188 (44)	0.232

Abnormal ALT: > 40 mg/dL. [1]P of student's t-test between the top- *vs* bottom-NFR tertile for the continuous variables; Cochran-Armitage Trend Test for categorical variables among tertiles; [2]Recent one year and more than one pack a day: Yes *vs* no; [3]Taiwanese metabolic syndrome criteria; [4]Significant anemia: Hb < 11 for females or < 12 mg/dL for males.

unfavorable in the top-tertile, in contrast to the subjects within the bottom-tertile of NFR scale score. The means of triglyceride (120.6, 121.7 and 124.5 mg/dL), AST (22.4, 23.4 and 24.2 U/dL), BMI (24.2, 24.2 and 24.4 kg/m^2) and waist circumference (80.7, 80.9 and 81.4 cm) were unfavorable in the top-tertile, but did not reach a statistical significance. The prevalence rates of elevated ALT (17%, 20% and 27%; P = 0.010), central obesity (21%, 20% and 26%; P = 0.017) and the percentages of shiftwork (22%, 33% and 44%; P < 0.001), smoking (8%, 10% and 13%; P = 0.007) rose along with the increased NFR scale scores. The abnormal rates of significant anemia and the other metabolic syndrome components were insignificantly different among workers stratified by tertiles of the NFR scale score.

As demonstrated in Figure 1, after controlling for confounders, shiftworkers had a 2.0-fold [95% confidence interval (CI) = 1.5-2.6], centrally obese employees had a 1.8-fold (95% CI = 1.2-2.7) and the workers with elevated ALT had a 1.4-fold (95% CI = 1.01-2.0) increased risk of high NFR. Smokers had a 1.4-fold increased risk of high-NFR, though we could not confirm its statistical significance (95% CI = 0.9-2.1). Anemic status and metabolic syndrome components, except for central obesity, could not be demonstrated to have a statistically significant association with high-NFR from the present analysis of our early-middle-aged workers.

DISCUSSION

To our knowledge, this is the first observation from the electronics manufacturing industry to report that the apparently health workers with elevated serum ALT, an objective measure for liver function[13], require a significantly higher NFR after work. Liver function impairment has been suggested to be a developer of oxidative stress[12,15-17], and its levels are raised among patients with chronic fatigue syndrome and associated with clinical symptoms[18-20]. In the general Taiwanese, elevated serum ALT is prevalent and predominantly caused by asymptomatic chronic hepatovirus infection, steatohepatitis[21] or by hepatic toxic chemical exposure in some workplaces[22]. The present findings might motivate further studies on the relationships between each etiological entity of elevated ALT and work-related fatigue. Since liver problems are prevalent in Taiwan and elevated ALT is closely connected to high-NFR in our workers, careful liver function evaluations should be performed for those apparently healthy workers with work-related fatigue in the modern workplaces.

Central obesity was found to be an independent risk factor for a significantly higher NFR in our multivariate risk analysis. A similar phenomenon has been observed in many studies of fatigue and self-reported fatigue is associated with a higher waist circumference among Western adults[23,24]. Physical fatigue of healthy adults is

Risk factor	OR[1]	95% CI	*P*
Shiftwork	2.0	1.5-2.6	< 0.001
Central obesity[2]	1.8	1.2-2.7	0.003
Abnormal ALT[3]	1.4	1.01-2.0	0.044
Smoking[4]	1.4	0.9-2.0	0.103
Hypo-HDL[2]	1.1	0.7-1.6	0.756
Hypertriglyceridemia[2]	1.1	0.8-1.5	0.616
Elevated fasting blood sugar[2]	0.9	0.6-1.3	0.478
Elevated blood pressure[2]	0.9	0.6-1.1	0.269
Anemia[5]	0.4	0.1-1.1	0.076

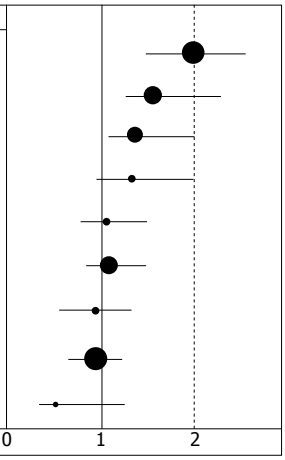

Figure 1 Odds ratio of risk factors for high NFR after work among workers, analyzed using logistic regression. Size of dark circle represents approximate overall prevalence for each risk factor. [1]Odds ratio adjusted for age, gender, working years, metabolic syndrome components, liver function test, anemia and smoking status; [2]Taiwanese metabolic syndrome criteria; [3]Alanine aminotransferase > 40 mg/dL; [4]Recent one year and more than one pack a day: Yes *vs* no; [5]Significant anemia: Hb < 11 for females or < 12 mg/dL for males.

associated with obesity independent of psychological factors[25], and visceral obesity related sleep apnea can result in general fatigue[26]. Whether waist circumference reduction helps our workers to moderate the work-related fatigue is worthy of subsequent exploration.

The high-NFR workers in our analysis had a significant larger percentage of doing shiftwork. As one of the independent risk factors for high-NFR, shiftwork carries the highest odds ratio for high-NFR when compared with the other risk factors. In our analysis, no significant association was observed between shiftwork and obesity or elevated ALT. Since previous studies of work style have highlighted the adverse effects of shiftwork on workers' physical and mental health, shiftworkers must adapt their life pattern to shiftwork styles, which can result in an increased fatigue level, or even illnesses[27-29]. Since shiftwork style is common in the electronics manufacturing industry and it was reported that fatigued workers are at a high risk of being injured in occupational accidents[2], the shiftworkers' health and safety should be emphasized in our modern workplaces. Our analysis did not address the linkage of high-NFR and shiftwork patterns, such as clockwise *vs* anticlockwise patterns, interval of shifts, or working hours in a shift. Further detailed investigations should be necessary.

Smoking, or even exposure to second-hand smoke, has been identified as a risk factor for fatigue in adults[30,31]. The present result also indicates that the percentage of current heavy smoking among the high-NFR workers was significantly greater than that in the low-NFR workers. However, the prevalence rate of smoking was lower in our study than in other studies[32], and the analysis for smoking merely demonstrated an insignificantly increased risk for high-NFR. A partial reason may be that we emphasized more than one pack of cigarettes consumed per day in our self-report questionnaires, so that we might have failed to take account of other smokers consuming less than one pack per day and underrated the risk of work-related fatigue in smokers. Further studies about work-related fatigue associated with smoking might take into consideration all the subjects' exposure to smoke.

One of the limitations of our study is that we did not survey the job types, work titles or leisure-time physical activity included in the study, thus we could not answer the question that workers differ in terms of physical activity that may influence both risks of central obesity and fatigue. The majority of participants in this study were early-middle-aged (mean age, 34.6 years). However, there are many different characteristics between younger and older workers in the NFR after work[4]. The present analysis results for a younger population may underestimate the impact of aging-related risk factors including metabolic syndrome on work-related fatigue[5,33] and our findings from a mostly male worker population may lack power for women, thus, some applications of our conclusion to the general working population should be cautious.

In conclusion, for the apparently healthy workers, high NFR after work is not simply a subjective experience. Objective measures such as elevated ALT and increased waist circumference are significantly associated with high NFR after work for the apparently healthy workers. We suggest that careful evaluations should focus on abnormal liver function and central obesity for those apparently healthy workers with higher NFR after work in the modern workplaces. Further studies should address if the prevalence of risk factors, particularly central obesity and elevated ALT, would reduce the risk of work-related fatigue.

COMMENTS

Background

Work-related fatigue is a common complaint encountered by the occupational physician in industrialized societies. The associations between work-related fatigue and general objective health measures such as liver function tests, metabolic syndrome components (waist circumference, blood pressure, sugar and lipids profile) or hematology test results are yet to be declared among the modern workplaces.

Research frontiers

The need for recovery (NFR) scale questionnaire is a validation tool used for the evaluation of work-related fatigue. In the present study, the authors surveyed the potential risk factors for work-related fatigue by utilizing NFR

scale questionnaire and health examination records. Their focus was put on the association between the NFR after work and the objective health measures.

Innovations and breakthroughs

The workers with elevated alanine aminotransferase (ALT) and central obesity had a significantly higher NFR after work, with increased risks of 1.4-fold [95% confidence interval (CI) = 1.01-2.0] and 1.8-fold (95% CI = 1.2-2.7), respectively.

Applications

The authors suggest that careful evaluations should focus on abnormal liver function and central obesity for those apparently healthy workers with a higher NFR in the modern workplaces. Reducing the prevalence of risk factors, particularly central obesity and elevated ALT, might reduce the risk of work-related fatigue.

Terminology

The 11-item NFR scale questionnaire containing yes/no questions, representing short-term effects of a day of work, is used for the evaluation of work-related fatigue.

Peer review

This article supports previous reports in the literature relating liver function to fatigue in the workplace. The significant results about work-related fatigue of this study for ALT and obesity are after adjusting for potential confounders.

Abstract

AIM: To investigate the prognostic value of the model for end-stage liver disease (MELD) and three new MELD-based models combination with serum sodium in decompensated cirrhosis patients-the MELD with the incorporation of serum sodium (MELD-Na), the integrated MELD (iMELD), and the MELD to sodium (MESO) index.

METHODS: A total of 166 patients with decompensated cirrhosis were enrolled into the study. MELD, MELD-Na, iMELD and MESO scores were calculated for each patient following the original formula on the first day of admission. All patients were followed up at least 1 year. The predictive prognosis related with the four models was determined by the area under the receiver operating characteristic curve (AUC) of the four parameters. Kaplan-Meier survival curves were made using the cut-offs identified by means of receiver operating characteristic (ROC).

RESULTS: Out of 166 patients, 38 patients with significantly higher MELD-Na (28.84 ± 2.43 *vs* 14.72 ± 0.60), iMELD (49.04 ± 1.72 *vs* 35.52 ± 0.67), MESO scores (1.59 ± 0.82 *vs* 0.99 ± 0.42) compared to the survivors died within 3 mo ($P < 0.001$). Of 166 patients, 75 with markedly higher MELD-Na (23.01 ± 1.51 *vs* 13.78 ± 0.69), iMELD (44.06 ± 1.19 *vs* 34.12 ± 0.69), MESO scores (1.37 ± 0.70 *vs* 0.93 ± 0.40) than the survivors died within 1 year ($P < 0.001$). At 3 mo of enrollment, the iMELD had the highest AUC (0.841), and was followed by the MELD-Na (0.766), MESO (0.723), all larger than MELD (0.773); At 1 year, the iMELD still had the highest AUC (0.783), the difference between the iMELD and MELD was statistically significant ($P < 0.05$). Survival curves showed that the three new models were all clearly discriminated the patients who survived or died in short-term as well as intermediate-term ($P < 0.001$).

CONCLUSION: Three new models, changed with serum sodium (MELD-Na, iMELD, MESO) can exactly predict the prognosis of patients with decompensated cirrhosis for short and intermediate period, and may enhance the prognostic accuracy of MELD. The iMELD is better prognostic model for outcome prediction in patients with decompensated cirrhosis.

INTRODUCTION

The model for end-stage liver disease (MELD) was developed as a prognostic model of short-term mortality in patients with cirrhosis treated with transjugular intrahepatic portosystemic shunt (TIPS)[1]. The scoring system has been widely applied in recent years and shown to predict mortality across a broad spectrum of liver diseases in most studies. But, there is not any parameter correlated with complications of cirrhosis in this formula. Its ability of prognosis is decreased. Some studies have indicated that serum sodium is the independent predictor of mortality in patients with cirrhosis[2,3]. And the incorporation of Na into the MELD may enhance its prognostic accuracy[4,5]. Then some scholars had successively introduced three new mathematical equations based on both MELD and Na,

known as the MELD with the incorporation of serum sodium (MELD-Na)[6], the integrated MELD (iMELD) score[7] and the MELD to sodium (MESO) index[8]. In this study, we compared the value of MELD and three new MELD-based models in combination with serum sodium in to evaluate the short-term and intermediate-term prognosis of decompensated cirrhosis patients through retrospective analysis of 166 decompensated cirrhosis cases.

MATERIALS AND METHODS

Patients

From October, 2005 to May, 2007, 166 patients with decompensated cirrhosis who had been in Department of Gastroenterology of Shanghai East Hospital affiliated to Tongji University were evaluated, and their medical profiles were retrospectively analyzed in this study. The clinical diagnosis was all based on the program of 2000 for the prevention and treatment of virus hepatitis established in Xi'an Congresses[9]. We excluded patients with past or current hepatocellular carcinoma, serious diseases in other systems, admission to hospital repeatedly and incomplete case records. This study included 105 (63.7%) males and 61 (36.3%) females, with mean age 62.3 ± 12.9 (range 29-87) years.

Clinical data

Baseline laboratory results of all the patients obtained at admission (i.e. serum bilirubin, serum creatinine, serum sodium, INR) were retrieved from the medical records. All patients were followed up for 1 year. The outcome was assessed as the 3-, 6- and 12-mo mortality.

Calculation of the MELD, MELD-Na, iMELD and MESO index

All prognostic models were calculated based on laboratory results obtained on the first day of admission. The MELD equation was used to calculate the severity score: $9.6 \times \log_e$ [creatinine (mg/dL)] + $3.8 \times \log_e$ [bilirubin (mg/dL)] + $11.2 \times \log_e$ (INR) + 6.43[10]. The MELD-Na equation was based on the MELD and Na: MELD + $1.59 \times (135 - \text{Na})$[6], with maximum and minimum Na values of 135 and 120 mmol/L, respectively. The iMELD equation was based on the MELD score, age (years), and Na (mmol/L): MELD + $(0.3 \times \text{age})$ - (0.7 + Na) + 100[7]. The MESO index was defined as [MELD/Na (mmol/L)] × 10[8].

Statistical analysis

All statistical analyses were conducted with the SPSS for Windows version 13 release. Categorical variables were compared by Pearson Chi-squared test and continuous variables were compared by Student's *t*-test. To assess the ability of the four MELD-based models in predicting the risk of mortality at 3, 6 and 12 mo, our analysis was performed by the measurement of the *c*-statistic equivalent to the area under the receiver operating characteristic curve (AUC). The cumulative transplant-free survival at different cut-offs were performed by Kaplan-Meier analysis and compared by log rank test. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical features between the survival group and the death group

Thirty-eight (22.9%) patients died at 3 mo, and 75 (45.2%) patients died at 1 year. At 3 mo of enrollment, 38 patients with significantly higher MELD-Na (28.84 ± 2.43 *vs* 14.72 ± 0.60), iMELD (49.04 ± 1.72 *vs* 35.52 ± 0.67), MESO scores (1.59 ± 0.82 *vs* 0.99 ± 0.42) compared to the survivors died ($P < 0.001$). At 1 year of enrollment, 75 patients with markedly higher MELD-Na (23.01 ± 1.51 *vs* 13.78 ± 0.69), iMELD (44.06 ± 1.19 *vs* 34.12 ± 0.69), MESO scores (1.37 ± 0.70 *vs* 0.93 ± 0.40) than the survivors died within 1 year ($P < 0.001$). The differences of age and serum sodium, two parameters incorporated into three new models, between the survival group and the death group, were also statistically significant at 3 mo and 1 year, especially serum sodium ($P < 0.001$) (Table 1).

Comparison of the AUC and predictive accuracy between four MELD-based prognostic models

At 3 mo of enrollment, the iMELD had the highest AUC (0.841), followed by the MELD-Na (0.766), MESO (0.723) and MELD (0.712) (Figure 1A). At 6 mo and 1 year, the iMELD still had the highest AUC (0.806 and 0.783, respectively), followed by the MELD-Na (0.738 and 0.714, respectively), MESO (0.715 and 0.694, respectively) and MELD (0.708 and 0.689, respectively) (Figure 1B and C). The iMELD had a significantly higher AUC in comparison with MELD at 3 mo, 6 mo and 1 year ($P < 0.05$).

Kaplan-Meier fractional survival curves of MELD-Na, iMELD and MESO

The most discriminative cut-offs from the ROC with the *c*-statistic and 1 year mortality for MELD-Na, iMELD and MESO were 20, 40 and 1.6, respectively. According to these cut-offs, survival curves are given in Figure 2. The cut-offs of three new models were indicated to discern between the patients who would be survived and dead in 3 mo and 1 year ($P < 0.001$).

DISCUSSION

MELD was initially created to predict survival following elective placement of TIPS[1]. The MELD scoring system has been widely applied in recent years and shown to predict mortality across a broad spectrum of liver diseases in most studies[11-14]. MELD has been demonstrated to have a better ability in short-term or intermediate-term outcome prediction in comparison with the Child-Turcotte-Pugh (CTP) system[15-17]. Nonetheless, MELD still has potential limitations[18-21]. Hepatic encephalopathy, esophageal varices bleeding and spontaneous bacterial peritonitis are common

Table 1 The clinical features of 166 patients with cirrhosis at 3 mo and 1 year follow-up[1]

Clinical features	3-mo follow-up		1-yr follow-up	
	Survival group	Death group	Survival group	Death group
Age (yr)	61.2 ± 12.7	66.1 ± 13.0[a]	60.3 ± 13.0	64.8 ± 12.4[a]
Bilirubin (μmol/L)	44.2 ± 40.1	106.2 ± 117.9[a]	43.1 ± 43.7	77.0 ± 91.0[a]
Creatinine (μmol/L)	85.5 ± 34.0	115.3 ± 67.7[a]	82.8 ± 32.2	103.8 ± 55.8[a]
INR	1.64 ± 0.51	2.21 ± 1.38[a]	1.58 ± 0.49	2.00 ± 1.07[a]
Serum sodium (mmol/L)	137.3 ± 4.9	130.4 ± 6.8[b]	137.7 ± 5.2	133.2 ± 6.3[b]
MELD	13.2 ± 5.6	20.5 ± 10.5[b]	8.63 ± 2.13	10.5 ± 2.52[b]
MELD-Na	14.7 ± 6.8	28.8 ± 15.0[b]	14.2 ± 5.31	20.5 ± 9.42[b]
iMELD	35.5 ± 7.6	49.0 ± 10.6[b]	34.1 ± 7.5	44.1 ± 10.3[b]
MESO	0.99 ± 0.42	1.59 ± 0.82[b]	0.93 ± 0.40	1.37 ± 0.70[b]

complications with cirrhosis, which had been considered one of the allocation policies of liver providing. The patients with these complications all had relatively ideal long-term survival rates. But, there is no parameter correlated with these complications in MELD. Portal hypertension is responsible for above-mentioned complications[22,23]. Hyponatremia is a common event in liver cirrhosis. It develops primarily as a result of free water retention, which is positively correlated with the severity of portal hypertension[24]. Consequently, the serum sodium (SNa) level may inversely reflect the severity of portal hypertension. Those with low MELD scores who have persistent ascites and low SNa are at a disadvantage. This group of patients has a higher mortality than that predicted by the MELD score alone[15]. Many studies have proposed serum sodium can be used to exactly evaluate the prognosis and mortality of patients with cirrhosis, which is objective, quantitative, and reproducible. The incorporation of Na into the MELD may enhance prognostic accuracy[4,5,25].

In 2006, Biggins *et al*[6] first established "MELD-Na". Under the new system, a patient with serum Na of

130 mEq/L and a MELD score of 14 will have a "MELD-Na" score of 22 and will be allocated an organ, whereas another patient with serum Na of 135 mEq/L and a MELD score of 20 ("MELD-Na" score of 20) will be given a lower priority. Obviously, the latter patient with a higher MELD score is being given a higher priority under the new system. Thus, this analysis suggests that a significant number of patients with low serum Na will benefit by receiving a priority score corresponding to their mortality risk. Studies in Korea and Hongkong both confirmed that MELD-Na performed better than MELD in predicting 3-mo and 1-year mortality[26,27]. Later, Huo *et al*[8] developed MESO as MELD to SNa ratio. The AUC was 0.860 for SNa, 0.795 for the MESO index and 0.789 for MELD at 3 mo of enrollment. Among patients with Child-Pugh class A or B, the MESO index had a significantly higher AUC compared with MELD ($P < 0.001$). In survival analysis, MESO index > 1.6 independently predicted a higher mortality rate (relative risk: 3.32; $P < 0001$) using the Cox model. The latest study[7] incorporated both serum sodium and age into the new formula: iMELD. The iMELD was better than original MELD in evaluating the mortality of cirrhosis patients 1 year after TIPS: AUC increased by 13.4% and the likelihood ratio statistic from 23.5 to 48.2; it was demonstrated for patients with cirrhosis on the waiting list for liver transplantation by increasing auROC (+8%) and likelihood ratio statistic (from 41.4 to 82.0).

Our study compared MELD with three new MELD-based models containing Na. It is discovered that the AUCs of MELD-Na, iMELD, MESO were all larger than MELD in evaluating the short-term and intermediate-term prognosis of decompensated cirrhosis patients. Among the four models, iMELD had the biggest AUC at different periods and showed significant differences with MELD. The iMELD was demonstrated to be better prognostic model for outcome prediction in patients with cirrhosis, which is similar to that reported by Huo *et al*[28]. Interestingly, in addition to the MELD and Na, the iMELD also takes into account the factor of age. Age was associated to the risk of mortality as a continuous variable, with older patients having worse survival. The association of aging with mortality in cirrhosis has been shown in the past[29,30]. Most recently, a systematic review of 118 prognostic studies in patients with cirrhosis showed that age is the most important independent prognostic factor of survival[31]. It has been suggested that aging may reflect a longer duration of cirrhosis and a more severe liver disease.

One of the important aspects of the MELD and its derived models is that they are continuous variables and account for the spectrum of disease severity. However, using the most discriminative cut-off from the ROC for different models may provide additional information in certain clinical settings. From the survival curves, it was indicated that the cut-offs of three new models may discern between the patients who would be survived and dead in 3 mo and 1 year. In our study, although the AUCs of MELD-Na and MESO were larger than MELD at 3 mo, 6 mo and 1 year, the comparisons showed no significant differences. The research should be improved more thoroughly and objectively using larger series of patients.

In conclusion, three new models combination with serum sodium (MELD-Na, iMELD, MESO) can all exactly predict the prognosis of patients with decompensated cirrhosis for short and intermediate period, and may enhance the prognostic accuracy of MELD. The iMELD is better prognostic model for outcome prediction in patients with decompensated cirrhosis.

The authors thank all colleagues in the Medical Record Library and the Department of Clinical Laboratory of Shanghai East Hospital Affiliated to Tongji University for their help in the work of data collection.

COMMENTS

Background

The model for end-stage liver disease (MELD) has been widely applied in recent years and shown to predict mortality across a broad spectrum of liver diseases. But MELD still has potential limitations and its ability of prognosis is decreased. In order to further improve the formula, many researches have been performed recent years.

Research frontiers

Some studies have indicated that serum sodium is the independent predictor of mortality in patients with cirrhosis. And the incorporation of Na into the MELD may enhance its prognostic accuracy. Some scholars had successively introduced three new mathematical equations based on both MELD and Na.

Innovations and breakthroughs

Limited data are available for a direct comparison of the performance of the MELD-Na and MELD, and the predictive ability of the other models has not yet been confirmed. In this study, authors compare the short- and intermediate-term prognostic ability of the 4 models-MELD, MELD-Na, iMELD, and MESO index - in a single institute to determine if Na-containing MELD systems have a better predictive accuracy in patients with cirrhosis.

Applications

The result of our study showed the prognostic value of the four models for end-stage liver disease. It will provide us the ideal formula which can exactly evaluate the prognosis of cirrhosis in clinic.

Terminology

The area under a receiver operating characteristic (ROC) curve (AUC) is a commonly used index for summarizing the ability of a continuous diagnostic test to discriminate between healthy and diseased subjects.

Peer review

This is a good paper with some practical value. The authors investigated the prognostic value of MELD and three new MELD-based models combination with serum sodium in decompensated cirrhosis patients.

Abstract

AIM: To investigate the protective effects and mechanisms of Baicalin and Octreotide on hepatic injury in rats with severe acute pancreatitis (SAP).

METHODS: The SAP rat models were prepared and randomly assigned to the model control group, Baicalin treated group, and Octreotide treated group while other healthy rats were assigned to the sham-operated group. Rat mortality, levels of ALT, AST, liver and pancreas pathological changes in all groups were observed at 3, 6 and 12 h after operation. Tissue microarray (TMA) sections of hepatic tissue were prepared to observe expression levels of Bax, Bcl-2 protein and Caspase-3, and changes of apoptotic indexes.

RESULTS: Rat survival at 12 h, expression levels of Bax, Caspase-3 protein and apoptotic indexes of liver were all significantly higher in treated groups than in model control group. While the liver and pancreas pathological scores, contents of ALT, AST, and expression levels of Bcl-2 protein were all lower in treated groups than in the model control group.

CONCLUSION: Both Baicalin and Octreotide can protect rats with SAP by decreasing the contents of ALT, AST and expression levels of Bcl-2 protein, and improving the expression levels of Bax protein, Caspase-3 protein, and inducing apoptosis.

INTRODUCTION

Severe acute pancreatitis (SAP) can cause systemic inflammatory response syndromes (SIRS) such as effusion of blood vessel, shock and multiple organ functional disturbances or even multiple organ dysfunction syndrome (MODS)[1-3]. SAP with extremely hazardous onset process and quite high mortality clinically remains unclear till now[4-7]. The main cause of early death is multiple organ failure, which most frequently affects liver, *etc.* Studies prove the incidence of hepatic injury and its severity degree are positively

correlated with the severity of pancreatitis and hepatic injury prolongs the course of pancreatitis[8,9].

Presently, the main medications for SAP in clinical practices are Somatostatin and its analogue Octreotide. Their mechanism of action is maily to inhibit pancreatin secretion, decreasing the generation of endotoxin, inhibiting the release of inflammatory mediators, and inhibiting platelet aggregation and other steps[10-12]. However, their high price, short half life and inconvenient administration have made it difficult to popularize their clinical application in economically poor and remote areas, resulting in the necessity of finding other cheap and effective alternatives that should be able to protect multiple organs[13-16]. There is a great prospect for developing and utilizing traditional Chinese medicine to treat SAP[17,18]. Its main advantages include cheap price, extensive pharmacological actions and fewer side effects. In this study, Baicalin, the main effective ingredient of baikal skullcap root has been chosen to treat rats with SAP. Antibacterial and anti-inflammatory Baicalin can inhibit platelet aggregation, eliminate oxygen free radicals and reduce the generation of endotoxin. Baicalein, the metabolite of Baicalin in body, is also potent at inhibiting pancreatin. Baicalin can block multiple phases during SAP onset. Baicalin also has many effects similar to those of Somatostatin and its analogues. Therefore, Baicalin can be used more extensively[13-16].

In this experiment, tissue microarray (TMA) was adopted to study the protective effects of Baicalin on the liver of rats with SAP. The therapeutic effects of Baicalin and Octreotide were compared to prove the therapeutic effects of Baicalin on SAP.

MATERIALS AND METHODS

Material

Experimental animals: Clean grade healthy male Sprague-Dawley (SD) rat in 250-300 g of body weight were purchased from the Experimental Animal Center of Medical School, Zhejiang University (China).

Experimental medicine and reagents: Sodium taurocholate and sodium pentobarbital purchased from USA Sigma Company, Octreotide purchased from Swiss pharmaceutical company Novartis, 5% Baicalin injection (China national invention patent number ZL200310122673.6) prepared by the first author with 305 mmol/L osmotic pressure. Bax and Bcl-2 antibody purchased from Santa Cruz Company. The main reagent Takara *in situ* Apoptosis detection Kit purchased from TaKaRa Biotechnology Co., Ltd, PK (protease K) purchased from Sigma Company, DAB (biphenyldiamine) purchased from China Huamei Company. The above determinations were all operated according to the instructions of the kits.

Experimental methods

Preparation methods of animal models: Prepared 135 SAP rat models *via* retrograde injection of 3.5% sodium taurocholate to the pancreatic duct through epidural catheter and duodenal papilla.

Rats grouping: The 135 SAP rat models were randomly assigned to the model control group, Baicalin treated group and Octreotide treated group, 45 rats in each group while other 45 rats were assigned to the sham-operated group. In sham-operated group, only exploratory laparotomy was performed, namely after entering abdominal cavity, checking pancreas and duodenum and then closing abdomen. After that, the above-mentioned groups were randomly divided into 3 h group, 6 h group and 12 h group, 15 rats in each group[13-16].

Dosage and methods

Baicalin treated group: The animal experiments of 5% Baicalin injection have been completed including the acute toxicity test and SAP rat treated by small, middle and large dose. The large dose can achieve the best therapeutic effect (dose is 10 mg/h per 100 g) and the dosage referred to the result of the previous preliminary experiment. Ten min after successful modeling, Baicalin treated group was first injected 5% Baicalin injection 10 mg/100 g *via* external jugular vein passage followed by continuous intravenous administration (10 mg/h per 100 g) by microinfusion pump[13-16].

Octreotide treated group: The octreotide treated group was first injected Octreotide 0.2 μg/100g *via* external jugular vein passage followed by continuous intravenous transfusion by a microinfusion pump at a transfusion speed of 0.2 μg/h per 100 g. All above dosages have been proved as effective dosages in the previous preliminary experiment.

Sham-operated group and model control group: Both groups were injected saline of equivalent volume at the corresponding time points after operation.

Observing indexes and methods

Observations were made at 2, 6 and 12 h after the operation. Mortalities of rats in all groups followed by batch execution of rats with observation of gross liver pathological changes.

Hepatic tissue samples were collected and fixed in accordance with relevant requirements and the pathological score changes of liver and pancreas under HE staining observed.

Changes of ALT (GPT) and AST (GOT) in serum *via* blood sampling from heart were determined.

Bax, Bcl-2 and Caspase-3 protein expression: TMA was applied to prepare the hepatic TMA sections (2 mm in diameter) and the SP method for immunohistochemical staining. After Bax, Bcl-2 and Caspase-3 protein expression of lung tissue was observed under light microscope, the comprehensive judgment was carried out basing on the percentage of positive cells: (-) in case positive cell count < 10%; (+) in case positive cell count 10%-20%; (++) in case positive

cell count 20%-50%; (+++) in case positive cell count > 50%.

TUNEL staining technique was performed to observe the changes of hepatic apoptotic cells and the apoptotic indexes were calculated. Apoptotic index = apoptotic cell count/total cell count × 100%.

Statistical analysis

Values were presented as mean and standard deviation for nomal distribution variables or median and quartile range for highly skewed variables. The significance of differences among the four groups was tested using the Kruskal-Wallis test for highly skewed data and analysis of variance (ANOVA) for normal distribution data. Mutiple comparisons were subjected to Bonfferoni correction test. The Chi-square test was used to evalute equality of frequencies for discrete variables. Correlations were tested using the Spearman rank correlation coefficients. $P < 0.05$ was considered statistical significant and all statistical analyses were conducted using SPSS version 11.5 for windows.

RESULTS

Survival rate

The mortalities of the model control group were respectively 0% (0/15), 13.33% (2/15) and 33.33% (5/15) at 3, 6 and 12 h, all the mortalities of Baicalin treated group and Octreotide treated group were 0% at different time points. The entire sham-operated group survived at the different time points. The survival of model control group was 66.67% (10/15) at 12 h while the survivals of both Baicalin treated group and Octreotide treated group were 100% at 12 h, indicating marked difference ($P < 0.05$)[13-16].

Pathological changes of liver

Model control group: (1) Gross changes. 3 h group: Mild swelling of liver, local grey plaques in liver of individual rat, obscure boundary; at 6 h and 12 h pale and muddy liver color or hemostasis change, part with scattered grey plaques or necrosis manifestation in irregular shapes, especially obvious at edge of liver; (2) Changes under light microscope. 3 h group: Swelling and apomorphosis of liver cells, inflammatory cell infiltration in portal area, dilation and hyperemia of sinus hepaticus, scattered focal or punctate necrosis in hepatic lobules; 6 h group: Obvious swelling of liver cells, collapse of liver cell cord within hepatic lobules caused by integrality damage due to relatively large area of focal necrosis of liver cells, local sinus hepaticus narrowing or vanishing, increased range and area of liver cell necrosis, visible focal or large lamellar necrosis, mainly hemorrhage necrosis and some coagulation necrosis, inflammatory cell infiltration within necrosis focus, obvious congestion in partial sinus hepaticus (Figure 1A); 12 h group: Obviously damaged hepatic lobule structure, further increased range and area of cell necrosis, residual metamorphic liver cells only at periphery of partial hepatic lobules; relatively large area of inflammatory cell infiltration within lobules or portal area, obvious congestion in sinus hepaticus (Figure 1B).

Baicalin and Octreotide treated group: (1) Gross changes. The gross liver pathological changes of the Baicalin and Octreotide treated group were milder than those of the model control group; (2) Changes under light microscope. Baicalin treated group at all time section: mild swelling of liver cells, mild dilation and hyperemia change of sinus hepaticus, scattered inflammatory cell infiltration in portal area; 6 h and 12 h group: Punctate necrosis and/or mild focal necrosis of liver cells, no obvious lamellar necrosis, inflammatory cell infiltration in portal area. The gross pathological changes in all groups were milder than those of the model control group; there was no marked difference between the Baicalin and Octreotide treated group, but Baicalin treated group had milder pathological manifestations (Figure 1C and D).

Sham-operated group: (1) Gross changes. No obvious swelling of liver, normal color; (2) Changes under light microscope. Complete structure of hepatic lobules, occasional inflammatory cell infiltration in portal area. Most liver cells have normal morphous, some local swelling of liver cells, cholestasis and stenosis of sinus hepaticus (Figure 1E).

Comparison of liver pathological scores in all groups: The pathohistological severity score standard made by first author[19]. The scores of the model control group, Baicalin treated group and Octreotide treated group were significantly exceeded the sham-operated group at the different time points ($P < 0.001$). The scores of the Baicalin treated group and Octreotide treated group were significantly lower than that of the model control group at 12 h ($P < 0.05$). There was no marked difference between the Baicalin treated group and Octreotide treated group at the different time points ($P > 0.05$) (Table 1).

Pathological severity score of pancreas: A modified Schmidt's severity score standard of pancreas made by us was referred[19]. The pancreatic severity score in model control group, Baicalin treated group and Octreotide treated group significantly exceeded than that in sham-operated group ($P_{3, 6, 12\,h} < 0.001$). The pancreatic severity score of Baicalin treated group was significantly lower than that in model control group at 12 h ($P_{12\,h} < 0.01$), and Octreotide treated group was significantly lower than those in model control group at 6 h and 12 h ($P_{6, 12\,h} < 0.01$). There was no marked difference in pancreatic severity score between Baicalin treated group and Octreotide treated group at 3, 6 and 12 h ($P_{3, 6, 12\,h} > 0.05$) (Table 1).

Comparison of serum ALT (GPT) contents in all groups: The model control group and treated groups were significantly higher than the sham-operated group

time points ($P < 0.001$), the Octreotide treated group were significantly lower than the model control group ($P < 0.001$). The Baicalin treated group was significantly lower than the Octreotide treated group at 3 h ($P < 0.01$), no marked difference between the Baicalin treated group and Octreotide treated group at 6 h ($P > 0.05$), the Baicalin treated group was significantly lower than the Octreotide treated group at 12 h ($P < 0.05$) (Table 2).

Comparison of serum AST (GOT) contents in all groups: The model control group and treated groups were significantly higher than the sham-operated group at all time points ($P < 0.001$). The Baicalin treated group was significantly lower than the model control group ($P < 0.001$), the Octreotide treated group significantly lower than the model control group ($P < 0.05$), and the Baicalin treated group significantly lower than the Octreotide treated group ($P = 0.001$) at 3 h. The Baicalin treated group was significantly lower than the model control group ($P < 0.001$), the Octreotide treated group significantly lower than the model control group ($P < 0.001$) at 6 h and 12 h. The Baicalin treated group was significantly lower than the Octreotide treated group at 6 h ($P < 0.05$), no marked difference between the Baicalin treated group and Octreotide treated group at 12 h ($P > 0.05$) (Table 2).

Comparison of the expression level of Bax protein in liver: The positive Bax protein staining position was in cytoplasm of liver cell. There was no marked difference in all groups at 3 h ($P > 0.05$). The Octreotide treated group significantly exceeded the sham-operated group at 12 h ($P < 0.01$). Both the Baicalin treated group and Octreotide treated group significantly exceeded the sham-operated group ($P < 0.05$) and the Baicalin treated group significantly exceeded the model control group ($P < 0.05$) at 6 h (Table 1 and Figure 2A).

Comparison of the expression level of Bcl-2 protein in liver: The positive Bcl-2 protein staining position was in cytoplasm of liver cell. There was no marked difference between the Octreotide treated group and sham-operated group, the model control group significantly exceeded the sham-operated group ($P < 0.05$), the Octreotide treated group significantly lower than the model control group ($P < 0.05$) at different time points. The Baicalin treated group significantly exceeded the sham-operated group at 3 h ($P < 0.05$), the Baicalin treated group significantly lower than the model control group at 6 h ($P < 0.05$), the Octreotide treated group significantly lower than the Baicalin treated group at 3 h ($P < 0.05$) (Table 1 and Figure 2B).

Comparison of the expression level of Caspase-3 protein in liver: The positive staining signal of Caspase-3 protein was localized in the cytoplasm of hepatic cells. At all time points after operation, the staining intensity of Caspase-3 protein in liver in the model control group, the Baicalin treated group and

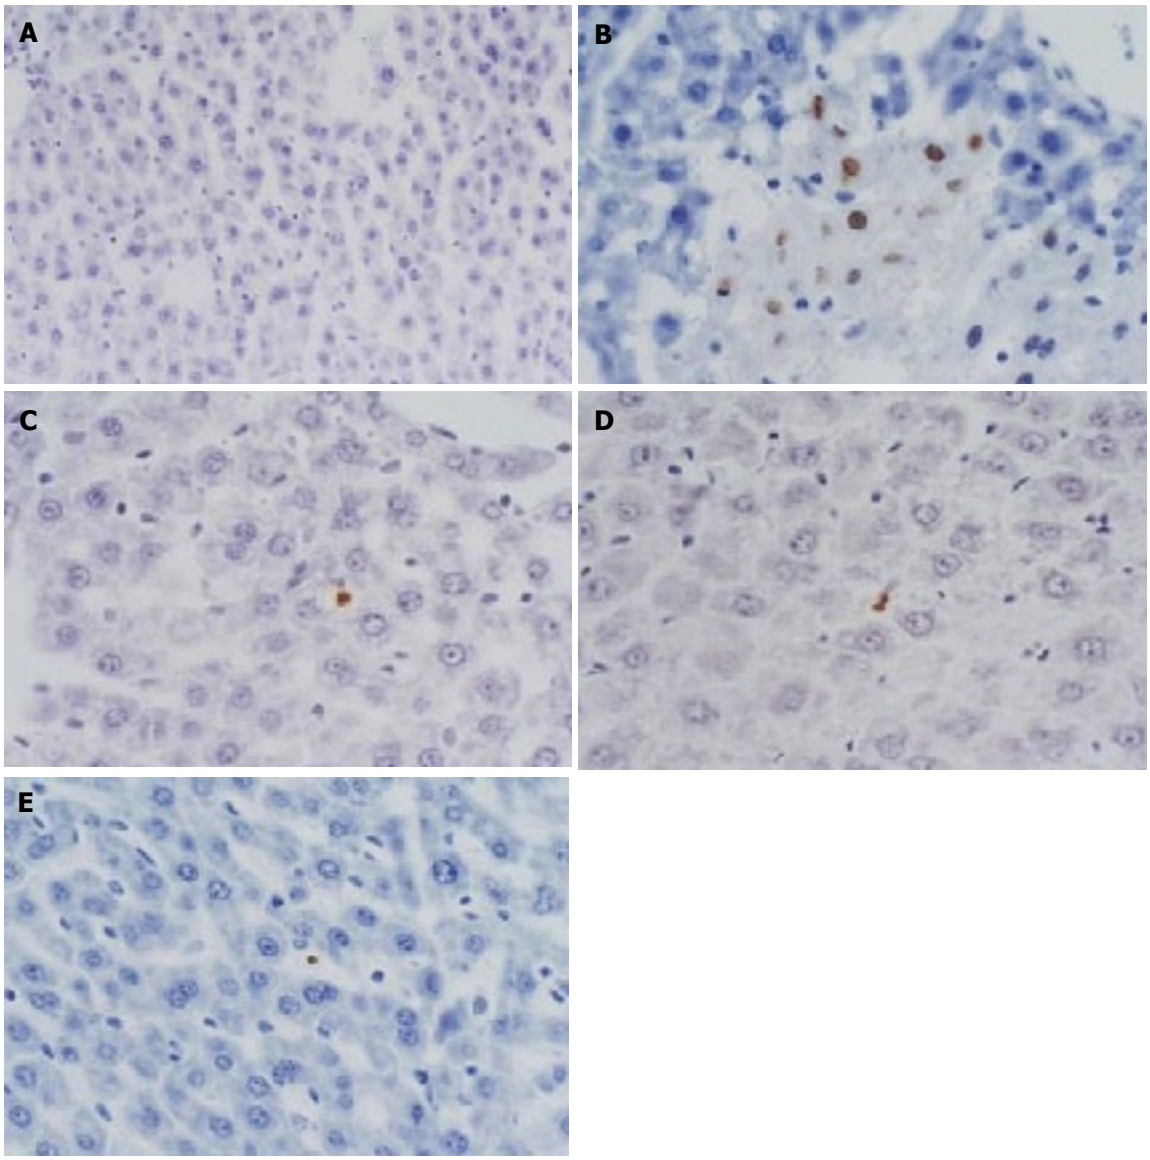

Figure 3 TMA of liver was prepared and conduced TUNEL staining, observing the changes of apoptotic indexes. A: model control group (3 h), there was no apoptotic cell; B: Baicalin treated group (3 h), several hepatic apoptotic cells appeared; C: Baicalin treated group (6 h), several apoptotic hepatic Kupffer cells; D: Baicalin treated group (12 h), several apoptotic hepatic Kupffer's cells; E: Octreotide treated group (3 h), several apoptotic hepatic Kupffer's cells. (TUNEL, × 400).

the Octreotide treated group were significantly higher than that in the sham-operated group ($P < 0.05$, $P < 0.01$ and $P < 0.05$, respectively); at 12 h after operation, the staining intensity in the Baicalin treated group was obviously higher than that in the model control group ($P < 0.05$); at all time points after operation, no marked difference was noted between the Baicalin treated group and the Octreotide treated group ($P > 0.05$) (Table 1 and Figure 2C).

Comparison of apoptosis indexes in liver: Apoptosis occurred to liver Kupffer cells and liver cells. There was no marked difference in all groups at 3 h ($P > 0.05$); the Baicalin treated group significantly exceeded the sham-operated group ($P < 0.05$) and model control group ($P < 0.01$) at 6 h; Octreotide treated group significantly exceeded the sham-operated group and model control group at 6 h and 12 h ($P < 0.05$) (Table 1 and Figure 3).

Comparison of correlations among all indexes

Correlations between hepatic apoptosis indexes and Bax, Bcl-2: The 3 h apoptosis indexes of the Baicalin treated group was positively correlated with Bax ($P < 0.001$); the 12 h apoptosis indexes of the Baicalin treated group was positively correlated with Bax ($P < 0.05$); the 3 h apoptosis indexes of the Octreotide treated group was positively correlated with Bax ($P < 0.01$); There was no correlation between apoptosis indexes in all groups and Bcl-2 ($P > 0.05$).

Correlations between pathological score of hepatic injury and ALT, AST: The 6 h pathological score of the model control group was positively correlated with ALT ($P < 0.01$). The 3 h pathological score of the Baicalin treated group was positively correlated with AST ($P < 0.01$); the 12 h pathological score of the Baicalin treated group was positively correlated

with ALT ($P < 0.05$). The 3 h pathological score of the Octreotide treated group was positively correlated with ALT ($P < 0.05$); the 6 h pathological score of the Octreotide treated group was positively correlated with ALT ($P < 0.001$) and meanwhile AST ($P < 0.05$); the 12 h pathological score of the Octreotide treated group was positively correlated with ALT ($P < 0.01$).

DISCUSSION

As the morbidity and mortality of SAP increases, improving the clinical therapeutic effects on SAP and finding cheap alternates with precise therapeutic effects and fewer side effects have been the hot spots of clinical research[20-23]. Our study results show the main mechanism of MODS onset during AP is the abnormal activation of mononuclear-macrophage system which generates excessive cytokines[24]. Kupffer cells of liver, which is the largest fixed macrophage population in body, account for 80%-90% of the total mononuclear macrophage system. They must affect the progression of SAP state. Therefore, it is necessary to find cheap alternates with precise therapeutic effects and fewer side effects to protect rats with SAP from hepatic injury.

As one of the common clinical SAP medications at present, Octreotide can effectively reducing SAP complications and improve survival[12,25]. However, it is also expensive and inconvenient. It is still not sure whether Octreotide can protect liver, leading to the need of further study. However, Baicalin is cheap and convenient. Baicalin also can protect liver. At present, our hospital is still the only hospital that has submitted a study report on SAP treated by Baicalin injection[13-16]. We have been granted a Chinese invention patent number for our Baicalin injection prescription, which has paved the way for further developing and utilizing the new drug.

This study showed the pancreatic score of Baicalin treated group was significantly lower than that in model control group at 12 h, which mentioned that Baicalin can relieve the severity of pancreas in SAP procedure. The protective effect of Baicalin may be related to inhibit secretion of pancreatin and decrease the contents of endotoxin and TNF-α. From the prospect of hepatic pathological score, spotty necrosis and/or mild focal necrosis, visible inflammatory cell infiltration in portal area and no lamellar necrosis were observed in Baicalin treated group microscopically. The gross pathological changes were milder in Baicalin treated group than in model control group. And there was no difference between Baicalin treated group and Octreotide treated group in gross changes[15].

ALT is the abbreviation for alanine aminotransferase. It is found mainly in liver cells. AST is the abbreviation for aspartate aminotransferase, which is found mainly in cardiac muscle, followed by the liver. Both are non-specific intracellular functional enzymes and are normally found in the serum at very low levels. When hepatic cells are damaged, their membrane permeability increases. As a consequence, cytoplasmic ALT and AST are released into the blood, resulting in an increase in the activities and contents of serum ALT and AST. Therefore, serum ALT and AST levels are sensitive parameters for the evaluation of hepatic cell damage. The correlation analysis has demonstrated a positive correlation between 6 h and 12 h pathological scores and ALT ($P < 0.01$ and $P < 0.05$), and a positive correlation between 3 h score and AST ($P < 0.01$) in Baicalin treated group, which means Baicalin can alleviate the hepatic injury of rats with SAP, and protect rats from SAP hepatic injury. We believe these effects of Baicalin are related to its many capacities. For instance, Baicalin can lower AST and AST content in serum, and down regulate the expression level of hepatic Bcl-2 protein. According to our results from a series of experiments, we believe that the protective effect of Baicalin and Octreotide on the liver may be mediated by reducing the contents of inflammatory mediators such as NO, MDA, TNF-α, IL-6 and PLA_2 *etc*[14-16].

Bax and Bcl-2 are two important components of apoptosis regulating system. When Bax forms dimers, it will induce apoptosis. As Bcl-2 expression increases, the apoptosis promoting effect of Bax dimers are inhibited. In this experiment, it was found that the expression levels of both Bax protein and Bcl-2 protein rose during SAP. It is possible that both apoptosis induction and inhibition have been enhanced so equally that no marked difference occurred between model control group and sham-operated group in apoptotic index. In addition, according to the experimental results, the expression level of Bax protein at 6 h was higher in Baicalin treated group than in model control group ($P < 0.05$). The expression levels of Bcl-2 protein at 6 h and 12 h were lower in Baicalin treated group than in model control group ($P < 0.05$). These findings indicate that Baicalin can induce Bax and inhibit the expression of Bcl-2 protein to let apoptosis inducing factor prevail in treated group. Therefore, Baicalin can protect liver and alleviate pathological changes. The expression levels of Bcl-2 protein were lower in Octreotide treated group than in model control group at different time points. The apoptotic indexes at 6 h and 12 h were higher in Octreotide treated group than in model control group ($P < 0.05$). These findings indicate that Octreotide can induce apoptosis in hepatic cells. From the prospect of correlation analysis, the apoptotic indexes at 3 h and 12 h were positively correlated with Bax, and not correlated with Bcl-2 in treated group, which means that *Bax* gene participates in the regulation of apoptosis of hepatic cell while *Bcl-2* gene may prevent the apoptosis of hepatic cell and promote its hyperplasia during hepatic injury of rats with SAP.

Caspase-3 is an interleukin-converting enzyme that belongs to a member of caspase family (cysteine protease)[26,27]. Some studies have demonstrated that cell apoptosis is negatively correlated with the severity of SAP[28,29]. Activated Caspase-3 is the main executor of cell apoptosis[30,31] and works as the final common signal molecule of various apoptotic mechanisms[32]. During apoptosis signal transduction, caspases function

as downstream signal molecules. The binding of caspases to cytochrome c can induce the activation of Caspase-3 which enables cell apoptosis completed. Some characteristic markers for cell apoptosis, such as chromosome condensation and DNA fragmentation, are directly related to Caspase-3[33,34]. This study showed that, at 12 h after operation, the expression level of Caspase-3 protein in liver in the Baicalin treated group was significantly higher than that in the model control group, suggesting that Baicalin is able to effectively upregulate the expression of Caspase-3 protein and promote apoptosis. Although some studies have indicated that cell apoptosis is positively correlated with hepatic injury[35-37], the results of the present study showed that low proportion of hepatic apoptosis at the early stage was favorable to the body. Considering that apoptotic cells do not release inflammatory mediators and, therefore, reduce their contents and weaken the body's inflammatory reaction[14], we believe that cell apoptosis which occurred at early stage of SAP has some protective effect on the liver.

The TMA we adopted has surpassed the traditional tissue pathological section technique that is inefficient only using a single sample[38]. There is a great potential for TMA in oncopathological research since it can achieve high-throughput, reliable results and so on. This field is also the focus of current study[39-41].

In conclusion, Baicalin and Octreotide can enhance the apoptosis promoting effect of Bax dimmers by lowering the expression level of Bcl-2 protein, leading to the apoptosis of hepatic Kupffer cells and hepatic cells, thus alleviating the pathological changes of liver. Baicalin and Octreotide also can lower the content of ALT, AST in serum to improve the survival of rats with SAP. Baicalin is more advantageous than Octreotide in many aspects. TMA is time and energy saving, highly efficient and representative for the pathological examination of pancreatitis. We believe that as a cheap new drug with precise therapeutic effects and fewer side effects, Baicalin can play certain role in future SAP treatment.

COMMENTS

Background

Severe acute pancreatitis (SAP), which is a systemic disease, seriously life-threatening with acute onset, severe state and multiple complications can cause multiple organ injuries, especially to liver. Octreotide mainly treats SAP by inhibiting trypsin secretion, lowering endotoxin generation, inhibiting the release of inflammatory mediators and platelet aggregation, *etc*. As the main effective ingredient of Scutellaria Baicalensis Georgi, the pharmacologic effects of Baicalin (monomer) can antagonize multiple phases during SAP onset, Baicalin is a possible medication for treating SAP. This article has observed the effects of Baicalin and Octreotide on SAP with hepatic injury at different time points, and compared their therapeutic effects and mechanisms, providing the theoretical basis for application of Baicalin to treat SAP with hepatic injury.

Research frontiers

Tissue microarray (TMA) has become a new member of the chip family recently. This technique has been extensively applied to the technological fields. It surpasses the concept of traditional histopathologic slide which can afford the relevant biological function study at the three levels including gene, genetic transcription and related expression product. Presently, there are some reports on Baicalin treatment of SAP made by the authors. This experiment is one of series studies about Baicalin treatment to SAP. The authors applied TMA technique to prepare the sections of liver samples, and conducted pathological examinations of different indexes.

Innovations and breakthroughs

Firstly, the authors applied TMA technique to study the pathological changes in SAP complicated with hepatic injury; Secondly, they found Baicalin injectin has good effects to treat SAP rats, and has a similar function with Octreotide.

Applications

The application of hepatic TMA in the study of SAP is economical and efficient, and it is worthy to be further popularized. This article will make us realize the value of applying Baicalin in SAP treatment.

Terminology

Caspase-3 is an interleukin-converting enzyme that belongs to a member of caspase family (cysteine protease). Activated Caspase-3 is the main executor of cell apoptosis and works as the final common signal molecule of various apoptotic mechanisms.

Peer review

This article showed that the Baicalin and Octreotide can protect rats with SAP by improving the expression levels of Bax protein, Caspase-3 protein, *etc*. This is a well-written paper.

Abstract

AIM: To study the risk factors for morbidity and mortality following total gastrectomy.

METHODS: We retrospectively reviewed the records of 125 consecutive patients who underwent total gastrectomy for gastric cancer at the Second Affiliated Hospital of Zhejiang University School of Medicine between January 2003 and March 2008.

RESULTS: The overall morbidity rate was 20.8% (27 patients) and the mortality rate was 3.2% (4 patients). Morbidity rates were higher in patients aged over 60 [odds ratio (OR) 4.23 (95% confidence interval (CI) 1.09 to 12.05)], with preoperative comorbidity [with *vs* without, OR 1.25 (95% CI 1.13 to 8.12)], when the combined resection was performed [combined resection *vs* total gastrectomy only, OR 2.67 (95% CI 1.58 to 5.06)].

CONCLUSION: Age, preoperative comorbidity and combined resection were independently associated with the rate of morbidity after total gastrectomy for gastric cancer.

Risk factors for operative morbidity and mortality in gastric cancer patients undergoing total gastrectomy. *World J Gastroenterol* 2008; 14(42): 6560-6563 Available from: URL: http://www.wjgnet.com/1007-9327/14/6560.asp DOI: http://dx.doi.org/10.3748/wjg.14.6560

INTRODUCTION

Gastric cancer is the second leading cause of cancer-related death worldwide[1]. It ranks first among all causes of death from cancer in China, with an annual mortality rate of approximately 25.2 per 100 000 people[2].

Despite the best efforts of clinicians, gastric cancer is usually diagnosed at a fairly advanced stage in most countries[3]. Complete surgical resection is the only potentially curative treatment for gastric cancer[4,5].

In most Western countries, there has been a rapid rise in the incidence of tumors at or close to the gastrooesophageal junction over the past 20 to 30 years[3]. Based on tumor location and growth pattern, a total gastrectomy is the procedure of choice for patients with middle and proximal third gastric cancer[6].

Preoperative preparation, anesthesiology, operative techniques, and postoperative care have improved considerably in recent years. However, total gastrectomy has been reported to have higher morbidity and mortality rates than subtotal gastrectomy[7–9].

The aim of this study is to document the frequency and nature of operative morbidity and mortality after total gastrectomy, and to identify factors that are predictive of complications and death.

MATERIALS AND METHODS

We retrospectively reviewed the records of 125 consecutive patients who underwent total gastrectomy for gastric cancer at the Second Affiliated Hospital of Zhejiang University School of Medicine between January, 2003 and March, 2008. The median age of the patients was 60 (range 29-78). All patients had histologically confirmed gastric cancer, without previous or coexisting cancer. None had received preoperative chemotherapy or radiation therapy. Abdominal terminolateral esophagojejunal anastomosis

was performed with staples in every patient. Criteria for exclusion from this study were surgery for gastric stump carcinoma and other nonresective palliative operations for gastric cancer including bypass procedures. Roux-en-Y oesophagojejunostomy with or without a Paulino pouch was performed in all patients after radical or palliative total gastrectomy. A D2 or D2+ lymph node dissection was performed in patients with radical total gastrectomy. All patients received prophylactic antibiotics starting half an hour before the laparotomy and continuing for over 72 h.

From these data, risk factors were analyzed with postoperative morbidity and mortality. Analyzed risk factors included sex, age, America Society of Anesthesiologists (ASA) grade, tumor site, tumor size, pTNM stage, intraoperative transfusion volume, intraoperative loss of blood, preoperative comorbidity, operative time, combined organ resection, and procedure. Classification of pTNM stage followed the 5th edition of the International Union Against Cancer (UICC) criteria. The operative time was defined as the time between initiation of skin incision and the completion of wound closure. Postoperative hospital stay was defined as the number of days in hospital from operation to discharge. Combined organ resection was referred to as splenectomy, pancreaticosplenectomy, transverse colectomy, cholecystectomy, and hepatic segment resection.

Operative complications analyzed in this study included both immediate postoperative minor complications and major complications that occurred during the same hospitalization. Late complications, such as gallstone formation, anemia, dumping syndrome, and weight loss, were not included in the scope of this study. Bleeding was defined by the need for postoperative transfusion. A fluid collection was defined by the presence of septic fluid in the abdominal cavity causing fever higher than 38℃ and verified by computer tomography (CT) or B-type ultrasound. Wound infection included the presence of septic fluid or pus at the incision leading to delayed suture removal or the need for wound re-suture. Pleural effusion was defined by the presence of fluid in the thoracic cavity requiring drainage. Pulmonary embolus was verified by pulmonary angiography. Pulmonary infection was verified by chest X-ray. The diagnosis of fungus infection and urinary tract infection was determined by sample microbiology culture.

Operative mortality in this study included all hospital deaths within 30 d.

Statistical analysis

The χ^2 test, Fisher's exact test and a binary logistic regression model were used for statistical analysis. $P < 0.05$ (two sided) was regarded as significant. SPSS® version 11.5 (SPSS, Chicago, IL, USA) was used for data analysis.

RESULTS

The postoperative morbidity of the 125 patients studied is listed in Table 1. The overall morbidity rate was 20.8% (27 patients), and the mortality rate was 3.2% (4 patients) and mean postoperative stay was 18.34 d. Univariate analysis showed that age, sex, extension of resection (combined or not), perioperative transfusion, and preoperative comorbidity were all significantly associated with operative morbidity (Table 2). Multiple logistic regression analysis identified older age [odds ratio (OR) 4.23 (95% confidence interval (CI) 1.09 to 12.05)], preoperative comorbidity [with *vs* without, OR 1.25 (95% CI 1.13 to 8.12)] and combined resection [combined resection *vs* total gastrectomy only, [OR 2.67 (95% CI 1.58 to 5.06)] as independent predictors of a higher operative morbidity rate.

Table 1 Postoperative morbidity

Morbidity	No. of patients
Pulmonary infection	7
Wound infection	4
Abdominal abscess	3
Intra-abdominal bleeding	3
Upper digestive tract bleeding	3
Duodenal stump leakage	3
Jejunum stump leakage	1
Chylous leaks	2
Pulmonary embolus	2
Arrhythmia	4
Pleural effusion	4
Ascite	3
Urinary tract infection	2
Fungus infection	3
Total	44

Four patients (3.2%) with preoperative comorbidity died in hospital. All four had undergone palliative or radical total gastrectomy without combined organ resection. The first of these patients died of a pulmonary infection with preoperative chronic bronchitis. The second patient, who died of sudden cardiac arrest, had preoperative coronary heart disease for 5 years. The third patient died of multiple organ dysfunction syndrome (MODS) with preoperative complete right bundle-branch heart block. The fourth patient, who died of heart failure, had preoperative pleural effusion.

DISCUSSION

Gastric cancer is the second leading cause of cancer-related death worldwide[1]. It ranks first among all causes of death from cancer in China, with an annual mortality rate of approximately 25.2 per 100 000[2]. In most Western countries, there has been a rapid rise in the incidence of tumors at or close to the gastrooesophageal junction over the past 20 to 30 years[3]. Based on tumor location and growth pattern, a total gastrectomy is the procedure of choice in patients with middle and proximal third gastric cancer[6].

Although morbidity and mortality rates for gastrectomy for gastric cancer were different in past studies, many recent studies show that they have now decreased significantly to less than 23% and 6%, respectively[8,10-14]. Total gastrectomy has been reported

to have higher morbidity and mortality rates than subtotal gastrectomy[7-9]. In our study, the morbidity and mortality rates for total gastrectomy was 20.8% and 3.2%, respectively. The most common complication was pulmonary infection, in accordance with other reports[9,12].

In keeping with other studies showing that postoperative morbidity and mortality rates are associated with age, sex and combined resection[15], univariate analysis in our study demonstrated that age, sex, and combined resection contributed to postoperative complications. Furthermore, besides combined resection, age was an independent contributor to postoperative complications, because elderly patients may harbor occult heart disease, and have reduced respiratory and liver function reserves.

Opelz *et al*[16] reported that homologous blood transfusion was associated with immunosuppression in renal allograft transplantation. Clinical evidence of a relationship between perioperative transfusion and postoperative septic complications has been reported in some studies of gastric cancer[17-20]. Although the exact mechanism of immunosuppression is still to be elucidated, reduced tumor necrosis factor-α levels, interleukin 10 (IL-10) induction, impairment of natural killer cells, increases in certain other cytokines, complement activation, decreased macrophage function, decreased CD4/CD8 ratio, and decreased IL-2 secretion are all involved[21-23]. Our univariate analysis also showed that perioperative transfusion was associated with postoperative morbidity.

Our study found that preoperative comorbidity was an independent predictor of postoperative morbidity, and that all of the 4 patients who died in hospital were preoperatively suffering from respiratory or cardiac disease. This relationship was also reported in other studies[9,24,25]. Thus, we believe that prior treatment of preoperative comorbid conditions is critical to the postoperative recovery of patients with gastric cancer.

There are some common drawbacks to undertaking any retrospective study, including sample insufficiency and operations performed by different surgeons, which apply to this study. This study also demonstrates that relatively low morbidity and mortality rates for total gastrectomy can be achieved in a large-volume hospital by experienced surgeons with careful perioperative treatment.

COMMENTS

Background

Gastric cancer is the second leading cause of cancer-related death worldwide. In most Western countries, there has been a rapid rise in the incidence of tumors at or close to the gastrooesophageal junction. A total gastrectomy is the procedure of choice for patients with middle and proximal third gastric cancer. However, total gastrectomy has been reported to have higher morbidity and mortality rates than subtotal gastrectomy. It is significant to identify factors that are predictive of complications and death.

Research frontiers

Although morbidity and mortality rates for gastrectomy for gastric cancer were different in past studies, many recent reports show that they have now decreased significantly to less than 23% and 6%, respectively. Furthermore, some reports showed that several risk factors were associated with the complications and death.

Innovations and breakthroughs

Age, preoperative comorbidity and combined resection were independently associated with the rate of morbidity after total gastrectomy for gastric cancer. Perioperative transfusion was also associated with postoperative morbidity.

Applications

This study demonstrates that relatively low morbidity and mortality rates for total gastrectomy can be achieved in a large-volume hospital by experienced surgeons and with careful perioperative treatment.

Terminology

Immunosuppression is defined as deliberate prevention or diminution of the host's immune response. It may be nonspecific as in the administration of immunosuppressive agents (drugs or radiation) or by lymphocyte depletion or may be specific as in desensitization or the simultaneous administration of antigen and immunosuppressive drugs.

Peer review

To document the frequency and nature of operative morbidity and mortality after total gastrectomy, the authors retrospectively reviewed the records of 125

consecutive patients who underwent total gastrectomy for gastric cancer. As a clinical experience, the results may provide some helpful information for the readers.

Abstract

AIM: To investigate the effect of a new infant formula supplemented with a low level (0.24 g/100 mL) of galacto-oligosaccharide (GOS) on intestinal micro-flora (*Bifidobacteria*, *Lactobacilli* and *E. coli*) and fermentation characteristics in term infants, compared with human milk and a standard infant formula without GOS.

METHODS: Term infants (n = 371) were approached in this study in three hospitals of China. All infants started breast-feeding. Those who changed to formula-feeding within 4 wk after birth were randomly assigned to one of the two formula groups. Growth and stool characteristics, and side effects that occurred in recruited infants were recorded in a 3-mo follow-up period. Fecal samples were collected from a subpopulation of recruited infants for analysis of intestinal bacteria (culture technique), acetic acid (gas chromatography) and pH (indicator strip).

RESULTS: After 3 mo, the intestinal *Bifidobacteria*, *Lactobacilli*, acetic acid and stool frequency were significantly increased, and fecal pH was decreased in infants fed with the GOS-formula or human milk, compared with those fed with the formula without GOS. No significant differences were observed between the GOS formula and human milk groups. Supplementation with GOS did not influence the incidence of crying, regurgitation and vomiting.

CONCLUSION: A low level of GOS (0.24 g/100 mL) in infant formula can improve stool frequency, decrease fecal pH, and stimulate intestinal *Bifidobacteria* and *Lactobacilli* as in those fed with human milk.

INTRODUCTION

Breastfeeding is the primary choice for newborns. However, for some reason, many infants are formula fed. Breast milk is superior over artificial formula in many aspects, including its effect on the development of intestinal microflora. Breast-fed infants have a higher level of intestinal *Bifidobacteria* and *Lactobacilli*[1,2], both of which are known to be potentially beneficial to the health of their hosts[3,4]. It is likely that oligosaccharides in human milk are more beneficial to intestinal flora[5-7].

The amount of oligosaccharides in mature human milk is in range of 12-15 g/L. Most of oligosaccharides are fermented in the large intestine[8,9]. Galacto-oligosaccharide (GOS) contained in oligosaccharides, is a short-chain galactose with a terminal glucose molecule[10], which is produced from lactose and commercially available. Studies have shown that GOS can selectively stimulate development of *Bifidobacteria*[11]. However, only a few studies are available on oligosaccharides in infant

formula[12,13], and there is no study using only GOS in infant formula.

Recently, Moro *et al*[13] showed that the number of *Bifidobacteria* and *Lactobacilli* increases significantly compared with a control formula with maltodextrin instead of the oligosaccharides in term infants fed with formula at the dose of 0.4 g and 0.8 g of oligosaccharide per 100 mL (90% GOS and 10% low-molecular weight fructo-oligosaccharides). There was no difference between the two supplemented groups. These values have been adopted by the Scientific Committee on Food (SCF: April, 2003) of the European Commission and probably will be implemented in European regulations. In preterm infants, the same mixture of oligosaccharide (1.0 g/100 mL) could stimulate growth of *Bifidobacteria* and result in stool characteristics as seen in human milk-fed infants[12]. Recently, however, a rat study[14] showed that the intestinal cell wall is irritated and the risk of bacterial translocation increases (following orally *Salmonella enteritidis* infection) when fructooligosaccharides are provided at a high (3% and 6% of dry matter), but not an unrealistic amount (maximum level adopted by the SCF is about 6% of dry matter). Therefore, positive effects of oligosaccharides on intestinal bacteria may not always justify the levels tested.

Our hypothesis is that a prebiotic effect of the human milk-like GOS is already present at a much lower level than that currently adopted by the SCF. This study was to investigate the effect of 0.24 g GOS per 100 mL on intestinal microflora colonization and fermentation in formula-fed term infants compared with breast-fed and control formula-fed counterparts, and to detect the lowest and safe effective level of GOS.

MATERIALS AND METHODS

Subjects

Three hundred and seventy-one healthy term infants, appropriate for gestational age, were approached in the study by Nanjing Children's Hospital of Nanjing Medical University (n = 181), Nanjing Maternal Hospital of Nanjing Medical University (n = 90) and Affiliated Hospital of South East University (n = 100). Finally, 164 infants were recruited for the 3-mo follow-up (Table 1). Those excluded from the study were due to refusal of their parents and failure in taking the fresh fecal samples. The Ethics Committees of the three hospitals approved the study and all the parents gave their informed consent before enrolment in the study.

Diets

When not breast-fed, the infants were randomly assigned to test formula group and control formula group (Table 1). The test formula (Frisolac Advanced, Friesland Nutrition, Netherlands) group was supplemented with GOS (0.24 g/100 mL), while the control formula (Frisolac H, Friesland Nutrition, Netherlands) group was not supplemented with GOS. The other infants were either breastfed or received a combination of breast milk and test formula.

Growth and stool characteristics of, and side effects in the infants were recorded during the 3-mo follow-up. The body weight of all infants was measured using a scale with an accuracy of ± 5 g. The crown-heel length and head circumference were measured using a special board for newborn infants with an accuracy of ± 1 mm. Stool consistency (score 1-4: 1 = watery, 2 = loose/mushy, 3 = soft formed, 4 = hard formed) and frequency were recorded based on an interview with the mother. Crying (score 1-3: 1 = practically not crying, 2 = crying in connection with feeding, 3 = crying independently from the meals), regurgitation (score 1-3: 1 = no regurgitation, 2 = 1-2 regurgitations, 3 = > 2 regurgitations per day), and vomiting (score 1-3: 1 = no vomiting, 2 = 1 episode of vomiting, 3 = > 1 episode of vomiting per day) were also recorded based on an interview with the mother.

Fecal samples were collected from a subpopulation (Tables 2 and 3) for analysis of intestinal bacteria (n = 82), short chain fatty acids (SCFAs) (n = 96) and pH (n = 112). For analysis of *Bifidobacteria* and *Lactobacilli*[1,12,13], one gram of fresh feces was homogenized and diluted in 10 mL of a pre-reduced brain and heart infusion broth in an anaerobic glove box within 1 h of collection. Ten μL of each dilution was spread on the surfaces of Rogosa SL agar (Difco, Detroit, USA) dishes and incubated anaerobically at 37℃. Colony forming units (cfu) of *Lactobacilli* were marked after 2 d, whereas cfu of *Bifidobacteria* were counted after 4 d. For detection of *E. coli*, 1 g of fresh feces was homogenized and diluted in 10 mL of a pre-reduced brain and heart infusion broth in a clean airflow bench. Ten μL of each dilution was spread on the surfaces of MacConkey agar (Difco, Detroit, USA) dishes and incubated aerobically at 37℃ for 1 d. Cfu were expressed as per gram of feces.

Concentration of SCFA acetic acid was determined by gas chromatography as previously described[15]. Briefly, weighed fecal samples were diluted at approximately 1:10 in a 0.1 mol/L sodium phosphate broth (pH 6.5), and suspensions were used to determine the concentration of acetate using a Hewlett-Packard 5890A Series Ⅱ gas chromatograph (Agilent, Wilmington, DE) and a glass column (180 cm × 4 mm i.d.) packed with 10% SP-1200/1% H_3PO_4 on 80/100 mesh Chromosorb WAW (Supelco, Bellefonte, PA). Nitrogen was the carrier gas with a flow rate of 75 mL/min. Temperature of the oven, detector and injector was 125℃, 175℃ and 180℃, respectively. SCFA concentrations in the blank tube were used to correct non-substrate SCFA production. pH of the fresh stool sample was measured with a piece of multicolor indicator paper with an accuracy of 0.2 U (Spezialindicatorpapier Merck Eurolab GmbH, Darmstadt, Germany).

Statistical analysis

All data were given as mean ± SD. An overall group effect on a measured variable was evaluated by ANOVA with F value. When significant, this was followed by t test for single factor group comparisons. $P < 0.05$ was considered statistically significant. SPSS 12 (SPSS Institute Inc., Chicago, USA) was used in analysis of data.

[1]Control formula does not contain added GOS.

RESULTS

At the end of a 3-mo feeding period, the number of intestinal *Bifidobacteria* and *Lactobacilli* was significantly increased both in GOS-supplemented formula-fed infants and in breast-fed infants, compared with those fed with the control formula. No difference was seen between the GOS formula-feeding and breast feeding groups. The number of cfu in *E. coli* did not differ between the 3 groups (Table 2).

Intestinal acetic acid production and stool frequency were significantly increased in infants fed with GOS formula or with breast milk, compared with those fed with standard formula. Fecal pH was significantly higher in those fed with the control formula. No difference in stool frequency, fecal pH and intestinal acetic acid production was found between GOS formula-fed and breast-fed infants, (Tables 3 and 4).

The GOS formula did not influence the incidence of side effects (crying, regurgitation, vomiting) (Table 4). Weight gain and body height increase were similar among the groups (Table 1).

DISCUSSION

This study showed that a 3-mo feeding period of a relatively low amount of GOS (0.24 g/dL) in infant formula stimulated the growth of *Bifidobacteria* and *Lactobacilli* as seen in breast-fed infants but not the growth of potentially harmful *E. coli*. Stool frequency, fecal pH and amount of produced acetic acid were also comparable in the breast-fed infants, indicating hat a low GOS formula has the same prebiotic effect as a high GOS formula, but a minimized risk of intestinal irritation.

Breast-fed infants have an intestinal microflora dominated by *Bifidobacteria* and *Lactobacilli*[1,2] and are

quite different from those fed with a standard infant formula[16]. Both *Bifidobacteria* and *Lactobacilli* are beneficial to infants. As a result, manufacturers of formula try to mimic the gastrointestinal flora in breast-fed infants by adding probiotics and/or prebiotics such as GOS. Although the addition of probiotics is able to manipulate the infants' microflora towards the breast-fed infants' microflora[17,18], this concept may be regarded as unphysiological since breast milk itself does not contain bacteria. Prebiotics are, therefore, the first choice.

Prebiotics serve as food for *Bifidobacteria* and *Lactobacilli* and increase their number by their competitive edge over the pathogenic bacteria. During the fermentation of prebiotics, organic acids (lactic acid and SCFA) are produced that can inhibit the growth (increase colonization resistance) of acid-sensitive pathogens like salmonella[19]. SCFA, also the preferred source of energy for colonic epithelial cells, may stimulate colonocyte proliferation, and are suggested to enhance small intestinal glucose uptake[20]. On the other hand, the same organic acids may induce injury to the intestinal mucosa and impair its barrier function, as indicated by increased cytotoxicity of fecal water and fecal mucin excretion[14]. The fermentation rate might play an important role in this detrimental effect. Since slow fermentation as seen in case of resistant starch does not increase fecal mucin and luminal cytotoxicity, providing a lower amount of fast fermentable prebiotics to the intestine may also prohibit irritation[21].

Ten Bruggencate *et al*[14], in a rat study, showed that 6% of FOS on dry matter increases the number of *Bifidobacteria*, but 3% of FOS significantly (100-fold) increases the number of Enterobacteria, indicating that the selectivity of fibers can be questioned. The increased levels of Enterobacteria in combination with an impaired barrier function may increase the risk of bacterial translocation[14]. Moro *et al*[13] reported that the number of *Bifidobacteria* and *Lactobacilli* increases significantly in full term infants following oligosaccharide supplementation of 0.4 g/dL and 0.8 g/dL (3% and 6% on dry matter respectively). Although the authors reported no significant increase in the number of infants with positive culture of Enterobacteria, this statement does not say anything about the levels of these gram negative bacteria in those with a positive culture. Boehm *et al*[22] showed that 1.0 g of a mixture of GOS and FOS per 100 mL preterm formula has a bifidogenic effect but no significant effect on the number of *Lactobacilli* and Enterobacteria.

In the present study, the effect of only 0.24 g/dL of GOS on intestinal microflora and fermentation was observed in term infants. The results show that even such a low amount of GOS could stimulates the growth of *Bifidobacteria* and *Lactobacilli* as in breast-fed counterparts, decrease fecal pH, and increase the production of intestinal SCFA. The frequency of stools was shorter and the stools became softer, as seen in breast milk-fed infants. These changes in stool characteristics could not be explained by the increased osmolarity (about 1 mOsmol/L) of the formula because of the addition of GOS, and are, therefore, probably related to the changes in bacterial flora and fermentation. Studies in adults showed that a greater amount of dietary oligosaccharides may lead to adverse effects, flatulence in particular[23]. In the present study, no adverse side effects were reported.

This study certainly has its limitations. The number of infants involved in bacterial and SCFA analysis as very small mainly due to the refusal of parents and the failure in taking fresh fecal samples. However, despite such limitations, the difference between GOS-fortified and non-fortified groups was significant. Furthermore, files of infants are not complete because of the poor communication and traffic facility for the follow-up. Therefore, this study was a pilot study with promising results that need to be confirmed in a larger and more appropriate study.

In summary, supplementation of GOS stimulates the growth of *Bifidobacteria* and *Lactobacilli*. Both bacteria are beneficial to infants. However, an increase in Enterobacteria cannot be excluded, although it may be dose-dependent. A small amount of GOS can stimulate the growth of *Bifidobacteria* and *Lactobacilli*, but not the growth of Enterobacteria in breast-fed infants.

COMMENTS

Background

Breast milk is superior over artificial formula in terms of newborn nutrition. Breast-fed infants have a higher level of intestinal *Bifidobacteria* and *Lactobacilli*, both of which are potentially beneficial to the health of their hosts. Oligosaccharides in human milk are more beneficial to intestinal flora. The amount of oligosaccharides in mature human milk ranges 12-15 g/L. Galacto-oligosaccharide (GOS) is a short chain galactose with a terminal glucose molecule. Studies have shown that GOS can selectively stimulate the development of *Bifidobacteria*. However, a large amount GOS (3%-6% of dry matter) supplementation to the artificial formula showed irritation of the intestinal cell wall and increased risk of bacterial translocation. This study investigated the effects of artificial formula supplemented with 0.24 g GOS per 100 mL (1.8% of dry matter) on intestinal microflora colonization and fermentation in infants, and detected the lowest and safe effective level of GOS.

Research frontiers

Moro *et al*[13] showed that in term infants fed with formula at the doses of 0.4 and 0.8 g of oligosaccharides per 100 mL (90% GOS and 10% low-molecular weight fructo-oligosaccharides), the number of *Bifidobacteria* and *Lactobacilli* increased significantly compared with a control formula with maltodextrin instead of oligosaccharides. These values have been adopted by the Scientific Committee on Food of the European Commission and probably will be implemented in European regulations. In preterm infants, the same mixture of oligosaccharides (1.0 g/100 mL) stimulated the growth of *Bifidobacteria* and resulted in stool characteristics as seen in human milk-fed infants. However, a recent rat study showed irritation of the intestinal cell wall and increased risk of bacterial translocation (following orally *Salmonella enteritidis* infection) when a large amount of fructooligosaccharide (3% and 6% of dry matter), but not an unrealistic amount (maximum level adopted by the SCF is about 6% of dry matter) was provided. Therefore, positive effects of oligosaccharides on intestinal bacteria may not always justify the levels tested.

Innovations and breakthroughs

This study showed that a 3 mo feeding period of a relatively small amount of GOS (0.24 g/dL) in infant formula could stimulate the growth of *Bifidobacteria* and *Lactobacilli*, but not the growth of potentially harmful *E. coli* in breast-fed infants. Stool frequency, fecal pH and the amount of produced acetic acid were also comparable, indicating that low GOS formula may have the same prebiotic effect as high GOS formula, but a minimized risk of intestinal irritation.

Applications

The present study was designed to investigate the effect of only 0.24 g/dL

of GOS on intestinal microflora and fermentation in term infants. The data show that even such a small amount of GOS could stimulate the growth of *Bifidobacteria* and *Lactobacilli*, decrease fecal pH, and increase the production of intestinal SCFA. Stools came more frequently and became softer in breast milk-fed infants, indicating that a mall amount of GOS (0.24 g/dL) supplementation can stimulate the growth of *Bifidobacteria* and *Lactobacilli*, but not the growth of *Enterobacteria* in breast-fed infants. It is, therefore, safe and effective when used in artificial infant formula.

Terminology

Prebiotics are "selectively fermented ingredients that allow specific changes both in composition and/or activity of gastrointestinal microflora that confers benefits to host well being and health". Probiotics are defined viable microorganisms, a sufficient amount of which can reach the intestine in an active state and thus exerting positive health effects.Synergistic combinations of pro- and prebiotics are called synbiotics. Today, only bifidogenic, non-digestible oligosaccharides (particularly inulin, its hydrolysis product oligofructose, and galactooligosaccharides), fulfill all the criteria for prebiotic classification.

Peer review

This study determined the effect of a lower-than-normal dose of a prebiotics on the gastrointestinal tract of infants. Its results show that a mall amount of GOS (0.24 g/dL) in artificial formula could stimulate the growth of intestinal *Bifidobacteria* and *Lactobacilli* but not *E. coli* in term infants, indicating that it is safe and effective when used in artificial infant formula.

Abstract

Gastrointestinal tract involvement by neurofibromatous lesions is rare and occurs most frequently as one of the systemic manifestations of generalized neurofibromatosis type 1 (NF1). In this setting, the lesions may manifest as focal scattered neurofibromas or as an extensive diffuse neural hyperplasia designated ganglioneuromatosis. Occasionally, such lesions may be the initial sign of NF1 in patients without any other clinical manifestations of the disease. Rarely, cases of isolated neurofibromatosis of the large bowel with no prior or subsequent evidence of generalized neurofibromatosis have been documented. We present the case of a 52 year-old female with abdominal pain and alternating bowel habits. Colonoscopic evaluation revealed multiple small polyps in the cecum and the presence of nodular mucosa in the colon and rectum. Pathologic evaluation of the biopsies from the cecum, descending colon, sigmoid colon, and rectum revealed tangled fascicles of spindle cells expanding the lamina propia leading to separation of the intestinal crypts. Immunohistochemical stains helped confirm the diagnosis of diffuse intestinal neurofibromatosis. A thorough clinical evaluation failed to reveal any stigmata of generalized neurofibromatosis. This case represents a rare presentation of isolated intestinal neurofibromatosis in a patient without classic systemic manifestations of generalized neurofibromatosis and highlights the need in such cases for close clinical follow-up to exclude neurofibromatosis type Ⅰ or multiple endocrine neoplasia type Ⅱ.

INTRODUCTION

Neurofibromatous lesions of the lower gastrointestinal tract may manifest in multiple forms and have accordingly been given various descriptive designations including intestinal neurofibromatosis, ganglioneuromatosis, diffuse plexiform neurofibromatosis, neuronal intestinal dysplasia, and diffuse colonic ganglioneuromatous polyposis. These lesions may be seen in up to 25% of cases of neurofibromatosis type 1 (NF1) and multiple endocrine neoplasia type 2b (MEN 2b), and their occurrence in the absence of other clinical features of NF1 and MEN 2b is extremely rare[1]. Neurofibromatous lesions of the gastrointestinal tract, unassociated with systemic features of NF1 or MEN 2b, have also been documented in distributions isolated to the esophagus and stomach[2]. No consensus has yet been reached in the medical community as to whether these isolated lesions represent different phenotypic manifestations of the neurocutaneous and multiple endocrine neoplasia syndromes or whether they represent separate and distinct entities.

CASE REPORT

A 51-year-old female presented to our institution with a three-year history of worsening gastroesophageal reflux. She stated that she had progressively developed dysphagia to solid foods and had begun to regurgitate solid food particles, but the episodes of vomiting were unassociated with nausea, epigastric pain, or abdominal pain. The patient denied weight loss and reported no

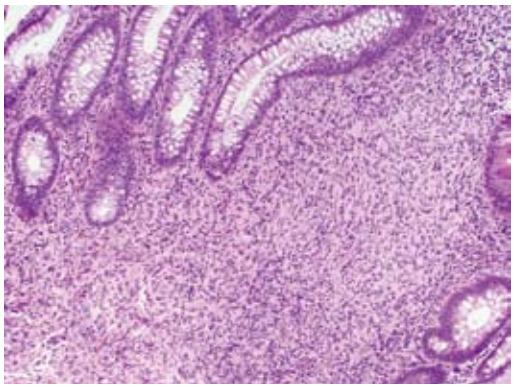

Figure 1 Proliferation of spindle cells admixed with scattered chronic inflammatory cells expanding the lamina propria and leading to separation of the intestinal crypts (HE, x 200).

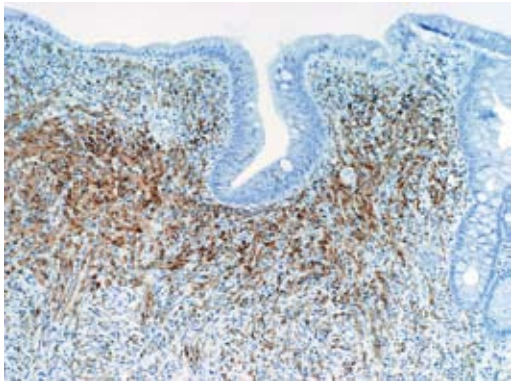

Figure 2 Immunohistochemical stain for S-100 protein (x 200).

improvement of her symptoms with smaller meals. For the last year, the patient also reported the development of frequent non-bloody diarrhea with associated abdominal cramping and bloating. There was no history of coffee-ground emesis, hematemesis, melena, or hematochezia. The patient's additional past medical history included Sjogren's syndrome, fibromyalgia, and cervical radiculitis. The patient had previously undergone colonoscopy with biopsy at a separate institution. At that time, multiple small polyps of the cecum and a 5-8 cm segment of mucosal nodularity of the descending colon were identified. Biopsies of the cecum and colon were diagnosed histologically as hyperplastic changes and as an inflammatory fibroid polyp. At our institution, the patient was placed on a lactose-free diet due to suspected lactose intolerance, but over the course of three months, she experienced an 8 lb. (3.63 kg) weight loss and continuing gastrointestinal distress. A subsequent colonoscopy again showed multiple cecal polyps and nodular large bowel mucosa. Biopsies were obtained from the cecum, descending colon, sigmoid colon, and rectum. Histologic analysis of the biopsies showed a proliferation of tangled fascicles of spindle cells admixed with scattered chronic inflammatory cells expanding the lamina propria and leading to separation of the intestinal crypts (Figure 1). Immunohistochemical stains for S-100 protein supported the diagnosis of neurofibroma for each of the biopsies (Figure 2). The biopsy specimens from the patients' prior colonoscopy were obtained from the outside institution, and immunohistochemical analysis confirmed a retrospective diagnosis of neurofibromas. A thorough physical examination failed to reveal any clinical signs of neurofibromatosis or multiple endocrine neoplasia. Following her diagnosis of isolated intestinal neurofibromatosis, the patient was lost to clinical follow-up in our healthcare system.

DISCUSSION

Isolated intestinal neurofibromatous proliferations (IINP) are benign neural lesions of the lower gastrointestinal tract which may be the initial manifestation of generalized systemic NF1 or MEN 2b. In these settings, IINP may manifest as single or multiple well-defined stromal neoplasms or as a diffuse neuronal hyperplasia, commonly termed ganglioneuromatosis. The clinical, radiographic, and histologic findings of such lesions are not specific to NF1 or MEN 2b, and identical features have been reported in association with juvenile and adenomatous colonic polyposis[3,4] and as an isolated finding in patients with no additional clinical evidence of neurocutaneous, intestinal polyposis, or multiple endocrine neoplasia syndromes[5,6].

The clinical presentation of neurofibromatous lesions of the lower gastrointestinal tract are myriad and are dependent upon the focal or diffuse nature of the lesions, their location, their effect on gastrointestinal motility, and their possible impingement on adjacent structures. Affected patients may present with altered bowel habits including constipation or diarrhea[7,8], abdominal pain[9], intestinal obstruction[10], or with palpable abdominal masses[6]. In the setting of NF1, associated clinical findings including the classic dermal neurofibromas, café-au-lait macules, and Lisch nodules may be seen. In the setting of MEN 2b, the characteristic facies including thickened lips from mucosal neuromas, marfanoid habitus, and even features of medullary carcinoma of the thyroid may be present. In IINP, the intestinal symptoms manifest without demonstrable clinical evidence of associated systemic syndromes.

Radiographically, lower gastrointestinal neurofibromatous lesions may manifest as diffuse, confluent thickening of portions of the intestine or as single or multiple discrete lesions of the intestinal wall or mesentery. The radiographic differential diagnosis of single or multiple nodular neurofibromatous lesions is wide and includes many epithelial and stromal neoplasms as well as nodular lymphomas. The diffuse forms of IINP may mimic the radiographic appearance of Crohn's disease on barium studies and computed tomography scans. In a report by Charagundla *et al*[7], a patient with signs and symptoms of colitis was found to have segmental thickening of an extended portion of the distal ileum radiographically. Clinically, Crohn's disease was suspected, but subsequent small bowel resection showed diffuse IINP. At least two other reports have documented similar findings[11,12].

The endoscopic appearance of IINP depends on

the focal or diffuse nature of the lesions. As the lesions arise deep to the epithelium, they manifest as single or multiple subepithelial masses of variable size and distribution. In some cases, numerous small lesions carpet a portion of the lower gastrointestinal tract, while in others, a larger lesion may predominate and significantly stenose the lumen of the affected area. Endoscopic biopsies are the mainstay of diagnosis, but when used in an attempt to sample deep-seated lesions, the biopsies may yield only unaffected overlying bowel mucosa or minimally diagnostic superficial lesional tissue. Ulceration, due to erosion of the epithelium over the surface of lesions, has been described, particularly in larger solitary lesions, but occasional cases have been described in which ulceration was sufficiently widespread and significant to raise the endoscopic differential diagnosis of idiopathic inflammatory bowel disease. In the current case, the endoscopic appearance was that of multiple small cecal polyps and nodular colonic mucosa, and endoscopic sampling yielded only the most superficial portion of the neurofibromatous proliferation. No associated ulceration was identified.

Grossly, the intestinal neurofibromatous proliferations tend to be firm, solid, and white to tan throughout. Hemorrhage and necrosis are exceptional, but superficial ulceration has been reported in lesions of varying size. The lesions may manifest as confluent neurofibromatous proliferations involving contiguous sections of bowel or as focal polypoid lesions with a sporadic distribution. The varied gross manifestations of IINP generally have a similar histologic appearance, consisting of a proliferation of neural elements including nerve fibers and supporting cells which may be diffusely intermingled or arranged in fascicles of bland spindle-shaped cells. The cells exhibit elongated nuclei with inconspicuous nucleoli and moderate amounts of eosinophilic cytoplasm. Ganglion cells may be present in variable numbers. Despite their sometimes striking cellularity and occasional cellular pleomorphism, mitotic activity in these lesions is minimal. Immunohistochemically, the cells show a variable degree of expression for S100 protein and synaptophysin.

IINP most frequently involve the colon, terminal ileum, and appendix[13], but similar neurofibromatous proliferations isolated to the upper gastrointestinal tract have been described. Siderits *et al*[2] reported a case of sporadic ganglioneuromatosis of the gastroesophageal junction in a patient with gastroesophageal reflux, and solitary neurofibromas of the esophagus have also been documented[14]. These lesions show endoscopic and biopsy features identical to their counterparts in the lower gastrointestinal tract.

The treatment of IINP is primarily surgical and is dependent on the location and size of the lesions. Solitary, well-circumscribed lesions may be only incidental findings at the time of screening endoscopy and require no further therapy, but larger solitary lesions may come to clinical attention due to intestinal obstruction or impingement on adjacent structures and require resection. For lesions that are more diffusely distributed, treatment strategies are dictated by the symptomatology. Intractable abdominal pain, constipation, and diarrhea may require palliative resection of the involved segment of lower gastrointestinal tract. Accurate histopathologic categorization of biopsy and resection specimens is required to guide appropriate surgical therapy.

Abstract

Progressive familial intrahepatic cholestasis type 3 (PFIC3) is a rare cholestatic liver disease. Such liver disease can get worse by female hormone disorder. Albumin dialysis or Molecular Adsorbent Recirculating System (MARS) has been reported to reverse severe cholestasis-linked pruritus. Here, we report the first use of MARS during a spontaneous pregnancy and its successful outcome in a patient with PFIC3 and intractable pruritus. Albumin dialysis could be considered as a pregnancy-saving procedure in pregnant women with severe cholestasis and refractory pruritus.

INTRODUCTION

Progressive familial intrahepatic cholestasis type 3 (PFIC3) is a rare autosomal recessive cholestatic liver disease due to mutations in the adenosine triphosphate-binding-cassette, subfamily B, member 4 gene (*ABCB4*) involved in biliary phospholipid excretion. A few years ago, we reported a case of a young female with PFIC3 revealed by oestro-progestative contraceptive pill-related cholestasis[1]. Here, we report, in the same patient, her first spontaneous pregnancy that resulted in a successful outcome after the use of Molecular Adsorbent Recirculating System (MARS) for intractable pruritus.

CASE REPORT

A 23-year-old woman, gravida 1, was referred to our liver unit for pruritus and recent diagnosis of pregnancy in November, 2005. This woman was diagnosed with PFIC3 five years ago and it was revealed by contraceptive pill consumption[1]. After stopping the contraceptive pill and the starting of a treatment with ursodeoxycholic acid (UDCA, 20 mg/kg per day), the patient remained asymptomatic with a normal physical examination, normal liver tests, no endoscopic signs of portal hypertension and no abdominal ultrasonographic abnormalities.

In November, 2005, the patient was at the 7th week of gestation. Because of potential teratogenic risks, UDCA was stopped until the end of the first trimester. As a consequence, itching recurred and moderate liver tests abnormalities were observed. Despite administration of emollients, hydroxyzine, zolpidem tartrate, cetirizine and cholestyramine, pruritus remained very intense leading to sleep disturbance. At the 11th week of gestation, UDCA (20 mg/kg per day) was started again. Within 15 d, no clinical effectiveness was

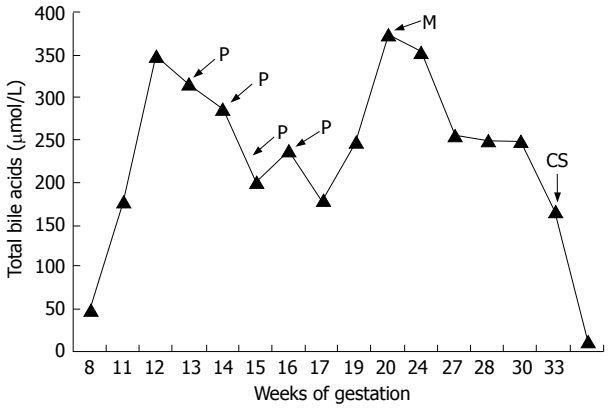

Figure 1 Course of total Bile Acids during the pregnancy. P: Plasmapheresis; M: MARS: Molecular Adsorbent Recirculating System; CS: Caesarean section.

observed: Pruritus became unbearable with insomnia and depressed mood. In addition, total serum bile acids rose to 316 μmol/L. At the 13th week of gestation, a first plasmapheresis was performed, and then continued weekly for 1 mo. The patient reported improvement in pruritus immediately after each procedure and total bile acids slowly decreased, but rose again over 300 μmol/L (Figure 1). Despite the four plasma exchanges (with 2000 mL using 5% albumin as replacement fluid) without any maternal or fetal complications, the pruritus worsened again. Procedure of extracorporeal albumin dialysis using the MARS was decided after giving explanations to the patient regarding the fetal risks. The fetus was careful monitored every week using ultrasonography, Doppler velocimetry and cardiotocography. Two consecutive sessions of MARS were performed at the 20th week of gestation. The procedure was well tolerated without maternal or fetal hemodynamic changes. The pruritus improved without recurrence until the delivery despite high serum total bile acids levels (Figure 1). During pregnancy, several ultrasound scans showed normal fetus growth without morphologic abnormalities and arterial Doppler showed normal uterine arteries and umbilical flow velocity. The patient was hospitalized for preterm labour at 33 wk of gestation and received nifedipine tocolysis, antibiotic prophylaxis and antenatal corticosteroids. Because fetal bowel dilatation observed by ultrasonography and maternal persistent cholestasis with high bile acids, a caesarean section was performed at 34 wk of gestation and the mother gave birth of a healthy, Apgar 10/10 (at 1 and 5 min), boy weighting 1960 g (20th percentile for gestational age), with a height of 42 cm (15th percentile) who was admitted in the neonatology unit. The newborn was discharged on the 15th day, his development was normal and 6 mo later he was still healthy. No intestinal pathology was found and his liver tests were normal. The histopathology analysis of the placenta showed multiple microscopic hypoxic lesions. The postoperative course of the mother was uncomplicated. UDCA was reintroduced just after the delivery and the mother bile acids normalized in few days in postpartum (Figure 1).

DISCUSSION

Regarding the medical literature, the course of pregnancy in PFIC3 has never been reported. In pregnant patients with chronic liver disease, such as primary biliary cirrhosis, primary sclerosing cholangitis or viral hepatitis, the high systemic and hepatic sex-hormones load levels may induce cholestasis and pruritus[2]. Our patient, who was affected by a cholestatic liver disease clearly aggravated by female hormones rapidly complained of intractable pruritus during the first half of pregnancy. Most likely, the withdrawn of UDCA at the 7th week of gestation triggered the onset of cholestasis with pruritus. Although UDCA has been widely and successfully used in the second and third trimesters of pregnancy in women with intrahepatic cholestasis of pregnancy (ICP)[3,4], we stopped its administration early during the first trimester of pregnancy of our patient for the lack of teratogenic effects of the drug is not well established in early pregnancy.

Refractory pruritus is a serious manifestation of cholestasis and its physiopathology remains unknown. Interventions using extra corporeal removal of pruritogens (bile acids, histamine) have been proposed including hemodialysis, charcoal hemoperfusion, or plasmapheresis[5]. Among these methods, only plasmapheresis provided relief, but with transient efficiency[6]. Plasmapheresis, an extracorporeal exchange procedure used to remove large-molecular-weight substances from the plasma, is generally safe although rare complications have been reported (bleeding, infection, coagulation abnormalities and electrolyte disturbances)[7]. Only one case of plasmapheresis has been reported in a woman with ICP-related pruritus[7]. Although four sessions of plasmapheresis were performed in our patient, the pruritus recurred and the serum bile acids levels remained high, largely above 40 μmol/L, a threshold value that has been shown to be associated with an increased risk preterm delivery, fetal distress and fetal loss[8]. Therefore, considering the failure of plasmapheresis to control the dangerous consequences of the cholestasis of our patient during her pregnancy, we decided to use MARS as a pregnancy-saving procedure.

MARS was developed as an extracorporeal hemofiltration system using an albumin-enriched dialysate to remove albumin-bound substances in patients with liver failure. However, MARS was also reported as a valuable and safe procedure for intractable pruritus either after orthotopic liver transplantation or in patients with primary biliary cirrhosis[9-11]. To date, 25 cases of successful use of the MARS in patients with refractory pruritus have been reported[9-13]. The mechanisms by which MARS ameliorates pruritus remain unclear. In patients with symptomatic cholestasis, removal of bile acids from serum should lead to a decline of their concentration in the skin causing amelioration of pruritus. However, several studies did not observe changes of serum bile acids concentration. A further possible explanation for efficacy of MARS

in cholestasis-related pruritus is the clearance of other lipophilic, albumin-bound substances from the patient's plasma that could induce pruritus, either as peripheral pruritogens or by binding to central serotonin or opioid receptors. To our knowledge, the use of MARS as a pregnancy-saving therapy in cholestasis-induced pruritus during pregnancy was not previously reported. In our patient, MARS led to a spectacularly rapid and protracted improvement in pruritus and allowed significant prolongation of pregnancy.

In conclusion, the successful use of MARS in our patient suggests that the procedure could be considered as a pregnancy-saving procedure in pregnant women with severe cholestasis and intractable pruritus.

Abstract

Here we report a new case of clear cell adenocarcinoma (CCA) of the colon in a 54-year-old Caucasian man. Despite of the previous reported cases, the lesion was located in the right colon and was not associated with the conventional adenoma. We performed immunohistochemical and molecular analyses in order to explore whether the CCA had the molecular features generally associated with conventional colorectal carcinoma. The immunohistochemical and molecular analyses showed that the different morphology of CCA does not reflect a distinct biological entity but only an unusual morphological variant of intestinal carcinoma.

INTRODUCTION

Clear cell adenocarcinomas (CCAs) are very rare in the colon[1-3]. They generally affect elderly men, are preferentially located in the left colon and almost all form part of a larger conventional adenoma[4,5].

It is not known whether they are biologically different from morphologically conventional colorectal adenocarcinomas[6-9].

Here, an intriguing variant of CCA, unusual in term of location and morphology is described. Moreover, we have evaluated some pathways reported as deregulated in the conventional colorectal adenocarcinoma[10]. To this, we performed an extensive immunohistochemical analysis and for the first time a molecular analysis, including the genomic sequencing of *KRAS* gene and the main deregulated genes belonging to the Wnt pathway such as APC and β-catenin.

CASE REPORT

In September, 2000, a 54-year-old Caucasian man with a family history of gastrointestinal cancer and a personal 7-year history of multiple colon polyps, came to our Institution for a routine annual control colonoscopy. On this occasion 14 flat lesions with a diameter of 5-15 mm were found extending throughout the large intestine, some of which were endoscopically removed and histologically analysed, including one located in the left colon that was histologically a tubulo-villous adenoma with extensive clear cell aspects. The patient underwent subsequent colonoscopies with polyp resections in 2001, 2002, 2003, 2004 and 2005. All of these lesions were tubular adenomas. At the time of the last control colonoscopy in September 2005, a flat 0.9 cm lesion of the hepatic flexure was endoscopically revealed and biopsied, and was found to be a high-grade dysplastic adenoma with extensive clear cell features. The same

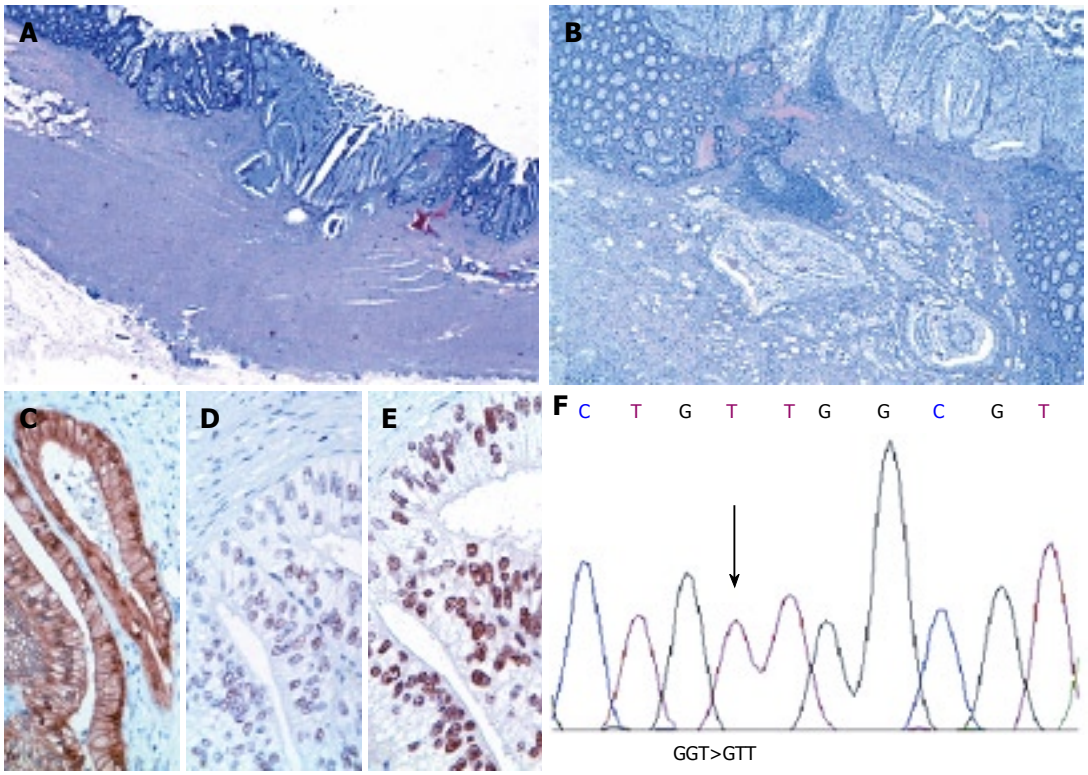

Figure 1 HE and KRAS sequencing. A: The 0.9 cm diameter lesion at the hepatic flexure was a CCA with surface erosion, focal invasion of the muscularis propria, and an abrupt transition from the normal adjacent mucosa (HE, × 4); B: Clear cells with a solid growth on the surface and budding with single-cell growth at the periphery; no conventional adenoma was seen near to the CCA (HE, × 2); C: Strong β-catenin nuclear positivity (× 20); D: Nuclear hMLH1 positivity (× 40); E: Nuclear hMSH2 positivity (× 40); F: *KRAS* sequencing revealed the point mutation GGT>GTT that leads to the activating aminoacid substitution Gly12Val.

lesion was re-biopsied in 2006 and 2007 with the same result. No conventional adenoma was identified. After undergoing total colectomy in June, 2007, the patient now feels well.

The gross specimen was a total colectomy of 115 cm with the flat, previously biopsied 0.9 cm lesion at the hepatic flexure and other pedunculated lesions in the rest of the colon. Microscopic examination showed that the pedunculated lesions were multiple tubular adenomas, and the 0.9 cm lesion of the hepatic flexure was a CCA invading the muscularis propria (Figure 1A). The CCA had a solid growth at the surface and a tendency to grow as single cells at the periphery (cellular budding); there was neither intratumoral inflammatory infiltration nor vascular invasion and no residual classic adenoma at the periphery (Figure 1B). Nodes were negative.

Five-micrometer thick, formalin-fixed (10% buffered formalin), paraffin-embedded tissue sections were immunohistochemically studied for CK20 (mouse KS20.8, BiOptica; 1:100; 6 min 95℃ heated in 0.01 mol/L citrate buffer, pH 6.0), CEA polyclonal antibody (rabbit poly, DAKO; 1:4000; 0.1% trypsin 15 min), CK7 (clone K72.7, NeoMarkers; 1:400; 0.1% trypsin 15 min), alpha-feto protein (rabbit poly, DAKO; 1:2000; 0.1% trypsin 15 min), CD 10 (mouse 56C6, Neo Markers, 1:20, 6 min 95℃ heated in 0.1 mol/L citrate buffer, pH6.0), vimentin (clone V9, DAKO; 1:400; 6 min 95℃ heated in 0.1 mol/L citrate buffer, pH 6.0), β-catenin (clone 14, Transduction; 1:4000; 6 min 95℃ heated in 0.1 mol/L citrate buffer, pH 6.0), hMLH1 (G168-15, Santa Cruz; 1:10; 2 min 120℃ heated in 0.1 mol/L citrate buffer, pH 6.0), hMSH2 (NA27-100 μg, Oncogene; 1:40; 2 min 120℃ heated in 0.1 mol/L citrate buffer pH 6.0) and p53 (clone DO7, Novocastra; 1:400; 6 min 95℃ heated in 0.1 mol/L citrate buffer, pH 6.0). The positive controls were a sporadic aggressive fibromatosis sample with a known mutation in the *CTNNB1* gene[11] for *β-catenin*; two colorectal cancer samples from hereditary non-polyposis colorectal cancer patients carrying *MLH1* or *MSH2* germline mutations for hMLH1 and hMSH2; a serous ovarian carcinoma with a known *TP53* mutation for p53. The samples were strongly positive for CK20 and CEA polyclonal antibody, and negative for CK7, alpha-feto protein, CD10 and vimentin, thus supporting the intestinal origin of the CCA[12]. They also showed p53 focal nuclear positivity, strong β-catenin nuclear positivity in the glands (Figure 1C) and nuclear positivity for hMLH1 and hMSH2 (Figure 1D to E). The proliferation index was high (> 90%).

After genomic DNA extraction (QIAmp DNA mini Kit, Qiagen, Chatsworth, CA, USA), exon 1 of the *KRAS* gene was amplified by means of polymerase chain reaction (PCR) in order to seek potential mutations on the two foremost codons[12-13], which have been reported to be mutated in morphologically conventional colorectal carcinoma. Given the strong β-catenin nuclear positivity revealed by immunohistochemistry, exon 3 of the *β-catenin* gene was sequenced. The PCR amplifications were carried out using a standard

protocol, and previously described primers and conditions[11,13]. In addition, specific primers were designed by means of Primer3 software to amplify codons 1368-1679 located in exon 15 of the *APC* gene and encompassing the mutation cluster region (MCR), where more than 60% of *APC* mutations have been detected in conventional colorectal cancer[14]. All of the PCR products were directly sequenced using an ABI Prism 377 (Applied Biosystems, Foster City, CA, USA) and evaluated by means of Sequence Navigator software (Applied Biosystems, Foster City, CA, USA). *KRAS* sequencing revealed the previously described point mutation GGT>GTT at codon 12, which leads to the activating aminoacid substitution Gly12Val (Figure 1F), whereas no mutations were found in the MCR of the *APC* gene or in the *β-catenin* gene.

DISCUSSION

Colon CCAs are rare, usually affect the left colon of elderly men, and are treated by means of polypectomy (in most cases) or segmental resection. Almost all CCAs form part of a larger conventional adenoma, thus supporting the hypothesis of a linear carcinogenetic sequence from conventional adenoma, to clear cell-type adenomas and CCAs.

However, our patient was a middle-aged man, the lesion was located in the right colon (hepatic flexure) and was not accompanied by a conventional adenoma, although many other tubular adenomas affected the whole colon, and the patient underwent total colectomy. Histologically, the CCA showed superficial solid growth and diffuse cellular budding at the periphery, but no vascular invasion. Immunohistochemistry ruled out other possible origin from extracolonic primary tumors, including renal clear cell carcinoma and carcinoma arising from the mullerian system.

We subsequently undertook immunohistochemical and molecular analyses in order to explore whether the CCA had the molecular features generally associated with conventional colorectal carcinoma. The positive nuclear immunostaining for hMLH1 and hMSH2 was consistent with microsatellite stability; the focal p53 nuclear immunoreactivity strongly suggested the absence of disabled p53 protein; and the β-catenin nuclear immunostaining was in line with activation of the Wnt pathway reported in conventional colorectal carcinoma[15]. However, neither *APC* nor *β-catenin* mutations were found, a result that we are inclined to attribute to the incomplete sequencing of *APC* exon 15 due to the very small amount of tumour tissue available.

However, molecular analysis of the *KRAS* gene by means of genomic DNA automatic sequencing revealed the activating KRAS mutation Gly12Val. This suggests that the analyzed CCA shares the KRAS genotype characterizing most (approximately 40%) conventional colorectal carcinomas.

The different morphology of CCA, therefore, does not seem to reflect a distinct biological entity, but an unusual morphological variant with similar molecular profile of conventional colorectal carcinoma.

Abstract

A 17-year-old gentleman was admitted to our hospital for headache, the differential diagnosis of which included Behçet's syndrome (BS). He developed an acute abdomen and was found to have air under the diaphragm on erect chest X-ray. Subsequent laparotomy revealed multiple perforations throughout the colon. This report describes an unusual complication of Behcets syndrome occurring at the time of presentation and a review of the current literature of reported cases.

INTRODUCTION

Behçet's syndrome (BS) is a multisystemic vasculitic disorder which can affect a number of different systems. It was first described by the Turkish dermatologist, Halushi Behçet in 1937, who described a triad of oral ulceration, genital ulceration and ocular inflammation[1]. BS is now recognized as a chronic, inflammatory, multisystemic disorder, which relapses in nature. It is a vasculitic process which can affect large and small vessels of both the venous and arterial systems[2].

Manifestations of BS are widespread and varied, the most common of which are cutaneous including oral and genital ulceration, erythema nodosum, pyoderma gangrenosum and many more. Up to half of patients will have musculoskeletal complications which include arthralgia and arthritis[3]. The diagnosis of BS is made using major and minor criteria devised by the International Study Group Criteria for Behçets disease in 1990[4]. The disease mainly affects young males and has a higher prevalence along the historic "silk route", i.e. from the eastern rim of Asia to the Eastern Mediterranean[5].

Gastrointestinal symptoms, such as nausea, vomiting and abdominal pain, can sometimes occur, but the presence of intestinal ulceration is rare (< 1%)[6]. Our report describes a case of extensive colonic perforation due to intestinal involvement.

CASE REPORT

A 17-year-old man was admitted to the Accident and Emergency Department due to a six-week history of occipital headache associated with vomiting and poor balance. He also reported decreased appetite and weight loss of approximately 28 lbs over a two-month period. He described transient tender skin nodules, which were present on the anterior tibial area, eight weeks prior to presentation. On direct questioning, he did reveal that he had oral ulceration previously, but this resolved spontaneously. Background medical history was unremarkable, as was his family history.

On examination in the Emergency Department, he appeared unwell. However, all his vital signs were within normal limits. Positive findings on examination included bilateral papilloedema and a seventh lower motor neuron lesion. There was bilateral scarring anteriorly

Figure 1 MRI post contrast with "Empty Delta" sign indicating a cerebral venous thrombosis.

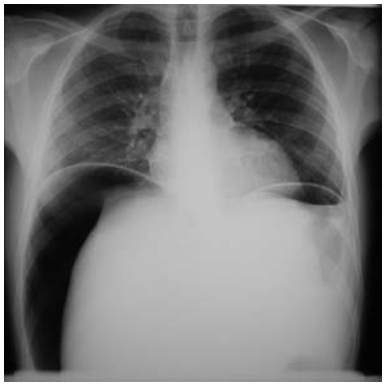

Figure 2 Erect chest X-ray demonstrating free air under the right hemidiaphragm.

on his skins. There was no evidence of oral or genital ulceration and abdominal examination at this time was normal. Hematological investigations were essentially normal except for a raised C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) at 119 mg/L and 84 mm/h, respectively. Further investigations performed included a lumbar puncture, Ziehl-Neelsen stain, autoantibody and infectious mononucleosis screen, all of which were non-contributory. He proceeded to have a CT brain and magnetic resonance studies, which demonstrated evidence of cerebral venous thrombosis. The "Empty Delta" sign on the post contrast MRI image is a characteristic finding in cerebral venous thrombosis (Figure 1).

A working diagnosis of vasculitis was formulated at this stage and the patient was placed on anticoagulation and steroids with proton-pump inhibitor cover. His symptoms gradually improved, but on day eight, he developed acute abdominal pain. On examination, his abdomen was distended, diffusely tender with absent bowel sounds. An erect chest X-ray demonstrated air under the right hemidiaphragm (Figure 2).

Marked fecal peritonitis was observed at laparotomy. There were five separate colonic perforations in the cecum, ascending, transverse and sigmoid colon. Surrounding these perforations were multiple areas of gangrenous colon with punched-out ulcerations extending throughout the colon to the level of the proximal sigmoid colon (Figure 3). A sub-total colectomy and terminal ileum resection with an end ileostomy were performed.

The histology specimen demonstrated a normal terminal ileum, but extensive ulceration in the proximal

Figure 3 Punched-out ulcer at laparotomy.

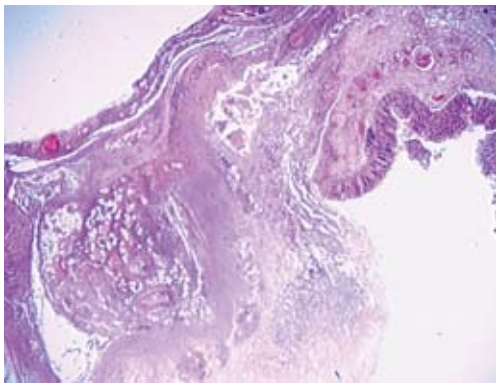

Figure 4 Microscopic specimen demonstrating loss of normal mucosa.

colon. The colon had numerous punched-out areas of ulceration, many of which were deeply penetrating with perforation. The intervening mucosa showed areas of normal mucosa. The distal segment of bowel, descending and sigmoid colon showed less ulceration than the proximal segment. However, there were nine distinct areas of necrosis, the largest of which was 2 cm in diameter. There was active inflammation with vasculitis, consistent with changes described in BS (Figure 4).

The patient made a good post-operative recovery, but developed a pelvic collection four weeks after the procedure. This was treated with a transrectal drain and intravenous antibiotic therapy. The patient was discharged home after a 51-d hospital stay on warfarin, azathioprine and a decreasing dose of corticosteroids. He remained well two months post discharge on immunosuppressant therapy.

DISCUSSION

BS involves the gastrointestinal tract in 10%-50% of patients, manifesting as diarrhoea, nausea, anorexia and abdominal pain. However, ulcerative changes are found in less than 1% of patients with BS[7]. Two types of ulceration can occur: localized and diffuse. Localized lesions tend to occur in the ileocaecal region, and are deep, often penetrating the serosal surface. In contrast, diffuse lesions are seen more commonly in the colon and may occur as multiple discrete, punched-out ulcers.

The main sites of involvement are the terminal ileum and cecum. Sometimes, BS can present with a cecal mass, anemia and weight loss, and thus mimick a cecal carcinoma[8]. In a recent literature review by Turan *et al*[9], the distribution of diffuse ulcers in twenty patients with BS was reviewed. Of these 20 patients, 9 had ulceration involving the entire colon, and only two cases (including their case) involved the sigmoid colon. Kyle *et al*[10] described the other case in 1991. Our case is the third reported case of sigmoid perforation in BS. In both previous cases, the diagnosis of BS was established. However, our case illustrates this rare complication at the time of presentation.

In a review by Kasahara *et al*[6], the most common site of involvement of the small intestine was the terminal ileum. Our case is also unusual in that the terminal ileum was unaffected.

BS often represents a diagnostic challenge, as an incomplete disease can be confused with other conditions which have similar clinical manifestations, for example inflammatory bowel disease (IBD). Not only do they share gastrointestinal manifestations, but the extra-intestinal features of both BS and IBD are very similar. Gastrointestinal disease in BS is associated with an overall poor prognosis, as approx 5%-10% will require surgery[3]. This poses a number of problems for patients with BS. Recurrent ulceration of the stoma is a relatively common complication, as is recurrence of disease adjacent to or at the surgical anastomosis. Most of these recurrent ulcers appear within two years of the resection. There are very few reports on the long term prognosis of intestinal BS. Naganuma *et al*[11] looked at 2-year follow-up in 20 patients with BS in Japan, and found that the postoperative recurrence rate is as high as 87.5%.

The pathergy phenomenon seen in BS, that is a cutaneous hyperreactivity following minor trauma[12], means that patients with BS are prone to problems at the incision site[13]. Fortunately, our patient has not experienced any such complications.

As BS is a relapsing condition, careful follow-up is necessary to detect any late complications or reactivation of disease. This report describes a rare complication of BS at the time of presentation, and highlights the importance of considering BS in the differential diagnosis of a complex patient presenting with such gastrointestinal manifestations.

Abstract

Retrorectal cysts are rare benign lesions in the presacral space which are frequently diagnosed in middle-aged females. We report here our experience with two symptomatic female patients who were diagnosed as having a retrorectal cyst and managed using a laparoscopic approach. The two patients were misdiagnosed as having an ovarian cystic lesion after abdominal ultrasonography. Computer tomography (CT) scan was mandatory to establish the diagnosis. The trocar port site was the same in both patients. An additional left oophorectomy was done for a coexisting ovarian cystic lesion in one patient in the same setting. There was no postoperative morbidity or mortality and the two patients were discharged on the 5th and 6th post operative days, respectively. Our cases show that laparoscopic management of retrorectal cysts is a safe approach. It reduces surgical trauma and offers an excellent tool for perfect visualization of the deep structures in the presacral space.

INTRODUCTION

The retrorectal space (Figure 1) is defined as the space bounded by the sacrum posteriorly, the rectum anteriorly, the peritoneal reflection superiorly, the levator ani and coccygeus muscles inferiorly. Its lateral margins are formed by the ureters and iliac vessels.

Cystic lesions arising in this space are known as retrorectal or presacral cysts and their incidence rate is one in approximately 40 000 patients[1]. Although they can be found in all age groups including infants, they are frequently diagnosed in women (81%), in their middle-age[2]. They are benign in most of the cases, but malignant degeneration is rare. If they turn malignant, they are commonly diagnosed histopathologically as adenocarcinoma or carcinoid[3]. In cases of malignancy, prognosis depends upon acheiving total surgical excision with clear margins as well as their histopathological criteria. The prognosis of adenocarcinoma is unfavourable.

Retrorectal cysts can be uni or multilocular. The content in retrorectal cysts varies from clear fluid to dense mucus. Calcifications can occur in the wall of the cyst and septa can be found inside. The lining consists of more than one type of epithelium. It is often surrounded by scattered bundles of smooth muscle but has no myenteric plexus or serosa.

CASE REPORT

Case 1

The first case was a 43-year-old woman. She underwent a diagnostic laparoscopy procedure after a suspecious cyst was found in the left ovary at sonography. The laparoscopic diagnosis was negative. The patient suffered from permanent abdominal pain and was further investigated using a computer tomography (CT) scan which showed a 9.5 cm × 4 cm × 6 cm well circumscribed cystic lesion in the presacral space, to the left of the rectum. Rectoscopy did not demonstrate any extraluminal pressure and coloscopy was also negative. The patient submitted to a laparoscopic operation for cyst excision. A 10 cm × 8 cm × 6 cm cyst with white mucous content was extracted laparoscopically (Figure 2).

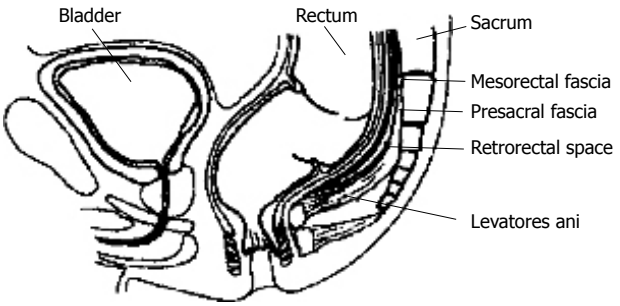

Figure 1 Retrorectal space.

Figure 2 Specimen of retrorectal cyst.

Histopathological examination of the cyst showed dysontogenetic origin with tuboendometrial metaplasia. Postoperative recovery of the patient was smooth with no complications. She was discharged on the 6th postoperative day.

The second case was a 28-year-old woman complaining of anal pain. She underwent repeated gynecological laparoscopic operations for cysts in both ovaries. A CT scan showed cystic lesions in the left ovary and another 9.3 cm × 5.8 cm × 6.4 cm cystic mass in the presacral space (Figure 3). A 10 cm × 5.5 cm × 5 cm cyst was extracted laparoscopically. Left oophorectomy was performed in the same setting. Histopathological examination of the cyst confirmed its benign origin which is lined by simple columnar ciliated epithelium. The postoperative recovery was smooth and the patient was discharged on the 5th postoperative day.

The same laparoscopic approach was used in both cases. After peritoneal insufflation, the pressure was maintained at 11 mmHg. A 10 mm umbilical trocar, a 12 mm trocar in the right hypogastrium and a 5 mm trocar in the right mesogastrium were used for camera and the surgeon working hands, respectively. A 10 mm trocar in the left hypogastrium and a 5 mm trocar in the left mesogastrium were used for the assistance. The retrorectal space was opened using a harmonic scalpel at the sacral promontory level, the mesorectum was dissected free and the cystic lesion was identified. The cyst was resected using a harmonic scalpel after its complete dissection and separation from the surrounding structures. The pelvic floor was reconstructed with suture and a drain was placed in the Douglas pouch. The total operation time was 75 min for the first case and 90 min for the second case.

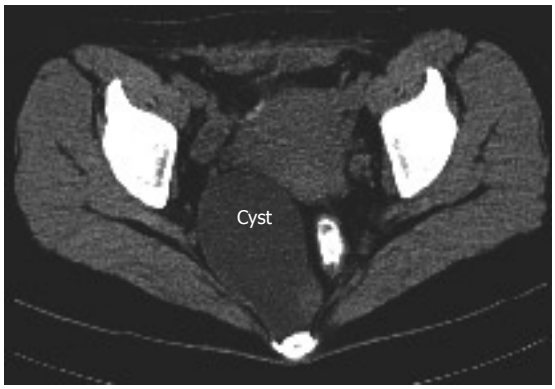

Figure 3 CT scan of cystic mass in the presacral space.

DISCUSSION

Retrorectal cystic hamartoma (hindgut cyst) is a rare developmental lesion arising from the vestiges of the embryonic hind gut[4]. Other developmental cysts (epidermoid, dermoid with skin appendages and rectal cystic duplication with well-defined muscle layers, myenteric plexus and serosa) can occur in retrorectal space[5]. Anal gland cysts can develop near the anal sphincter. All these cysts are similar to retrorectal cystic hamartoma and their exact diagnosis depends on the histopathological examination including immunohistochemical profile.

Retrorectal cysts are asymptomatic in 50% of the cases and the lesion is an incidental finding. A cyst becomes symptomatic due to its mass effects on surrounding organs (rectal fullness, painful defecation, dysuria). Cysts with secondary infection have typical symptoms of abscess and fistula. Perianal changes and a draining sinus in the sacrococcygeal area can be found. The presence of retrorectal cyst can bring about the risk of complicated labor.

Diagnosis of cysts by ultrasound is difficult, and cysts can be easily misdiagnosed as an ovarian lesion, especially if the ovaries are not visualized precisely. Since diagnostic laparoscopy can be false-negative because of retroperitoneal localization of the cyst, it is necessary to think of a retrorectal cyst when ultrasound shows a cyst and laparoscopic findings are negative.

Computed tomography (CT) and MR imaging are necessary to confirm the diagnosis of cysts[6]. CT scans usually show the cyst as a well-circumscribed hypodense retrorectal lesion without invasion of its adjacent structures. Infection of a cyst may cause wall thickening. Parietal calcifications can be found, but they are more typical in dermoid cysts, teratoma, neuroblastoma, chordoma and mucinous adenocarcinoma. The cyst signal on MR imaging depends on its content. Malignant changes are suspected in a case of focal parietal thickening or with invasion of the adjacent organs[7].

Endorectal ultrasound can also be useful[8]. Rectoscopy or sigmoidoscopy can verify external

compression on the rectum. Digital rectal examination is simple, but essential for cyst diagnosis because 75% of retrorectal masses are palpable.

Routine preoperative biopsy (transrectal or transcutaneous) is not recommended because it carries a significant hazard of spillage of possible malignant cells into the peritoneal cavity and can lead to infection of cyst[2,8]. CT-guided extrarectal or presacral approach is indicated in case of inoperable or locally advanced lesion or in patients at a high surgical risk[2,8]. Histopathological examination is necessary to determine adjuvant therapy.

The differential diagnosis of a retrorectal cyst includes malignant and inflammatory lesions which can occur in presacral space. Chordoma is the most common primary tumor, followed by leiomyosarcoma, neuroblastoma, ganglioneuroblastoma, chondrosarcomas, hemangiopericytoma, teratocarcinoma, squamous-cell carcinoma, neuroendocrine carcinoma[9], carcinoid[10] and adenocarcinoma. Adnexal tumor or endometriosis is difficult to diagnose[11]. Malignant lesions are solid with signs of local invasion and bone destruction. Sacrococcygeal teratoma with cystic and solid components and calcification is usually discovered in neonates. Anterior sacral meningocele is associated with sacral defect. Primary retrorectal adenocarcinoma arising from cystic lesions (hind gut cysts) is rare[12]. Lipoma, myelolipoma and hemangioma are rare in presacral space too. For completeness, it is necessary to mention bone tumors including osteosarcoma, chondrosarcoma, giant cell tumor, bone cysts and bone metastases. Infected hindgut cyst may be misdiagnosed as a pilonidal cyst, an anorectal fistula or a recurrent rectal abscess.

Surgery is the first line in management. Simple cyst marsupialisation with drainage is insufficient and leads to recurrence and possible infection. Surgical approaches used for excision are as follows: anterior (abdominal), posterior (intersphincteric, parasacrococcygeal, transsphincteric, transsacral, transsacrococcygeal[13], transanorectal, transvaginal) or combinated. The approach depends on location, size of the lesion and its relationship with adjacent structures[14]. Digital rectal examination is helpful for the choice of approach. If the superior border of tumor can be palpated, the posterior approach can be performed successfully. The posterior (most often transsacral or parasacral) approach is indicated for low-lying tumors (below the sacral promontory) and the abdominal approach is recommended for lesions above the sacral promontory. Laparoscopic transabdominal approach presents a minimally invasive approach with reduced surgical trauma and an excellent means for visualization of the presacral space and its contents[15,16].

In conclusion, laparoscopic excision of retrorectal systs is a safe and efficient option. Laparoscopic approach minimizes the surgical trauma and offers perfect visualization of the deep structures in the presacral space.

Abstract

Multiple lymphomatous polyposis (MLP) is an unusual form of non-Hodgkin's lymphoma characterized by polyps throughout the gastrointestinal tract. It has been reported that most MLP are observed in cases with mantle cell lymphoma of B-cell type. We herein present a case of a 66-year-old man with adult T-cell leukemia/lymphoma (ATLL). Colonoscopy revealed MLP throughout the colon and histopathological findings of ATLL cell infiltration. The patient died despite combination of chemotherapy. The literature of manifestations of colonic involvement of ATLL is reviewed and the importance of endoscopic evaluation to differentiate ATLL intestinal lesions from opportunistic infectious enterocolitis is discussed.

INTRODUCTION

Adult T-cell leukemia/lymphoma (ATLL) is a malignancy associated with retrovirus, human T-cell lymphotropic virus type 1 (HTLV-1)[1-3]. Although it is well-known that ATLL cells infiltrate into systemic organs including gastrointestinal (GI) tract[4], colonic involvement has not been fully documented[5]. We herein report a case of ATLL presenting MLP and provide a literature review on this rare entity.

CASE REPORT

A 48-year-old man presented with fever and watery diarrhea of a history for three weeks. He had been diagnosed as having smouldering ATLL with erythematopapular cutaneous lesions, in which monoclonal integration of proviral DNA of HTLV-1 into the host genome was confirmed by the Southern blot analysis. He had been managed conservatively without leukemic change or visceral invasion for

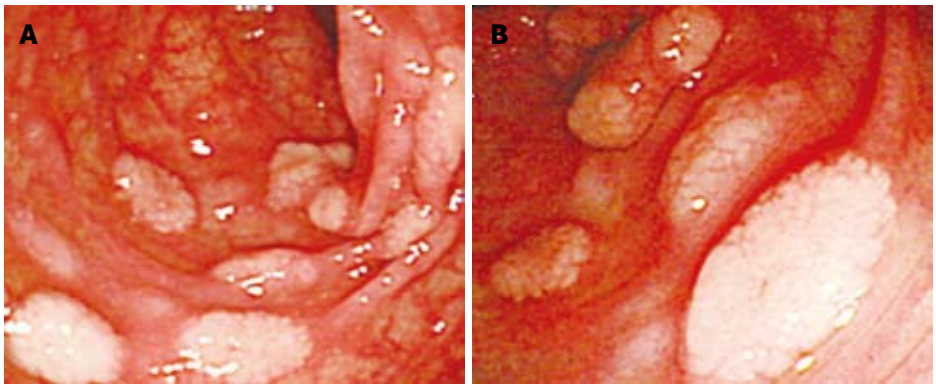

Figure 1 Colonoscopic images of the transverse colon. A: Multiple small polypoid lesions were presented; B: Closer observation revealed tiny submucosal tumors as well as whitish polypoid lesions.

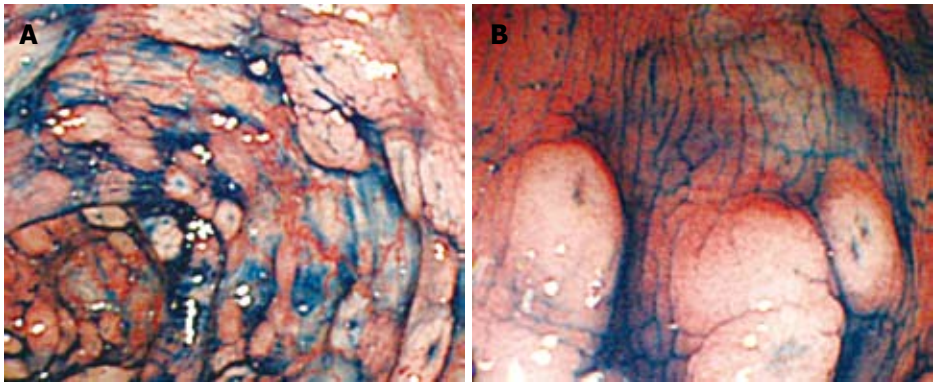

Figure 2 Colonoscopic images with indigo carmine dye. A: Multiple lymphomatous polyposis was clearly depicted; B: Closer observation revealed polypoid and aphthoid lesions had tiny central depression.

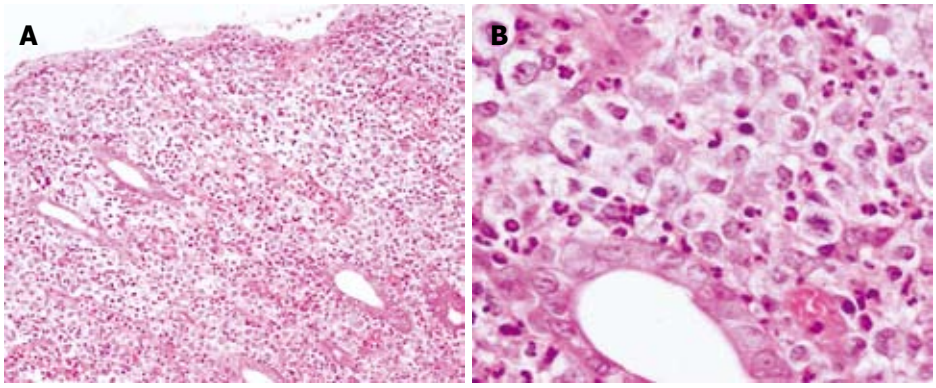

Figure 3 Pedunculated colonic mucosal tissue. Biopsy specimens of the polypoid lesion showing diffuse proliferation of atypical lymphoid cells in the mucosal layer (A, HE, × 100). The lymphoma cells display pleomorphic nuclei and pale cytoplasm. (B, HE, × 400).

20 years. Physical examination revealed mandibular lymphadenopathy and multiple erythema and papules on the skin of face, abdomen and back. Abdominal examination showed hyper bowel sounds, but no hepatosplenomegaly. The white blood cell count was 7600/mm^3 (normal: 3500-8000/mm^3), with a normal differential. Serum lactate dehydrogenase and calcium were normal. The soluble interleukin 2 receptor was 23070 U/mL (normal: 220-530 U/mL) and anti-HTLV-1 antibody was positive. Stool cultures and parasites including *Strongyloides stercoralis* were negative. Colonoscopy disclosed multiple whitish polyps throughout the colon (Figure 1). Indigo carmine dye spraying showed a central depression on the polyps (Figure 2). Pedunculated colonic mucosal tissue was replaced by diffuse proliferation of large lymphoid cells with pleomorphic nuclei and pale cytoplasm (Figure 3). Immunohistochemically, these cells were positive for CD3, CD25, and CD30, but not for CD20, suggesting anaplastic large cell variant of ATLL (Figure 4). All of these findings indicated the diagnosis of anaplastic variant of ATLL with colonic involvement presenting MLP. Subsequent ATLL infiltration to the heart, lungs and central nervous system occurred rapidly. An esophagogastroduodenoscopy was not performed. Despite combination chemotherapy consisting of cyclophosphamide, doxorubicin, vincristine and prednisolone, the patient died 3 mo later.

DISCUSSION

HTLV-1 infection is endemic in southern Japan, Caribbean, West Africa, South America, and the Middle East. Worldwide 10-20 million people are infected approximately[1,2]. Although the majority of HTLV-1 carriers remain asymptomatic, the virus is associated with severe diseases that can be subdivided into three categories: neoplastic diseases (ATLL and

cutaneous T-cell lymphoma), inflammatory syndromes (HTLV-1 myelopathy, uveitis, arthropathy, polymyositis and thyroiditis), and opportunistic infections (*S. stercoralis* hyperinfection, scabies, tuberculosis and leprosy)[1,2].

ATLL is a systemic multiple lymphoma with a strong tendency to infiltrate various organs or to manifest as leukemic change. Based on the disease manifestations, ATLL is classified into four subtypes: smouldering type, chronic type, lymphoma type, and acute type[6]. Disease progression to the acute or lymphoma from in patients with smouldering and chronic ATLL sometimes occurs, which has a poor prognosis with median survival time of less than 1 year. The case we present was smouldering ATLL with progression to the lymphoma form. A study of 47 autopsied patients with ATLL revealed that tumor cells infiltrate various organs including the spleen (85.1%), bone marrow (72.3%), lungs (72.3%), and GI tract (70.2%). In the GI tract, the stomach is most frequently involved (40.4%), followed by the colon (38.3%) and the small intestine (34.0%)[4]. Precise mechanisms for ATLL cell infiltration in GI tract have not been clarified; however, Chen *et al*[7] described that ATLL cells from patients with GI tract involvement showed considerably higher expression of an adhesion molecule integrin β7, suggesting a critical role of this molecule in adhesion and subsequent infiltration of a certain type of ATLL cells into intestinal mucosa. Regarding colonic lesions, Utsunomiya *et al*[5] first described radiographic and endoscopic manifestations of colonic involvement of ATLL in the English literature. They classified the colonic lesions into three types: Edema with erosion, granular appearance, and multiple polypoid lesions with central depression. Table 1 shows colonic involvement of ATLL reported in the English literature. In addition to the prior categories, tumor type[8,15] and colitis type[12] have been reported. A search of the MEDLINE database retrieved only 5 reported cases of ATLL with MLP[5,9-11,13]. Although the molecular mechanisms which may influence phenotypes

of colonic lesions have not been clarified, colonic MLP may be correlated with coexistence of upper gastrointestinal MLP or polypoid lesions (Table 1). In addition, patterns and degree of ATLL cell infiltration have been suspected to be reflected to the morphological differences[17]. MLP was coined by Cornes, in 1961, to describe polypoid involvement of long segments of the gastrointestinal tract by lymphoma[17]. Although most of MLP were observed in cases with mantle cell lymphoma (MCL) of B-cell type[18-20], recent studies have shown that follicular lymphoma (FL) and mucosa-associated lymphoid tissue (MALT) lymphoma cases also showed MLP with emphasis of the importance of differentiating MCL, FL and MALT presenting MLP because of distinct prognosis among them[21]. Based on prior reports, definite differences of endoscopic morphology have not been observed between MLP of various types of lymphoma. ATLL may have the worst prognosis of MLP; therefore, pathological diagnosis will be much more important.

Patients with ATLL are immunocompromised and develop opportunistic infections that complicate the disease course[2]. Among these infections, there is an increasing body of evidence regarding a strong association between HTLV-1 and *S. stercoralis* co-infection[22]. Endemic region of HTLV-1 is overlapped with that of *S. stercoralis* worldwide and co-infestation by *S. stercoralis* can be severe and fatal[23]. Therefore, great attention should be paid to immunocompromised ATLL patients with refractory diarrhea and malabsorption to differentiate ATLL colonic lesions from opportunistic infectious enterocolitis caused by *S. stercoralis*, *Entamoeba histolytica*, *Isospora belli*, cytomegalovirus, or *Mycobacterium tuberculosis*.

The prognosis of ATLL is still poor with a median survival of less than one year for the acute and lymphoma forms despite advanced therapy including new multiagent chemotherapy, allogenic hematopoietic stem cell transplantation, and antiretroviral therapy[1,2]. Especially, gastrointestinal involvement of ATLL was reported to be one of the poor prognostic factors in acute type ATLL[11,24]. Therefore, endoscopic evaluation may be important for estimating prognosis of ATLL patients.

In conclusion, although this condition is rare, ATLL should be included in the differential diagnosis of MLP. We also emphasize the importance of endoscopic evaluation to differentiate neoplastic intestinal lesions from infectious enterocolitis for abdominal symptoms in patients with leukemia/lymphoma.

Abstract

A Killian-Jamieson diverticulum (KJD) is an unfamiliar and rare cervical esophageal diverticulum. This diverticulum originates on the anterolateral wall of the proximal cervical esophagus through a muscular gap (the Killian-Jamieson space) below the cricopharyngeal muscle and lateral to the longitudinal muscle of the esophagus. To date, only surgical treatment has been recommended for a symptomatic KJD due to its close proximity to the recurrent laryngeal nerve and the concern of possible nerve injury. Recently, traditional open surgery for a symptomatic KJD is being challenged by the development of new endoscopic techniques and devices. We present here a case of a symptomatic KJD that was successfully treated with the flexible endoscopic diverticulotomy using two new devices. An isolated-tip needle-knife papillotome (Iso-Tome) was used for the dissection of the tissue bridge of the diverticulum. And a flexible overtube with a modified distal end (a fitted overtube) was used for adequate visualization of the tissue bridge of the diverticulum and protection of the surrounding tissue during dissection of the tissue bridge. Our successful experience suggests that the flexible endoscopic diverticulotomy with the use of appropriate endoscopic devices can be a safe and effective method for the treatment of a symptomatic KJD.

INTRODUCTION

A Killian-Jamieson diverticulum (KJD) is an unfamiliar and rare disease entity as compared with Zenker's diverticulum (ZD), which is the most commonly encountered diverticulum of the cervical esophagus[1-4]. These two types of cervical esophageal diverticula can be diagnosed and can be differentiated by radiological studies or by the use of endoscopy. A KJD originates on the anterolateral wall of the proximal cervical esophagus through a muscular gap (the Killian-Jamieson space) below the cricopharyngeal muscle and lateral to the longitudinal muscle of the esophagus[1-4]. A ZD develops at the anatomically weak posterior zone (the Killian's triangle) just above the cricopharyngeal muscle[1-4]. Although a KJD is anatomically distinct from a ZD, the symptoms attributable to a KJD are similar to those of a ZD[3]. To date, only surgical management has been recommended in symptomatic patients with a KJD[2]. Very recently, the first report of the flexible endoscopic treatment of a KJD was published[4].

We present here a rare case of a symptomatic KJD that was successfully treated with the flexible endoscopic diverticulotomy using an isolated-tip needle-knife papillotome (Iso-Tome) and a fitted overtube.

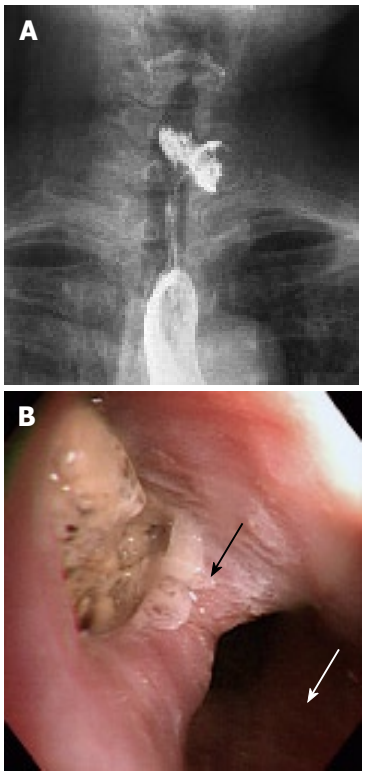

Figure 1 Barium swallow and endoscopic images. A: An antero-posterior view of a barium swallow image, showing a diverticular sac filled with contrast and food debris in the left lateral side of the cervical esophagus; B: An endoscopic view of the KJD that originates on the anterolateral wall of the cervical esophagus, which was filled with impacted food debris (black arrow: the tissue bridge; white arrow: The esophageal lumen).

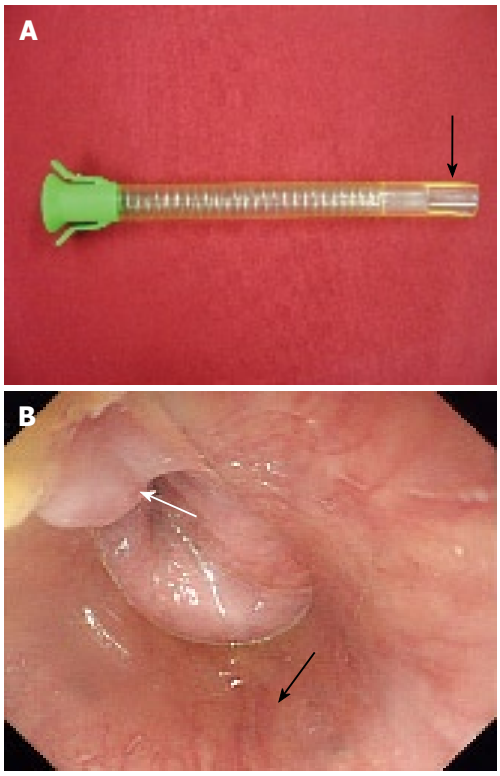

Figure 2 A fitted overtube. A: A photograph of a fitted overtube. The distal end of a standard overtube is snipped off with a scissor in a rectangular form according to the size of the diverticular opening (arrow); B: An endoscopic view following insertion of a fitted overtube (white arrow: Tissue bridge; Black arrow: Overtube). The tissue bridge of the diverticulum is exposed in the fixed operational field. The surrounding esophageal wall is completely protected and stabilized.

CASE REPORT

A 55-year-old woman was referred from a local clinic for a 6-mo history of pharyngeal discomfort and an abnormal contrast esophagogram. An anteroposterior projection of a barium swallow image revealed a 1.6 cm left-sided KJD with a wide neck (Figure 1A). The diverticulum was filled with contrast and food debris, as demonstrated by filling defects in the contrast pool. Contrast retention was persistent regardless of the barium swallow. An initial esophagoscopy showed a diverticulum protruding into the anterolateral wall of the cervical esophagus (Figure 1B). Despite overnight fasting, the diverticular wall was not clearly identified as food debris, was fully impacted inside the diverticular sac. The opening of the esophageal lumen was identified at the posterolateral side of the diverticular opening. Based on the esophagogram and the endoscopic finding, we could diagnose a true KJD. There was no coexisting ZD.

An endoscopic diverticulotomy, with the use of a forward-viewing flexible endoscope (GIF-Q260; Olympus Optical, Tokyo, Japan), was performed on an inpatient basis under conscious sedation with the administration of midazolam and propofol. Informed written consent was obtained before the procedure. In order to obtain good visualization of the tissue bridge of the KJD and to maintain a clear operational field, we used an overtube designed for endoscopic variceal ligation (Flexible Overtube; Sumitomo Bakelite Inc, Tokyo, Japan). Before the procedure, the distal end of an overtube was snipped off with a scissor in a rectangular form (Figure 2A). This 'fitted' overtube was advanced into the esophageal lumen under an endoscopic view. The position of the modified distal end of the overtube was adjusted so that it was possible to locate the tissue bridge of the KJD within the hollow rectangle (Figure 2B).

The diverticular sac was not clearly visualized during the procedure due to the presence of impacted food debris. We used an isolated-tip needle-knife papillotome (Iso-Tome, MTW Endoskopie, Wesel, Germany) and Endo-cut (VIO 300D, ERBE, Tübingen, Germany) for dissection of the tissue bridge (Figure 3A). The direction of the cut was from the diverticular lumen towards the esophageal lumen. Dissection of the tissue bridge was performed at its midpoint by direct contact of the needle of the Iso-Tome with the tissue bridge of the diverticulum in a slightly vertical manner (Figure 3B). About three-fourths of the height of the tissue bridge was separated after the dissection. Minor blood oozing developed at the incised wound, but the bleeding was successfully controlled with the use of argon plasma coagulation (APC). The total time of the procedure from insertion of the endoscope to complete hemostasis with APC was 11 min. The patient was discharged two days after the procedure without any procedure-related complications.

A follow up esophagoscopy was performed at three months after the procedure. The esophagoscopy revealed a wide communication between the diverticular sac and the esophageal lumen without a significant tissue bridge (Figure 4). There was no residual food debris inside the diverticular sac and the patient denied having any of the previous symptoms.

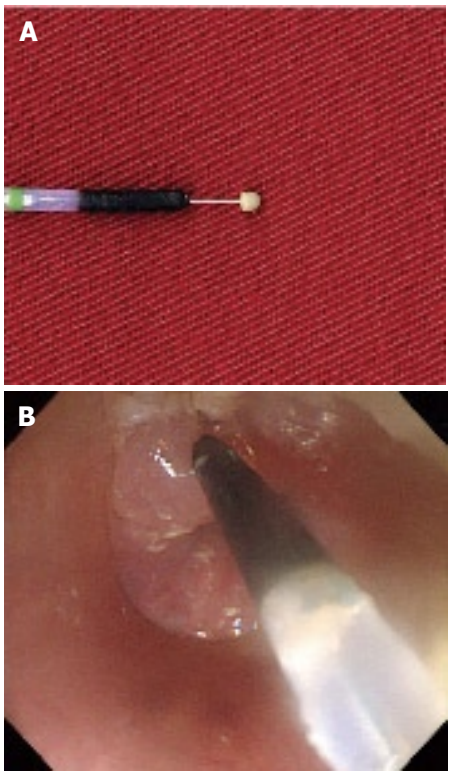

Figure 3 Isolated-tip needle-knife papillotome. A: A photograph of an isolated-tip needle-knife papillotome (Iso-tome). Note the semi-oval shaped, isolated-tip composed of epoxide adhesive. B: An endoscopic view during the diverticulotomy. The Iso-Tome is inserted into the diverticular sac before dissection.

DISCUSSION

A KJD is an uncommon cervical esophageal diverticulum located on the proximal lateral side of the cervical esophagus (also called as proximal lateral cervical diverticulum)[1-4]. Because of the unfamiliarity and rarity of this entity, a KJD is often unrecognized and misdiagnosed as a ZD on an endoscopic finding. Accurate differentiation between a ZD and KJD relies on radiological studies, especially the use of a contrast esophagogram. Unfortunately, we had no initial lateral view of the esophagogram, but we finally confirmed the presence of a KJD after a serial esophagogram and interpretation of the endoscopic findings at our institution. Although the pathogenesis of a KJD is unclear, only surgical treatment has been recommended for a symptomatic KJD due to its close proximity to the recurrent laryngeal nerve and the concern of possible nerve injury[3]. Recently, the use of flexible endoscopic diverticulotomy for the treatment of a symptomatic KJD was introduced by Tang *et al*[4]. The technique is primarily based upon a needle-knife incision of the esophageal circular muscle under the assistance of an auxiliary transparent hood as reported by the investigators. The investigators recommended that endoscopic management of a symptomatic KJD was designed to widen the opening of the diverticulum and allow subsequent fluent drainage of food material. The basic principle is not different from that for a ZD, to dissect the septum between the diverticular sac and the esophagus and then allow an overflow of food material from the diverticular sac into the esophageal lumen[5]. The aim of performing the diverticulotomy in the present case was the creation of a communication between the diverticular sac and the esophageal lumen for fluent drainage of food debris without retention inside the diverticulum, thereby resolving the patient symptoms.

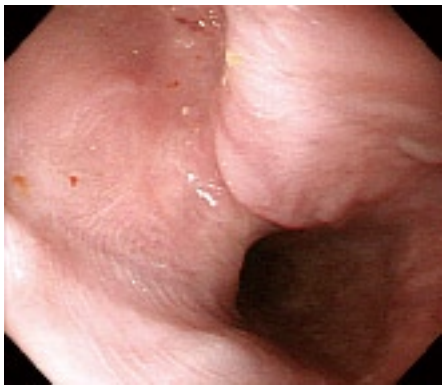

Figure 4 An endoscopic view at three months after the diverticulotomy. A wide communication between the diverticular sac and the esophageal lumen without a significant tissue bridge or retained food debris is shown.

Endoscopic treatment of the KJD was successful with a good symptomatic resolution in this case. We want to introduce two new devices for a safe diverticulotomy. First, we used an isolated-tip needle-knife papillotome (Iso-Tome) for the dissection of the tissue bridge of the diverticulum instead of a classical needle-knife. The most feared complication of needle-knife based endotherapy of the esophageal diverticula is mediastinitis[6]. The Iso-Tome was originally introduced in our institution for a safe and effective pre-cut papillotomy during an ERCP[7]. The Iso-Tome has a semi-oval shaped isolated-tip made of epoxide adhesive, which prevents electrical leakage from the tip of the incising needle, thereby preventing an unintended deep cut and perforation. This definite merit has been reported for the endoscopic treatment of an intraluminal duodenal diverticulum[8]. The semi-oval shape of the tip is also advantageous for placing the Iso-Tome into a narrow space, such as a diverticular sac filled with impacted food debris. A diverticular sac is not often clearly visualized on endoscopy due to impacted food debris inside the diverticulum. If the depth of the diverticulum is not measured endoscopically, a blind dissection with a needle-knife incision may be associated with overextension beyond the inferior border of the diverticulum and subsequent mediastinitis. In our practice, the Iso-Tome was inserted through the biopsy channel of the endoscope. The tip of the Iso-Tome was intentionally pushed into the gap between the food material and the inner wall of the diverticulum, and was then positioned at the bottom of the diverticulum (Figure 3B). The lower bottom of the diverticulum could be assumed by placement of the Iso-Tome inside the diverticulum before dissection. Another advantage of the use of the Iso-Tome is stable control of the direction of dissection. The dissection with the use of the Iso-Tome is made from the diverticular lumen

towards the esophageal lumen. Unintended slippage of the knife on the inner wall of the diverticulum can be prevented by hooking the inner diverticular wall by the shoulder of the semi-oval tip of the Iso-Tome. These advantages suggest that the use of the Iso-Tome is a safe and effective alternative to the use of the classical needle-knife in the treatment of cervical esophageal diverticula.

As a second device, we used a fitted overtube for adequate visualization of the tissue bridge of the diverticulum and protection of the surrounding tissue during dissection of the tissue bridge. Several accessory tools (a nasogastric tube, transparent hood and diverticulosope) have been introduced for flexible endoscopic treatment of cervical esophageal diverticula to overcome technical problems, especially for a ZD[9-12]. All of these accessory tools are commercially available and can be useful for flexible endoscopic treatment of a ZD. In our case, the use of a flexible overtube with a modified distal end allowed clear isolation and better exposure of the tissue bridge within the fixed operational field (Figure 2B). The surrounding esophageal wall, except for the operational field, could be prevented from exposure to unintended electrical damage. Effective stabilization of esophageal motility allowed free movement of the tip of the endoscope inside the overtube. Direct compression of the more proximal esophageal wall by the overtube could prevent aspiration of undigested food debris during the procedure. Modification of the distal end of the overtube was easily adjusted according to the form and size of the diverticular opening before the procedure.

In conclusion, the flexible endoscopic diverticulotomy can be a safe and effective method for the treatment of a symptomatic KJD. We expect that the two new devices can assist a safer and easier flexible endoscopic treatment for any kind of cervical esophageal diverticula, including both a KJD and a ZD.

Abstract

Fundic gland polyps are the most common gastric polyps. They are usually small in size, sporadic and asymptomatic. We present a case of giant fundic gland polyp. Our case is particular because of the clinical presentation, the endoscopic and endosonographic documented findings, and the treatment options followed.

Giant sporadic fundic gland polyp: Endoscopic and endosonographic features and management. *World J Gastroenterol* 2008; 14(42): 6593-6595 Available from: URL: http://www.wjgnet.com/1007-9327/14/6593.asp DOI: http://dx.doi.org/10.3748/wjg.14.6593

INTRODUCTION

Fundic gland polyps (FGPs) account for about 47% of all gastric polyps[1]. They are found in up to 1.9% of the general population, 5% of patients presenting for upper gastrointestinal endoscopy, 84% of patients with familial adenomatous polyposis (FAP), and in 93% of those with attenuated-FAP (AFAP)[1,2]. FGPs are usually asymptomatic, though some patients may complain of dyspepsia. Most FGPs are sporadic and number less than 10 in a given patient. Typically their size is between 1 and 5 mm; however, larger polyps are occasionally observed[3]. FGPs tend to occur mostly in women during the 5th or 6th decade of life[4], but they have been described as early as 8 years of age in patients with FAP[1].

We present a case of giant sporadic FGP that was associated with positive fecal occult blood test (FOBT). We describe its endoscopic, endosonographic and histologic features and discuss the decision for surveillance.

CASE REPORT

An asymptomatic 63-year-old male was referred for evaluation of borderline microcytic anemia and positive FOBT. Past medical history was positive for long-standing systemic lupus erythematosus (SLE) for which he was maintained on prednisone 5 mg daily, hydroxychloroquine, oral calcium, Vitamin D, and alendronate. Physical exam was unremarkable. Laboratory tests revealed: Hemoglobin, 12.9 g/dL; hematocrit, 37.5%; mean corpuscular volume (MCV), 79 fl; serum iron, 34 μg/dL (37-160); total iron binding capacity (TIBC), 309 μg/dL (270-450); and ferritin 36.7 ng/mL (20-280). Colonoscopy was performed and was normal. Upper endoscopy showed a sessile, broad-based, smooth-surfaced polyp, similar in color to the surrounding mucosa and extending around 8 cm (with a width of 2 cm) from the cardia along the lesser curvature with two small satellite polyps (Figure 1). Multiple biopsies from the polyp were compatible with FGP (Figure 2). Rapid urease test for *Helicobacter pylori* (*H pylori*) was negative. Endoscopic ultrasound (EUS), performed at a frequency of 12 MHz using radial sector transducer (GF-UM-240, Olympus Tokyo, Japan), revealed a wide-based, large, predominantly hypoechoic polyp that involved the mucosa without reaching the submucosa or muscularis propria (Figure 3). Small intestinal series (SIS)

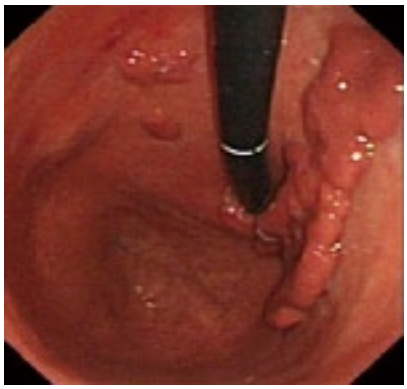

Figure 1 Endoscopic appearance of the giant FGP and the two small satellite polyps.

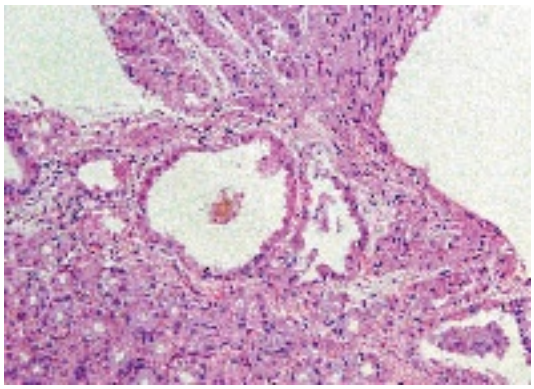

Figure 2 Fundic gland polyp biopsy showing numerous fundic glands, several of which are cystically dilated (HE, ×100).

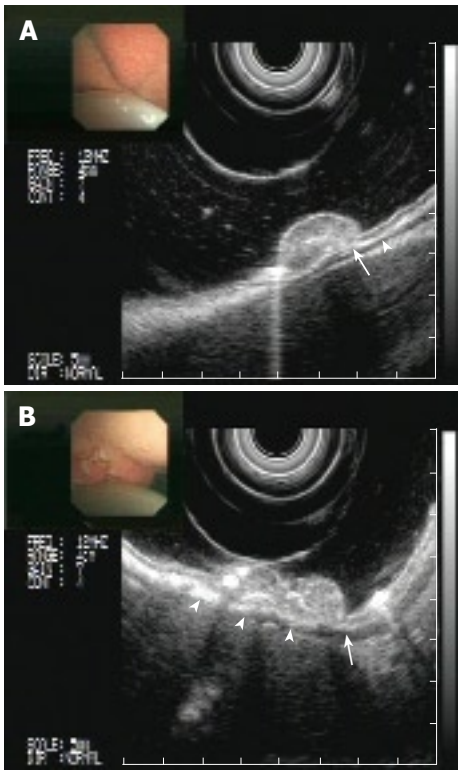

Figure 3 EUS images of the gastric polyp. A: The polyp involves the mucosa without reaching the submucosa (arrow) or muscularis propria (arrowhead); B: Mixed echogenicity of the polyp (EUS view at a different level).

exam was normal. The treatment was conservative and the patient was started on iron supplementation.

The patient was re-evaluated at 3 and 8 mo. He remained asymptomatic. Repeat stool occult blood was positive on 3 occasions. Laboratory studies showed normal hemogram and iron studies. A repeat esophagogastrod uodenoscopy (EGD) and EUS confirmed the previous findings. Biopsies from the polyp were unchanged, while biopsies of the surrounding mucosa revealed mild chronic active gastritis and rare *H pylori*-like organisms for which the patient received eradication therapy.

DISCUSSION

FGPs are the most common gastric polyps. The size of FGPs varies between 1 and 5 mm. Unlike adenomatous polyps where a size more than 2 cm has been suggested as critical in the determination of malignant potential, the size of sporadic FGPs is not considered a risk factor for malignancy[5]. Six cases of giant FGPs of different sizes have been reported in the literature[6-11]. The histologic diagnosis of sporadic FGP was reported in only one of the cases[8], making our case the second case of giant FGP.

The diagnosis of FGPs is based on pathology. The presence of cystically dilated fundic glands that are lined by attenuated, but otherwise normal-appearing chief and parietal cells is characteristic. The overlying foveolae are usually shortened. Inflammatory changes in the surrounding mucosa are usually absent[3]. In our patient, the surrounding mucosa was involved by an *H pylori*-positive mild chronic active gastritis. This association between sporadic FGPs and *H pylori* gastritis has been rarely reported. It seems like patients with sporadic FGPs are largely protected from *H pylori* colonization and that these patients rarely acquire the infection after the regression of the polyps[12].

Sporadic FGPs have distinct endoscopic features[13]. They are confined to the acid secreting oxyntic mucosa of the gastric fundus and gastric body. They are small, sessile, smooth-surfaced, hemispherical or dome-shaped, and similar in color to the surrounding mucosa. The role of EUS in the evaluation of gastric mucosal and submucosal lesions is well established. However, its use in the evaluation of giant gastric polyps has been described in four cases only[7-9,14]. It may be helpful in defining the depth and the extension of the lesion through the layers of the gastric wall, ruling out a possible malignancy.

The natural history of FGPs is unclear and there are no guidelines for surveillance and treatment. The number and size of FGPs in the FAP and sporadic forms can slowly increase, decrease or remain the same[3]. Since forceps biopsy sampling may fail to provide adequate tissue for histological diagnosis, it is recommended to remove all gastric polyps larger than 5 mm in diameter[15]. Whether this recommendation applies to FGPs is still unclear. Endoscopic mucosal resection (EMR) seems to be a safe and fast procedure for the diagnosis and treatment of gastric polypoid lesions[16]. However, a very high bleeding rate of 32% may complicate EMR for polyps greater than 3 cm in

size[17]. Moreover, surgical resection (partial gastrectomy) of large polyps may be associated with serious acute and chronic complications[18].

In our patient, the polyp is most likely the cause of positive stool occult blood. The question whether to remove such a giant polyp by EMR or surgical resection or to observe is debatable. We opted for surveillance of the polyp for the following reasons: The patient is asymptomatic and his hemogram normalized on iron therapy; FGPs may regress, progress or remain unchanged in size, FGPs carry no malignant potential, and finally endoscopic or surgical resection of such a polyp carries a high risk of bleeding and complications respectively. We felt that keeping this large polyp imposes a negligible risk to the patient.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open access peer-reviewed journal supported by an editorial board consisting of 1208 experts in gastroenterology and hepatology from 60 countries. The aim of the journal is to deliver the most clinically relevant original and commentary articles to readers, and to make the full text publicly available to all clinicians, scientists, patients and biomedical students on an unrestricted platform, so that they can access and learn about the most recent key advances in the field.

In addition to the open access nature, another key characteristic of *WJG* is its reading guidance for each article which includes background, research frontier, related reports, breakthroughs, applications, terminology, and comments of peer reviewers for the general readers.

WJG publishes articles on esophageal, gastrointestinal, hepatobiliary and pancreatic tumors, and other esophageal, gastrointestinal, hepatic-biliary and pancreatic diseases in relation to epidermiology, immunology, microbiology, motility & nerve-gut interaction, endocrinology, nutrition & obesity, endoscopy, imaging and advanced hi-technology.

The main goal of *WJG* is to publish high quality commentary articles contributed by leading experts in gastroenterology and hepatology and original articles that combine the clinical practice and advanced basic research, to provide an interactive platform for clinicians and researchers in internal medicine, surgery, infectious diseases, traditional Chinese medicine, oncology, integrated Chinese and Western medicine, imaging, endoscopy, interventional therapy, pathology and other basic medical specialities, and thus eventually improving the clinical practice and healthcare for patients.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was carried out; author contributions; disclosure of any financial support for the research; and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (remove all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s), and full family name.

Author controbutions: The format of this section should be like this: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed research; Wang CL, Zou CC, Hong F and Wu XM performed research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed data; and Wang CL, Liang L and Fu JF wrote the paper.

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipment, and the experimental procedures should be included. RESULTS: The observed and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and also include any significant data. CONCLUSION: Accurate view and the value of the results should be included.

The format for structured abstracts can be found at: http://www.wjgnet.com/wjg/help/11.doc.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication

and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, should be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information for journal citations is very important. Using the reference testing system, the authors and editor should check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in an ASP file so that the readers can immediately access the abstract of the citations online.

DOI requirement

A CrossRef DOI® (Digital Object Identifier) name is a unique string created to identify a piece of scholarly content in the online environment. The author should supply the DOIs for journal citation(doi:10.3748/wjg.13.6458). This link (http://www.crossref.org/SimpleTextQuery/) allows you to retrieve Digital Object Identifiers (DOIs) for journal articles, books, and chapters by simply cutting and pasting the reference list into the box. You may use the form with any reference style, although the tool works most reliably if references are formatted in a standard style such as shown in this example: Assimakopoulos SF, Scopa CD, Vagianos CE. Pathophysiology of increased intestinal permeability in obstructive jaundice. *World J Gastroenterol* 2007; 13(48): 6458-6464

The accuracy of the information of journal citations is very important. We will interlink all references with DOI in ASP file so that readers can access the abstracts of cited articles online immediately.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those linked with a hyphen when the difference between the two numbers is greater than five. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/15.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903
Ocean International Center, Building D
No. 62 Dongsihuan Zhonglu
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/9.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/10.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Studies on rodents and humans demonstrate an inherited predisposition to hepatocellular carcinoma (HCC). Analysis of the molecular alterations involved in the acquisition of a phenotype resistant or susceptible to hepatocarcinogenesis showed a deregulation of G1 and S phases in HCC of genetically susceptible F344 rats and a G1-S block in lesions of resistant Brown norway (BN) rats. Unrestrained extracellular signal-regulated kinase (ERK) activity linked to proteasomal degradation of dual-specificity phosphatase 1 (DUSP1), a specific ERK inhibitor, by the CKS1-SKP2 ubiquitin ligase complex occurs in more aggressive HCC of F344 rats and humans. This mechanism is less active in HCC of BN rats and human HCC with better prognosis. Up-regulation of iNos cross-talk with IKK/NF-κB and RAS/ERK pathways occurs in rodent liver lesions at higher levels in the most aggressive models represented by HCC of F344 rats and c-Myc-TGF-α transgenic mice. iNOS, IKK/NF-κB, and RAS/ERK upregulation is highest in human HCC with a poorer prognosis and positively correlates with tumor proliferation, genomic instability and microvascularization, and negatively with apoptosis. Thus, cell cycle regulation and the activity of signal transduction pathways seem to be modulated by HCC modifier genes, and differences in their efficiency influence the susceptibility to hepatocarcinogenesis and probably the prognosis of human HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent human cancers, with 1 million of newly diagnosed cases each year. The highest frequencies are found in sub-Saharan Africa and far eastern Asia, where hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are endemic, and in regions where food contaminated with Aflatoxin B1 is consumed[1-3]. Other risk factors associated with the development of HCC include: long term use of oral contraceptive (female), high dose of androgen steroids, type 2 diabetes, genetic disorders such as hemochromatosis, hereditary tyrosinemia, glycogen storage disease (types 1 and 2), α1-antitrypsin deficiency, Wilson's disease; porphyria cutanea tarda, galactosemia, orotic aciduria, congenital cholestatic syndrome, and environmental agents (Thorotrast, Aflatoxins, Cycasin, Pyrrolizidine alkaloids, Vinyl chloride, tobacco smoke, N-nitrosylated compounds). HCC incidence appears to be rising, even in countries with relatively low incidence[4]. HCC is prevalently male associated with M:F ratios ranging from 1.3 to 12.9 according to the geographic area[1]. It is a rapidly fatal disease, with a life expectancy of about 6 mo from the time of diagnosis. Partial liver resection or liver transplantation are potentially curative, but only a minority of the cases is amenable to these treatments.

The frequency of HCC, similarly to that of other

tumor types, shows great differences within a human population as a response to environmental risk agents[5]. This suggests that additional environmental and/or genetic factors may be involved in the pathogenesis of the disease. Genetic polymorphisms of Cytochromes P450 2E1 and 2D6, Aldehyde dehydrogenase, Arylamine N-acetyltransferase 2, Epoxide hydrolase and L-*MYC*, and mutation of the Glutathione S-transferase gene have been associated with increased risk of HCC[6-10]. The genetic susceptibility has been shown to be one of the factors involved in familial aggregations of HCCs, even in HBV endemic areas where perinatal transmission of HBV is mainly responsible of familial HBV clustering[11]. The absence of an obviously inherited predisposition to the majority of liver cancers and of familial aggregations of HCC, independent of environmental agents such as HBV and HCV infections indicates that high-penetrance mutations are rare for this tumor, and suggests instead the involvement of low-penetrance genetic variants. Indeed, studies of families at risk seem to confirm the implication of a polygenic control of cancer incidence[12,13], and are in keeping with a polygenic model of autosomal recessive inheritance with a major gene involved in the genetic predisposition of HCC onset at an earlier age[14].

The development of cancers in mammals depends on accumulation within somatic cells of a number of genetic alterations including activation of proto-oncogenes and inactivation of oncosuppressor genes. Genetic instability plays an important role in the accumulation of these alterations[1]. Although various interindividual and interspecies differences have been documented, several morphological, biochemical and biological commonalties have been found in human and rodent preneoplastic and neoplastic liver lesions[3,15-17]. This suggests that the basic mechanisms of HCC development, in different species, are closely similar. Furthermore, studies with experimental models of complex diseases, different from cancer, indicate that the genetic variants controlling susceptibility map to orthologous regions of the mouse and human genomes, and various diseases are caused by polymorphism of equivalent mouse and human genes[18]. On the basis of these observations and considerations; in recent years, mouse and rat hepatocarcinogenesis models have been used to map susceptibility genes, define the genetic model responsible for an increased risk of HCC, and examine the effector mechanisms of tumor susceptibility genes.

RESISTANT PHENOTYPE

Liver carcinogenesis is a multistage process[1,15-17,19]. The clonal expansion of carcinogen-initiated cells (promotion) leads to the development of foci of altered hepatocytes (FAHs) that, in the rat, can be identified by immunohistochemical staining of glutathione S-transferase 7-7 (GST 7-7). Most liver preneoplastic lesions re-differentiate or no further evolve to cancer, whereas a subset of lesions acquires the capacity of autonomous growth and progress to neoplastic nodules (dysplastic nodules, adenomas) and HCCs[19,20]. Genomic instability, up-regulation of oncogenes and downregulation of oncosuppressor genes, and in late stages, alteration of cell adhesion mechanisms drive the process evolution[15,21].

A striking behavior of rodents' genetic resistance to hepatocarcinogenesis is the fact that resistance genes apparently do not affect the initiation of the process, but only the capacity of initiated cells to grow autonomously[22-25]. In recent years the Brown norway (BN)[26] and Copenhagen (Cop)[27,28] rat strains have been shown to be strongly resistant to hepatocarcinogenesis. Both strains, crossed with F344 rats, susceptible to hepatocarcinogenesis, dominantly transmit their resistance to (BN × F344) F1 (BFF1) and (Cop × F344) F1 (CFF1) rats. Treatment of rats with DENA/AAF/partial hepatectomy, according to the "resistant hepatocyte" model of hepatocarci nogenesis[19], results in the development in the liver of resistant strains of an elevated number of fast-growing early preneoplastic lesions, positive for GST 7-7 expression. After exhaustion of the promoting stimulus, GST 7-7 positive lesions undergo a progressive decrease in growth capacity and intensive phenotypic reversion (remodeling)[29], thus showing inability to grow autonomously. In carcinogen-treated Cop rat strain, the block of progression of preneoplastic lesions exclusively depends on re-differentiation, whereas DNA synthesis in these lesions proceeds at the same rate as in the lesions of susceptible strains[27,28,30]. The analysis of BN and Cop rats excluded apoptosis in the preneoplastic lesions as a mechanism of resistance to hepatocarcinogenesis and attributed a preeminent role to redifferentiation[26-28]. However, apoptosis occurs in HCC from the resistant BN[31] and DHB[32] rats. These observations indicate that in the presence of dominant resistance alleles the subset of autonomously growing preneoplastic lesions, selected during promoting treatments, is very small or absent.

MAPPING OF THE LOCI CONTROLLING THE SUSCEPTIBILITY TO HEPATOCARCINOGENESIS

Linkage analysis experiments, made in various models of rodent hepatocarcinogenesis, led to the identification of different hepatocarcinogenesis susceptibility (*Hcs*) and resistance (*Hcr*) loci[25]. Mouse *Hcs1*, *Hcs2*, and *Hcs3* loci were identified on chromosomes 7, 8, and 12, respectively, in urethane-treated F2 male mice generated by crossing the susceptible C3H/HeJ strain with the resistant A/J strain[33]. Interspecific testcrosses between the phylogenetically distant C3H/HeJ and *Mus spretus* mice, followed by the cross of the resulting F1 with the resistant C57BL/6J (B6) strain, to increase interstrain polymorphism[23], led to the identification of 3 additional *Hcs* loci (numbered from 4 to 6), mapping to chromosomes 2, 5, and 19, respectively. More recently a seventh *Hcs* locus (*Hcs7*) was mapped to

distal chromosome 1 by analysis of the backcrosses and intercrosses between the susceptible C3H/HeJ or CBA/J strains and the resistant B6 strain[35]. Congenic B6.C3H (*D1Mit5-D1Mit17*) and B6.BR (*D1Mit5-D1Mit17*) were generated in which a approximate 70 cm segment (between *D1Mit5* and *D1Mit17*) from C3H or C57BR/cdj (Br) susceptible strains, was introgressed onto a B6 background. These recombinant congenic strains (RCSs) develop more liver tumors than B6 mice, indicating that distal chromosome 1 carries potent modifier gene(s) sufficient to confer susceptibility to liver cancer.

Two loci involved in the susceptibility to HCC have been identified in crosses between BR and B6 mice[35]. BR females are extremely sensitive to HCC induction, since they are genetically insensitive to the inhibition of hepatocarcinogenesis exerted by ovarian hormones. This property is dominantly transmitted to B6BRF1 and BRB6F1 mice. BR alleles at two loci, on chromosomes 17 and 1, identified in backcrosses and F2 progeny, are associated with increased susceptibility in both sexes. They were denominated *Hcf1* and *Hcf2* (hepatocarcinogenesis in females) loci. *Hcf1* and at a lower extent *Hcf2* accounted for the higher sensitivity of BR mice to hepatocarcinogenesis.

In addition to susceptibility loci, two resistance loci, with negative phenotypic effects have been discovered in mouse genome. *Hcr1* and *Hcr2* loci map on chromosomes 4 and 10, respectively[36]. Further work[37] has shown that a resistant F1 mouse may be generated by crossing the resistant BXD-15 recombinant inbred mouse, presumably carrying *Hcr* genes contributed by the parental strain DBA/2J, to susceptible recombinant BXD-11 mice, which should carry DBA/2J *Hcs* genes. This strongly suggests that *Hcr* genes may modify the activity of several sensitivity loci.

The genome of the BALB/c mouse strain provides alleles that semi dominantly inhibit hepatocellular tumor development in F1 crosses with the highly hepatocarcinogenesis-susceptible C3H/He strain[39]. Recent genome-wide linkage analysis in a F2 population produced by intercrossing the BALB/c to the C3H/He mouse strain revealed a hepatocarcinogen resistance 3 (*Hpcr3*) locus with a major role in the resistance to urethane-induced hepatocarcinogenesis[40]. This locus, mapping to central Chromosome 15, accounts for 40% of the phenotypic variance. A gene expression profile of normal adult mouse liver showed a significant association with susceptibility of BALB/c, C3H/He, and F1 mice to hepatocarcinogenesis, and identified the genes expressed in the *Hpcr3* locus region. This analysis implicated the E2F1 pathway in the modulation of the phenotype susceptibility to hepatocarcinogenesis.

The first locus regulating the susceptibility of rats to chemical hepatocarcinogenesis, denominated *rcc* locus, has been identified in the telomeric end of chromosome 20 of MHC-recombinant rat strains, congenic for the MHC genes and its linked region *grc* (growth reproduction complex)[41,42]. The rcc^+ locus has many properties in common with tumor-suppressor genes: it is recessive, its deletion causes phenotypic susceptibility to various carcinogens, and it inhibits tumor development in many organs and tissues, including liver, skin, kidney and mesenchyma[41].

Numerous other loci have been identified by linkage analysis of male backcrosses and intercrosses of resistant BN and/or Cop rats to susceptible F344 rats. Seven susceptibility loci have been identified: rat *Hcs1* and *Hcs2* loci on chromosomes 7 and 1 respectively, in BN × BFF1 backcross progeny[43], *Hcs3* and *Hcs4* loci in BFF2 rats[44], and *Hcs3*, *Hcs5*, *Hcs6* and *Hcs7* in CFF2 intercrosses[45]. *Hcr* loci numbered 1 to 3 have been mapped to chromosomes 10, 4, and 8, respectively, in BN × BFF1 backcrosses[43]. Four additional *Hcr* loci, numbered from 9 to 12, (Rat genome database, www.rgd.mcw.edu/; previously numbered from 4 to 7) were identified on chromosomes 4, 6, and 8 of BFF2 rats[44]. *Hcr13* and *Hcr14* (RGD; previously numbered 8 and 9) were mapped to chromosomes 4 and 18 of CFF2 rats[45].

The results of genomic scanning of crosses of BN and Cop rats with F344 rats are consistent with some observations on a resistant mutant of Donryu rats strain, the DRH rats[46,47], indicating the presence of two clusters of genes on chromosomes 1 and 4 of (DRH × F344) F2 rats, designated collectively as *Drh1* and *Drh2*, and considered to be resistance genes. These genes are transmitted dominantly from DHR rats to the F2 progeny. The *Drh1* locus affects the development of FAH induced by 3'-Me-DAB[46,47], whereas *Drh2* seems to control the progression of FAH to carcinoma. On the basis of the chromosomal localization, *Dhr2* seems to correspond to *Hcr2* on chromosome 4, while *Drh1* corresponds to *Hcs3* and *Hcs5*.

The phenotypic effect of *Hcs3* locus in BFF2 rats, consisting in a marked increase in the volume of neoplastic nodules, accounts for 49% of the total phenotypic traits[44]. In CFF2 rats, *Hcs3* and *Hcs5* loci apparently account for only 14.6% and 8.4% of the phenotypic trait, respectively, consisting in about a 100% rise in number of non-remodeling nodules[45]. These nodules represent less than 20% of the total lesions in these rats. Thus, a diluting effect of the large number of remodeling lesions may be responsible for the apparently low penetrance of the *C* allele at the *Hcs3* locus. In DRH rats, the presence of *F* alleles at the *Drh1* locus has a dominant positive effect on the number of FAH (about 100% increases)[46]. These phenotypic effects of *Hcs3*/*Drh1* have been recently confirmed in a congenic DRH.F344-*Drh1* strain in which an about 43 cm segment of Drh1 from F344 rats has been introgressed onto a DRH background[32]. Above observations are consistent with a major role of *Hcs3* in the predisposition to liver cancer. It should be noted that the analysis of phenotypic effects of susceptibility/resistance loci in rats showed the presence of susceptibility loci in resistant BN rats. Given that BFF1 rats, heterozygous at all loci, are resistant to hepatocarcinogenesis[26], the behavior of backcross rats suggests the existence of inhibitory mechanisms of susceptibility genes in these animals.

Interestingly, the *Hpcr3* locus in the middle region of mouse chromosome 15 is synthetic to the rat *Hcs1*

locus which has been linked with dominant resistance to hepatocarcinogenesis in a backcross between the genetically resistant BN and the susceptible F344 rat strains[43]. Thus, it is possible that the mouse *Hpcr3* and the rat *Hcs1* locus modify hepatocarcinogenesis susceptibility by functional alleles of the same gene in both species. Moreover, both the mouse *Hpcr3* and the rat *Hcs1* regions are homologous to the human chromosome 8q region which undergoes frequent structural alterations in HCCs, including copy number gains that have been associated with tumor growth[48-50]. Consistent with these findings, the gain of chromosome 15 occurs in primary HCCs of B6C3F1 mice[51]. These findings suggest that *Hpcr3* represents a major modifier locus for hepatocarcinogenesis.

The progressive disappearance of molecular markers of preneoplastic lesions, followed by the disappearance of histological evidence of these lesions (phenotypic reversion, remodeling), during rat liver carcinogenesis, has been interpreted, at least in some instances, as re-differentiation[19,20,26-28]. The regulation of marker expression may involve the activity of various genes. We have identified in BFF2 rats' two loci, denominated liver neoplastic nodule remodeling, *Lnnr1* and *Lnnr2* whose phenotypic effect was the reduction in the percentage of remodeling lesions[52]. Due to an intensive remodeling of preneoplastic lesions in the Cop strain, more detailed information was obtained by genomic scanning of CFF2 rats, in which four *Lnnr* loci were discovered: *Lnnr3* downregulated the number of remodeling neoplastic nodule, whereas *Lnnr4* and *Lnnr5* had the opposite effect. An additional locus, on chromosome 6, *Lnnr6*, had a negative phenotypic effect on the volume of remodeling nodules[45]. These observations are consistent with a model of hepatocarcinogenesis in which only a relatively small subset of early preneoplastic lesions is genetically programmed to evolve to HCC, whereas the remainder undergoes phenotypic reversion. The importance of this phenomenon is underlined by the observation of hepatocarcinogenesis prevention by compounds inducing remodeling[20], as well as by its implication in some cases of spontaneous regression of liver nodules and carcinomas in humans[53].

The recent construction of the F344.BN-*Hcs4* RCS, by introgressing a 4.41 cm portion of Hcs4 from BN strain in an isogenic F344 background, allowed the important identification of a high penetrance gene(s), activated by estrogens and inhibited/unaffected by testosterone, conferring resistance to females towards liver cancer[54]. The volume and positivity for Proliferating Cell Nuclear Antigen (PCNA) were much higher in chemically induced preneoplastic lesions of F344 than BN rats, of both sexes. These parameters were lower in females than males. It was found that lesion volume and PCNA values of male RCS were similar to those of F344 rats, but corresponded in females to those of BN females. Carcinomatous nodules and HCC developed, at 32 and 60 wk, respectively, in male F344 and congenics and, rarely, in F344 females. Gonadectomy of congenic males, followed by β-estradiol administration, caused decrease in *Ar* (Androgen receptor) gene expression, increase in *Er-α* (Estrogen receptor-α) expression, and development of preneoplastic lesions comparable to those from BN females. Administration of testosterone to gonadectomized females leads to *Ar* increase and development of preneoplastic lesions as in F344 males. This indicates a role of homozygous *B* alleles at *Hcs4* in determination of phenotypic patterns of female RCS.

Research on rodent models of liver cancer have clearly shown a model-based on the polygenic inheritance of low penetrance genes with a few predominant susceptibility/resistance loci. Furthermore, the study of epistatic interactions between microsatellite loci, inducing phenotypic effects not predictable on the basis of the sum of their separate effect, resulted in the identification of several novel tumor modifier loci in rats, indicating that gene-gene interactions have a major role in hepatocarci nogenesis[25]. We can envisage the existence of different subsets of low-penetrance genes at play in different subsets of population.

Overall, these findings prove the existence of a great complexity of the inherited predisposition to liver cancer. A complex combination and interplay of susceptibility or resistance alleles determines the individual risk. Some individuals may inherit a predominance of susceptibility alleles and/or a major allele and may be highly cancer prone. However, since human individuals are generally casually assorted, independently of genetic factors, a situation of high or low genetic risk should be rare, and most humans should be at average risk. A corollary of this situation is that the effect of polygenic inheritance can be masked by a predominant presence of environmental high risk factors. Nevertheless, taking into account the effect of susceptibility/resistance genes on the proliferative activity and re-differentiation of initiated cells, it may be expected that the genetic substrate largely influences the prognosis.

PUTATIVE TARGETS OF SUSCEPTIBILITY/RESISTANCE GENES

Cell cycle deregulation

The deregulation of signal transduction pathways, cell cycle control, and genes involved in cell death signals characterizes initiated cells and influences their evolution to malignancy[1-3,15]. Several genes implicated in these activities, in mouse and rats, can be targeted by the susceptibility/resistance genes. This mechanism could be responsible for the acquisition of a phenotype susceptible or resistant to HCC development.

According to recent evidence HCCs developing in c-*Myc* transgenic mice undergo sustained regression, associated with re-differentiation of tumor cells, following inactivation of c-*Myc* transgene expression[55]. The re-differentiation is not terminal, and tumor growth starts again after restoration of c-*Myc* expression. These results, linking re-differentiation of tumor cells to the expression of c-*Myc*, a gene located at *Lnnr1*[52], are in keeping with the observation that

inhibition of c-*Myc* expression by antisense strategy contributes to the deregulation of E2f1 expression, and blocks *in vitro* growth of human and rat HCC cells[56]. In addition, *in vivo* studies have shown c-*Myc* hypomethylation in preneoplastic and neoplastic rat liver lesions[57]. The decrease in c-*Myc* expression, induced by prolonged administration of the methyl donor S-adenosylmethionine to rats, is associated with growth restraint and re-differentiation of liver lesions[20,57,58]. No differences in c-*Myc* expression occur in the liver of normal F344 and BN rats[56,58,59]. However, the expression of this gene is much higher in preneoplastic and neoplastic lesions of F344 rats than in the lesions of BN rats[56,58,59]. c-*Myc* is frequently amplified in preneoplastic and neoplastic lesions of the susceptible strain, but not in the lesions of the resistant BN and Wistar strains[60]. Taken together, these observations suggest the existence of some connections between c-*Myc* and the susceptibility genes that regulate re-differentiation.

Since c-*Myc* regulates the pRb-E2F pathway, we evaluated cell cycle gene expression in neoplastic nodules and HCCs, induced by initiation/selection protocols, 40 and 70 wk after diethylnitrosamine treatment, in susceptible F344 rats, and resistant Wistar and BN rats[59]. No interstrain differences in gene expression were observed in normal livers. Overexpression of c-*Myc*, *Cyclins D1*, *E*, and *A*, and *E2f1* genes, at mRNA and protein levels, rise in Cyclin D1-Cyclin-dependent kinase 4 (CDK4), Cyclin E-CDK2 and E2f1-DP1 complexes, and pRb hyperphosphorylation occurred in nodules and HCCs of F344 rats. In nodules and/or HCCs of Wistar and BN rats, low or no increases in c-*Myc*, *Cyclins D1*, *E*, and *A*, and *E2f1* expression, and Cyclin-CDKs complexes formation were associated with pRb hypophosphorylation. These results are consistent with a deregulation of the G1 and S phases in liver lesions of susceptible rats, and a block of G1-S transition in lesions of resistant strains, which explains their low progression capacity.

Autonomously growing preneoplastic liver nodules develop in susceptible rat strains, initiated by diethylnitrosamine and subjected to the initiation/selection treatments of the "resistant hepatocyte" protocol, after the cessation (about 6 wk after initiation) of the promotion stimulus represented by partial hepatectomy[19,20,61]. In contrast, only very few preneoplastic lesions of resistant BN rats grow autonomously after the end of the promoting stage; the majority of lesions remodel or no further evolve to neoplasia[61]. To evaluate the molecular mechanisms underlying the appearance of the resistant phenotype in BN rats[61], the behavior of the *p16*^{INK4A} and some genes regulating cell cycle inhibition by p16^{INK4A} have been analyzed. Preneoplastic liver (7 wk after initiation), neoplastic nodules (32 wk) and HCC (57 wk) showed high *p16*^{INK4A} expression at mRNA and protein levels, in both F344 and BN rat strains. This was associated with increase in the expression of Heat shock protein 90 (Hsp90) and Cell division cycle 37 (Cdc37) protein,

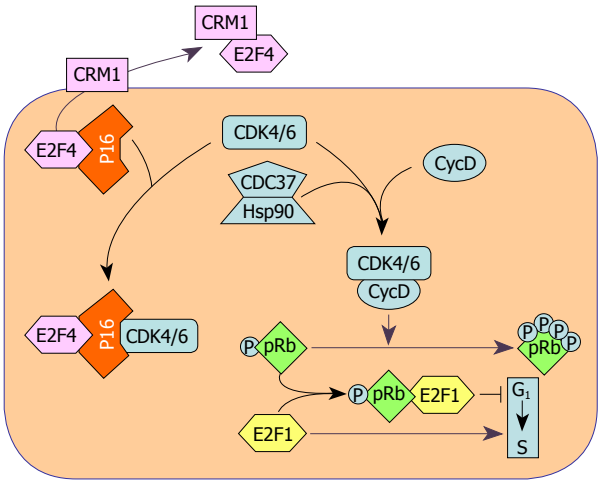

Figure 1 Cell cycle protection from inhibition by P16^{INK4A} through the CDC37-HSP90 complex and CRM1 transporter protein. P16^{INK4A} forms complexes with CDK4 and CDK6 which, as a consequence, cannot by activated by Cyclin D1 and cannot phosphorylate pRb. The chaperons CDC37 and HSP90 form complexes with CDKs protecting them from inactivation by P16^{INK4A}. CRM1 forms a complex with E2F4, a P16^{INK4A} effector, transporting it outside of the nucleus, thus inactivating P16^{INK4A}.

and Cdc37-Cdk4 complex. The HSP90-CDC37 complex protects several kinases, including Cdk4 and Cdk6 from the formation of inhibitory complexes with p16^{INK4A}[62-64] (Figure 1). Consequently, the increase in Cdc37-Cdk4 complex resulted in a decrease in p16^{INK4A}-Cdk4 complex in the lesions of F344 rats, whereas lower/no changes occurred in BN rats[61].

The transcription factor E2f4, is a p16^{INK4A} effector, acting as a growth repressor[65], equally expressed in the lesions of both F344 and BN rats. Required for chromosome region maintenance 1 protein (Crm1) is a receptor for various proteins containing a specific nuclear export sequence, including E2f4[66]. Crm1 and the cytoplasmic E2f4-Crm1 complex are highest in preneoplastic and neoplastic lesions of F344 rats. This indicates more elevated nuclear E2f4 efflux in the susceptible rats leading to a decrease in the interaction of p16^{INK4A} with G1 kinases (Figure 1). Furthermore, lower P16^{INK4A} level and highest upregulation of the HSP90/CDC37, and E2F4/CRM1 systems occur in human HCCs with a poorer prognosis (HCCP), based on survival rate, compared to HCCs with a better prognosis (HCCB)[61]. Accordingly, the P16^{INK4A}-CDK4 complex is higher in HCCB than in HCCP, whereas the complexes of CDK4 with HSP90 and CDC37 are higher in HCCP than in HCCB. Consistent with a protective role of CDC37 against growth inhibition is the observation that a decrease in its expression, induced by specific siRNAs, leads to inhibition of DNA synthesis in HepG2 cells, without modifying P16^{INK4A} expression[61]. This suggests that *CDC37* could be a target for HCC chemoprevention and therapy. These findings underline the role of the Hsp90/Cdc37 and E2f4/Crm1 systems in the acquisition of a susceptible or resistant phenotype in rats and suggest that the protection by CDC37 and CRM1 against cell cycle inhibition by P16^{INK4A} may influence the prognosis

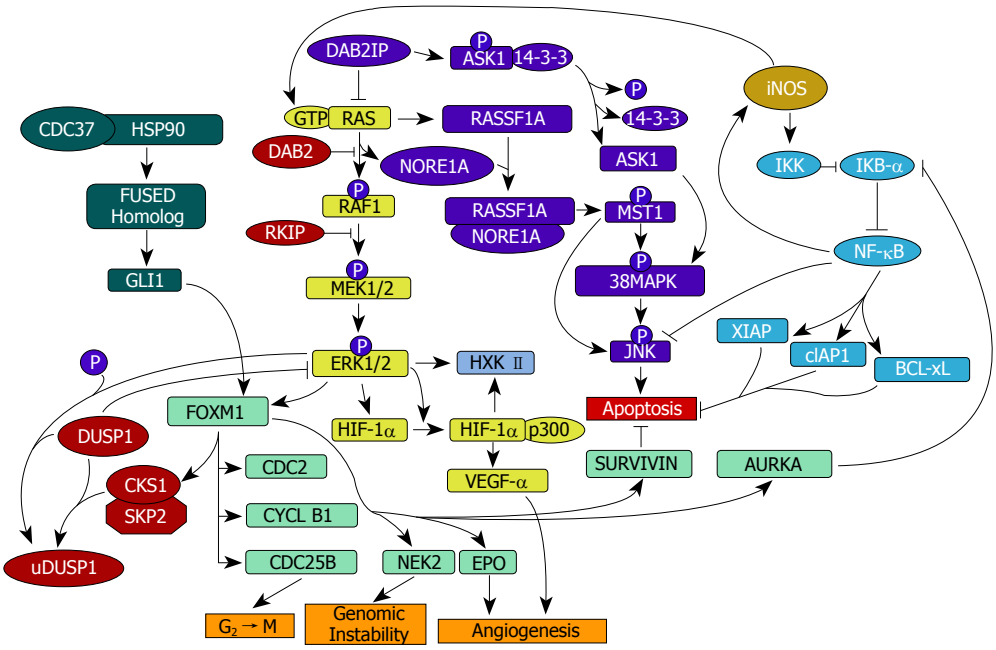

Figure 2 Schematic representations of the activated RAS-MAPK, RASSF1A/NORE1A, and Dab2IP/ASK1 pathways, iNOS signalling, and FOXM1-related pathways involved in the dysregulation of cell growth and apoptosis in HCC. Active Ha-RAS (GTP-RAS) triggers the MAPK pathway leading to activation of ERK1/2. Active ERK can down-regulate DUSP1 by phosphorylation at ser296 allowing the formation of the SKP2/CSK1/DUSP1 complex, which facilitates DUSP1 ubiquitination and proteasomal degradation. In addition, ERK may further contribute to DUSP1 proteolysis *via* induction of its target FOXM1, leading to transcriptional activation of *SKP2* and *CKS1*. These mechanisms result in decreased inhibition of ERK by DUSP1 (blunt arrow). Moreover, FOXM1 favors the growth of neoplastic cells by targeting genes involved in $G_2 \rightarrow M$ transition, genomic instability, angiogenesis, NF-κB activation, and anti-apoptosis. iNOS activates IKK that allows proteasomal degradation of the NF-κB inhibitor, IkB-α. This results in NF-κB activation. iNOS also activates Ha-RAS, thus triggering the MAPK pathway leading to activation of ERK1/2. NF-κB activation by ERK may occur through AURORA-A (AURKA) which inhibits IkB-α. NF-κB activates various antiapoptotic genes (*XIAP*, *cIAP1*, *BCL-xL*) and inhibits the proapoptotic gene *JNK*. The inhibition of RAS activation by DAB2IP leads to the activation of ASK1, whereas active RAS favors the formation of the RASSF1-NORE1A complex. Both the ASK1 and RASSF1-NORE1A complexes trigger pro-apoptotic pathways. ASK1: Apoptosis signal-regulating kinase 1; BCL-Xl: BCL2-related protein, long isoform; CDC37: Cell division cycle 37; CKS1: CDC28 protein kinase 1b; cIAP: Iinhibitor-of-apoptosis protein 1; DAB2: Disabled homolog 2; DAB2IP: DAB2-interacting protein; DUSP1: Dual-specificity phosphatase 1; EPO: Erythropoietin; ERK: Extracellular signal-regulated kinase; GLI1: Glioblastoma associated oncogene 1; HIF-1α: Hypoxia-inducible factor 1 α; HSP90: Heat shock protein 90; HXK Ⅱ: Hexokinase Ⅱ; IKK: Inhibitor of kB kinase; iNOS: Inducible nitric oxide synthase; MST1: Mammalian sterile twenty kinase 1; NEK2: NIMA-related kinase 2; NF-κB: Nuclear factor-κB; NORE1A: Novel RAS effector 1A; RASSF1A: RAS association domain family 1A; RKIP: RAF kinase inhibitory protein; SKP2: S-phase kinase-associated protein 2; VEGF-α: Vascular endothelial growth factor α; XIAP: Inhibitor of apoptosis, X-linked. Pointed and blunt arrows indicate activation and inhibition, respectively.

of human HCC.

Overall, these observations indicate that susceptible F344 rats develop various adaptive mechanisms for protection against stress-responsive tumor suppressors, such as $p16^{INK4A}$, that confer to their liver cells the ability to proliferate under stressful conditions, such as hypoxia, oxidative stress, DNA damage, abnormal conditions of growth and differentiation, inappropriate extracellular matrix, and improper cell-to-cell contracts. In the resistant BN strain, a shut off of these mechanisms, associated with cell cycle deregulation and growth inhibition, occurs in coincidence with the exhaustion of promoting stimuli.

Mitogen activated protein kinase pathway

The best characterized *RAS* effector promoting cell cycle progression is the mitogen activated protein kinase (MAPK) pathway[67] (Figure 2). Active RAS (RAS-GTP) drives the RAF1-MAPK kinase kinase 1/2 (MEK1/2)-extracellular signal-regulated kinase 1/2 (ERK1/2) cascade which mediates proliferative and survival signals and, through the binding to RAS association domain family 1A (RASSF1A) and the related protein Novel RAS effector 1A (NORE1A), may induce apoptosis[68,69]. RASSF1A and NORE1A are members of the RASSF family of *RAS* inhibitors and form homo- and hetero-dimers, which activate the mammalian sterile twenty kinase 1 (MST1 kinase), an upstream effector of the p38MAPK and JNK pathways[67-72]. Following activation, phosphorylated MST1 induces apoptosis *via* caspase-dependent and -independent mechanisms[60-72]. Furthermore, RASSF1A may inhibit the ERK pathway by its association with the plasma membrane calcium pump (PMCA) 4b protein[73]. Finally, p38MAPK may be also activated by Disabled homolog 2 (DAB2)-interacting protein (DAB2IP), a RAS-GTP inhibitor, *via* activation of Apoptosis signal-regulating kinase 1 (ASK1), which phosphorylates p38MAPK[74].

Studies on the role of the inhibitors of RAS/ERK pathway in the acquisition of a phenotype resistant or susceptible to hepatocarcinogenesis, showed moderate activation of Ras, Raf1, and Mek1/2 proteins, paralleled by strong induction of Dab2 and Raf kinase inhibitory protein (Rkip) inhibitors, in neoplastic nodules and HCC of both F344 and BN rats, induced by the "resistant hepatocyte" protocol[31]. This is compatible with the limitation of Ras-GTP-mediated activation of Raf1

due to the upregulation of the Raf1 inhibitor, Dab2[31,75] (Figure 2). Indeed, in the lesions developed in the resistant BN strain, lower Dab2 expression is associated with relatively low Ras-GTP and Raf1 expression and, consequently, low pRaf1 level[31]. Presumably, similar mechanisms may be envisaged for the inhibitory effect of Rkip1 on Mek activation[76] and determine the absence of interstrain differences in pMek1/2 expression[31]. However, the possibility that other phosphatases interfere with Raf and Mek activation, during rat liver carcinogenesis, cannot be excluded and should be the object of further research.

High levels of Dual-specificity phosphatase 1 (Dusp1), a specific Erk inhibitor (Figure 2), may be found only in neoplastic nodules and HCC of the resistant BN rat lesions, leading to modest Erk activation, whereas a progressive Dusp1 decline occurs in corresponding lesions from susceptible F344 rats and is accompanied by elevated Erk activation[31]. Interestingly, Dusp1 is slightly upregulated in preneoplastic liver of both F344 and BN strain, but its level progressively decreases in early liver nodules (12 wk after initiation), as well as in neoplastic nodules and HCC of F344 rats[31], i.e. in coincidence with the development of autonomously growing lesions in susceptible rats[25,61]. In contrast, Dusp1 further increases in the lesions of BN rats after the 12th week. This suggests that even in the presence of a limited increase in the levels of upstream activators (Raf1, Mek1/2) of Erk1/2, a failure of Dusp1 induction might sustain Erk1/2 activation and contributes to the development of autonomously growing liver lesions in F344 rats. This conclusion is further substantiated by the observed overexpression of pErk1/2 target genes, such as *Hif1-α* (hypoxia-inducible factor 1α) and *Vegf-α* (Vascular endothelial growth factor α), regulating angiogenesis, and *Hxk II*[31] (Hexokinase Ⅱ). The latter gene is a key glycolytic enzyme whose expression is correlated with *Hif1-α* mRNA, and may promote HCC development by different mechanisms, including enhanced energy production, overproduction of antiapoptotic enzymes and metabolic precursors for cell growth[77]. In BN rats, progressive increases in Dusp1 expression in preneoplastic and neoplastic lesions is associated with low expression of pErk1/2 and its target genes. This could contribute to the low propensity of BN rat lesions to progress.

The mechanisms underlying the effect of susceptibility genes on the deregulation of the inhibitors of Ras/Erk cascade in rat hepatocarcinogenesis are not yet completely known. The progressive rise in expression of the inhibitors of Ras/Erk pathway, including Dab2 and Rkip, in preneoplastic and neoplastic liver lesions of F344 rats, suggests a compensatory mechanism controlling (at least in part) Ras-GTP, pRaf1, and pMek1/2 upregulation in this rat model. Sustained Erk activation in F344 nodules and HCC promotes the phosphorylation of Dusp1 at the ser296 residue. This is followed by proteasomal degradation of Dusp1[78,79] (see below) and enhancement of Erk-driven HCC growth. The presence of *Dusp1* overexpression in late lesions of BN rats speaks in favor of a possible low proteasomal disruption of Dusp1 protein, thus resulting in a further inhibition of pErk1/2. These findings support the hypothesis that *Dusp1* is at least one of the genes involved in the acquisition of a resistant phenotype. Interestingly, *Dusp1* co-localizes with the resistance locus *Hcr1* on chromosome 10, in correspondence of the LOD score peak, a region frequently affected by loss of heterozygosis (LOH) during rat hepatocarcinogenesis[80]. Nevertheless, the existence of localization and functional plausibility does not prove *per se* that *Dusp1* is a hepatocarcinogenesis "modifier" gene[25]. *Dusp1* could be indeed controlled by modifiers of hepatocarcinogenesis. In accordance with the latter statement, the absence of functional polymorphisms at the *Dusp1* in F344 and BN rat liver tissues as detected by DNA sequencing (Feo *et al*, unpublished data) speaks against a role of *Dusp1* as a tumor modifier gene. Further work is necessary to clarify this point.

A gradual increase of Rassf1A/Nore1A/Mst1-driven apoptosis has been detected in HCC of both F344 and BN strains, with highest levels in BN HCC, whereas loss of Dab2IP (Figure 2) occurs only in F344 rat HCC[31]. These changes are associated with significantly higher apoptosis in BN than F344 HCC. Taken together, these results indicate a control of the Ras/Erk pathway, as well as of the pro-apoptotic Rassf1A/Nore1A and Dab2IP/Ask1 pathways by HCC susceptibility genes. Dusp1 possesses a prominent role in the acquisition of the phenotype resistant to HCC by BN rats, whereas late activation of RassF1A/Nore1A and Dab2IP/Ask1 axes is implicated in the highest apoptosis characteristic of BN HCC[31].

Sustained ERK activity is associated with various types of human tumors, including lung, breast, colon, pancreas, and kidney[81-83]. This frequently depends on upregulation of the RAS/MEK cascade. However, constitutive ERK overexpression may also occur independently of the RAS/MEK signaling[84,85]. Recent studies[86] indicate that prolonged activation of ERK promotes phosphorylation at the Ser296 residue of DUSP1. Phosphorylation of this specific residue renders the DUSP1 protein susceptible to ubiquitination and proteasomal degradation by the Skp1/Cul1/F-box protein SKP2 (SCFSKP2)[79]. On the other hand, constitutive ERK expression may induce SKP2/CSK1 ubiquitin ligase which can phosphorylate DUSP1 and determine its ubiquitination (Figure 2). This mechanism, which contributes to maintain elevated ERK expression, could be at least partially attributed to induction by ERK of the *FOXM1* (Forkhead box M1B)[86,87] (Figure 2) which, in turn, upregulates the SKP2/CSK1 ligase[88]. It should be noted, however, that transient activation of ERK induces the catalytic activation of DUSP1, followed by inactivation of ERK[87,88]. This body of evidence indicates that DUSP1 feedback inhibits its activation by ERK and that DUSP1 might be a crucial regulator of ERK activity in the cell. DUSP1 inactivation is frequent in prostate and urothelial tumors[89,90], and recent observations indicate that immunohistochemical

positivity for DUSP1 in human HCC is associated with longer patients' survival[91].

The interactions of DUSP1 with CKS1-SKP2 ubiquitin ligase have been recently evaluated in human HCC subtypes with different survival times, in the attempt to correlate the effects of DUSP1 molecular interactions with tumor growth and patients' survival, and explore DUSP1 prognostic role[92]. It was found that the levels of DUSP1 are significantly higher in HCCB when compared with both normal and non-tumorous surrounding livers, whereas DUSP1 protein expression sharply declines in HCCP[92]. In the latter subtype, DUSP1 inactivation is due to either ERK/CKS1/SKP2-dependent ubiquitination or promoter hypermethylation associated with loss of heterozygosity at the DUSP1 locus. Notably, expression levels of DUSP1 inversely correlate with those of activated ERK as well as with HCC proliferation index and microvessel density, and directly correlate with HCC apoptosis and patients' survival rate. Functional studies revealed that DUSP1 reactivation leads to suppression of ERK, CKS1 and SKP2 activities, inhibition of proliferation and induction of apoptosis in human hepatoma cell lines. Taken together, these data indicate that ERK achieves unrestrained activity during HCC progression by triggering ubiquitin-mediated proteolysis of its specific inhibitor DUSP1. Thus, DUSP1 may represent a valuable prognostic marker and ERK, CKS1 or SKP2 potential therapeutic targets for human HCC.

FOXM1: A pleiotropic regulator of hepatocarcinogenesis

FOXM1 transcription factor is a major downstream effector of ERK whose overexpression occurs in various experimental and human tumors[93,94]. FOXM1 promotes cell proliferation through its ability to influence various cell cycle phases. Indeed, FOXM1 triggers the activation of SKP2/CKS1 ubiquitin ligase, which targets $P21^{WAF1}$, $P27^{KIP1}$ and $P57^{KIP2}$ proteins for degradation during the G1-S transition[93-98] (Figure 2). Furthermore, FOXM1 induces transcription of genes promoting cell cycle progression (*AURKA*, *CDC2*, *CYCLIN B1*, *NEK2*, and *CDC25B*), genomic instability generators (*NEK2*, *CDC25B*), suppressors of cell cycle inhibitors (*SKP2*, *CKS1*), and apoptosis inhibitors (*SURVIVIN*)[93-97]. In the mouse liver, Foxm1 depletion results in block of proliferation and resistance to hep atocarcinogenesis[98-102]. Recently, the role of *FOXM1* during hepatocarcinogenesis has been studied in both, the susceptible/resistant comparative rat model and the human HCC (Feo *et al*, unpublished results). Activation of Foxm1 and its targets (*AurkA*, *Cdc2*, *Cyclin* B1, *Nek2*) occurs earlier and is most pronounced in liver lesions from F344 than BN rats, leading to highest Cdc2-Cyclin B1 complexes (implying highest G2-M transition) in F344 rats. In humans, FOXM1 is ubiquitously and progressively induced from surrounding non-tumorous liver to HCC, reaching highest levels in tumors with poorer prognosis and its expression levels directly correlate with proliferation index, genomic instability rate, and microvessel density, and inversely correlate with apoptosis. Interestingly, the strong correlation between FOXM1 levels and both genomic instability rate and adverse outcome in HCC agrees with the existence of a molecular signature, including *FOXM1* overexpression, which is significantly associated with degree of genomic instability and accurately predicts patients survival in multiple tumors[87,103,104].

Some reports showed *FOXM1* upregulation following either ERK or Glioblastoma associated oncogene 1 (*GLI1*) induction[105-107] (Figure 2). FOXM1 is a direct transcriptional target of *GLI1*[105,106]. GLI family proteins, including GLI1, 2, and 3, are the terminal effectors of the Hedgehog signaling[107,108]. The interaction of Sonic hedgehog (SHH) with its plasmamembrane receptor PTCH1, releases PTCH-induced inhibition of the membrane protein Smoothened (SMO). This results in GLI proteins activation and nuclear translocation, where they activate target gene transcription[109]. According to recent observations GLI2 is overexpressed in some HCC cell lines, and its inhibition by antisense oligonucleotides inhibits cell proliferation[110]. GLI1 overexpression occurs in a lower number of HCC cell lines and its inhibition causes lower decrease in growth rate[110].

High levels of phosphorylated ERK1/2 (pERK1/2) and Gli1 proteins occur in neoplastic nodules and HCC induced by the resistant hepatocyte protocol in F344 rats and, at a lower extent, in BN rats (Feo *et al*, unpublished results). Furthermore, pERK1/2 and GLI1 expression are higher in human HCC than normal and non-neoplastic surrounding livers, and most pronounced in HCCP. Silencing of either *ERK2* or *GLI1 via* siRNA in human HCC cell lines, leads to strong decreases in FOXM1 levels, whereas forced *ERK2* or *GLI1* overexpression results in a remarkable elevated rise in FOXM1 level[107]. These findings suggest a reciprocal activation of *ERK2* and *GLI1*, but the mechanisms underlying this phenomenon and its role in the activation of Hedgehog signaling are unclear and require further investigation.

Interestingly, a recent report implies the combined overexpression of HSP90 and CDC37 in sustaining elevated Fused Homolog expression[111]. Accordingly, a previous report from our laboratory showed a strong induction of HSP90 and CDC37 in F344 rat liver lesions and human HCCP[61]. Thus, it might be hypothesized a role of HSP90 and CDC37 combined activity in the highest activation of GLI1 observed in F344 neoplastic lesions and human HCCP.

The observation that FOXM1 induces SKP2 and CKS1 expression, involved in DUSP1 degradation, underlines the role of FOXM1 in the active proliferation of HCC cells, though its implication in a positive feedback loop reinforcing ERK cascade, by its ability to inhibit DUSP1[78] (Figure 2).

Inducible nitric oxide synthase signaling

Inducible nitric oxide synthase (iNOS) produces sustained nitric oxide (NO) concentrations in response to pro-inflammatory agents. NO is a major mediator of

chronic inflammation and may modulate tumorigenesis by regulating cell proliferation, survival, and migration, angiogenesis, drug resistance, and DNA repair[112,113]. In particular, iNOS might promote unrestrained cell growth *via* its ability to inactivate the retinoblastoma (pRb) pathway[114]. Some observations envisage a cross talk between iNOS and inhibitor of kB kinase (IKK)/ nuclear factor-κB (NF-κB) and RAS/ERK pathways. The Ikk and NF-κB activities are strongly reduced in *iNos* knockout mice[115]. NO activates Ha-RAS/ERK pathway in T lymphocytes[116]. Phosphorylated ERK activates iNos in melanoma[117] and *NF-κB* in HeLa cells[118].

iNOS, NF-κB, RAS, and ERK are upregulated in preneoplastic rat liver lesions[119], dysplastic and neoplastic liver from c-Myc/TGF-α transgenic mice[120], and human HCCs[121,122], and elevated NO plasma levels are present in patients with cirrhosis and HCC[123]. A recent analysis of iNos function and interactions with NF-κB and Ha-RAS/ERK signalling was performed during hepatocarcinogenesis in F344 and BN rats, possessing different genetic predisposition to HCC, and TGF-α and c-Myc-TGF-α transgenic mice, characterized by different susceptibility to HCC[124]. iNos upregulation was found always at higher levels in the most aggressive preneoplastic and neoplastic liver lesions of F344 rats and c-Myc-TGF-α transgenic mice. Moreover, the determination of iNOS expression in human HCC shows highest values in HCC with poorer prognosis[124]. The suppression of iNOS signaling by Aminoguanidine[125] in c-Myc/Tgf-α mice and human HCC cell lines results in decreased HCC growth and NF-κB and RAS/ERK expression, and increased apoptosis[124]. In contrast, NO production by Glyco-S-nitroso-N-acetyl penicillamine 2 (Glyco-Snap-2) inhibits apoptosis of *in vitro* growing human HCC cells. Conversely, the block of NF-κB signalling by Sulfasalazine[126] or siRNA, or ERK signaling by the MEK inhibitor UO126[127] causes iNOS downregulation in HCC cell lines. In transgenic mice and human HCC cell lines, iNOS anti-apoptotic effect seems to be mediated by the NF-κB cascade. The latter induces various antiapoptotic proteins, such as BCL2-related protein, long isoform (BCL-xL), Inhibitor of apoptosis, X-linked (XIAP), and Inhibitor-of-apoptosis protein 1 (cIAP1), and inhibits the proapoptotic pJNK[124]. Accordingly, iNOS suppression by Aminoguanidine triggers downregulation of NF-κB and antiapoptotic proteins, and upregulation of pJNK, in c-Myc/TGF-α and HCC cell lines. However, these findings cannot exclude the contribution of other mechanisms to the antiapoptotic action of iNOS.

Above results assign a role to iNOS upregulation in the control of the proliferative phenotype of preneoplastic and neoplastic liver cells through the activation of the IKK/NF-κB axis (Figure 2). They also imply a cross-talk between iNOS and Ha-RAS/ERK. The mechanism of NF-κB regulation by pERK1/2 is not fully understood. Recent observations show that pERK1/2 activates *AURORA-A* (AURKA), which in turn may activate NF-κB through Inhibitor of kB (IKB-α) inhibition[128]. The possibility that pERK1/2 contributes to NF-κB upregulation *via* direct activation of iNOS may also be taken into account, but requires experimental support.

The observation that the expression of iNOS and its downstream targets is highest in HCCs prone to progression both in rodents and humans, and that iNOS levels are directly correlated with genomic instability, proliferation rate and microvessel density of HCC, and inversely correlated with apoptosis and patients' survival[124], suggests that iNOS upregulation and changes in iNOS/NF-κB and iNOS/Ha-RAS/ERK cross-talks are prognostic markers for HCC. These results agree with the observation of a significant association of iNOS and Metalloproteinase-9 expression with HCC recurrence[121], and iNOS overexpression with poor prognosis for gastric cancer[129], adenoid cystic carcinoma of salivary glands[130], fibrous histiocytoma[131], colorectal cancer[132]. These iNOS effects seem to be mediated by its angiogenic properties and intensified by Cycloxygenase 2 (COX2) upregulation[133]. However, no correlation of iNOS overexpression with prognosis has been reported for pancreatic and ovarian tumors[134,135]. Furthermore, iNos ablation did not prevent hepatocarcinogenesis induced by a choline-deficient, L-aminoacid-deficient diet in mice[136], suggesting a relatively minor role of iNOS signaling. In this model of hepatocarcinogenesis, high production of lipid peroxides in hepatocyte nuclei[137] may cause DNA damage and contribute to HCC development *via* generation of genomic instability in an iNOS-independent manner.

In conclusion, iNOS overexpression contributes to growth deregulation in preneoplastic and neoplastic liver cells through a cross-talk with Ha-RAS/ERK and IKK-NF-κB axis. This does not exclude *per se* the activation of iNOS signaling by other mechanisms, such as inflammatory cytokines or the Wnt/β-catenin signaling[138]. However, the role of Wnt/β-catenin signaling in iNOS upregulation seems to be unlikely due to the observation of equal β-catenin activation (nuclear localization) in HCCs from both F344 and BN rats (M. Frau, unpublished data) expressing sharply different *iNos* mRNA levels. β-Catenin activation also occurs in a lower percentage of HCC cells from c-Myc/TGF-α than TGF-α transgenics (12% *vs* 30%)[139]. The highest iNos expression occurs in HCC from double transgenic mice.

The association of the block of iNOS signaling by a specific inhibitor such as Aminoguanidine with a consistent decrease in HCC growth and increase in apoptosis *in vitro* indicates that the key component of this pathway could represent therapeutic targets that may contribute to create networked biological therapies[140]. Thus, determination of iNOS immunoreactivity status can be proposed as a promising candidate for the identification of high risk patients who may benefit from new anticancer drugs targeting iNOS and its interplay with IKK/NF-κB and Ha-RAS/ERK signalling.

CONCLUSION

Studies on mouse and rat models of hepatocarcinogenesis have shown the existence of a great complexity of the inherited predisposition to liver cancer, and support a model based on the polygenic inheritance of low penetrance genes, with several gene-gene interactions and a main susceptibility locus (i.e. *Hcs7*, *Hpcr3* for mice, and *Hcs3*/*Hcr5* for rats)[25]. A complex combination and interplay of susceptibility or resistance alleles determines the individual risk. It has been proposed that the polymorphic variants of these "cancer modifier" genes can foster phenotypic expression of previously unexpressed alleles with consequent positive or negative influences on cell growth and differentiation[25]. Thus, the type of influence of modifiers on the carcinogenesis process may largely depend on interindividual differences in gene polymorphism, gene-gene interactions and gene-environment interactions. Epidemiologic and segregation studies strongly suggest a similar genetic model for the inherited predisposition to human HCC[11-14]. Taking into account the effect of susceptibility/resistance genes on the proliferative activity and re-differentiation of initiated cells, it may be expected that the genetic substrate largely influences the prognosis.

The mechanisms underlying the acquisition of the resistant phenotype have not been completely defined, as yet. A lower genomic instability of liver lesions developing in the resistant animals compared to the susceptible strains has been documented[80,141,142]. This may be tentatively attributed to interstrain differences in the activity of care taker and DNA repair genes, resulting in the prevention of the accumulation of DNA damage by initiated cells of the resistant rat strains. This hypothesis, however, needs experimental support. Nevertheless, accumulating evidence indicates that the predominance of susceptibility or resistance genes in individuals can largely influence the molecular control of cell proliferation and cell death. The susceptible rats develop various adaptive mechanisms for protection against stress-responsive tumor suppressors, such as $p16^{INK4A}$, that confer to their liver cells the ability to proliferate under stressful conditions. In the resistant BN strain, a shut off of these mechanisms, associated with strong cell cycle deregulation and growth inhibition, occurs in coincidence with the exhaustion of promoting stimuli.

Among the effectors promoting cell cycle progression, ERK achieves unrestrained activity during HCC progression by triggering ubiquitin-mediated proteolysis of its specific inhibitor DUSP1. This mechanism is much more active in neoplastic nodules and HCC of susceptible rats than in the lesions of the resistant rats. The observation that FOXM1 induces the expression of CKS1-SKP2 ligase, involved in DUSP1 degradation, underlines the role of FOXM1 in the active proliferation of HCC cells, though its implication in a positive feedback loop reinforcing ERK cascade, by its ability to inhibit DUSP1[77]. These data indicate that FOXM1 upregulation is associated with the acquisition of a susceptible phenotype in rats and may influence human HCC development and prognosis. A role in the control of the proliferative phenotype of preneoplastic and neoplastic liver cells has been also assigned to higher iNos upregulation, inducing higher activation of the IKK/NF-κB and Ha-RAS/ERK signaling, in neoplastic nodules and HCCs of susceptible than resistant rats[124]. In the latter rats, HCC growth is also contrasted by relatively high cell death by apoptosis, which, at least in part depends on the activation of pro-apoptotic Rassf1A/Nore1A and Dab2IP/Ask1 pathways. Thus, Dusp1 possesses a prominent role in the acquisition by BN rats of a phenotype resistant to HCC. Late activation of RassF1A/Nore1A and Dab2IP/Ask1 axes is implicated in the highest apoptosis of BN HCC.

Importantly, most of the alterations responsible for the acquisition of a resistant or susceptible phenotype by rats have also been found in human HCC with better of poorer prognosis. A link between fast growth and signaling deregulation characterizes human HCC with poor prognosis, whereas the behaviour of HCC with better prognosis is more similar to that of the lesions of resistant rats. This does not necessarily imply a genetic regulation of signaling pathways in humans like that found in rodents. Further studies are needed to clarify the influence of susceptibility genes on signaling pathways supporting tumor growth and progression in humans.

The study of signal transduction pathways in rats differently predisposed to HCC development and prone to HCC progression, allowed the identification of numerous potential prognostic markers of hepatocarcinogenesis, such as the cell cycle protective mechanisms against $p16^{INK4A}$, represented by CDC37-HSP90 complex and CRM1 protein, the ERK inhibitor DUSP1, iNOS, FOXM1. The prognostic role of these proteins was confirmed by analyzing the correlation of their expression with clinicopathological parameters of human HCC[91,124]. They therefore represent promising candidates for the identification of high risk patients who may benefit from new anticancer drugs against key components of signaling pathways.

Future work should focus on HCC prevention obtained by blocking key compounds of signal transduction network. Early blockage of signaling pathways may result in more efficient prevention, and rodent models may be useful to identify progression markers and therapeutic targets in early stages of the process, and in a large number of HCC subtypes. The study of experimental models recapitulating early preneoplastic alterations of human liver carcinogenesis may lead to the discovery of biomarkers of the risk of cirrhosis evolution to full malignancy, as well as of new key genes and signal transduction pathways involved in hepatocarcinogenesis. The existence of numerous interspecies commonalties in the biological behaviour and molecular changes of preneoplastic and neoplastic liver lesions[1-3,15,25] underlines the usefulness of this approach. The complexity of molecular changes of HCC predicts the impossibility to cure HCC

development by interfering with only one signaling pathway. To overcome this difficulty and the occurrence of resistance to therapy, networked biologic therapies have been proposed[140,143,144] in which a combination of non-cytotoxic interventions must be performed to interrupt the damage. These interventions may be directed to interfere with different cell survival pathways, enhance apoptosis, block angiogenesis and extrahepatic fibrosis, induce the lysis of tumor cells, stimulate antitumor immunity, decrease HBV and HCV replication, *etc*. Furthermore, the combination of gene therapy with conventional therapeutic approaches with cytotoxic drugs may improve the treatment and reduce the doses of toxic compounds.

Abstract

The disposition of most drugs is highly dependent on specialized transporters. OAT1 and OAT3 are two organic anion transporters expressed in the basolateral membrane of renal proximal tubule cells, identified as contributors to xenobiotic and endogenous organic anion secretion. It is well known that cholestasis may cause renal damage. Impairment of kidney function produces modifications in the renal elimination of drugs. Recent studies have demonstrated that the renal abundance of OAT1 and OAT3 plays an important role in the renal elimination of organic anions in the presence of extrahepatic cholestasis. Time elapsed after obstructive cholestasis has an important impact on the regulation of both types of organic anion transporters. The renal expression of OAT1 and OAT3 should be taken into account in order to improve pharmacotherapeutic efficacy and to prevent drug toxicity during the onset of this hepatic disease.

INTRODUCTION

Pharmacotherapeutic efficacy and toxicity are governed by pharmacodynamic and pharmacokinetic factors. The ability of a drug to reach its site of action is dependent on absorption, distribution, metabolism and excretion, all of which are intimately related to transport mechanisms in barrier epithelia. The majority of drugs and their metabolites have a positive or negative charge in the body, rendering them somewhat polar and hydrophilic. This polarity limits passive permeation across lipophilic barrier membranes. Thus the disposition of most drugs is highly dependent on specialized transporters embedded in these barrier epithelia. Transporters mediate selective permeation of charged molecules through barrier membranes and are thought to play a pivotal role in detoxification and drug disposition[1,2]. Membrane transporters have been classified into the solute carrier (SLC) and the ATP-binding cassette (ABC) transporter families. The SLC22 family comprises organic cation transporters (OCTs), zwitterion/cation transporters (OCTNs), and organic anion transporters (OATs). These transporters contain 12 predicted alpha-helical transmembrane domains (TMDs) and one large extracellular loop between TMDs 1 and 2. Transporters of the SLC22 family function in different ways: (1) as uniporters that mediate facilitated diffusion in either direction (OCTs), (2) as anion exchangers (OAT1, OAT3 and URAT1), and (3) as Na(+)/l-carnitine cotransporters (OCTN2)[1-5].

OATs play an essential role in the elimination of numerous endogenous and exogenous organic anions from the body. Numerous compounds, such as drugs, environmental substances, plant and animal toxins, and metabolites of both foreign and endogenous origins, are classified as organic anions. As for drugs of pharmacological interest, it is possible to mention β-lactam antibiotics, diuretics, nonsteroidal anti-inflammatory drugs, and several antiviral drugs that are organic anions[1-5].

Two organic anion transporters, OAT1 (*Slc22a6*) and OAT3 (*Slc22a8*), are expressed in the basolateral membrane of renal proximal tubule cells and have been identified as contributors to xenobiotic and endogenous organic anion secretion[3-5]. This membrane localization and function position them for an active role in determining drug exposure and efficacy. The regulation of OATs expression is not well understood.

The function of OATs in renal cells under physiological and pathological conditions has not been, as yet, fully elucidated. Recent studies indicated that the expressions of OATs are affected by pathological states. Modifications in the renal expression of OAT1 and OAT3 have been described in renal diseases; for example, chronic renal failure[6], ischemic acute renal failure[7] and obstructive nephropathy[8,9] and in other diseases, such as arterial calcinosis[10,11] and extrahepatic cholestasis[12-14].

GENERAL CHARACTERISTICS OF OAT1 AND OAT3

OAT1 has been cloned from rat, mouse, flounder, human, pig, rabbit and *C. elegans*[1-5,15-17]. OAT1 is expressed predominantly in the kidneys and weakly in the brain. OAT1 couples organic anions entry to dicarboxylate exit[16]. This protein has been immunolocalized to the basolateral surface of the proximal tubule[18]. OAT1 mediates the transport of many compounds (dicarboxylates, nucleotides, prostaglandins, antivirals, loop and thiazide diuretics, β lactam antibiotics, and nonsteroidal anti-inflammatory drugs, including the prototypical substrate of the classical organic anions secretion pathway, para-aminohipurate (PAH)). For methotrexate, transport was demonstrated for rat OAT1, but not for human OAT1, suggesting species differences. This has been demonstrated *in vitro* by its heterologous expression following microinjection of OAT1 cRNA into *Xenopus* oocytes or transfection of OAT1 cDNA into epithelial cell lines[3-5,15-17]. Eraly *et al*[19] have recently generated a colony of OAT1 knockout mice, permitting elucidation of the role of OAT1 in the context of other potentially functionally redundant transporters. They found that the knockout mice manifest a large loss of organic anion transport (e.g. PAH) both *ex vivo* (in isolated renal slices) as well as *in vivo* (as indicated by loss of renal secretion). In the case of the organic anion, furosemide (FS), loss of renal secretion in knockout animals resulted in impaired diuretic responsiveness to this drug. These results indicate an important role for OAT1 in the functioning of the classical pathway. The gene for human OAT1, SLC22A6, is located on chromosome 11q12.3, being paired with the gene for OAT3. The mammalian OAT1 consist of 545-551 amino acids, and secondary structure algorithms predict 12 TMDs with the N- and C-termini located at the cytosolic side of the plasma membrane. In man, a longer splice variant with 563 amino acids and two shorter, non functional splice variants were found[1-5].

OAT3 was cloned from human, monkey, pig, rabbit, rat and mouse kidneys. The human OAT3 is mainly expressed in kidneys, and to a lesser extent in the brain. The human OAT3 gene is paired with that of OAT1 and located on chromosome 11q12.3. In rats, more message for rat OAT3 was found in liver than in kidneys and brain suggesting species differences. The mammalian OAT3 proteins consist of 536-542 amino acids, arranged in 12 TMDs. Inmunohistochemistry revealed the location of OAT3 at the basolateral membrane of human, rat and mouse renal proximal tubules[18,20]. In rats, OAT3 was also found in several other nephron segments including the thick ascending limb of Henle's loop, distal convoluted tubule and collecting ducts. OAT3 in proximal tubules is involved in organic anion secretion, but the physiological and pharmacological roles of OAT3 in deeper nephron segments are presently not clear. Based on message abundance, OAT3 is the predominant organic anion transporter in the human kidney. Besides kidneys and liver, OAT3 was also found in human choroid plexus and in rat cerebral capillaries. Rat OAT3 contains three potential PKC phosphorylation sites and human OAT3 contains eight. OAT3 recognizes a broad spectrum of substrates, and it mediates the transport of PAH, ochratoxin A, estrone sulfate (ES), cimetidine, benzylpenicillin, cephaloridine and glutarate. Although it is evident that the selectivity of OAT3 overlaps that of OAT1, affinities for several substrates appear to permit discrimination between both transporters. For example, OAT3 displays a moderately high affinity for ES, whereas OAT1 interacts little with ES[2]. So, ES has been frequently used as a test substrate in studies for OAT3 activity. The mechanisms of OAT3 activity revealed that it can operate as an organic anion/dicarboxylate exchanger[21,22]. Consistent with an important role for OAT3-mediated uptake in kidney and choroid plexus, recent experiments with tissue from OAT3 knockout mice show reduced uptake of PAH, ES, and taurocholate in renal cortical slices and nearly complete inhibition of transport of the fluorescent organic anion fluorescein in intact choroid plexus[23]. For some drugs, there are differences in the specificity between human and rodent OAT3. For example, rat OAT3 transports ranitidine, famotidine and AZT, and human OAT3 transport little ranitidine and no famotidine and AZT[5]. Nevertheless, a systematic survey of possible species differences does not exist.

CHOLESTASIS AND RENAL DAMAGE

Kidney and liver play a major role in the elimination of numerous potentially toxic xenobiotics, including drugs, toxins, and endogenous metabolites. In some cases, the loss of one route of elimination can be compensated by another[24-26]. It must also be mentioned that impairment of liver or kidney functions can cause syndromes characterized by injury of the alternative elimination organ[24,27,28]. For example, prolonged cholestasis, characterized by retention of bile compound, may cause renal damage (reduction in renal hemodynamics, impairment of renal excretion of water and salts, and sensitization of the kidney to anoxia damage), which sometimes leads to renal failure. Moreover, obstructive

jaundice predisposes the kidney to acute renal failure and oxidative stress[29-32]. Extrahepatic biliary obstruction significantly decreased the reduced and oxidated forms of glutathione, and significantly inhibited glutathione peroxidase activity in rat kidneys. Increases of thiobarbituric acid reactive substances were also observed[32]. The F2-isoprostanes formed during oxidant injury are renal vasoconstrictors acting *via* thromboxane (TX)-like receptors. Holt *et al*[30] have demonstrated that the antioxidants N-acetyl-cysteine and α-lipoid acid and a TX receptor antagonist can prevent renal dysfunction in experimental cholestasis. Endothelin, a potent renal vasoconstrictor and modulator of the tubular action of arginine vasopressin, shows an increased synthesis in kidneys from rats with extrahepatic cholestasis, which is reflected by increased urinary excretion and may reduce distal tubular water reabsorption in these rats, being also involved in the renal damage observed during this liver pathology[31]. In human beings and rats, extrahepatic cholestasis has been shown to render the kidney susceptible to a variety of nephrotoxic agents[29,30]. The pathophysiological cause of renal damage during the course of bile flow impairment is not well understood, even if several phenomena, such as increased access of various constituents into the kidney (bilirubin and bile salts), have been suggested[30-34]. Impairment of kidney function produces modifications in the renal elimination of drugs mediated by alterations in blood flow to the kidney, glomerular filtration, active tubular secretion, and passive tubular reabsorption[6-11,35]. Because ethical considerations usually preclude meaningful clinical investigation in patients with acute obstructive jaundice, most studies in this condition have been carried out in animals, usually dogs and rats[31,32,36]. Bile duct ligation in dogs and rodents serves as an experimental model of extrahepatic cholestasis[33,34].

RENAL ELIMINATION OF ORGANIC ANIONS AND EXPRESSION OF OAT1 AND OAT3 IN EXTRAHEPATIC CHOLESTASIS

Brandoni *et al*[12,13]. have studied the cortical renal expression of OAT1 and OAT3 in association with the pharmacokinetics and renal excretion of PAH and FS in rats with acute extrahepatic cholestasis. Male Wistar rats underwent bile duct ligation (BDL rats). All studies were carried out 21 h after surgery. The systemic and renal clearance of both PAH and FS increased in BDL rats. In kidneys from BDL rats, immunoblotting showed a significant increase in the abundance of both OAT1 and OAT3 in homogenates from renal cortex. In basolateral membranes from the kidney cortex of BDL rats, OAT1 abundance was also increased and OAT3 abundance was not modified. Immunohistochemical techniques confirmed these results. Acute obstructive jaundice is associated with an upregulation of OAT1 and OAT3, which might explain, at least in part, the increased systemic and renal elimination of PAH and FS.

In this connection, extrahepatic cholestasis is associated with the production of various cytokines and growth factors that may affect gene transcription[37]. Similarly, with OAT1 and OAT3, MRP2 upregulation in BDL rats has been described[38-40]. These authors found that bilirubin ditaurate, sulfate-conjugated bile acids, and some components of the human bile upregulate the expression of MRP2 in human renal tubular cells. MRP2 and MRP4 are two members of the multidrug resistance protein (MRP) family located at the apical membranes from the proximal tubule cells[3-5]. Both proteins mediate the apical renal transport of several anionic substances, such as PAH[3-5,41]. An up-regulation of renal MRP2 has been described at 1 d and 3 d after BDL[38-40]. On the contrary, MRP4 decreases at 3 d after BDL[42].

Three days of BDL is the period in which serum bile acids and bilirubin levels reach the peak of elevation[38,40,43]. Brandoni *et al*[14] have also studied OAT1 and OAT3 function and expression after 3 d of BDL. After this time, BDL rats displayed a reduction in the renal elimination of PAH. OAT1 protein expression in kidney homogenates was not modified, but it decreased in the basolateral membranes. In contrast, OAT3 abundance in both kidney cortex homogenates and in basolateral membranes increased by 3 d after the ligation. This study demonstrated the key role of OAT1 expression in the impaired elimination of PAH after 3 d of obstructive cholestasis.

OAT1, when heterologously expressed in oocytes or mammalian cells, is inhibited by more or less selective PKC activators. It was demonstrated that PKC induces human OAT1 down-regulation through carrier retrieval from the cell membrane without phosphorylation[3-5,44]. Angiotensin Ⅱ[45] modulates the renal proximal tubule function *via* activation of PKC. Although the role of the renin-angiotensin system in the BDL model remains controversial[30], some humoral factors including angiotensin Ⅱ induced by the 3 d BDL may induce the activation of PKC. Moreover, bile acids and high bilirubin levels can activate PKC[46,47]. Three days of BDL is the period in which serum bile acids and bilirubin levels reach peak elevation. So, it was postulated that the peak elevation of bile acids and bilirubin can also trigger PKC activation. This PKC activation may cause the phosphorylation of caveolin-2, which may induce internalization of caveolae with OAT1 protein anchored with caveolin, as has been recently suggested by Kwak *et al*[48]. This OAT1 downregulation (30%) was associated with a concomitant decrease of renal and systemic PAH clearance (40% and 30% respectively). The medium PAH plasma concentrations reached during the renal clearance infusion studies were 295 μmol/L and 376 μmol/L for the Sham and BDL rats respectively. The OAT1 mediated uptake of PAH is saturable with apparent Michaelis constants ranging from 15 μmol/L to 70 μmol/L for rat OAT1[6]. Therefore, PAH concentrations that we obtained in our "*in vivo*" experiments were

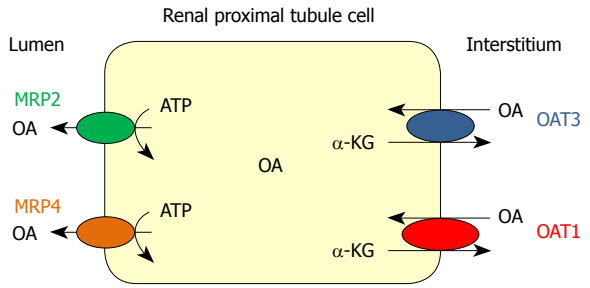

Figure 1 Schematic presentation of a renal proximal tubule cell, showing Organic Anion Transporters 1/3 (OAT1/3) and Multidrug Resistance Proteins 2/4 (MRP2/4). OA: organic anion; α-KG: α-ketoglutarate.

sufficiently higher than the reported Km of rat OAT1. The diminished secreted load of PAH measured under saturating conditions was in part accounted for by the lower number of OAT1 protein units observed in renal basolateral plasma membranes after 3 d of BDL by immunoblot technique. The opposite was observed in the early phase of extrahepatic cholestasis where an increase of 30% of OAT1 abundance was associated with a similar increase in PAH clearance[12]. The differences observed in OAT1 abundance between 21 h and 72 h of BDL remain to be explained. The increased OAT1 abundance observed in the early phase of extrahepatic cholestasis suggests a transient up-regulation similar to those described for renal OCT1 in cholestatic rats[49]. Different levels of cytokines and growth factors that may affect gene transcription might be involved in this differential response[50].

On the contrary, OAT3 expression increased both in homogenates and basolateral membranes from BDL kidneys. OAT3 is found in various cells and in all parts of the nephron, whereas OAT1 is confined to proximal tubules. The human and rat OAT3 transport PAH with relatively high affinity (87 μmol/L and 65 μmol/L respectively)[3-5,20], similarly to OAT1. On the contrary, ES, cholate, and taurocholate are substrates for OAT3 and not for OAT1 using *in vivo* and *in vitro* methodologies[3-5,19,20,23]. The over-expression of OAT3 does not compensate for the down-regulation of OAT1 regarding PAH transport because in this disease the high plasma levels of bile acids compete with PAH for OAT3 transport. Moreover, bile acids regulate the expression of several genes involved in bile salt transport[51,52]. It is possible that high bile acid levels up-regulate OAT3 expression without affecting OAT1 expression; this being another example of substrate specific regulation.

As has been mentioned above, MRP2 up-regulation was observed in the kidneys from rats with BDL of 1 d and 3 d[38-40]. On the other hand, renal MRP4 was down-regulated at 3 d after biliary obstruction[42]. Therefore, the protein expression of the luminal (MRP2 and MRP4) and basolateral organic anion renal transporters (OAT1 and OAT3) are differently regulated in extrahepatic biliary obstruction, thus indicating that different roles are played by these transporters in the pathogenesis of cholestasis. Tubular secretion is a vectorial transcellular transport system consisting of basolateral entry into the epithelial cells and secretion across the brush border membranes. Defects in either of these two processes should therefore influence the tubular secretion of anionic drugs.

Therefore, the time elapsed after obstructive cholestasis has an important impact in the regulation of OAT1 and OAT3. Studies regarding the possible role of bile acids and bilirubin, which are increased in this pathology, in the regulation of OATs are currently being performed in our laboratory.

Highly accumulated anionic drugs, as observed during cholestasis, may cause general body deterioration. The molecular mechanism(s) involved in the differential renal regulation of MRP2, MRP4, OAT3 and OAT1 expression should therefore be elucidated to prevent the occurrence of drug-induced toxicity. The renal expression of OAT1 and OAT3 should be taken into account in order to improve pharmacotherapeutic efficacy and to prevent drug toxicity during the onset of this hepatic disease.

Figure 1 shows the expression pattern of the transporters OAT1, OAT3, MRP2 and MRP4 in a cell of renal proximal tubule.

Abstract

The sphincter of Oddi is located at the distal end of the pancreatic and bile ducts and regulates the outflow of bile and pancreatic juice. A common channel can be so long that the junction of the pancreatic and bile ducts is located outside of the duodenal wall, as occurs in pancreaticobiliary maljunction (PBM); in such cases, sphincter action does not functionally affect the junction. As the hydropressure within the pancreatic duct is usually greater than in the bile duct, pancreatic juice frequently refluxes into the biliary duct (pancreatobiliary reflux) in PBM, resulting in carcinogenetic conditions in the biliary tract. Pancreatobiliary reflux can be diagnosed from elevated amylase level in the bile, secretin-stimulated dynamic magnetic resonance cholangiop ancreatography, and pancreatography *via* the minor duodenal papilla. Recently, it has become obvious that pancreatobiliary reflux can occur in individuals without PBM. Pancreatobiliary reflux might be related to biliary carcinogenesis even in some individuals without PBM. Since few systemic studies exist with respect to clinical relevance and implications of the pancreatobiliary reflux in individuals with normal pancreaticobiliary junction, further prospective clinical studies including appropriate management should be performed.

INTRODUCTION

The main pancreatic duct and the common bile duct open into the duodenum either separately or *via* a common channel. The incidence of common channel formation ranges from 55%[1] to 82%[2,3]. Dowdy *et al*[4] have reported that the length of the common channel ranged from 1 mm to 12 mm, with an average length of 4.4 mm. The sphincter of Oddi, which is composed of the sphincter choledochus, the sphincter pancreaticus and the sphincter ampullae, is located at the distal end of the pancreatic and bile ducts and regulates the outflow of bile and pancreatic juice[2,3]. A common channel can be so long that the junction of the pancreatic and bile ducts is located outside of the duodenal wall, as occurs in pancreaticobiliary maljunction (PBM); in such cases, sphincter action does not functionally affect the junction, resulting in two-way regurgitation (biliopancreatic reflux: regurgitation of bile juice into the pancreatic duct, and pancreatobiliary reflux: Regurgitation of pancreatic juice into the common bile duct)[5,6].

Given that the hydropressure within the pancreatic duct is usually greater than that in the bile duct, pancreatic juice frequently refluxes into the biliary duct in PBM[7-9]. Pancreatobiliary reflux can be examined by several methods, and it has become obvious that this reflux can occur in individuals without PBM. Recent advances in diagnosis of pancreatobiliary reflux and its clinical implications were reviewed.

DIAGNOSIS OF PANCREATOBILIARY REFLUX

In PBM patients, pancreatic enzymes, especially amylase, are generally at extremely high levels in the bile within the bile duct and gallbladder obtained percutaneously or immediately after laparotomy[5,10]. It has been reported that, in PBM patients, the amylase level in the bile of the gallbladder was 123.568 ± 180.827 IU/L (mean ± SD), and the amylase level in the bile of the bile duct was 99.018 ± 162.506 IU/L[11]. Levels close to or below

the serum amylase level are rarely observed in patients with PBM. However, the normal upper limit of the bile amylase level is unknown.

Pancreaticobiliary reflux in PBM patients can be visualized radiologically using secretin-stimulated dynamic magnetic resonance cholangiopancreatography (MRCP)[12,13]. In normal pancreaticobiliary dynamics, the extrahepatic and intrahepatic bile ducts show no change following secretin injection. On the other hand, in PBM patients, the volume of the extrahepatic bile duct and the gallbladder increases due to regurgitation of pancreatic fluid secreted after secretin injection into the bile duct[12,13]. However, since bile is also secreted after secretin stimulation, enlargement of the gallbladder may imply pancreatobiliary reflux, bile secretion, or both[14].

Pancreatography *via* the minor duodenal papilla can also demonstrate pancreatobiliary reflux in PBM patients. The contrast medium injected endoscopically *via* the minor duodenal papilla refluxes into the bile duct through a long common channel without outflow into the duodenum[15].

PANCREATICOBILIARY MALJUNCTION

PBM is a congenital anomaly defined as a junction of the pancreatic and biliary ducts located outside the duodenal wall, usually forming a markedly long common channel ($\geqslant$ 15 mm) (Figure 1)[5,6]. PBM can be divided into PBM with biliary dilatation (congenital choledochal cyst) and PBM without biliary dilatation (maximal diameter of the bile duct $\leqslant$ 10 mm). In PBM patients, since the pancreatic duct and bile duct are joined outside the duodenal wall, the action of the sphincter of Oddi does not functionally affect the junction. Therefore, continuous reciprocal reflux between pancreatic juice and bile occurs, resulting in various pathological conditions in the biliary tract and pancreas[5,6,15].

Given that the hydropressure within the pancreatic duct is usually greater than that in the bile duct, pancreatic juice frequently refluxes into the biliary duct[7-9], which results in a high incidence of carcinoma in the biliary tract. According to a nationwide survey[16] performed in Japan, cancer of the biliary tract was found in 278 (17%) of 1627 of patients with PBM, which was distinctly higher than the incidence of biliary tract cancer in the general population (0.26%-1.8%). In 1239 patients with PBM with biliary dilatation, the occurrence rate of biliary cancer was 11% (131/1239), and cancer of the gallbladder was seen in 85 (65%) out of the 131 patients. In 388 patients with PBM without biliary dilatation, biliary cancer occurred in 147 patients (38%), and 93% (137/147) of the associated biliary cancers were gallbladder cancers.

The etiology of gallbladder cancer in patients with PBM has not been fully clarified. In PBM patients, gallstones do not appear to contribute to carcinogenesis, based on the low rate of gallstone detection[17]. The age of patients with gallbladder cancer associated with PBM without biliary dilatation is significantly younger than in those without PBM[17,18]. The

Figure 1 Endoscopic retrograde cholangiopancreatography of a patient with PBM shows a long common channel.

mechanism of carcinogenesis in PBM is considered to be related to stagnation of refluxed pancreatic juice into the biliary tract. Refluxed proteolytic pancreatic enzymes and phospholipase A2 are activated in the biliary tract. Phospholipase A2, which has a direct proliferative effect on the gallbladder mucosa, produces lysophosphatidylcholin, which has a cytotoxic effect[19]. These agents may injure the epithelium of the biliary tract and induce metaplasia or promote cancer progress.

Epithelial hyperplasia of the gallbladder has been reported to be a characteristic pathologic change in PBM patients. The incidence of epithelial hyperplasia of the gallbladder associated with PBM reportedly ranges from 39%[20] to 63%[21], and it is as high as 91%[22] to 100%[23] in PBM without biliary dilatation. Tanno *et al*[22] have reported that the Ki-67 labeling index of epithelial hyperplasia of the gallbladder with PBM was 6.1% $\pm$ 1.5% (mean $\pm$ SD), which was significantly greater than the index of 1.2% $\pm$ 1.0% in control gallbladder mucosa without PBM. K-ras mutations in the non-cancerous gallbladder epithelium have been detected in 22%[22] to 50%[24] of PBM patients. Considering that increased cell proliferation is linked to the development of cancer by means of tumor promotion and an increased rate of random mutations, the gallbladder mucosa of PBM patients can be considered to be a premalignant region.

The treatment of choice for PBM with biliary dilatation is prophylactic flow-diversion surgery (bile duct resection and bilioenteric anastomosis) before malignant changes can take place in the biliary tract[25]. Although a standard treatment protocol for PBM without biliary dilatation has not been established, prophylactic cholecystectomy is performed in many institutes, as most biliary cancers that develop in cases of PBM without biliary dilatation are gallbladder cancers[16,18].

HIGH CONFLUENCE OF PANCREATICOBILIARY DUCTS

There are some cases with a relatively long common channel that are not classified as PBM because the sphincter of Oddi includes the pancreaticobiliary ductal junction.

Sterling[1] have reported that it varies from 1.2 mm to 8.4 mm, averaging 4.4 mm. Rienhoff and Pickrell[26]

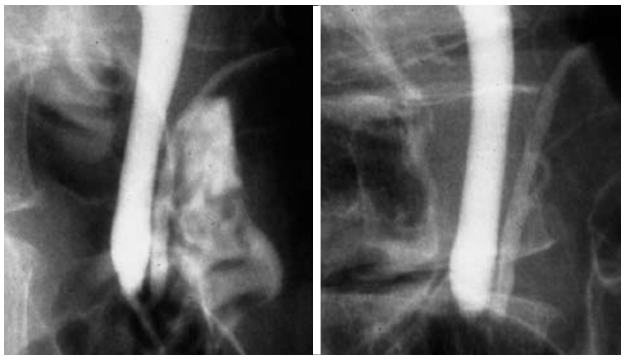

Figure 2 HCPBD. Cholangiopancreatogram of a patient with high confluence of pancreaticobiliary ducts and a common channel of 9 mm in length (left). The communication between pancreatic and bile ducts was destroyed with sphincter contraction (right).

have reported that 92 (53%) of 173 cases had a common channel length within 2 mm, 62 (36%) had a common channel length ranging from 3 mm to 5 mm, and 19 (11%) had a common channel length > 6 mm. Based on the above findings, to investigate the clinical significance of a relatively long common channel, we defined a high confluence of pancreaticobiliary ducts (HCPBD) as a common channel length ⩾ 6 mm, in which the communication was occluded when the sphincter was contracted (Figure 2)[27-29].

In a series of 3459 patients who underwent endoscopic retrograde cholangiopancreatography (ERCP) in our hospital, 74 patients (2.1%) had PBM, including 41 with biliary dilatation (congenital choledochal cyst) and 65 (1.9%) with HCPBD. Although PBM occurred predominantly in females, there was no difference between genders in patients with HCPBD. The average age at the time of diagnosis was significantly younger in PBM patients with biliary dilatation. Reflux of contrast medium into the pancreatic duct was detected in 12 (86%) of 14 patients with HCPBD who underwent postoperative T-tube cholangiography. The average bile amylase level was elevated to 47 774 IU/L in seven HCPBD patients, but it was lower than that of PBM patients. Compared to controls, the incidences of gallbladder cancer were significantly higher in PBM patients with biliary dilatation (17%) and without biliary dilatation (73%), and HCPBD patients (11%). The average age at the time of diagnosis of the gallbladder cancer patients with HCPBD (64.5 years old) was between that of the PBM patients without biliary dilatation (57.0 years old) and patients without these maljunctions (69.5 years old). The incidence of gallbladder stones in conjunction with gallbladder cancer associated with HCPBD (14%) or PBM (6%) was significantly lower than in those with gallbladder cancers without these maljunctions (62%). Similar to PBM patients without biliary dilatation, hyperplastic change of the gallbladder mucosa with increased epithelial cell proliferative activity was detected in cases of HCPBD. Furthermore, K-ras mutations of the non-cancerous epithelium of the gallbladder were detected in five (28%) of 18 HCPBD cases. A relatively long common channel, as well as a long common channel with PBM, appears to be an important risk factor for the development of gallbladder cancer. However, since there are several differences in gender, age at diagnosis, bile amylase level, and incidence of associated gallbladder cancer between HCPBD and PBM patients, HCPBM should be treated at present as an entity separate from PBM. Although further research is necessary to determine the appropriate management, including prophylactic cholecystectomy, of patients with HCPBD, clinicians should be vigilant regarding the development of gallbladder cancer in such patients.

PANCREATOBILIARY REFLUX IN INDIVIDUALS WITH A NORMAL PANCREATICOBILIARY JUNCTION

By demonstrating elevated levels of pancreatic enzymes in bile sampled from the common bile duct or gallbladder, or by MRCP evidence of biliary duct dilatation after secretin injection, it has been recently recognized that pancreatobiliary reflux can occur with normal pancreaticobiliary junction.

High bile amylase levels are found in some patients without PBM. Anderson *et al*[30] have reported that the bile amylase level obtained through an indwelling T-tube was higher than the serum amylase level in 21 (81%) of 26 patients with biliary tract disease, and that bile amylase level fluctuated considerably in the same patient. Therefore, they have suggested that intermittent reflux of pancreatic juice might initiate inflammatory changes in the gallbladder and could play a role in gallstone formation by altering the constituents that maintain cholesterol in a soluble state. A high bile trypsin level has also been reported in patients with bile duct stones[31]. Itokawa *et al*[32] have reported that the amylase level in the bile obtained during ERCP was higher than the serum amylase level in 22 (26%) of 86 patients, and the rate of a high amylase level in the bile was significantly higher in patients who were elderly, had a dilated common bile duct, and in those who had choledocholithiasis. Recently, Sai *et al*[33] have demonstrated enhanced visualization of the intrahepatic and extrahepatic bile ducts and gallbladder with increased maximal diameter of the extrahepatic bile duct and short axis of the gallbladder on secretin-stimulated dynamic MRCP in four (5%) of 74 patients who had a normal pancreaticobiliary junction on ERCP. The bile amylase level was markedly elevated in all four patients, and three of these four patients had gallbladder cancer. This would suggest that there is a relationship between pancreatobiliary reflux in individuals with a normal pancreaticobiliary junction and gallbladder cancer.

Pancreatobiliary reflux can also occur in cases of sphincter dysfunction[30,34], periampullary diverticula[35], as well as after endoscopic sphincterotomy[36] or endoscopic papillary balloon dilatation[37]. Pancreatobiliary reflux in many cases with normal pancreaticobiliary junction seems to be caused by dysfunction of the sphincter of Oddi. Furthermore, unlike in PBM, pancreatobiliary reflux in individuals with a normal pancreaticobiliary

junction occurs not continuously but transiently. Carcinogenesis in the biliary tract is strongly related to stagnation of bile intermingled with refluxed pancreatic juice. Since, in individuals with a normal pancreaticobiliary maljunction, the pancreatic juice refluxes into the common bile duct and is cleared rapidly without stasis, the occurrence of gallbladder cancer poses a problem in these cases. It seems rather obvious that pancreatobiliary reflux might be related to carcinogenesis of the gallbladder. However, the clinical relevance of pancreatobiliary reflux in individuals with normal pancreaticobiliary junction is unknown. Further prospective clinical studies are needed to determine which patients require evaluation of biliary amylase levels and prophylactic cholecystectomy.

CONCLUSION

Pancreatobiliary reflux can be examined using various methods, and it has become clear that reflux can occur in some individuals without PBM. Although the true prevalence and the mechanism of pancreatobiliary reflux in individuals without PBM are unclear, the reflux might be related to biliary carcinogenesis even in individuals with a normal pancreaticobiliary junction. More cases need to be studied in order to determine the clinical implications, including appropriate management.

Abstract

Over the past decade, significant improvements have been made in the treatment of chronic hepatitis C (CHC), especially with the introduction of combined therapy using both interferon and ribavarin. The optimal dose and duration of treatment is still a matter of debate and, importantly, the efficacy of this combined treatment varies with the viral genotype responsible for infection. In general, patients infected with viral genotypes 2 or 3 more readily achieve a sustained viral response than those infected with viral genotype 1. The introduction of a pegylated version of interferon in the past decade has produced better clinical outcomes in patients infected with viral genotype 1. However, the published literature shows no improvement in clinical outcomes in patients infected with viral genotypes 2 or 3 when they are treated with pegylated interferon as opposed to non-pegylated interferon, both given in combination with ribavarin. This is significant because the cost of a 24-wk treatment with pegylated interferon in less-developed countries is between six and 30 times greater than that of treatment with interferon. Thus, clinicians need to carefully consider the cost-*versus*-benefit of using pegylated interferon to treat CHC, particularly when there is no evidence for clinically measurable benefits in patients with genotypes 2 and 3 infections.

INTRODUCTION

The hepatitis C virus (HCV) is a non-cytopathic member of the Flaviviridae family that causes acute and chronic hepatitis and can lead to the development of hepatocellular carcinoma (HCC). An estimated 3% of the world's population is infected with HCV[1]. Acute infection is usually asymptomatic, which makes early diagnosis difficult. A distinct feature of HCV infection is its proclivity towards becoming chronic in as many as 70% of acute infections. Importantly, chronic hepatitis C (CHC) is associated with the progressive development of fibrosis and cirrhosis that, if left untreated, can lead to end-stage liver disease with an estimated 5%-20% mortality rate.

PREVALENCE AND VIRAL GENOTYPE

Preliminary surveys from Pakistan suggest that the seroprevalence of HCV is > 5%, while other surveys suggest rates as high as 10%[2-6]. In one study[7] of prospective blood donors in Faisalabad, Pakistan, 78/294 individuals or 26.5% were found to be seropositive for HCV. If representative, this would be appreciably greater by far than the prevalence rate of 2.9% estimated for Egypt, a country with one of the highest HCV infection rates[8].

The predominant form of HCV infections in Pakistan is of the genotype 3 variety, and this genotype is also predominant in northern, northeastern, and central India, with infection rates as high as 71% in acute

hepatitis patients, and as high as 82% in chronic hepatitis patients[9,10]. From a global public health perspective, sizeable fractions of CHC populations outside southern Asia are also infected with viral genotypes 2 and 3. For example, 26.9% of CHC patients in Serbia and Montenegro have been reported to be infected with genotypes 2 or 3[11]. An estimated 37% of 90 consecutive liver patients from Novara, Italy, had genotype 2[12]. In Cordoba, Argentina, 55% of 96 consecutive liver patients had genotype 2 and 5% had genotype 3[13]. An estimated HCV prevalence of 31% for genotype 3 and 4.3% for genotype 2 has been reported in Brazil[14]. These data from the more densely populated areas of the world suggest that the actual number of people infected with either genotype 2 or 3 is quite substantial compared to those with genotype 1, the predominant form in North America and northern Europe, although an estimated 16% of CHC patients in the United States are also infected with genotypes 2 or 3, as compared to 72% with genotype 1 (http://www.hepatitis.va.gov/vahep?page=diag-tests-03-05).

TREATMENT OPTIONS AND CLINICAL OUTCOMES

In the past two decades, considerable progress has been made in the treatment of this disease with the introduction of interferon (IFN), and, subsequently, with the addition of the guanosine analogue, ribavarin (RBV), in 1998. Typically, patients are treated with IFN by subcutaneous injection three times per week in conjunction with a daily oral dose of RBV (800-1200 mg/day, adjusted by body weight) for between 24 and 48 wk. The therapeutic efficacy is typically measured by the following end points: (1) a sustained virologic response (SVR), defined as no detectable levels of the viral RNA in serum at least 24 wk after the end of treatment; (2) a decrease in the liver enzyme, alanine aminotransferase (ALT) to within the normal reference range; and (3) signs of histological improvement as demonstrated typically by a paired liver biopsy performed prior to the initiation of therapy and at 24 wk after the end of therapy.

Correlations between serum virus levels, serum ALT levels, and liver pathology, while generally acceptable[15,16], have not been definitively established. The primary measure of current therapy is the achievement of virtually no detectable levels of HCV in serum at least 24 wk following the end of therapy, defined as the SVR. The SVR correlates well in clinical practice with patient recovery and wellbeing.

In the past decade, it has been reported that the addition of a polyethylene glycol (Peg) moiety to IFN (termed, Peg-IFN) significantly enhances its half-life in the blood, such that patients can be dosed with the Peg-IFN once weekly as compared to three times a week for the non-pegylated IFN.

In a study[17] of 531 CHC patients (190 of whom were HCV genotype 2 or 3, and 329 were genotype 1), treated with Peg-IFN or IFN, without RBV, for 48 wk and followed up for an additional 24 wk, the overall SVR at 72 wk was 39% (95% CI, 33%-45%) for Peg-IFN and 19% (95% CI, 14%-24%) for IFN. The data were not separated by genotype. The authors noted that the rate of relapse between weeks 48 and 72 was higher among patients who had a response to Peg-IFN compared to those treated with IFN. In a randomized double-blind study[18] of 1219 patients treated with Peg-IFN alone compared to IFN, both administered without RBV, significant improvements, including SVR, were noted in patients with genotype 1 virus, with a trend towards an improved, although not significant, response in patients with genotypes 2 and 3.

Treatment of CHC patients with Peg-IFN + RBV (the RBV dose typically weight-based but sometimes flat-dosed between 800 and 1200 mg/day, per os) has been shown to result in appreciably better clinical outcomes and has been touted as the so-called gold standard in the treatment of CHC. This conclusion stems almost exclusively from two studies[19,20] in which CHC patients were treated with Peg-IFN + RBV or with IFN + RBV. The data from these two studies have shown that the single greatest advantage of the Peg-IFN over IFN, both given in combination with RBV, has been the achievement of a statistically significant SVR in CHC patients with genotype 1, the recalcitrant form of this viral disease. The studies showed no consistent advantage of Peg-IFN over IFN (either one given in combination with RBV) in patients with viral genotypes 2 or 3. In the Manns *et al* study[19], the SVR was 76% for genotypes 2 or 3 and ranged from 36 to 56% in genotype 1 patients treated with IFN + RBV or Peg-IFN + RBV. In a randomized study of 1311 CHC patients given only Peg-IFN + RBV, Hadziyannis *et al*[21] reported an SVR of approximately 80% in those infected with genotype 2 or 3 virus *versus* approximately 52% in those with genotype 1 virus. Several other studies[22-38] of CHC patients with genotype 2 or 3 virus, treated with either Peg-IFN or IFN, both administered with RBV, are summarized in Table 1 and show no better results with either IFN, when given in combination with RBV, for genotypes 2 and 3 viruses.

Notwithstanding the published clinical data[19-38] summarized in Table 1, the debate on the optimal duration of Peg-IFN treatment with RBV continues. In a recent paper, Shiffman *et al*[34] have suggested that it may be prudent to treat CHC patients with genotype 2 or 3 virus for 24 wk as opposed to 16 wk, to ensure a lower percentage of relapses. The concept of an early virological response, sometimes referred to as a rapid viral response (RVR), reported in some fraction of CHC patients within 4 wk, has been proposed as a clinically useful predictor of SVR[39]. However, while this concept is valuable in CHC patients infected with genotype 1 or 4 virus, some 97% of patients with genotypes 2 and 3 viruses show an RVR, and therefore, this concept is less useful in CHC patients infected with genotype 2 or 3[40]. Importantly, the rates of relapse can increase with therapies of shorter duration, although

Table 1 Achievement of SVR by treatment with IFN + RBV or Peg-IFN + RBV in CHC patients

the SVR rates (27.8% and 58.8%) were inexplicably low in one particular study of genotype 3 CHC patients in Pakistan[41].

Emerging data[27,30,32,38-40] suggest differences in SVR between patients with genotype 2 or 3 HCV, with genotype 2 yielding better responses than 3. There may also be additional nuances between genotypes 2a and 2c that could be used to the benefit of patients with these sub-types of HCV infection.

NEWER SUPPLEMENTAL TREATMENT OPTIONS TO INCREASE THERAPEUTIC EFFICACY AND PREVENT RELAPSE

Two new adjuvants to existing therapies with IFN + RBV or Peg-IFN + RBV are noteworthy in their potential to vastly improve SVR and clinical outcomes, and importantly, to decrease relapse rates in CHC patients. While abnormalities in glucose metabolism in CHC patients were recognized as far back as 1994[42], the application of this knowledge in the clinical setting has been introduced in just the past few years, as the epidemic of obesity and pre-diabetes or diabetes has come into sharp focus as a matter of great public health concern.

Eighty-two CHC patients[36] with genotype 2 or 3 virus were treated with IFN + RBV or Peg-IFN + RBV. Insulin resistance was measured by the homeostasis model (HOMA-IR). Patients with HOMA-IR values < 2 had an SVR of 94%, those with HOMA-IR values of 2-4 or > 4 had an SVR of 65%. The authors concluded that SVR rates > 90% are achievable in persons with low HOMA-IR values in genotype 2 and 3 patients, but drop to the 60% level more typically seen in CHC genotype 1 patients when their HOMA-IR values are > 2. Similar results have been reported more recently by others[43-46].

In an elegant series of papers from the Siddiqui Laboratory at the University of California at San Diego, *in vitro* studies on the mechanisms of HCV-induced changes in liver cells have identified the importance of intracellular calcium and oxidative stress in activating signal transducer and activator of transcription and nuclear factor-κB which in turn, contribute to the release of pro-inflammatory cytokines and contribute to liver pathology in HCV-infected cells[47-51]. This mechanism has been confirmed by others[52,53] and summarized in a recent review, in the context of immune system derangements observed in CHC[54].

We are in the early stages of designing a pilot study to evaluate the effectiveness of drugs, such as exenatide, used to overcome insulin resistance and agents that would block calcium derangements in the liver of CHC patients infected with HCV genotype 2 or 3.

CONCLUSION

Published and unpublished clinical observations suggest that an SVR is achieved in 70%-88% of CHC patients infected with genotype 2 or 3 HCV treated with IFN + RBV. A weight-of-evidence analysis using the data cited in Table 1, suggests no greater benefit in treating genotype 2 or 3 infections with Peg-IFN, which can be as much as six to 30 times more expensive than IFN (unpublished data). While the number of patients studied (Table 1) may be smaller than optimally required for a definitive answer to the issue of whether Peg-IFN, despite its additional costs, brings any clinical benefit to CHC patients with genotype 2 or 3 infection, the similarities in SVR between the two IFNs suggest that neither offers a measurable clinical benefit over the other when administered with RBV.

The 2002 National Institutes of Health (NIH) Consensus Conference Statement[55] on Management of Hepatitis C stated, "Among patients with genotypes 2 or 3, SVRs with standard interferon and ribavarin were comparable to those with pegylated interferon and ribavarin, and thus standard interferon and ribavarin could be used in treating patients with those genotypes". The published data since the 2002 NIH Consensus Statement have not falsified this recommendation. Thus, the recommendation of duration of Peg-IFN therapy for hepatitis C with these genotypes needs to be tempered by whether or not Peg-IFN offers any clinical advantage, given its much higher cost, when used with RBV, and especially in less-developed countries.

Abstract

The pathogenesis of colon cancer involves sequential and multistep progression of epithelial cells initiated to a cancerous state with defined precancerous intermediaries. Aberrant crypt foci (ACF) represent the earliest identifiable intermediate precancerous lesions during colon carcinogenesis in both laboratory animals and humans. ACF are easily induced by colon-specific carcinogens in rodents and can be used to learn more about the process of colon carcinogenesis. For over two decades, since its first discovery, azoxymethane (AOM)-induced rodent ACF have served as surrogate biomarkers in the screening of various anticarcinogens and carcinogens. Several dietary constituents and phytochemicals have been tested for their colon cancer chemopreventive efficacy using the ACF system. There has been substantial effort in defining and refining ACF in terms of understanding their molecular make-up, and extensive research in this field is currently in progress. In chemoprevention studies, AOM-induced rat ACF have been very successful as biomarkers, and have provided several standardized analyses of data. There have been several studies that have reported that ACF data do not correlate to actual colon tumor outcome, however, and hence there has been an ambiguity about their role as biomarkers. The scope of this mini-review is to provide valuable insights and limitations of AOM-induced rat ACF as biomarkers in colon cancer chemoprevention studies. The role of the dynamics and biological heterogeneity of ACF is critical in understanding them as biomarkers in chemoprevention studies.

INTRODUCTION

Aberrant crypt foci (ACF) have been identified and defined as putative precancerous lesions of the colon in both experimental models and humans[1-4]. In animal models, ACF as a biological marker have been functional in identifying both naturally-occurring and synthetically-derived compounds, as well as foods and nutritive agents for their ability to prevent or control the process of colon carcinogenesis[5-7]. On the other hand, they have also been vital in understanding toxic effects of various compounds[8]. The use of the rodent ACF as a biomarker has been successful in chemoprevention studies mainly due to the fact that they are: (a) preneoplastic lesions; (b) morphologically distinguishable from normal crypts; (c) induced in colons of several animal models; (d) remarkable similarity between human and rodents; (e) rapidly detectable; (f) easily modified by genetic changes or drug/dietary interventions; (g) amenable in short term experimental modules (8 wk); (h) classifiable according to their progression; and (i) generally present in larger populations. Whether addressing aspects of cancer prevention/control or toxicity, studies have essentially focused on the ability to modulate the incidence of total ACF or incidence of ACF displaying advanced biological features related to size, dysplasia and crypt multiplicity. It has been widely accepted that the incidence of ACF in rodents correlates strongly with the final tumor outcome[9,10]. Several factors such as dose of carcinogen, route of administration, time of intervention during the carcinogenic state, age and sex of the animals,

location and appearance of lesions in the colon, as well as the choice of animal models play a critical role in understanding the modulation of ACF, tumor outcomes, and their incidental correlation[11].

For colon cancer chemoprevention studies, the ability of compounds to regress or inhibit the incidence of total or subtypes of ACF has been utilized using either short-term (6-8 wk) or long-term (12-54 wk) carcinogen-injected rodent studies. While interpreting data arising from these studies, especially outcome of ACF and their sub-types as well as tumors, two points need special consideration. Firstly, it has to be understood that ACF, which are dynamic in nature, are amenable to growth and expansion, and may differ in number and growth features at different end-points. Secondly, in the course of their dynamics, ACF undergo several genetic changes, plausibly acquire novel phenotypes conducive to their progression, and discard those that render them normal or make them susceptible to regression[12,13]. Detailed review of the molecular features of ACF can be found in the papers by Cheng and Lai[12] and Alrawi *et al*[14], and recent advances in human ACF and their potential as biomarkers of human colorectal cancer have been elegantly discussed by Orlando *et al*[15], Stevens *et al*[16] and Gupta *et al*[17]. Depending on their growth/developmental stage, ACF are heterogeneous in their molecular make-up[12-14]. The growth and development of ACF on one hand could be regressed or inhibited, while on the other augmented by various compounds; both depend on the ACF dynamics as well as their heterogeneity[7].

ACF DYNAMICS AND CHEMOPREVENTION

In screening compounds for their efficacy to prevent or control colon cancer, the popular choices of *in vivo* models are male rats of F344, Sprague-Dawley or Wistar strains that are approximately 5-6 wk old, at least 180-200 g in weight, and injected s.c. with two weekly doses of AOM at 15 mg/kg body[5,11]. In such protocols, the test compounds are added to the diet either at the time of the first AOM injection, or after a period of 4-8 wk. While in the former protocol, the emphasis is to determine the efficacy to prevent the appearance and growth of ACF at the initiation and post-initiation stages; the latter focuses on changes in ACF that have been established for a given period at the post-initiation and promotion stages[7]. In these models, two week after the second injection, the colonic epithelial cells are initiated, and a huge population of ACF that are primal (1-3 crypts per foci) in appearance are observed in the colons[13,18]. With time (promotion stages), the cells of the aberrant crypt within the same foci clonally grow and expand to morphologically distinctive larger aberrant crypts, or those that could be classified as either intermediate (foci with 4-6 crypts) or advanced lesions. These changes are generally seen 12-wk post-carcinogen injection. With time, a decline in the incidence of primal lesions and the gradual increase in the incidence of other ACF types such as large, intermediate or advanced are noted. Towards and beyond 24 wk post-carcinogen injection which can be categorized as the progression stage, the incidence of advanced lesions reaches a peak and the appearance of microadenomas, adenomas and adenocarcinomas is evident. Another important criterion for understanding the early stages of colon carcinogenesis is the differential growth dynamics of ACF in different regions of the colon[19,20]. Spatial distribution of ACF differs among the proximal, mid and distal sections of the colon of AOM-injected F344 rats, with more incidence of ACF in the mid sections compared to the distal colon[20]. In understanding the ability of compounds to modulate the incidence of ACF and their subtypes, several comparisons can be made. For instance, the incidence of ACF or their subtypes could be compared between an experimentally-treated group and the controls (placebo, vehicle-treated) at a single time point. Otherwise, a comparison between time-frames within a single treatment group could be made. Comparisons of ACF incidence made between different colonic sections, but within same time point or same treatment group would give regional differences in modulation. An ideal method would be detailed simultaneous comparisons between time-points, treatment groups and colonic regions on the incidence of ACF and subtypes to give a cross-sectional review of the data. Similarly, the incidences of adenomas and adenocarcinomas can be compared. The entire data such as the incidences of ACF and their subtypes, adenomas and adenocarcinomas have to be considered holistically before making conclusions on the modulating efficacy of a compound.

HETEROGENEITY OF ACF AND CHEMOPREVENTION

The initiation of a single epithelial cell within the crypt to undergo histogenetic changes and gradually proliferate to form morphologically distinct foci is the first and foremost stage in the genesis of ACF in the colon. Monoclonality in ACF, including those without dysplasia, put ACF at the earliest identifiable stage of this carcinogenic process[21]. These colon precancerous lesions progressively advance by acquiring novel genotypes and phenotypes segregating these lesions into different histological and morphological sub-types identified by: (a) size, (b) degree of dysplasia, (c) crypt multiplicity, and (d) a combination of dysplasia and crypt multiplicity. Segregation of ACF into sub-types is vital to understand the disease process and to delineate the novel changes exhibited at the microscopic level in conjunction with the given appearance and characteristics of tumors. As ACF progress from one stage to another, epithelial cells within the ACF undergo genetic changes that lead to their radical behavior to skip growth inhibition or apoptosis and favor proliferation and growth[11,12]. Their goal seems to be achieving a "neoplastic bliss". Those molecular features that result in neoplastic transformation appear sequentially, and are due to a complex interplay/crosstalk of several signal transduction pathways. Purported

chemopreventive agents retard or cease the growth and/or inhibit the development of ACF or their subtypes. Compounds are known to inhibit preneoplastic changes by blocking key molecular pathways in the colonic epithelial cells. As a result, either the progression within the preneoplastic stages, or the conversion of preneoplasia to neoplastic transformation is halted. The response of a single crypt within an ACF with multiple crypts (those with four or more crypts per foci) may differ in the modulatory influence of a compound. In such a case (within multicrypt foci), although all the crypts are proposed to have developed by clonal expansion of a single transformed cell, each crypt plausibly branches itself from others by acquiring differential genotypic changes, influenced largely by the environment. The rate at which the changes are acquired by different crypts within a focus may differ considerably owing to a biological heterogenous subtype within the ACF. Hence, within one ACF, each crypt may succumb differently to growth inhibition by a particular compound. However, signals from those crypt cells that undergo inhibition may be transferred to cells that may be avoiding the inhibitory function of the compound, making the latter initiate growth inhibition. Eventually, a complex dialogue within a single ACF is created, and the crypt eventually succumbs to the inhibitory actions of the compound. Genetic and molecular heterogeneity of crypts can also be evident as histological differences such as hyperplastic and dysplastic crypts[12].

LIMITATIONS OF THE AOM-INDUCED RAT ACF AS A BIOMARKER

Limitations to the use of ACF and their sub-types as a biomarker to identify cancer preventive agents is compromised as the disease progresses from early to late stages. Increased biological segregation from normal crypts increases the specificity to the diseased state but the ability of early lesions, such as the ACF to predict the differences between two or more experimental groups are limited by the fact that their number also declines. With time, ACF undergo the selection process; while some regress, remodel or even get eliminated; others progress forward to the next stage. For example as shown in Figure 1, consider a pool of AOM-injected rat colonic ACF with different sub-types at varied duration (8, 12 and 24 wk post-initiation). In 8 wk, ACF with 1, 2 or 3 crypts per foci appear, and at this time point the incidence of total ACF (irrespective of their crypt multiplicity) becomes a valid biomarker. In subsequent weeks, ACF with higher crypt multiplicities or those with advanced biological features appear, while those with lower crypt multiplicities regress. So, at this time point, incidences of higher crypt multiplicities or those displaying advanced features could be considered more specific. In more advanced stages of the carcinogenic process, the value or sensitivity of ACF as a biomarker to predict tumor outcome diminishes; however, their specificity as an indictor of the stage remains uncompromised. The use of ACF and its sub-types as biomarkers thus depend much on the stage of

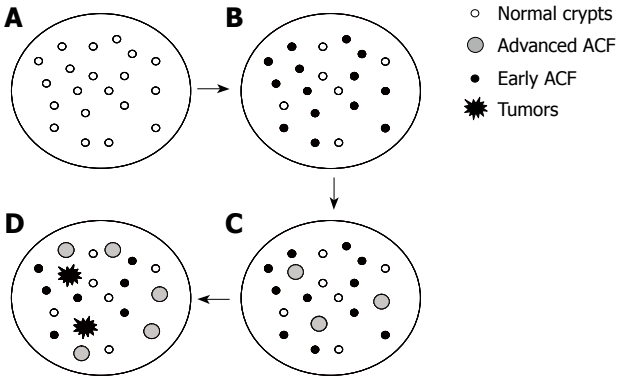

Figure 1 A pictorial representation of the dynamics of ACF during azoxymethane-induced rat colon carcinogenesis. A: Colon with normal crypts prior to AOM injection; B: Colon bearing early ACF at approximately 8-wk post AOM injections; C: Colon bearing early and advanced ACF at approximately 12-wk post AOM injections; D: Colon bearing early and advanced ACF and tumors at approximately 24-wk post AOM injections. As the population of ACF (inclusive of all sub-types) increase with time after AOM injections, a relative decline in the specificity as a biological marker is observed.

colon carcinogenesis. Only at early stages, total number of ACF and ACF displaying different biological features may be considered as a valid biomarker. At very early stages the relevance of utilizing a parameter involving advanced lesions such as aberrant crypts per ACF (AC/ACF) becomes invalid, as at early stages to begin with there may not be a significant pool of ACF with varied features. The description as 'very early', 'early' and 'advanced' stages of colon carcinogenesis have been used cautiously and have considered the AOM-induced rats as the model system (described in the former Section).

ACF with severe dysplasia have been identified as the actual precursors of colonic adenomas and adenocarcinomas[22]. The recent findings of the presence of β-catenin accumulated aberrant crypts (BCAC)[23], mucin-depleted crypts (MDF)[24], and flat-dysplastic ACF (FDACF)[25] in carcinogen-treated rat colons are significant advances in the identification of events leading to tumor development. The morphological features of these lesions resemble those of advanced ACF, as described earlier[10,13,14]; strongly suggesting that they plausibly are subtypes of advanced ACF. However, it is still unclear as to the exact evolutionary sequence of BCAC, MDF or FDACF, and their relevance to the human situation. These specific ACF-subtypes are purported to accurately predict tumor outcome[20-22]. However using them as valid biomarkers to screen chemicals/agents for potential colon cancer chemoprevention requires further scrutiny. Indeed, the simplistic methylene blue staining method in assessing ACF in whole mounts of colon remains a valuable tool in screening compounds for their colon cancer chemopreventive potential.

CONCLUSION

ACF are unique biological markers for the purpose of assessing potential colon cancer chemopreventive efficacy of compounds during the early stages of colon carcinogenesis. Interpreting the ability of compounds

to retard or inhibit the incidence of ACF is becoming evidently complex. Sometimes, ACF data seem not to correlate with that of tumor outcome; in such cases, a single variable such as ACF incidence at a given time point to that of tumor outcome may have to be taken for correlative consideration. Incorporation of the cross-sectional criteria described in the earlier sections may facilitate a realistic correlation between the incidences of ACF and tumor outcome. Thus, in interpreting ACF data, their dynamics and heterogeneity need to be considered in order to formulate stronger correlations to tumor outcomes. A recent trend in the identification of ACF subtypes are certainly useful in understanding their biology, but their use as biomarkers in efficacy studies requires caution, especially when the relation between their specificity and predictability at a given time of the carcinogenic process is taken in to account. More studies are encouraged to identify the molecular repertoire of ACF that categorize them as preneoplastic lesions of the colon. Abrogating the growth and development of preneoplastic lesions emphasizes an early strategy on cancer prevention or control. Defining the role of ACF in colon carcinogenesis is vital to understand the relevance as a biological marker in the study of chemopreventive agents. The short-term AOM-induced rat ACF thus remains an ideal early biomarker for the identification of various chemopreventive agents against colon cancer.

ACKNOWLEDGMENTS

I thank Dr. Ranjana P Bird at the University of Windsor, Canada for valuable discussions during the preparation of this review.

Abstract

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder. According to the Rome Ⅲ criteria, IBS is defined as recurrent abdominal pain or discomfort for at least 3 d per month during the previous 3 mo associated with two or more of the following symptoms: improvement with defecation, onset associated with a change in the frequency of stool and/or onset associated with a change in form or appearance of stool. There is growing evidence regarding the genetic contribution in IBS, however the precise etiology of IBS is still unknown. The evaluation of the genetic influence is based on twin studies, familial aggregation and genetic epidemiological investigations. Most studies showed a concordance for IBS significantly greater in monozygotic than in dizygotic twins. The majority of the studies have shown that familial aggregation may represent exposures to a similar environment, as well as the influence of genetic factors. Whereas no specific gene has been identified in association with IBS, recent studies have noticed the importance of polymorphisms in the promoter region of the serotonin reuptake transporter gene, G-protein beta 3 subunit gene (*C825T*), cholecystokinin receptor (*CCKAR* gene 779T>C), and high-producer tumor necrosis factor genotype. Further studies are necessary to determine how genetic factors influence the clinical manifestations and therapeutical response in IBS patients.
