INSULIN-LIKE GROWTH FACTORS (IGF-I, IGF-II)

The insulin-like growth factor family consists of insulin, IGF-I, and IGF-II. The liver is the major site of synthesis for IGF-I, but it is also synthesized in other tissues including the gastrointestinal tract[1,2]. IGF-I and IGF-II are found in human milk[3], and these peptides are members of a complex mixture of growth factors that the neonate is exposed to during the suckling period.

Intestinal development may involve IGF-I and IGF-II[4-6]. IGF-I receptor (IGF-1R) is detectable in the fetus and the neonate of animals[7,8]. In humans, IGF-I, IGF-II and IGF-IR are also present in fetal intestine[9-11].

Intestinal cells proliferate *in vitro* when exposed to IGF-I[12-14]. Transgenic mice that over express IGF-I demonstrate increased small intestinal growth[15], particularly in the muscle layers of the distal small intestine and large intestine[16]. IGF-I receptor gene knockout animals have fetal growth retardation, but distinctive effects on the gastrointestinal system have not been found[17]. This may indicate the presence of redundant systems in the gastrointestinal tract that compensate for the lack of IGF-I.

In vivo studies show variable responses depending on the dose of IGF-I that is used. Pharmacological doses of IGF-I, given orally to colostrum-deprived 5 d old piglets, increase electrolyte and nutrient absorption[18]. Neonatal pigs fed formula supplemented with IGF-I from birth to 4 d of age had increased mucosal growth[19]. Parenterally fed 1 d old piglets given enteral IGF-I had increased brush border malease (BBM) disaccharidase levels[20]. Houle *et al*[21] administered IGF-I orally to neonatal rats, and demonstrated increases in mucosal growth and BBM enzymes. Similarly, Burrin *et al*[19] showed increases in intestinal weight, protein, and DNA in neonatal pigs fed

Table 1 Hormones and peptides which affect intestinal nutrient absorption

Hormones/ Peptides	Cell types which express the specific peptide	Cell types in the intestine and elsewhere which express corresponding receptors
IGF I & II	Granulosa cells[158]	Non-Islet cell tumors[163]
	Prostate stromal cells[159]	Hepatoma cells[164]
	Neonatal bone marrow-mesenchymal stem cells[160]	Intestinal smooth muscle[165]
		Astrocytoma cells[166]
	Systemic sclerosis lung fibroblasts[161]	Camel intestinal lamina propria[167]
	Melanoma Cells (SK-MEL2)[162]	Camel epithelia of the crypt cells[167]
		Camel villi[167]
EGF	Rat submandibular glands cells[168]	Keratinocytes[169]
	HaCaT cells[169]	Urothelial cells[172]
	Porcine cumulus cells[170]	Fibromyoblasts[173]
	Esophageal epithelial cell[171]	Smooth muscle cells[173]
		Fibroblasts[173]
		Colonic epithelial cells[174]
		Murine pancreatic beta cells[175]
TGF-α	Hypothalamic astrocytes[176]	Pancreatic cancer cells[180]
	Granulosa cells[177]	Osteoblasts[181]
	Ovarian theca cells[177]	Murine conjunctival goblet cells[182]
	Endometrial stromal cells[177]	Fundic mucous cells[183]
	Eosinophhils[178]	Murine intestinal epithelial cells[184]
	Colon cancer cells[179]	
HGF	Lung microvascular endothelial cells[185]	Cardiomyocytes[189]
	Umbilical vein endothelial cells[185]	Liver progenitor cells[190]
	Neutrophils[186]	Glioblastoma cells[191]
	Monocytes[187]	Myeloma cells[192]
	Adipocytes[188]	Tumor plasma cells[192]
		Neuroblasts[193]
		Hepatocellular carcinoma cells[194]
		Epithelial tubular cells[195]
		Antroduodenal G cells[196]
		Rectal enterochromaffin cells[196]
		Pancreatic A and B cells[196]
		Intestinal epithelial cells[196]
Erythropoietin	Amniotic epithelial cells[197]	Erythroid cells[202]
	Schwann cells[198]	Endothelial cells[203]
	Interstitial fibroblasts[199]	Neuronal cells[203]
	Metanephric adenoma cells[200]	Cardiac myocytes[203]
	Mesenchymal stromal cells[201]	Vascular smooth muscles[203]
		Murine fetal enterocytes[204]
		Intestinal epithelial cells[205]
KGF	Mucosal and dermal fibroblasts[206]	Alveolar epithelial type II cells[209]
	Gastric fibroblasts[207]	Breast cancer cells[210]
	Endometrial stromal cells[208]	Cholesteatoma cells[211]
		Enterochromaffin cells[212]

Note: All of these are in humans until stated otherwise.

orogastrically. Alexander and Carey[18] examined the effect of oral IGF- I on neonatal piglet intestine, and found increases in D-glucose uptake in everted jejunal sleeves, independent of the intestinal mass or surface area. Lane et al[22] used RT-PCR and laser scanning confocal microscopy to show that intragastric IGF- I or IGF- II increased the expression of the glucose transporters SGLT1 and GLUT2 in suckling rat intestine.

The mechanisms responsible for increased jejunal transport rates observed in tissues treated with orally administered IGF- I may include the increases in Na⁺K⁺-ATPase seen with IGF- I treatment. The PI3-kinase pathway may also be important, as preincubation with a PI3-kinase inhibitor abolishes the effects of IGF- I on ion and nutrient transport[23].

Although pharmacological doses of IGF- I have clear effects on the neonatal intestine, studies using physiological doses show only limited effects. For example, recent studies with both neonatal pigs[21,24] and calves[25] have shown that the oral administration of physiological concentrations of IGF- I in formula results in measurable increases in crypt cell proliferation, but there are no demonstrable increases in intestinal mucosal mass or length.

EPIDEMAL GROWTH FACTOR AND TRANSFORMING AND TRANSFORMING GROWTH FACTOR-α (TGF-α)

EGF and TGF-α are two ligands of the EGF receptor

that have been postulated to play a role in intestinal ontogeny. Both peptides are present in human breast milk, with TGF-α at a 5-10-fold lower concentration than EGF[26]. Transforming growth factor β (TGFβ) is a family of growth factors, with the three isoforms (TGFβ1, TGFβ2, TGFβ3) having nearly identical biological activities. TGFβ1 and TGFβ2 are present in human milk[27], and mRNA and protein corresponding to the three TGFβ isoforms are found in the intestinal mucosa[28-30]. Small intestinal development, however, is not severely impaired by the targeted disruption of the TGFβ gene[31].

EGF and TGF-α have been isolated in human 15-20 wk gestation fetal intestine, with TGF-α levels as much as 10 times higher than EGF[32]. EGF receptor expression is detectable throughout the GI tract in the human fetus and neonate. EGF receptor is developmentally regulated with expression being low during the human suckling period, and in rodents, unlike humans, EGF receptor expression is delayed until weaning[33].

Oral EGF administration augments gut growth and functional development in neonatal rats and pigs[34-36]. Gene targeting studies have demonstrated that disrupting the expression of the EGF receptor in mice resulted in impaired intestinal development, and death associated with a necrotizing enterocolitis-like disorder[37].

The postnatal development of intestinal transport and the physical composition of the BBM were examined in New Zealand White rabbits receiving EGF (40 mg/kg per day) either intraperitoneally or orogastrically from day 3 to day 17 of life. Intestinal water, Na$^+$ and glucose absorption expressed per cm of intestine were significantly increased in animals receiving EGF by either route. Increased absorption induced by orogastric EGF appeared to be secondary to mucosal hyperplasia. The BBM isolated from EGF-treated animals was significantly more fluid than that of controls. These results suggest that EGF modulates the development of transport function during the postnatal period, both by stimulating mucosal growth and by inducing specific transport processes[38].

Experimental necrotizing enterocolitis (NEC) was induced by exposure of newborn animals to asphyxia and cold stress. The newborn rats were artificially fed either with growth factor-free rat milk substitute or the same formula supplemented with 500 ng/mL of EGF[39]. EGF supplementation of formula reduced the incidence and severity of NEC, as assessed by gross and histological scoring of the ileum. This finding suggests a potential therapeutic approach for the prevention and treatment of NEC.

HEPATOCYTE GROWTH FACTOR, ERYTHROPOIETIN, KERATINOCYTE GROWTH FACTOR AND THYROID HORMONES

Erythropoietin (Epo) is present in breast milk[40], and receptors for Epo are present on intestinal cells[41]. Modest changes in small intestinal length and surface area are observed following subcutaneous Epo injections in artificially fed rat pups. Hepatocyte growth factor (HGF) is also present in breast milk, and both HGF and its receptor are present in fetal intestinal tissue[42,43]. Keratinocyte growth factor (KGF) promotes proliferation and up-regulates SI expression in fetal human small intestine explant culture[44]. It remains to be seen if KGF plays a physiological role in postnatal intestinal development.

The effect of thyroid hormones on the ontogeny of BBM enzymes has been examined. An *in vivo* study of lactase phlorizin hydrolase (LPH) catalytic activity, synthesis, and degradation was performed in propylthiouracil-induced hypothyroid rat pups, hypothyroid pups injected with thyroxine, and normally weaned rats. T4 regulates LPH ontogeny by posttranslational mechanisms that include altered processing and increased degradation of the BBM lactase enzyme[45]. Monteiro *et al*[46] examined the role of T4 on the precocious enhancement of GLUT5 in weanling rats. Rat pups were made hypothyroid by giving the dam 0.01% propylthiouracil in the drinking water from day 18 of gestation. The hypothyroid pups and age-matched euthyroid control pups were then fed high-fructose solutions by gavage, twice a day starting at 17 d of age for 3 d. Although serum T4 levels were five times lower in the hypothyroid pups, the mRNA level for the BBM fructose transporter (GLUT5) increased in euthyroid and hypothyroid pups fed high fructose. This result paralleled the increase in fructose uptake. This suggests that during weaning, dietary fructose can precociously enhance intestinal fructose uptake and GLUT5 mRNA expression, independent of developmental increases in serum T4 levels.

GLUCOCORTICOSTEROIDS

Biochemistry

Steroids can be divided into two categories: glucocorticosteroids (GC), if potency is based on liver glycogen deposition, and mineralocorticoids, if potency is based on sodium retention. The hormones that are secreted in significant amounts are cortisol, corticosterone, and aldosterone. In humans, the major naturally occurring steroid is cortisol, while in rodents the main steroid is corticosterone.

Steroids are synthesized from cholesterol in the inner mitochondrial membrane of the adrenal glands, through a series of reactions including hydroxylations. The release of cortisol from the adrenal glands is regulated by the hypothalamic-pituitary-adrenal axis, and involves the secretion of corticotropin-releasing hormone from the hypothalamus, and the subsequent secretion of adrenocorticotropin hormone (ACTH) from the pituitary gland. The rate-limiting step in steroid synthesis is the transport of cholesterol to the inner mitochondrial membrane by sterol carrier protein 2 (SCP2), steroidogenesis activator protein polypeptide (SAP), peripheral benzodiazepine receptor (PBR), and

steroidogenic acute regulatory protein (StAR)[47]. Because corticosteroids are not stored in adrenal tissues, the rate of secretion equals the rate of biosynthesis[48-51].

GC are classified as lipids because they are more soluble in organic solvents than aqueous solvents. Their solubility is affected by the presence of hydroxyl or carbonyl groups[52]. GC enter cells by diffusion across the plasma membrane. About 90% of circulating cortisol is reversibly bound to a plasma protein, the corticosteroid binding globulin (CBG)[48,51,52]. CBG is a high affinity, low capacity plasma protein, while albumin has a low affinity and high capacity to bind steroids[48,51-53]. The bioavailablility of GC in specific tissues is determined by the presence of tissue specific metabolizing enzymes (11-β-hydroxysteroid dehydrogenase (11β-HSD)), CBG levels, the presence of efflux proteins (such as multi-drug resistance protein 1, MDR1), and the expression of the glucocorticosteroid receptors (GR). Other levels of regulation include variations in the receptor protein (isoforms, polymorphisms), alternative receptor dimerization, co-chaperones, levels of hsp, and posttranslational modifications[54].

Approximately 70% of corticosteroid metabolism occurs in the liver, and involves the cytochrome P450 system[55]. Intestinal metabolism is also important, as the intestinal sites of cortisol and cortisone metabolism in humans are saturated before the hepatic sites[56]. The majority of corticosteroids are excreted in the urine, although small amounts are detectable in fecal, biliary and pulmonary CO_2 excretions[48,49,57].

Glucocorticosteroid receptors (GR) are 94 kDa proteins found in the cytoplasm of cells from many tissues. When ligand binding occurs, an inhibitory protein is released, the receptor dimerizes, hyperphosphorylation occurs[58-60], and a DNA binding site is exposed (Figure 1). This conformational change, which may unmask nuclear localization signals, allows the GR to translocate to the nucleus. The GR may affect gene transcription and subsequent protein synthesis by interacting with specific nuclear binding sites (referred to as glucocorticosteroid response elements, GRE). This causes either stimulation or, less frequently, inhibition of transcription. Also, the binding of the GR homodimer to the GRE may induce rearrangement of the chromatin, allowing other transcription factors to bind to previously inaccessible DNA[61].

The GR may also interact with other transcription factors, such as AP-1, in which case transcription is commonly inhibited[62,63]. There are several other transcription factors that have been linked to the GR, including the p65 subunit of NFκB[64,65].

The unliganded GR may be associated with heat shock proteins (hsp), including hsp56, hsp70 and hsp90. There may be constant cycles of dissociation/reassociation of these components, as well as constant bi-directional shuttling of GR between the cytosol and the nucleus[66,67]. Furthermore, the action of hsp70 and hsp90 may be further regulated, either positively or negatively, by co-chaperones[68-71]. These proteins may

Figure 1 Simplified model of GR-mediated transcriptional modulation. (from Bamberger *et al* 1996).

also be involved in recruiting transport proteins to the receptor complex, regulating hormone binding to the receptor, and modulating the regulatory function of GR by disassembling transcription complexes[70-73].

Several other factors may influence GR-mediated transcriptional activation. For example, it has been suggested that competition between transcription factors for limited coactivator molecules may lead to gene repression[74,75]. Alternatively, cofactor effects may be restricted to designated compartments, and dynamic cofactor modules may hit promoters in a cyclic way during transcription[72-73,76-77]. In addition to acetylation, methylation and phosphorylation of histones may influence transcriptional control[78-80], as also could phosphorylation of the GR[81].

Some of the effects of GC occur too rapidly to be explained at the genomic level of transcription. Distinct GR forms or a cytosolic subset of GR may interact with signal transduction pathways, which are usually associated with membrane receptor signalling events[82]. Extensive crosstalk between steroid- and growth factor-stimulated signalling pathways occurs, and may impact the functioning of steroid receptors and genes that are regulated by steroids[83].

A number of synthetic GC have been developed with increased potency when compared to the naturally occurring substances. The increased potency, however, comes with an increased potential for adverse effects. The high potency of the synthetic steroid is attributed to its long half life and high affinity for the GR. DEX is commonly used in the research setting due to its' unique properties. The synthetic DEX differs from the naturally occurring cortisol due to the addition of a double bond between carbon 1 and 2, fluorination of the 9 position, and the addition of a methyl group. Therefore, while most GC in the plasma is bound to the CBG, DEX circulates freely, with blood concentrations unaffected by changes in CBG levels. This is particularly important in studies of development, as CBGs are known to be developmentally regulated[84]. The placental enzyme 11-β hydroxysteroid dehydrogenase type-2 (11β-HSD2) protects the fetus by converting maternal cortisol into inactive cortisone, due to its dehydrogenase

activity[85]. However, the unique structure of DEX allows it to cross the placenta by escaping deactivation by 11β-HSD2.

Intestinal maturation

The effect of GC on prenatal intestinal maturation was investigated by Gartner *et al*[86], using mice lacking a functional glucocorticoid receptor (GR-/). Although a temporal association exists between the prenatal GC surge and corresponding intestinal development, the results of this study suggest that steroids are not mandatory for prenatal intestinal maturation. Histological examination of 18 d old fetal mice failed to demonstrate any effects of the GR-/- phenotype on intestinal morphology, or on measures of functional development (including enterocyte, Goblet and enteroendocrine cell numbers). LPH activity (as measured by X-gel staining) and the number of proliferating cells (as assessed by KI-67 staining) were also unaffected by the absence of GR. Thus, the rodent intestine appears to pass through a period of unresponsiveness to GC during fetal life, prior to becoming responsive in the postnatal period.

The role of GC in postnatal development has been well characterized. Indeed, adrenalectomy during the suckling period retards the functional maturation of the small intestine, while exogenous administration of GC may cause precocious maturation[87-89]. The mechanisms by which GC may influence maturation are not completely understood. There may be direct as well as indirect effects of GC. For example, Schaeffer *et al*[90]) injected hydrocortisone (50 g/g, *sc*) into 11 d old rats; they showed that the precocious induction of the BBM enzyme sucrase isomaltose (SI) paralleled decreases in TGF-β and the cytokine IL-1α, and increases in TNF-α. This finding suggests that cytokine levels may mediate the effects of GC on postnatal intestinal maturation.

The development of GC responsiveness was characterized in more detail by Solomon *et al*[89] using trehalase as a marker of intestinal maturation, they showed three phases of responsiveness to GC in mice: (1) a prenatal phase during which time Dexamethasone (DEX) did not induce maturation; (2) an early postnatal phase (first 2 postnatal weeks) of moderate responsiveness; and (3) a subsequent phase of increasing responsiveness in the third postnatal week. Postnatal increases in responsiveness were not paralleled by increases in GR abundance, but were associated with elevated circulating T4 concentrations. This observation fits with previous work demonstrating a synergistic effect of GC and T4 on BBM enzyme expression[91-93] also previously demonstrated three post-natal phases of responsiveness to GC. Based on the effects on SI mRNA and activity in rats, they identified (1) an early phase (day 10) when activation of the gene occurs; (2) a late phase (day 16) when changes in cell kinetics are observed; and (3) a loss of responsiveness (day 18) to GC. Although the exact timing of the various phases is not consistent between studies, it is clear that steroids

have maximal effects in the early postnatal period.

Although some studies have shown that GC are not important in fetal development[86,89], not all researchers would agree with the suggestion that the fetus is unresponsiveness to GC. For example, Buchmiller and colleagues[94] showed that maternal DEX administration produced increases in small intestinal length and a trend towards an increase in LPH and maltase activity in fetal rabbits. The everted sleeve technique was used to demonstrate increases in glucose and proline transport in fetal rabbits exposed to DEX. When the fetal rabbits were subdivided into categories based on uterine position, runt fetuses exposed to DEX exhibited high nutrient uptake rates, surpassing the rates of the favored fetuses. This suggests that the runt intestine may be more responsive to steroid treatment, an observation with interesting implications regarding the potential clinical treatment of low birth weight or growth retarded infants.

The effects of GC on fetal intestine were also examined in a rabbit gastroschisis model. Gastroschisis is a herniation (displacement) of the intestines through a defect on one side of the umbilical cord. Intra-amniotic DEX (0.2 μg/g per day) infusion enhanced intestinal disaccharidase activity and glucose uptake in fetuses with experimentally induced herniation of the small intestine into the amniotic cavity[95]. While this study looks at a specific congenital dysfunction, it clearly demonstrates that the fetal intestine is capable of responding to GC.

What is the effect of GC on the intestine of human neonates? Nanthakumar *et al*[96]. used human intestinal xenografts to characterize the response of the developing intestine to GC. Responsiveness was determined by lactase activity and cytokine induction after a proinflammatory stimulus. Immature transplants (20 wk) responded to GC, but that this effect was lost in the mature (30 wk) transplants. This suggests that in humans there may also be a brief period of responsiveness *in utero* to GC.

Costalos *et al*[97] showed that in humans, maternal DEX administration increased fetal and neonatal plasma gastrin concentrations, while motilin was increased only in neonates, and vasointestinal peptide concentrations were unchanged. The authors speculate that the effects of GC on the gastrointestinal tract may be at least partially mediated by their actions on other GI hormones.

Clearly, there is contradictory evidence regarding the ability of the fetus to respond to steroids. The discrepancies may be due to the use of different indicators (trehalase, SI, nutrient uptake, morphology) of GC responsiveness. Maternal DEX administration may have a direct effect on the fetus, as DEX is known to cross the placenta[98]. However, it is also possible that the maternal administration of DEX has an indirect effect on the fetus, through the modulation of other factors such as cytokines, hormones or growth factors.

There are many other adverse effects of the therapeutic administration of GC, such as glaucoma,

poor wound healing, muscle atrophy, hypertension, hyperglycemia/diabetes, withdrawal syndrome, increased risk of infection, GI ulcers/perforation/bleed, thin skin, poorly developed muscle, thin extremities, fat collection in abdomen and upper back ("buffalo hump"), salt and water retention "moon face", osteoporosis, avascular necrosis, and CNS effects such as increased appetite, insomnia, euphoria and frank psychoses.

GC may also be used to accelerate lung maturation and surfactant production in premature infants, although DEX is not recommended as it is associated with impaired growth and neurodevelopmental delay. GC administration reduces the incidence of NEC in infants: a prospective experiment looking at prenatal or postnatal steroid use demonstrated a reduction in NEC in neonates[99]. Animal models of DEX administration demonstrate increased mucosal maturation, with increased enterocyte and goblet cells, coupled with a thinning of the muscularis[100]. Unfortunately, between early postnatal administrations of DEX is associated with the development of focal small bowel perforation[100,101]. The mechanism associated with the differential effect of GC on intestinal mucosa and muscularis is not fully understood. Although *in vitro* work on intestinal smooth muscle cells suggests that DEX alters the expression of collagen and other basement membrane elements[102,103], *in vivo* remodelling of the extracellular matrix by DEX has not been shown.

The tissue specific effects of GC may be the result of a redistribution of growth factors. DEX administration in newborn mice alters IGF-I immunolocalization, with increased protein detected in the mucosa, and reduced levels in the muscularis[104]. *In situ* hybridization analyses for IGF-I transcripts showed no differences in localization between the groups. In addition to its' effects on IGF-I immunolocalization, DEX (i.p. 1 μg/g, once daily) altered IGF-I binding protein composition in the mucosa in newborn mice. This alteration may be responsible for drawing IGF-I from the mesenchyme to the mucosa, and subsequently influencing intestinal maturation[105].

Further support for the involvement of the IGF-I system in NEC comes from the work of Burrin *et al*[106], who showed that in addition to decreases in circulating IGF-I and alterations in IGF-I binding proteins, neonatal pigs treated with DEX (subcutaneous, 1 mg/kg, for 7 d) had increased IGF-I receptor mRNA abundance. This increase was only observed in the stomach and ileum, with no effect seen in the jejunum. This corresponds well with the authors' observation that the effects of DEX are most pronounced in the ileum. The catabolic effects of DEX were also characterized in this study: small intestinal growth, particularly in the ileum, was inhibited due to increases in protein degradation, without significantly affecting protein synthesis.

GC have well documented effects on the ontogeny of BBM hydrolases. Adrenalectomy delays enzyme maturation during the third post-natal week, while exogenous GC administration may induce the precocious appearance of SI activity[107]. In adult animals, however, disaccharidase activities in the small intestine are unaffected by adrenalectomy or by GC administration[108]. The administration of DEX in the neonatal period increases the intestinal uptake of sugars (Drowdowski *et al*, unpublished observations, 2005).

There may be a syngeristic interaction between GC and T4 on BBM enzyme maturation. This was thought to involve the ability of T4 to increase corticosteroid-binding globulin, which subsequently reduces the clearance of hydrocortisone[109]. However, work by McDonald and Henning[110] demonstrated synergism between DEX and T4. This indicates that an additional mechanism must be involved since DEX does not bind to CBG. In this study, animals received daily injections of subcutaneous T4 (130 pmol/g body weight) and a non-saturating dose of DEX (0.01 μg/g body weight) from post-natal day 5 to12. The hormones synergistically increased jejunal SI as well as ileal and duodenal alkaline phosphatase, and decreased ileal β-galactosidase activity, but did not affect jejunal or ileal LPH activity. When administered alone, T4 did not affect intestinal maturation, and DEX only partially stimulated maturation, when compared to the combination of hormones. The authors concluded that enzymes that rise post-natally responded to treatment with the combination of the T2 and DEX, while enzymes that decline post-natally show a mixed response.

In suckling rodents, GC regulate the expression of BBM enzymes such as SI-isomaltase and trehalase[107,111,112]. However, following GC administration, it takes 12-24 h to observe increases in the transcription of these genes. This delayed time-course suggests the involvement of secondary response genes[113]. Oesterreicher and Henning[114] identified a region of the trehalase promoter with potential binding sites for several transcription factors. Electromobility shift assays were performed using oligonucleotides from this region, as well as nuclear extracts from jejunum of 8 d old control or DEX-treated (1 g/g body wt) mice. They found that DEX stimulated expression of GATA-4 and GATA-6 proteins. These transcription factors are recognized as being important regulators of intestinal gene expression, and may interact with other transcription factors including those from the Sp family, Cdx, HNF-1 and HNF-4[115-120]. Indeed, GATA factors may allow cooperating transcription factors to bind to the DNA by altering the chromatin structure[119]. Although this study failed to prove that the induction of GATA factors leads to transcriptional activation of the BBM hydrolases, it does increase our understanding of possible mediators of GC effects.

Other molecular signals that may be responsible for the ontogenic changes in intestinal gene expression include a group of transcription factors called CCAAT/enhancer binding proteins (C/EBPs). In an attempt to determine regulatory mechanisms involved in the expression of the C/EBP α, β and δ isoforms, Boudreau *et al*[120] examined their expression in response to GC in the rat intestinal epithelial crypt-derived cell line

IEC-6, using Northern blot, transcription run-on assays, indirect immunofluorescence, Western blot, and electrophoretic mobility shift assays. Whereas C/EBP α expression was not regulated by GC, C/EBP β and δ mRNA and protein levels were rapidly induced. Moreover, C/EBP β- and δ-containing DNA binding complexes were increased by GC as determined by supershift assays, in contrast to C/EBP α containing complexes. Immunofluorescence studies showed cytoplasmic and nuclear localization for C/EBP α. This is in contrast to a restricted nuclear localization for both C/EBP β and C/EBP δ. Differential regulation by GC as well as the different localization of three C/EBP isoforms suggest a role for this class of transcription factors in the control of gene expression in intestinal epithelial cells.

Mechanisms of action

The mechanisms by which GC exert their effects may involve several other factors. Boudreau *et al*[121] showed that DEX increases c-fos and c-jun, and increased AP-1 DNA-binding capacity in IEC-6 cells. Ras transformation repressed the growth-inhibitory properties of DEX, and inhibited the induction of c-fos protein and mRNA. This suggests that Ras negatively modulates the response of intestinal epithelial cells to GC. Thiesen *et al*[122] have shown that early response genes may be involved in the effect of GC on the enhancement of intestinal absorption of nutrients that occurs after intestinal resection. This further illustrates the cross-talk that occurs between GC and intracellular signaling pathways.

GC may also exert their effects by influencing cellular proliferation, differentiation and apoptosis. Foligne *et al*[123] investigated the effects of 10-dbilateral adrenalectomy on morphometry, proliferation and apoptosis in the small intestine of 3 mo old Sprague-Dawley rats. Adrenalectomy led to partial atrophy and disorganization of the epithelium, with an increased number of goblet and Paneth cells. A reduction of crypt cell proliferation was paralleled by a marked increase in apoptosis in the villus.

Several other studies suggest that steroids may increase apoptosis. *In vitro* studies using rat jejunal epithelial cells (IEC-6) cells show that the locally acting budesonide increases apoptosis, while *in vivo* studies show that steroids increase apoptosis in intraepithelial lymphocytes[124,125].

There are conflicting reports on the effect of GC on intestinal proliferation. Low to medium doses (10^{-6}-10^{-11}) increase proliferation in IEC cells, while high doses (10^{-5}) inhibit proliferation[126]. Other studies suggest that the effect of steroids on proliferation depends on the developmental stage of the animal[127], Similarly, the location of the cells along the crypt-villous axis is an important factor as DEX reduced proliferation in the upper but not the lower crypt of fetal mouse duodenal explants[128]. This points to an important role of the adrenal glands and GC in the trophic status of the adult small intestinal mucosa. These results also highlight that the atrophy associated with GC is associated with

a reduction in proliferation together with an increase in apoptosis. It is possible that some of the negative effects of GC on the intestine could be reduced or prevented by the administration of a trophic agent.

Early exposure to GC has been associated with lasting effects on cardiovascular, endocrine and metabolic systems. For example, prenatal glucocorticiod exposure results in reduced birth weight[129-134], increased blood pressure[135] increased expression of the glucocorticoid receptor in visceral fat[136], impaired coping in adverse situations[137], increases in corticosterone levels[135,137] hyperglycemia/hyperinsulinemia[131,138,139], increased susceptibility of the inner ear to acoustic noise trauma[140] and increases in PEPCK (rate-limiting enzyme in gluconeogenesis) mRNA and activity[141]. Steroids may also influence the development of the retina, although studies have shown both a positive effect on experimentally-induced retinopathy[142,143] and an increased risk of retinopathy of prematurity[144]. Furthermore, neurodevelopmental problems including an increased risk of cerebral palsy[145] have been documented following postnatal steroid administration.

It is not known if early exposure to GC results in lasting effects on intestinal function. However, because steroids are known to influence intestinal transport in adult animals[146], and because steroids influence the ontogeny of the intestine[110,147], it seems plausible that they may also play a role in the programming of intestinal function.

Effects on adult intestine

Does the adult small intestine remain responsive to steroids? Foligne *et al*[123] attempted to answer this question: three month old Sprague Dawley rats underwent bilateral adrenalectomies, and were sacrificed 10 d after surgery. Adrenalectomy modified maturation and differentiation, particularly in the proximal small intestine. A partial atrophy and disorganization of villous architecture was noted, coupled with decreases in crypt cell proliferation and increases in apoptotic cells in the upper villous region. LPH and SI were increased by adrenalectomy, while aminopeptidase N and intestinal alkaline phosphatase activities were reduced. These results indicate that the adrenal glands and GC play an important role in the trophic status of the small intestine in adult rats.

GC are used to treat various disorders including rheumatoid arthritis, inflammatory bowel disease, systemic lupus erythematosus, allergies and asthma due to their anti-inflammatory effects[148]. Both NFκB and AP-1 are crucial for the induction of many genes involved in inflammation. GC may interfere with the transcriptional activity of these and other factors. Alternatively, GC may also interact with a negative GRE (nGRE) and thereby inhibit transcription. Although the anti-inflammatory effects of GC may be due to negative modulation of pro-inflammatory factors (transrepression), the side effects may be the result of transactivation[149]. This has created interest in developing "dissociating steroids", in which

the desirable transrepression effect is separated from undesirable transactivation effect.

Glucocorticoid resistance may occur as GC reduce GR expression[150]. The importance of GC is clear from the clinical symptoms associated with a deficiency or excess of the hormones. Cortisol deficiency (Addison's disease) is characterized by postural hypotension, weight loss and hypoglycaemia GC excess (Cushing's syndrome) is characterized by hypertension, central obesity and glucose intolerance.

Quaroni et al[151] found that exposing IEC cells to GC cause growth arrest, the formation of tight junctions, the appearance of tall slender microvilli, reorganization of the ER and Golgi, and decreased cdk6 as well as p[27kip1] protein. These results are consistent with the activation of multiple genes important in the functioning of absorptive villous cells, but likely not involved in the induction of cell differentiation.

The role of the mesenchyme in mediating the effects of GR was studied by Simo et al[152] GC treatment of mesenchyme-derived cell populations resulted in an accumulation of laminin at the cell surface, accompanied by enhanced expression of BBM enzymes. This effect was abolished by anti-laminin, suggesting that GC may lead to accelerate laminin organization at the epithelial-mesenchymal interface, leading to epithelial cell differentiation.

Glucocorticosteroids and sugar transport

GC alter sugar transport in a number of other tissues. GLUT4 expression in adipose tissue is diminished in response to DEX, while GLUT4 in muscle is increased[153]. In adipocytes, DEX increased GLUT4 levels at the plasma membrane in the basal state, while GLUT4 translocation in response to insulin was inhibited.

Oral glucocorticosteroids increase intestinal sugar transport. For example, using an in vivo recirculation-perfusion technique in rats, Batt and Peters[154] showed that 7 d of prednisolone increased intestinal galactose absorption per enterocyte, without influencing the intestinal mucosa or cell kinetics. Similarly, short-term pharmacological doses of prednisolone increased digestive/absorptive function, while paradoxically decreasing the epithelial cell population in rats[155]. Long-term (28 d) administration of prednisolone or betamethasone in rats increased the activity of BBM proteins and galactose absorption, but induced atrophy of the mucosa and inhibition of cell turnover[156].

When the proximal jejunum of humans was perfused with glucose (28 mmol), intraluminal (100 mg/L) hydrocortisone increased sodium, water and glucose absorption[157] when compared to controls. Thiesen et al[146] assessed the influence of the glucocorticosteroids budesonide and prednisone on the in vitro uptake of sugars in weaning male rats. The steroids had no effect on the uptake of D-glucose by SGLT1. In contrast, the uptake of D-fructose by GLUT-5 was increased with both budesonide and prednisone. The increases in the uptake

of fructose were not due to variations in the weight of the intestinal mucosa, food intake, or in GLUT-5 protein abundance or mRNA expression. This enhanced uptake of fructose was likely regulated by posttranslational processes, such as enhancement of the intrinsic activity of the transporters. There were no steroid-associated changes in mRNA expression of c-myc, c-jun, c-fos, proglucagon, or selected cytokines. However, the abundance of ileal ornithine decarboxylase mRNA was increased with Prednisone.

Thiesen et al[122] further characterized the effect of steroids using a model of intestinal resection. Adult male Sprague Dawley rats underwent transection or resection of 50% of the middle portion of the small intestine. Prednisone had no effect on the in vitro uptake of glucose or fructose in resected animals. In contrast, in resected rats budesonide increased by over 120% the value of the jejunal maximal transport rate (Vmax) for the uptake of glucose, and increased by over 150% ileal uptake of fructose. Changes in SGLT1, GLUT5, GLUT2, and Na^+K^+-ATPase protein abundance and mRNA expression did not explain the enhancing effect of budesonide. The steroids reduced c-jun, ODC and proglucagon expression. These data suggest that the influence of GC on sugar uptake in resected animals may be achieved by post-translational processes involving signalling with c-jun, ODC, and proglucagon, or perhaps also other as yet unknown signals.

GLUCAGON-LIKE PEPTIDE-2 (GLP2)

Biochemistry

Proglucagon is a 160 amino acid peptide encoded by the glucagon gene, and is present in intestinal L cells and α cells of the islets of Langerhans[213,214]. Proglucagon undergoes post-translational processing in the pancreas liberating glucagon as the main product. In the intestine, several peptide products (collectively referred to as "enteroglucagon") are produced including glucagon-like peptide-1 (GLP1) and glucagon-like peptide-2 (GLP2) (Figure 2).

Both GLP1 and GLP2 are secreted from the L cells of the distal small intestine and colon in response to enteral nutrients[215]. Both fatty acids[216] and glucose[217] stimulate secretion from L cells, but protein meals do not increase GLP1 or GLP2 secretion[218,219]. However, amino acid mixtures have been shown to stimulate GLP1 release in humans[220], and meat hydrolysates do stimulate GLP1 secretion from rat intestinal L cells in vitro[221].

The secretion of these peptides is biphasic, with an early peak within 30 min of a meal, followed by a later peak at 60-120 min[219]. It is thought that neuroendocrine pathways may be responsible for the early secretion, as luminal nutrients are not likely to reach the distal L cells within 30 min of ingestion[216,222].

The peptides are degraded in the plasma by dipeptidyl peptidase IV (DPPIV)[223], with a half-life for GLP2 of 7

Figure 2 Post-translation processing of proglucagon in the pancreas and the intestinal L-cells. The numbers represent the amino acid at which enzymatic cleavage occurs.

min[224]. DPPIV-resistant analogs (ALX-600, Teduglutide) with greater potency have been developed for clinical use. These will be discussed in more detail in later sections.

The receptor is a G-protein coupled receptor with 7 transmembrane domains, and is encoded by a single gene localized to chromosome 17p13.3. GLP2R expression is highest in the proximal small intestine, and decreases distally along the longitudinal axis[225]. GLP2R has been localized to intestinal enteroendocrine cells in humans using immunohistochemistry[226], to enteric neurons in mice using reverse transcription polymerase chain reaction (RT-PCR) and immunohistochemistry[227], and to rat enterocytes using ^{125}I-GLP2[228]. Orskov *et al*[229] found GLP2 receptors mainly on subepithelial myofibroblasts in rat, mouse, and human small and large intestine by immunohistochemistry and *in situ* hybridization. By double labelling they found that these GLP2 receptor immunoreactive cells also produce smooth muscle actin and keratinocyte growth factor (KGF). KGF antibody abolished the growth promoting effect of GLP2 in the large intestine, but not in the small intestine. This suggests that GLP2 in the gut may act by activating receptors on the subepithelial myofibroblasts, thereby causing the release of growth factors, which in turn stimulate intestinal growth. Therefore, at this time it remains unclear whether the intestinotropic effects of GLP2 are due to direct effects on enterocytes, or are mediated by secondary factors.

Physiological effects

While GLP1 has potent insulinotropic effects[230], GLP2 has been found to be an important intestinotrophic factor. The relationship between enteroglucagon and small bowel growth was first documented by Gleeson *et al*[231]: a patient with an enteroglucagon-producing tumor exhibited small bowel hyperplasia, and injection of the tumor extract into mice resulted in intestinal growth[232]. Drucker *et al*[233] demonstrated that GLP2 was the specific agent responsible for this effect. GLP2 appeared to exert a "tissue specific" effect on the gut, as no changes were found in other tissues including spleen, heart, brain and liver.

GLP2 given subcutaneously adult to mice (6-43 g, twice daily, for 10 d) increases small bowel weight and crypt-villous height[234,235]. Intestinal proliferation was increased, and apoptosis was reduced. The effect of GLP2 was not due to changes in food consumption. The effects of GLP2 were sustained, as increases in growth were still evident after three months of administration. The rapid turnover of the epithelium was thought to contribute to the lack of densensitization that was observed with prolonged GLP2 treatment.

In addition to its morphological effects, GLP2 (when administered intravenously or subcutaneously) also increases the activity and expression of BBM enzymes including SI, LPH, maltase-glucoamylase and aminopeptidase N[236-238]. Although the effects on gastric physiology in humans have been conflicting[239,240], inhibition of gastric emptying in pigs has been observed with GLP2 treatment[241]. Reductions in meal-stimulated gastric acid secretion have also been observed with GLP2 administration in humans[242]. GLP2 enhances barrier function in murine intestinal epithelium[243], making it a potential therapeutic for disorders such as inflammatory bowel disease and necrotizing pancreatitis, both of which are characterized by increases in intestinal permeability[243,244].

While the mechanism by which GLP2 stimulates the adaptive response is unknown, its effects on an immediate early gene, PC4/TIS7, have been observed. In postconfluent, quiescent IEC 18 cells in culture, a stable derivative of GLP2, r(gly2)GLP2, increased PC4/TIS7 expression. r(gly2)GLP2 administered intraperitoneally to mice similarly induced increased PC4/TIS7 mRNA compared with vehicle control[245].

A number of studies aimed at establishing the effect of GLP2 on intestinal transport. Cheeseman and Tsang[246] showed that a two hour vascular perfusion of GLP2 (4 h, 400 and 800 pmol/L) in rats increased D-glucose Vmax by about 65% in the baselateral membrane, and by three-fold in the BBM, with a concomitant increase in SGLT1 protein[247]. An anti-GLP antibody abolished the GLP2-induced increase in transport[246].

Not all studies have demonstrated an effect of GLP2 on nutrient transport. For example, Brubaker *et al*[237] treated mice subcutaneously with GLP2 (2.5 μg) for a 10 d period, and failed to reveal increases in the absorption of glucose or maltose. Curiously, an increased capacity for nutrient digestion was found to be due to increases in BBM enzyme activities, resulting in an apparent uncoupling of digestive capacity from subsequent sugar absorption. It is unclear if there is this discrepancy in the results of these studies on the effect of GLP2 or nutrient uptake.

The rapid trafficking the glucose and fructose transportation contributes to the sugar uptake GLUT2 into the BBM following a glucose infusion of meal[248-250]. GLUT2 protein levels in the BBM increased two-fold when luminal perfusions were increased from

0 mmol/L to 100 mmol/L glucose. One hour vascular infusion of GLP2 doubled the rate of fructose uptake into BBM following luminal fructose perfusion[251]. Fructose absorption in this study was determined by the appearance of fructose in the vascular bed. Western blotting of biotinylated surface-exposed protein showed a doubling of GLUT2 expression in the BBM following GLP2 infusion. Thus, GLP2 may promote the insertion of GLUT2 into the BBM, thereby providing a low affinity/ high capacity route in addition to SGLT1 and GLUT5 by which fructose or glucose may be absorbed into the enterocyte.

Ramsanahie et al[252] examined the effect of chronically administered GLP2 on diurnal SGLT1 expression. Rats were treated with [Gly2]GLP2 (twice daily; 1 mg/g body weight) or vehicle (control) for 10 d. GLP2 administration did not alter the diurnal increase in mRNA levels of SGLT1, GLUT2, or GLUT5. However, SGLT1 protein was increased three-fold by GLP2, and in situ hybridization showed that SGLT1 mRNA was distributed along the entire length of the villi. This is in contrast to what was seen in control animals, where SGLT1 was restricted to the mid and upper villus, with less SGLT1 mRNA localized to the villous tip. Also, in contrast to the diffuse staining seen in control animals, immunofluorescence microscopy showed that SGLT1 protein in GLP2 treated animals was preferentially localized to the BBM, with little or no staining in the cytoplasm. This may represent another mechanism by which GLP2 increases intestinal glucose uptake.

The effect of GLP2 on in vivo nutrient absorption may also be attributed to nitric oxide-dependent increases in intestinal blood flow. Infusing GLP2 (500 pmol/kg per hour) for 4 h in TPN-fed piglets led to increased portal-drained visceral (PDV) blood flow rate, intestinal blood volume, and PDV glucose uptake. GLP2 also increased intestinal constitutive nitric oxide synthase (NOS) activity and endothelial NOS protein abundance[253]. Thus, in TPN-fed neonatal pigs, GLP2 acutely stimulates intestinal blood flow and glucose utilization, and that this response is nitric oxide-dependent.

Walsh et al[254] studied GLP2 signalling in isolated rat intestinal mucosal cells expressed mRNA transcripts for the GLP2R, as well as for chromogranin A and β-tubulin Ⅲ, markers for enteroendocrine and neural cells, respectively. cAMP production in response to [Gly2]GLP2, a degradation-resistant analog of GLP2, was maximal at 10^{-11} mol/L with reduced cAMP accumulation observed at higher doses. The cAMP response was abolished by pretreatment with 10^{-6} mol/L GLP2, indicating receptor desensitization. GLP2 treatment of isolated mucosal cells increased ^{3}H-thymidine incorporation, and this was prevented by inhibition of the protein kinase A pathway. In contrast, GLP2 did not affect p44/p42 MAPK phosphorylation or the levels of cytosolic calcium in the mucosal cell preparation. These results provide evidence that activation of the endogenous rat mucosal GLP2 receptor is linked to activation of a cAMP/protein kinase A-dependent, growth-promoting pathway in vitro.

Estall et al[255] examined the mechanisms regulating signaling, internalization, and trafficking of the GLP2R to identify determinants of receptor activation and desensitization. Heterologous cells expressing the transfected rat or human GLP2R exhibited a rapid, dose-dependent, and prolonged desensitization of the GLP2-stimulated cAMP response and a sustained GLP2-induced decrease in levels of cell surface receptor. Surprisingly, inhibitors of clathrin-dependent endocytosis failed to significantly decrease GLP2R internalization, whereas cholesterol sequestration inhibited ligand-induced receptor internalization and potentiated homologous desensitization. The hGLP2R localized to both Triton X-100-soluble and -insoluble (lipid raft) cellular fractions and colocalized transiently with the lipid raft marker caveolin-1. Although GLP2R endocytosis was dependent on lipid raft integrity, the receptor transiently associated with green fluorescent protein tagged-early endosome antigen 1-positive vesicles and inhibitors of endosomal acidification attenuated the reappearance of the GLP2R on the cell surface. This data demonstrates that GLP2R desensitization and raft-dependent trafficking represent distinct and independent cellular mechanisms and provide new evidence implicating the importance of a clathrin- and dynamin-independent, lipid raft-dependent pathway for homologous G protein-coupled receptor internalization.

Intestinal resection

Plasma GLP2 levels rise following intestinal resection in rats[256-258]. When rats were subjected to a 70% midjejunoileal resection or ileal transection, and were maintained with TPN or oral feeding. Resection-induced adaptive growth in TPN- and orally-fed rats was associated with a significant positive correlation between increases in plasma bioactive GLP2 and proglucagon mRNA abundance in the colon of TPN-fed rats and in the ileum of orally fed rats[259]. While these increases were transient in the TPN-fed group, luminal nutrients produced a sustained increase detected at 3 and 7 d post-resection. These data support a significant role for endogenous GLP2 in the adaptive response to mid-small bowel resection in both TPN and orally fed rats.

GLP2 administration in rats increases the adaptive response to massive intestinal resection[260]. Sprague-Dawley rats were divided into two groups, with a 75% mid-jejunum-ileum resection and a sham operated group. Animals were given 0.1 μg/g GLP2 analog (protease resistant human GLP2) or placebo given subcutaneously twice daily for 21 d. Administration of the GLP2 analog was associated with an increase of the mucosal mass in the proximal jejunum and terminal ileum.

Martin et al[261] investigated the effects of GLP2 in a total parenteral nutrition (TPN)-supported model of experimental short bowel syndrome. Juvenile Sprague-Dawley rats underwent a 90% small intestinal resection, and were randomized to three groups: enteral diet and intravenous saline infusion, TPN only, or TPN +

10 μg/kg per hour GLP2. TPN plus GLP2 treatment resulted in increased bowel and body weight, villos height, intestinal mucosal surface area, crypt cell proliferation, and reduced intestinal permeability, as compared with the TPN alone animals. GLP2 increased serum GLP2 levels and intestinal SGLT-1 protein abundance as compared with either TPN or enteral groups. This demonstrates that GLP2 is capable of stimulating intestinal adaptation in the absence of enteral feeding. Because a number of hormones and growth factors have been shown to influence intestinal function, Washizawa *et al*[262] compared the effects of GLP2, growth hormone (GH) and keratinocye growth factor (KGF) on markers of gut adaptation following massive small bowel resection (MSBR). KGF increased goblet cell numbers and TTF3, a cytoprotective trefoil peptide, in both the small bowel and the colon. While both GH and KGF increased colonic mucosal growth, GLP2 exerted superior trophic effects on jejunal growth. GLP2 also increased the glutathione/glutathione disulfide ratio, resulting in improved mucosal glutathione redox status throughout the bowel. Because of the differential effects of GLP2, GH and KGF on gut adaptation following MSBR, the authors conclude that a combination of these agents may be most beneficial.

Human studies with GLP2 have also been performed: a non-placebo controlled study was conducted in 8 patients with short bowel syndrome (SBS) with an end-enterostomy type of anastomasis (6 had Crohn's disease and 4 were not receiving HPN)[263]. Treatment with GLP2 (400 μg subcutaneously twice a day for 35 d) increased intestinal absorption of energy, body weight, and lean body mass. Crypt depth and villous height were also increased in 5 and 6 patients, respectively.

The results of more recent studies of GLP2 in SBS have been reviewed[264] and concluded that "Currently, hormonal therapy in short-bowel patients should be considered experimental and it is only recommended in research studies. The optimal duration and concentration requirements for GLP2 to induce beneficial effects on intestinal secretion, motility, morphology and most importantly absorption, are not known. Optimal dosage and administration of this new treatment to short-bowel patients may eventually result in long-term improvements in nutritional status and independence of parenteral nutrition in a larger fraction of short-bowel patients".

Intestinal development
The topic of the Development of the Infant Intestine: Implications for Nutrition Support and a consideration of trophic factors essential to intestinal development, have recently been considered[265]. A role for GLP2 in the ontogeny of the intestine has been proposed. Lee *et al*[266] established that proglucagon mRNA was detectable in the rat fetus, and that immunoreactivity increased in the early neonatal period. Prohormone convertases, which are required for the liberation of GLP2 from proglucagon, are also detected in the fetal rat. Lovshin *et al*[267] detected GLP2R mRNA during fetal

and neonatal development in the rat, with levels being higher in the fetal and neonatal gut as compared to adult rats. High levels of GLP2 (1-33) were also detected in the circulation of 13 d old neonatal rats, and GLP2 immunoreactivity was found in the fetal rat intestine. In order to prove that fetal cells were capable of secreting GLP2, fetal rat intestinal cell cultures were studied, and were found to secrete correctly processed GLP2 (1-33). The administration of a degradation resistant GLP2 analog [h (Gly2)-GLP2] to 1 d old rat pups for a period of 10 d resulted in increases in both small bowel weight and length. Thus, the GLP2/GLP2R axis is functional in early life, and that the developing intestine is capable of synthesizing, secreting and responding to GLP2.

A subsequent study done by Petersen *et al*[236] on premature (92% gestation) TPN fed piglets demonstrated that in addition to increases in maltase mRNA and activity, increases in SI and aminopeptidase N activities were observed. Thus, it appears that some of the effects that GLP2 exerts on intestinal function may be related to gestational age at birth, as the premature intestine was more responsive to exogenous GLP2 than the term neonatal intestine. The authors also noted that GLP2 infused into pig fetuses *in vivo* passed into the maternal circulation[268]. This suggests that GLP2 may pass through the placenta, and conversely, may expose the fetus to maternal GLP2. This raises the possibility that GLP2 given to pregnant animals may alter the form and function of the offspring.

Signalling events
Even before the GLP2 receptor was cloned, the role of the PI3K pathway in mediating the effects of GLP2 on intestinal sugar transport was studied by Cheeseman *et al*[247]: *in vivo* infusions of GLP2 produced an acceleration of sodium-dependent glucose uptake into BBM vesicles, with similar increase in SGLT-1 abundance. The effect of GLP2 could be inhibited by luminal brefeldin A, which blocks protein trafficking from the Golgi to the plasma membrane, or by the PI3K inhibitor, wortmannin. These results indicate that GLP2 is able to induce trafficking of SGLT-1 from an intracellular pool into the BBM and that PI3K may be involved in the intracellular signaling pathway in this response.

Because the GLP2R is not expressed on any intestinal cell lines, *in vitro* studies on GLP2 receptor signalling have been carried out in transfected heterologous cell types. Work done on transfected baby hamster kidney fibroblasts showed that GLP2 stimulated AP-1 dependent pathways increased cAMP, but did not change intracellular calcium levels[269]. There is decreased apoptosis and reduced caspase-3 activation following GLP2 treatment *in vitro*[270]. PKA, PI3K and the ERK pathways were not found to be essential for GLP2 inhibition of apoptosis, which was associated with reductions in cytochrome c release and cleavage of poly ADP-ribose polymerase (PARP).

GLP2-treated cells (10 μm, 3 d) demonstrated a greater than 10-fold increase in proliferation in Caco2

cells[271]. This response was inhibited by PI3K and mitogen activated/extracellular signal-regulated kinase (MEK) inhibitors. A significantly greater abundance of the phosphorylated forms of both ERK-1 and ERK-2 was present in cells following GLP2. This suggests that the increase in Caco-2 proliferation in response to GLP2 may be due, at least in part, to the involvement of both the PI 3-kinase and the MAPK pathways.

The limitations of this work, however, centers around the fact that both the authors of this study as well as Yusta et al[270] were unable to show, using Western blotting or RT-PCR, that Caco2 cells express endogenous GLP2R. This suggests that the proliferative effect of GLP2 on Caco2 cells may be mediated by other receptors, such as the EGFR, which mediates GLP1 induced proliferation in pancreatic β cells[272]. Furthermore, the observation that GLP2 is able to induce proliferation in a tumor cell lines, raises a concern regarding the role of GLP2 in promoting tumor growth. Indeed, recent work by Thulesen et al[273] showed that GLP2 promotes the growth of mucosal neoplasms in female C57bl mice whose colonic tumours were experimentally induced by administering a methylating carcinogen.

Koehler et al[274] identified several expressed sequence tags from human cervical carcinoma cDNA libraries that correspond to GLP2R nucleotide sequences. GLP2R mRNA transcripts were detected by RT-PCR in HeLa cervical carcinoma cells and Ca Ski cervical carcinoma cells. GLP2 increased cAMP accumulation and activated ERK1/2 in HeLa cells transiently expressing the cloned human HeLa cell GLP2R cDNA. However, the GLP2R-induced activation of ERK1/2 was not mediated through Gαs, adenylyl cyclase, or transactivation of the epidermal growth factor receptor, but was pertussis toxin sensitive, inhibited by dominant negative Ras, and dependent on betagamma-subunits. GLP2 also induced a significant increase in bromodeoxyuridine incorporation that was blocked by dominant negative Ras. Furthermore, GLP2 inhibited HeLa cell apoptosis induced by LY294002 in a protein kinase A-dependent, but ERK-independent, manner. These findings demonstrate that the HeLa cell GLP2R differentially signals through both G(α)s/cAMP- and G(i)/G(o)-dependent pathways, illustrating for the first time that the GLP2R is capable of coupling to multiple heterotrimeric G proteins defining distinct GLP2R-dependent biological actions.

Finally, the effects of GLP2 may be due to transactivation of other cell surface receptors. For example, GLP1 increases PI3K activity and enhances β-cell proliferation via transactivation of the EGFR[272].

Yusta et al[275] demonstrated that GLP2, in a cycloheximide-insensitive manner, enhanced survival in baby hamster kidney cells stably transfected with the rat GLP2R, reduced mitochondrial cytochrome c efflux, and attenuated the caspase-dependent cleavage of Akt, poly (ADP-ribose) polymerase, and β-catenin following inhibition of phosphatidylinositol 3-kinase

(PI3K) by LY294002. The prosurvival effects of GLP2 on LY294002-induced cell death were independent of Akt, p90 (Rsk), or p70 S6 kinase activation; were mimicked by forskolin; and were abrogated by inhibition of protein kinase A (PKA) activity. GLP2 inhibited activation of glycogen synthase kinase-3 (GSK-3) through phosphorylation at Ser (21) in GSK-3α and at Ser (9) in GSK-3β in a PI3K-independent, PKA-dependent manner. GLP2 reduced LY294002-induced mitochondrial association of endogenous Bad and Bax and stimulated phosphorylation of a transfected Bad fusion protein at Ser (155) in a PI3K-independent, but H89-sensitive manner, a modification known to suppress Bad pro-apoptotic activity. These results suggest that GLP2R signaling enhances cell survival independently of PI3K/Akt by inhibiting the activity of a subset of pro-apoptotic downstream targets of Akt in a PKA-dependent manner.

Rocha et al[276] assessed the proliferative actions of GLP2 on the human Caco-2 cell line. GLP2 stimulated proliferation was inhibited in a dose-dependent fashion by both pertussis and cholera toxin (specific G protein inhibitors). This suggests that a G-protein-linked signaling pathway is involved with GLP2 bioactivity in Caco-2 cells. GLP2 stimulated proliferation was also augmented by 2',5'-dideoxyadenosine, which increases adenylate cyclase. Proliferation rates were inversely proportional to changes in intracellular cAMP concentration. These findings suggest that a G-protein linked signaling pathway is involved with GLP2 bioactivity in the intestinal epithelial cell line Caco-2.

Clinical

Burrin et al[277] studied 38 TPN-fed neonatal piglets infused intravenously with either saline or GLP2 at three rates (2.5, 5.0, and 10.0 nmol/kg per day for 7 d). GLP2 infusion dose-dependently increased small intestinal weight, DNA and protein content, and villus height; however, stomach protein synthesis was decreased by GLP2. Intestinal crypt and villus apoptosis decreased and crypt cell number increased linearly with GLP2 infusion rates, whereas cell proliferation and protein synthesis were stimulated only at the high GLP2 dose. The intestinal activities of caspase-3 and -6 and active caspase-3 abundance decreased, yet procaspase-3 abundance increased markedly with increasing infusion rate and plasma concentration of GLP2. The GLP2-dose-dependent suppression of intestinal apoptosis and caspase-3 activity was associated with increased protein kinase B and glycogen-synthase kinase-3 phosphorylation, yet the expression phosphatidylinositol 3-kinase was unaffected by GLP2. Intestinal endothelial nitric oxide synthase mRNA and protein expression was increased, but only at the high GLP2 dose. These authors concluded that the stimulation of intestinal epithelial survival is concentration-dependent at physiological GLP2 concentrations. However, induction of cell proliferation and protein synthesis is a pharmacological response. Moreover, they showed that GLP2 stimulates intestinal cell survival and proliferation

in association with induction of protein kinase B and glycogen-synthase kinase-3 phosphorylation and Bcl-2 expression.

Thus, GLP2 increases intestinal growth in premature, TPN-fed pigs by decreasing proteolysis and apoptosis, and enteral nutrition was not required for these effects to occur. The actions of GLP2 are transduced by the GLP2 receptor (GLP2R), which was characterized and cloned by Munroe *et al*[225]. GLP2R was detected in several rat tissues including the stomach, small bowel, colon, and in small quantities in other tissues such as brain and lung[225]. This raises the possibility that GLP2 may have effects beyond the small intestine. Indeed, Haderslev *et al*[278] found that GLP2 administration significantly increased spinal bone mineral density in short-bowel patients with no colon, due to beneficial effects of GLP2 on bone resorption[279]. Centrally administered GLP2 increases satiety in rodents[280,281], while peripherally administered GLP2 does not influence gastric emptying, food intake or satiety in humans[238,282].

Although the effects of early exposure to hormones such as GLP2 are unknown, the presence of circulating GLP2 and the detection of the GLP2R in fetal and neonatal rats[267] suggests a role for GLP2 in regulating intestinal development. Drozdowski *et al* (unpublished observations, 2006) has shown that GLP2 modifies intestinal morphology when given to suckling rats, and enhances sugar uptake into the intestine of rats whose mothers were given GLP2 during pregnancy and lactation. Therefore, it is possible that exposing young animals to GLP2, either directly or *via* their pregnant and lactating dams, may also have lasting effects on intestinal function.

GLP2 and glucocorticosteroids

The possibility of a growth factor or hormone acting additively or synergistically with a steroid hormone has been demonstrated in various tissues. For example, EGF potentiates the proliferative effects of progesterone and estrogen in the mammary gland[283]. In a review, Lange[83] discusses the cross-talk that occurs between steroid hormone receptors and intracellular signalling pathways. There is clearly evidence of non-genomic and extra-nuclear functions of steroid receptors, including the initiation of signal transduction pathways. Indeed, this type of cross-talk may explain how genes are coordinately regulated by mitogenic stimuli in hormone responsive tissues. For example, Migliaccio *et al*[284] reported MAPK activation by estradiol, and interactions between the progesterone receptor, the estrogen receptor and p60-Src kinase.

A synergistic effect between DEX and GLP2 may occur in the intestine, as GC have a permissive effect on several hormones including catecholamines, thyroid hormones, growth hormone and ACTH[285]. GC mediates a permissive action, mostly for hormones, which act on G-protein coupled receptors, and increases adenylate cyclase[286,287]. This occurs because DEX alters adenylyl cyclase, enhancing the effects of cAMP generating agonists. Therefore, an interaction between DEX and GLP2 is like-

ly, as the GLP2 receptor is a G-protein coupled receptor.

Furthermore, cAMP and PKA, which are activated by GPCRs like GLP2R, may increase the steroid sensitivity of a target cell by increasing the DNA binding ability of the GR for its response elements. In a study by Rangarajan *et al*[288] using embryonal carcinoma cells lacking cAMP response element binding protein (CREB), activation of PKA increased hormone-dependent trans-activation of the GR. The effect of PKA was related to the DNA binding domain of the GR, as deletion of the amino-terminal or the ligand-binding domain did not alter PKA's effect. However, the absence of a consensus PKA phosphorylation site within the GR DNA binding domain led the authors to suggest that the GR is not a direct substrate for phosphorylation by PKA. Instead, they propose a multistep process involving other cellular kinases and phosphatases that may interact with the GR.

As discussed previously, there are several pieces of evidence that suggest that GLP2 may exert its effect *via* the PI3K pathway. Steroid receptors may interact with this pathway as Simoncini *et al*[82] showed that the estrogen receptor binds to p85 subunit of PI3K.

Although there are no reports of the effect of DEX on PI3K in the intestine, an association has been observed in other tissues. For example, Saad *et al*[289] showed that DEX induced a 69% increase in the level of PI 3-kinase in adipocytes as determined by immunoblotting. Conversely, Buren *et al*[290] demonstrated that DEX decreases PI3K, PKB, insulin-stimulated PKB phosphorylation and glucose transport in isolated rat adipocytes, without changes in GLUT4. These results suggest that glucocorticoids, independently of the surrounding glucose and insulin concentration, impair glucose transport capacity in fat cells. Finally, Krasil'nikov *et al*[291] showed that prolonged exposure to DEX increased PI3K in Rous sarcoma virus-transformed hamster fibroblasts. Certainly in other tissues, such as adipose and muscle, PI3K is involved in regulating insulin-stimulated glucose uptake[292]. In the intestine, EGF stimulated increases in intestinal glucose transport in rabbits is abolished by the PI3K inhibitor LY294002[293]. Similarly, IGF- I associated increases in jejunal glucose uptake and Na^+K^+-ATPase activity are abolished by wortmannin, another PI3K inhibitor[23]. So clearly this pathway plays an important role in transducing signals from hormones and growth factors to the proteins involved in sugar transport. Indeed, preliminary studies in the young rat show that GLP2 and DEX may stimulate the intestinal uptake of glucose, and this is essential with increased abundance of Akt and mTOR, part of the PI3K pathway.

Abstract

Intussusception of the bowel is defined as the telescoping of a proximal segment of the gastrointestinal tract within the lumen of the adjacent segment. This condition is frequent in children and presents with the classic triad of cramping abdominal pain, bloody diarrhea and a palpable tender mass. However, bowel intussusception in adults is considered a rare condition, accounting for 5% of all cases of intussusceptions and almost 1%-5% of bowel obstruction. Eight to twenty percent of cases are idiopathic, without a lead point lesion. Secondary intussusception is caused by organic lesions, such as inflammatory bowel disease, postoperative adhesions, Meckel's diverticulum, benign and malignant lesions, metastatic neoplasms or even iatrogenically, due to the presence of intestinal tubes, jejunostomy feeding tubes or after gastric surgery. Computed tomography is the most sensitive diagnostic modality and can distinguish between intussusceptions with and without a lead point. Surgery is the definitive treatment of adult intussusceptions. Formal bowel resection with oncological principles is followed for every case where a malignancy is suspected. Reduction of the intussuscepted bowel is considered safe for benign lesions in order to limit the extent of resection or to avoid the short bowel syndrome in certain circumstances.

INTRODUCTION

First reported in 1674 by Barbette of Amsterdam[1] and further presented in a detailed report in 1789 by John Hunter[2] as "introssusception", intussusception represents a rare form of bowel obstruction in the adult, which is defined as the telescoping of a proximal segment of the gastrointestinal (GI) tract, called intussusceptum, into the lumen of the adjacent distal segment of the GI tract, called intussuscipiens. Historically, Sir Jonathan Hutchinson was the first to operate on a child with intussusception in 1871[3].

Adult intussusception represents 5% of all cases of intussusception and accounts for only 1%-5% of intestinal obstructions in adults[4]. The condition is distinct from pediatric intussusception in various aspects. In children, it is usually primary and benign, and pneumatic or hydrostatic (air contrast enemas) reduction of the intussusception is sufficient to treat the condition in 80% of the patients. In contrast, almost 90% of the cases of intussusception in adults are secondary to a pathologic condition that serves as a lead point, such as carcinomas, polyps, Meckel's diverticulum, colonic diverticulum, strictures or benign neoplasms, which are usually discovered intraoperatively[5-7]. Due to a significant risk of associated malignancy, which approximates 65%[8,9], radiologic decompression is not addressed preoperatively in adults. Therefore, 70 to 90% of adult cases of intussusception require definite treatment, of which surgical resection is, most often, the treatment of choice[10].

MECHANISM-PATHOPHYSIOLOGY

In adults, the exact mechanism of bowel intussusception

is unknown (primary or idiopathic) in 8%-20% of cases and is more likely to occur in the small intestine[4,10,11]. On the other hand, secondary intussusception is believed to initiate from any pathologic lesion of the bowel wall or irritant within the lumen that alters normal peristaltic activity and serves as a lead point, which is able to initiate an invagination of one segment of the bowel into the other[10,12]. Schematically, intussusception could be described as an "internal prolapse" of the proximal bowel with its mesenteric fold within the lumen of the adjacent distal bowel as a result of overzealous or impaired peristalsis, further obstructing the free passage of intestinal contents and, more severely, compromising the mesenteric vascular flow of the intussuscepted segment. The result is bowel obstruction and inflammatory changes ranging from thickening to ischemia of the bowel wall.

LOCATION-ETIOLOGY

The most common locations in the gastrointestinal tract where an intussusception can take place are the junctions between freely moving segments and retroperitoneally or adhesionally fixed segments[13]. Intussusceptions have been classified according to their locations into four categories: (1) entero-enteric, confined to the small bowel, (2) colo-colic, involving the large bowel only, (3) ileo-colic, defined as the prolapse of the terminal ileum within the ascending colon and (4) ileo-cecal, where the ileo-cecal valve is the leading point of the intussusception and that is distinguished with some difficulty from the ileo-colic variant[5,8,14].

Intussusceptions have also been classified according to etiology (benign, malignant or idiopathic). In the small intestine, an intussusception can be secondary either to the presence of intra- or extra-luminal lesions (inflammatory lesions, Meckel's diverticulum, postoperative adhesions, lipoma, adenomatous polyps, lymphoma and metastases) or iatrogenic, e.g. due to the presence of an intestinal tube[15] or even in patients with a gastrojejunostomy[16]. Malignancy (adenocarcinoma) accounts for up to 30% of cases of intussusception occurring in the small intestine[10]. A very rare case from our department's experience was a 29-year old male patient with a diffuse, small B-cell (Burkitt-like) non-Hodgkin lymphoma of the ileum who developed an ileo-colic intussusception. On the other hand, intussusception occurring in the large bowel is more likely to have a malignant etiology and represents up to 66% of the cases[10,12,17].

CLINICAL PRESENTATION

The clinical presentation of adult intussusception varies considerably. The presenting symptoms are nonspecific and the majority of cases in adults have been reported as chronic, consistent with partial obstruction[4,18]. The classic pediatric presentation of acute intussusception (a triad of cramping abdominal pain, bloody diarrhea and a palpable tender mass) is rare in adults. Nausea, vomiting, gastrointestinal bleeding, change in bowel habits, constipation or abdominal distension are the nonspecific

symptoms and signs of intussusception[5,8].

Intussusception in adults can be further classified according to the presence of a lead point or not[19]: transient non-obstructing intussusception without a lead point has been described in patients with celiac[20] or Crohn's[21] disease, but is more frequently idiopathic and resolves spontaneously without any specific treatment. On the other hand, intussusception with an organic lesion as the lead point usually presents as a bowel obstruction, persistent or relapsing, necessitating, however, a definite surgical therapy.

DIAGNOSIS-IMAGING

Variability in clinical presentation and imaging features often make the preoperative diagnosis of intussusception a challenging and difficult task. Reijnen et al[22] reported a preoperative diagnostic rate of 50%, while Eisen et al[17] reported a lower rate of 40.7%.

Plain abdominal films are typically the first diagnostic tool, since in most cases the obstructive symptoms dominate the clinical picture. Such films usually demonstrate signs of intestinal obstruction and may provide information regarding the site of obstruction[17,23]. Upper gastrointestinal contrast series may show a "stacked coin" or "coil-spring" appearance, while a barium enema examination may be useful in patients with colo-colic or ileo-colic intussusception, during which a "cup-shaped" filling defect or "spiral" or "coil-spring" appearances are characteristically demonstrated[17,24,25].

Ultrasonography is considered a useful tool for the diagnosis of intussusception, both in children and in adults[26,27]. The classical imaging features include the "target" or "doughnut" signs on the transverse view and the "pseudo-kidney" sign or "hay-fork" sign in the longitudinal view[27,28]. Undoubtedly, this procedure requires handling and interpretation by an experienced radiologist, in order to confirm the diagnosis. However, obesity and the presence of massive air in the distended bowel loops limit the image quality and the subsequent diagnostic accuracy.

Abdominal computed tomography (CT) is currently considered as the most sensitive radiologic method to confirm intussusception, with a reported diagnostic accuracy of 58%-100%[4,12,29-33]. The characteristic features of CT scan include an unhomogeneous "target" or "sausage"- shaped soft- tissue mass with a layering effect (Figure 1); mesenteric vessels within the bowel lumen are also typical[10]. A CT scan may define the location, the nature of the mass, its relationship to surrounding tissues and, additionally, it may help staging the patient with suspected malignancy causing the intussusception[17]. In a recent interesting report by Kim et al[19], abdominal CT was able to distinguish between intussusception without a lead point (features: no signs of proximal bowel obstruction, target-like or sausage-shaped mass, layering effect) from that with a lead point (features: signs of bowel obstruction, bowel wall edema with loss of the classic three-layer appearance due to

Figure 1 Abdominal computed tomography in adult intussusception. A: The characteristic "target"-shaped soft-tissue mass with a layering effect of a 29-year old male patient with a diffuse, small B-cell (Burkitt-like) non Hodgkin lymphoma of the ileum who developed an ileo-colic intussusception; B: A "sausage"-shaped soft tissue mass in the ascending colon of the same patient.

Figure 2 Colonoscopy. Revealing the presence of the inverted terminal ileum (intussusceptum) in the ascending colon (intussuscipiens) in a patient with an ileo-cecal intussusception due to an ileal lipoma.

Figure 3 Intraoperative findings. A: Thickened, congested and inflamed terminal ileum with proximal small bowel obstruction in a 75-year old woman with ileo-colonic intussusception; B: The surgical specimen after the en bloc resection of the terminal ileum and the ascending colon in the same patient; C: The cause of the intussusception was a lipoma of the ileo-cecal valve (arrow).

impaired mesenteric circulation and demonstration of the lead mass), and this may help reducing the number of unnecessary surgical interventions.

DIAGNOSIS-ENDOSCOPY

Flexible endoscopy of the lower GI tract is considered invaluable in evaluating cases of intussusception presenting with subacute or chronic large bowel obstruction[10]. Confirmation of the intussusception, localization of the disease and demonstration of the underlying organic lesion serving as a lead point are the main benefits of endoscopy. Snare polypectomy is not advisable in individuals with chronic intussusception presenting with a polypoid mass on barium or endoscopic examination, due to the high risk of perforation occurring in a background of chronic tissue ischemia and possible necrosis of the intussuscepted bowel segment's wall[34,35]. In the case of a lipoma as a lead point of an intussusception (Figure 2), typical colonoscopic features include a smooth surface, the "cushion sign" or pillow sign" (forcing the forceps against the lesion results

in depression of the mass) and the "naked fat sign" (fat extrusion during biopsy)[36-38].

SURIGICAL TREATMENT

Due to the fact that adults present with acute, subacute, or chronic nonspecific symptoms[9], the initial diagnosis is missed or delayed and is established only when the patient is on the operating table (Figure 3). Most surgeons accept that adult intussusception requires surgical intervention because of the large proportion of structural anomalies and the high incidence of occurring malignancy. However, the extent of bowel resection and the manipulation of the intussuscepted bowel during reduction remain controversial[10]. In contrast to pediatric patients, where intussusception is primary and benign, preoperative reduction with barium or air is not suggested as a definite treatment for adults[10,17,39].

The theoretical risks of preliminary manipulation and reduction of an intussuscepted bowel include: (1) intraluminal seeding and venous tumor dissemination,

(2) perforation and seeding of microorganisms and tumor cells to the peritoneal cavity and (3) increased risk of anastomotic complications of the manipulated friable and edematous bowel tissue[4,5,10,17,22]. Moreover, reduction should not be attempted if there are signs of inflammation or ischemia of the bowel wall[33]. Therefore, in patients with ileo-colic, ileo-cecal and colo-colic intussusceptions, especially those more than 60 years of age, due to the high incidence of bowel malignancy as the underlying etiologic factor, formal resections using appropriate oncologic techniques are recommended, with the construction of a primary anastomosis between healthy and viable tissue[8,10,17,22,38,40]. Azar et al[4] report that, for right-sided colonic intussusceptions, resection and primary anastomosis can be carried out even in unprepared bowels, while for left-sided or rectosigmoid cases resection with construction of a colostomy and a Hartmann's pouch with re-anastomosis at a second stage is considered safer, especially in the emergency setting.

However, when a preoperative diagnosis of a benign lesion is safely established, the surgeon may reduce the intussusception by milking it out in a distal to proximal direction[40], allowing for a limited resection. Wang et al[41] report that for enteric intussusceptions due to benign lesions, reduction and limited resection resulted in non-recurrence of intussusception. In patients with a risk of a short bowel syndrome due to multiple small intestinal polyps causing intussusception, such as Peutz-Jeghers syndrome, a combined approach with limited intestinal resections and multiple snare polypectomies should be mandatory[42]. Moreover, in patients complicated with postoperative bowel obstruction due to an intussusception, reduction is also recommended, provided that the bowel appears non-ischemic and viable[4].

Finally, several reports have been published regarding the laparoscopic approach of adult intussusception, due to benign and malignant lesions of the small and large bowel[43-53]. Laparoscopy has been used successfully in selected cases, depending on patients' general status and availability of surgeons with sufficient laparoscopic expertise. After establishing the diagnosis of intussusception and the underlying disease laparoscopically, reduction and/or *en bloc* resection can be performed with the same method.

CONCLUSION

Adult bowel intussusception is a rare but challenging condition for the surgeon. Preoperative diagnosis is usually missed or delayed because of nonspecific and often subacute symptoms, without the pathognomonic clinical picture associated with intussusception in children. Abdominal CT is considered as the most sensitive imaging modality in the diagnosis of intussusception and distinguishes the presence or absence of a lead point. Due to the fact that adult intussusception is often frequently associated with malignant organic lesions, surgical intervention is necessary. Treatment usually requires formal resection of the involved bowel segment. Reduction can be attempted in small bowel

intussusceptions provided that the segment involved is viable or a malignancy is not suspected.

Abstract

Midkine (MK) is a heparin-binding growth factor with its gene first identified in embryonal carcinoma cells at early stages of retinoic acid-induced differentiation. MK is frequently and highly expressed in a variety of human carcinomas. Furthermore, the blood MK level is frequently elevated with advance of human carcinomas, decreased after surgical removal of the tumors. Thus, it is expected to become a promising marker for evaluating the progress of carcinomas. There is mounting evidence that MK plays a significant role in carcinogenesis-related activities, such as proliferation, migration, anti-apoptosis, mitogenesis, transforming, and angiogenesis. In addition, siRNA and anti-sense oligonucleotides for MK have yielded great effects in anti-tumor activities. Therefore, MK appears to be a potential candidate molecular target of therapy for human carcinomas. In this paper, we review MK targeting at nucleoli in different tumor cells and its role in carcinogenesis to deepen our understanding of the mechanism of MK involved in carcinogenesis.

Key words: Midkine; Nuclear localization; Carcinogenesis

Dai LC. Midkine translocated to nucleoli and involved in carcinogenesis. *World J Gastroenterol* 2009; 15(4):

INTRODUCTION

Midkine (MK), also known as MDK, FLJ27379, and NEGF2, is a 13-kDa heparin-binding growth factor with a high affinity for heparin, which shares a 50% homology in amino acid sequence with pleiotrophin (PTN), another member of MK family. Previous findings indicate that MK could be internalized depending on lipoprotein receptor-related protein (LRP), a low-density lipoprotein (LDL) receptor-related protein, and is further transported to nuclei depending on nucleolin. In our study, MK could be translocated to and accumulated in nuclei and nucleoli of different kinds of tumor cell[1]. Furthermore, K79R81, K86K87, and C-terminal tail of MK constitute the nuclear localization determinants of MK. The C-terminal tail is the key element controlling MK nucleoli accumulation though the N-terminal tail. K79R81 and K86K87 also contribute to this process. Immunogold-labeling electron microscopy can investigate the exact location of MK mainly localized in granular component (GC), dense fibrillar component (DFC) and the border between DFC and FC[1]. The phenomenon of nuclear targeting of MK is related to the promotion of cell survival and anti-apoptotic activity[2].

MK is detectable in various carcinomas such as breast, prostate, grastric, colon, hepatocellular and urinary bladder carcinomas, neuroblastoma, glioma and Wilms' tumor, exhibiting a proto-oncogene function[3-6]. However, its expression is low or undetectable in adult normal tissues. MK is deeply involved in cancer progression, onset of inflammatory diseases and repair of injured tissues. MK suppresses tumor growth both *in vitro* and *in vivo* and it is believed that MK is a new therapeutic target for curing tumors.

MK TRANSLOCATED TO AND ACCUMULATED IN NUCLEI

It has been reported that MK localizes in the nuclei[2,7], nucleoli[8], or cytosol[9], which is inconsistent with the intracellular localization of MK. Human MK exclusively

Figure 1 Subcellular localization analysis of MKS-GFP and MKN-GFP fusion proteins in carcinoma cell lines. MKS-GFP and MKN-GFP fusion proteins were localized to nuclei and accumulated in nucleoli, but rarely localized to cytoplasm. The high light "spots" in the center of nuclei are nucleoli. HepG2 cells (upper panel) and DU145 cells (bottom panel) are transfected with pEGFP-N2, and diffuse freely in the whole cell except in nucleoli.

localizes in nuclei and nucleoli in HepG2, DU145, and MCF7 cells by using GFP as a tracking molecule. GFP protein is stable *in vivo* and fused to the C or N terminus of many cellular and extracellular proteins without loss of activity, permitting tagging of proteins for gene regulation analysis, protein localization, or specific organelle labeling, and thus can be used as a perfect positive control to detect the information of MK. We cloned two MK gene fragments with or without signal peptide and separately inserted them into pEGFP-N2 plasmids (enhanced green fluorescent protein N-terminal protein fusion vector). Then, two recombinant plasmids pEGFP-MKS (EGFP fused with MK with signal peptide) and pEGFP-MKN (EGFP fused with MK without signal peptide) were obtained. The results showed that 24 h after transfection, both fusion proteins of MKS-GFP and MKN-GFP in the two cell lines, HepG2 and DU145, were localized exclusively in the nuclei and accumulated in the nucleoli, while GFP control was detected diffusely over the entire cell body except in nucleoli, indicating that signal peptide in pEGFP-MKS does not participate in nuclear and nucleolar localization (Figure 1). Similar results were obtained in MCF7 cell line (data not shown).

MK IS INTERNALIZED IN A LRP-DEPENDENT MANNER AND PROTEASOMAL DEGRADATION

Lipoprotein receptor-related protein (LRP), also known as a low-density lipoprotein (LDL), is a midkine-binding protein[10]. LRP belongs to the LDL receptor family, which includes five prototype members: LDL receptor, ApoE receptor2, very low-density lipoprotein (VLDL) receptor, LRP, and LRP2/megalin. The major functions of these receptors are to endocytose and deliver their

ligands to lysosomes for degradation or catabolism[11,12]. MK is not internalized in LRP-deficient cells, whereas transfection of a LRP expression vector can restore MK internalization and subsequent nuclear translocation, suggesting that LRP binds to heparin-binding growth factor, MK, and mediates nuclear targeting by MK. Internalized MK in cytoplasm binds to nucleolin, a nucleocytoplasmic shuttle protein and tanslocates to nuclei. When the nuclear localization signal located next to the acidic stretches is deleted, the mutant nucleolin not only accumulates in cytoplasm but also suppresses the nuclear translocation of MK. With respect to nuclear targeting by MK, 37-kDa laminin-binding protein precursor (LBP) binds to MK and is cotranslocated with MK into nuclei[7]. It is possible that MK uses both nucleolin and LBP precursor as shuttle proteins, revealing a novel role of LRP in intracellular signaling by its ligand, and the importance of nucleolin and LBP in the process of nuclear target of MK (Figure 2).

It is widely held that growth factor signaling is terminated by lysosomal degradation of its activated receptor and endocytosed growth factor is transported to lysosome. Nuclear targeting is another important pathway through which signals of growth factors are mediated. The nuclear targeting pathway is down-regulated by the proteasome system. Degradation of endocytosed MK is suppressed by both proteasome and lysosome inhibitors. By contrast, proteasome inhibitor rather than lysosome inhibitor accelerates the nuclear accumulation of MK. Expression vector of less signal sequence MK in cytosol, can be constructed because endocytosed MK may be translocated to cytosol from cellular compartments before entering nuclei. Cytosol-produced MK undergoes proteasomal degradation, accumulates in nuclei as endocytosed MK, and is polyubiquitinated with its nuclear accumulation increased by proteasome inhibitors. MK

Figure 2 Nuclear targeting by growth factor MK. MK was endocytosed into cell cytosol through binding to the receptor of LRP, and then tanslocated to nuclei in the presence of nucleulin or LBP. At the same time, the internalized MK is degraded by proteasome to "off" the signals from the cell surface receptors.

Figure 3 Biological function and medical application of MK. The most attractive feature of MK is its involvement in carcinogenesis, which plays a great role in proliferation, migration, anti-apoptosis, mitogenesis, transformation, and angiogenesis. Furthermore, MK is expected to be a target molecule of diagnosis of and therapy for tumor.

molecule can be further dissected by cytosol-produced MK to investigate its role in degradation and trafficking. The N terminal half-domain of MK is more significantly susceptible to proteasomal degradation, whereas the C terminal half-domain is sufficient to locate nuclei. These data highlight the desensitization of nuclear targeting by growth factor MK and indicate that the proteasome system plays a critical role in desensitization of nuclear targeting. MK is prone to proteasomal degradation[13]. Because "off" signaling is essential for life, it is reasonable that nuclear targeting growth factor MK is prone to degradation by proteasome (Figure 2).

CONFORMATIONAL DETERMINANTS OF INTRACELLULAR LOCALIZATION OF MK

Nuclei orchestrate the running of cells and is a highly dynamic organelle containing dynamic compartments created by relatively immobile binding or assembly sites[14]. In order to function properly, nuclei should rely on a constant flow of molecules between cytosol and nuclei. Many proteins can be translocated into nuclei by the presence of import signals such as nuclear localization signal or sequence (NLS) which can be specifically recognized by receptors on nuclear pore complex[15], or certain shuttling proteins such as nucleolin[16]. After transported into nuclei, proteins can be docked at different subnuclear compartments. In subnuclear structures such as nucleoli, proteins may accumulate in a steady-state compartment mediated by nucleolar localization sequence (NoLS) or domain which might interact with local high-affinity binding sites[17]. We have identified the conformational determinants for MK nuclear and nucleolar localization[18], showing that K79R81, K86K87, and C-terminal tail of MK constitute the nuclear localization determinant, and play an important role in nuclear localization.

DISTRIBUTION OF MK IN NUCLEOLI

At ultra-structure level, nucleoli include three compo-

nents: fibrillar center (FC), dense fibrillar component (DFC), and granular component (GC)[19,20]. Although MK tanslocated to nucleoli and accumulated in nucleoli, its exact location in nucleoli is still unclear. Immunogold-labeling electron microscopy shows that MK is mainly localized in GC, DFC and the border between DFC and FC (data unpublished). Because each component is corresponding to a special biological function, the nascent transcripts appear in the junction region between FC and DFC, accumulate in DFC and continue intranucleolar migration of rRNA towards GC[21,22], suggesting that the role of MK in nucleoli may be related to the control of rRNA gene transcription, pre-rRNA processing, and nascent ribosome subunit assembly, the downstream elements to control cell proliferation.

INVOLVEMENT OF MK IN CARCINOGENESIS

MK exhibits various cancer-related activities and is involved in carcinogenesis and cancer advancement. MK exerts its fibrinolytic activity by enhancing the level of plasminogen activator in endothelial cells[23], and transforms NIH3T3 cells[24]. MK promotes migration of neutrophils, osteoblastic, osteosarcoma cells, neural cells, and macrophages, which is always dependent on the receptors: N-syndecan and PTPζ[25]. MK mediates cell survival and growth mainly through P13-kinase and extracellular signal-regulated kinase (ERK) in intracellular signaling[26]. MK exerts its anti-apoptotic activity to rescue Wilms' tumor cells from cisplatin[27]. MK also induces a strong angiogenic response in rabbit cornea, when its cDNA is transfected[28]. Resistance to cytotoxic agents is a major limitation for its use in treatment of human cancers. MK has been recently identified as a mediator of intercellular transfer of drug resistance[29] (Figure 3).

MEDICAL APPLICATION OF MK IN CANCER THERAPY

MK is frequently over-expressed in most carcinomas[30].

Serum and urinary MK levels are becoming prognostic and diagnostic markers of various tumors. Furthermore, MK demonstrates many activities that are significantly correlated to carcinogenesis, indicating that MK is a candidate target of therapy for carcinomas.

MOLECULAR TARGET

Anti-sense ODNs have a huge potential as agents to turn off the expression of specific proteins *in vitro* and *in vivo*. Indeed, anti-sense MK ODNs show anti-tumor activities in various carcinoma cells. Moreover, they also suppress the growth of pregrown tumors in nude mice via atelocollagen-mediated gene transfer, and exert their inhibitory effect on mitosis of cancer cells[31-33]. Thus, abolition of MK production or disruption of its signaling pathway is a good treatment modality for human carcinomas.

GENE TARGET

Currently, studies on gene therapy for cancer are carried out. The most difficult aspect of developing an *in vivo* approach to cancer is correctly targeting cancer cells. Many vectors target tumors for gene delivery, including viral and synthetic vectors (liposome and emulsion), which show promise in targeting cancer cells. It is essential to use a strong and tissue-specific promoter region if a suicide gene is to be expressed selectively in cancer cells. Compared with cytomegalovirus (CMV) promoter, MK promoter exhibits a stronger expression in Wilms' tumor cells than CMV promoter[34]. Furthermore, adenovirus containing CMV promoter-thymidine kinase gene can cause severe side effect to liver, while the MK promoter-thymidine kinase gene does not have such a side effect. Therefore, a suicide gene under the control of MK promoter is a highly potential strategy for the treatment of carcinomas[35].

CONCLUSION AND PERSPECTIVES

In this review, we have described that MK can be translocated to nucleoli, where it accumulates in different tumor cells. A growing body of evidence indicates that nuclear targeting plays an indispensable role in the biological activities of growth factors. For example, nuclear localization of fibroblast growth factor 1 and Schwannoma-derived growth factor is necessary for their mitogenic activity[36,37]. Increased ribosomal gene transcription and cell proliferation are closely correlated to the nuclear translocation of fibroblast growth factor-2[38]. It is, thus, important to make clear that signals from tumor cell surface receptors and ligands translocated to nuclei play a role in the biological activities of MK.

MK is comparatively ubiquitous in many kinds of tumor, whereas its expression is usually low or undetectable in normal adult tissue. Serum MK levels are also elevated in patients with various carcinomas, such as gastric, colon, hepatocellular, and lung carcinomas[27]. These observations indicate that MK should be considered indispensable

to the development and enlargement of tumors. Further analyses of MK mechanisms related to carcinogenesis should shed light on therapies for tumors and cancers. To further establish blood MK as a tumor marker, prospective studies on blood levels and prognosis will provide useful information. Further study should focus on the application of MK in gene therapy for cancer.

Abstract

The hypothesis postulating that *Mycobacterium avium paratuberculosis* (MAP) is the cause of Crohn's disease (CD) has been circulating for many years. Advances in molecular techniques, such as polymerase chain reaction and culture methods, have enabled researchers to demonstrate that there is an association between MAP and CD. Recently, genome-wide association studies have identified novel susceptibility genes for CD, which are critical for generation of an adaptive immune response that is protective against intracellular pathogens, including *M. tuberculosis* infection. However, the role of MAP as a cause of CD suffered a setback with the report that administration of antimycobacterial therapy failed to lead to a sustained response in CD patients. Accordingly, this review sought neither to confirm nor refute this, but instead to survey recent literature on the role of MAP in CD.

Key words: *Mycobacterium avium* subspecies *paratuberculosis*; Crohn's diasease; Inflammatory bowel disease

Peer reviewer: Christian D Stone, MD, MPH, Director, Inflammatory Bowel Disease Program, Assistant Professor of Medicine, Division of Gastroenterology, Washington University School of Medicine, 660 South Euclid Avenue, Campus Box

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are two related, chronic, remitting and relapsing inflammatory diseases of the gastrointestinal tract, commonly known as inflammatory bowel diseases (IBDs). While the causes of IBDs are unknown, it is thought that inflammation results from an inappropriate chronic activation of the innate and adaptive mucosal immune systems in a genetically susceptible host, and that enteric microflorae play a pivotal role in the initiation and maintenance of disease[1]. The key factors responsible for IBDs are fairly well defined, namely, the environment, genetic makeup, commensal florae, and immune response. Insofar as the components of IBD pathogenesis are concerned, investigation of the role of infectious agents and gut commensal florae is an area in which relatively less progress has been made[2]. One of the most controversial questions is whether or not any given microbe plays a role in promoting disease. The similarities between CD and some forms of infectious enterocolitis are sufficiently evident for numerous specific microbial etiologies for CD to have been proposed over the years, including *Pseudomonas maltophilia*, *Mycobacterium kansasii*, *Chlamydia trachomatis*, *Bacteroides fragilis*, *Listeria monocytogenes*, *Escherichia coli* and *Mycobacterium avium* subspecies *paratuberculosis* (MAP). Just recently, the status of MAP as an infectious cause of CD-an enduring and controversial topic-suffered a severe setback in the form of a multicenter study which reported that administration of antimycobacterial therapy over 2 years afforded no substantial or prolonged benefits for patients with CD[3]. However, MAP is a recurrent candidate for several reasons: it causes epidemic chronic colitis in cattle and other species, including primates; it is reportedly detectable in the intestinal tissues and blood of many CD patients; antibodies to the organism are often disease-associated; and in some cases,

antimycobacterial drugs ameliorate disease.

Four not necessarily mutually exclusive mechanisms have been proposed to drive pathogenic immunologic responses to luminal microbial antigens: (1) microbial pathogens induce intestinal inflammation, (2) dysbiosis of commensal microbiota, (3) host genetic defects in containing commensal microbiota, (4) defective host immunoregulation. These mechanisms increase exposure of bacterial antigens to mucosal T cells or alter host immune responses to commensal bacteria. The detection of MAP DNA in the blood of CD patients may suggest that this organism is a persistent pathogen in CD. However, these results could be a secondary phenomenon due to increased gut permeability or the inability of macrophages in CD to kill MAP. The increased gut leakiness hypothesis is supported by the more frequent detection of other organisms in CD patients compared with controls and suggests a lack of specificity of MAP detection.

Another recent study supports the possibility that *M. paratuberculosis*, though not itself a very effective pathogen in humans, might induce local suppression of phagocyte function in infected tissue, and that this, in turn, might lead to chronic replication within macrophages of other bacteria, including perhaps the mucosal *E. coli* isolates that have now been found in CD tissue samples by several independent groups[4].

MAP

MAP is a member of the *M. avium* complex. *M. avium* strains are widely distributed in the environment and also inhabit normal animal and human intestines. *M. avium* strains do not usually cause disease unless the host is debilitated or immunocompromised. MAP, in contrast, is a specific pathogen with the ability to cause chronic inflammation of the intestine (Johne's disease) in many species, including ruminants and primates[5]. Moreover, it has been suggested that MAP can exist in animal tissue for years without causing clinical disease. Initial clinical signs follow a prolonged incubation period of 2 to 10 years, depending upon the exposure level and the individual animal's ability to fight the infection[6]. MAP invades macrophages in lymphoid tissue in the ileum, where it inhibits phagosome maturation and induces the recruitment of inflammatory cells, resulting in granulomatous enteritis. Characteristics distinguishing MAP from other *Mycobacterium* spp. include: its extremely slow growth; its inability to produce mycobactin; its possession of the insertion element IS900 that occurs as 14-18 copies within the *MAP* genome[7]. The DNA sequence, IS900, is considered the "gold standard" for differentiating MAP from other mycobacteria[8]. Although other IS900-like elements have been described in environmental mycobacteria, the entire IS900 gene is unique to MAP[9].

In common with other mycobacteria, MAP possesses a thick, waxy cell wall containing 60% lipid, which confers on it the properties of acid fastness (the ability to resist decolorization by acidified alcohol), hydrophobicity, and increased resistance to chemicals (e.g. chlorine) and physical processes (e.g. pasteurization)[7]. At least two potential modes of MAP transmission from the host animal to humans have been hypothesized, i.e. ingestion of either contaminated water or milk[10]. The detection of cell wall-deficient forms, also known as spheroplasts, in tissue cultures from affected humans, and subsequent identification of the agent as positive for the IS900 insertion sequence found in MAP by polymerase chain reaction (PCR) and *in situ* hybridization (ISH), has been the basis for suggesting MAP as a potential cause of CD[11]. Hence, MAP spheroplasts may play a role in the development of these human diseases, as well as in paucibacillary forms of Johne's disease in other species.

DETECTION OF MAP IN CROHN'S DISEASE

The association of MAP with CD is supported by identification of MAP in CD patients but not in appropriate controls. The gold standard for detection of MAP is based on isolation of the organism through culture methods. However, such methods are time consuming, because of the organism's fastidious nature and slow growth. Molecular and serologic methods are widely-used alternatives[12].

MAP CULTURE

Advances in culture methods now enable researchers to grow MAP from intestinal tissue, milk, and blood in CD patients[13]. The introduction of commercially available BACTEC and MGIT liquid culture systems, together with the application of IS900 PCR to such cultures, have led to substantial improvements in the ability to detect subclinical MAP infection in ruminants[14]. Some researchers have suggested that bacterial culture using liquid media has greater analytical sensitivity than that using solid media. Recently, two types of culture media have been shown to determine differential growth of MAP strains. This should be borne in mind when evaluating the detection capabilities of diagnostic tests or interpreting data from molecular epidemiologic studies performed using different type of culture medium[15]. MAP has been cultured from the milk of two women with active CD, who were breastfeeding[16]. This observation has not been replicated by other researchers. In another study[17], MAP was recently cultured in 50% of blood samples from CD patients, 20% of samples from UC patients and 0% of samples from healthy controls. In this study, the observation that MAP could be cultured from CD patients did not correlate with the use of immunosuppressive medications. Finally, MAP has also been cultured in a higher percentage of bowel-pinch biopsies from CD patients (42%) than from controls (9%)[18]. A preliminary report issued by a National Institutes of Health-sponsored blinded study

showed no differences in the culture recovery rates of two independent laboratories, and no detection of MAP 16s rRNA[19].

DETECTION OF THE INSERTION SEQUENCE IS900

The two main methods used to detect the insertion sequence IS900 include PCR and ISH assays. Previous studies have shown that reliable and reproducible detection of *MAP* by PCR applied directly to DNA extracted from human tissue and other samples, is extraordinarily difficult. The use of suboptimal sample-processing procedures results in false-negative results[18]. The results of MAP detection using nucleic acid-based techniques have recently been reported in two meta-analyses. These suggest that there is sufficient evidence for the presence of MAP in the gut of CD patients, regardless of whether CD patients are compared with individuals without inflammatory bowel disease or with UC patients[9,12]. Nevertheless, this association remains controversial and inconclusive. PCR data are open to criticism because the technique assays DNA that could come, either from live bacteria, or merely from the scattered debris of killer organisms and thus be of questionable biologic importance[13].

SEROLOGIC STUDIES OF MAP

Another approach to studying the possible role of MAP in the etiology of CD is to evaluate CD patients for the presence of antibodies reactive against MAP antigens[20]. Serologic tests for diagnosis of paratuberculosis, such as agar gel immunodiffusion, enzyme-linked immunosorbent assay and complement-fixation, are relatively easy to perform but suffer from a lack of sensitivity[10]. In a recent meta-analysis[12], the prevalence of MAP antibodies was higher in CD patients than in controls in most of the studies but there were high levels of inter-study heterogeneity. For the studies using serologic markers, the sources of heterogeneity remained unclear: confounding factors, bias and differences in study populations are all likely to have contributed to heterogeneity[12]. The p35 and p36 antigens were the most frequently used, and several studies have shown that CD patients display specific reactivity to the p35 and p36 antigens[21]. However, both p35 and p36 are present in *M. avium* subsp. *avium*, suggesting that a similar reaction would be obtained with the *M. avium* subsp. *avium* p35 and p36 homologs[20]. Accordingly, though positive tests were more common among CD patients than among UC patients and controls, this is not necessarily because of MAP infection but may be attributable to other MAP-like bacteria.

MAP AND GENETIC SUSCEPTIBILITY TO CROHN'S DISEASE

The simultaneous discovery, by two groups using positional cloning and candidate-gene approaches, of Nucleotide Oligomerization Domain 2/Caspase Recruitment Domain 15 (NOD2/CARD15) as a susceptibility gene for CD[22], provided specific support for the long-held theory that a genetically dysregulated host immune response to luminal bacteria results in CD. Muramyl dipeptide, a component of bacterial peptidoglycan, is recognized by the NOD2 receptor; nonetheless, the exact mechanism whereby NOD2 polymorphisms contribute to increased propensity to develop CD is still not completely understood. NOD2/CARD15 deficiency induces abnormal development and function of Peyer's patches, characterized by an exaggerated immune response and increased permeability[23]. Thus, patients carrying CARD15/NOD2 mutations are unable to control bacterial infections, which results in an inadequate innate response to bacterial invasion and enables bacteria to accumulate[24]. CARD15/NOD2 mutations are associated with defective clearance of invasive *Salmonella* infection in epithelial cells. Hence, an attractive explanation linking CARD15/*NOD2* to CD is that of ineffective clearance of intracellular MAP infection: indeed, a recent clinical study has shown that the mononuclear cells of CD patients, which are mutant for NOD2, display defective recognition of MAP bacteria[25].

However, no association between MAP serologies and NOD2 polymorphisms was observed in a large population-based study conducted in Manitoba[26]. Elsewhere, in a small-scale Sardinian study[27], the possibility of an interaction between MAP positivity and NOD-2 gene mutations was raised, with the authors suggesting that there might be a trend towards an association between the presence of CARD15/NOD2 mutations and MAP-positive status. However, this association was only present when CD subjects were compared against controls who had CARD15/NOD2 mutations, whereas having NOD2 mutations had no impact on MAP status among the CD subjects[27]. The same team failed to observe any association between SLC11A1 polymorphisms in the Sardinian population and MAP infection[28].

A genome-wide association study identified the interleukin-23 receptor (IL-23R) as a novel susceptibility gene for CD[29]. Mounting evidence suggests that IL-23, which is similar to IL-12, is critical for generation of an adaptive immune response that is protective vis-à-vis intracellular pathogens, including *M. tuberculosis* infection[30]. Recently, two studies demonstrated an association between CD and a coding variant of autophagy-related-16-like 1 (ATG16L) gene[31] and IRGM gene[32], thereby implicating the autophagy pathway of the innate immune system. The autophagy trafficking pathway is critical in inhibiting *M. tuberculosis* survival in infected macrophages[33]. Accordingly, infection of a subset of CD patients with intracellular killing defects caused by ATG16L1, IRGM, IL-23, NCF4, or any other as yet unreported gene, needs to be investigated[34].

ANTIMYCOBACTERIAL ANTIBIOTICS FOR CROHN'S DISEASE

Another approach to identifying disease causation is the use of chemotherapeutic agents to eliminate the infectious agents. The most irrefutable evidence of the fact that a microbial agent causes a given disease is long-term remission of clinical manifestations and an altered natural history of disease following clearance of the infection. In common with other atypical mycobacteria, MAP has characteristics that limit the number and type of potentially effective antibiotics[35]. *In vitro* sensitivity analyses show that clinical isolates of MAP are not responsive to traditional anti-*M. tuberculosis* agents, and so isoniazid, ethambutol, and rifampicin are not effective. Clarithromycin and azithromycin are considered to be the most effective drugs for treatment of MAP. In 2000, a meta-analysis[36] suggested that antimycobacterial treatment may be effective in maintaining remission achieved by corticosteroids. Treatment of CD with antimycobacterial therapy does not seem to be effective without a course of corticosteroids to induce remission. However, because of the small number of studies included in this meta-analysis and the heterogeneity of the trials, which used a wide range of antibiotic combinations administered for variable periods, these results should be interpreted with caution. Lastly, the largest study, a well-designed, randomized, placebo-controlled trial of clarithromycin, rifabutin and ethambutol, failed to show a sustained response in CD patients. Although the antibiotics registered a short-term benefit at 16 wk, in addition to the effect of the corticosteroid therapy, the study showed no prolonged advantage of the antibiotic combination, whether during the 2-year treatment phase or, more importantly, after the therapy had been halted[3].

An argument against a role for MAP in CD is that, if CD were indeed a chronic mycobacterial infection, then immunosuppressive therapies (corticosteroids, thiopurine drugs and tumor necrosis factor (TNF)-α suppressive therapies) should be associated, not with improvement, but rather with increased rates and severity of mycobacterial disease[35]. Currently, there is no published evidence, clinical or experimental, to establish whether or not MAP infection is exacerbated by TNF-α antibodies[37]. In one study[38], corticosteroid therapy was associated with lower MAP detection rates. However, in the case of the most commonly used immunosuppressive drugs used to treat CD symptoms, such as thiopurine drugs, e.g. azathioprine, and their metabolites, e.g. 6-mercaptopurine, inhibit the growth of MAP *in vitro*[39]. It is possible that intracellular cell deficient (spheroplast) MAP may not replicate well despite immunosuppression[35]. A recent study[40] showed that antimycobacterial and thiopurine drugs used in concert may produce an interactive effect. The apparent bacteriostatic effects of 6-mercaptopurine on *M. paratuberculosis* rendered the organism less susceptible to the bactericidal effects of antibiotics. These findings should also influence the design of therapeutic trials aimed at evaluating antibiotic treatments of CD: thiopurine drugs may confound interpretation of data on therapeutic responses for both antibiotic-treated and control groups.

EPIDEMIOLOGIC EVIDENCE FOR MAP AS A CAUSE OF CD

Other arguments against a role for MAP in CD are based on the difficulty of reconciling some of the epidemiologic features of CD with a causative role for chronic MAP infection[41]. First, farmers (and persons in rural settings) should be at increased risk of a livestock-associated pathogen, yet there is no evidence that they have increased rates of CD[42]. Second, environmental conditions, such as poor sanitation and overcrowding which should favor transmission of an infection, actually appear to protect against CD. Third, there is a remarkable paucity of evidence for vertical or horizontal transmission of CD[41]. Finally, detection of MAP in CD is neither disease- nor bacterium-specific. Detection of bacterial DNA in the granulomas of intestinal CD is not specific to MAP, in that other forms of bacterial DNA are also present[43]. However, a study which reviewed epidemiologic models of disease causation, has concluded that the current epidemiologic evidence strongly supports the conjecture (especially among those who believe in the theory of inductivism) that CD is caused by MAP[5]. Inductivism is one of the major philosophical doctrines about causation. This doctrine holds that science proceeds from observation to theory, beginning with observations derived from experiments, and extrapolating from these to general laws[5].

CONCLUSION

MAP is the causative agent of Johne's disease. It seems likely that chronic infection with MAP does occasionally occur in humans. MAP is widely present in our food chain and the DNA of this organism can be recovered from the intestine of CD patients. Studies have shown that a high percentage of subjects with CD are infected with MAP, though whether the association of this bacterium and CD is causal or coincidental is not known. Epidemiologists have gathered enough information to indicate an association between MAP and CD. Nonetheless, the role of MAP in CD etiology is not known, and may be determined from consistent results of studies using improved methods of isolation and detection of MAP bacilli and/or MAP-elicited immune responses in the host.

Abstract

Hepatitis B virus (HBV) infection is a global public health problem that concerns 350 million people worldwide. Individuals with chronic hepatitis B (CHB) are at increased risk of developing liver cirrhosis, hepatic de-compensation and hepatocellular carcinoma. To maintain undetectable viral load reduces chronic infection complications. There is no treatment that eradicates HBV infection. Current drugs are expensive, are associated with adverse events, and are of limited efficacy. Current guidelines try to standardize the clinical practice. Nevertheless, controversy remains about management of asymptomatic patients with CHB who are hepatitis B e antigen (HBeAg)-positive with normal alanine aminotransferase, and what is the cut-off value of viral load to distinguish HBeAg-negative CHB patients and inactive carriers. We discuss in detail why DNA level alone is not sufficient to begin treatment of CHB.

Key words: Hepatitis B virus; Viral DNA; Alanine transaminase; Antiviral drug; Hepatitis B e antigen; Antiviral drug resistance

INTRODUCTION

Hepatitis B virus (HBV) infection is a global public health problem. An estimated 350 million people worldwide are chronically infected with HBV. Approximately 500 000 die annually from HBV-related liver disease[1]. The prevalence and concerns to public health institutions about HBV infection vary according to geographical origin.

Individuals with chronic hepatitis B (CHB) are at increased risk of developing serious problems including liver cirrhosis, hepatic de-compensation and hepatocellular carcinoma (HCC). Fifteen to forty percent of these individuals will develop serious sequelae during their lifetime and have greater evolution to cirrhosis or HCC[2,3]. The 5-year rate of progression from CHB to cirrhosis is estimated to be 12%-20%[4-7]. In patients with cirrhosis, the 5-year cumulative risk of developing HCC is 17% in East Asia and 10% in Western Europe and the United States, and the 5-year liver-related death rate is 15% in Europe and 14% in East Asia[8,9]. Seropositivity for the hepatitis B surface antigen (HBsAg) is one of the most important risk factors for HCC[10]. Seropositivity for hepatitis B e antigen (HBeAg) is associated with an increased risk for HCC, and it is significant regardless of serum level of alanine aminotransferase (ALT) and status of liver cirrhosis[8,10,11]. The risk of progression appears to be greatest in patients who progress from an immunotolerant to an immune-clearance phase[12], in patients who have delayed HBeAg seroconversion[13], and in patients who have reactivation of HBV replication after HBeAg seroconversion[14-16].

Disease progression is variable and multifactorial. It is influenced by several factors including replicating activity of the virus, and host and environmental factors[17]. Four phases of CHB have been defined: immunotolerant phase, immune active phase, HBeAg seroconversion to anti-HBeAg, and inactive carrier.

HBV eradication should be useful for patients and society at large. General actions have been developed to prevent HBV infection: universal vaccination at birth, pregnancy screening measures, sexual education, and preventive and prophylactic management of clinical devices. Immigration, cheap air travel and globalization, are changing epidemiological patterns and pre-core mutation prevalence[18]. HBV suppression and reduction of necro-inflammatory activity in CHB may prevent cirrhosis, liver failure and HCC[19,20]. Unfortunately, because of extra-hepatic reservoirs, integration of HBV DNA into the host genome and protected intracellular, covalently closed circular DNA, HBV cannot be eradicated with current therapies. The next best alternative is sustained suppression of HBV replication until HBV DNA is undetectable. A viral load of > 10 000 copies/mL (2000 IU/mL) is a strong risk predictor of HCC, independent of HBeAg status, ALT level and liver cirrhosis[10,21,22]. Secondary targets are ALT normalization (biochemical response), hepatic necro-inflammatory improvement (histological response) and HBeAg seroconversion. Complete response includes fulfilling biochemical criteria, virological response and loss of HBsAg.

CONSENSUS GUIDELINES

There are consensus guidelines that help the clinician to make decisions about whether or not to treat a patient[23-27]. Treatment decision items are: HBeAg-positive or HBeAg-negative, serum viral load measured by polymerase chain reaction, elevated transaminases, histological lesions, duration of CHB (age > 40 years is likely to be a surrogate marker of disease duration) and family history of HCC. However, there are still areas of controversy in actual treatment of CHB. The long-term efficacy and safety are unknown. The question is who should be treated, how and especially when. The main guidelines are from the American Association for the Study of Liver Disease (AASLD Practice Guidelines)[24]. Their recommendations are summarized.

AASLD practice guidelines (I)
Treatment of patients with HBeAg-positive CHB: (1) Treatment should be considered if ALT is > 2 ULN or moderate/severe hepatitis is found upon biopsy, and HBV DNA is > 20 000 IU/mL; liver biopsy may be considered prior to treatment if illness is compensated. Treatment should be delayed for 3-6 mo in persons with compensated liver disease, to determine if spontaneous HBeAg seroconversion occurs. Patients with icteric flares or clinical de-compensation should be promptly treated. (2) If ALT is persistently normal or minimally elevated (< 2 ULN) and viral DNA is > 20 000 IU/mL, current treatment has low efficacy. Generally, treatment should not be initiated in these patients. Liver biopsy may be considered in patients with fluctuating or minimally elevated ALT, especially in those aged > 40 years old, or those with a family history of HCC. Treatment may be initiated if there is a moderate or severe necro-

inflammation or significant fibrosis upon liver biopsy.

Recommendation for monitoring HBeAg-positive patients: (1) Patients with persistently normal ALT should be tested for ALT at 3-6-mo intervals, and for ALT/HBV DNA more often if ALT becomes elevated. (2) HBeAg status should be checked every 6-12 mo. (3) Patients who remain HBeAg-positive with HBV DNA > 20 000 IU/mL after 3-6 mo with elevated ALT levels of 1-2 ULN, or DNA levels > 20 000 IU/mL and aged < 40 years old, should be considered for liver biopsy. Treatment should be considered if liver biopsy shows moderate/severe inflammation.

AASLD practice guidelines (II)
Treatment of patients with HBeAg–negative CHB: (1) If ALT is > 2 × ULN, and HBV DNA is > 2000 IU/mL, treatment should be considered. (2) If ALT is 1-2 × ULN and DNA is 2000-20 000 IU/mL, liver biopsy may be considered. Treatment may be initiated if liver biopsy shows moderate/severe necro-inflammation or significant fibrosis. (3) If ALT level is normal and DNA is < 2000 IU/mL, patients should not be treated. Patients should be tested for ALT every 3 mo during the first year to verify that they are truly in the inactive carrier state, and then every 6-12 mo. Test DNA and more frequent monitoring should be performed if ALT or AST increases above the normal limit. Patients should be observed and treated if HBV DNA or ALT increase.

HbeAg-negative and anti-HBeAg-positive patients with cirrhosis: Patients with compensated cirrhosis and HBV DNA > 2000 IU/mL and those with de-compensated cirrhosis and detectable HBV DNA by PCR assay should be considered for antiviral therapy, regardless of serum ALT level. The aim of the treatment in CHB patients is to achieve a maximum decrease in viral load. If serum DNA levels decrease to undetectable levels, by PCR, there is a reduction, not absence, of complications associated with HBV.

AASLD PRACTICE GUIDELINES

The new AASLD practice guidelines follow the traditional criteria of treatment, but, as with other guidelines[26,27], incorporate current tendencies to increase the viral load value. This adds the recommendation of treatment for HBeAg-negative patients with serum DNA level > 2000 IU/mL (10^4 copies/mL) and ALT < 2 × ULN, if biopsy shows moderate/severe necro-inflammation and significant fibrosis.

There is no doubt in the management of cases according to the guidelines. There are two areas of controversy. Management of asymptomatic HBeAg-positive patients with normal ALT levels and without the following criteria: advanced histological findings, recurrent hepatitis flares, age > 40 years with persistently high HBV DNA levels, and family history of HCC. The other area of ongoing debate is the differentiation between the inactive carrier state and asymptomatic

HbeAg-negative CHB with normal ALT. We do not know what is the cut-off value of DNA used to define these two phases of CHB infection. The main question in CHB treatment is if the new antiviral therapies permit treatment only guided by DNA levels and ignore other factors such as ALT level or histology.

Lok and McMahon consider that treatment is indicated if the risk of liver–related mortality and morbidity in the near future (5-10 years), and the likelihood of achieving maintained viral suppression after a defined course of treatment are high[24]. However, present therapies have a high cost and limited efficacy. Response to treatment is limited by adverse events [interferon (IFN)α and pegylated (PEG)-IFNα], drug interactions, drug resistance [nucleotide and nucleoside analogs (NAs)], relapses after suspension of treatment, and limited adherence to long-term treatments.

It may be that the approach to treatment of CHB patients with normal ALT must be done on an individual basis, and must consider serum viral levels measured by PCR, elevated transaminases, histological lesions, age, CHB phases, and family history of HCC. The response to treatment changes with the different phases of illness.

VIRAL LOAD AND TREATMENT: FAVORABLE ARGUMENTS

It is known that maintained high levels of HBV DNA are associated with progressive liver disease. Serum DNA levels are a prognostic factor, and contribute to define the phase of CHB infection, the treatment indication, and allow an assessment of the efficacy of antiviral therapy. High levels of HBV DNA are an independent risk factor for cirrhosis[28] and HCC in Asia[22,29].

The REVEAL (Risk Evaluation of Viraemia Elevation and Associated Liver Disease)-HBV study group followed a cohort of 3653 HBsAg-positive patients in Taiwan. Their average age was 45 years and they acquired HBV infection perinatally. A baseline high HBV-DNA level > 10 000 copies/mL was associated with a significant increased risk of HCC[30] and with progression towards cirrhosis[22]. Those patients that have persistently high levels of viral replication, for up to four decades, are at highest risk for HCC/cirrhosis after adjusting for HbeAg status, age, sex, ALT level, cigarette smoking and alcohol consumption. Many Asian patients may be in an immunotolerant phase, and the applicability of these data to western countries is not clear.

However, Fattovich *et al*[28] have re-evaluated a cohort of 70 Caucasian patients with HBeAg-positive chronic hepatitis at presentation, and they have shown that the risk of liver-related mortality in Caucasian adults with chronic hepatitis is strongly related to sustained disease activity and ongoing high levels of HBV replication, irrespective of HBeAg status. Other risk factors for liver-related death are older age, male sex, cirrhosis at entry, and absence of sustained remission.

It seems that a high level of HBV DNA is an independent risk factor for development of cirrhosis

and HCC. The correlation between HBV DNA level and degree of liver injury upon biopsy is not well characterized. Serum HBV DNA level of > 100 000 copies/mL is not correlated with histological grade or stage of liver disease in CHB patients, whatever the status of HBeAg[9]. Kumar *et al*[31], in a recent, large prospective study, have shown clearly that baseline ALT and DNA level are good predictors of histologically significant fibrosis. However, in an analysis of clinical trial data using NAs, Mommeja-Marin *et al*[32] have shown that there is a strong linear correlation between log-reduction of HBV-DNA levels and improvement in inflammation and fibrosis in liver biopsy.

The interpretation of serum DNA level is not easy, because we do not know the cut-off value for defining indication for and response to treatment. The 2000 National Institutes of Health conference chose an arbitrary value of 20 000 UI/mL (> 10^5 copies/mL)[33]. As DNA levels have a fluctuating nature, monitoring changes in serum DNA levels is an essential tool.

VIRAL LOAD AND TREATMENT: UNFAVORABLE ARGUMENTS

Presently, the viral load cannot be considered as the only treatment criterion. HBV DNA persists even in persons who have serological recovery from acute HBV infection[34]. Patients with low HBV-DNA levels, between 300 and 10^4 copies/mL, have, although a very low one, a risk of progression to cirrhosis and HCC[9]. The progression in CHB infection is a multi-factorial process including interaction between host and environmental factors.

ALT value

Host immune response against HBV is essential to control infection. Immune response produces necrosis and inflammation of the liver. Liver biopsy assesses necro-inflammatory activity and cirrhosis, and it is measured indirectly by aminotransferase level. There is no significant interaction between ALT and HBV-DNA levels[35].

Many studies have shown a low prevalence of significant liver injury in CHB patients with normal ALT levels[36-39]. There is a possible bias for including blood donors, and a high proportion of patients in the immunotolerant phase. However, ALT values may vary with body mass, sex, abnormal lipid and carbohydrate metabolism. In addition, recent studies have suggested that ALT is an imperfect marker for liver disease activity. Some studies have detected significant liver injury in CHB patients with normal ALT[40,41]. In a retrospective study, Lai et al have investigated 192 CHB patients, with viral DNA at 10 000 copies/mL and hepatic biopsy or clinical cirrhosis. There were significant fibrosis and inflammation in 37% of patients with persistently normal ALT, and a trend for the normal ALT group to include younger patients[42].

Kumar *et al*[31] have found a correlation between

histologically significant fibrosis (F score > 2) and persistently or intermittently elevated baseline ALT and baseline DNA > 10 000 copies/mL. However, a normal ALT level in an individual patient does not always indicate absence of significant liver disease. Among HBeAg-positive patients with persistently normal ALT, 60.3% have baseline DNA levels > 5-log copies/mL, 63% have histological activity of hepatitis (HAI) > 3, and 39.7% have fibrosis stage > 2. Concerning HbeAg-negative CHB patients with persistently normal ALT (PNALT), they observed that 35.3% of patients have baseline DNA levels > 5-log copies/mL, 39.7% have HAI > 3, and 13.8% have fibrosis stage > 2. Following ASSLD practical guidelines, the inactive carrier state is differentiated from HBeAg-negative CHB by serial testing of ALT and serum HBV levels, because of the fluctuating pattern of AST/ALT. The inactive carrier state is defined by normal ALT and HBV DNA < 2000 IU/mL (10 000 copies/mL). Some studies have observed that a cut-off of 10 000 copies/mL may lead to misclassification of 13%-20% of HBeAg-negative CHB patients[43,44]. Kumar et al[31] have obtained similar results: 21 of HBeAg-negative patients with baseline DNA levels < 5-log copies/mL and PNALT, have HAI > 3 and fibrosis stage > 2.

Revision of normal limits for ALT level is advisable. The current standards for normal ALT level have been defined by using populations that include persons with subclinical liver disease, chronic HCV infection or non-alcoholic fatty liver disease. We considered normal ALT to be 40 IU/mL and normal aspartate aminotransferase (AST) to be 30 IU/mL. Recently, new upper limits of normal for ALT for men (30 IU/mL) and women (19 IU/mL) have been proposed. Revision of normal limits for ALT level is advisable to obtain a new cut-off, i.e. ALT = 39 IU/mL (men) and 19 IU/mL (women)[45]. Patients with a persistently normal ALT, HBV-DNA level >10 000 copies/mL, and significant fibrosis and inflammation upon liver biopsy usually have an ALT in the high range of normal (26-40 IU/mL), and are older than 40 years old. This is consistent with new AASLD guidelines and recent data from Lin et al[46], which correlate parameters of progressive disease with high normal ALT. AASLD guidelines suggest decreasing the upper limits of normal for ALT.

ALT, likely with a new-updated cut-off value, is a factor to consider in the treatment of HBC patients. A high ALT value is a predictor of necro-inflammatory activity and a marker of response to actual treatment. In HBeAg-negative patients, its role as predictor of response to therapy is unclear. However, a high ALT level helps to distinguish between the inactive carrier state and asymptomatic HBeAg-negative CHB patients with normal ALT. A normal serum ALT level alone in patients with active viral replication does not predict mild or normal histological findings.

Value of biopsy: fibrosis and necro-inflammatory activity
Patients with moderate/severe inflammation or bridging fibrosis/cirrhosis must be treated[24]. The degree of

fibrosis or inflammation upon liver biopsy cannot be predicted for HBV-DNA levels >10 000 copies/mL. ALT is an imperfect marker for liver disease (see above). Traditional and current guidelines recommend liver biopsy for patients who meet the criteria for chronic hepatitis (HBsAg positive for > 6 mo, serum HBV DNA > 10^5 copies/mL or > 20 000 IU/mL, persistent or intermittent elevation in ALT/AST levels). These patients must be treated if we follow the guidelines, and we believe that liver biopsy may be unnecessary.

Liver biopsy is more important for patients who do not meet the current criteria for treatment but have serum HBV-DNA levels of 10^4 to 10^5 copies/mL (2000-20 000 IU/mL) and/or ALT/AST levels that are normal or mildly elevated (< 2 × ULN). The presence of significant inflammation or bridging fibrosis/cirrhosis is an indication for treatment. In a subgroup of these patients, hepatic elastography can avoid the need to carry out a liver biopsy for detection of significant fibrosis. This is a novel non-invasive method to assess hepatic fibrosis in patients with a chronic disease, by measuring liver stiffness. Its failure rate is about 5% of cases, mainly in obese patients[47,48]. Elastography has a high positive predictive value (92%) for diagnosing significant fibrosis (F3 and F4) in Asian CHB patients[49]. This method does not have a defined role in HBeAg-negative patients because histological inflammation during reactivation may affect the results[50].

GENOTYPE VALUE

The relationship between genotype and treatment indication is not well known as yet. The characteristics of the virus during evolution of the illness and the response to the treatment are acquiring an ever-increasingly important role. The prevalence of HBV genotypes varies depending on geographical location. It differs between Asia and Europe, and within European countries. Genotypes B and C are almost the only ones present in Asia. Genotypes A and D, with a lower prevalence of types F and G, are the most frequent in Europe[51]. Migration is changing this distribution[52,53]. In Europe, different genotypes may play a role in establishing the response to treatment, the manner and time of transmission, and the rate of HBeAg seroconversion with or without therapy[54]. HBV genotype may be associated with disease progression[55].

PROBBABILITY OF RESPONSE TO TREATMENT AND APPEARANCE OF RESISTANCE

Treatment is indicated if there is a high risk of liver-related mortality and morbidity and a high likehood of manteined viral supression after a defined course of therapy[24]. This risk is variable during the course of HBV infection.

There are several treatment strategies for CHB: IFN and PEG-IFN, lamivudine, adefovir dipivoxil,

telbivudine and entecavir. None of theses achieves complete HBV eradication and they have limited long-term efficacy. In the majority of patients, particularly those with HBeAg-negative disease, HBV is suppressed but not eradicated by treatment, and relapses occur when drug treatment is interrupted.

For HBeAg-positive patients, the likelihood of a sustained virological response to antiviral therapy is < 20%-30% of treated patients, but long-term response depends upon HBeAg seroconversion. IFN has proven to be efficacious for ALT and DNA normalization, and for HBeAg seroconversion in 25%-40% of HBeAg-positive patients. HBeAg seroconversion is sustained in < 20% at 12 mo. After HBeAg seroconversion is achieved, viral suppression is sustained in 50%-90% of patients[56,57]. PEG-IFNα2A combined response (HBeAg and DNA suppression, and ALT normalization) is better than IFN response at 6 mo (24% *vs* 12%)[58,59]. For NAs, HBeAg/anti-HBeAg seroconversion rate is 16%-24%, and is similar among different drugs[60-63]. These patients have a sustained remission even after therapy is stopped. Entecavir seroconversion rates increase in time but there are no studies after 3 years of treatment, therefore, we do not know if these responses will be maintained[64,65].

For HBeAg-negative patients, the sustained response is low: 15% show normalization of serum ALT and suppression of serum HBV DNA[66-69]. For HBeAg-positive patients, the likelihood of response to nucleoside64/nucleotide analogs[70-74] and IFN[75,76]/PEG-IFN[77] depends greatly upon degree of serum aminotransferase elevation. In general, treatment with any of these drugs does not result in higher rates of HBeAg seroconversion compared to non-treatment in those who have a serum ALT < 2 × ULN. After a year of treatment, HBeAg seroconversion occurs in < 10% of these patients treated with IFN, lamivudine or adefovir. ASSLD guidelines do not recommend treatment in normal ALT patients, because it is unlikely to achieve HbeAg seroconversion.

IFNs are administered for predefined durations, do not select antiviral-resistant mutants, but produce more secondary effects (5%-8% treatment withdrawal). NA oral agents are administrated until specific endpoints are achieved. NA treatment is costly and their long-term safety and efficacy have yet to be proven. The HBeAg-positive patients with normal/low pre-treatment ALT level must not be treated with IFNs because the sustained response is very low. This subgroup and HBeAg-negative patients need long-term or continuous treatment. The hardest challenge for NAs is the selection of antiviral-resistant mutants, with long-term treatment. The rate at which resistant mutants are selected is related to pre-treatment serum HBV-DNA level, speed of viral suppression, duration of treatment, and prior response to NA therapy. Therefore, resistance is greater in normal-level ALT, HBeAg-positive patients, because slower DNA suppression occurs in the first 6 mo of treatment (12 mo for adefovir)[78]. In patients without an early virological decrease (3 and 6 mo), treatment should be maintained for the long term, which does increase the risk of resistance developing.

Lamivudine has the higher rate of resistance, 70% after 4 years of treatment in both HBeAg-positive/negative patients. Adefovir and telbivudine have the same problem. Adefovir resistance in the first year is lower than lamivudine resistance, but later, the accumulated resistance is of the order of 2.5% per year. Telbivudine selects the same resistant mutants as lamivudine. Entecavir-resistant mutation is observed in < 1% of nucleoside-naive patients after 2 and 3 years of treatment; data are lacking after 3 years, although resistance is higher in lamivudine-refractory patients[79,80]. The most effective method against the development of antiviral-resistant HBV is not to treat if therapy is not indicated.

Many new treatments are undergoing testing. None of the combination therapies has been proven to be superior to monotherapy, but with some disadvantages, such as greater cost, toxicity and drug interactions. Finally, current treatments do not eradicate HBV and have limited long-term efficacy, especially if ALT is below two times the normal upper average limit. For HBeAg-negative patients, prediction of response is unclear. While IFNs are administered for predefined durations, NAs are usually administrated until specific endpoints. Treatment is long term in normal-level ALT, HBeAg-positive and -negative patients, and is associated with adverse events and drug resistance.

CONCLUSION

DNA viral load is associated with disease progression, cirrhosis and HCC. In the subgroup of HBeAg-positive patients with DNA levels > 20 000 IU/mL and normal (or minimally elevated) ALT, current therapies are of limited efficacy and treatment should be considered long-term. The risk of this attitude is the appearance of secondary effects and drug resistance. Therefore, viral load is not sufficient for treatment, and we must give some thought to other factors, such as histological factors (fibrosis/cirrhosis and liver inflammation), patient age, disease evolution time, family history of HCC, adverse drug events and development of resistance. If patients have high DNA levels and normal ALT, without other unfavorable prognostic factors, it is advisable to follow the patients and not to treat them. The fluctuations in viral DNA, ALT and liver histology in patients with CHB allow us to choose the best time to begin treatment. The time required for the best response following clinical guidelines may be with the same as that required for the best sustained response. In HBeAg-negative patients, the cut-off value of viral load needed to distinguish asymptomatic HBeAg-negative CHB patients from those with normal ALT and inactive carrier state is not known.

Therefore, it is not the time to treat CHB patients, guided only by viral load. We agree with the clinical practice guidelines of the European Association for the Study of the Liver)[81], in which there are three criteria

for beginning HBV therapy: serum HBV-DNA levels, serum aminotransferase levels, and histological grade and stage. Patients should be considered for treatment when HBV-DNA levels are > 2000 IU/mL (10 000 copies/mL) and/or serum ALT is above ULN, and liver biopsy (or non-invasive markers when validated) shows moderate to severe active necro-inflammation and/or fibrosis (greater than A2 or F2 by METAVIR histological scoring). This may change if new, short-term therapies appear, and HBV eradication should be possible during long-term treatment, without development of resistance.

Abstract

AIM: To explore the possibility of reversing multi-drug resistance (MDR) to HepG2/mdr1 *in vitro* and *in vivo* with RNA interference (RNAi).

METHODS: HepG2/mdr1 was obtained by cloning the whole gene mdr1 into HepG2 cells. shRNA targeting sequence was designed to be homologous to the P-gp encoding MDR1 mRNA consensus sequence. pSUPER-shRNA/mdr1 was constructed using the enzyme-digested technique. HepG2/mdr1 cells were transfected with vectors of pSUPER-shRNA/mdr1 to measure their efficacy by real-time PCR for mdr1 mRNA, flow cytometry (FCM) for P-gp expression, and Rhodamine efflux, MTT method for HepG2/mdr1 function, respectively. *In vivo*, mice tumors were treated by injecting pSUPER-shRNA/mdr1 *in situ* and into intra-abdominal cavity. Tumors were collected to create cell suspension and cryosections after chemothearpy with adiramycin and mytomycin. The cell suspension was incubated in RPMI-1640 supplemented with G418 to screen stable cells for appreciating the reversal of MDR. Cryosections were treated with immunohistochemistry technique to show the effectiveness of transfection and the expression of P-gp.

RESULTS: pSUPER-shRNA/mdr1 was successfully constructed, which was confirmed by sequencing. The MDR phenotype of HepG2/mdr1 was decreased significantly *in vitro* transfection. HepG2/mdr1 showing its MDR was reversed notably in P-gp expression (11.0% *vs* 98.2%, *P* < 0.01). Real-time PCR showed that mRNA/mdr1 was lower in test groups than in control groups (18.73 ± 1.33 *vs* 68.03 ± 2.21, *P* < 0.001). Compared with HepG2, the sensitivity of HepG2/mdr1 and HepG2/mdr1-dsRNA cells to ADM was decreased by 1.64 times and 15.6 times, respectively. The accumulation of DNR in positive groups was decreased evidently. *In vivo*, the p-gp expression in positive groups was significantly lower than that in control groups (65.1% *vs* 94.1%, *P* < 0.05). The tumor suppressing rate in test groups was 57.8%. After chemotherapy, the growth rate in test groups was lower than that in control groups (700.14 ± 35.61 *vs* 1659.70 ± 152.54, *P* < 0.05). Similar results were also observed under fluorescence microscope, and confirmed by Image-Pro Plus 4.5 analysis.

CONCLUSION: pSUPER-shRNA/mdr1 vector system allows simple, stable and durable nonviral knockdown of P-gp by RNAi in malignant cells and animals to restore their sensitivity to adriamycin.

INTRODUCTION

It has been reported that a relatively new technique using RNA interference (RNAi) is able to inhibit gene expression[1]. RNAi is triggered by the presence of

double-stranded RNA (dsRNA) in cells and results in a rapid destruction of mRNA containing an identical or nearly identical sequence[2]. Studies on the RNAi pathway in invertebrates, however, have demonstrated that cleavage of long dsRNAs to a length of 21-25 bp results in dsRNAs that are active in eliciting RNAi[3,4]. It has recently been shown that RNAi can be achieved in cultured mammalian cells using small interfering RNA (siRNAs) with a length of 21-23 bp[5].

Liu et al[6] have developed a technique to efficiently deliver plasmid DNA to organs of postnatal mice by rapidly injecting a large volume of physiological solution into their tail vein. A further research showed that high-pressure delivery technique can deliver siRNAs for RNAi induction used as a reporter gene, the modified luciferase gene, luc+[7]. In liver, injection of 0.5 μg siRNA-luc+ can increasingly inhibit luc+. These results indicate that inhibition of target gene expression by siRNA in organs of postnatal mice can efficiently deliver siRNA.

Resistance to cytotoxic drugs represents a serious hindrance in cancer chemotherapy. One form of multi-drug resistance (MDR) is caused by over-expression of P-gp, a mdr1 gene product[8]. P-gp is a transmembrane phosphoglycoprotein capable of transporting a variety of structurally and functionally diverse chemotherapeutic drugs, such as vinblastine, doxorubicin and paclitaxel, leading to reduced intracellular drug concentration and cytotoxicity[9]. In human hepatocellular carcinoma (HCC), the best treatment is radical operation of the tumor. However, only 30%-40% of HCC can undergo a radical operation, while others must receive chemotherapy[10]. To circumvent the MDR of HCC resulting from chemotherapeutic drugs, several ways including inhibitors of P-gp, oligonucleotide，anti-sense RNA, transient siRNA, hammerhead ribozyme techniques and others regulating MDR-related gene measurements have been developed[11-16]. However, the half-life of P-gp (at least 16 h) makes it difficult to achieve a complete knockdown of P-gp[17]. To solve this problem, siRNA vectors have been used in retro-, adeno-, and lentiviral systems. Virus-associated difficulties, such as insertional mutagenesis and cis-activation of silent genes by their strong promoters, and difficult generation of recombinant viruses, have limited the use of such systems[18,19].

Reports showed that RNAi technology is currently used not only as a powerful tool for analyzing gene function, but also for developing highly specific therapeutics[20,21]. In the RNAi approach, sequence-specific post-transcriptional gene silencing is achieved by siRNA, short double-stranded RNA molecules in which the anti-sense strand is complementary to the target mRNA of a given gene[22,23]. It has not been determined whether suppressing mdr1 expression with siRNA is sufficient to reverse the MDR of HepG2/mdr1 in vitro and in vivo.

An alternative new strategy is the plasmid-based expression system. We used the plasmid-based RNAi system for the knockdown of MDR-1, restoring its sensitivity to adriamycin and doxorubicin in P-gp over expression. This vector system-pSUPER is a powerful tool for the attenuation of P-gp-mediated drug resistance in malignant cells.

The effective dsRNA sequence has been screened from 4 siRNA transfecting HepG2/mdr1 cells with an oligofectamine kit (result not shown). In the present study, we used this sequence in design of shRNA template oligonucleotide.

MATERIALS AND METHODS

Cell culture
HepG2/mdr1 was obtained by cloning the whole gene mdr1 into HepG2 cells to construct its MDR[24]. HepG2 and HepG2/mdr1 cells were cultured in RPMI-1640 containing 2% glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin, 10% fetal calf serum, and 200 μg/mL G418 at a density of 2×10^5 and sub-cultured upon reaching a density of 1×10^6 cells per Ml. Three days before transfection, G418 was omitted from the medium.

Design of shRNA template oligonucleotides and construction of plasmid
ShRNA target sequence was designed to be homologous to the P-gp encoding MDR1 mRNA consensus sequence (GeneBank accession number AF 16535) tested by transfection assay[24]. Complementary oligonucleotides encoded a hairpin structure with a 19-mer stem derived from the mRNA target site. A 19-bp loop sequence separated the two complementary domains. Near the 3' end of shRNA template is a 5 nucleotide poly (T) tract recognized as a RNA pol III termination signal. The 5' end of two oligonucleotides was Bal II and Hind III restriction site overhangs. shRNA insert template oligonucleotides, MDR1 DNA oligos, control insert sequence DNA oligos encoding the GFP shRNA (sense: 5'-GATCCGGTTATGTACAGGAACGCATTCAAGA GATGCGTTCCTGTACATAACCT-TTTTGGGAA A-3' and anti-sense: 5'-AGCTTTTCCAAAAAGGTT ATGTAC-AGGAACGCATCTCTTGAATGCGTTCC TGTACATA-ACCG-3') were synthesized, annealed and ligated into the Bal II and Hind III sites of linearized pSuper RNA system shRNA expression vector for each target site.

Cloning shRNA insert into pSUPER neo vector
Ligation products were transformed into E. coli, clones were selected, and plasmid DNA was isolated. Plasmid was digested, clones with the shRNA insert were selected, and purification of pSUPER-neo shRNA plasmid for transfection was performed using the Wizard plus SV Minipreps DNA purification system (Promega, USA).

Cell lines and culture
HepG2/mdr1 was kindly provided by Dr. Yong-Bing Chen (Department of Biliary-hepatology Surgery, Beijing Youan Hospital, Beijing 100000, China). All

cells were cultured in RPMI-1640 medium (Sigma, USA) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin. The cells were plated in a fully humidified atmosphere containing 5% CO_2, 95% air at 37℃. HepG2/mdr1 cells were established by gene clone technique. In brief, the mdr1 gene was cloned into the vector and then transfected into HepG2 cells to construct its MDR[20]. In order to maintain the MDR phenotype, cell culture medium for P-gp-expressing HepG2/mdr1 cells was supplemented with 0.05 μg/mL of doxorubicin, 400 μg/mL of G418. HepG2/mdr1 cells were incubated in a doxorubicin-free medium with 400 μg/mL of G418 for over 2 wk and then used in study. All the cells were discarded after 3 mo and new cells were obtained from frozen stocks.

Transfection with siRNA expression vector

HepG2/mdr1 cells in the exponential phase of growth were plated in 6-well plates at 2×10^5 cells per well, grown for 24 h, then transfected with siRNA expression plasmid pSUPER-shRNA (OligoEngine Co, USA) according to the manufacturer's protocol. Negative control cells were treated with pSUPER negative control plasmid consisting of a circle plasmid encoding a siRNA whose sequence was not found in mouse, human or rat genome databases. Seventy-two hours after transient transfection, silencing was examined, then the cells were trypsinized for 72 h and seeded onto selective media. HepG2/mdr1 cells stably expressing siRNA were established by selection with a medium containing 400 μg/mL of G418 (Sigma, USA). The medium was renewed every 3 d. After 2 wk, resistant colonies were trypsinized, combined in pools and cultured in a selective medium. Stable expression was examined 8 wk after transfection.

Real-time fluorescence quantitative PCR

Sequences of the primers and probes were selected from the mdr1 gene for MDR and P-glycoprotein. The primers and TaqMan probes were designed using the Primer Express Software (Applied Biosystems, Foster City, CA). Molecular beacons were designed according to the guidelines available at internet. A DNA folding program was used to estimate the stability of stem and loop structures of the molecular beacons. The forward and reversed primer sequences for mdr1 gene and GAPDH are 5'-GACATGACCAGGTATGCCTA-3' and 5'-CTTGGAGACATCATCTGTAAGTC-3', and 5'-TGGGTGTGAACCACGAGAA-3' and 5'-GGCAT GGACTGTGGTCATGA-3', respectively. The primer sequences of TaqMan probes for mdr1 and GAPDH are 5'-CTGCACCACCAACTGCTTAGC-3' and 5'-CT GACTCACCACACCAATGAC-3', respectively. First, total RNA was extracted from all groups with a RNA extraction kit (Omega, USA) and verified by 1% gel electropherogram and A260/A280. Reverse transcription PCR was carried out to produce cDNA. PCR was performed in a 50 μL volume containing 10 × buffer, 25 mmol/L $MgCl_2$, 25 mmol/L dNTP mix, 10 μmol/L

primer F, 10 μmol/L primer R, Taq DNA polymerase and DEPC-H_2O. The reactions were initially heated to 94℃ for 4 min, and then subjected to 35 cycles at 94℃ for 30 s, at 55℃ for 30 s, at 72℃ for 1 min, at 72℃ for 1 min in an iCycle iQ PCR detection system (Bio-Rad, CA). Finally, real-time PCR was performed in a 30 μL volume containing 10 × buffer, 10 mmol/L dNTPs, 250 mmol/L $MgCl_2$, 10 Pmol/μL primer F, 10 Pmol/μL primer R, 10 Pmol/μL Taq Man probe, Taq enzyme, cDNA template and ddH_2O, for 35 cycles at 94℃ for 2 min, at 94℃ for 20 s, at 50℃ for 30 s, and at 60℃ for 40 s for the measurement of mdr1 mRNA level. Data were collected during reactions. PCR threshold cycle (Ct) defined as the fractional cycle number at which the fluorescence reaches 10 times the standard deviation (SD) of the baseline, was determined. Average Ct for duplicate standards and test samples was calculated. Standard curve equations were calculated by regression analysis of average Ct *versus* log10 of the standard copy number. ΔCt and ΔΔCt of all samples were calculated to produce $2^{-\Delta\Delta Ct}$. The results were linearized and analyzed by ANVON.

Flow cytometry (FCM) for P-gp expression

Nucleofected cells of HepG2/mdr1, including test groups-HepG2/mdr1-si and control groups-HepG2/ mdr1 were collected, analyzed for Pgp expression with staining 50 μL of Pgp monoclonal antibody for 60 min at 37℃, and washed two times in phosphate-buffered saline (PBS). The cells were incubated fro another 60 min with 50 μL of PE-labled antibody against Pgp antibody, washed two times with PBS, and finally, analyzed with a flow cytometer (FACSCalibur, BD, Vienna, Austria). The data were then subjected to CellQuest software (BD).

Cytotoxicity assay for cell survival

All cells in the exponential growth phase were plated in a 96-well plate at 2×10^4 cells/well, and grown for 24 h. The cells were incubated for 48 h after different concentrations of doxorubicin were added. The cells were incubated for 4 h after 20 μL of 5 mg/mL MTT (Sigma, USA) was added. The absorbance at 490 nm was read and the IC50 values were determined (at least three times) in multiple independent experiments. Relative reversal rate = ($IC_{50}A$-$IC_{50}B$)/($IC_{50}A$-$IC_{50}C$), where $IC_{50}A$ is IC_{50} values for non-transfected multi-drug resistant cells, $IC_{50}B$ is IC_{50} values for sensitive cells. Survival data of cells transfected with shRNA vectors were evaluated by ANOVA for statistical significance.

FCM for accumulation of daunorubicin

To assess the steady accumulation of daunorubicin, all cells transfected with shRNA expression plasmids or control plasmids and transfected reagents were incubated with 1.0 μg/mL daunorubicin for 1 h at 37℃, washed three times with ice-cold PBS. The fluorescence intensity of intracellular daunorubicin was determined by FCM.

Subcutaneous tumorigenesis in nude mice

Animal care and sacrifice were approved by Sichuan University Medical School Animal Studies Committee. Prior to injection, HepG2/mdr1 and HepG2 cells were resuspended in a serum-free medium at 2×10^7 cells/mL. Nude mice (BALBC/C-nu/nu, Animal Breeding Center, Sichuan University, Chengdu, China) were divided into experimental group and control group. Mice in each group were subcutaneously injected with 200 µL cell suspension into the right flank. The process of tumorigenesis was monitored and newly formed tumor volume (volume = $m_1^2 \times m_2 \times 0.5236$, m_1 represents the short axis, and the m_2 long axis) was measured every 2-3 d.

In situ and intraperitoneal injection of pSUPER-shRNA-mdr1

When the newly formed subcutaneous tumor reached 0.5-0.6 cm in diameter, mice in the experimental group underwent 2 variant tests (5 mice per test): pSUPER-shRNA-MDR1 at the ratio of 1 mg/kg and 1.5 mg/kg was injected into the tumor *in situ* and peritoneal cavity, respectively. Mice in the negative control group were injected with blank pSUPER vectors and mice in the blank control group of HepG2 were not treated. The vectors were mixed with liposome at the ratio of 1:1 for transfection. Seventy-two hours after injection, mice in all groups underwent chemotherapy with adriamycin (ADM) at a dose of 1.5 mg/kg, twice a week, for two weeks. Then, tumorigenic tissue was carefully separated from its surrounding fibrous capsule for measurement of tumor volume. The relative growth rate of tumorigenic tissue [$\Delta TV = (V_2 - V_1)/V_1$, V_1: tumor volume before chemotherapy; V_2: tumor volume at mouse sacrifice] demonstrated the sensitivity of variant cells to ADM *in vivo*. Tumorigenic tissue was further ground, suspended as single cells, and cultured in RPMI-1640 medium supplemented with 200 µg/mL of G418. Cells with stable expression of shRNA were selected for flow cytometry or incubated with different concentrations of ADM (0.032-5 µg/mL). Their IC_{50} values were determined by MTT assay.

Sensitivity of HepG2/mdr1 to ADM

Seventy-two hours after treatment with pSUPER-shRNA-mdr1 injection, mice in all groups underwent chemotherapy with adiramycin at a dose of 1.5 mg/kg, two times a week, for two weeks, and executed to harvest the tumor for monoplast suspension. The exact volume and relative growth rate of tumor [$\Delta TV = (V_2 - V_1)/V_1$, where V_1 is the tumor volume before chemotherapy and V_2 is the tumor volume after mouse sacrifice] were measured to evaluate drug sensitivity of cell lines to ADM. Cell suspension was cultured in a RPMI-1640 medium supplemented with 200 µg/mL of G418 to screen stably expressing cells. The screened cells were incubated at 1×10^6 cells/mL to study the sensitivity of HepG2/mdr1 to ADM. Cells were treated at different concentrations of ADM (0.032-5 µg/mL) to determine their IC_{50} by MTT assay.

Figure 1 shRNA/mdr1 expression plasmids digested by restriction enzyme Bag Ⅱ and Hind Ⅲ, and a fragment produced in 1.5% agarose gel electrophoresis. Lanes 1 and 7: positive clone size of 310 bp (insert element 64 bp).

Flow cytometry for P-gp expression

Variant cells were incubated with 50 µL of monoclonal antibody to P-gp at 37℃ for 60 min, washed twice in phosphate-buffered saline (PBS), incubated for another 60 min with 50 µL of PE-labeled secondary antibody, sorted with a flow cytometer (FACSCalibur, BD, Vienna, Austria) and analyzed using CellQuest software (BD).

Immunohistochemistry

Sections of tumorigenic tissue were fixed in cold acetone at 4℃ for 10 min. The sections were incubated for 10 min at room temperature with an endogenous peroxidase blocking solution, and then with 1:100 anti-P-gp mouse monoclonal antibodies at 37℃ for 1 h. After washed with PBS, the cells were incubated with 1:150 PE-labeled rabbit anti-mouse IgG at 37℃ for 1 h, stained with glycerine and photographed under inverted light microscope (Olympus, Japan) and confocal fluorescence microscope (Olympus, Japan). The images were analyzed with Image-Pro Plus 4.5 system (Media Cybernetics, Inc. USA). The total OD value and area of intracellular fluorescence for each section were measured.

Statistical analysis

Average values were expressed as mean $\pm$ SD. The statistical significance of differences in mean values was assessed by Student's t test and ANVON using SPSS 10.0 statistical software. $P < 0.05$ was considered statistically significant.

RESULTS

Identification of shRNA expression plasmids

The shRNA/mdr1 expression plasmids were digested by restriction enzyme Bag Ⅱ and Hind Ⅲ, and 1.5% agarose gel electrophoresis produced a fragment of 64 bp (Figure 1). DNA sequencing confirmed that ligation reaction between the shRNA insert and pSUPER-shRNA/mdr1 expression vector was correct. No.1 and No.7 indicated the positive clone size of 310 bp (insert element 64 bp) (Figure 2).

Table 1 Effect of stable expression of MDR1 targeting shRNA on MDR1 mRNA, P-gp and resistance to cytotoxic drugs in HepG2/mdr1 cells

| | Real-time PCR | P-gp | DNR accumulation | Drug resistance | | | |
| | mdr1 mRNA | | | Adiramycin | | Mytomycin | |
Cell line	$2^{-\Delta\Delta Ct}$	Mean fluorescence	Mean fluorescence	IC_{50}	Fold-resistance	IC_{50}	Fold-resistance
HepG2	75.58	1.0	87.56	0.40	1.0	0.07	1.0
HepG2/m	1.0	98.6	39.76	25.0	62.5	9.67	138.1
HepG2/m-sh	56.30[b]	1.07[b]	79.32[a]	0.56[b]	1.4[b]	0.08[b]	1.14[b]

The unit of IC_{50} was μg/mL. [a]$P < 0.05$; [b]$P < 0.01$ *vs* HepG2/m.

Figure 3 Real-time PCR showing significantly reduced mdr1 mRNA expression in cells treated with pSUPER-shRNA/mdr1 vector. 1: HepG2; 2: HepG2/mdr1; 3: HepG2/m-sh; 4: HepG2/mdr1 empty vector; M: Marker; Mdr1: 218 bp; GAPDH: 145 bp.

Inhibition of mdr1 gene mRNA expression using shRNA expression vectors

Seventy-two hours after transient transfection, mdr1 mRNA expression was significantly reduced in cells treated with pSUPER-shRNA/mdr1 vector, compared with the control (56.3-fold *vs* 1.0-fold, $P < 0.01$; Figure 3 and Table 1).

Knockdown of P-gp protein expression after transfection with pSUPER-shRNA/mdr1 vectors

The effect of transfection with pSUPER-shRNA/mdr1 vectors on cellular P-gp expression in HepG2/mdr1 cells was assessed by FCM. Seventy-two hours after transient transfection with pSUPER-shRNA/mdr1 vectors, the protein expression of P-gp was decreased from 98.6% to 11.0% ($P < 0.01$, Table 1 and Figure 4), indicating that transfection with pSUPER-shRNA/mdr1 vectors could significantly decrease the cellular P-gp expression levels in HepG2/mdr1 cells after transient and stable transfection.

Cell survival

MTT assay was performed to examine the effects of doxorubicin after transient and stable transfection. Seventy-two hours after transient transfection, pSUPER-shRNA/mdr1 vectors decreased the resistance to adiramycin and mytomycin from 44.6-fold to 1.4-fold and from 138.1-fold to 1.14-fold compared to the control groups (Table 1 and Figure 5). The IC50 was lower than that in control groups (0.56 μg/mL *vs* 25.0 μg/mL, 0.08 μg/mL *vs* 9.67 μg/mL, $P < 0.01$), suggesting that transfection of pSUPER-shRNA/mdr1 vectors could reverse the resistance to adiramycin and mytomycin.

Steady accumulation of daunorubicin

Transfection with hairpin shRNA vectors improved intracellular drug accumulation. Compared with control groups, accumulation of daunorubicin in cells treated with shRNA vectors was significantly increased (79.32% *vs* 37.96%, $P < 0.05$). There was no difference in sensitive cells of HepG2 (79.32% *vs* 87.56%) between test groups (Table 1 and Figure 6).

Figure 4 FCM showing P-gp expression of HepG2/mdr1 in test groups (A) and control groups (B).

Figure 5 Sensitivity of HepG2/mdr1 and HepG2/mdr1-siRNA to ADM. After transfected with pSUPER-shRNA/mdr1 vectors, the resistance of HepG2 cells to adiramycin and mytomycin decreased from 44.6-fold to 1.4-fold and from 138.1-fold to 1.14-fold.

Establishment of tumor implants

Two weeks after HepG2/mdr1 and HepG2 cells were injected into the right flank of 4-wk-old nude mice, all mice suffered from tumors measuring 0.5 cm × 0.6 cm × 0.6 cm to 0.6 cm × 0.6 cm × 0.65 cm (Table 1). There was no difference in the mean tumor volume between HepG2/mdr1 and HepG2 groups (64.23 ± 2.15 mm^3 vs 66.41 ± 1.58 mm^3).

Figure 6 DNR accumulation of HepG2/mdr1 (A, B) and HepG2 cells (C) pre- and post-transfection. Compared with control groups, accumulation of daunorubicin in cells treated with shRNA vectors increased significantly (79.32% vs 37.96%, $P < 0.05$). There was no difference in sensitive cells of HepG2 between test groups (79.32% vs 87.56%).

Changes in tumor volume after treatment with ADM

After treatment with ADM, changes of tumor volume were more significant in the transfected groups than in the control groups (1695.70 ± 152.54 mm^3 vs 700.14 ± 25.61 mm^3, $P < 0.01$; Figure 7, Table 2). *In vivo* implant of HepG2/m-sh was more sensitive to ADM than that of HepG2/m. However, the difference in ADM sensitivity between *in vivo* implant of HepG2 and HepG2/m-sh was not significant. The results demonstrate that tumor cells in transfected groups could reverse their sensitivity to ADM.

Table 2 Effect of expression of MDR1 targeting shRNA on P-gp expression, tumor growth and adiramycin sensitivity *in vivo*

Group	Mean growth time (d)	Mean volume (mm^3) pretreatment	P-gp expression	ΔVolume (mm^3) pre- & post-chemotherapy	Growth rate of tumor
HepG2	13.12 ± 1.35	66.41 ± 1.58	-	530.58 ± 23.12	8.46 ± 0.63
HepG2/m	12.65 ± 2.31	64.23 ± 2.15	97.90[b]	1659.70 ± 152.54[b]	23.12 ± 5.32[b]
HepG2/m-sh	-	-	15.75	700.14 ± 25.61	10.39 ± 1.54

[b]$P < 0.01$ *vs* HepG2/m-sh.

Figure 7 Changes in volume and growth ratio of tumor after treatment with ADM. More changes in tumor volume occurred in transfected groups than in control groups (1695.70 ± 152.54 mm^3 *vs* 700.14 ± 25.61 mm^3, $P < 0.01$).

FCM for P-gp expression in mice

P-gp expression was detected by FCM after the mice were sacrificed. P-gp expression in test groups was lower than that in control groups (65% *vs* 94.1%, $P < 0.05$), but there was no significant difference between groups treated with *in situ* and intra-abdominal injection of pSUPER-mdr1 (65.1% *vs* 58.7%), showing that effect of pSUPER-shRNA-mdr1 could be achieved both by *in situ* injection and by intra-abdominal injection of pSUPER-mdr1 (Figure 8).

Immunohistochemistry

After chemotherapy, nude mice were sacrificed the next day. Tumors were collected by cervical dislocation or by drawing blood from heart, and cryo-sectioned (8 μm). The sections were treated with immnohistochemistry and analyzed by Image-Pro Plus 4.5 software (Media Cybernetics, Inc USA). The density of green fluorescence represented the tranfected vector pSUPER-shRNA/mdr1 into tumor. The density of red fluorescence was equal to the amount of P-gp antibodies binding to cellular membrane. The transfection ratio of test groups was greater than that of control groups (86.70% *vs* 35.20%, $P < 0.05$). The expression of P-gp in test groups was lower than that in control groups (15.75% *vs* 97.90%, $P < 0.05$). However, there was no difference in expression of P-gp between *in situ* and intra-abdominal injection of pSUPER-shRUA/mdr1 (97.90% *vs* 92.62%, Figure 9).

DISCUSSION

In cancer, over-expression of mdr1 P-glycoprotein

Figure 8 FCM showing lower P-gp expression in HepG2 cells (A) and HepG2/mdr1-shRNA (B) in test groups than in control groups (65% *vs* 94.1%, $P < 0.05$). There was no significant difference between groups treated with *in situ* injection and intra-abdominal injection of pSUPER-mdr1 (65.1% *vs* 58.7%).

(ABCB1) is a possible cause of chemotherapy-based treatment failure[25]. P-glycoprotein confers cross-resistance to unrelated drugs that differ widely in molecular structure and target specificity, including natural agents and new anticancer agents[26].

Of the novel strategies to circumvent MDR, hammerhead ribozymes against the mdr1 mRNA and anti-sense oligonucleotides have been widely used[12-15]. Both hammerhead ribozymes and anti-sense must be delivered across the plasma membrane, and are susceptible to degradation. Recent studies exploiting the promise of RNAi in mammalian cells have led to the reversal of gene-dependent MDR using short hairpin RNA expression vectors[27,28]. *In vitro* study has not achieved complete reversal of MDR with RNAi[29]. Use of shRNAs, when

Figure 9 Immunohistochemistry showing green fluorescence in test groups (A) and control groups (B), P-gp expression in test groups (C) and control groups (D), P-gp expression in test groups transfected with *in situs* injection (E) and intra-abdominal injection of pSUPER-mdr1 (F) (× 200). The transfection ratio for test groups was higher than that for control groups (86.70% *vs* 35.20%, *P* < 0.05). The expression of P-gp in test groups was lower than that in control groups (15.75% *vs* 97.90%, *P* < 0.05).

expressed in stably integrated plasmids, can decrease mdr1 mRNA by 95%-97% in intact cells and restore drug sensitivity to that of parent cell lines.

In the present study, shRNA expression cassettes targeting mdr1 were used not only in cells in culture, but also in animals. Pichler *et al*[27] reported that gene silencing induced by pSuper and pRetrosuper constructs is specific and potent in cell lines, and stably express shRNAi for several months. It was reported that high-pressure delivery technique of siRNA through tail vein inhibits expression of genes in a specific manner *in vivo*[7]. However, in this study, siRNA delivered with this method was susceptible to degradation, the effect of RNAi only lasted several days, a time frame insufficient for its application.

The potent and ubiquitous gene-silencing mechanism of RNAi is to generate considerable excitement in the fields of molecular biology and gene therapy[30], but

delivery is probably the single biggest obstacle to the development of RNAi-based therapeutic agents[31]. Vector-based delivery of shRNA could improve the efficiency of siRNA delivery. pSUPER RNAi system provides a mammalian expression vector that directs intracellular syntheses of siRNA-like transcripts. The vector uses a polymerase Ⅲ H1-RNA gene promoter, since it produces a small RNA transcript lacking a polyadenosine tail and has a well-defined start of transcription and a termination signal consisting of five thymidines in a row (T5). Cleavage of the transcript at the termination site is after the second uridine, yielding a transcript resembling the ends of synthetic siRNAs, which also contain two 3'overhanging T or U nucleotides (nt)[32,33]. The pSUPER RNAi system has been used to induce efficient and specific down-regulation of gene expression[34,35], resulting in functional inactivation of targeted genes. This vector-induced stable expression

of siRNAs mediates persistent suppression of gene expression, allowing analysis of loss-of-function phenotypes that develop over a longer period of time. We used this vector system to deliver shRNA/mdr1. Combined with bioluminescence imaging, pSUPER was easier to be followed, especially *in vivo*. shRNA-mediated down-regulation of P-glycoprotein transport activity both in cultured cells and in tumor implants in living animals could be followed by direct noninvasive bioluminescence imaging using the *Renilla* luciferase fluorophore. *In vitro*, the vector of pSUPER-shRNA/mdr1 was constructed using enzyme-digested technique according to the pSUPER protocol. Transfected with the recombinant plasmid, HepG2/mdr1 showed that its MDR was reversed notably in P-gp expression between positive and control groups (11.0% *vs* 98.2%, $P < 0.01$). Real-time PCR showed that mRNA/mdr1 in test groups was lower than that in control groups (56.30-fold *vs* 1.0-fold, $P < 0.001$). Compared with HepG2/mdr1 cells, the sensitivity of HepG2/mdr1-dsRNA cells to adiramycin and doxorubicin was decreased from 15.6-fold to 1.64-fold and from 138.1-fold to 1.14-fold, respectively. The accumulation of DNR in positive groups was decreased evidently. These results indicate that plasmid vector of pSUPER-shRNA/mdr1 can effectively transfect target cells and suppress gene function. *In vivo*, after transfected with pSUPER-shRNA/mdr1 through the peritoneal cavity and *in situ*, carcinoma cells(HepG2 and HepG2/mdr1) measured by flow cytometry and immunohistochemistry analysis showed that dsRNA/mdr1 was successfully and effectively brought into cells, and that p-gp expression in positive groups was significantly down regulated compared to control groups(65.1% *vs* 94.1%, $P < 0.05$). The tumor suppressing rate for test groups was 57.8%. After chemotherapy, the growth rate of tumor for test groups was slower than that for control groups (700.14 ± 35.61 *vs* 1659.70 ± 152.54, $P < 0.05$). Similar results were also observed under fluorescence microscope, and confirmed by Image-ProPlus 4.5 software analysis.

The results indicate that vector-based delivered RNAi can improve its efficiency *in vitro* and *in vivo*. There was no difference in the efficacy of vector pSUPER-shRNA/mdr1 transfected with *in situ* injection and that intra-abdominal injection (data not shown). Our study showed that transfection of vector pSUPER- shRNA/mdr1 with intra-abdominal injection was effective due to its diffusivity, which can extend from location to system. It was recently reported that administration of RNAi targeted mdr1 gene can effectively reverse MDR both *in vitro* and *in vivo* human epidermoid carcinoma KB(v200) cells[21]. This is the first time to investigate the possibility of reversing MDR in HepG2/mdr1 cells and tumor implants with RNAi.

ACKNOWLEDGMENTS

COMMENTS

Background

Hepatocellular-carcinoma is very resistant to chemotherapy.There is a growing interest in the reversal of multi-drug resistance to tumors with RNA interfer-ence (RNAi). In hepatocellular carcinoma, such research is almost restricted *in vitro*. In the present study, the authors investigated the effect of RNAi on the reversal of multi-drug resistance to hepatocellular carcinoma *in vitro* and *in vivo*.

Research frontiers

This study focused on the reversal of multi-drug resistance to hepatocellular carcinoma with RNAi *in vivo*.

Innovations and breakthroughs

The present study showed that RNAi targeting mdr1 gene could reverse the resistance of hepatocellular carcinoma to chemotherapy. Transfection with *in situ* injection and intra-abdominal injection showed that RNAi could reverse multi-drug resistance of hepatocellular carcinoma.

Applications

These data demonstrate that RNAi targeting mdr1 gene could reverse drug resistance of hepatocellular carcinoma *in vivo*, thus contributing to the development of drugs used in gene therapy for hepatocellular carcinoma.

Peer review

This is a carefully performed study with novel findings, which can be used in the diagnosis and treatment of hepatocellular carcinoma. The study showed that RNAi targeting mdr1 gene can reverse drug resistance of hepatocellular carcinoma *in vivo*, and therefore improves its sensitivity to chemotherapy for HepG2/mdr1 cells and transplant tumors of HepG2/mdr1.

Abstract

AIM: To study the possible actions and mechanisms of peroxisome proliferator-activated receptor γ (PPARγ), a ligand-activated transcription factor, in pancreatic carcinogenesis, especially in angiogenesis.

METHODS: Expressions of PPARγ and retinoid acid receptor (RXRα) were examined by reverse-transcription polymerase chain reaction (RT-PCR) with immunocytochemical staining. Pancreatic carcinoma cells, PANC-1, were treated either with 9-cis-RA, a ligand of RXRα, or with 15-deoxy-$\Delta^{12,14}$ prostaglandin J$_2$ (15d-PGJ$_2$), a ligand of PPARγ, or both. Antiproliferative effect was evaluated by cell viability using methyltetrazolium (MTT) assay. A pancreatic carcinoma xenograft tumor model of nude mice was established by inoculating PANC-1 cells subcutaneously. Rosiglitazone, a specific ligand of PPARγ, was administered *via* water drinking in experimental group of nude mice. After 75 d, all mice were sacrificed. Expression of proliferating cell nuclear antigen (PCNA) in tumor tissue was examined with immunohistochemical staining. Expression of vascular endothelial growth factor (VEGF) mRNA in PANC-1 cells, which were treated with 15d-PGJ$_2$ or 9-cis-RA at various concentrations or different duration, was detected by semi-quantitative RT-PCR. Effects of Rosiglitazone on changes of microvascular density (MVD) and VEGF expression were investigated in xenograft tumor tissue. Neovasculature was detected with immunohistochemistry staining labeled with anti-IV collagen antibody, and indicated by MVD.

RESULTS: RT-PCR and immunocytochemical staining showed that PPARγ and RXRα were expressed in PANC-1 cells at both transcription level and translation level. MTT assay demonstrated that 15d-PGJ$_2$, 9-cis-RA and their combination inhibited the growth of PANC-1 cells in a dose-dependent manner. 9-cis-RA had a combined inhibiting action with 15d-PGJ$_2$ on the growth of pancreatic carcinoma. *In vivo* studies revealed that Rosiglitazone significantly suppressed the growth of pancreatic carcinoma as compared to control group (0.48 ± 0.23 cm^3 *vs* 2.488 ± 0.59 cm^3, $P < 0.05$), and the growth inhibition rate was 80.7%. Immunohistochemistry study showed that PCNA was down regulated in Rosiglitazone-treated group compared to the control group. 15d-PGJ$_2$, 9-cis-RA and their combination inhibited the expression of VEGF mRNA in PANC-1 cells in a dose- and time-dependent manner. MVD was decreased more significantly in Rosiglitazone-treated mice (10.67 ± 3.07) than in the control group (31.44 ± 6.06) ($P < 0.01$). VEGF expression in xenograft tumor tissue was also markedly down-regulated in Rosiglitazone-treated mice.

CONCLUSION: Activation of PPARγ inhibits the growth of pancreatic carcinoma both *in vitro* and *in vivo*. Suppression of tumor angiogenesis by down-regulating the expression of VEGF may be one of the mechanisms by which PPARγ activation inhibits the growth of pancreatic carcinoma.

Key words: Pancreatic carcinoma; Peroxisome proliferator-activated receptor γ; Angiogenesis; Vascular endothelial growth factor

Dong YW, Wang XP, Wu K. Suppression of pancreatic carcinoma growth by activating peroxisome proliferator-activated receptor γ involves angiogenesis inhibition. *World J Gastroenterol*

INTRODUCTION

Pancreatic carcinoma is currently the fifth most common cause of cancer death in Western Countries[1]. Despite surgical resection, radiotherapy and conventional chemo-therapy, the prognosis of advanced pancreatic carcinoma has not been significantly improved over the last 30 years. The inability to detect pancreatic carcinoma at an early stage, its aggressiveness, and lack of effective systemic therapy, are responsible for the rapid death of pancreatic carcinoma patients. Even the recent introduction of de-oxycytidine analogue, gemcitabine, does not extend the median survival time of patients with advanced pancreatic carcinoma beyond 6 mo[2]. Clearly, novel approaches to human pancreatic carcinoma therapy are needed.

Pancreatic carcinoma can entail the substantial development of new blood vessels in tumor tissue. It is well established that the growth and progression of solid tumors depend on angiogenesis[3]. Many cytokines or growth factors contribute to angiogenesis. Vascular endothelial growth factor (VEGF) is one of the most important factors.

Peroxisome proliferator-activated receptors (PPARs) are members of the steroid receptor super-family and as such, are ligand-activated nuclear transcription factors[4]. Three subtypes of PPARα, PPARβ (also called δ, NUC-1, or FFAR), and PPARγ have been identified and cloned. Like other members of this super-family, PPARs mediates transcriptional regulation by binding to their central DNA domain that recognizes response elements in the promoters of specific target gene[5]. Activation of PPARγ has been linked to adipocyte differentiation and regulation of glucose homeostasis in humans. Recent tudies also showed that the natural receptor ligand for PPARγ, 15-deoxy-$\Delta^{12,14}$ prostaglandin J2 (15d-PGJ2)[6,7], and synthetic antidiabetic thiazolidinedione drugs, inhibits the activation of macrophages and monocytes[8,9] as well as tumor cell growth[10-12]. PPARγ can heterodimerize with retinoid acid receptor (RXR). For the PPAR: RXR heterodimer, binding of the ligand to either receptor can activate the complex, but binding to both ligands simultaneously is more potent[5]. It has been shown that PPARγ gene expression is observed in a variety of tissues, including adipose tissue and tumor tissue. Some in vitro studies have recently reported that PPARγ activation has inhibitory effects on the growth of pancreatic carcinoma cells[13-15], probably due to its up-regulation of cellular apoptosis and its down-regulation of tumor invasion[16-18]. However, little attention has previously been paid to PPARγ action on the growth of pancreatic carcinoma in vivo, especially its regulation action on tumor angiogenesis.

In this study, the potent inhibitory effects of PPARγ ligand, 15d-PGJ2, Rosiglitazone, RXR ligand, 9-cis-reti-noid acid (9-cis-RA), on the growth of human pancre-atic carcinoma were investigated both in vivo and in vitro. Expression of proliferating cell nuclear antigen (PCNA)

in tumor tissue was also examined. To further clarify the effect of PPARγ on angiogenesis, both in vivo and in vitro VEGF expression, and neovasculature indicated by microvascular density (MVD) in vivo were determined.

MATERIALS AND METHODS

Reagents

15d-PGJ2 was obtained from Cayman Co (Ann Arbor, MI, USA). 9-cis-RA was from Sigma (St Louis, MO, USA). Rosiglitazone was from SmithKline Beecham Co (Pittsburgh, PA, USA). Anti-PCNA, PPARγ and RXRα polyclonal antibodies were purchased from Santa Cruz Biotechnology, Inc (San Diego, CA, USA). Anti-IV col-lagen monoclonal antibody was from DAKO Co. (Glos-trup, Denmark). Anti-mouse and anti-rabbit detection reagents (HRP) were purchased from Antibody Diag-nostica Inc., (Shanghai, China). Oligonucleotides were synthesized by Sangon Co (Shanghai, China). Methyltet-razolium (MTT) and dimethylsulfoxide (DMSO) were purchased from Amresco Inc (Solon, OH, USA).

Cell cultures and treatment

PANC-1 cell line, purchased from American Type Culture Collection (Rockville, MD, USA), was routinely main-tained in DMEM containing 10% fetal bovine serum (FBS) (Gibco-BRL, Grand Island, NY, USA), 2 mL glutamine, 100 U/mL penicillin, and 100 mg/mL streptomycin in a humidified atmosphere containing 950 mL/L air and 50 mL/L CO2 at 37℃. PANC-1cells were passaged and expanded by trypsinization of cell monolayers followed by relating every 2 or 3 d.

PANC-1 cells were seeded at a concentration of 5×10^5 cells/well in 6-well plates, and treated with 15d-PGJ2 and 9-cis-RA and their combination with various con-centrations or different duration 24 h later. Cells were then collected for RNA analysis. Control cells were not exposed to the above agents and maintained under the same conditions as the treated cells.

RNA extraction and reverse-transcriptional polymerase chain reaction (RT-PCR)

Total RNA was extracted using Trizol reagent (Gibco Life Technologies, Inc., Langley, OK, USA) following its manufacturer's instructions. Fist-strand cDNA was synthesized from 3 μg of RNA in 20 μL of reaction solution using a random primer and Superscript II reverse transcriptase reagent (Gibco Life Technolo-gies, Inc., Langley, OK, USA). Synthesized cDNA was stored at -80℃ for PCR. The sequences of primers used for amplifying PPARγ, RXRα, and VEGF are 5'-AT-GACAGCGACTTGGCAATA-3' and 5'-GCAACTG-GAAGAAGGGAAAT-3', 5'-CTCTCAGGTTGAACT-CACCT-3' and 5'-ATCTCTGACAGCCTGTCTCG-3', 5'-ATGAACTTTCTGCTGTCTTG-3' and 5'-TGCAT-GGTGATGTTGGAC-3', respectively. The sequences of GAPDH used as a control are 5'-GTGAAGGTCG-GAGTCAACG-3' and 5'-GGTGAAGACGCCAGTG-GACTC-3'. After denaturation of the samples at 94℃ for 5 min, 35 cycles were carried out at 94℃ for 45 s, at

55℃ (PPARγ, RXRα) for 45 s, at 54℃ (VEGF) for 45 s, at 60℃ (GAPDH) for 45 s, at 72℃ for 45 s and at 72℃ for 10 min. The PCR products were electrophoresed on 1.5% agarose gels stained with ethidium bromide. The expected molecular size of amplified products was 341 bp of PPARγ, 422 bp of RXRα, 382 bp of VEGF and 223 bp of GAPDH, respectively. Semi-quantitative data about the PCR products were obtained by comparing the intensity of PCR band of VEGF with that of internal control of GAPDH using genetools software.

Immunocytochemistry

Cells were seeded at a concentration of 2×10^5 cells/ well in 12-well plates containing slides. Cells were fixed in PBS containin 4% paraformaldehyde (pH 7.4) for 20 min at room temperature, washed 3 times with PBS and incubated with mouse anti-PPARγ (diluted at 1: 150) or rabbit anti-RXRα antibody (diluted at 1: 100) in a humid chamber at 4℃ overnight. Slides were washed with PBS. Secondary antibody (anti-mouse or anti-rabbit antibody) labeled with HRP was applied in humid chambers for 30 min at room temperature. The staining result was detected using a 3, 3'-diaminobenzidine tetrahydrochloride solution (DAB) (DAKO Co., Glostrup, Denmark) for 10 min.

Cell viability assay

PANC-1 cells were seeded at the concentration of 5×10^4 cells/well in 96-well plates and incubated in complete fresh media for 24 h. The cells were subsequently incubated for 48 h and treated either with 0, 2.5, 5, 7.5 and 10 μmol/L of 15d-PGJ₂, or with 0, 5, 10, 15, 20 μmol/L of 9-cis-RA, or with their combination (0, 2.5, 5, 7.5 or 10 μmol/L of 15d-PGJ₂) and (10 μmol/L of 9-cis-RA), respectively. After treatment, MTT solution was added to cells at a final concentration of 500 μg/mL and incubated at 37℃ for an additional 4 h. Then the medium was aspirated, and formazan product was dissplved with DMSO. Cell viability was determined by differences in absorbance at wavelength 490 nm and presented as percentage of control culture conditions.

Animals and tumor cell inoculation

Thirty female BALB/c nu/nu mice (Bikai Experimental Animal Center, Shanghai, China), at the age 6 to 7 wk, were used in the study. The mice were maintained in a laminar airflow cabinet under specific pathogen-free conditions with free access to sterile food and water. For mice inoculation, PANC-1 cells in log-phase growth were harvested by trypsinization, and a medium containing 10% FBS was added. After washed three times with serum-free DMEM, cells were resuspended in phosphate-buffered saline (PBS) at the concentration of 1×10^9/mL, and inoculated subcutaneously into the hindlimb region of each mouse. All experiments were approved by the University Animal Care Committee and carried out according to the National Animal Welfare Law.

Tumor growth in nude mice and Rosiglitazone administration

From the second week of tumor cell inoculation, tumor bearing mice were randomly divided into control groups ($n = 15$) and Rosiglitazone treatment group ($n = 15$). Mice in the control group received distilled water and mice in the Rosiglitazone treatment group received Rosiglitazone at the dose of 10 μmol/kg. d. Tumor sizes were measured with a vernier caliper at 25 d intervals and calculated according to the formula: A (length) × B (width) × C (height) × 0.5236. At end of the experiment (75 d), blood was collected for hepatic function analysis. All mice were euthanized and autopsies were performed. Tumors were removed, weighed, and fixed in 10% neural buffered formalin and embedded in paraffin for histological analysis. The growth inhibition rate of Rosiglitazone was calculated.

Immunohistochemistry

Four-μm thick paraffin sections were air-dried, and then placed in a 60℃ oven overnight. The sections were dewaxed in xylene, immersed in a solution of 750 μL 30% hydrogen peroxide and 50 mL methanol for 10 min to block endogenous peroxide, and rehydrated to tap water for antigen retrieval. After boiled in a 10 mmol/L citrate buffer (pH 6.0), slides were incubated overnight at 4℃ with optimum dilutions of primary antibodies, including anti-PCNA mouse polyclonal antibody (× 50 dilution), and anti Ⅳ-collagen mouse monoclonal antibody (× 200 dilution). The sections were washed with PBS and then secondary antibody (anti-mouse antibody) labeled with HRP was applied in humid chambers for 40 min at room temperature. Staining was detected using DAB for 10 min. The sections were counterstained with hematoxylin. Substitution of the primary antibodies with immunoglobin G served as negative controls in all cases.

Measurement of microvessel density (MVD)

Microvessels were shown by staining endothelial cells for Ⅳ collagen using a standard immunoperoxidise technique. MVD was assayed under light microscope. The "*hot spot*" area of neovascularization was identified. Individual microvessels were counted in four separate fields in this area. Two pathologists, blinded to the protocol, examined all slides in each group on three separate occasions. Data were expressed as the average number of four fields that were counted.

Statistical analysis

Data are expressed as mean ± SE. Statistical analysis was performed using Student's unpaired *t*-test. $P < 0.05$ was considere statistically significant.

RESULTS

Expressions of PPARγ and RXRα in human pancreatic carcinoma cell line PANC-1

RT-PCR showed that PPARγ mRNA and RXRα mRNA were expressed in PANC-1 cells (Figure 1). Immunocytochemical staining showed that PPARγ and RXRα protein were also expressed in PANC-1 cells (Figure 2). These results indicate that PANC-1 cell line significantly expressed PPARγ and RXRα, and could be used in this protocol.

Figure 1 RT-PCR showing expression of 341 bp PPARγ (A) and 422 bp RXRα mRNA (B) in PANC-1 cells. Three micrograms of total RNA from PANC-1 cell line was subjected to RT-PCR. The PCR products were electrophoresed on 1.5% agarose gel. The products were visualized with ethidium bromide staining. GAPDH was used as an internal control. PPARγ, RXRα and GAPDH were detected at the expected molecules sizes.

Figure 2 Immuncytochemistry study for the expressions of PPARγ (A) and RXRα protein (B) in PANC-1 cells. Cells were cultured in 12-well plates containing slides. Slides were fixed, washed, and incubated with mouse anti-PPARγ (× 150 dilution) or rabbit anti-RXRα antibody (× 100 dilution), then incubated with the secondary antibody labeled with HRP. The staining was detected using DAB and demonstrated expressions of the nuclei with brown staining (HE staining, × 200).

Effects of 15d-PGJ2 and 9-cis-RA on proliferation of PANC-1 cell line

MTT assay demonstrated that 15d-PGJ2, 9-cis-RA and their combination inhibited the growth of PANC-1 cells in a dose-dependent manner. PANC-1 cells were suppressed to more than 50% of control group at the concentration of 10 μmol/L 15d-PGJ2, 20 μmol/L 9-cis-RA and 5 μmol/L 15d-PGJ2 plus 10 μmol/L 9-cis-RA,

Figure 3 Dose-dependent effects of PPARγ and RXRα ligands on the growth of human pancreatic carcinoma in 15d-PGJ2 group (A), 9-cis-RA group (B), and combined 15d-PGJ2 and 9-cis-RA group (C). Cells were seeded into 96-well plates and treated with different concentrations of 15d-PGJ2, 9-cis-RA and their combination. MTT was used to determine the cellular proliferation. Asterisks indicate statistically significant differences ($P < 0.05$, $n = 6$) based on a two-tailed Student's t-test. Experiments were performed in triplicate.

respectively. 9-cis-RA had a combined action with 15d-PGJ2 on the growth of pancreatic carcinoma (Figure 3).

Effects of 15d-PGJ2 and 9-cis-RA on expression of VEGF in PANC-1 cells

VEGF is a major stimulator of tumor angiogenesis. We used semi-quantitative RT-PCR to determine whether

Figure 4 Dose-dependent inhibitory effects of 15d-PGJ2 and 9-cis-RA on expression of VEGF. A: Three micrograms of total RNA from PANC-1 cell line was subjected to RT-PCR. The PCR products were electrophoresed on 1.5% agarose gel and visualized with ethidium bromide staining. GAPDH was used as a control. VEGF expression was detected at the expected molecules sizes (382 bp). Lanes 1, 7, 13: size marker; lanes 2-6, cells treated with 15d-PGJ2 at 0, 2.5, 5, 7.5, 10 μmol/L, respectively; lanes 8-12, cells treated with 9-cis-RA at 0, 5, 10, 15, 20 μmol/L, respectively; lanes 14-18, cells treated with combined 9-cis-RA (10 μmol/L) and 15d-PGJ2 at 0, 2.5, 5, 7.5, 10 μmol/L, respectively; B: Semi-quantitative analysis of VEGF mRNA expression in human pancreatic carcinoma PANC-1 cell line. Data on PCR products were obtained by comparing the intensity of PCR band of VEGF with that of internal control of GAPDH using genetools software.

Figure 5 Time-dependent inhibitory effects of 15d-PGJ2 and 9-cis-RA on expression of VEGF mRNA. A: Three microgram of total RNA from PANC-1 cell line was subjected to RT-PCR. The PCR products were electrophoresed on 1.5% agarose gel and visualized with ethidium bromide staining. GAPDH was used as a control. VEGF expression was detected at the expected molecules sizes (382 bp). Lanes 1, 7, 13: size marker; lanes 2-6: cells treated with 10 μmol/L 15d-PGJ2 for 0, 12, 24, 48, 72 h, respectively; lanes 8-12: cells treated with 20 μmol/L 9-cis-RA for 0, 12, 24, 48, 72 h, respectively; lanes 14-18: cells treated with combined 10 μmol/L 9-cis-RA and 5 μmol/L 15d-PGJ2 for 0, 12, 24, 48, 72 h, respectively; B: Semi-quantitative analysis of VEGF mRNA expression in human pancreatic carcinoma PANC-1 cell line. Data on PCR products were obtained by comparing the intensity of PCR band of VEGF with that of internal control of GAPDH using genetools software.

15d-PGJ2 and 9-cis-RA exert any effects on the expression of VEGF mRNA. RT-PCR demonstrated that 15d-PGJ2, 9-cis-RA and their combination inhibited the expression of VEGF mRNA in PANC-1 cells in a dose- and time-dependent manner (Figures 4 and 5).

Effect of Rosiglitazone on PANC-1 cell tumor growth in nude mice

As shown in Figure 6, over a 75-d experimental period, Rosiglitazone (10 μmol/kg. d) inhibited the PANC-1 cell tumor growth. Existing tumors began to regress 3 wk after treatment. The average tumor size was (0.48 ± 0.23) cm^3 in Rosiglitazone treatment group and (2.488 ± 0.59) cm^3 in control group ($P < 0.05$, $n = 15$). The inhibitory rate was 80.7%. The average weight was (0.887 ± 0.48) g in Rosiglitazone treatment group and (2.333 ± 1.66) g in control group ($P < 0.05$, $n = 15$). Tumors in 2 of 15 Rosiglitazone-treated mice were not palpable, indicating a complete regression of these tumors after drug administration. Hepatic function analysis demonstrated that no drug-related hepatic toxicity to any of the mice (Table 1).

Effect of Rosiglitazone on expression of PCNA in xenograft tumor of nude mice

Immunohistochemical study revealed that Rosiglitazone

Figure 6 Rosiglitazone supresses PANC-1 cell tumor growth in nude mice. From the second week of PANC-1 cell inoculation, tumor bearing mice were randomized to receive either distilled water or Rosiglitazone, 10 μmol/kg a day, for 75 d. Tumor size was measured every 25 d. Tumor size in Rosiglitazone treatment group was significantly smaller than that in control group ($P < 0.05$).

had a substantial effect on tumor cell proliferation as detected with staining of antibody against PCNA (Figure 7). PCNA was presented in both groups. PCNA was obviously down-regulated in Rosiglitazone treatment group compared with control group.

Figure 7 Immunohistochemical analysis of PCNA expression in tumor tissue from control group (A) and Rosiglitazone treatment group (B). From the second week of PANC-1 cell inoculation, tumor bearing mice were randomized to receive either distilled water or Rosiglitazone, 10 μmol/kg per day, for 75 d. Mice were then euthanized. Tumors were removed and cut into 4-μm thick sections for immunohistochemical analysis. The sections were incubated with anti-PCNA antibody, and then with secondary antibody labeled with HRP. The staining was detected using DAB and demonstrated as expression of nuclei with brown staining. The result showed that PCNA expression was significantly down regulated in Rosiglitazone treatment group (original magnification × 200).

Figure 8 Immunohistochemical analysis of microvessel density in tumor tissue from control group (A) and Rosiglitazone treatment group (B). From the second week of PANC-1 cell inoculation, tumor bearing mice were randomized to receive either distilled water or Rosiglitazone, 10 μmol/kg per day, for 75 d. Mice were then euthanized. Tumors were removed and cut into 4 μm-thick sections for immunohistochemical analysis. The sections were incubated with anti-IV collagen antibody, and then with secondary antibody labeled with HRP. The staining was detected using DAB. A single microvessel was defined as any immunohistochemistry- stained brown endothelial cell separated from the adjacent microvessels, tumor cells, and other connective tissue elements. MVD was calculated. The result showed that MVD was significantly down regulated in Rosiglitazone treatment group. (original magnification × 200).

Table 1 Alterations of liver function analyses in two groups (mean ± SE)			
	Rosiglitazone treatment	**Control**	**P value**
AST	123.6 ± 17.9	132.1 ± 22.6	0.51
ALT	23.2 ± 7.3	21.4 ± 9.6	0.74
LDH	1953.8 ± 324.5	2037.7 ± 378.4	0.70
AMYL	86.5 ± 24.1	73.5 ± 22.1	0.33

Effect of Rosiglitazone on angiogenesis of xenograft tumor in nude mice

Staining with anti-IV collagen antibody demonstrated that MVD was significantly decreased in Rosiglitazone treatment group, which was (10.67 ± 3.07) in Rosiglitazone treatment group and (31.44 ± 6.06) in control group ($P < 0.01$, $n = 30$). Tumor blood vessels in control group showed a sinusoidal pattern and rather well-developed vascular networks. In contrast, tumor blood vessels in Rosiglitazone treatment group were consisted of randomly distributed endothelial cells that did not form organized vascular networks (Figure 8).

Effect of Rosiglitazone on VEGF expression in xenograft tumor of nude mice

To determine whether Rosiglitazone exerts its inhibitory effect on tumor angiogenesis by suppressing VEGF, tumor tissues from mice in control and Rosiglitazone treatment groups were assayed for the expression of VEGF mRNA. Semi-quantitative RT-PCR showed that the expression of VEGF mRNA was down-regulated in Rosiglitazone treatment and control groups (Figure 9).

DISCUSSION

PPAR, a member of the family of ligand-activated nuclear receptor transcription factors, forms a heterodimer with the RXR upon ligand binding. This complex binds to a PPAR-responsive element (PPRE) located in the promoter region of various genes and acts to regulate their expression. There are three members of the PPAR family, α, β and γ. PPARα is highly expressed in the liver, heart, proximal tubules of kidney, and intestinal mucosa. PPARβ is almost ubiquitously expressed in adipose tissue, and PPARγ is highly expressed in adipose tissue where it plays a critical role in the differentiation of preadipocytes into adipocytes. High concentrations of PPARγ protein have also been identified in the colon. PPARγ is also expressed in the immune system including the spleen, monocytes, and bone-marrow precursors. Recently, great attention

Figure 9 RT-PCR showing expression of VEGF mRNA in human pancreatic carcinoma PANC-1 cell xenograft tumor. A: Three micrograms of total RNA from PANC-1 cell xenograft tumor tissue was subjected to RT-PCR. The PCR products were electrophoresed on 1.5% agarose gel. GAPDH was used as a control. VEGF expression was detected at the expected molecule sizes of 382 bp (M: size marker; lanes 1-2: control mice; lanes 3-4: Rosiglitazone-treated mice); B: Semi-quantitative analysis of VEGF mRNA expression in human pancreatic carcinoma PANC-1 cell xenograft tumor tissue. Data on PCR products were obtained by comparing the intensity of the PCR band of VEGF with that of internal control of GAPDH using genetools software. The result showed that expression of VEGF mRNA in tumor tissue was down-regulated in Rosiglitazone treatment group compared with control group.

has focused on PPARγ. PPARγ plays an important role in insulin sensitization and differentiation of adipocytes, monocytes and macrophages[5]. Activation of PPARγ can also induce growth inhibition in human prostate cancer cells, colon cancer cells, gastric cancer cells[10], pancreatic cancer cells[12-17] and liposarcoma cells[18].

The expression of PPARγ and its role in human pancreatic carcinoma have not been fully elucidated. We have previously reported that PPARγ is the only isoform of PPAR which exists in PC-3 pancreatic carcinoma cell line[20]. In this study, PPARγ and RXRα were strongly expressed in human pancreatic carcinoma cell line PANC-1, suggesting that PPARγ might play a role in the regulation of pancreatic cancer growth. In addition, we demonstrated an antiproliferative effect of PPARγ and RXRα ligands on pancreatic cancer growth pancreatic cancer growth *in vitro*. MTT assay demonstrated that 15d-PGJ2, 9-cis-RA and their combination inhibited the growth of PANC-1 cells in a dose-dependent manner. PANC-1 cells were suppressed to more than 50% of the control group at 10 μmol/L of 15d-PGJ2 and 20 μmol/L of 9-cis-RA. The inhibitory effect of 5 μmol/L 15d-

PGJ2 plus 10 μmol/L 9-cis-RA on cancer cell growth was stronger than that of 5 μmol/L 15d-PGJ2 or 10 μmol/L 9-cis-RA alone. These results indicate that PPARγ ligand, 15d-PGJ2, and RXRα, 9-cis-RA, can strongly inhibit the growth of pancreatic cells *in vitro*, and 9-cis-RA combined with 15d-PGJ2 can inhibit the growth of pancreatic carcinoma, further confirming that activation of PPARγ and RXRα may suppress pancreatic carcinoma growth *in vitro*[15]. To investigate the *in vivo* effect of PPARγ ligand, a pancreatic carcinoma xenograft model of nude mice was established by inoculating PANC-1 cells subcutaneously, and Rosiglitazone, a PPARγ activator, was administered *via* water drinking in experimental group for 75 d. Systemic administration of Rosiglitazone not only inhibited PANC-1 tumor cell growth, but also dramatically reduced the size of existing tumors. The average tumor volume and weight in experimental group were less than those in the control group. The growth inhibition rate of Rosiglitazone was 80.7%. In addition, PCNA, as an important marker of cell proliferation, was presented in both groups, but immunohistochemistry showed that PCNA was down regulated in experimental group compared with the control group. However, such a dosage of Rosiglitazone had no systemic toxic action. Take these into account, activation of PPARγ could inhibit pancreatic cancer growth.

Although the mechanism of PPARγ by which the growth of human pancreatic carcinoma cells is inhibited has not been fully elucidated, its action on inducing apoptosis and G1 cell cycle arrest has been reported[15]. As other tumors, pancreatic carcinoma is also neovascularization dependent. This process is usually mediated by angiogenic factors. Of these factors, VEGF is currently the major proangiogenic factor for most types of human cancer including pancreatic carcinoma[21,22]. In our study, 15d-PGJ2, 9-cis-RA and their combination inhibited the expression of VEGF in PANC-1 cells in a dose- and time-dependent manner. *In vivo* study showed that the expression of VEGF in tumor tissue was significantly down-regulated in Rosiglitazone treatment group compared with control group. Furthermore, Rosiglitazone can also reduce pancreatic carcinoma microvessel density, a marker of tumor angiogenesis, indicating that PPARγ ligand can inhibit cancer growth *in vitro* or *in vivo*, which might be, at least in part, related to the suppression of tumor angiogenesis. VEGF may be one of the important factors related to the suppression of angiogenesis in pancreatic carcinoma by activating PPARγ.

In summary, human pancreatic carcinoma cell line PANC-1 expresses PPARγ, and activation of PPARγ inhibits cellular growth. Suppression of tumor angiogenesis by down-regulating the expression of VEGF may be one of the mechanisms of PPARγ activation by which pancreatic carcinoma growth is inhibited, thus providing a new insight into the mechanism of PPARγ ligand, as an inhibitor of pancreatic tumor growth and a novel means to control pancreatic carcinoma in clinical practice.

COMMENTS

Background

Peroxisome proliferator-activated receptor γ (PPARγ), a member of the family

of ligand-activated nuclear receptor transcription factors, is expressed in many human solid tumors. It was reported that activation of PPARγ can inhibit the growth of pancreatic carcinoma cells, colon cancer cells, gastric cancer cells and liposarcoma cells. So far, the underlying mechanism of PPARγ activation by which the growth of human pancreatic carcinoma is inhibited has not been fully elucidated.

Research frontiers

The growth and progression of solid tumors including pancreatic carcinoma depend on angiogenesis. Vascular endothelial growth factor (VEGF) is the major proangiogenic factor for most types of human cancer. However, whether activation of PPARγ is related with expression of VEGF in human pancreatic carcinoma is still unclear.

Innovations and breakthroughs

Human pancreatic carcinoma cell line PANC-1 expresses PPARγ, and activation of PPARγ inhibits cellular growth both *in vivo* and *in vitro*. Pancreatic carcinoma microvessel density, a marker of tumor angiogenesis, was reduced in this study. Moreover, suppression of tumor angiogenesis by down-regulating the expression of VEGF may be one of the mechanisms of PPARγ activation by which the growth of pancreatic carcinoma is inhibited, thus providing a new insight into the mechanism of PPARγ ligand, as an inhibitor of pancreatic tumor growth.

Applications

Suppression of tumor angiogenesis by down-regulating the expression of VEGF may be one of the mechanisms of PPARγ activation by which the growth of pancreatic carcinoma is inhibited, suggesting that the drugs used in our study can control pancreatic carcinoma in clinical practice.

Terminology

PPAR is a member of the family of ligand-activated nuclear receptor transcription factors and forms a heterodimer with the RXR upon ligand binding. This complex then binds to a PPAR-responsive element (PPRE) located in the promoter region of various genes and acts to regulate their expression.

Peer review

This is a well designed study. The results suggest that activation of peroxisome PPARγ suppresses pancreatic carcinoma growth by inhibiting angiogenesis.

Abstract

AIM: To investigate the efficacy and safety of capecitabine plus irinotecan ± bevacizumab in advanced or metastatic colorectal cancer patients.

METHODS: Forty six patients with previously untreated, locally-advanced or metastatic colorectal cancer (mCRC) were recruited between 2001-2006 in a prospective open-label phase Ⅱ trial, in German community-based outpatient clinics. Patients received a standard capecitabine plus irinotecan (CAPIRI) or CAPIRI plus bevacizumab (CAPIRI-BEV) regimen every 3 wk. Dose reductions were mandatory from the first cycle in cases of > grade 2 toxicity. The treatment choice of bevacizumab was at the discretion of the physician. The primary endpoints were response and toxicity and secondary endpoints included progression-free survival and overall survival.

RESULTS: In the CAPIRI group vs the CAPRI-Bev group there were more female than male patients (47% vs 24%), and more patients had colon as the primary tumor site (58.8% vs 48.2%) with fewer patients having sigmoid colon as primary tumor site (5.9% vs 20.7%). Grade 3/4 toxicity was higher with CAPIRI than CAPIRI-Bev: 82% vs 58.6%. Partial response rates were 29.4% and 34.5%, and tumor control rates were 70.6% and 75.9%, respectively. No complete responses were observed. The median progression-free survival was 11.4 mo and 12.8 mo for CAPIRI and CAPIRI-Bev, respectively. The median overall survival for CAPIRI was 15 mo (458 d) and for CAPIRI-Bev 24 mo (733 d). These differences were not statistically different. In the CAPIRI-Bev, group, two patients underwent a full secondary tumor resection after treatment, whereas in the CAPIRI group no cases underwent this procedure.

CONCLUSION: Both regimens were well tolerated and offered effective tumor growth control in this outpatient setting. Severe gastrointestinal toxicities and thromboembolic events were rare and if observed were never fatal.

Capecitabine and irinotecan with and without bevacizumab for advanced colorectal cancer patients. *World J Gastroenterol* 2009; 15(4): 449-456 Available from: URL: http://www.wjgnet.com/1007-9327/15/449.asp DOI: http://dx.doi.org/10.3748/wjg.15.449

INTRODUCTION

Until relatively recently, the anti-metabolite 5-fluorouracil (5-FU) was the only effective first-line treatment for metastatic colorectal cancer (mCRC). Subsequent attempts to improve its efficacy centered on its co-administration with leucovorin (LV)[1]. An alternative approach to optimize 5-FU-based therapy was made possible with the advent of oral fluoropyrimidine derivatives. Capecitabine is such an oral FU pro-drug specifically designed to deliver 5-FU to tumor cells with predictable bioavailability and sustained exposure[2-4]. Capecitabine has shown promising results and clinically meaningful safety advantages over 5-FU/LV, although with no improved efficacy[5-8]. Its oral administration makes it more convenient, and its proven safety might increase its appeal to patients who have expressed a preference for oral cytotoxic therapy over intravenous regimens (iv)[9,10].

Additionally, over the last decade improved survival has been achieved with the arrival of new agents, including irinotecan and oxaliplatin[11,12]. Two large randomized clinical trials have shown that irinotecan combined with 5-FU/LV (FOLFIRI or bolus IFL) significantly improved response rates, time to progression and overall survival[12,13]. Based on data from these, and other trials[12-16] the combination regimens FOLFIRI and oxaliplatin/5-FU/LV (FOLFOX) replaced 5-FU/LV as a standard treatment of mCRC.

Thus, following promising data from phase I / II trials in colorectal cancer (CRC), interest in the combination of capecitabine with irinotecan (CAPIRI) as an equally effective, more convenient alternative to the FOLFIRI and FOLFOX regimens has grown[17-19]. CAPIRI in the first-line treatment of advanced disease has been associated with response rates of 38%-45% and a time-to-progression (TTP) of about 8 mo with manageable side-effect profiles[20-24], although in some studies an acceptable safety was only achieved by lowering the irinotecan doses[21-23].

Furthermore, the most recent advances in the treatment of mCRC have been possible with the advent of targeted drugs. These include bevacizumab, a recombinant humanized monoclonal antibody to the vascular endothelial growth factor VEGF-A; the predominant member of the VEGF ligand family which is mainly involved in tumor angiogenesis[25]. Bevacizumab was approved by the European Medicines Agency in 2004 for use in combination with any i.v. 5-FU-based therapy for CRC in the first-line setting[26]. Although the trials could be criticized in the choice of a bolus 5-FU/LV regimen which is now considered to be obsolete, a consistent benefit from the addition of bevacizumab has been demonstrated in several studies, including those with capecitabine[27-33].

Whilst still under debate, it appears that combinations of capecitabine, irinotecan and bevacizumab may improve outcome of mCRC patients in trial-experienced hospital centers. However, as many small non-university community-based outpatient clinics are slow to adapt to new combination protocols due to their lack of experience in clinical studies and unfamiliarity with the side effects of these novel combinations, patient data from these out-patient clinics may be quite different to that usually presented from large trials. In the absence of available data on safety and efficacy of CAPIRI +/- bevacizumab (CAPIRI-Bev) in community-based out-patient clinics, we initiated this prospective open-label multicentric trial with a high emphasis placed on such typically community-based out-patient clinics not participating in other clinical mCRC trials[15,16].

MATERIALS AND METHODS

Patient eligibility, study design and treatment

Patients with previously untreated locally advanced or mCRC were eligible for entry into this trial. Histological confirmation of CRC or CRC liver metastases that were not resectable at the time of patient inclusion in the study was required. Additional requirements were an Eastern Cooperative Oncology Group (ECOG) performance status of $\leqslant 2$ (Karnofsky index > 70%) at least one measurable lesion and normal major organ function. Patients were eligible for inclusion, if a previous adjuvant chemotherapy regimen did not include irinotecan and/or bevacizumab. Patients did not have any age restrictions, but life expectancy had to be at least 3 mo.

This was a prospective, open-label multicentric non randomized phase Ⅱ study conducted by Mainz University, with an inclusion period from 2001 to 2006, particularly in nine small community-based German out-patient clinics. Patients were consecutively recruited according to whether they had received either a standard CAPIRI-regimen [capecitabine 1000 mg/m² twice daily (bid), on days 1-14 and irinotecan 200 mg/m² on day 1] or the same regime CAPIRI combined with bevacizumab (CAPIRI-Bev plus bevacizumab 7.5 mg/kg body weight, also on day 1). Patients in both groups received treatment, every 3 wk, in regional out-patient clinics in Germany; treatment choice of bevacizumab was at the discretion of the physician. Treatment continued until first documented tumor progression under therapy. Treatment was halted in cases of clinical progression, severe therapy-associated adverse events and withdrawal of written informed consent. The protocol was approved by the local ethics review boards of all participating institutions. Patient follow up commenced with treatment initiation and ended on 25th July 2008 or with the death of a patient. The resulting median follow-up times for CAPIRI and CAPIRI-Bev were similar, 19.5 and 17.0 mo, respectively.

Participation in the study required patient written informed consent. Patients who had undergone a major surgical procedure within 4 wk before start of treatment were excluded from the trial. Major exclusion criteria included previous treatment with capecitabine, irinotecan and bevacizumab in a palliative setting and participation in another study during treatment. Patients with malignant tumors other than basalioma, successfully treated in situ carcinoma of the cervix or a tumor relapse free period more than 5 years, were excluded from the trial.

Due to the toxicities associated with bevacizumab,

patients with myocardial infarction within 1 year before start of treatment, stroke, thromboembolic events, severe bleeding within 6 mo prior to treatment, hemorrhagic diathesis, unhealing wounds or fractures or proteinuria $\geq$ 1 in urine sample were excluded. Anticoagulant treatment, thrombocyte-aggregation inhibitors, as well as St. John's wort were prohibited on the date of enrollment to our study.

Statistical analysis

Endpoints: Primary endpoints were response rates (RR) and the toxicity profile; secondary endpoints were progression free survival (PFS) and overall survival (OS) under study treatment.

Response assessment: Tumor response classification was based on the definitions set out in the Response Evaluation Criteria in Solid Tumors (RECIST)[34]. Tumor response was assessed after 12 wk (4 cycles) and all responses were confirmed by further radiological assessment every 12 wk if applicable. The following parameters were calculated: response rates, PFS and OS. The tumor control rate was defined as: complete response (CR) + partial response (PR) + stable disease (SD).

Toxicity measurements: Toxicity was defined as the frequency of hematological and non-hematological, chemotherapy associated adverse events and laboratory changes after 3 mo of treatment. Toxicity of treatment was evaluated at all visits and graded 1 to 4 using the National Cancer Institute Common Toxicity Criteria (NCI-CTC) Version 2.0. For each toxic event the documented maximal NCI-CTC grading throughout treatment was taken into account, to record chemotherapy-associated toxicity in both treatment groups. Particular emphasis was placed on the management of late-onset diarrhea.

Statistical analysis: The study was not set up to significantly compare both groups. However statistical analysis was performed using the full analysis set (intent-to-treat). Statistical analysis including survival analysis according to Kaplan-Meier was performed with the SPSS software package. Survival was measured from the time of diagnosis to the date of death or last follow-up. PFS were calculated from the first day of treatment until progression. Differences in the toxicity profile of both study groups were analyzed by χ^2 test. Value of significance was calculated *via* Fisher's test and $P < 0.05$ was considered significant.

RESULTS

Patient population

A total of 46 patients were enrolled and included in the intent-to-treat analysis of this prospective trial, of whom 17 (37.0%) received treatment with CAPIRI and 29 (63.0%) treatment with CAPIRI-Bev. The patient demographics and baseline characteristics are presented in Table 1. Since patients were not directly randomized but included into the treatment groups at the discretion of the investigators,

Table 1 Patient characteristics

	Treatment group	
	CAPIRI	**CAPIRI-Bev**
N (%)	17 (37%)	29 (63%)
Age (median), years (range)	66 (55-81)	60 (37-80)
Gender, M/F	9/8	22/7
Site of primary tumor, *n* (%)		
Rectum	7 (41.2)	15 (51.7)
Colon	10 (58.8)	14 (48.2)
Site of metastases, *n* (%)[1]		
Hepatic	12 (71)	24 (83)
Pulmonary	6 (35)	11 (38)
Lymphatic and nodal	4 (24)	17 (59)
Skeletal	1 (6)	4 (14)
Peritoneal	1 (6)	5 (17)
Other sites	6 (35)	5 (17)
Performance status (Karnofsky)		
100%	4 (23.5)	17 (58.6)
90%	1 (5.9)	5 (17.2)
85%	1 (5.9)	0 (0)
80%	2 (11.8)	3 (10.3)
70%	4 (23.5)	0 (0)
Adjuvant chemotherapy received	8 (47%)	8 (27.6%)

[1]Patients could have more than one metastatic site.

some clinical parameters (e.g. gender, location of rectum, lymph node metastasis) differed between both groups, but were not statistically different. Patients' age was similar between both patient groups, however there were more female patients in CAPIRI than in the CAPIRI-Bev group (47.1% *vs* 24.1%). The colon was more frequently the primary tumor site in CAPIRI than in the CAPIRI-Bev group (58.8% *vs* 48.2%), which contained fewer patients with sigmoid colon as primary site (5.9% *vs* 20.7%). The liver was the most common metastatic site in both groups (71% and 83%), followed by lymphatic and pulmonary metastases. Previous adjuvant chemotherapy regimen consisted of 5-FU/LV for 6 patients receiving CAPIRI and 4 patients receiving CAPIRI-Bev, and FOLFOX for 2 patients receiving CAPIRI and 4 receiving CAPIRI-Bev.

Treatment compliance

The median number of cycles received was 9 (*n* = 17, CAPIRI) and 8 (*n* = 29, CAPIRI-Bev), and the median duration of therapy was 133 d (> 4 mo) for both groups. Patients in the CAPIRI group received a median dose of 3500 mg capecitabine and 400 mg irinotecan per cycle whereas patients in the CAPIRI-Bev group received 3876 mg capecitabine and 382 mg irinotecan per cycle. At least 1 dose reduction had to be undertaken in 9/29 patients (31%) treated with CAPIRI-Bev and 8/17 patients (47%) treated with CAPIRI. In 55% of the CAPIRI and 53% of the CAPIRI-Bev patients, treatment had to be delayed at least once. The number of hospital admissions during treatment with CAPIRI-Bev was higher than during treatment with CAPIRI (44.8% *vs* 29.4%).

toxicities is displayed, by treatment group, in Table 2. Neutropenia and leukopenia were the most frequently reported hematological toxicities, although the number of patients affected by grade 3-4 hematological events was minimal in both groups. Leukopenia was observed in 23.5% *vs* 20.7% (CAPIRI *vs* CAPIRI-Bev). The frequency of neutropenia was equally distributed (17.6% CAPIRI *vs* 17.2% CAPIRI-Bev). Most frequently reported non-hematological toxicities included diarrhea, nausea/vomiting, and hand-foot syndrome (Table 2). The total incidence of diarrhea was similar for CAPIRI and CAPIRI-Bev (41.2% *vs* 44.8%) and grade 3-4 diarrhea was more frequent with CAPIRI (23.5% *vs* 17.2%). Further statistical analysis did not reveal any significant differences between the two groups for non-hematological toxicities. The CAPIRI-Bev group had a significantly higher total incidence of alopecia ($P = 0.049$) and proteinuria ($P = 0.036$), with one Grade 3 proteinuria. Without reaching the level of significance ($P = 0.286$) three cases of arterial hypertension and non-severe thromboembolism were observed for CAPIRI-Bev whereas these events were not observed in the CAPIRI group. All three cases of arterial hypertension were of low NCI-CTC level and were easily managed with oral antihypertensive therapy. One case of minor thromboembolism led to continuation of therapy only without Bev. One cardiovascular event was reported in each group: whereas a stable angina pectoris was reported for CAPIRI, one case of ST-elevated myocardial infarction led to discontinuation of therapy in a patient receiving treatment with CAPIRI-Bev. Thus, the overall grade 3-4 toxicity was reported to be statistically not significant

higher in CAPIRI compared to CAPIRI-Bev, 82.4% *vs* 58.6%, respectively.

Response

Following 3 mo of therapy, response was evaluated in 45 patients. One patient withdrew from CAPIRI-Bev before the 1st assessment. Both groups achieved similar tumor growth control rates (TCR): 70.6% and 75.9% patients treated with CAPIRI or CAPIRI-Bev, respectively. However, there was a difference in response rates, with a not significantly different but higher number of partial responses in the CAPIRI-Bev group (34.5%) compared with the standard CAPIRI group (29.4%) (Table 3). Two patients who achieved a partial response in the CAPIRI-Bev group during the course of treatment were able to undergo a full secondary tumor resection in terms of a curative therapy. No complete responses were observed in either group during follow-up after 3 mo.

Survival

Progression-free survival and overall survival (Figure 1) were in favor of patients receiving CAPIRI-Bev. The median PFS was 11.4 mo (i.e. 342 d) and 12.8 mo (i.e. 385 d) for the CAPIRI or CAPIRI-Bev group, respectively. This difference was not statistically significant (Log Rank, $P = 0.199$). Following second-line protocols in nearly half of all patients (Table 4), the median overall survival was approximately 24 mo in the CAPIRI-Bev group and approximately 15 mo in the CAPIRI group which was not significantly different (Log Rank, $P = 0.53$). The 60 d all

Figure 1 Kaplan Meier survival estimates by treatment group. A: Progression-free survival; B: overall survival. Bev: bevacizumab.

cause mortality was 0% for CAPIRI *vs* 3.4% (1 patient) for CAPIRI-Bev. This patient died 15 d after the first administration of therapy due to unknown cause, (most likely due to progressive disease), with no signs of a cardiovascular or thromboembolic event.

DISCUSSION

This open-label, multicentric, community-based phase II trial aimed to prospectively evaluate safety and efficacy of CAPIRI +/- Bev. Most of the 46 patients were recruited by out-patient clinics inexperienced with phase I -III studies. Thus we propose that these clinics are clearly different from the highly sophisticated centers regularly participating in large registration trials, but however represent the small drug-prescribing centers broadly seen in mCRC patient care for many European and non-European countries. This is also likely to be the reason why the ECOG performance status was not documented in 9 patients. As these primarily conservatively oriented out-patient clinics are relatively slow to adapt to new combination protocols, they also recruited more slowly and enrolled less than one third of their patients into our study (Moehler, personal communications). In addition these patients were those to be treated in a truly palliative setting.

Despite this relatively inexperienced clinical setting, the safety and efficacy of both protocols CAPIRI +/- Bev were remarkably positive. Consistent with other larger trials[29,32,33], a higher RR was obtained with bevacizumab than without (34.5% *vs* 29.4%). The RR in addition to the TCR were almost as high as in a recently presented phase IV study incorporating FOLFIRI + Bev[35]. Our results also show a higher median PFS and clearly better OS (24 *vs* 15 mo) in patients receiving CAPIRI plus bevacizumab compared to CAPIRI alone, even with less second-line therapies being given (Table 4). Furthermore the increased RR was achieved without a marked increase in toxicity. The incidence of grade 3-4 toxicities was higher in patients not receiving bevacizumab than those receiving it (82.4% *vs* 58.6%, respectively). Notable among these toxicity differences was the higher incidence of Grade 3-4 diarrhea in the CAPIRI group (29.4% *vs* 17.2%), as this was early in recruitment time without clear patient recommendation for the prompt use of loperamide in these relatively inexperienced centers[15,16].

Our efficacy results compare favorably with those obtained with the standard FOLFIRI or FOLFOX regimens[11,12]. Saltz showed in 683 patients, a significant improvement in median PFS and median OS (14.8 *vs* 12.6 mo) and RR were almost doubled; 39% 5-FU/LV + irinotecan *vs* 21% 5-FU/LV, respectively[13]. In the randomized phase II study (BICC-C) examining three regimens; FOLFIRI, modified bolus mIFL or CAPIRI, PFS times of 7.8, 6.0 and 5.8 mo and OS of 23.1, 17.6 and 18.9 mo were observed, respectively[36]. After subsequently amending the protocols to include the addition of bevacizumab to the FOLFIRI and mIFL arms, they achieved median PFS times of 11.2 and 8.3 mo and median OS times of 19.2 mo with mIFL + Bev but it was not reached with FOLFIRI + Bev[36].

Furthermore, our results compare well with those from the pivotal phase III study with 813 previously untreated patients who received IFL + bevacizumab or placebo[37]. OS for IFL + bev was shown to be 20.3 mo compared to 15.6 mo in the placebo + IFL group. Here, the relatively low median OS for CAPIRI in our study may reflect the fact that our population consisted of patients with poor prognostic factors (5 patients with ECOG PS2) receiving palliative therapy and were not always the typical trial patient population used in large trials. Herein, two large observational studies of the use of chemotherapy plus bevacizumab in broader clinical practice (the BRiTE and BEAT trials) confirm our safety and efficacy results[30,32,33]. The BRiTE community-based registry found that mCRC patients with FOLFIRI + Bev, FOLFOX + Bev, or capecitabine + oxaliplatin (XELOX)-Bev achieved median PFS times of 10.9, 10.3 and 9.0 mo, respectively[30]. The efficacy data from the BEAT community-based trial showed similar median PFS data[32,33].

Thus, in concordance with the early promise of this novel combination in phase I / II trials[17,18], we postulate that CAPIRI is at least as effective, but is a more convenient alternative to the standard FOLFIRI and FOLFOX regimens. The dose-limiting toxicities were neutropenia

and diarrhea, and dose regimens of capecitabine 1000 mg/m^2 bid for 14 d, and irinotecan of between 250 and 300 mg/m^2 on day 1, once every 3 wk, were proposed. In our study we used capecitabine 1000 mg/m² (bid) on days 1-14 and irinotecan 200 mg/m² on day 1 (with or without bevacizumab 7.5 mg/kg body weight on day 1), in accordance with Borner's study (2005) with good patient compliance[38]. Furthermore, the safety profile of the recent multicentric phase Ⅱ AIO trial with 247 patients comparing XELOX-Bev with CAPIRI-Bev with a dose of capecitabine 800 mg/m², which was 200 mg/m² less than used in our trial[39,40] was favorably comparable with the number of adverse events reached in our study. Moreover, the group reported an incidence of Grade 3-4 thromboembolic events of 5% and hypertension of 3%, where these events were not observed in our trial. Similarly, Hochster et al[27] reported from both TREE studies a decrease in Grade 3-4 toxicities of approximately 10%-20% for oxaliplatin-based regimens in combination with bevacizumab, which compares well with the decrease of approximately 25% reached by the addition of bevacizumab to CAPIRI in our study.

The overall incidence of grade 3-4 toxicity was higher with CAPIRI than with the CAPIRI-Bev combination: 82.4% vs 58.6%, respectively. The grade 3-4 diarrhea, which is the most common dose-limiting toxicity with CAPIRI, was also reduced in those patients receiving CAPIRI-Bev: 29.4% vs 17.3%, respectively. This is in clear concordance with recent efficacious and tolerable data on CAPIRI [capecitabine 1000 mg/m^2 (bid), days 1-14; irinotecan 250 mg/m^2 on day 1] in 398 patients, which did not to replicate the toxicity and mortality observed in earlier phase Ⅲ studies incorporating high doses of irinotecan[36,41,42].

In summary, these data are preliminary and should be treated with caution due to the small numbers of patients studied, and because the patients were not randomized to either treatment arm, neither was the study statistically set up to compare treatments. However, taken together, both regimens-CAPIRI alone or with the addition of bevacizumab-were well tolerated and are useful for efficient tumor control in out-patient settings of non-university based out-patient clinics, with the emphasis of patients' recommendations for its possible side effects. Severe gastrointestinal and thromboembolic events seen in other studies[43,44] were rarely observed and never fatal in our study. Thus, many authors concluded that combinations of CAPIRI with both, VEGF or EGFR1 antibodies seemed to be safe and feasible[39].

ACKNOWLEDGMENTS

COMMENTS

Background

Novel combinations of new chemotherapeutic agents with the increasing number of targeted monoclonal antibodies to tumor expressed antigens, have demonstrated an improvement in tumor response and overall survival in patients with advanced colorectal cancer (CRC) when investigated in the setting of a clinical trial.

Research frontiers

Capecitabine, an oral fluoropyrimidine, irinotecan a topoisomerase inhibitor, and the vascular endothelial growth factor (VEGF) bevacizumab, have demonstrated improved efficacy and tolerable toxicity when compared to with standard therapy following randomized trials in advanced colorectal cancer patients. However few studies have investigated their use in community-based hospital outpatient clinics where many patients with the disease are typically treated.

Innovations and breakthroughs

This is one of the first studies of its kind to investigate capecitabine in combination with irinotecan (CAPIRI) with and without bevacizumab in a community-based hospital out-patients clinic. The data suggest that both treatment regimens demonstrate efficacy and tolerable toxicity in this setting.

Applications

These data are in accordance with the preliminary findings emerging from larger community-based trials which are examining many different treatment combinations in advanced CRC. The data suggest that the improvements in efficacy and safety observed in trials performed in experienced university-based settings in selected patients will be in some cases translated to patients treated in the routine community-based setting, where experience of the use of such new agents is limited, but a substantial proportion of patients with this disease are treated.

Terminology

Capecitabine is an orally administered derivative of 5-fluorouracil (5-FU), sometimes given in preference to intravenously delivered 5-FU due to its ease of administration. It kills tumor cells by preventing DNA synthesis through the inhibition of thymidylate synthase, which is active in proliferating cells. Irinotecan also kills cells by inhibiting the enzyme topoisomerase I which is also involved in DNA synthesis in proliferating cells. Bevacizumab is a monoclonal antibody that inhibits VEGF that is expressed in some CRC aiding the blood supply to tumors; bevacizumab inhibits this process, stopping the tumor cells from growing.

Peer review

This is a non randomized study comparing the efficacy and safety of CAPIRI with and without bevacizumab in the treatment of patients attending community based clinical out-patients clinics. The preliminary results are interesting and may confirm the usefulness of CAPIRI with or without bevacizumab in this clinical setting.

Abstract

AIM: To evaluate the risk factors-other than nonsteroidal anti-inflammatory drugs-for colonic diverticular bleeding in a westernized population.

METHODS: One hundred and forty patients, treated for symptomatic diverticular disease in a community based hospital, were included. Thirty (21%) had signs of diverticular bleeding. Age, gender, and the results of colonoscopy were collected and compared to a group of patients with nonbleeding symptomatic diverticulosis. Records were reviewed for comorbidities, such as obesity, alcohol consumption, smoking habits and metabolic diseases. Special emphasis was put on arterial hypertension, cardiovascular events, diabetes mellitus, hyperuricemia and hypercholesterinemia.

RESULTS: There was no difference between patients with diverticular hemorrhage and those with nonbleeding symptomatic diverticulosis regarding gender ratio (male/female 9/21 *vs* 47/63) and diverticular localisation. Bleeding patients differed in respect to age (73.4 ± 9.9 *vs* 67. 8 ± 13.0, *P* < 0.013). Significant differences were found between both groups regarding the presence of hyperuricemia and use of steroids and nonsteroidal anti-inflammatory drugs. Patients with three concomitant metabolic diseases were also identified as being at risk of bleeding. A forward stepwise logistic regression analysis revealed steroids, hyperuricemia and the use of calcium-channel blockers as independent risk factors of bleeding.

CONCLUSION: Beside nonsteroidal anti-inflammatory steroid drug use, antihypertensive medication and concomitant arteriosclerotic diseases are risk factors for colonic diverticular hemorrhage. Our results support the hypothesis of an altered arteriosclerotic vessel as the source of bleeding.

INTRODUCTION

Diverticular disease is common in Westernized countries[1]. In adults under 40, less than 10% are affected. This increases to a prevalence of up to 60% in those aged over 80. Prevalence is equal between men and women. In Western countries the disease usually affects the left side of the colon[2], whereas in Eastern countries diverticulosis is more common in the right side[3]. In 80% of affected individuals, the condition remains asymptomatic. The remaining patients develop signs of diverticular disease. These include left sided lower abdominal pain, change in bowel habits and abdominal distension. Complicated diverticular disease presents as diverticulitis with perforation, obstruction, formation of abscesses and fistulation[4]. The second severe complication is the acute diverticular bleeding, which affects 3% to 15% of individuals with diverticular disease[5,6]. The pathogenesis of diverticular bleeding includes an asymmetric intimal proliferation and segmental weakening of the associated vas rectum arising from traumatic factors within the diverticular or colonic lumen. The bleeding is thought to be the

result of an acute rupture of the altered vasa recta close to the diverticulum[7]. Arteriosclerosis and associated diseases such as the metabolic syndrome could therefore play an important role in the pathogenesis of acute diverticular bleeding. Nonsteroidal anti-inflammatory drugs (NSAID), including aspirin, have already been identified as risk factors for acute lower gastrointestinal bleeding, including acute diverticular bleeding[3,8-10]. In a recently published survey, several potential risk factors for diverticular bleeding have been analysed in Japanese patients. Apart from NSAID and anticoagulants, arterial hypertension has been shown to be an independent risk factor for colonic diverticular bleeding[3]. Risk factors for diverticular bleeding in Western populations have not been explored before. We therefore analysed patients admitted to a Western community based hospital with colonic diverticular bleeding regarding comorbidities and medications as possible risk factors.

MATERIALS AND METHODS

Two hundred and one patients, treated for symptomatic diverticular disease at the medical Department of the St. Elisabeth Hospital, Dorsten, between January 2004 and July 2006, were included in this study. Overall, 140 patients with proven diverticulosis and colonoscopy during the hospital stay were reviewed retrospectively. The remaining patients either refused endoscopy or went directly to surgical intervention. None of the latter patients suffered from intestinal bleeding.

Thirty of the 140 investigated patients had signs of lower intestinal bleeding on admission. Data from these patients was compared to data from patients without signs of lower gastrointestinal bleeding.

Data collection

We collected data on age, gender and results of colonoscopy. The records were also reviewed for information on comorbidities, ongoing medication, body mass index (BMI), alcohol consumption and smoking habits. Special emphasis was put on concomitant diseases such as arterial hypertension, cardiovascular events (stroke, coronary heart disease), diabetes mellitus including prediabetes (impaired glucose utilization), hyperuricemia and hypercholesterolemia. In addition, outcome, development of complications and length of hospital stay were compared. Concomitant diseases were assumed when patients were on appropriate medication. Obesity was defined as BMI > 25 kg/m^2.

Colonoscopy

Colonoscopy was performed after using polyethylene glycol-containing lavage solution for colon preparation by use of electronic video endoscopes (Model Exera CF-Q 145/160, Olympus Optical Co, Hamburg, Germany). Diagnosis of colonic diverticular hemorrhage was made based on the criteria reported by Jensen et al[6]. These criteria include the observation of active bleeding from a diverticulum, the observation of blood clots

Table 1 Characteristics of patients with and without colonic diverticular hemorrhage n (%)

Data are mean ± SD; NS: Non significant.

in the colon in the presence of diverticula, absence of blood in the terminal ileum, and no other demonstrable cause of bleeding.

Statistical analysis

The data were evaluated using descriptive statistical methods (mean ± SD, ranges). For comparison of two means the unpaired Students's t-test was used. Frequency distribution was calculated by the χ^2 test or Fisher's exact probability test. Factors with $P < 0.2$ in the univariate analysis were included in a forward stepwise logistic mulitivariante regression analysis. Statistical calculations were performed using SPSS Version 16.0 for Windows (SPSS Inc Chicago, USA).

RESULTS

The characteristics of patients with and without colonic diverticular hemorrhage are shown in Table 1. While gender distribution was comparable, patients with diverticular bleeding were significantly older. None of our patients had isolated right-sided colonic diverticula. Isolated left-sided colonic affection was most frequent in both groups.

Colonoscopy was performed in the bleeding group after 3.8 ± 2.3 d (range 1-9) and in the nonbleeding group after 6.0 ± 3.7 d (range 1-28, $P = 0.003$). Colonoscopy was successful in 83% of bleeding patients and in 79% of nonbleeding patients. The reasons for early termination were obstruction in 10% of patients in the bleeding group and 17% in the nonbleeding group. In the remaining patients colonoscopy was incomplete because of inappropriate cleaning or pain.

Endoscopic signs of diverticular inflammation (petechial bleeding, pus, reddening, and swelling) were found in 63.3% of patients in the bleeding group and 59.1% of patients in the nonbleeding group (NS).

Since polyps are also potential sources of bleeding we compared the prevalence of such lesions in both groups. In the bleeding group polyps were found in seven patients (23%) whereas, in the nonbleeding group, 29 patients (26%, NS) had polyps. None of the polyps showed signs of recent hemorrhage.

The definitive source of bleeding was identified in nine (30%) patients (bleeding vessels, nonbleeding

[1]Including malignant disease, chemotherapy, regular intake of methotrexate or steroids, reduced general condition due to old age.
[2]Including stroke and myocardial infarction.

vessel in the diverticulum and adherent clot in the diverticulum). The bleeding was localized in the right colon in one patient and in the left colon in the remaining patients. Colonoscopy was performed with these patients within three days (1.8 ± 0.7 d), whereas patients without definitive signs of bleeding were examined between day two and nine after admission (4.7 ± 2.2, *P* < 0.001).

To identify potential risk factors for diverticular bleeding we compared bleeding and nonbleeding patients regarding comorbidities and medications. The results are shown in Table 2. Hyperuricemia was present significantly more often in patients with diverticular bleeding. All other comorbities showed no significant differences. However, patients were more likely to develop diverticular bleeding when more than three concomitant diseases, out of seven (obesity, hypertension, hypercholesterolemia, hyperuricemia, impaired glucose utilization, arteriosclerosis, immunosuppression), were present (*P* = 0.013). By univariate analysis, steroid and NSAID use were also increased in patients with bleeding. In addition, diabetes mellitus, BMI, calcium channel blockers and digitalis had a *P* value < 0.2. Using these factors, we performed a multivariate forward logistic regression analysis: steroid use (*P* = 0.01), hyperuricemia (*P* = 0.004), and use of calcium channel blockers (*P* = 0.03) were confirmed independent factors of bleeding.

There was no difference in length of hospital stay between the bleeding and the nonbleeding group. During hospital stay, four patients from the bleeding group (13.3%) and eight from the nonbleeding group

(7.3%, *P* = NS) required surgery.

Severity of diverticular hemorrhage was classified according to the initial RBC in 28 patients. Patients with an initial hemoglobin level lower than 10 g/dL were considered to have more severe bleeding. These patients were older than those with a less severe bleeding (81 ± 4 *vs* 72 ± 10 years, *P* = 0.037). All other potential risk factors showed no differential distribution between the groups, although trends could be seen in steroid use, NSAID use and cardiovascular events.

Length of hospital stay differed between severe and non-severe bleeding patients (17 ± 10 d *vs* 10 ± 7 d, *P* = 0.067). Two patients in the severe group died due to cardiovascular events and multiple organ failure. No patient of the non-severe group died.

DISCUSSION

Our study shows that the risk of diverticular bleeding increases with age. In particular, higher age is associated with a more severe bleeding. Steroid and NSAID use predisposes to diverticular bleeding. Hyperuricemia, steroid and calcium channel blockers use are independent risk factors for bleeding out of a variety of ateriosclerotic diseases and medications. A higher bleeding risk is also associated with the concomitant presence of more than three of such conditions.

The prevalence of diverticular disease, in general, increases with age[5]. Complicated diverticulitis, including obstruction, perforation and abscess formation leading to operation, however, is more likely in patients younger than 50 years of age with coexisting conditions, including obesity[11]. Our results show that in contrast diverticular bleeding is an event which occurs in older age. In addition, obesity has no influence. The association of obesity and diverticular disease is controversial. A slight association between elevated BMI and symptomatic diverticular disease was reported by Aldoori *et al*[12], whereas other authors did not find such a correlation[13,14]. In our study the prevalence of obesity in the bleeding and nonbleeding group was comparable to the reported prevalence of obesity in the general population of this urban area[15]. Thus, the presence of diverticula and the occurrence of a bleeding episode are both independent of obesity.

Diverticular bleeding and complicated diverticular disease are of different pathogenesis. This is supported by our observation that patients with bleeding had no higher frequency of inflammation than patients without bleeding[16]. Diverticular bleeding is thought to be the result of a rupture of an arteriosclerotic altered diverticular vessel[7,17]. Since arteriosclerosis increases with age, age itself might not be an independent risk factor for bleeding[13]. Instead, arteriosclerotic disease could be the true risk factor for bleeding. In our study,, we could not find an association of bleeding with a single arteriosclerotic disease. Arteriosclerosis is also the result of different metabolic diseases. Therefore we speculate that the presence of these diseases increases

the risk of bleeding. Our results show that this is only true for hyperuricemia, but not for other metabolic diseases, including obesity. A recent survey on Japanese patients confirms our results, that arteriosclerosis in general and obesity are not single independent risk factors for bleeding. However, these authors identified arterial hypertension as the only independent risk factor for hemorrhage[3]. Although in our study arterial hypertension is not associated with a higher bleeding risk, hyperuricemia is. Yamada *et al*[3] speculate from their findings that microscopic hemorrhages occur frequently in diverticulosis and progress into severe bleeding in the presence of unfavorable conditions, such as arterial hypertension. This speculation is supported by the finding that NSAID use, by causing microscopic bleeding, also increases the risk of significant diverticular bleeding.

From our results we can conclude that, beside arterial hypertension and NSAID use, additional conditions, like hyperuricemia and steroid use, are additional risk factors of bleeding. Furthermore, the combination of several arteriosclerotic risk factors is also associated with a higher bleeding risk. This supports the hypothesis that vascular fragility is increased in elderly patients, and especially in patients with multiple concomitant diseases. NSAIDs reduce mucosal prostaglandin production, which leads to enhanced mucosal permeability and reduced microcirculation, and, in turns, to mucosal inflammation and bleeding[18,19].

In our study, hyperuricemia was a risk factor for diverticular bleeding. This fits into the concept that metabolic diseases leading to arteriosclerosis could cause the bleeding episode. And indeed, uric acid has been identified as a risk factor for stroke and myocardial infarction[20]. In our study, hyperuricemia was assumed when patients were on adequate medication (allopurinol). Thus we cannot exclude that allopurinol itself could have an influence on diverticular bleeding. Calcium channel blockers use was also associated with a higher bleeding risk. An elevated risk for gastrointestinal bleeding is known to be present in older adults following calcium channel blocker use[21,22]. Thus, our observation shows that diverticula are a possible source of bleeding in these patients. Therefore, it should be kept in mind that older patients with arterial hypertension and diverticula have an elevated risk for gastrointestinal bleeding when treated with calcium channel blockers.

In our study, most patients suffered from left sided diverticular disease. Accordingly, this was also the most frequent localisation of the bleeding diverticulum. This is in contrast to the general opinion where right sided diverticula are thought to be the most frequent source of bleeding. However there are only limited data which support this hypothesis. Even a recent Japanese study could not find such an association[3].

ACKNOWLEDGMENTS

COMMENTS

Background
Diverticular disease of the colon is common in Westernized countries. One of its complications is bleeding. Our study tried to identify the risk factors for this event.

Research frontiers
To know potential risk factors for bleeding is essential for treating patients with diverticulosis and concomitant diseases.

Innovations and breakthroughs
In Westernized countries, the risk factors for diverticular bleeding are the use of nonsteroidal anti-inflammatory drugs (NSAID), the use of steroids, antihypertensive medications and concomitant arteriosclerotic diseases. Anticoagulation and antiplatelet therapies were not identified as risk factors.

Applications
Patients with known diverticula should avoid NSAID, and during antihypertensive medication the risk for diverticula bleeding should be kept in mind.

Terminology
Diverticula are herniations of the mucosa and submucosa through the muscular coat of the colon. There is a close relationship between the herniated sac and the arterial supply. This is of importance for the pathophysiology of bleeding.

Peer review
It is a well written paper, substantiating evidence for some known risk factors and identifying some new, like hyperuricemia, and use of calcium channel blocker.

Abstract

AIM: To investigate the prevalence of the clinical parameters of insulin resistance and diabetes in patients affected by chronic hepatitis C (CHC) or chronic hepatitis B (CHB).

METHODS: We retrospectively evaluated 852 consecutive patients (726 CHC and 126 CHB) who had undergone liver biopsy. We recorded age, sex, ALT, type 2 diabetes and/or metabolic syndrome (MS), body mass index (BMI), and apparent disease duration (ADD).

RESULTS: Age, ADD, BMI, prevalence of MS and diabetes in patients with mild/moderate liver fibrosis were significantly higher in CHC. However, the degree of steatosis and liver fibrosis evaluated in liver biopsies did not differ between CHC and CHB patients. At multivariate analysis, age, sex, BMI, ALT and diabetes were independent risk factors for liver fibrosis in CHC, whereas only age was related to liver fibrosis in CHB. We also evaluated the association between significant steatosis (> 30%) and age, sex, BMI, diabetes, MS and liver fibrosis. Diabetes, BMI and liver fibrosis were associated with steatosis > 30% in CHC, whereas only age and BMI were related to steatosis in CHB.

CONCLUSION: These data may indicate that hepatitis C virus infection is a risk factor for insulin resistance.

INTRODUCTION

Recent years have seen numerous studies devoted to the relationship of such clinical variables as age, gender and body mass index (BMI) with metabolic alterations involving the liver in patients affected by hepatitis C virus (HCV)-related chronic hepatitis. Attention has focused on the metabolic syndrome (MS), diabetes[1-5], steatosis/steatohepatitis[6-10] and associations between these conditions[11-15]. It remains to be established whether the relationship between HCV and deranged cellular metabolic pathways is casual or whether it results from a direct effect exerted by HCV.

In an attempt to shed light on this issue, we examined the prevalence of these phenomena in chronic hepatitis C (CHC) and in chronic hepatitis B (CHB) in order to distinguish between alterations due to presence of an advanced liver disease and those due to HCV[16-18].

We have investigated the prevalence of MS and/or diabetes and their effect on liver fibrosis and/or steatosis/steatohepatitis in a large cohort of patients affected by HCV- or hepatitis B virus (HBV)-related chronic hepatitis. Our aim was to look for differences and simi-

larities between the two types of viral hepatitis and to confirm or refute the hypothesis of metabolic cofactors in HCV-related liver disease(s).

MATERIALS AND METHODS

We retrospectively evaluated 852 consecutive patients (726 CHC and 126 CHB) who underwent clinical evaluation and liver biopsy for HBV- or HCV-related hypertransaminasemia in the Internal Medicine and Hepatology Unit at the Second University of Naples from April 1999 to November 2005. The inclusion criterion was HBsAg-positive or HCV-Ab-positive chronic hepatitis. The exclusion criteria were: patients with a recent (< 6 mo) history of high alcohol consumption (> 30 g/d in females, > 40 g/d in males) or a history of intravenous drug abuse, clinical and/or ultrasound evidence of cirrhosis, an human immunodeficiency virus (HIV)-positive test and HBV/HCV co-infection. In addition to a complete blood count, each patient underwent tests for: serum markers for hepatitis B infection determined by radioimmunoassay (Abbott Laboratories, North Chicago, IL, USA), antibodies to HCV assayed by a second-generation enzyme-linked immunoassay (ELISA; Ortho Diagnostic Systems, Raritan, NJ, USA), the presence of type 2 diabetes according to American Diabetes Association criteria[19] by assessing fasting serum glucose and/or the oral glucose tolerance test (OGTT) on two different occasions, and for the presence of MS based on NCEP-ATP III criteria[20]. BMI (kg/m^2) was recorded and the apparent disease duration [(ADD) in years] was determined by considering the exposure to major risk factors as the start of infection. Each patient underwent an echo-assisted liver biopsy performed with a 17G Menghini modified needle (Surecut, TSK Laboratory, Japan) through an intercostal entry. The liver specimens were formalin-fixed, embedded in paraffin and evaluated with the Ishak scoring system for viral liver disease[21] by skilled liver pathologists, who also evaluated the presence of liver steatosis and steato-hepatitis according to Brunt *et al*[22].

Statistical analysis of data was performed using the SPSS® 13.0 software for Windows®. Non-parametric tests (χ^2 or Fisher's exact), Spearman's rho test, ANOVA, linear and logistic regression tests were performed where appropriate.

RESULTS

As shown in Table 1, HCV-positive patients had a significantly longer ADD ($P < 0.005$), a significantly older age ($P < 0.0001$) and a significantly higher BMI ($P < 0.005$) *vs* HBV-positive subjects. The MS was present in 76 out of 726 HCV patients (10.46%) and in only 2 of the 126 HBV subjects ($P < 0.005$). The prevalence of diabetes did not differ significantly between the two groups, but it was significantly higher in HCV subjects when comparing only patients with mild fibrosis (Ishak S0-S3) at liver biopsy ($P < 0.005$) (Figure 1). The prevalence of diabetes in mild fibrosis patients did not differ between the two groups when patients were stratified by age. No differences were found at liver biopsy as regards grading

Table 1 Epidemiological and histological data of the two groups studied

and staging, neither was there a difference in the prevalence of patients with higher degrees of steatosis.

To evaluate whether age, sex, BMI, ALT, diabetes, MS and steatosis were independent risk factors for liver fibrosis we carried out a univariate and a multivariate analysis in the two groups of patients. At univariate analysis, all the variables tested were significantly related to higher degrees of fibrosis in HCV patients, whereas only age was correlated to liver fibrosis in HBV patients (Table 2). The results of the multivariate analysis confirmed these findings, namely age, sex, BMI, ALT and diabetes were independent risk factors for fibrosis in HCV subjects, whereas only age was related to fibrosis in HBV patients (Table 3).

We next carried out statistical analyses to evaluate whether age, sex, BMI, ALT or diabetes were related to steatosis, which is a well known negative predictor of both disease outcome and response to therapy in HCV patients[23-26]. None of these parameters were significantly associated with degree of steatosis. However, when we did the same analysis considering only patients with steatosis > 30%, a higher BMI, diabetes and fibrosis were correlated with severe steatosis in CHC patients (Tables 4 and 5).

DISCUSSION

In our cohort study, the prevalence of MS and diabetes was significantly higher in patients with HCV-related chronic hepatitis than in patients with HBV-related

fect of severe liver disease on diabetes onset should be considered when comparing groups of patients affected by chronic liver disease. In our study, we were able to rule out that diabetes was related to the altered hepatic glycaemic homeostasis due to severe liver disease (i.e. cirrhosis). In fact, whereas the total prevalence of diabetes did not differ between HCV and HBV patients, the prevalence of diabetes among patients with mild chronic hepatitis was significantly higher in HCV subjects.

This finding confirms reports of a higher prevalence of diabetes in HCV patients[14,29,34], and, *vice versa*, a report of a higher prevalence of HCV in diabetic patients[30]. Moreover, our data are in line with recent reports of a higher prevalence of diabetes in HCV patients compared with other liver diseases (e.g. HBV infection)[1]. In particular, Jan et al[17] reported a significantly higher prevalence of MS in HCV patients *vs* HBV patients, and an inverse ratio between HBV infection and clinical expression of MS in a population-based study carried out in Taiwan.

The association between diabetes and HCV-related chronic hepatitis was reported to influence the clinical outcome of liver disease[35-37]. Moreover, diabetes and/or obesity were found to be cofactors of liver disease in that they affect liver fibrosis progress and response to antiviral therapy[23,24,37-39]. Here we report that, besides ALT, sex and age, also diabetes and BMI were independent risk factors for more severe liver fibrosis in HCV-positive patients, whereas they were not associated with the severity of liver fibrosis in HBV subjects. This finding supports the idea that obesity and diabetes might represent clinical epiphenomena of the pathogenesis of HCV infection. In line with this hypothesis, using an animal model, Shintani et al[40] found that HCV directly affects serum glycaemic

chronic liver disease. This suggests that insulin resistance, which is the mechanism underlying MS, might at least in part be related to HCV infection. Insulin resistance is identified with the euglycemic clamp technique[27] or with the homeostasis model assessment insulin resistance (HOMA-IR) test[28]. Neither euglycemic clamp nor the HOMA-IR test was performed in our patients. However, we used the most practical worldwide accepted definition of MS according to the ATP-III NCEP clinical criteria[20]. Moreover, unlike other authors[16,29-32], we were able to measure, using these criteria, central obesity which is considered the fundamental condition for a clinical diagnosis of MS[33]. The association of diabetes and severe chronic liver disease is widely recognized[4,16,32,34], therefore the ef-

and insulinaemic levels, probably by acting *via* TNF-α. Similarly, Kawaguchi *et al*[41] reported that HCV directly affects intracellular insulin metabolic pathways *via* genetic up-regulation. However, we cannot exclude the possibility that synergism between the two diseases (diabetes/non-alcoholic steatohepatitis and virus-related chronic hepatitis) affects the outcome of liver fibrosis[7,11].

Steatosis has been associated with more severe liver fibrosis[23-26] as well as with a worse response to antiviral therapy. Moreover, steatosis is defined "metabolic steatosis" in non-3-genotype-infected patients as opposed to the viral steatosis typical of genotype 3 patients[11]. In our cohort of HCV patients, steatosis did not appear to be an independent risk factor for fibrosis stage. The discrepancy between our results and previous findings is apparent. Indeed, univariate and multivariate analyses *vs* fibrosis showed that steatosis was associated with the severity of liver fibrosis in our HCV patients if they were also affected by diabetes and/or obesity. Moreover, at multivariate analysis *vs* steatosis, BMI, diabetes and fibrosis were independent risk factors only for steatosis > 30%. This suggests that histological features of fibrosis, whether related to non-alcoholic steatohepatitis or to virus-associated steatohepatitis, will be found only in cases in which steatosis is > 30%.

This study provides clinical evidence that HCV directly affects insulin resistance in a large Italian retrospective, single-centre, consecutive population of HCV- and HBV-infected subjects. Biological, molecular and genetic studies are required to test this hypothesis.

COMMENTS

Background

Glucose metabolism derangements are common in hepatitis C virus (HCV) patients but there is still a lot of deliberation as to whether the relationship between HCV and deranged cellular metabolic pathways is casual or whether it results from a direct effect exerted by HCV.

Research frontiers

To investigate the prevalence of the clinical parameters of insulin resistance and diabetes in patients affected by chronic hepatitis C (CHC) or chronic hepatitis B (CHB).

Innovations and breakthroughs

A direct comparison of the prevalence of clinical features of insulin resistance in HCV and HBV infection in a large cohort of Italian patients.

Applications

To shed light on the association between insulin resistance and HCV infection and recommend further biological, molecular and genetic studies, and finally to suggest a careful assessment of insulin resistance status in HCV clinical care.

Peer review

The authors retrospectively analyzed a large cohort of consecutively-enrolled HCV (726) and HBV (126) patients undergoing liver biopsy in order to find a correlation between clinical expressions of insulin resistance (diabetes and metabolic syndrome) and HCV liver disease in comparison with HBV-related chronic hepatitis. This is an interesting paper and is of importance.

Abstract

AIM: To evaluate the effects of preoperative immunonutrition and other nutrition models on the cellular immunity parameters of patients with gastrointestinal tumors before surgical intervention. In addition, effects on postoperative complications were examined.

METHODS: Patients with gastrointestinal tumors were randomized into 3 groups. The immunonutrition group received a combination of arginine, fatty acids and nucleotides. The second and third group received normal nutrition and standard enteral nutrition, respectively. Nutrition protocols were administered for 7 d prior to the operation. Nutritional parameters, in particular prealbumin levels and lymphocyte subpopulations (CD4+, CD8+, CD16+/56+, and CD69 cells) were evaluated before and after the nutrition protocols. Groups were compared in terms of postoperative complications and duration of hospital stay.

RESULTS: Of the 42 patients who completed the study, 16 received immunonutrition, 13 received normal nutrition and 13 received standard enteral nutrition. prealbumin values were low in every group, but this parameter was improved after the nutritional protocol only in the immunonutrition group (13.64 ± 8.83 *vs* 15.98 ± 8.66, *P* = 0.037). Groups were similar in terms of CD4+, CD16+/56, and CD69+ prior to the nutritional protocol; whereas CD8+ was higher in the standard nutrition group compared to the immunonutrition group. After nutritional protocols, none of the groups had an increase in their lymphocyte subpopulations. Also, groups did not differ in terms of postoperative complications and postoperative durations of hospital stay.

CONCLUSION: Preoperative immunonutrition provided a significant increase in prealbumin levels, while it did not significantly alter T lymphocyte subpopulation counts, the rate of postoperative complications and the duration of hospital stay.

INTRODUCTION

Protein-energy malnutrition occurs in 30% to 90% of patients with cancer[1]. Malnutrition causes adverse effects on immunity through several mechanisms, including atrophy in lymph nodes, decreased lymphocyte count and IgA production and suppression of cellular immunity. Many studies have shown beneficial effects of nutritional support in patients with malnutrition[2-4].

Immunonutrient compounds with a suggested positive effect on immune parameters such as arginine, glutamine, omega 3 fatty acids, and ribonucleic acid are now being studied with regard to their contribution to immune response when given as supplements to nutritional treatments[5-8].

Immunonutrition is usually given preoperatively, since it prevents the decrease in cellular immunity and phagocytic capacity of polymorphonuclear neutrophils (PMN's) during the early postoperative period[9]. There have been several prospective studies examining the effects of immunonutrition support on the rate of postoperative complications, infection rates, length of hospital stay, wound repair, weight gain, cost, and mortality[10-15]. However, the mechanisms through which beneficial effects occur have not been studied in detail. The basic immune response in the host against the tumor is mediated by cellular immunity. Studies looking at the changes in cellular immunity after immunonutrition-especially those that occur before surgical trauma- are scarce[9,16,17].

In this prospective randomized study, we examined different nutritional models in preoperative patients with endoscopically and histopathologically documented gastrointestinal tumors. The effects on nutritional parameters, quantitative measures including changes in lymphocyte subpopulations responsible for the cellular immunity [CD4+ (T helper), CD8+ (T cytotoxic, suppressor), CD16+/56+ (natural killer) cells], and qualitative measures such as changes in the expression of CD69+ were explored in immunonutritional and other nutritional models. Our objective was to avoid the possible effects of the inflammatory process due to surgical trauma on the results by evaluating the preoperative effect of immunonutrition on immunological parameters.

MATERIALS AND METHODS

A total of 56 patients with gastrointestinal tumors admitted to the General Surgery Unit of Haydarpasa Numune Hospital were included in this study. Patients with diabetes mellitus, renal and/or hepatic failure, and active infection were excluded, as were the patients with a history of immunosuppressive drug use or clinical signs of vitamin or trace element deficiency.

Informed consent was obtained from all patients. Height, weight, and midarm muscle circumference measurements were made, and weight changes in the previous six months period were evaluated. PPD and cytometric measurements were used to evaluate the cellular response. C-Reactive Protein (CRP), an acute phase reactant, and prealbumin levels were measured to demonstrate and monitor any effect that may be due to the inflammatory process.

Subjective global assessment (SGA) was based on history taking and physical examination, and patients were categorized as follows: normal nutritional status, or mild, moderate, or severe malnutrition.

Body mass index was calculated as follows: BMI =

Table 1 Distribution of patients by nutrition models

	Patients (n)	Nutrition model	Nutritional products[1]
Group 1	n = 16	Immunonutrition	Enteral product with addition of arginine, omega-3 fatty acids and RNA (IMPACT®)
Group 2	n = 13	Normal nutrition	Normal feeding planned by a dietitian
Group 3	n = 13	Standard enteral nutrition	Standard enteral product without RNA or Omega-3 fatty acids (FRESUBIN®)

[1]One liter of Impact (Novartis Nutrition, Bern, Switzerland) contains 780 non-protein calories, 43 g of protein, 12.5 g of arginine, 3.3 g of ω-3 fatty acids and 1.2 g of RNA.

kg/m^2, weight in kilograms and height in meters. The midarm muscle circumference, forearm circumference (C) and triceps skin fold thickness (TST) were measured and calculated according to the modified Heymsfield formula[18].

Before nutrition, blood samples were obtained for the measurement of hemoglobin, albumin, prealbumin, CRP, and lymphocyte, CD4+, CD8+, CD16+/56+, CD69+ counts.

T-lymphocyte subpopulations were determined with immunofluorescent stained mouse anti-human monoclonal antibodies. At least 5000 cells from each subpopulation were evaluated in the flow cytometry device (Becton Dickinson, Mountainview, Ca, USA) using the Cell Quest program. For this purpose, lymphocytes were initially plotted according to their size and granularity. The accuracy of lymphocyte frames was confirmed by using CD45 FITC and CD14 FE monoclonal antibodies. CD45(+) and CD14(-) cells formed the basis for the assessments. All other cell surface markers were evaluated within this context. In another tube, cells were labeled with CD69 for the qualitative assessment of T lymphocyte responsiveness. Some of these cells were counted in flowcytometry, and others were incubated with phytohemaglutinin for 2.5 h. Then cells were re-counted in flowcytometry and the changes in CD69 expression before and after the stimulation were recorded.

Subsequently, patients were randomized to one of the preoperative nutrition models shown in Table 1 for 7 d. The energy needs were calculated using Harris-Benedict formula. For patients not receiving standard enteral nutrition, an isonitrogenous and isocaloric feeding was provided. The ratio of non-protein energy to nitrogen was 1/142 in the standard enteral product and 1/78 in the immunonutrition group.

The efficacy of nutritional support was evaluated using CRP and prealbumin measurements on days 4 and 7, and nitrogen balance on day 4. On the morning of day 8, blood samples were obtained for the assessment of the changes in nutritional parameters before patients were operated. In patients undergoing radical surgical procedures, duration of the procedure, blood loss, infection rate and duration of hospitalization

were recorded.

The Graph Pad Prisma V.3 software package was used for statistical evaluations. For data analysis, in addition to descriptive statistics (mean ± SD), the Friedman test for repeated multiple measures, the Kruskal-Wallis test for independent multiple group comparisons, Dunn's multiple comparison test for sub-group comparisons, the Wilcoxon test for paired group comparisons, and Fisher and χ^2 tests for repeated measures of qualitative data were used. A *P* value < 0.05 at the 95% confidence interval was considered significant.

RESULTS

A total of 14 patients were excluded from the study due to following reasons: gastrointestinal bleeding

Table 5 Percentage of lymphocyte subgroups in the peripheral blood of patients after nutrition (mean ± SD)

	IM	NN	SE	*P*
CD4	44.5 ± 10.09	41.62 ± 10.97	48.08 ± 12.98	> 0.05

that started after the nutrition programme, emergency surgery to relieve obstruction, and uncontrolled blood sugar levels. A total of 42 of patients completed the study. There were no significant differences between nutrition groups with regard to age, gender, albumin, prealbumin, lymphocyte count, and body mass index (BMI) values (Table 2).

At baseline, prealbumin levels were low in all groups, with no significant between-group differences (Table 3). Repeated measurements showed a significant increase only in the IMN group compared to baseline (15.98 ± 8.66, *P* = 0.037).

The number of lymphocytes with a CD4+ surface marker was higher in patients receiving SE nutrition before nutritional support (Table 4), but the difference was not significant. Within and between-group comparisons at the end of nutrition showed no significant differences between groups with regard to CD4+ lymphocyte counts (Table 5).

In patients that received normal nutrition (NN) and SE, the number of CD8+ cells was higher compared to normal counts (Table 5). Also, in patients who received NN, the proportion of CD8+ lymphocytes was significantly higher compared to IMN (*P* < 0.05). Following the nutrition, although a slight increase above the normal values was observed in IMN patients, the difference was not significant compared to baseline and other groups (*P* > 0.05).

CD4+/CD8+ ratio was within the normal range

Table 6 Data on the operation and postoperative follow-up (mean ± SD)

	IM n = 13	NN n = 9	SE n = 11	P
Duration of operation (min)	303.8 ± 160.1	248.9 ± 87.67	288.6 ± 71.28	> 0.05

Non-infectious complications	5	3	2	> 0.05
Duration of hospital stay (d)	16.54 ± 14.83	12 ± 3.69	14.22 ± 9.12	> 0.05

IM: Immunonutrition; NN: Normal nutrition; SE: Standard enteral nutrition.

before the nutrition (0.8%-1.8%) in all groups. There was a non-significant increase in that parameter in all groups after nutrition.

CD16+/56+ cell counts were below normal in all groups before and after the nutrition period, with no significant differences compared to baseline in any group. Similarly, there were no significant differences in the proportion of T cells with CD4+, CD8+ (double positive) surface markers before and after the nutrition in any group. Also, groups were similar with regard to these parameters at both time points.

CD69+ counts did not differ between or within the groups before and after the nutrition. In IM group, CD 69 counts after nutrition were obtained higher than the before nutrition group, however it was not statistically significant. Also, when the proportional increase in CD69 surface marker in response to a non-specific immune stimulator such as phytohemaglutinin (PHA) is considered, a significantly higher increase was observed in IM group compared to NN group and SE group (P < 0.05).

Of the 42 patients completing the study, 33 underwent radical surgical procedures. Among these patients, there were also no intergroup differences with regard to the duration of operation, incidence of infection, and length of hospital stay (P > 0.05) (Table 6).

DISCUSSION

Initially, nutritional support was aimed at meeting the energy needs and providing proteins and other essential micronutrients in order to prevent muscle breakdown and immunosuppression, while now it is more directed at modulation of the immune functions[5].

Among the nutrients with a suggested positive effect on immune functions, arginine, glutamine, fatty acids, and nucleotides have been studied most extensively. The two products that have been studied most are IMPACT, which contains arginine, fatty acids, and nucleotides, and IMMUNE-AID, which contains glutamine in addition[5]. In our study IMPACT was used.

Arginine stimulates T lymphocytes, provides a substrate for nitric oxide, and increases the secretion of insulin and growth hormone. Nitric oxide enhances the splanchnic micro-perfusion via vasodilator effects. Ornithine and proline are synthesized from arginine. Polyamine, an important factor for cell division, is synthesized from ornithine. Again, arginine causes volume increase in the thymus, and enhances the functions of macrophages and NK cells. It also accelerates wound healing[7,8,19-22].

Omega 3 fatty acids are the precursors for eicosanoids which include prostaglandin, prostacyclin, thromboxane and leukotrienes. They have anti-inflammatory properties which act through three different mechanisms[8,23].

Nucleotides are the precursors for RNA and DNA and are believed to enhance protein synthesis and T-cell functions[9,24]. Addition of nucleotides in nutrients has led to decreased incidence of fungal infections[25].

T lymphocyte activation, interferon γ, NK cell, immunoglobulin M, phagocytic capacity of leukocytes and increase in the number of lymphocytes have commonly been used by the investigators for the assessment of immune functions[5,26-29]. In the present study we examined certain lymphocyte subpopulations such as CD4+ (T helper), CD8+ (T cytotoxic, suppressor), CD16+/56+ (Natural killer), and CD69 cells.

The value of preoperative immunonutrition has now gained widespread acceptance. A shift from the production of acute phase proteins to building-block protein production, effective control of the immune disorder during the early postoperative period, and improved intestinal micro perfusion and oxygen metabolism have been reported in patients receiving immunonutrition[13,30]. At 2001 Consensus Meeting, a 5 to 10 d period was recommended for preoperative immunonutrition[31]. Thus, in this study nutrition was given for 7 d.

The suppression of immunity has been proposed to affect the prognosis adversely in cancer patients by increasing the growth and metastatic potential of residual tumor cells[32]. It can be expected that the preoperative nutrition may attenuate this suppression.

The patient group(s) most likely to benefit from immunonutrition has not been defined yet. Immunonutrition has been proposed to provide benefits in patients undergoing elective surgery for GIS tumors, while no benefit has been reported for intensive care patients, and increased mortality has been reported in patients with sepsis[12,33,34]. Generally, malnourished patients are accepted as candidates for artificial nutrition. On the other hand, Braga et al[15] recommend the use of perioperative immunonutrition in all patient groups regardless of the nutritional status. Our patient group consisted of subjects with moderate or severe malnutrition compared to SGA.

Despite continuing controversy, many studies have been examining the role of immunonutrition in patients with upper GIS tumors, trauma, or in ICU patients. Usually a lower incidence of infections and shortened length of hospital stay were observed in patients with

upper GIS tumors and in ICU patients[5].

Braga et al. found that in the first postoperative day, standard diet and immunonutrition did not differ significantly in their effects on phagocytic capacity, cytokine profile, immunoglobulin levels, number of active T and B lymphocytes, and lymphocyte mitogenicity. However, from the 4th postoperative day, an improvement in immunodepression was observed. In patients receiving normal nutrition preoperatively for whom a significant level of immunosuppression is expected, preoperative immunonutrition has been shown to decrease the postoperative infection rate[15]. Matsuda et al. observed an improved TH1/TH2 balance with the use of pre- and postoperative immunonutrition[34].

Most of the patients with cancer suffer from protein-energy malnutrition. The prealbumin levels were low in every 3 patient groups. After nutrition there was a significant increase only in the immunnutrition group. However, Riso et. al declared that there was no increase in the prealbumin levels between postoperative immunonutrition and control patients[35].

The association between major surgery and the decrease in total number of T lymphocytes, suppressor or cytotoxic T lymphocytes and NK cells has been recognized since 1975[36]. In the present study, in contrast with many other studies, preoperative assessment of immune functions allowed us to examine the effect of immunonutrition on immunosuppression caused exclusively by the tumor and malnutrition. No effect on CD4+ and CD8+ cells was observed, although a partial improvement was observed in the IMN group.

Before nutrition, the number of natural killer cells (CD16+/56+) were below the normal range, and none of the nutritional models caused a significant increase in this parameter. CD69+ counts did not differ significantly between the groups.

In the present study, cellular immune response was assessed only by peripheral blood measurements shortly after the termination of nutrition on day 8. On the other hand, Sakurai *et al*[37] (in non-surgical patients) administered enteral immunonutrition to their patients for 12 wk with positive results. In our opinion, such a delay is not acceptable for patients who will undergo cancer surgery.

In conclusion, in the present study preoperative immunonutrition provided a significant increase in prealbumin levels, but did not alter the T lymphocyte subpopulation counts significantly. Further studies are warranted for the assessment of the effect of immunonutrition on antitumor immune response, and we believe that evaluation of tumor infiltrating cells in addition to peripheral blood parameters may provide new insights on this issue.

COMMENTS

Background
Malnutrition is known to have adverse effects on immunity, such as atrophy in lymph nodes, decrease in lymphocyte count and IgA secretion, and suppression in immunity. It is reported in several studies that nutritional support is useful in patients with malnutrition. With addition of immunonutrient products to nutritional therapies, their beneficial effect on immune response is searched for in many prospective clinical studies. Most of the studies are about postoperative complications, frequency of development of infection, hospital stay, wound healing, weight gain, cost, and mortality. The basic defensive response developed by the host against tumors is directed by cellular immunity. There are few studies detecting the changes in cellular immune response after immunonutrition and before the patient has had the surgical trauma. By evaluating the effect of immunonutrition on immunologic parameters preoperatively, the effects of the inflammatory process produced by surgical stress on the results can be avoided.

Research frontiers
The advantages of the nutritional support can be evaluated by the operative mortality, morbidity, and hospital stay. However, how and with which mechanisms this useful effect develops must be detected separately. For that we must see the nutritional subparameters, albumin, prealbumin, immuneglobulin, and immune parameters such as lymphocyte count, change in T lymphocytes, and NK cells.

Innovations and breakthroughs
The authors emphasized changes in T lymphocytes responsible for cellular immunity with immunonutrition before the operation, and measurement of other parameters responsible for immune response, such as tumor infiltrating lymphocytes.

Application
Immune parameters can also be evaluated when the patients are prepared for operations and patients can be supported with immunonutrition if found deprived.

Peer review
This study is a straightforward analysis of the effects of immunonutrition on immune cellular markers and prealbumin on the postoperative course of patients with tumors. Although this is a negative study, it is helpful in avoiding expensive nutritional supplements in those patients requiring cancer surgery.

Abstract

AIM: To evaluate the prevalence and clinical characteristics of Nonalcoholic fatty liver disease (NAFLD) among asymptomatic Brazilian adolescents.

METHODS: Transversal observational study included asymptomatic adolescents with central obesity from private and public schools in Salvador-Bahia, northeastern Brazil. The children answered a questionnaire that included age, gender, race, and medical history, and were submitted to a complete physical exam and abdominal ultrasound. Biochemical exams included: ALT, AST, GGT, C reactive protein (CRP), fasting glucose, insulin, cholesterol and triglycerides. Criteria for NAFLD included: the presence of steatosis in ultrasound and/or high level of ALT, negative or occasional historic of intake of alcohol ($\leqslant$ 140 g/wk), negative investigation for hepatitis A, B, C, auto-immune hepatitis, Wilson disease and hemochromatosis.

RESULTS: From October, 2005 to October, 2006, the study included 1801 subjects between 11 and 18 years of age and a mean age of 13.7 ± 2.0 years. One hundred ninety-nine had central obesity. The prevalence of NAFLD was 2.3%, most of whom were male and white. Insulin resistance (IR) was observed in 22.9% of them and had positive correlations with ALT and GGT ($P < 0.05$). Elevated CRP was observed in 6.9% of the cases; however, it was not associated with WC, IR or liver enzymes.

CONCLUSION: The prevalence of NAFLD in Brazilian adolescents was low. The ethnicity may have influence this frequency in the population studied, which had a large proportion of African descendents.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is a clinical-pathological condition of wide spectrum, which includes steatosis and steatohepatitis, that has a potential to advance to cirrhosis and hepatocellular carcinoma[1].

Obesity is the most relevant risk factor for NAFLD in children and several studies have described the prevalence and risk factors of NAFLD in these populations[2,3].

Reports of NAFLD in the child population was described in boys and girls between 10 and 13 years of age who showed elevated aminotransferase levels and variable degrees of steatosis, inflammation and fibrosis

in hepatic biopsies[4]. NAFLD occurrence varies with race/ethnicity and gender[5]. A recent study shows body mass index (BMI) as an independent factor for hepatic fibrosis in children and adolescents with NAFLD[6]. In adults and adolescents, visceral obesity has been considered the main risk factor for the development of hepatic steatosis[7,8]. However, most studies have been done with convenient samples of obese adolescent groups treated in clinics for obesity, which may influence the prevalence of NAFLD in these individuals[9,10].

In Brazil, previous studies estimated that 15% of students are overweight or obese[11,12]; however, the prevalence of NAFLD in this population is not known. The present study aimed to evaluate the prevalence and the clinical characteristics of NAFLD among asymptomatic Brazilian adolescents.

MATERIALS AND METHODS

Study design and population selection

Transversal observational study included asymptomatic adolescents from seven high schools in Salvador, Bahia, Brazil who presented central obesity. Salvador is a city in the northeast of Brazil, where it is relevant to account for the proportion of African descendents.

The study was approved by the Ethics Committee for Research from MCO-Programa de Pós Graduação em Medicina e Saúde-Universidade Federal da Bahia, Brazil.

Inclusion criteria: Age between 11 and 18 years old; abdominal circumference > 75th percentile, according to age and sex[13]; free and pre-explained consent term, signed by the adolescents and their caregivers.

Exclusion criteria: Previous historic or serologic markers for liver diseases (hepatitis A, B, C), auto-immune disease, metabolic diseases such as Wilsons Disease and hemochromatosis and intake of alcohol above 140 g/wk.

Criteria for diagnosis of NAFLD: Presence of steatosis in ultrasound scan and/or high levels of ALT and/or AST; negative or occasional historic alcohol intake ($\leqslant$ 140 g/wk); negative diagnosis of other liver diseases (A, B and virus, autoimmune hepatitis, metabolic liver disease).

Clinical evaluation

For anthropometric evaluation, a sample of blood was collected and a superior abdomen ultrasound scan was performed during the same session at the nursing of the schools.

Anthropometric measures: waist circumference (WC) was measured at the end of normal expiration in the middle portion between the last rib and the iliac ridge. For evaluation, reference values were adopted that consider normal abdominal circumference to be $\leqslant$ 75th percentile and increased abdominal circumference to be > 75th percentile according to age and sex[13].

Participants were weighed while not wearing coats

or shoes or carrying any objects. A Filizola balance was used, with a scale resolution of 0.1 kg. Height was measured by a stadiometer with no shoes and hair accessories; the resolution was 0.5 cm. BMI was calculated by dividing weight by height squared. Subjects were considered to be overweight at a BMI between the 85th and 95th percentile and obese at a BMI above the 95th percentile for a given age and sex, based on Cole[14].

All adolescents underwent superior abdomen ultrasound scan (AUS). The AUS was performed by only one medical doctor. The scanner used was an Aloka, model DynaView II, with colored Doppler and a 3.5 MHz drill. The discrepancy of echogenicity between the liver and kidney was considered as a criterion. Hepatic steatosis was graded as mild, moderate or severe, according to the Saverumuttu et al[15] classification.

Serological assays

Blood samples were collected by the technical staff from adolescents after a 12 h fast. The samples were analyzed in a referential laboratory for AST, ALT, GGT, C reactive protein (CRP), fasting glucose and insulin. Aminotransferase alterations were considered when AST was > 36 U/L for girls and > 59 U/L for boys, ALT > 52 U/L for girls and >72 U/L for boys, and GGT > 43 for girls and > 73 U/L for boys. High-sensitivity CRP assay was conducted using latex-enhanced nephelometry.

Individuals who presented elevated ALT, AST and GGT levels underwent the following exams: HBsAg, anti-HCV, anti-HAV-IgM, antibodies (anti-nuclear, anti-muscle, anti-LKM, anti-mitochondrial) α_1-antitrypsin, ceruloplasmin and serum copper.

Serum glucose and insulin were used for the calculation of *homeostasis model assessment* (HOMA) = [fast insulin (μIU/mL) × fast glucose (mg/dL)/22.5] (mg/dL = mmol/L × 18.182), considering $\geqslant$ 3.16 as a cutoff point to define insulin resistance[16].

The adolescents diagnosed with NAFLD were provided assistance at the NASH Group.

Statistical analyses

The data were analyzed using Statistical Package for Social Science (SPSS) 13.0. Mistake type I was estimated to be 5%. Spearman was used for the correlation between variables and t-test to compare the mean. The data are expressed as percentage, medium and standard deviation.

RESULTS

Between October, 2005 and October, 2006, seven public and private schools participated in the study. This corresponded to 3500 students. Among these students, 1801 (51.5%) adolescents agreed to participate in the study. The present study included 199 individuals who had central obesity (WC > 75 percentile). Twenty-four (12.1%) of them were excluded: one had a history of alcohol consumption above 140 g/wk and 23 had incomplete data.

Among 175 adolescents evaluated, the mean age was 13.7 ± 2.0 years, 54.3% were female and 71.4% (125)

Table 1 Clinical characteristics of 175 asymptomatic adolescents with central obesity second ethnicity (mean ± SD)

Variable	Nonwhite (*n* = 125)	White (*n* = 50)
Sex F/M (%)	58.4/41.6	44.0/5.0
Age (yr)	13.74 ± 2.02	13.70 ± 2.00
BMI (kg/m^2)	27.41 ± 3.27	26.64 ± 3.26
WC (cm)	88.09 ± 7.76	88.65 ± 9.26
AST (U/L)	24.11 ± 4.83[a]	26.53 ± 6.77
ALT (U/L)	31.41 ± 7.32	32.96 ± 13.70
GGT (U/L)	22.03 ± 6.68	21.04 ± 11.69

Table 2 Clinical characteristics of 4 asymptomatic adolescents with NAFLD

Adole-scents	Age (yr)	Sex	Elevated enzyme	Steatosis	Class BMI	Ethnicity
1	17	Boy	AST, ALT, GGT	Moderate steatosis	Obese	White
2	15	Boy	No	Mild steatosis	Obese	White
3	12	Boy	No	Mild steatosis	Overweight	White
4	15	Girl	ALT	No	Obese	Nonwhite

Figure 1 Correlation between body mass index and waist circumference in 175 asymptomatic adolescents with central obesity, Salvador-Bahia, 2005-2006.

were nonwhite. AST level was statistically higher in white adolescents as compared to nonwhite adolescents (*P* < 0.05), as shown in Table 1.

Overweight was observed in 64.0% of studied adolescents with central obesity. There was a positive correlation between BMI and WC values, as shown in Figure 1.

Hepatic steatosis to AUS was observed in 1.7% (3) individuals. All of them were males and white, two were obese and one was overweight. One of the obese adolescents showed moderate steatosis on ultrasound and elevated ALT, AST and GGT. Two of them had mild steatosis on AUS and normal ALT, AST and GGT.

Among the 175 adolescents studied, 2.8% (5) showed elevated aminotransferases. One girl had isolated elevated ALT. One boy had elevated AST, ALT and GGT. All had BMI > 95th percentile. Elevated GGT was observed in 3 cases, two girls and one boy.

According NAFLD criteria (presence of steatosis in ultrasound scan and/or high levels of ALT and/or AST) four (2.3%) adolescents had NAFLD diagnosis (Table 2).

WC had a statistically significant correlation with ALT and GGT (P < 0.05). This finding remained after exclusion of a few outliers. IR was observed in 22.9% (40) of adolescents. Only one (1) adolescent with isolated elevated GGT had IR. Insulin resistance also had a statistically significant correlation with ALT and GGT (*P* < 0.05) after exclusion of a few outliers.

Elevated CRP was observed in 6.8% (12) of adolescents. However, adolescents with hepatic steatosis and/or elevated aminotransferases did not have elevated CRP.

DISCUSSION

The present study shows the prevalence and clinical

characteristics of NAFLD among Brazilian asymptomatic adolescents.

The prevalence of 2.3% is consistent with some studies based on the frequency of elevated aminotransferases or fatty liver in obese populations[8,17]. Tominaga *et al*[18] found a prevalence of 2.5% fatty liver in a Japanese study of 810 obese children between 4 and 12 years old, and Alavian *et al*[19] found among 966 obese children in Iran aged 7-18 years 1.8% with elevated ALT.

However, the majority of the cases presented central obesity, identified through isolated measure of WC. It also has been demonstrated as an independent risk factor for development of NAFLD in adults and children, and it is considered more important than obesity[20]. Central obesity has been related to IR, one of the factors related to the pathogenesis of NAFLD[21,22].

Positive correlation between BMI and WC in adolescents, as observed in this study, is also a common finding related to cardiovascular disease in this population[23,24].

This investigation also observed that the majority of adolescents with fatty liver on AUS were obese (BMI ≥ 95th percentile), which may be related to the degree of association between steatosis and BMI[9,25].

Higher frequency of NAFLD in adolescents has been shown[5,9]; however, other factors may explain this difference between the present investigation and prior ones. The majority of them have included adolescents or children from obesity clinics[26,27]. Another factor was that only half of the eligible children agreed to participate of the study. The discrimination that may occur among obese young people may influence the decision of these people to not consent to the study.

Another influence factor may be ethnicity. It has been considered as an important factor for the different frequencies of NAFLD in children populations. It is more common in Hispanic and less so in black adolescents[5]. In Salvador-Bahia, a city in the northeast of Brazil, the majority of the population are of African descendents. Although this study did not aim to evaluate race, these simple of the population came from an area

in Brazil where a relevant factor is the proportion of African descendents, and it may explain the low prevalence of NAFLD in this study.

The characteristics of disease appear to be similar to those in other studies. Gender has not been considered to be a risk factor for NAFLD in children[28]; however, a higher degree of hepatic steatosis has been found in boys compared to girls, at a ratio of 2:1[5,18]. In this sample, the adolescents with NAFLD were males, corroborating previous reports.

Elevated ALT levels in asymptomatic individuals have been considered useful as a marker to screen patients with NAFLD; they have a correlation with abdominal fat[29], and higher levels of ALT correlated to grades of fat in hepatocytes[3,25]. In obese children, ALT has been considered as a predictor of NAFLD[27]. Elevated levels of ALT were observed only in one adolescent, who had moderate degree of liver steatosis, and in one adolescent with normal AUS, thus showing a correlation between WC and IR.

The frequency of IR was relevant to this study. And despite the positive correlation with ALT and GGT, elevated hepatic enzymes or steatosis were not common. The literature shows that IR is a risk factor for and is associated with NAFLD, mainly with elevated ALT[2,30].

The elevation of CRP in obese adults has been considered a risk factor for progression of NASH[31], and the low prevalence of NAFLD in this study may justify the low occurrence of elevated CRP.

Two female adolescents had isolated elevated GGT. However, GGT is not considered a predictor of NAFLD in obese children. In studies with adults, GGT is associated with NAFLD and the metabolic syndrome, especially in women[32-34]. Fraser et al[35], when studying hepatic enzymes in women who had and had not diabetes, observed an association of serum GGT with IR in both groups. We observe that one adolescent with elevated GGT also had IR.

In conclusion, NAFLD in asymptomatic Brazilian adolescents was most frequent among white males with central obesity and the mean age of 13.7 ± 2.0 years. These adolescents came from an area in Brazil where it is relevant to consider the proportion of African descendents, and the influence of ethnicity on the prevalence the NAFLD may be an important factor in this population. However, this hypothesis deserves future study.

ACKNOWLEDGMENTS

COMMENTS

Background

Non-alcoholic fatty liver disease (NAFLD) is a common condition among in obese children patients. However, the prevalence of NAFLD has varied in different populations. The influence of gender, risk factors and ethnicity have been discussed. However, more studies are considered necessary to elucidate the relevance of this liver disease in adolescents.

Research frontiers

This study reported the findings of NAFLD prevalence of 2.3% in 175 adolescents with central obesity. The prevalence of NAFLD in these adolescents was lower than others studies and we speculate that ethnicity may influence the prevalence in this population. They come from an area in Brazil where a relevant factor is the proportion of African descendents. However, this hypothesis deserves future study.

Innovations and breakthroughs

This is one of the first Brazilian studies which evaluated the prevalence of NAFLD in adolescents with central obesity. This investigation showed a low prevalence of this liver disease and we hypothesized the influence of ethnicity in the lower frequency NAFLD in this population.

Applications

The prevalence of NAFLD and associated factors in different populations is important for understanding its development, and to implement preventive strategies to control of the disease.

Terminology

NAFLD means Non-alcoholic Fatty Liver Disease; HOMA-IR is homeostasis model assessment index-insulin resistance

Peer review

The work is interesting. Rocha et al describe the epidemiology of NAFLD in a cohort of children from Brazil. The study is strengthened by a solid research design and large numbers. While the findings are not particularly novel, it is helpful to have this sort of basic epidemiology data in the literature.

Abstract

AIM: To compare the histologic features of the liver in intrahepatic neonatal cholestasis (IHNC) with infectious, genetic-endocrine-metabolic, and idiopathic etiologies.

METHODS: Liver biopsies from 86 infants with IHNC were evaluated. The inclusion criteria consisted of jaundice beginning at 3 mo of age and a hepatic biopsy during the 1st year of life. The following histologic features were evaluated: cholestasis, eosinophilia, giant cells, erythropoiesis, siderosis, portal fibrosis, and the presence of a septum.

RESULTS: Based on the diagnosis, patients were classified into three groups: group 1 (infectious; $n = 18$), group 2 (genetic-endocrine-metabolic; $n = 18$), and group 3 (idiopathic; $n = 50$). There were no significant differences with respect to the following variables: cholestasis, eosinophilia, giant cells, siderosis, portal fibrosis, and presence of a septum. A significant difference was observed with respect to erythropoiesis, which was more severe in group 1 (Fisher's exact test, $P = 0.016$).

CONCLUSION: A significant difference was observed in IHNC of infectious etiology, in which erythropoiesis was more severe than that in genetic-endocrine-metabolic and idiopathic etiologies, whereas there were no significant differences among cholestasis, eosinophilia, giant cells, siderosis, portal fibrosis, and the presence of a septum.

INTRODUCTION

The frequency of cholestatic jaundice is difficult to evaluate with certainty, but varies between 1:2500 and 1:5000 newborns[1-3]. The initial approach in the diagnosis of cholestasis is to distinguish between intrahepatic and extrahepatic causes, as the latter etiology requires early surgical intervention[4]. In general, intrahepatic neonatal cholestasis (IHNC) represents 2/3 of the cases of neonatal cholestasis[5-9]. The most common causes of IHNC are of infectious origin[10-12]. In septicemia, manifestations of hepatic origin represent only one component of the involvement of multiple organs, of which adequate treatment offers the best chance of recovery[13]. Any serious bacterial infections during the neonatal period can result in jaundice[14]; however, there seems to be a more frequent association with urinary tract infections, especially when the pathogen is *E. coli*[15]. In addition, other

infections have been observed, such as syphilis, toxoplasmosis, rubella, and cytomegalovirus (CMV)[16-20].

Despite the many possible etiologies for IHNC[5], 13%-78% of the cases have been reported to be idiopathic[21-24]. Idiopathic IHNC implies that the liver suffers inflammatory alterations of unknown cause, with no evidence of blockage of the biliary tree, and infectious agents or metabolic errors have been ruled out[1,25,26]. There are cases of idiopathic IHNC which are considered spontaneous in which there is familial recurrence, therefore sporadic cases could possibly consist of a viral injury or another environmental factor that affect the transitory form of the immature liver of the newborn; however, the characteristics are similar in both cases[13,27].

Liver biopsy is currently used to confirm the clinical diagnosis and to assess the degree of necroinflammatory injury or fibrosis. Most studies of percutaneous liver biopsy are retrospective analyses and the aim is usually to differentiate biliary atresia from neonatal hepatitis[12,21,28-32].

There are no data available in the literature pertaining to the histologic features present in neonatal hepatitis to aid in the differential diagnosis of IHNC. The objectives of the present study were to analyze and compare the histologic features of the liver in IHNC of infectious, genetic-endocrine-metabolic, and idiopathic etiologies, in the search for features which can facilitate the diagnostic process.

MATERIALS AND METHODS

Eighty-six patients submitted to liver biopsy during IHNC investigation between March 1982 and December 2005, 72 from the State University of Campinas Teaching Hospital (UNICAMP) and 14 from the Children's Institute of the University of São Paulo (USP). Among the 86 hepatic biopsies, 5 were surgical and 81 were percutaneous. The inclusion criteria consisted of jaundice beginning at 3 mo of age and hepatic biopsy during the first year of life.

In order to establish the etiology of IHNC, the following were reviewed: serum alpha-1-antitrypsin, sweat sodium and chloride test, innate metabolic errors in urine, polymerase chain reaction for CMV antigenemia, and serology for CMV, human immunodeficiency virus, hepatitis B virus (HBV), hepatitis C virus (HCV), Epstein-Barr virus, rubella virus, *Toxoplasma gondii*, and *T. pallidum.*

Seven histologic variables were evaluated by means of an investigation protocol: cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis, portal fibrosis and the presence of a septum. Siderosis and cholestasis were evaluated by Perls' staining and portal fibrosis and the presence of a septum by Masson staining.

The histologic variables (cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis and portal fibrosis) were classified according to the degree of intensity using a grading system (Table 1). The histologic variable, septum was classified by: presence or absence.

Ethical aspects
The present research study was approved by the medical research ethics committees of both institutions. Informed consent was not required because liver biopsies were performed during the course of clinical evaluation.

Statistical analysis
In order to verify associations between categorical variables, the χ^2 test was used. When the expected values were < 5, the Fisher's exact test was used[33]. Significance was established as $P \leqslant 0.05$ in all tests. The computer software used was SAS for Windows, version 8.02 (SAS Institute Inc., Cary, NC, USA).

RESULTS

Based on the etiology of IHNC, the patients were classified into three groups: group 1 (infectious; $n = 18$), group 2 (genetic-endocrine-metabolic; $n = 18$), and group 3 (idiopathic; $n = 50$). The etiologies of IHNC are presented in Table 2.

Twenty-seven patients were females and 59 were males. Patients were predominantly boys in all 3 groups ($P = 0.407$).

The mean age at the time of liver biopsy was as follows: group 1, 2 mo and 15 d (range, 1-6 mo and 9 d); group 2, 2 mo and 15 d (range, 1-6 mo and 8 d); and group 3, 2 mo and 24 d (range, 13 d-9 mo and 5 d). There were no statistical differences among the groups ($P = 0.428$).

Table 3 shows values for birth weight, weight during the first medical visit and stature at birth for the groups. There were no significant differences among the groups according to the variables: weight during the first medical visit and stature at birth. However, a significant difference was observed for birth weight, which was lower in group 1 in relation to groups 2 and 3 ($P = 0.014$).

The degree of cholestasis was not significantly different between the 3 groups studied ($P = 0.078$; Figure 1A). The presence of giant cells, graded as absent, mild, moderate, and severe in groups 1, 2, and 3 did not show any significant differences ($P = 0.144$; Figure 1B).

The presence of eosinophils in the inflammatory infiltrate did not differ when the genetic-endocrine-metabolic and/or idiopathic groups were compared ($P = 0.056$; Figure 1C). A significant difference was observed for to the variable, erythropoiesis in group 1 ($P < 0.05$; Figure 1D).

With respect to siderosis, there was no correlation with the etiology of IHNC ($P = 0.973$; Figure 1E).

With respect to progression of IHNC to chronic stages, portal fibrosis (Fisher's exact test $P = 0.86$) and the presence of a septum ($\chi^2 = 3.83$; $P = 0.147$) were not related to the etiology of IHNC (Figure 1F and G).

DISCUSSION

Liver biopsy is recommended for the diagnosis of cholestasis of unknown etiology. The interpretation of a single liver biopsy in a child with neonatal cholestasis is

Table 1 Grading system used for histological parameters: cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis, and portal fibrosis

	Mild	Moderate	Severe
Cholestasis	Biliary pigment deposits in few hepatocytes of zone 3 acini	Hepatocytes with biliary pigment in two zone 3 acini associated with the presence of rare canalicular bilirubinostasis	The majority of the hepatocytes with biliary pigment biliary associated with several canalicular bilirubinostasis
Eosinophilia in the inflammatory infiltrate	Rare eosinophils in few space-porta	Some eosinophils in many space-porta and rare in the parenchyma	Many eosinophils in all the space-porta and several in the parenchyma
Presence of giant cells	Occurring in a maximum of 30% of the hepatocytes	Between 30% and 60% of the hepatocytes	> 60% of the hepatocytes
Erythropoiesis	Rare groupings of erythroblasts	Some groupings of erythroblasts	Groupings of erythroblasts and megakaryocytes
Siderosis	Deposits of ferric pigment in only a few Kupffer cells	Deposits of ferric pigment in Kupffer cells and a few hepatocytes	Deposits of ferric pigment in the majority of Kupffer cells and many hepatocytes
Portal fibrosis	Discrete widening of some space-porta	Widening of some space-porta	Widening of all space-porta

Total		86

Table 3 Clinical characteristics of the patients during the first evaluation, in accordance with groups 1 (infectious), 2 (genetic-endocrine-metabolic) and 3 (idiopathic)

	Group 1	Group 2	Group 3	P
Birth weight (g)	2160	2780	2750	0.014
	(SD = 650)	(SD = 594)	(SD = 767)	
Weight during the first medical visit (g)	3040	3567	3970	0.105
	(SD = 1014)	(SD = 1170)	(SD = 1074)	
Stature at birth (cm)	44.5	47	48	0.373
	(SD = 4.26)	(SD = 3.51)	(SD = 5.22)	

A significant difference was observed for birth weight, which was lower in group 1 in relation to groups 2 and 3 ($P < 0.05$).

limited by the dynamics of the disease. Interpretation of the biopsy findings is pathologist-dependent and requires experience[4,33].

Most studies involving percutaneous liver biopsies are retrospective analyses, using the clinical course, surgical or autopsy results as a gold standard. However, the goal is usually to differentiate biliary atresia from neonatal hepatitis[21,28-32].

Many cholestatic conditions are expressed differently with time. Liver biopsy can also provide disease-specific findings. Examples include PAS-positive granules in alpha-1 antitrypsin deficiency, paucity of ducts in Alagille syndrome, necroinflammatory duct lesions in sclerosing cholangitis, and other findings that are relatively specific for metabolic and storage diseases[4,34,35].

Hepatic erythropoiesis was more evident in INHC of infectious etiology. This was not clear in the idiopathic group, which was likely due to the participation of an undetected infectious agent. On the other hand, hepatic erythropoiesis strongly suggests an infection.

Fetal hematopoiesis has an onset in the beginning of gestation. Initially, hematopoiesis is restricted to the vitelline bag up to the gestational age of 6-8 wk, when the liver starts to be the predominant organ of production.

At 20 wk, the bone marrow becomes the main organ of hematopoiesis and remains as the primary reservoir for the circulating population of immune cells. However, when there are infectious processes, hepatic production persists[34].

The presence of eosinophilia in the inflammatory infiltrate, an important marker of neonatal hepatitis[35], did not show significant differences when compared to the genetic-endocrine-metabolic and/or idiopathic groups. The degree of cholestasis, a morphologic variable, which is extremely important for the differential diagnosis of extra- and intra-hepatic cholestasis, did not show a significant difference between the 3 patient groups. Similar findings were observed in relation to progression to chronic stages, demonstrating that portal fibrosis or a septum is not related to the etiology of the process. In relation to siderosis and the presence of giant cells, our findings did not demonstrate any correlation with the etiology of IHNC.

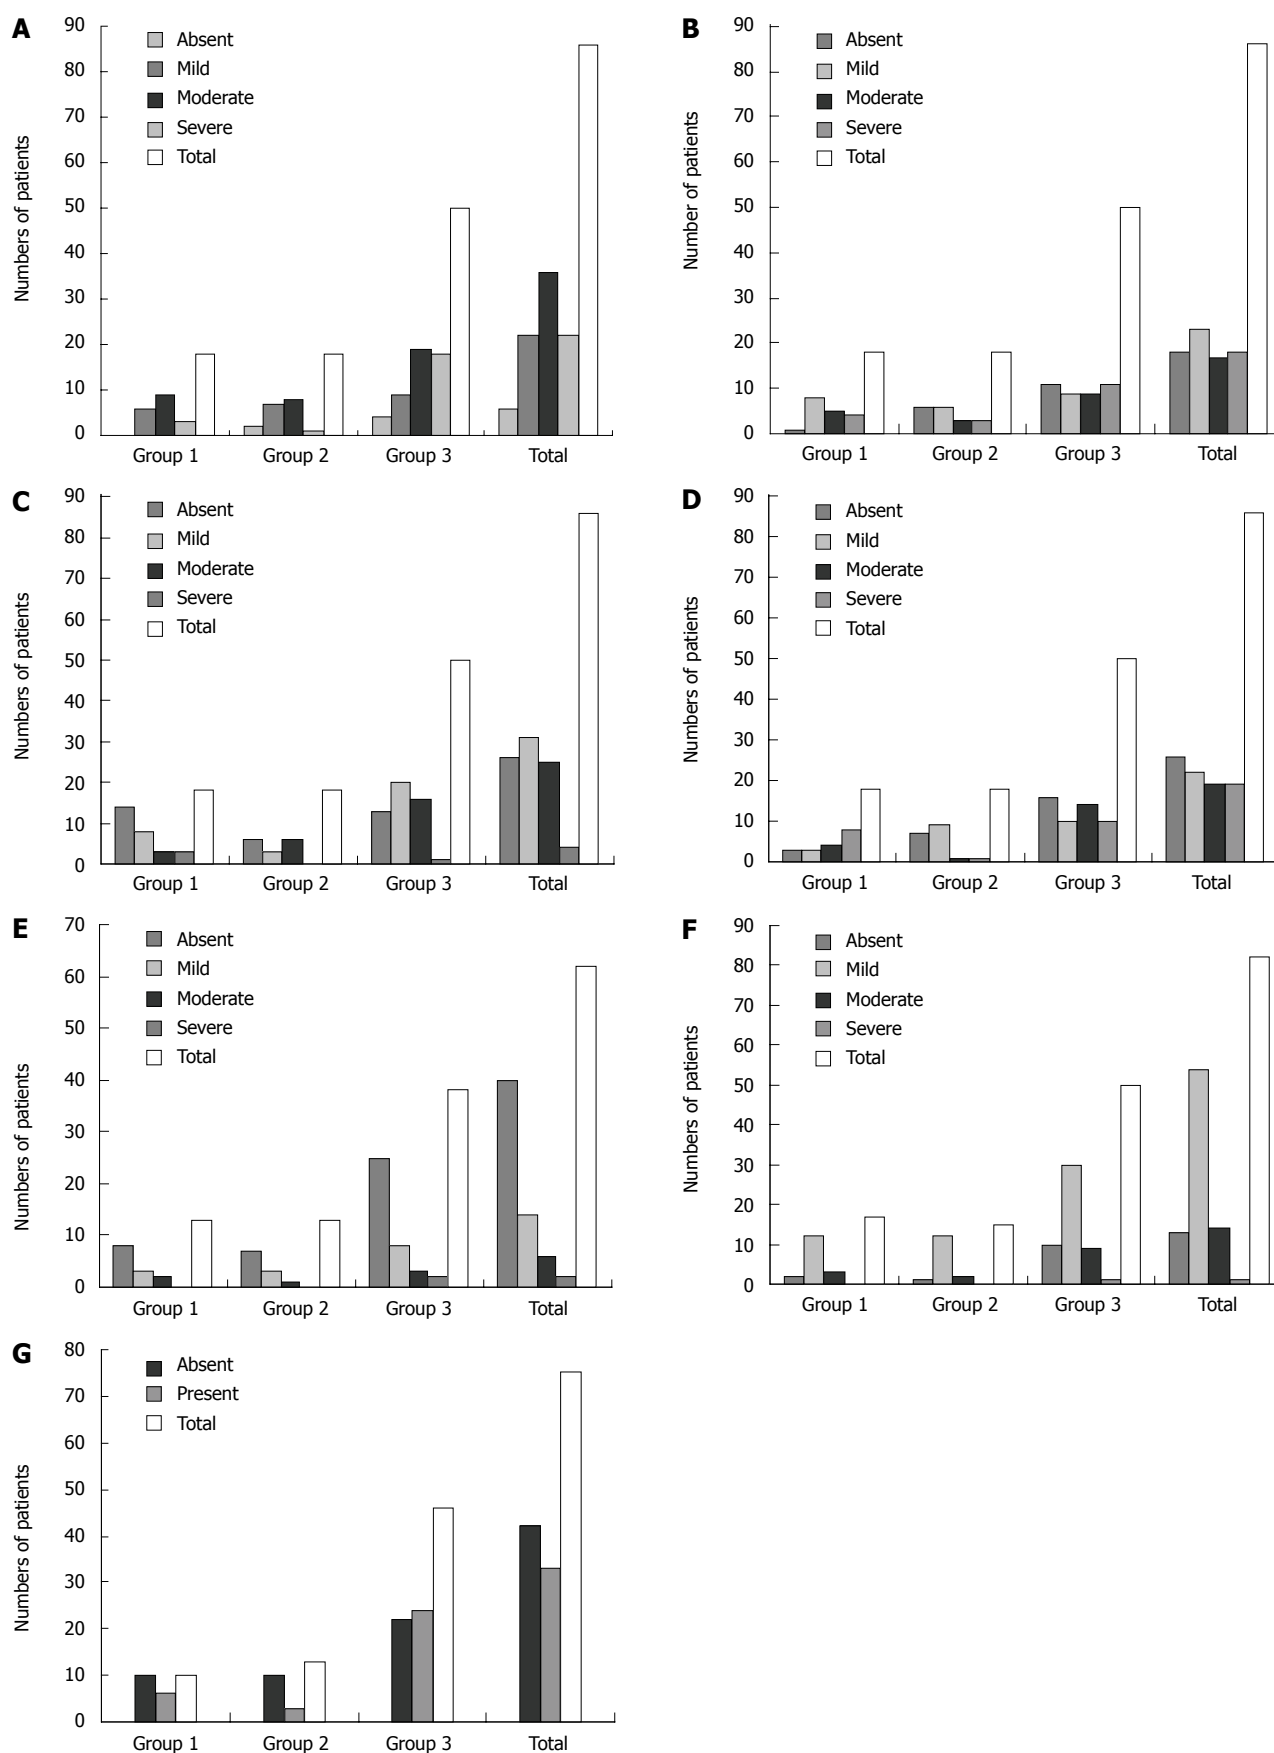
In conclusion, there are no data available in the literature analyzing the histologic features usually present in neonatal hepatitis in the differential diagnosis of IHNC. There were no significant differences among different etiologies of IHNC in relation to the following histologic features: cholestasis, eosinophilia, giant cells, portal fibrosis, the presence or absence of a septum, and siderosis. A significant difference was observed in IHNC of infectious etiology, which presented with more severe


Figure 1 Results of analysis of histologic features present in intrahepatic neonatal cholestasis (IHNC). A: Cholestasis: there was no significant difference between the 3 groups studied ($P > 0.05$); B: Giant cells: there was no significant difference between the 3 groups studied ($P > 0.05$); C: Eosinophils: there was no significant difference between the 3 groups studied ($P > 0.05$); D: Erythropoiesis: there was a significant difference in group 1 ($P < 0.05$); E: Siderosis: there was no significant difference between the 3 groups studied ($P > 0.05$); F: Portal fibrosis (graded as absent, mild, moderate, and severe): there was no significant difference between the 3 groups studied ($P > 0.05$); G: Septum (graded as absent or present) in groups 1 (infectious), 2 (genetic-endocrine-metabolic) and 3 (idiopathic): there was no significant difference between the 3 groups studied ($P > 0.05$).

erythropoiesis than the genetic-endocrine-metabolic and idiopathic etiologies.

In the present study, erythropoiesis was more severe in cases of infectious etiology than in genetic-endocrine-metabolic and idiopathic etiologies and should prompt an investigation for infection.

COMMENTS

Background

Seven histologic variables were evaluated in 86 patients submitted to liver biopsy during intrahepatic neonatal cholestasis (IHNC) investigation: cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis, portal fibrosis and the presence of a septum. There were no significant differences among the different etiologies of IHNC in relation to: cholestasis, eosinophilia, giant cells, portal fibrosis, the presence or absence of a septum, and siderosis. A significant difference was observed in IHNC of infectious etiology, which presented with more severe erythropoiesis than the genetic-endocrine-metabolic and idiopathic etiologies and should prompt an investigation for infection.

Research frontiers

Because of the several possible diagnoses with similar clinical presentation we need to look for features that can help in the diagnostic process of IHNC and a scoring system for histologic features could be useful.

Innovations and breakthroughs

The initial approach of liver biopsy is usually used to distinguish between intrahepatic and extrahepatic neonatal cholestasis. This is the first study to analyze standardized histologic features usually present in IHNC (cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis, portal fibrosis and the presence of a septum) in the differential diagnosis of IHNC.

Applications

Liver biopsy should be interpreted by a pathologist with expertise in pediatric liver disease.

Terminology

Cholestasis, eosinophilia in the inflammatory infiltrate, presence of giant cells, erythropoiesis, siderosis, portal fibrosis and the presence of a septum are histologic features usually present in neonatal hepatitis. A scoring system for these histologic features was used in the differential diagnosis of IHNC.

Peer review

This is a well written analysis of the histologic features in the differential diagnosis of IHNC. Although it is not a landmark finding the report is of value in that it points out that severe erythropoiesis would be a criterion indicating IHNC of infectious etiology.

Abstract

AIM: To evaluate the usefulness of stool-PCR test for diagnosis of *Helicobacter pylori* (*H pylori*) infection in pediatric populations.

METHODS: Based on endoscopic features (including nodular gastritis, erosive duodenitis and ulcer) and/or a positive rapid urease test (RUT) obtained during endoscopy, 28 children from a group of children admitted to the Children's Medical Center of Tehran for persistent upper gastrointestinal problems were selected to compare biopsy-based tests with stool-PCR. Their gastric activity and bacterial density were graded by the updated Sydney system, and their first stool after endoscopy was stored at -70℃. Biopsies were cultured on modified campy-blood agar plates and identified by gram-staining, biochemical tests, and PCR. Two methods of phenol-chloroform and boiling were used for DNA extraction from *H pylori* isolates. Isolation of DNA from stool was performed using a stool DNA extraction kit (Bioneer Inc, Korea). PCR was performed using primers for detection of *vacA*, *cagA*, and *16srRNA* genes in both isolates and stool.

RESULTS: Sixteen out of 28 child patients (57%) were classified as *H pylori* positive by biopsy-based tests, of which 11 (39%) were also positive by stool-PCR. Sensitivity and specificity of stool-PCR was 62.5% and 92.3% respectively. *H pylori* was observed in histological sections for 10 out of 11 stool-positive patients. Association was observed between higher score of *H pylori* in histology and positivity of stool-PCR. Also association was observed between the more severe form of gastritis and a positive stool-PCR.

CONCLUSION: Association between higher score of *H pylori* in histology and a positive stool-PCR make it a very useful test for detection of *H pylori* active infection in children. We also suggest that a simple stool-PCR method can be a useful test for detection of *H pylori* virulence genes in stool.

INTRODUCTION

Helicobacter pylori (*H pylori*) infection in humans is associated with gastritis, gastric ulcer, and gastric cancers[1,2]. Infection occurs mainly in childhood and infected individuals usually carry it for life unless treated[3,4]. Epidemiology of infection by *H pylori* has been characterized by a linear increase with age in western industrial countries and by a large number of children and juveniles being infected in developing countries[5]. Currently used methods for diagnosis of *H pylori* infection, such as culture, histology, and rapid urease test (RUT) are very sensitive and highly specific tests, but require invasive sampling. The non-invasive methods, such as serology and urea breath test (UBT), are also sensitive and specific; however, positive results obtained by serology do not necessarily indicate current infection by *H pylori*[6,7]. UBT requires an expensive instrument, which is not always available in routine clinical laboratories, especially in developing countries. In addition the performance of the test has been associated with

some disadvantages for infants and very young children, as well as patients with certain neurological disorders[6,7]. *H pylori* is not an intestinal pathogen, and therefore is expected to be present in low concentrations in stool; however, it can be detected in stool specimens by *H pylori* stool-antigen (HpSA) test, PCR, or even culture[8-12]. The HpSA test has been shown to be very useful, especially in children; however, various commercial tests have shown some discrepancies in different geographical areas[13-15]. Stool-culture is a very specific method; however, the massive numbers of diverse micro-organisms in stool makes it very difficult in routine practice[8,12]. Stool-PCR may also be a very useful method in detection of *H pylori* infection, but reported success rates for the detection of *H pylori* DNA in feces vary from 25% to 100%[6,8]. This variability is probably due to *H pylori* degradation in the gastrointestinal tract and/or the presence of inhibitors such as complex polysaccharides[16,17]. The purpose of this study was to evaluate the usefulness of the stool-PCR test for diagnosis of *H pylori* infection in pediatric populations.

MATERIALS AND METHODS

Patients
Based on endoscopic features (including nodular gastritis, erosive duodenitis, or ulcers) and/or a positive rapid urease test obtained during endoscopy, 28 children from a group of children admitted to a children's medical center in Tehran for persistent upper gastrointestinal problems were selected to compare biopsy-based tests and stool-PCR. Of these patients, two antral biopsies similar to that of RUT were obtained for culture and histology, and the first stool after endoscopy but before antibiotic therapy was collected and stored at -70℃. These children were asked to have a vegetable free diet 24 h before sampling. Stool samples were also collected from a few healthy children that showed no symptoms. Patients who tested positive by culture or positive by both RUT and histology were considered as positive controls and those who tested negative by all three endoscopy-based tests were considered as negative ones.

Biopsy-based tests
Culture of biopsy samples was performed as previously described[12,18]. Briefly, antral biopsies were placed in a modified campy-thio medium and incubated at 37℃ under a micro-aerobic atmosphere. After 3 d, 20 μL of the enrichment culture was streaked onto modified campy-blood agar and incubated for 5-10 d until colonies were evident. The grown colonies were identified by gram-staining, oxidase, urease, and nitrate-reduction tests.

RUT was performed using urea broth as previously described. The RUT result was read either within 2 h at endoscopy room or after overnight incubation under a micro-aerobic atmosphere at 37℃ according to the previously described protocol[12,18]. Histological examination of the biopsies was performed after H&E, and Geimsa staining *H pylori* density, gastritis, and inflammation were graded according to the modified Sydney system[19,20]. The cases of gastritis with follicular formation were classified as follicular gastritis either with or without activity[20].

DNA extraction and PCR
Two methods of phenol-chloroform and boiling were used for DNA extraction from *H pylori* isolates. For the first one, a pool of colonies in 2 mL sterile 0.9% NaCL, was centrifuged at 10000 g, the pellet was resuspended in 400 μL of extraction buffer (10 mmol/L Tris-HCL, pH 8.0; 5 mmol/L EDTA, 0.1% sodium dodecyl sulfate), and proteinase K at final concentration of 0.5 mg/mL was added to homogenizates. Samples were incubated at 55℃ for 2-4 h before incubation at 95℃ for 10 min. DNA was purified by phenol-chloroform, precipitated by absolute ethanol at -20℃ in presence of 0.3 mol/L sodium acetate, pelleted by centrifugation at 12000 g for 30 min and allowed to dry in air. The pellet in sterile double-distilled water was quantified by measuring the optical density at 260 nm and stored at -20℃ until they were used as PCR templates. For the second method, a loopful of colonies was suspended in 1 mL of phosphate buffer saline (PBS, pH 7.6), washed by centrifugation at 14000 g for 2 min, and resuspended in 50 μL of sterile, double distilled water. Tubes were then boiled at 95℃ for five minutes and 2 μL of 1/5 dilution of this extract (containing approximately 20 ng of DNA) was immediately used as template for PCR. Isolation of DNA from stool was performed using a stool DNA extraction kit (Bioneer Inc, Korea), where substances inhibiting PCR were removed by filtration according to the manufacturer's instructions. Stool-PCR controls were 3 uninfected feces from the *H pylori*-negative patient (as determined by endoscopy-based tests) seeded or not seeded with known concentrations (equivalent to McFarland No. 5) of 26695 *H pylori* ATCC strain.

PCR primers (Faza Biotech Inc, Iran) were designed on the basis of published sequences of *H pylori* *16SrRNA*, *vacA*, and *cagA*[8,21]. Table 1 resumes the sequences and experimental details for PCR.

RESULTS

The H pylori status
Sixteen out of 28 child patients (57%) were classified as *H pylori* positive by biopsy-based tests. Of 16 *H pylori* positive children 6 were positive by culture, 5 were positive by all of the 3 tests, and 5 were positive by RUT plus histology.

PCR results
DNA isolated from culture positive controls showed amplification for *H pylori* specific primer(s) including *vacA* (*s*, m), *cagA*, and *16srRNA*. Stool-PCR positive controls, which were 3 uninfected feces from the *H pylori*-negative patient containing known concentrations of 26695 *H pylori* ATCC strain, showed amplification for *H pylori* DNA only after purification by column chromatography procedure. No amplification was observed for the negative stool-PCR controls (stool

specimens from *H pylori*-negative patients), even after purification procedure. Eleven biopsied children showed positive stool-PCR of which 10 were positive by biopsy-based tests (Table 2). Sensitivity and specificity of stool-PCR were 62.5% and 92.3% respectively.

In this work, detection of *H pylori* specific virulence genes in both isolates and stool (Table 3) was compared. Also, association between endoscopic features, pathology, score of bacteria, and a positive stool-PCR was studied (Table 4). *H pylori* was observed in histological sections of 10 out of 11 stool-positive patients and association was observed between higher score of *H pylori* in histology and a positive stool-PCR.

DISCUSSION

In our previous study[12], we successfully cultured *H pylori* from stool; however, the sensitivity of stool-culture was low. Using PCR, we detected *H pylori* specific genes in isolates and stool in sick and healthy children. However, when fecal extracts were not subjected to column chromatography, there were no results even for the positive controls. This suggests that the method of DNA extraction used in this work efficiently removed the PCR inhibitors. Various methods has been used for the removing of inhibitors or for the purification of DNA

NSPC: No significant pathologic change; NST: No suitable tissue.

such as the removal of PCR inhibitors by a polypropylene filter, dilution of fecal suspension, and DNA purification by various biochemical techniques; in many studies with filtration of stool and column chromatography, high sensitivity was observed[8,10-11,14,22-24].

In this work, by detection of various *H pylori* specific genes in stools, 62.5% sensitivity and 92.3% specificity was observed for stool-PCR (Table 2). Nevertheless, by PCR only one or two out of three *H pylori* specific genes were detectable (Table 3). While this permits us to think that the absence of amplification is related to the absence of the detecting gene from the genome or the absence of intact template DNA (in stool), it would be a premature conclusion, since PCR-based absence of an ORF does not necessarily mean its absence from the genome. Also, in a highly recombining genome like *H pylori*, PCR primer annealing sites can pose problems and amplifications may not be generated[25,26]. Thus, we think that for genotyping of *H pylori* from stool, using more than one primer for each gene may enhance detection rate. Many investigators have proposed semi-nested or nested PCR as more sensitive methods for stool-PCR[8,10]. Although these methods reduce background, their disadvantages would be presence of false positive results due to detection of dead bacteria in stool even in low amounts. Sensitivity and specificity of stool-PCR method in this work were acceptable, suggesting that PCR method used in this work was quite adequate for this evaluation.

H pylori is not an intestinal pathogen, and therefore is expected to be present in low concentrations in stool; however, the status of the infection of *H pylori* may influence its density in stool. Thus, we compared histological scoring of *H pylori* with pathological grading and also with the results of stool-PCR. Concordance was observed between higher score of *H pylori* in histological sections and a positive stool-PCR (Table 4). Also, association was observed between the more severe form of gastritis and a positive stool-PCR. Therefore, the degree of stomach colonization by *H pylori* may be important for successful detection of DNA in stool samples. Otherwise, the amount of bacteria excreted in stool may reveal information on the status of *H pylori* infection. Consequently, the association between a higher score of *H pylori* in histology and a positive stool-PCR make it a very useful test for detection of pediatric *H pylori* infection.

COMMENTS

Background

A reliable non-invasive test for detection of *Helicobacter pylori* (*H pylori*) infection in routine practice is essential, especially for children since the application of biopsy-based tests is more difficult for them. Serological tests do not necessarily indicate active infection by *H pylori*, and urea breath test (UBT) is expensive and not available in routine clinical laboratories, especially in developing countries. The *H pylori* stool-antigen (HpSA) test has been shown to be very useful, especially in children; however, various commercial tests have shown some discrepancies in different geographical areas. Stool-PCR may be a very useful test in specific detection of *H pylori*. In this study, we evaluated the performance of stool-PCR in diagnosis of active infection in children.

Research frontiers

Stool-PCR is a very useful method for detection of *H pylori* genes in stool. It is interesting because *H pylori* specific genes, including virulence genes and the genes involved in its resistance to antibiotics, can be detected by this method. Furthermore, a positive stool-PCR has significance in relation to the status of stomach colonization by *H pylori*.

Innovations and breakthroughs

A stool-PCR method such that used in this work may represent a very specific test for diagnosis of *H pylori* infection. This is the first study to report association between a positive stool-PCR and the degree of stomach colonization, manifested by higher score of *H pylori* in histology.

Applications

A simple PCR method such that used in this work will be quite adequate for detection of *H pylori* infection.

Peer review

In this study, Falsafi *et al.* evaluated the performance of stool-PCR test for diagnosis of current *H pylori* infection in children. The content of the article can be interesting for gastroenterologists who work with the pediatric population, especially with very young children and patients with certain neurological disorders. Stool-PCR may be a very useful method in detection of *H pylori* infection.

Abstract

AIM: To investigate the macroscopic and clinico-pathologic features of gastric cancer in patients with biopsy-suggested high grade intraepithelial neoplasia.

METHODS: Patients with biopsy-confirmed gastric high grade intraepithelial neoplasia were reviewed from January 2001 to March 2008. Pathologic sections were re-evaluated by two senior pathologists. Patients with an *en-bloc* resection of the lesion within two months after the diagnosis of high grade intraepithelial neoplasia were enrolled in the study. Clinical manifestations, endoscopic features, biopsy and surgical pathology of all patients were collected and analyzed. The data acquired were subjected to univariate and multivariate analysis.

RESULTS: Seventy-two superficial gastric lesions with a pathologic diagnosis of high grade intraepithelial neoplasia based on biopsy specimens were enrolled. True high grade intraepithelial neoplasia was finally proved in 16 lesions and gastric cancer in the rest 56 lesions, most of which (96.4%) were differentiated carcinomas. The result of univariate analysis indicated that the size and the presence of marked ulcer plaque or scar in a superficial lesion were independently associated with gastric cancer ($P < 0.05$), when high grade intraepithelial neoplasia was diagnosed by biopsy pathology. The results of multivariate analysis revealed the size greater than 1.5 cm [odds ratio (OR) 18.400, $P < 0.001$] and the presence of 5-odd mm ulcer plaque or scar (OR 10.000, $P = 0.044$) were associated with gastric cancer. Accordingly, the sensitivity, specificity and negative predictive value of multivariate analysis for predicting "true high grade intraepithelial neoplasia" was 87.5%, 89.3% and 96.2%, respectively.

CONCLUSION: Macroscopic findings are of value in differentiation between high grade intraepithelial neoplasia and superficial gastric cancer. This may simplify patient work-up and save costs for patients and healthcare system.

INTRODUCTION

The reported incidence of severe gastric dysplasia developing into gastric carcinoma varies from 10% to 85% in different studies[1-10]. These studies were mainly performed in the 1980s[2,3] and 1990s[4-7], except for a recent study drawing a significantly different conclusion compared with the other studies[8]. Although these studies contributed to the current understanding of gastric cancer, their results were obtained mainly through

long-term follow-up and re-biopsy. In clinical practice and in our experience, a pathologic diagnosis based on biopsy samples may be inadequate in evaluating the severity of lesions. Besides site and quantity, biopsy bias is inevitably associated with the activity of tissue inflammation and regeneration. For instance, it is well recognized that a biopsy sample containing glandular distortion and atypia on an apparent inflammatory background always leads to a diagnosis of regeneration rather than a diagnosis of neoplasia.

A two-stage evaluation system of intraepithelial neoplasia (IEN) was introduced to gastrointestinal tumors by International Authority for Research on Cancer (IARC) in 2000 to replace the term "dysplasia"[9]. Few relevant studies have been published since then. Our preliminary study on the association between gastric HGIEN and invasive cancer has drawn promising results[10]. Further researches will enhance the clinical understanding of precancerous lesions and help distinguish HGIEN from invasive cancer under routine conventional endoscope, without the aid of complex methodologies like magnifying endoscopy or narrow-band imaging. This would improve the work-up of such patients, potentially saving costs for healthcare system and patients. In the present study, we analyzed the macroscopic and clinicopathologic features of superficial neoplastic lesions in an attempt to identify the macroscopic features independently associated with the presence of cancer.

MATERIALS AND METHODS

Patients

One hundred and four lesions in 103 consecutive patients were pathologically diagnosed as HGIEN of gastric mucosa based on biopsy samples obtained by EGD procedures in Shanghai Ruijin Hospital from January 2001 to March 2008. The charts, EGD reports and histologic sections were reviewed. Histopathologically, suspected stromal invasion was identified in 4 lesions. Endoscopically, lesions with an appearance strongly suggestive of advanced gastric cancer (i.e. Borrmann-type gastric cancer) were found in 21 patients, including fungating type in 1 patient, ulcerated in 7 and infiltrative ulcerated in 13 patients. These patients, excluded from the study, were later proved to have advanced gastric cancer. Seventy-nine superficial lesions were confirmed in 78 patients. Of these 78 patients, 6 refused interventional treatment while the remaining one was not a candidate for resection because of severe co-morbidities and poor overall condition. Seventy-one patients (59 males, 12 females, range 35-82 years, and a mean age of 60.5 ± 9.9 years) with 72 superficial neoplastic lesions were finally enrolled in the present study.

All patients gave their written consent to undergo endoscopic or surgical resection with the knowledge that the lesion may not be carcinomatous or infiltrative and the widely recognized guideline in treating GI neoplastic lesions with a biopsy diagnosis of HGIEN was not well established. Patients for endoscopic treatment were well informed about possibilities of incomplete resection, tumor recurrence, hemorrhage and other complications beforehand.

Endoscopy

EGD procedures were carried out on each patient prior to resection using either EG 410HR or EG 590WR video endoscope (Fujinon, Saitama, Japan). Characteristics of the lesion, including its location, size, contour, and ulceration if present, as well as changes in mucosal rugae and endoscopic type, were documented. If an ulcer or ulcer scar was noted, descriptive terms and an estimation of the size of ulcer plague or scar was obtained. Lesions were classified according to the Paris endoscopic classification of superficial neoplastic lesions[11]. "Superficial" lesions are defined when endoscopic appearance suggests either a small cancer or a noninvasive neoplastic lesion[11]. Recognition of superficial gastric lesions was also based on our experience in the endoscopic diagnosis of early gastric cancer. Biopsy was obtained and all patients were diagnosed as HGIEN based on biopsy samples.

Treatment

Abdominal US and enhanced CT scan were performed and distant metastasis was ruled out in all patients. All patients received *en-bloc* resection within two months after the initial diagnosis of HGIEN. Surgery was preferentially carried out given its advantage in curative resection irrespective of tumor size and invasion depth. Endoscopic resection was strictly limited to type 0-I or 0-IIa lesions with fine deformability and no ulceration. Lesions less than 15 mm in size were subjected to EMR using a strip biopsy method[12] and otherwise to endoscopic submucosal dissection (ESD) using the insulated-tip knife[13].

Pathologic diagnosis

The diagnosis of HGIEN was confirmed by two senior pathologists (Y-B. Z & Q. W). The IARC diagnostic criterion for HGIEN was applied[1], in which HGIEN is characterized by increasing architectural distortion with glandular crowding and prominent cellular atypia. An increased proliferative activity was present throughout the epithelium where no stromal invasion occurred. A lesion suspected of stromal invasion was ruled out of this series. Standardized sectioning of the resected specimen was carried out according to the guideline by JGCA[14]. Photograph of the specimen was taken before sectioning and a schematic map of sectioning was drawn. "True HGIEN" was diagnosed when each section of the *en-bloc* resected specimen met the criteria of HGIEN. Gastric carcinoma is diagnosed when the tumor invades to the lamina propria[1].

Statistical analysis

Endoscopic and clinicopathologic variables that might be predictive of gastric cancer were analyzed, including age, sex, history of melena or weight loss, time frame between the diagnosis of HGIEN and resection, endoscopic type (0-I/0-IIa, 0-IIc, 0-IIa + IIc/0-IIc + IIa, 0-

Ⅱc + Ⅲ/0-Ⅲ; mixed type), exact lesion size, location, mucosal rugae changes and presence of marked ulcer plaque or ulcer scar on the lesion. Continuous variables (age, time frame, exact lesion size) were compared using group t test when the variables were normally distributed and Wilcoxon test when a normal distribution was not observed. Categorical variables [sex, history of melena or weight loss, endoscopic type (0-Ⅰ/0-Ⅱa, 0-Ⅱc, 0-Ⅱa + Ⅱc/0-Ⅱc + Ⅱa, 0-Ⅱc + Ⅲ/0-Ⅲ; mixed type), lesion size with a cut-off value of 1.5 cm, location, mucosal ruga changes and presence of marked ulcer plaque or ulcer scar] were compared using χ^2 test or continuity-adjusted χ^2 test. Multiple logistic regression analysis was used to identify the factors independently associated with gastric cancer. $P < 0.05$ was considered statistically significant. All analyses were performed using the SAS software (SAS Institute, Cary, NC, USA).

RESULTS

Clinical manifestation

Of the 71 patients, 69 were presented with symptoms while the other 2 were asymptomatic. The time of symptoms ranged 1 wk-11 years. The indications for EGD are presented in Table 1.

Endoscopy and final diagnosis

Of the 71 patients, 69 were proved to have isolated HGIEN lesions in the stomach, one was found to have two biopsy-proven HGIEN lesions both in antrum and in fundus, and the other one was found to have gastric polyposis involving antrum and corpus. Of the 72 lesions, 28 were located in antrum, 20 in angularis, 10 in corpus, 1 in fundus and 11 in cardia. Antrum, angularis and corpus were involved in another 2 lesions.

All patients received either surgical or endoscopic resection within two months of initial diagnosis. The time frame between initial diagnosis of HGIEN and resection was 19.2 ± 11.8 d. Open gastrectomy and laparoscopic-assisted gastrectomy were performed on 53 and 14 patients, respectively. Three patients received EMR and one received ESD. All surgical and endoscopic resections were proved curative with horizontal and vertical R0 margins.

Of the 72 lesions, 16 (22.2%) were pathologically confirmed as true HGIEN of gastric mucosa, 51 (70.8%)

Figure 1 A case of true HGIEN of gastric mucosa. A: Endoscopic view of a sessile polypoid lesion (types 0-Ⅰ) in the greater curvature of gastric corpus. The lesion is approximately 1.2 cm in size with a smooth contour. Biopsy pathology indicated high grade intraepithelial neoplasia; B: Low-power view of the en-bloc resected specimen, showing negative vertical and horizontal margins (HE staining, × 25); C: High-power view shows prominent cellular atypia and increased proliferative activity without stromal invasion, indicating high grade intraepithelial neoplasia (HE staining, × 200).

were early gastric cancer and 5 (6.9%) were advanced gastric cancer. Among the early gastric cancer, 34 were intramucosal and 17 were submucosal cancer.. Advanced gastric cancer in the 5 cases invaded the superficial layer of muscularis propria. Differentiated adenocarcinoma was found in 54/56 lesions (96.4%) while undifferentiated adenocarcinoma was found in 2/56 lesions (3.6%). A case of true HGIEN of gastric mucosa is presented in Figure 1.

Differentiation of "true HGIEN" and gastric cancer

All lesions were divided into "true HGIEN" group ($n = 16$) and gastric cancer group ($n = 56$), according to their final diagnosis. A comparison of endoscopic and clinicopathological parameters of the two groups is shown in Table 2.

Twenty-three patients previously underwent EGD procedure within past 2 years. Of the 23 patients, one had normal EGD and 22 were identified to have 23 lesions. Targeted biopsy revealed high grade intraepithelial

Table 2 Comparison between true HGIEN and gastric cancer lesions confirmed by *en-bloc* resection (mean ± SD) *n* (%)

Parameter	True HGIEN group (*n* = 16)	Gastric cancer group (*n* = 56)	P value

[1]The mixed type included 0-Ⅰs + Ⅱc, 0-Ⅱa + Ⅱc, 0-Ⅱc + Ⅱa and 0-Ⅱc + Ⅲ in this series; [2]*P* < 0.05, Wilcoxon test for continuous variables without a normal distribution and χ^2 test for categorical variables; [3]One or several ulcer plaques/scars at least 5 mm in size.

Table 3 Results of logistic regression analysis of the clinical variables

Variable	Odds ratio (95% CI)	P value
Age (yr)	-	0.773
Gender (male)	-	0.328
Endoscopic findings		
0-Ⅱc + Ⅲ/0-Ⅲ	-	0.548
Mixed type[2]	-	0.947
Lesion size >1.5 cm	18.400 (3.364-100.653)	< 0.001[1]
Mucosal ruga changes	-	0.685
Marked ulcer plaque[3] or ulcer scar	10.000 (1.062-94.111)	0.044[1]

[1]*P* < 0.05, multiple logistic regression analysis; [2]The mixed type included 0-Ⅰs + Ⅱc, 0-Ⅱa + Ⅱc, 0-Ⅱc + Ⅱa and 0-Ⅱc + Ⅲ in this series; [3]One or several ulcer plaques/scars at least 5 mm in size.

neoplasia in 17 cases, low-grade intraepithelial neoplasia in 2 and no neoplasia in 4 cases, respectively. Six out of the 23 lesions were finally proved to be true HGIEN of gastric mucosa.

Since endoscopy is an essential method in the diagnosis of gastrointestinal neoplasm and endoscopic appearance of a lesion plays an important role in predicting its characteristics and its invasion depth or metastasis[15], macroscopic findings under conventional endoscopy were analyzed in this study, including macroscopic type, lesion size, location, mucosal ruga changes (e.g. convergence, tapering, abruption, *etc*) and presence of ulcer plaque or ulcer scar, all of which are easily accessible in daily practices. Location was categorized as proximal (body, cardia and fundus of stomach) or distal (antrum and angularis). Presence of marked ulcer plaque/ulcer scar was defined as one or several ulcer plaques/ulcer scars at least 5 mm in size noted on the lesion.

The results of univariate analysis indicate that gastric cancer was associated with the size of lesion and the presence of marked ulcer plaque or ulcer scar (*P* < 0.05). Abruption of mucosal rugae was noted around 5 lesions, all of which were proved to be gastric cancer, so did the 8 lesions presenting with an ulcerated type (0-Ⅱc + Ⅲ or 0-Ⅲ). However, no statistical significance was identified in these parameters.

Multivariate analysis revealed that a lesion larger than 1.5 in size (OR 18.400, 95% CI 3.364-100.653, *P* < 0.001) and the presence of marked ulcer plaque or ulcer scar (OR 10.000, 95% CI 1.062-94.111, *P* = 0.044) were associated with gastric cancer (Table 3). The value of ulcer plaque in the diagnosis of invasive cancer is demonstrated in Figure 2.

A macroscopic criterion for true HGIEN of gastric mucosa was accordingly proposed as a lesion ≤ 1.5 cm in size, and absence of 5-odd mm ulcer plaque or ulcer scar on the premise that HGIEN was suggested by biopsy pathology. A total 20 lesions in this series met the above criteria, of which, 14 were finally proved to be "true HGIEN" of gastric mucosa, and 6 were proved to be intramucosal gastric cancer. The sensitivity, specificity and negative predictive value of multivariate analysis for predicting "true HGIEN" was 87.5%, 89.3% and 96.2%, respectively.

DISCUSSION

Dysplasia is now replaced by IEN to indicate intraepithelial neoplastic changes with the absence of stromal invasion. It was reported that 0%-23% of mild dysplasia might progress to invasive cancer while the incidence of severe dysplasia is estimated to be 70%-85% in Western studies[1-7,16] and 10% in Japanese reports[8]. Most of these studies focusing on long-term follow-up results had a limited number of patients enrolled. Furthermore, the initial patient status is usually decided by endoscopy, which may fall into the pit of underestimation caused by inevitable biopsy bias.

China is an East Asian country with a high risk of gastric cancer[9]. The incidence of age-adjusted gastric cancer in males and females was 46.5 and 21.0 per 100 000 in Shanghai, China in 1996[17]. The number decreased to 27.4 and 14.0 per 100 000 in 2002 and 2004, still significantly higher than that in most Western countries and Japan[18]. The number of gastric cancer patients per year in the authors" institution, however, has increased significantly in recent years with a total of 2355 cases of surgically proved gastric cancer from January 2001 to March 2008[19]. In addition, intestinal-type gastric carcinoma, a consequence of HGIEN if left untreated[20], is found more common in high risk areas than in low risk areas of gastric cancer. In this study, all patients received curative resection at a mean interval of 19 d between the diagnosis of HGIEN and resection, and invasive carcinoma was found in up to 77.8% lesions. It was reported, however, that the time frame between initial diagnosis of severe dysplasia

Figure 2 Presence of ulcer plaque is associated with gastric cancer. A: Retroflex view of a flat depressed lesion in the lesser curvature of cardia. The lesion is presented with a reddish area approximately 1.4 cm in size, scattered with irregular ulcer plaque; B: Forward view of the same lesion. The ulcer plaque can be clearly observed with a size larger than 5 mm (arrows); C: Low-power view of biopsy specimen shows irregular tubules with increased branching and architectural distortion. Prominent cellular atypia can be noted, indicating high grade intraepithelial neoplasia (HE staining, × 100); D: The entire lesion was removed by surgery which showed tumor invasion into lamina propria and partly the muscularis mucosae (HE staining, × 100). The final diagnosis was a type 0-Ⅱc well-differentiated adenocarcinoma with muscularis mucosae invasion, T1 N0 M0.

and identification of gastric cancer, was between four and twenty-three months on average[2,4-9,21]. It implys that most gastric lesions diagnosed as HGIEN (severe dysplasia) are underestimated and a lot biopsy-proven "HGIEN" lesions actually are gastric cancer in the meantime. The process of HGIEN advancing to gastric cancer may not be what meets the eye through repeated biopsy.

Although the diagnosis of HGIEN was carefully considered in the study to rule out possible invasion in biopsy samples, it was almost inevitable to get rid of biopsy bias. Multiple causes lead to biased biopsy sampling, including missed target and inadequate tissue amount. Active inflammation of the tissue sample may conceal neoplastic architectural distortion and lead to false negative results. Short-course (2 wk) proton pump inhibitor treatment is suggested for such condition and re-biopsy should be performed. A combination of well-differentiated cancer tissue and absent muscularis mucosa is a typical case in a biopsy sample leading to a diagnosis of HGIEN. The reason why there were not so many well-differentiated adenocarcinomas in this series is probably due to the fact that gastric cancer tends to be less differentiated as it penetrates into deeper layer[22]. It was reported that as high as 11% of biopsy-proven differentiated early gastric cancer turns out to be undifferentiated at surgery[23]. Cryptal dysplasia is another case in which atypia originates from deeper portion

of the mucosa and penetrates downward; the epithelium is sometimes spared with little trace of IEN[21]. In this series, only 3.6% of the lesions were proved to be undifferentiated gastric cancer, indicating that this histological type is unlikely to present in biopsy-proven HGIEN.

Macroscopically, superficial changes or markedly ulcerated appearance can be found in a lesion diagnosed as HGIEN by biopsy. However, all "true HGIEN" lesions in this series were less than 20 mm in size while 87.5% of which were less than 15 mm in size. To draw a definite line between HGIEN and gastric cancer is almost unworkable under endoscope, yet a marked lesion suggestive of Borrmann-type gastric cancer always turns out to be invasive cancer[3]. We hereby propose a macroscopic criterion for true HGIEN which can better differentiate true HGIEN from superficial gastric cancer. The criterion involves endoscopic and biopsy parameters easy to be measured in daily practices with conventional endoscope and without the aid of complicated techniques. The relatively low predictive value (70%) for true HGIEN is primarily attributed to the overlapping macroscopic feature of HGIEN and early gastric cancer, both of which can be small and inconspicuous, yet the former seems much unlikely to be a large one. Since HGIEN is a precancerous change without stromal invasion or lymph node metastasis, endoscopic *en-bloc* resection, both preserving gastric

function and improving quality of life of patients, is considered sufficient and curative.

The authors hold that an ulcerated lesion with biopsy-proved HGIEN should always turn out to be invasive cancer, which is supported by the theory of ulcerated early gastric cancer progression proposed by Kyoichi[24], in which the Hauser's cancer is considered a sporadic case. In this series, although the comparison of ulcerated type between the groups did not reach a level of statistical significance, all the patients (8/8) were proved to have invasive cancer. The lack of significance could be attributed to inadequate population size. Same explanation also goes to the issue of mucosal ruga changes, which has been recognized as signs indicating submucosal tumor invasion[24,25]. Experienced pathologists are warranted in making the proper diagnosis of HGIEN without confusion of regenerative changes associated with erosion or healing ulcer or cases suggestive of gastric cancer with inadequate tissue.

In conclusion, a superficial gastric lesion diagnosed as HGIEN by biopsy is most likely to be an early gastric cancer at the time of diagnosis. Lesions greater than 1.5 cm in size and presence of 5-odd mm ulcer plaque or ulcer scar are independently associated with invasive cancer, especially differentiated gastric carcinoma in such a setting. Combining endoscopic characteristics with biopsy results could greatly enhance the diagnostic accuracy of superficial gastric neoplastic lesions, thus reducing the risk of unnecessary gastrectomy, simplifying patient work-up and improving the quality of life of patients. Further investigations are, however, necessary to validate these contentions and to clarify the impact of repeated biopsy on the diagnosis of true HGIEN lesions.

COMMENTS

Background
Intraepithelial neoplasia has been proposed by the WHO to replace dysplasia in gastrointestinal epithelial neoplastic changes. However, differential diagnosis between high grade intraepithelial neoplasia and invasive cancer is still confusing when the diagnosis is based on biopsy pathology.

Research frontiers
Both intraepithelial neoplasia and early gastric cancer can be presented as superficial lesions. Conventional endoscopy provides direct observation of the lesion, yet the appearance of intraepithelial neoplasia and early gastric cancer resembles each other. It is unhelpful to macroscopically differentiate intraepithelial neoplasia from early cancer. Biopsy pathology may also fail to differentiate intraepithelial neoplasia from early cancer. This study focused on the macroscopic features of gastric lesions with a biopsy diagnosis of high grade intraepithelial neoplasia, suggesting that certain macroscopic features can help for better differentiation.

Innovations and breakthroughs
Conventional endoscopy observation has not been considered to play a role in differential diagnosis between intraepithelial neoplasia and early cancer. Likewise, gastric pit pattern observation either by magnifying endoscopy or by NBI lacks the accuracy to better characterize the lesion. Our study suggested that under typical conditions conventional endoscopy would be capable of differentiating between high grade intraepithelial neoplasia and gastric cancer.

Applications
The results of this study enhance the value of routine conventional endoscopy in the diagnosis of clinically confusing conditions. It could simplify the work-up of patients with a biopsy diagnosis of high grade intraepithelial neoplasia and save costs for patients and healthcare system.

Terminology
Intraepithelial neoplasia means to replace dysplasia for precancerous status with cellular and structural atypia. High grade intraepithelial neoplasia denotes increasing architectural distortion with prominent cell atypia without invasion to lamina propria.

Peer review
The authors investigated the macroscopic features of gastric superficial lesions with a biopsy diagnosis of high grade intraepithelial neoplasia and compared endoscopic findings with surgical results. It revealed that a lesion > 1.5 cm in size and the presence of ulcer/scar are associated with invasive cancer. The results are of interest and value for better patient work-up.

Abstract

AIM: To investigate the feasibility of fast track clinical pathway for esophageal tumor resections.

METHODS: One hundred and fourteen patients with esophageal carcinoma who underwent esophagogastrectomy from January 2006 to October 2007 in our department were studied. Fast track clinical pathway included analgesia control, fluid infusion volume control, early ambulation and enteral nutrition. Nasogastric tube was removed 3 d after operation and chest tube was removed 4 d after operation as a routine, and full liquid diet 5 d after operation.

RESULTS: Among 114 patients (84 men and 30 women), 26 patients underwent fast track surgery, including 17 patients over 65 years old and 9 under 65 ($P = 0.014$); 18 patients who had preoperative complications could not bear fast track surgery ($P < 0.001$). No significant differences in tolerance of fast track surgery were attributed to differences in gender, differentiated degree or stage of tumor, pathological type of tumor, or operative incision. The median length of hospital stay was 7 d (5-28 d), 4% patients were readmitted to hospital within 30 d of discharge. Three patients died and postoperative mortality was 2.6%. All 3 patients had no determinacy to fast track surgery approach.

CONCLUSION: The majority of patients with esophageal carcinoma can tolerate fast track surgery. Patients younger than 65 or who have no preoperative diseases have the best results. Median length of hospital stay has been reduced to 7 d.

INTRODUCTION

Recently, a new surgical model, fast track surgery, appears[1,2]. Fast track surgery combines various new techniques and new theories used in pre-operative, peri-operative and post-operative care of patients. The methods include anaesthesia, nutritional monitoring, optimal pain control and surgical techniques[3]. The combination of these approaches lowers the stress response, morbidity as well as mortality rates, thus greatly reducing the time required for full recovery. Fast track surgery has significantly changed many clinical therapeiutic modes.

To date, few existing data can prove whether such concept could also be safely applied to esophageal surgery such as esophageal tumor resection[4]. This study reviews the outcome of a single-center survey regarding the application of the new "fast-track surgery" model and its effects in patients undergoing esophagus tumor resection.

MATERIALS AND METHODS

General data

The records of patients with esophageal carcinoma who

underwent esophagogastrectomy from January 2006 to October 2007 in our department were studied. All the patients received preoperative examinations including gastroscope, barium meal of upper gastrointestine, abdominal ultrasonography, chest CT, pulmonary function and hematological examinations.

Operative indications

The diagnosis of esophageal carcinoma was identified, and no obvious surgical contraindications were detected. There was no evidence of metastasis in intrathoracic lymph nodes, such as the signs of recurrent laryngeal nerve paralysis, diaphragmatic paralysis or Horner's syndrome. There was no supraclavicular and cervical lymphadenectasis. If distant metastasis had been found or resection was impossible temporarily, neoadjuvant chemotherapy or radiotherapy was suggested preoperatively. One hundred and fourteen cases were selected according to the surgical criteria. All these patients received preoperative healthy education: (1) respiratory function exercise to improve pulmonary ventilation function; (2) effective cough and expectoration to promote lung reventilation postoperatively; and (3) diet guide to help patients switch from full liquid diet to semiliquid diet after operation. Preoperative preparations: Patients were fasted for 8 h and supplemented with sugar and salt through intravenous infusion 2 h before operation to increase energy. Anesthesia: Double channel lumen intubation general anesthesia combined with epidural block was used. Anesthetists actively removed sputum, closely controlled the intake and output liquid to maintain the stabilization of effective circulation. A classic radical correction of esophageal carcinoma was performed through opening the chest between ribs and preserving rib bed. Intercostal nerves were removed for assisted analgesic effect. A mechanical anastomosis was performed between the end of the esophagus and the side of the stomach. Jejunal tube was placed at 20-30 cm away from distal Treitz ligament. Both thoracic and celiac lymph nodes were excised referring to the Korst's profile of lymph nodes of esophageal carcinoma[5]. Patients were transferred to anesthesia recovery room after operation. The tracheal intubations were removed when their spontaneous breath, stable circulation, cough reflex, swallowing reflex, and oxygen saturation recovered. But patients with histories of severe diseases such as coronary artery diseases or ventilation dysfunction would be sent to the ICU for tracheal extubation. Enteral feedings combined with parenteral alimentation were used for postoperative patients. Parenteral alimentation was supported with enteral feedings via the jejunostomy tube, primarily with a rate of 20 mL/h in the first 48 h after operation and 65 mL/h 2 d later and then with parenteral alimentation. If swallow showed no leak, full liquid diet was started on the fifth day after operation. Patient controlled analgesia was suggested to be a common practice for 48-72 h after operation. Discharge standard: taking food totally through mouth without intravenous infusion and walking freely in rehabilitation home. The first telephone follow-up was carried out in 72 h after the patients dis-

charged from hospital, with regular visits one week after the operation as the clinical follow-up. Later telephone follow-up was done once every week, until 30 d after operation.

Major complications were defined as any complication excluding transient atrial arrhythmias, urinary retention, or nonoperatively managed air leak. Mortality was defined as any death occurring during the hospital stay or within 30 d postoperatively. Outcome data were analyzed by SPSS 13.0 package using Chi-square test or Fisher exact test. $P < 0.05$ was considered to be significant.

RESULTS

Clinical characteristics of patients with esophageal carcinoma

There were 114 patients, 84 men and 30 women. The ratio of male to female was 2.8: 1. The average age was 58.6 years, ranging from 38 to 85. Lesions were located in distal thoracic esophagus in 60 cases (52.6%), in mid-thoracic esophagus in 35 cases (31.6%), and in upper thoracic esophagus in 18 cases (15.8%). Twenty-eight of 114 cases had histories of various diseases: 14 with respiratory diseases (12.3%), 9 with cardiocerebrovascular disease (7.9%), 8 with other diseases (7.0%), and 3 with more than two kinds of diseases. Twenty-six patients could not undergo the fast track surgery. Seventeen patients were over 65 years old and nine were under 65 ($P = 0.014$); 18 patients who had a preoperative complication could not bear fast track surgery ($P < 0.001$). No significant differences in tolerance of fast track surgery were attributed to differences in gender, degree of differentiation, stage of tumor, pathological type, or operative incision (Table 1).

Anesthsia and analgesia

Sixty percent of the patients received tracheal extubation immediately at the end of the operation, 30% received tracheal extubation a few hours later in recovery room, and 10% demanded mechanical ventilation. The fluid infusion was controlled between 1.5 L and 2.5 L, between 2.5 L and 3.5 L and above 3.5 L for 71%, 25% and 4% of the total number of patients, respectively. A total of 109 (96%) patients accepted PCA, including vein PCA (44%), epidural PCA analgesia (52%) and 5 patients refused PCA for various reasons. PCA lasted 48-72 h ordinarily (Table 2).

Postoperative daily guideline (Table 3)

Postoperative patients relied mainly on enteral feedings and assisted by parenteral alimentation. During the first 48 h after operation, parenteral alimentation was primarily supported with enteral feedings via the jejunostomy tube with a rate of 20 mL/h 2 d later, jejunostomy tube feedings with a rate of 65 mL/h were given priority with supplement of parenteral alimentation. If swallow showed no leak, full liquid diet was started on postoperative day 5. All the patients were educated to prevent aspiration. Nasogastric tube was removed on postoperative day 3 and chest tube was routinely removed on postoperative

with anastomotic complications, and 21% with other complications (Table 4).

DISCUSSION

Fast track surgery was suggested by Henrik Kehlet *et al*[1,2] who thought postoperative degression process of body function could be shortened from a few weeks to a few days. One hundred and fourteen patients undergoing fast-track rehabilitation got good therapeutic effect, compared with the traditional surgery of esophageal cancer[6-9] (Table 5) .Fast track surgery were successful in many general surgical patients, especially in colorectal surgery patients[10-12]. In our study, postoperative hospital stay was significantly shortened and cost of hospitalization was reduced without increase of morbidity or mortality. Postoperative hospital stay was declined from traditionally 12-14 d to now 7 d through the use of fast track surgery. Multivariate analysis showed that age (> 65 years) and

day 4. Patients were encouraged to walk and cough effectively. Respiratory tract care was strengthened in order to promote lung reventilation postoperatively. The average length of hospital stay was 7 d (5-28 d), and 4% of the patients were readmitted within 30 d of discharge (Figure 1).

Major complications
Postoperative mortality was 2.6% (3 cases). Nevertheless, all 3 patients had no relation to fast track surgery. The causes of death: respiratory failure in two patients and multiple organ failure in one. Nineteen patients had a variety of 34 major complications: 38% with pulmonary complications, 26% with cardiac complications, 15%

preoperative complications were the main factors that determined whether patients could bear fast track surgery clinical pathway.

In brief, fast track surgery uses multiple modes to control pathophysiological process of perioperative patients. It can improve the prognosis and promote their recovery. How to attenuate the stimulation is the basis of reduction of stress response. Basically, the approaches include three aspects: (1) make good physical and mental preparation preoperatively; (2) minimize therapeutic stress; and block nerve conduction to stress signal[13]. In a wide view of these measures, there are not many higher demands of surgical skills. Fast track surgery approach mainly optimizes perioperative management on the basis of various effective methods confirmed by evidence-based medicine. As a result, fast track surgery reduces common complications, relieves patients' pain and accelerates patients' recovery.

Intravenous nutrition, gastrointestinal decompression and chest tube are all necessary for traditional esophagogastrectomy. Postoperative pain is common. We used fast track surgery to optimize traditional measures. It is known that gastrointestinal decompression and delayed eating are conventional means. However, nasogastric tube made 88% patients discomfort to a moderate to severe degree, and 70% patients with even more severe feelings[14,15]. It is obvious that functional restoration of gastrointestine was delayed. Some studies found that cancellation of gastrointestinal decompression might be a vital step for faster functional restoration of gastrointestine and decrease of hospital stay. A recent meta-analysis showed that gastrointestinal decompression had not reduced the complications of operation on digestive tract[16]. Nevertheless, our research indicated that function of gastrointestine was in the stage of overall recovery during 48 after operation, therefore, gastrointestinal decompression would be

helpful. In our opinion, gastrointestinal decompression is essential in the early postoperative stage, and the discomfort can be relieved by drugs.

Pulmonary complications are not only the most common but also the main death cause after operation[17]. So how to effectively prevent pulmonary complications becomes the focus of fast track surgery. Satisfying health education could relieve patients' anxiety and fear, and partially reduce postoperative pain. Patients could benefit from good partner treatment and sufficient cardiorespiratory function exercise preoperatively. Full communication with anesthetist perioperatively is very helpful for anesthetist to grasp patient's condition. On the premise of ensuring effective circulation, anesthetist controlled the fluid infusion volume, actively sucked sputum, and gave early tracheal extubation to promote lung reventilation postoperatively. Recently, the evidence shows that the reduction of fluid volume in the operation would help reduce postoperative complications and shorten the hospital stay[18,19]. After operation, anesthetist performed a various kinds of patient control analgesia. Postoperative analgesia is not only the demanding of humanism but also the vital component of fast track surgery. It is very helpful for patients to ambulate earlier so that muscles will not be hypertrophied because of long-term bed-ridden. It is also very helpful for patients to cough and expectorate effectively to recruit their lungs. This could reduce thrombogenesis and pulmonary infection. Epidural analgesia has advantages in the early recovery of pulmonary function and early physical therapy. And effective cough for the effect of epidural analgesia was regional and weaker compared with vein analgesia. But the manipulation of epidural analgesia is complex. It is hard to control anesthesia plane and its effect is instable. We have found that the cooperation of surgeons, anesthestists, and dietitian is very important because they can work together with multiple means to effectively decrease the complications of lung and heart.

Early enteral nutrition not only gurantee the structure and function of intestinal mucosa cells, maintain intestinal mechanical, chemical and biological barrier, but also increase portal circulation, activate intestinal digestive secretary system and accelerate organ recovery. Enteral nutrition has also been an important measure for fast-track. Now perioperative nutritional support

contains the full regulation of pathophysiological process as well as simple nutritional regulation. In the past decade, advantage of diversion from parenteral nutrition to enteral nutrition has been generally accepted. Enteral nutrition is more suitable for physiological demanding with less complications and lower price. Enteral alimentation should be small in amounts and short in time. Parentral nutrition is the major supplement and the whole enteral nutrition should be given 48 h later. Immunological enteral nutrition could be used for some indicated patients. A recent meta-analysis demonstrated that immunological enteral nutrition could reduce postoperative infection complications[20].

Enteroparalysis and anastomotic leakage have been two major puzzles for early eating after operation. Enteroparalysis was considered to be inevitable in the past. There are a few factors related to enteroparalysis which could be ameliorated by intestinal rest and gastrointestinal decompression. However, some studies indicated that intestinal rest and nasogastric tube decompression were not indispensable[21,22]. That fast track encourages patients to have a diet early did not increase discomfort but promoted the intestinal recovery. Postoperative anastomotic leakage was a dangerous complication in the past. Late diet was thought to prevent leakage. However, with the development of evidence-based medicine, there has been no proof that late diet can reduce this kind of complication. Recent research showed that severe complications were mainly related to the condition of patients before operation and surgical techniques[23]. In our study, 4 cases had leakage in neck and 1 case had leakage in the chest. But no evidence indicated leakage related to early diet.

Age and preoperative disorders are also the key factors influencing whether patients can tolerate fast track surgery. Organic functions of patients over 65 years of age are in the degenerating stage. They had intense stress caused by the operation and so their recovery was relatively slow. Fast track surgery would increase their complications and had a disadvantage in early restoration. Patients with preoperative disorders especially heart and lung diseases might fail in the fast-tracking protocol. So it is suggested that the primary diseases should be ameliorated actively and cardiac-pulmonary functions should improve before operation. If organ disorders and nutrition status achieve good improvement, patients can accept fast track surgery mode.

Our research demonstrated that the majority of patients with esophageal carcinoma can tolerate fast track surgery clinical pathway. Patients less than 65 years or without preoperative diseases have the best effect. Average length of hospital stay has been reduced to 7 d. The major goal of fast track surgery is to control pathophysiological process and improve patients' prognosis, not only for early discharge, but also for early recovery. Fast track surgery is not only the responsibility of surgeons, it also needs a team that could cooperate effectively. This involves surgeons, anesthestists, dietitians, and nurses[24]. Fast track surgery clinical pathway increases patients' satisfaction and reduce costs. It can also use medical resources in the most efficient way. As a result, fast track surgery will be the tendency of surgery development.

ACKNOWLEDGMENTS

COMMENTS

Background

A new surgical model, fast track surgery, has appeared recently. Many clinical therapeutic modes have been significantly changed due to fast track surgery. However, the mechanism of this treatment in esophageal tumor resection is still unclear.

Research frontiers

To date, few existing data can prove whether such concept in fast track surgery could be safely applied to esophageal surgery such as esophageal tumor resection. This study reviews the outcome of a single-center survey regarding the application of the new "fast-track surgery" clinical pathway and its effects in patients undergoing esophagal tumor resections.

Innovation and breakthroughs

Patients were preoperatively fasted for 8 h only and supplemented with sugar and salt by intravenous infusion 2 h before operation to increase energy. Postoperative patients relied mainly on enteral feedings and were assisted by parenteral alimentation. Nasogastric tube was removed on postoperative day 3 and chest tube was removed on postoperative day 4.

Applications

The majority of patients with esophageal carcinoma can tolerate fast track surgery clinical pathway. Patients less than 65 years of age or without preoperative diseases have the best effect in the treatment.

Terminology

FTS stands for fast-track surgery, a combination of various new techniques which reduce the stress response as well as morbidity and mortality rates, thus greatly shortening the time required for full recovery.

Peer review

Several articles have evaluated fast-tracking pathways. The primary objective of this study was to determine if fast-tracking pathway can be applied with satisfaction without increasing morbidity or mortality as compared to other reports. The initial observation is interesting.

Abstract

The antiphospholipid syndrome (APS) is a multi-systemic disease being characterized by the presence of antiphospholipid antibodies that involves both arterial and venous systems resulting in arterial or venous thrombosis, fetal loss, thrombocytopenia, leg ulcers, livedo reticularis, chorea, and migraine. We document a previously unreported case of a 37-year-old female in whom APS was first manifested by infarction and cecal perforation following cesarean section. At laparotomy the underlying cause of colonic perforation was not clear and after resection of the affected bowel an ileo-colostomy was performed. The diagnosis of APS was established during post-operative hospital stay and the patient was commenced on warfarin. Eventually, she made a full recovery and had her stoma reversed after 4 mo. Pregnancy poses an increased risk of complications in women with APS and requires a more aggressive approach to the obstetric care. This should include full anticoagulation in the puerperium and frequent doppler ultrasound monitoring of uterine and umbilical arteries to detect complications such as pre-eclampsia and placental insufficiency.

INTRODUCTION

Antiphospholipid syndrome (APS) is characterized by the presence of antiphospholipid antibodies and multiple systemic abnormalities including arterial or venous thrombosis, fetal loss, thrombocytopenia, leg ulcers, livedo reticularis, chorea, and migraine[1-5]. Venous thrombosis commonly involves deep venous system of the leg, but the renal vein, pulmonary vein, inferior vena cava, hepatic vein, and portal vein may also be involved[2,6,7]. The most common site of arterial thrombosis is the cerebral circulation, but occlusion of coronary, renal, or retinal arteries has also been reported[6,7]. Only rarely has mesenteric arterial thrombosis been noted[1,6]. We report an unusual case where APS was first manifested by infarction and cecal perforation following cesarean section.

CASE REPORT

A 37-year-old lady was admitted for elective induction of labor, but proceeded to have an emergency cesarean section due to prolonged second stage of labor. During the postpartum period she developed abdominal distention and exhibited signs of peritonitis. Laboratory tests showed a leukocyte count of 21×10^9 with 19×10^9 neutrophils, hemoglobin of 11.9 g/dL and INR of 1.15. Renal and liver biochemistries were normal. Computer-

Figure 1 CT revealed free gas and fluid in the abdomen.

Figure 2 Histopathology showed bowel wall necrosis.

ized tomography (CT) revealed a large amount of free gas and free fluid in the abdomen indicative of bowel perforation (Figure 1).

After initial resuscitation, she underwent emergency laparotomy which revealed generalized fecal peritonitis and multiple perforations of the cecum. Macroscopically the entire right colon looked inflamed. After peritoneal lavage a right hemicolectomy was performed. A double barrelled stoma (ileo-colostomy) was fashioned due to fecal soiling of the peritoneal cavity and unknown etiology of the perforation. Post operative recovery was complicated by intra-abdominal serous collections, necessitating percutaneous drainage, and pleural effusion for which she needed a chest drain insertion.

Histopathology of the resected bowel revealed transmural infarction with the presence of occasional fibrin thrombi in adjacent blood vessels without evidence of vasculitis (Figure 2). Background bowel and the resection margins showed peritonitis, but the wall was viable and did not show any significant abnormalities.

Clotting profile confirmed the presence of lupus anti-coagulant, but it was negative for anticardiolipin antibodies. Magnetic resonance angiography (MRA) revealed occlusion of the inferior mesenteric artery and stenosis of the hepatic artery. Ultrasound scan of the hepatobiliary system was normal. A diagnosis of APS was established and she was subsequently commenced on life-long warfarin (target INR 3-4).

The stoma was closed 4 mo later after a normal contrast enema. The patient made an uneventful recovery and remains well on follow-up.

DISCUSSION

APS is characterized by a state of hypercoagulability potentially posing a risk of thrombosis to all segments of the vascular bed and may result in pregnancy related morbidity. It is associated with the presence of a specific group of autoantibodies called antiphospholipid antibodies (aPL) which are circulating immunoglobulins that cross-react with cell membrane phospholipids. The two main types of aPL are the anticardiolipin antibodies (aCL) and the lupus anticoagulant (LA). These antibodies are found in 2% of the general population and in 30%-40%

of systemic lupus erythematosus patients[7,8]. Although patients with syphilis, acquired immunodeficiency syndrome or other connective tissue disorders may have these antibodies, they may not manifest clinical features. About 30% of patients with the LA and 30%-50% with high or medium positive IgM aCL antibodies have clinical features of APS. The exact prevalence remains unknown[9]. The aCL test is positive in about 80% of patients with APS, the LA positive in approximately 20%, and both are present in 60% of the cases[10]. The Sapporo criteria require the positivity on two occasions, at least 6 wk apart of aCL at medium-high titres or LA[11]. However, this was recently revised to 12 wk by international consensus[12].

Anticardiolipin antibodies are strongly associated with thromboembolic phenomenon, thrombocytopenia, and prolonged prothrombin and partial thromboplastin times[8]. The suggested mechanisms for reaction of antibodies with epitopes are anticardiolipin binding to acidic phospholipids on platelet membranes resulting in platelet activation[13,14], anticardiolipin blocking prothrombinase activation, anticardiolipin binding to membrane phospholipids to cause endothelial cell injury, and anticardiolipin alteration of the local endothelial levels of prostacyclin, prekallikrein, antithrombin III, or protein C[15-18]. However, lupus anticoagulants are a stronger risk factor for thrombosis than anticardiolipin antibodies in APS[19]. This was the case in our patient who was anticardiolipin negative, but lupus anticoagulant positive.

A wide range of abdominal manifestations of APS have been reported, with hepatic involvement being the most common, followed by thrombotic events involving different branches of the intestinal vasculature[20]. Sporadic splenic infarction and acute pancreatitis have also been reported. A wide range of hepatic diseases are associated with APS including both thrombotic (Budd-Chiari syndrome and hepatic infarction) and non-thrombotic conditions (cirrhosis, autoimmune hepatitis and portal hypertension). Intestinal infarction, due to thrombosis of mesenteric vessels, has been relatively less frequently reported in patients with APS[21].

Cases of mesenteric venous thromboses presenting with intestinal ischemia in patients with APS have been

reported in the literature[22]. The presentation may be acute, often preceded by intestinal angina, or rarely results in intestinal bleeding and ulceration[20]. The occurrence of celiac artery and/or superior mesenteric artery stenosis has also been documented[23].

Computerized tomography (CT) is considered to be first-line investigation in APS patients presenting with abdominal symptoms. CT features of mesenteric ischemia have been reported to show thickening of both small and large bowel walls with prominence of the supplying mesenteric vessels[24]. Mesenteric MRA (magnetic resonance angiogram) in cases of suspected intestinal ischemia may confirm the diagnosis if the patients' condition allows. In our case, the patient underwent an emergency laparotomy and spontaneous perforation of the cecum was found. The underlying cause, however, was not clear at the time of surgery and the diagnosis of APS was made during post-operative hospital stay.

Venous or arterial intestinal thromboses and infarctions may be prominent features of APS. The presentation may be non-specific and a high index of suspicion is needed for any signs of abdominal involvement in these patients. Pregnancy poses increased risks of complications (e.g. hypertension/pre-eclampsia, prematurity or thrombosis) and requires a more aggressive approach to the obstetric care. This should include full anticoagulation in the puerperium and frequent ultrasound monitoring with uterine and umbilical artery Doppler blood flow analyses to detect complications such as pre-eclampsia and placental insufficiency.

It is recommended that all women with APS should maintain antithrombotic treatment throughout their entire pregnancy and during the postpartum period. The treatment of choice is combined low-dose aspirin and full antithrombotic doses of low molecular weight heparin. In high risk groups, such as history of previous thrombotic events, warfarin may be used during pregnancy, but only after organogenesis (6th-12th wk) because of high risks of fetal malformations. Despite the significant risks associated with pregnancy in patients with APS, with the correct management the likelihood of a live birth is around 75%-80%[25].

To the best of our knowledge, this is the first report in the English literature of spontaneous colonic perforation due to APS following cesarean section. Our patient was previously fit and healthy and received the standard prophylaxis for thromboembolism with low molecular weight heparin. The underlying APS in combination with pregnancy and surgery, both of which are risk factors for thromboembolism, caused mesenteric thrombosis and cecal infarction.

Abstract

The role of *nm23H1* genetic instability is not limited to gastrointestinal malignances. A similar close relationship exists between *nm23H1* genetic instability and other non gastrointestinal systemic malignancies. For instance, in oral malignant melanomas with lymphoid metastasis, the *nm23H1* expression is significantly lower in contrast to tumors with no lymphoid metastasis. Similarly, increased metastasis is seen in non small cell lung cancers following down regulation of *nm23H1* in conjunction with KAI-1 down regulation. There is an inverse relationship between tumor stage and metastasis and *nm23H1* expression in individuals with prostate carcinomas and a similar relationship exists between microsatellite instability of the *nm23H1* gene and ovarian carcinogenesis. For instance, nearly 70.5% of stage I - II ovarian tumors express *nm23H1* in sharp contrast to only 25% of stage III-IV ovarian tumors. As is clearly evident, *nm23H1* has a major role in gastrointestinal and non-gastrointestinal carcinogenesis. The coming few years will hopefully see the development of new strategies by virtue of which we can alter *nm23H1* expression and thus decrease the risk of metastasis in malignant tumors.

Key words: *nm23H1*; Non small cell lung cancers; Prostate carcinomas; Nasopharyngeal carcinomas

Kapoor S. *nm23H1* expression and its role in the evolution of non-gastrointestinal malignancies. *World J Gastroenterol* 2009; 15(4): 506-507 Available from: URL: http://www.wjgnet. com/1007-9327/15/506.asp DOI: http://dx.doi.org/10.3748/wjg.15.506

TO THE EDITOR

The recent article by Yang *et al*[1] about the relationship between gastrointestinal malignancies and *nm23H1* genetic instability is highly interesting. Interestingly, the role of *nm23H1* genetic instability is not limited to gastrointestinal malignancies. In fact, a similar close and intricate relationship exists between *nm23H1* genetic instability and other non gastrointestinal systemic malignancies.

For instance, Korabiowska *et al*[2] have shown that the *nm23H1* expression is significantly lower in oral malignant melanomas with lymphoid metastasis than in tumors with no lymphoid metastasis. Similarly, increased metastasis is seen in non small cell lung cancers following down regulation of *nm23H1* in conjunction with KAI-1 down regulation[3]. Similarly, there is an inverse relationship between tumor stage and metastasis and *nm23H1* expression in individuals with prostate carcinomas[4]. A similar relationship exists between microsatellite instability of the *nm23H1* gene and ovarian carcinogenesis. For instance, nearly 70.5% of stage I - II ovarian tumors express *nm23H1* in sharp contrast to only 25% of stage III-IV ovarian tumors[5].

Similarly, *nm23H1* expression may be used to determine response to treatment. For instance, following radiotherapy, the five-year survival rate in patients with nasopharyngeal carcinomas and high expression of *nm23H1* is 53.2% in comparison to only 22.7% in individuals with low expression of *nm23H1*[6]. In fact, transfer of *nm23H1 via* adeno viruses is rapidly emerging as a potential therapeutic tool to prevent metastasis. For instance, this method has been shown to decrease metastasis in implantation models of ovarian cancer[7].

As is clearly evident, *nm23H1* plays a major role in gastrointestinal and non-gastrointestinal carcinogenesis. The coming few years will hopefully see the development of new strategies by virtue of which we can alter *nm23H1* expression and thus decrease the risk of metastasis in malignant tumors.

Global Collaboration for Gastroenterology
For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1212 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: Introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Leader Frontier: Comment on excitement and existing problems of core fields, and offer suggestions for the future research; (3) Topic Highlight: Experts in liver cancer to focus on certain individual hot topics and try to provide answers to the clinical questions on the topics; (4) Observation: Which updates the development of old and new questions, highlights unsolved questions, and provides strategies on how to solve the questions; (5) Guidelines for Basic Research: Which provides Guidelines for basic research; (6) Guidelines for Clinical Practice: Which provides guidelines for clinical diagnosis and treatment; (7) Review Articles: Summarize the representative progress in core scientific disciplines, comment on the research status, and make suggestions for the future work; (8) Original Articles: Originally report the innovative and valuable findings in liver cancer; (9) Brief Articles: Briefly report the novel and innovative findings in liver cancer; (10) Case Report: Report a rare or typical case; (11) Letters to the Editor: Discuss and make reply to the contributions published in LCRL, or introduce and comment on a controversial issue of general interest; (12) Book Reviews: Introduce and comment on quality monographs of liver cancer; and(13) Guidelines: Guidelines or common understanding for liver research from international academic committee.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials. gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www. wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the aim should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520. pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H pylori*, *E coli*, *etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No.62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Hepatocellular carcinoma (HCC) is a major health problem, being the sixth most common cancer world-wide. Dysregulation of the balance between proliferation and cell death represents a pro-tumorigenic principle in human hepatocarcinogenesis. This review updates the recent relevant contributions reporting molecular alterations for HCC that induce an imbalance in the regulation of apoptosis. Alterations in the expression and/or activation of p53 are frequent in HCC cells, which confer on them resistance to chemotherapeutic drugs. Many HCCs are also insensitive to apoptosis induced either by death receptor ligands, such as FasL or TRAIL, or by transforming growth factor-beta (TGF-β). Although the expression of some pro-apoptotic genes is decreased, the balance between death and survival is dysregulated in HCC mainly due to overactivation of anti-apoptotic pathways. Indeed, some molecules involved in counteracting apoptosis, such as Bcl-X$_L$, Mcl-1, c-IAP1, XIAP or survivin are over-expressed in HCC cells. Furthermore, some growth factors that mediate cell survival are up-regulated in HCC, as well as the molecules involved in the machinery responsible for cleavage of their pro-forms to an active peptide. The expression and/or activation of the JAK/STAT, PI3K/AKT and RAS/ERKs pathways are enhanced in many HCC cells, conferring on them resistance to apoptotic stimuli. Finally, recent evidence indicates that inflammatory processes, as well as the epithelial-mesenchymal transitions that occur in HCC cells to facilitate their dissemination, are related to cell survival. Therefore, therapeutic strategies to selectively inhibit anti-apoptotic signals in liver tumor cells have the potential to provide powerful tools to treat HCC.

INTRODUCTION

Apoptosis represents a physiological way to eliminate excess cells during both liver development and regeneration[1]. Indeed, insufficient apoptosis has been associated with development and progression of tumors of the liver and the biliary tree[1,2]. Hepatocellular carcinoma (HCC) is a major health problem, being the sixth most common cancer world-wide[3]. It is a heterogeneous tumor commonly associated with chronic liver diseases which frequently culminate in cirrhosis, such as alcoholic cirrhosis and chronic hepatitis B and C infections. During recent years, major advancements in the knowledge of this complex disease have been reported[3]. This review is an effort to update the recent relevant contributions reporting molecular alterations for HCC that induce an imbalance in the regulation of apoptosis.

THE P53 PATHWAY

Among the most common alterations observed in HCC are mutations in the p53 tumor suppressor gene (*TP53*)[4]. Different chemotherapeutic agents require p53 to induce apoptosis. Indeed, tumors with a disruption in the p53 pathway are generally resistant to chemotherapy. The presence of specific mutational hotspots in *TP53* in different types of human cancer implicates environmental carcinogens and endogenous processes. In this sense, somatic mutations at the third base in codon 249 of *TP53* in HCC have been related to exposure to aflatoxin B1 (AFB1), in association with HBV infection[4]. Chronic infection with HBV and HCV viruses and exposure to oxidative stress, including hemochromatosis or inflammation, induce damage in the DNA and mutations in cancer-related genes, including *TP53*. Thus, it would

seem plausible that p53 mutation might operate in either HCC initiation or progression, depending on the context. However, adenoviral delivery of p53 recombinant DNA into mice models bearing hepatocellular carcinomas did not apparently suppress tumor growth[5]. De-Pinho et al in a recent work[6] have helped to clarify this point. They have demonstrated that the effect of p53 loss in hepatocellular carcinoma that is associated with chronic liver disease is dependent on cellular context, in particular intact or dysfunctional telomeres, and they have hypothesized that a decreased p53 function might contribute to hepatocyte survival in the presence of telomere-induced chromosomal instability.

THE TGF-β PATHWAY

The transforming growth factor-beta (TGF-β) family of cytokines plays a physiological role during embryonic development and its misregulation can result in tumorigenesis[7]. TGF-β-1 is an important regulatory suppressor factor in hepatocytes, inhibiting proliferation[8] and inducing cell death[9]. Paradoxically, TGF-β may also modulate other pro-tumorigenic processes, such as cell invasion, immune regulation or microenvironment modification[7]. Blocking TGF-β up-regulates E-cadherin and reduces migration and invasion of hepatocellular carcinoma cells[10]. Furthermore, liver tumors expressing late TGF-β-responsive genes (anti-apoptotic and metastatic) display a higher invasive phenotype and increased tumor recurrence when compared to those that show an early TGF-β signature (suppressor genes)[11]. Indeed, the escape from the antiproliferative and pro-apoptotic actions of TGF-β might be a prerequisite for hepatocarcinoma progression[12].

Disruption of the TGF-β pathway occurs in HCC[13] and might cause dysregulation of apoptosis. In favour of this hypothesis, recent studies have demonstrated that overexpression of SMAD3 reduces susceptibility to develop hepatocarcinoma, by sensitizing hepatocytes to apoptosis through down-regulation of Bcl-2[12]. However, perturbations at receptor or SMAD levels do not appear to be as frequent as they are in colon or pancreatic cancer[13] and expression of TGF-β is up-regulated in a great percentage of HCC patients[11,13]. Thus, other possible ways to disrupt TGF-β signalling might exist and they remain to be explored. Interestingly, Mishra et al have recently demonstrated that HCC might arise from loss of TGF-β signalling adaptor protein embryonic liver foldrin (ELF), a crucial Smad3/4 adaptor[14,15]. HCC cells might also overexpress a specific set of microRNAs (miRNAs) that would allow the escape from TGF-β-induced apoptosis[16,17]. Furthermore, recent results have indicated that TGF-β might play a dual role in controlling apoptosis in hepatocytes and hepatoma cells. On one hand, it induces cell death, but on the other it could activate anti-apoptotic signals, the epidermal growth factor receptor (EGFR) being required for this effect[18-20]. Indeed, EGF is an important survival signal for TGF-β-induced apoptosis in hepatocytes[21]. The enzyme phosphatidylinositol 3-kinase (PI3K) mediates the effect of EGF on TGF-β-induced death by acting upstream from the mitochondrial

changes, probably counteracting TGF-β-induced oxidative stress[22]. The autocrine loop of EGFR activated by TGF-β in hepatoma cells would require a high activity of TACE/ADAM17[20], the metalloprotease responsible for shedding of the pro-tumor necrosis factor (proTNF-α) that it is also necessary for shedding of the EGF family of growth factors[23]. Although the possible role of an increased expression of TACE/ADAM17 in the development of human hepatocellular carcinoma (HCC) has been barely studied, a recent report indicates that the quantities of ADAM17 mRNA vary among different pathological types of HCC, but are significantly higher in poorly differentiated HCC than in well or moderately differentiated HCC[24]. Overexpression of TACE/ADAM17 might confer an advantage on HCC cells by impairing TGF-β-induced apoptosis through transactivation of the EGFR. Concluding, HCC cells might impair the suppressor arm in TGF-β-signalling, with enhancement of the response to this factor in terms of tumor progression and invasion (Figure 1).

THE DEATH RECEPTOR PATHWAYS

HCCs show resistance to apoptosis mediated by several death receptors. The majority of the HCCs show one or more alterations in the Fas pathway molecules, which inhibit Fas-mediated apoptosis[25]. The status of Fas and Fas ligand (FasL) expression can predict HCC recurrence[26]. Loss of response to Fas in HCC cells may be produced either by down-regulation of Fas expression[25,27], concomitant with decreased expression of downstream molecules, such as FADD or FLICE[27], or by up-regulation or over-activation of molecules that counteract its pro-apoptotic effect, including nuclear factor-kappaB (NF-κB), Bcl-2 or Bcl-X$_L$[28-30]. The cellular FLICE/caspase-8-inhibitory protein (cFLIP), an intracellular inhibitor of caspase-8 activation, is constitutively expressed in human HCC cell lines and displays higher levels in HCC tissues than in nontumor liver tissues[31]. It has also been described that HCC tissues show overexpression of BRE, an antiapoptotic protein that binds to the cytoplasmic domains of tumour necrosis factor (TNF) receptor-1 and Fas, attenuating death-receptor initiated apoptosis[32]. Furthermore, it has been suggested that extracellular factors might counteract Fas-induced apoptosis in HCC cells. Indeed, hepatocyte growth factor (HGF), through activation of the PI3K/AKT pathway, suppresses Fas-mediated cell death in human HCC cell lines, by inhibiting Fas-death-inducing signalling complex (DISC) formation, especially FADD and caspase 8 interaction[33] (Figure 2).

TNF-related apoptosis-inducing ligand (TRAIL) selectively induces apoptosis in various transformed cell lines but not in almost normal tissues[34]. HCC cells constitutively express TRAIL mRNA and protein, but there are contradictory and confusing data about the expression of the different TRAIL receptors in HCC cells and tissues[35-37]. Certain evidence indicates that most HCC cells are insensitive towards TRAIL-mediated apoptosis, suggesting that the presence of mediators can inhibit the

TRAIL cell-death-inducing pathway in HCC[36,37]. It has been reported that hepatitis B virus core protein inhibits TRAIL-induced apoptosis by blocking the expression of the TRAIL receptor 2 (TRAIL-R2/DR5)[38]. Overactivation of NF-κB and Bcl-X_L in HCC cells might also restrain the TRAIL-mediated apoptosis[39]. After an initial debate about the potential liver toxicity of TRAIL in freshly isolated human hepatocytes[37], there is a recent interest in the development of new therapeutic approaches that can sensitize HCC cells to TRAIL-induced apoptosis. Indeed, it has been proposed that TRAIL, in combination with chemotherapeutic agents, may have potential in the treatment of HCC[40]. Of clinical relevance, proteasome inhibitors and histone deacetylase (HDAC) inhibitors might sensitize HCC cells but not primary human hepatocytes for TRAIL-induced apoptosis[41,42].

ALTERATIONS IN THE EXPRESSION OR FUNCTION OF APOPTOSIS REGULATORY PROTEINS

It is worthy of note that many of the genetic alterations observed in HCC lead to an imbalance in the pro- and anti-apoptotic members of the Bcl-2 family[43]. Bcl-X_L is overexpressed in a great percentage of HCCs[44], and so is Mcl-1[45]. In contrast, pro-apoptotic members of the family, such as Bax or Bcl-X_S are down-regulated in HCC with dysfunction in the p53 pathway[46]. Furthermore, recent results have indicated that some pro-apoptotic members of the BH-3-only family, such as Bid, show decreased expression in HCC related to hepatitis B or C infection[47].

Recent investigations have revealed that nearly 90% of clinical tumors from advanced HCC patients express high levels of X-linked inhibitor-of-apoptosis protein (XIAP), a well known inhibitor of caspases. Studies in established HCC cell lines with different metastatic capabilities indicated a correlation of metastasis with resistance to apoptosis and increased expression of XIAP[48]. Interestingly, it had previously been suggested that XIAP might also function as a cofactor in TGF-β signalling[49]. Thus, overexpression of XIAP might confer resistance to the apoptotic effects of TGF-β, allowing HCC cells to respond to this cytokine in terms of migration and invasion. Genome-wide analyses of tumors in a mouse model of liver cancer and in HCC tissue have recently revealed a recurrent amplification in a region of human chromosome 11q22, delineating *cIAP1*, the known inhibitor of apoptosis, as one of the candidate oncogenes in the amplicon[50]. Survivin, another member of the family of inhibitor of apoptosis proteins, is also overexpressed in HCC cell lines and tissues[51,52] and it has been suggested that it might play a pivotal role in metastasis[53]. Survivin might play an important role in progression of HCC not only by inhibiting apoptosis[54], but also by promoting cell proliferation[51] and may be positively correlated with high risk of disease recurrence and poor prognosis[55]. Concluding, HCC cells show an imbalance

in the expression of pro- and anti-apoptotic proteins, which favours cell survival (Figure 2).

OVERACTIVATION OF SURVIVAL SIGNALS IN HCC CELLS

Some autocrine signal activators, such as EGF receptor (EGFR) ligands, might protect liver tumor cells from apoptosis induced by stress, physiological factors or pro-apoptotic drugs[56]. Dysregulation of growth factor signalling, including EGF and IGF-1 pathways, has been well established in human HCCs[57,58]. Viral hepatitis infections might contribute to the enhancement of the expression of EGFR ligands[59]. The tyrosine kinase p60^{c-src} is also overactivated in hepatoma cells[56,60] that protect themselves from death stimuli[61], and it accounts in a large part for the desensitization of liver tumor cells to TRAIL and CD95. Interestingly, blockade of EGFR or c-Src in primary hepatocytes only marginally increases cell death[56,61], which indicates that both tyrosine kinases are critical effectors that specifically protect liver cancer cells from death stimuli, providing a weak point in cancer cells for a potential therapeutic approach.

Signal transducer and activator of transcription (STAT) proteins become activated by tyrosine kinases in response to cytokines and growth factors. It has been reported that suppressor of cytokine signalling (SOCS)-1 and (SOCS)-3, negative regulators of the JAK2-STAT signalling pathway, are silenced by methylation in human hepatoma cell lines and HCC tissues, which leads to constitutive activation of STAT3 in these cells[62,63]. Deletion of the *(SOCS)-3* gene in hepatocytes promotes the activation of STAT3, resistance to apoptosis and accelerated proliferation, resulting in enhanced hepatitis-induced hepatocarcinogenesis[64]. In addition, hepatitis C virus (HCV) core protein exerts an inhibitory effect on *(SOCS)-1* gene expression[65]. Hepatitis viruses also activate STAT-3 *via* oxidative stress[66-68], which might contribute to cellular transformation[69]. Abrogation of constitutive STAT3 activity sensitizes human hepatoma cells to apoptosis induced by TRAIL or drugs[70,71].

The PI3K/Akt pathway is also altered in HCC. The expression of the *PTEN* gene product is reduced or absent in almost half of HCCs and hepatocyte-specific abrogation of *PTEN* expression in mice results in the development of HCCs[72]. Recent results have indicated that the expression of a negative regulator of PI3K (phosphatidylinositol-3-kinase interacting protein I: PIK3IP1) is reduced in most cases of human HCC, pointing to a tumor suppressor-like function for this protein[73]. Interestingly, hepatic overexpression of PIK3IP1 negatively regulates PI3K activity in the tissue and suppresses the development of HCC[73].

Overexpression of Ras proteins is frequently observed in HCC[74], at least in part due to epigenetic silencing of inhibitors of the Ras pathway[75]. Furthermore, it has been reported that the expression of different ERK inhibitors, such as the Spred family of Ras/ERK inhibitors or the dual-specificity phosphatase-1 (DUSP1), is dysregulated in

Figure 1 Dysregulation of the TGF-β pathways in HCC cells favours its pro-tumorigenic activities. In red, molecules whose expression is down-regulated; in green, molecules either up-regulated or overactivated. See text for details.

Figure 2 Alterations in the expression or functions of death receptor pathways and apoptosis regulatory proteins in HCC cells. In red, proteins either down-regulated or inactivated; in green, proteins either up-regulated or overactivated. See text for details.

Figure 3 Overactivation of survival signals in HCC cells. In red, proteins either down-regulated or inactivated; in green, proteins either up-regulated or overactivated. See text for details.

HCC[76,77]. Activated *RAS* oncogene collaborates with the hepatitis B virus HBx protein to transform cells by suppressing HBx-mediated apoptosis[78]. Thus, dysregulation of the Ras pathway might also be playing a role in balancing pre-neoplastic hepatocytes towards survival in HBV- or HCV-mediated HCC.

In summary, different molecular alterations may contribute to an enhancement of anti-apoptotic signals in HCC cells that allow them to survive pro-apoptotic stimuli (Figure 3).

LIVER INFLAMMATION AND RESISTANCE TO APOPTOSIS

A link between inflammation and liver cancer was suspected some years ago, but the precise mechanisms are just beginning to be understood[79]. Recent experimental data support the hypothesis that inflammation promotes carcinogenesis and that NF-κB signalling is at the heart of such inflammation[79]. Different studies have implicated members of the NF-κB/Rel family in both HBV- and HCV-induced neoplastic development of the liver[80].

Several mechanisms have been proposed for activation of NF-κB by the hepatitis virus. Overall, inflammatory hepatitis might activate NF-κB by the concerted action of cytokines, such as TNF-α, chemokines or interleukins, and viral proteins, which likely will promote cell survival of pre-cancerous hepatocytes[80]. Furthermore, a correlation between EGFR ligands and NF-κB activity has been provided by studies in transforming growth factor-alpha (TGF-α)/c-Myc mice. Indeed, an important role for NF-κB in inhibiting c-Myc-induced apoptosis was found essential for hepatocarcinogenesis[81]. Two pro-survival NF-κB targets are an antiapoptotic member of the Bcl-2 family, Bcl-XL, and a member of the caspase inhibitors, XIAP, which are frequently overexpressed in human HCCs, as commented above[44,48]. Interestingly, the NF-κB/Bcl-XL/XIAP axis potently counteracts the TGF-β-induced apoptosis[82] and exerts a general cytoprotective role on preneoplastic hepatocytes[83]. Recent results also link NF-κB to the increase in the autocrine expression of EGF receptor ligands, such as TGF-α, in hepatocytes and hepatoma cells[84,85]. In summary, overactivation of the NF-κB pathway might generate resistance to apoptosis, through different mechanisms, in HCC cells (Figure 2).

Many epidemiological studies demonstrate that treatment with non-steroidal anti-inflammatory drugs (NSAIDs) reduces the incidence and mortality of certain malignancies, especially gastrointestinal cancer[86]. The cyclooxygenase (COX) enzymes are well known targets of NSAIDs. Overexpression of COX-2 in HCC cells increases proliferation and survival through Akt activation[87]. Accordingly, recent evidence indicates that selective inhibition of COX-2 in HCC cells leads to a marked induction of apoptosis and inhibition of proliferation and, thus, may offer therapeutic and preventive poten-

tial in human hepatocarcinogenesis[88]. COX-2 inhibitors might induce apoptosis signalling in HCC cells via death receptors and mitochondria[89]. Recent data have demonstrated that simultaneous inhibition of PI3K/Akt/mTOR and COX-2 activity in *in vitro* models causes massive apoptosis of neoplastic hepatocytes[90].

EPITHELIAL-MESENCHYMAL TRANSITIONS AND APOPTOSIS RESISTANCE

During later stages in the development of liver tumors, a loss in cell-cell contacts and the acquisition of fibroblastic-like phenotype is observed. This phenomenon, known as epithelial-to-mesenchymal transition (EMT), might contribute to increasing the migratory and metastatic capabilities of the cells[91]. Cytokines, such as TGF-β and extracellular matrix molecules are thought to fundamentally contribute to the microenvironmental interaction between stromal and malignant cells, and provide the basis for a broad repertoire of epithelial transdifferentiation. Interestingly, EMT of liver cells also results in enhanced resistance to apoptosis[92,93], probably due to up-regulation of *SNAI1*, the gene that codifies for Snail, a repressor of E-cadherin expression that also has effects on cell homeostasis, inhibiting the cell cycle and preventing cell death[94] (Figure 1).

A high percentage of human HCCs show high levels of β-catenin[95,96], either through stabilizing mutations of the β-catenin or overexpression of *FZD*, therefore favouring the intracellular accumulation of the protein[95]. Furthermore, certain evidence indicates that TGF-β might induce nuclear β-catenin accumulation, through induction of PDGF signalling[97] (Figure 1). β-catenin expression leads to elevated EGFR levels in hepatocytes and inmunohistological analysis shows high correlation between the expression of nuclear/cytoplasmic β-catenin and EGFR in most hepatoblastomas[57]. β-catenin also participates in homotypic cell-cell interactions through its association with E-cadherin. Thus, β-catenin accumulation in HCC cells might contribute to impairing E-cadherin expression, mediating the EMT process, migration and survival. Indeed, there is evidence suggesting that up-regulation of *CTNNB1*, the gene encoding for β-catenin, also contributes to the enhancement of hepatocellular carcinoma cell survival[98].

In summary, a significant number of relevant molecular mechanisms altered in HCC initiation and progression are compromising the balance between survival and apoptotic signals in the pre-neoplastic hepatocytes. Some physiological pro-apoptotic molecules are down-regulated or inactivated in HCC, but the balance between death and survival is mainly disrupted due to overactivation of anti-apoptotic signals. Therefore, liver cancer cells might show stronger requirements of these intracellular pathways to survive. The absence of standard systemic therapy for advanced cases of HCC has changed with the recent positive randomized trial testing the multikinase sorafenib, which represents a breakthrough in the management of this neoplasm[3,58]. Interestingly, sorafenib induces tumor

cell apoptosis in HCC cells, through, at the least, inhibiting the RAF/MEK/ERK pathway[99]. Similar situations might be found with other multikinase inhibitor drugs that are on the way towards approval for HCC therapy[58,100]. Of relevance here is certain evidence indicating that erlotinib-induced growth inhibition in HCC cells correlates with overexpression of pro-apoptotic factors like caspase and gadds, as well as down-regulation of anti-apoptotic factors, such as Bcl-X$_L$[101]. Another receptor tyrosine kinase inhibitor, sunitinib, which has also shown intriguing outcomes in advanced HCC[100], is a strong apoptosis inducer in different tumor cells, an effect that is enhanced in the presence of inhibitors of the PI3-K/Akt/mTOR pathway[102]. Bevacizumab, an anti-vascular endothelial growth factor (VEGF) monoclonal antibody, has been proven to be efficient in inhibiting the growth of nonmetastatic HCC[103]. Interestingly, recent evidence indicates that VEGF signalling inhibitors might be effective in inhibiting tumorigenesis more through their pro-apoptotic than their anti-angiogenic properties[104]. Therefore, therapeutic strategies to selectively inhibit anti-apoptotic signals in HCC cells might have the potential to provide powerful tools in the future to treat liver cancer.

Abstract

The gastrointestinal tract uses a system of tolerance and controlled inflammation to limit the response to dietary or bacteria-derived antigens in the gut. When this complex system breaks down, either by a chemical or pathogenic insult in a genetically predisposed individual the resulting immune response may lead to inflammatory bowel disease. Although the aetio-pathogenesis of inflammatory bowel disease remains unsolved current evidence indicates that defective T-cell apoptosis and impairment of intestinal epithelial barrier function play important roles. In inflammatory bowel disease, it has been reported that activation of macrophages seems to be as important as increased production of the macrophage-derived cytokines such as TNF-α, IL-1 and IL-6. The triggering factor for this cascade is still to be elucidated as to whether it represents an auto-antigen or a hetero-antigen. It has been also demonstrated that a serologic anti-microbial response exists. This response includes antibodies against saccharomyces cerevisiae (ASCA), *E. coli* outer membrane porin C (Omp-C), flagelin (cBir1) and pseudomonas aeroginosa (I2). Host response to microbial pathogens includes self-defense mechanisms including defensins, pattern recognition receptors and Toll-like receptors. Neuroimmunomodulation in inflammatory bowel disease (IBD) is another interesting approach with implications on the influence of brain-gut axis on intestinal inflammation and its perpetuation. It is probable that inflammatory bowel disease represents a heterogenic group of diseases that share similar mechanisms of tissue damage but have different initiating events and immunoregulatory abnormalities. A better understanding of all these events will hopefully provide new insights into the mechanisms of epithelial responses to microorganisms and ideas for therapies.

INTRODUCTION

Although the pathogenesis of inflammatory bowel disease (IBD) still remains unexplained, its pathophysiological mechanisms have been more extensively investigated and correspond to what is known about inflammatory disease processes in general. Our understanding of these disorders has benefited enormously from the development of novel animal models and recent advances in cell and molecular biology. Nowadays, it is commonplace that in IBD, a wide diversity of immunological changes occurs, including altered populations of inflammatory cells and activation of a range of inflammatory pathways.

TOLERANCE AND CONTROL OF INFLAMMATION IN IBD

The gastrointestinal tract uses a system of tolerance and controlled inflammation to limit the response to dietary or bacteria-derived antigens in the gut[1-3]. When this complex system breaks down, either by a chemical or pathogenic insult in a genetically predisposed individual

the resulting immune response may lead to IBD[4-8]. Although the aetiopathogenesis of IBD remains unsolved, current evidence indicates that defective T-cell apoptosis and impairment of intestinal epithelial barrier function play important roles[9,10]. Differences in T-cell responses between Crohn's disease (CD) and ulcerative colitis (UC) have been identified, with mucosal T-cell apoptosis being defective in CD but not in UC[7]. In both CD and UC, it has been reported that activation of macrophages seems to be as important as increased production of the macrophage derived cytokines TNF, IL-1 and IL-6[11,12].

Chemokines play a central role in the pathogenesis of IBD as they are able to trigger multiple inflammatory actions including leukocyte activation and chemoattraction, granulae exocytosis, production of metalloproteinases for matrix degradation and upregulation of the oxidative burst[13]. Dysregulated cytokine production by mucosal lymphocytes and macrophages has been implicated in the pathogenesis of IBD. In fact, an exclusive increase of CD4+ T cells in inflammatory bowel disease and their recruitment as intraepithelial lymphocytes has been demonstrated[14,15], while a potential therapeutic effect of capthesin inhibition *via* macrophages *in vivo* has been also suggested[16,17]. Over the past few years, various murine models of chronic intestinal inflammation resembling IBD have been discovered that have provided important clues as to the nature of this dysregulation and to its possible treatment with cytokines, for example IL-10[18,19].

It is clear from various studies that nuclear factor kappa B (NF-κB) and various other regulatory proteins are very likely to play a key role and it seems that we will gain new, fundamental insights into the pathogenesis, prognosis and treatment of IBD by analyzing further transcriptional regulatory mechanisms in chronic intestinal inflammation. This allows us to understand the basis for altered cytokine gene transcription in patients with IBD. Furthermore, such studies will hopefully permit the design of new treatment strategies that will be able to add specificity but reduced toxicity compared with standard immunosuppressive therapies[20].

TRIGGERING FACTORS OF THE INFLAMMATORY CASCADE IN IBD

The symptomatic phases of IBD are characterized by migration of large numbers of neutrophils and accumulation in the intestinal lumen. The triggering factor for this cascade is still to be elucidated whether it represents an auto-antigen or a hetero-antigen, i.e. a microbial component. Dysbiosis is the disturbance of intestinal microflora resulting in the breakdown in the balance between 'protective' *vs* 'harmful' intestinal bacteria[21]. Dysbiosis is implicated in many chronic diseases such IBD, which are associated with 'westernized' life style. It has been shown that enteric bacteria do not have equal capacities to induce or protect from inflammation and, interestingly, even *H pylori* infection has been implicated in CD pathogenesis[22].

It has been also demonstrated that in CD patients a serologic 'anti-microbial' response exists. In fact, granulomas in mesenteric lymph nodes from CD patients are composed of centrally located T-lymphocytes and of epithelioid cells, which are of monocyte/macrophage origin and have the characteristics of antigen presenting cells[23].

Currently available 'anti-microbial' response panel of laboratory tests includes antibodies against saccharomyces cerevisiae (ASCA), *E. coli* outer membrane porin C (Omp-C), flagelin (cBir1) and pseudomonas aeroginosa (I2)[24-26]. Of particular interest is that ASCA may develop before the obvious clinical diagnosis of CD according to a study using serum samples from the Israeli Defense Corp repository. In this study, 32% of patients were ASCA (+) 38 mo before CD clinical diagnosis was established[27]. The target antigen for pANCA is currently unknown and there is still variation regarding the inter-observer agreement with the several assays used for their determination. These serologic markers may be of great potential importance as they can provide more information on the IBD pathogenesis, the differentiation between UC and CD, the definite diagnosis of indeterminate colitis cases, the prediction of pouchitis and prediction of response to therapies. It is of importance that ASCA have a genetically modulated expression as they are found in 20%-25% of relatives of CD patients and are absent in spouses. In addition, pANCA are present in up to 20% of unaffected relatives of UC patients and they persist after colectomy indicating into two points: that the target antigen in IBD is not fully eradicated and that it is not just the colon which is immunologically targeted in UC[28-31].

It has to be emphasized that the serological markers are far from being the gold standard in IBD diagnostics and need to be combined, as they do not work separately in the clinical setting.

HOST RESPONSE TO MICROBIAL PATHOGENS

Host response to microbial pathogens includes self-defense mechanisms such as defensins, pattern recognition receptors (PRRs), pathogen-associated molecular patterns (PAMPs) and Toll-like receptors (TLRs). Toll-like receptors recognize conserved motifs on pathogens that are not found in higher eukaryotes and initiate 'innate' (rapid and non-specific) immune response. Subsequently, specific receptors recognizing chemo-attractant molecules mobilize phagocytic leukocytes and induce their migration to inflammatory sites. There, leukocytes encounter the invading microorganisms and ingest them through the activation of phagocytic receptors that mediate the uptake process. Innate immune responses are linked to the generation of corresponding adaptive immune responses and studies of genetically engineered or cellularly manipulated animal models have generated a great deal of new information[32].

Leukocyte-epithelial interactions are of special inter-

est as exposure of epithelial TLRs to microbial ligands has been shown to result in transcriptional upregulation of inflammatory mediators whereas ligation of leukocyte TLRs modulate specific antimicrobial responses[26]. It has been shown that Paneth cells play an important role in innate host defense *via* their ability to secrete antimicrobial peptides and proteins[33]. In addition, it has been shown that NOD2 mutations lead to loss of negative regulatory effects on TLR signaling while activation of the CARD domain results in activation of NF-κB[34].

THE MOLECULAR BASIS OF THE INTESTINAL IMMUNITY

Major advances in our understanding of the molecular basis of Rho guanine-triphosphatases (GTPases) function in regulating the phagocytic leukocytes that constitute the innate immune response have also been made. However, significant challenges remain. The molecular mechanisms involved in sensing chemotactic gradients, in maintaining polarized movement, and in coordinating the dynamics of the actin, myosin and microtubule cytoskeletons that are mediated by Rho GTPases remain to be worked out[32].

Matrix metalloproteinases (MMPs) seem also to play a crucial role in physiological and pathophysiological reactions such as leukocyte accumulation into inflamed tissue, cytokine production from inflammatory and epithelial cells, T lymphocyte homing to the intestine, wound healing and proliferation of epithelial cells, and intestinal innate immunity and permeability[35].

Neuroimmunomodulation in IBD remains a challenging theory with implications on the influence of brain-gut axis on intestinal inflammation and its perpetuation[36-38]. In recent years, considerable evidence has accumulated that psychological stress does indeed contribute to the risk of relapse in IBD. Furthermore, laboratory research has indicated a variety of mechanisms by which stress can affect both the systemic and gastrointestinal immune and inflammatory responses[39].

UNDERSTANDING THE MULTIFACTORIAL CHARACTER OF IBD

Despite decades of research the etiology of IBD remains largely unexplained, even though there is agreement with regard to these disorders' multifactorial character. Considering the epidemiological, genetic and immunological data, we can conclude that IBD are heterogeneous disorders of multifactorial etiology in which hereditary (genetic) and environmental (microbial, behavior) factors interact to produce the disease. It is probable that patients have a genetic predisposition for the development of the disease coupled with disturbances in immunoregulation. The disease can then be triggered by any of a number of different unknown environmental factors and sustained by an abnormal immune response to these factors. Rather, the intensive

interaction between intestinal epithelial cells and immune competent cells is critical to maintain and perpetuate the chronic inflammatory process characteristic for IBD.

Once the role of genetic determinants is fully understood, early interventions can be designed to prevent disease in predisposed individuals. Gene therapy or modification of bacterial flora with probiotics or antibiotics or both for specific pathogens is expected to be central to this approach. From population-based data, important hypotheses for more specialised studies can be created. Especially if environmental influences are suspected in the onset and/or cause of a disease, population-based studies are indispensable[40]. However, good population-based studies are rare, probably because of the difficulties in organization and the long-term engagement needed[41].

Regarding the role of environmental factors, Hippocrates wrote in his "Epidemics"[42] that "patients with abscesses without fever, as well as patients with bloody stools became sick because of the same reason: at younger age they used to live under very difficult conditions and they were forced to use their body energy and muscular power to survive. However, later on, by becoming older they turned to work less harder, their body weight increased dramatically and their flesh became soft and vulnerable."

Parallel to Hippocratic skepticism, forty years ago Burrill B. Crohn[43] asked himself a rhetoric question: "Are these inflammatory bowel diseases the product of our modern civilization, the end product of industrial revolution? The answer is not evident."

THE PRESENT AND THE FUTURE OF THERAPY IN IBD

Today we target different immunological mechanisms and we use basically two groups of treatment: immunosuppressives and anti-inflammatory molecules.

The target point(s) of the currently used immunosuppressives is still unclear. However it has been suggested that azathioprine has a direct effect on the leukocyte nucleus and migration ability towards the site of inflammation[44] while methotrexate acts as an antimetabolite of the folic acid[45].

The anti-inflammatory therapies are various depending on the mechanism designed to hit: proinflammatory cytokines inhibitors (i.e. anti-TNF-α therapies), anti-inflammatory cytokine mediators (IL-10, IL-11), adhesion molecule inhibitors (i.e. anti-a4 integrin monoclonal antibody), T-cell inhibitors (anti-CD3 monoclonal antibody), cell based therapies (i.e. absorption aphaeresis), signal transduction inhibitors, transcription factor inhibitors and hematopoietic growth factors[46].

All physicians caring for patients with inflammatory bowel disease have an expanding arsenal of medications that can achieve symptomatic remission and mucosal healing. Adding biologics to existing immunomodulators improves our rates of sustained remission and healing of mucosal ulcerations. However, further studies are

needed to help determine what our final therapeutic endpoint should be.

Abstract

Primary anaplastic carcinoma is a rare variant of small intestinal cancer. Most reports of primary anaplastic carcinoma of the small intestine are isolated case reports, therefore the clinicopathological features, therapeutic management, and surgical outcome of this tumor type remain unclear. This review analyzes the available clinical characteristics of primary anaplastic carcinoma of the small intestine and investigates key differences from differentiated adenocarcinoma of the small intestine. A Medline search was performed using the keywords 'small intestine' and 'anaplastic carcinoma' or 'undifferentiated carcinoma'. Additional articles were obtained from references within the papers identified by the Medline search. The literature revealed a poor prognosis for patients who underwent surgical resection for anaplastic carcinoma of the small intestine, which gave a 3-year overall survival rate of 10.8% and a median survival time of 5.0 mo. The literature suggests that anaplastic carcinoma is markedly more aggressive than differentiated adenocarcinoma of the small intestine. Surgical resection with the aim of complete tumor removal provides the only beneficial therapeutic option for patients with anaplastic carcinoma of the small intestine, because chemotherapy and radiation therapy have no significant effect on the rate of survival. However, despite complete tumor resection, most patients with anaplastic carcinoma of the small intestine are at great risk of disease recurrence. Multicenter clinical trials are expected to provide additional therapeutic strategies and establish the efficacy of multimodality adjuvant therapy. This report also highlights the importance of a systematic diagnostic approach for anaplastic carcinoma of the small intestine.

INTRODUCTION

The small intestine represents more than 75% of the length and 90% of the total mucosal surface area of the alimentary tract; however, it contributes only about 1% of malignant gastrointestinal tumors[1]. Several hypotheses have been proposed to explain why small intestinal tumors are rare[2]. While there are many reported reviews of small intestinal tumors[3-7] including sarcomas[8,9], only a few describe the occurrence of small intestinal carcinoma[10-13]. Small intestinal carcinomas are uncommon among the malignant tumors that occur throughout the entire alimentary tract but represent 50% of small intestinal malignant tumors. Anaplastic carcinoma is a rare variant of small intestinal carcinoma. Most reports describing the occurrence of anaplastic carcinoma of the small intestine do not include a detailed description of the pathology of this disease. The aim of the present study was to review the clinical presentation, surgical management, and prognostic factors of primary anaplastic carcinoma of the small intestine.

PATIENTS AND CLINICAL PRESENTATION

We reviewed 18 patients who underwent surgical resection for anaplastic carcinoma of the small

intestine between 1974 and 2008. Seventeen cases were identified in the available literature using a Medline search and Japan Centra Revuo Medicina (Table 1). One reported case was a patient treated in our hospital. The clinicopathological features of the 18 reported cases are listed in Table 1. The mean age of patients with anaplastic carcinoma of the small intestine was 58 years (range, 38-81 years). There was a slight male predominance, with a male-to-female ratio of 11:7. The most common presenting signs and symptoms of small intestinal cancer were nausea, vomiting, abdominal pain, melena, weight loss, anemia, and palpable mass, none of which is pathognomonic for small intestinal tumors. The most common presenting complaint of patients with anaplastic carcinoma of the small intestine was abdominal pain, which was present in 47% of patients. For malignant small bowel neoplasms the most common symptom was pain followed by gastrointestinal bleeding, weight loss, nausea, and vomiting. The nonspecific nature of the reported symptoms usually leads to a delay in presentation and work-up. The average diameter of tumors was 8.3 cm (range, 3.5-21 cm).

The most common location for small intestinal carcinoma is the duodenum[4]. More distal tumors are found more frequently in the jejunum than in the ileum[4,12]. By comparison, anaplastic carcinoma of the small intestine was not found in the duodenum but in the jejunum in 10 cases and in the ileum in 8 cases. The symptoms associated with primary small intestinal tumors were usually vague and nonspecific. The nonspecificity of the symptoms associated with this disease is considered a contributing factor in the delayed diagnosis associated with small intestinal tumors.

The pathogenesis of small intestinal carcinoma is largely unknown. Small intestinal regional enteritis, or Crohn's disease, is reported to be associated with small intestinal carcinoma. It is estimated that a carcinoma will develop in 2%-3% of patients with small intestinal regional enteritis[14]. One investigator reported a linear correlation between the incidence of small intestinal cancer and colon cancer[15].

Survival analyses of patients with small intestinal carcinoma were performed using the Kaplan Meier method with the log rank test to assess statistical significance. Values were expressed appropriately as the mean ± SD. The Cox proportional hazards regression model was used to assess the combined effects of covariates on survival. *P* values of less than 0.05 were considered significant.

TREATMENT OF SMALL INTESTINAL CANCER

In most studies, surgery as a curative treatment option for small intestinal cancer was performed in 40%-65% of patients, with reported 5-year survival rates of 40%-60% for resected tumors *versus* 15%-30% for nonresected tumors[10,11,16]. Many reports indicated that chemotherapy and radiation therapy did not significantly influence survival[12,17]. According to published reports, jejunal or ileal adenocarcinoma should be treated aggressively with segmental resection and primary anastomosis[18]. Pancreaticoduodenectomy with complete resection of the tumor and negative margins is associated with favorable long-term survival[19]. On the basis of this finding, patients with a tumor at the proximal duodenum should be treated by pancreaticoduodenectomy. Analysis of the findings of previous reports suggests that radical curative surgery is the most important prognostic factor for survival of patients with small intestinal cancer. Complete surgical resection has emerged as the most important prognostic variable in the management of this disease. A similar management strategy can be applied for the treatment of patients with anaplastic carcinoma

Figure 1 Survival after surgical resection for anaplastic carcinoma of the small intestine (*n* = 18).

of the small intestine. However, the prognosis for patients with small intestinal cancer is dismal.

PROGNOSTIC FACTORS OF RESECTABLE SMALL INTESTINAL CANCER

The 5-year survival rate for primary adenocarcinoma of the small intestine ranges from 17.5% to 37%[12,13,17]. In this review, the overall 3-year survival rate of anaplastic carcinoma of the small intestine after surgical resection was 10.8% (Figure 1). There were no patients who survived over 4 years. Thus, patients with anaplastic carcinoma of the small intestine have a poorer prognosis than patients with adenocarcinoma of the small intestine. In general, anaplastic carcinoma has a high malignancy grade potential. Consistent with findings reported in previous reviews, the prognostic factors that influence the survival of patients with anaplastic carcinoma include patient age, tumor site, clinical staging, curative resection surgery, tumor size, histological grade, nodal metastases, lymphangiosis carcinomatosa, and vascular invasion[6,12,17]. Univariate analysis of the different prognostic factors predicted to contribute to patient prognosis revealed that age and lymph node metastases were unfavorable prognostic factors. Overall median survival of patients over 65 years old with lymph node metastases was significantly worse than that for patients under 65 years old without lymph node metastases. Gender, tumor depth, tumor location, and tumor size were not significant prognostic factors (Table 2). By comparison, Veyrières *et al*[10] (1997) revealed the degree of tumor differentiation to be a significant prognostic factor. However, multivariate analysis demonstrated that lymph node metastases, and not tumor differentiation, was an independent prognostic factor[11]. For patients with anaplastic carcinoma of the small intestine, the median survival period was significantly shorter for patients with positive lymph nodes than for patients with negative lymph nodes, according to the Cox proportional hazards model (Table 3). When a curative surgical

Table 2 Clinical characteristics after surgical resection of anaplastic carcinoma of the small intestine (mean ± SD)

Characteristics	No. of patients	3 yr survival rate (%)	Median survival in months	*P* value

Lymph node metastasis		
Negative	13.7 (1.6-114.1)	0.016
Positive		
Age (yr)		
< 65	2.9 (0.7-11.8)	0.145
> 65		

resection is performed before lymph node metastases, the chance of long-term survival is greatly increased. A previous study revealed a significant positive correlation between the survival of patients with adenocarcinoma of the small intestine and pathological differentiation (Table 4). In the present review, more patients with anaplastic carcinoma had a poorer prognosis than patients with adenocarcinoma, despite curative resection of the tumor. However, the number of patients is too small to allow an accurate evaluation of prognosis. The establishment of a multicenter registry would provide a basis for multivariate analysis of factors influencing survival.

METHODS AND EFFICACY OF EARLY DIAGNOSIS

The poor prognosis for anaplastic carcinoma of the small intestine may be related to a delay in the diagnosis and treatment of the disease. An early and accurate diagnosis is essential to improve the prognosis for patients with small intestinal cancer. The correct

Table 4 Survival rates of patients with adenocarcinoma of the small intestine according to pathological differentiation

Author	Differentiation	No. of patients	Survival rate (%)		Significance
			5 yr	10 yr	
Miles[7]	Well differentiated	13	15	8	0.18
	Undifferentiated	5	60	33

	Undifferentiated	6	0		

[1]Mean survival time (months ± SD).

diagnosis of small intestinal tumors remains difficult, because the tumors are rare and the symptoms are ambiguous. Performance of a conventional double-contrast series of the small intestine proved to be an excellent diagnostic modality, but is increasingly being replaced by cross-sectional imaging methods including computed tomography (CT) and magnetic resonance imaging (MRI). CT was the most efficient method for demonstrating the presence of a mass lesion, which suggests a locally advanced tumor with contiguous organ invasion, and for confirming the absence of distant metastases. Recent advances in multidetector CT (MDCT) technology have allowed the production of high-resolution cross-sectional images of the abdomen and the small intestine[20]. Upper gastrointestinal endoscopy is an accurate method for the diagnosis of duodenal tumors, but deep insertion of an endoscope by the push technique is difficult. A novel double-balloon enteroscopy system, which was developed by Yamamoto *et al*[21], has been applied for diagnosis in patients with obscure gastrointestinal bleeding or chronic abdominal pain. The double-balloon enteroscopy system has the advantage of allowing examination of the entire small intestine by direct visualization. It is apparent from these studies that early enteroscopic examination must be performed as soon as carcinoma of the small intestine is suspected, to allow accurate and early diagnosis.

CONCLUSION

Anaplastic carcinoma of the small intestine is an extremely rare disease, is often diagnosed at an advanced stage, and displays an aggressive clinical course. Despite treatment by means of optimized surgical procedures, patients who have undergone complete tumor resection have a poor prognosis. To improve the outcome of surgical treatment, additional therapy, such as multimodality adjuvant therapy or the administration of novel molecular targeted drugs, should be considered for patients with anaplastic carcinoma of the small intestine. Furthermore, randomized, prospective clinical trials need to be conducted to demonstrate an unequivocal survival advantage for patients who have received chemotherapy or radiation therapy after resection of anaplastic carcinoma of the small intestine.

INTRODUCTION

The standardization and application in clinical practice of quantitative assays of nucleic acids enable us to measure the quantity of virus or viral load in the blood (viremia), and to study its fluctuations during treatment with antivirals in patients with chronic viral hepatitis. Since viremia represents the equilibrium between virus production by the infected cells and virus clearance by the antiviral reaction of the immune system or host's antiviral immune response, viremia variations are the consequence of continuous alterations of the equilibrium between virus and host antiviral responses, which may vary during the natural course of the infection and are associated with the fluctuations of the liver disease activity[1,2]. However, the equilibrium between virus production and clearance can be artificially altered, which increases the clearance (removal) of circulating viruses (i.e. plasma-apheresis[3]), or reduces virus production with antiviral drugs. A rapid decline in viremia has been shown in patients with chronic human immunodeficiency viruses (HIV), hepatitis B virus (HBV) and hepatitis C virus (HCV) infections a few hours after administration of antivirals[4-6]. We may study the mechanisms responsible for these viral kinetics using mathematical models that can interpret viremia fluctuations according to hypotheses based on biological knowledge. The simulation of the complex biological phenomena by means of mathematical equations based only on suppositions, hypotheses or biological evidence has progressed consistently in several fields of medicine during the past few decades. Such modeling provides a simplified description of the biological process, but it maintains sufficient complexity to uncover the major determinants of the process itself, by studying the fluctuations of measured variables and predicted parameters with several simulations.

Abstract

The simulation of the dynamics of viral infections by mathematical equations has been applied successfully to the study of viral infections during antiviral therapy. Standard models applied to viral hepatitis describe the viral load decline in the first 2-4 wk of antiviral therapy, but do not adequately simulate the dynamics of viral infection for the following period. The hypothesis of a constant clearance rate of the infected cells provides an unrealistic estimation of the time necessary to reach the control or the clearance of hepatitis B virus (HBV)/hepatitis C virus (HCV) infection. To overcome the problem, we have developed a new multiphasic model in which the immune system activity is modulated by a negative feedback caused by the infected cells reduction, and alanine aminotransferase kinetics serve as a surrogate marker of infected-cell clearance. By this approach, we can compute the dynamics of infected cells during the whole treatment course, and find a good correlation between the number of infected cells at the end of therapy and the long-term virological response in patients with chronic hepatitis C. The new model successfully describes the HBV infection dynamics far beyond the third month of antiviral therapy under the assumption that the sum of infected and non-infected cells remains roughly constant during therapy, and both target and infected cells concur in the hepatocyte turnover. In clinical practice, these new models will allow the development of simulators of treatment response that will be used as an "automatic pilot" for tailoring antiviral therapy in chronic hepatitis B as well as chronic hepatitis C patients.

STANDARD MODELS

In chronic viral infections, standard models consider the existence of two separate but linked compartments: in the former, viruses replicate inside the infected cells, and in the latter, free virions circulate in the blood (Figure 1).

Dynamics and relations among uninfected target cells (T), infected cells (I) and viral load (V) are described by three different equations. Briefly, these models assume that target liver cells (T) replicate at rate s, die at rate d, and become infected (I) at a certain rate (βTV) proportional to both T and V when they encounter free virions circulating in the blood. The infected cells are eliminated at the rate of δ I and free virions, which are produced at the rate of Ψ I, are cleared at the rate of λ V. The parameters d, β, δ, Ψ, λ are the specific constant rates of formation and clearance of infected cells and circulating free virions. Antiviral therapy can reduce target-cell sensitivity to infection or the production rate of free virions that are released in the blood from the already infected cells. The former mechanism was assigned originally to interferon (IFN) in cell cultures[7,8], and the latter to drugs that block viral replication, such as nucleos(t)ide analogs or protease inhibitors[9].

In this model, the impact of antiviral drugs on the dynamics of viral infection is considered by the coefficients (1-η) and (1-ϵ) of the equations that describe the rate of target cell infection and free virion production, where η and ϵ represent the reduction in cell susceptibility to virus infection and the reduction in free virions production, respectively (Figure 2). It is understood that the time required by the drug to achieve complete antiviral efficacy is quite short and much shorter that the circulating virion half-life.

The standard model predicts that the pattern of viral load decline in patients treated with potent antivirals that block virus production is biphasic if the half-life of the circulating virions ($T_{1/2} = \ln2/\lambda$) and that of the infected cells ($T_{1/2} = \ln2/\delta$) are different. The short half-life of the first phase of viral load decline suggests that it is associated with the clearance of circulating virions rather than infected cells (Figure 3).

Originally, Perelson et al[5], applying this approach to study HIV dynamics in patients treated with strong HIV-1 protease inhibitors, showed a very short half-life (nearly 6 h) of the virions in the blood and of infected cells (lymphocytes) (1.6 d)[5]. Likewise, when Neumann et al[6] used the same model approach in HCV-infected patients treated with IFN, they estimated that the virion half-life was 2.7 h. Moreover, contrary to HIV patients, they found that, just at the beginning of therapy, the estimated infected cell half-life (hepatocytes) was much longer (1.7-70 d), and was directly correlated with baseline viral load and inversely correlated with baseline alanine aminotransferase (ALT) levels.

With this analytical approach, the mechanism of IFN action in HCV patients is clear, and shows that the major antiviral effect is caused by a dose-dependent block of viral production in the infected cells. Therefore, the typical biphasic pattern of viral load decline observed in responder patients is to the result of a rapid reduction

Figure 1 Two-compartment model.

Figure 2 Basic model of viral dynamics.

Figure 3 Predicted decline of viral load (V) and infected cells (I) in the basic model of viral dynamics.

of free virion production, followed by a slower decrease in the number of infected cells. The modeling approach suggests monitoring the effectiveness of therapy individually, using the viral load, and predicting carefully the antiviral treatment outcome, in order to tailor the therapy schedule[9,10]. On the contrary, the standard models, although describing well the viral load decline in the first 2-4 wk of therapy, cannot adequately simulate the dynamics of the infection for the following period of treatment. Thus, the standard models, with the hypothesis of a constant clearance rate of the infected cells, provide an unrealistic estimation of time necessary to reach control or clearance of HBV/HCV infection.

MULTIPHASIC VIRAL DYNAMICS MODEL

To bypass this inconvenience, we have developed a multiphasic viral dynamics model in which we suppose a modulation of the immune system during therapy, according to negative feedback caused by a reduction in the number of infected cells. In addition, we utilized the ALT kinetics as a surrogate marker of infected-cell clearance. By this approach, we can compute the dynamics of infected cells during the whole treatment course, and we can find a good correlation between the infected cells number computed at the end of the therapy and the long term virological response in patients with chronic hepatitis C[11,12].

Concerning HBV infection, in 1996, Nowak *et al*[13] applied the standard model to analyze the decrease in viral load in patients treated with lamivudine (LMV), the first drug to show strong antiviral action on hepatitis B e antigen (HBeAg)-positive chronic hepatitis B. LMV is able to reduce significantly new viral production by infected cells and inihibit viral reverse transcriptase (RT)/polymerase. During the first rapid phase of viral load decline until the second day of treatment, Nowak *et al*[13] estimated the virus decline constant rate (u) at 0.67/d, which corresponded to a half-life of nearly 1 d for free virions. Moreover, seeing the slowing down of viral load decline after a few days of treatment, the authors reached the conclusion that the drug might have blocked only partially virus production by infected cells. Thus, to show the partial efficacy of the drug, they introduced a new factor, ρ, defined as ε in following studies, and, to explain the second phase decline of the viral load, they hypothesized that this phase may be related to the decline in the number of infected cells. Accordingly, Nowak *et al*[13] estimated with different approaches the infected cell clearance rate, by comparing viral production rate before and after therapy, and by analyzing the decline in HBeAg, an HBV secretory protein that is produced continuously by infected cells during LMV therapy. By these two methods, it was estimated that the infected cells' half-lives were equivalent and showed a wide range from 10 to 100 d (on average 16 d).

Another approach to the HBV model was implemented by Tsiang *et al*[14], who discarded the hypothesis that the number of infected cells is constant during therapy. They introduced the possibility that nucleos(t)ide analogs interfere with *de novo* infection of target hepatocytes since the RT/polymerase activity hampers the completion of the double-stranded DNA before migration towards the just-infected cell nucleous[15]. They have suggested that such an antiviral effect reduces the number of infected cells during treatment, and by this assumption, they were able to detail the HBV-DNA kinetics for 12 wk in patients treated with 30 mg/d adefovir (ADV)[14]. Using this model, Tsiang *et al*[14] have been able to show that the loss of infected hepatocytes is a rather slow process that can be described only from the second phase of viral load decline. They have reported half-lives for free virions and infected hepatocytes of 1.1 and 18 d, respectively, similar to those calcuated previously by Nowak *et al*[13].

Lewin *et al*[16], 2 years later, proposed instead a new model that suggests the possibility that infected cells can revert to their uninfected state after losing covalently closed circular DNA (cccDNA) by a non-cytolytic endogenous antiviral mechanism, similar to the one applied in the experimental models of acute HBV infection[17]. The authors have suggested that LMV or famciclovir (FCV) can partially inhibit new infections since cell polymerases in the hepatocytes nuclei can transform the circular HBV-DNA into cccDNA, which represents HBV matrix transcription. They have also found higher levels of variability in half-lives of free virions (from 1 to 92 h) and infected cells (from 2 to > 120 d). This variability is explained by the fact that even if most of the patients show a typical biphasic profile, the others show complex viral decline with "staircase" or multiphasic patterns.

Some of these patients, after the rapid first phase decline, had steady HBV-DNA levels for several days (even 4 wk) before viremia decreased, or in some cases, stabilized again. Variability in viremia decline may be explained by the patients' heterogeneity according to their different conditions of HBV infection. In fact, a phase in which viremia remains stable may depend on a patient's immunological condition, in which the infected cell clearance is very poor. This has been observed in patients at an early phase of HBV immune activation, which assumes a very low immune activation (very low δ) and a baseline number of infected cells approaching 100%. Wolters *et al*[18], following this interpretation, have

shown that higher baseline ALT levels are significantly associated with a greater rapidity of viral load decline in the second phase.

Different profiles of viremia decline may be caused by many reasons: modulation during therapy of cytolytic and non-cytolytic mechanisms of infected cell loss; presence of two or more infected cell populations with different half-lives; and infected cells with heterogeneity in their expression of drug-efflux pumps[16].

Lewin et al[16] have emphasized the complexity of HBV dynamics for treatments longer than a few weeks. Moreover, they have demonstrated the need for tight sampling immediately after drug administration, to warrant an accurate definition of viral clearance rate, and the need to evaluate the early stages of the delay before the drug starts its effect, as shown in HCV and HIV infections[5]. With tight viremia monitoring soon after the beginning of therapy (every 6 h in the first 2 d, compared to the 1-d interval adopted in previous studies), Wolters et al[18] have shown that the virion half-life is shorter (mean 15 h) than previously stated (24 h). These findings have been confirmed recently by other studies using higher sampling frequencies in the first 2 d of therapy (Table 1)[19,20].

In one of these studies, Sypsa et al[19] analyzed HBV dynamics in HBeAg-negative patients during the first 4 wk of treatment with pegylated IFN-2b (PegIFN-2b) monotherapy or combined with LMV. The standard model was applied to patients receiving LMV alone or in combination, and accounted for the decreasing effectiveness of the drug between the weekly doses to patients treated with PegIFN-2b monotherapy. In this model, the impact of antiviral drugs on the dynamics of viral infection is considered by the terms $(1-\eta)$ and $(1-\varepsilon)$ of the equations 1, 2 and 3 (Figure 2), where η and ε represent the reduction in cell susceptibility to virus infection and the reduction in free virion production. This holds that the time required by the drug to achieve complete antiviral efficacy is quite short and much shorter than the circulating virion half-life. In this way, they could observe the fluctuations of viral load across the week of treatment in some patients, and this was ascribed to the decline of drug concentration between dosages. Besides the dependence of ε from the PegIFN 2b concentration, the authors suppose that the number of target and infected cells remain constant during the period of analysis (4 wk) and for the first 7 d of treatment. Starting from these assumptions, they emphasized that the mean antiviral efficacy of LMV monotherapy was superior to that of PegIFN-2b monotherapy (96.4% vs 82.6%) and comparable to that of PegIFN-2b + LMV (92.8%-94.4% for 100 μg or 200 μg, respectively). Moreover, they found that the infected cell half-life was comparable among the various groups of treatment (9.8 d vs 5.0 d vs 6.0 d for PegIFN-2b monotherapy, combination or LMV monotherapy, respectively), ranging from 2.7 to 75 d. Standard modeling of HBV dynamics was limited to the first 4-12 wk of therapy and was used to study direct antiviral activity of the drug. Instead, when using the

model to tailor the treatment, it is mandatory to simulate viral dynamics throughout the whole treatment course, and this means introducing additional hypotheses about hepatocyte proliferation and immune system activity after the first month of therapy.

The hypothesis that the infected cell clearance activity by the immune system remains constant during therapy is in contrast with some common observations in HBV infection. For example, IgM anti-HBc levels, as surrogate markers of HBV-induced liver damage, decline progressively during treatment[1,2]. Thus, we have to hypothesize that the decrease in infected cells during treatment leads to a reduced immune stimulation that, in turn, could determine a decrease in the clearance of infected cells. It is likely that the kinetics of viral load decline during the first month of treatment are not simply biphasic in a significant proportion of patients treated either with LMV or PegIFNs + LMV. The average slope of weekly viral load declines observed by Sypsa et al[19] was similar during days 14-21 and 21-28 (-0.027 and 0.033 log10 cp/mL per day, respectively), but slower than those observed during days 7-14 (-0.067 log10 cp/mL per day).

These findings were ascribed to the prolonged first phase decline of viral load in some patients. In fact, we highlighted that all patients treated with LMV or Peg2a + LMV[20] had a viral load decline characterized by a rapid drop during the first phase of therapy (average HBV-DNA half-life of about 10 h during days 0-4), followed by another rapid drop (average HBV-DNA half-life of about 2 d) between days 4 and 14 (in particular between days 4-7). Attributing this second phase to the reduction in infected cells, according to the biphasic model, the infected cell half-life would be about 2 d only, and this would mean that chronic hepatitis patients with about 50% infected hepatocytes could lose > 10% of their overall hepatic mass every day. We could overcome this criticism if we suppose that the virion production in these patients was really inhibited in two phases: firstly a sharp drop as described in the model by the term "1-ε", followed by a second slower drop with exponential decline.

It is evident from all these studies that investigation of the long-term dynamics of HBV infection during the whole course of the antiviral therapy needs more specific models that take into account the complexity of HBV biology and its interplay with the host's immune system. In consideration of the limitations previously described we developed a new model with simple biological assumptions on target and infected hepatocyte dynamics to make possible the simulation of the antiviral effects during the whole course of different antiviral treatments[20]. Briefly, the model holds that: (1) the sum of target and infected cells remains roughly constant and equals the total hepatocyte number in the normal liver ($H_0 = 2.5 \times 10^{11}$ cells); (2) infected hepatocytes can generate infected daughter cells, as shown in animal models[21]; and (3) both target and infected cells contribute to the hepatocyte turnover in proportion to their relative numbers.

The following equation describes the full dynamics of the infected hepatocytes during therapy: $dI(t)/dt =$

Figure 4 Biphasic *versus* multiphasic fitting of the early HBV-DNA decline in patients treated with LMV.

$(1-\eta)\beta \cdot T(t) \cdot V(t) - \delta(t) \cdot I(t) \cdot [1-I(t)/H_0]$. where η takes into account any variation of the susceptibility of target cells to get infected, as induced by therapy.

ALT serum levels as a marker of hepatocyte damage[22], as in other models[11,23], were used to determine the infected hepatocyte number at baseline, according to the following equation: $I_0 = [ALT_0-20]/[\Phi \cdot \delta_0]$, where the numerical value of the constant Φ is equal to $3.24 \times 10^{-4[11]}$, calculated under the assumption that the normal ALT value is equal to 20 U/L and the natural hepatocyte turnover is $300/d^{[24]}$.

The new model integrated the above hypothesis that the clearance rate of infected cells in HBeAg-negative chronic hepatitis patients could decrease after the first month of therapy because of the negative feedback derived from the progressive reduction of infected hepatocytes. Thus the equation describing the immune system activity was changed to: $\delta(t) = \delta_0 \cdot [I(t-\sigma)/I_0]^k$ where σ is the time elapsing between the variation in the number of infected cells and the variation in the immune system activity (that is assumed to be 35 d), and k (which can vary from 0 to 1), which is the feedback parameter that links the variation in the virus-specific immune clearance activity to the variation in the number of infected cells. The multi-phase profile of the viral load decline observed in patients treated with LMV or Peg-IFNs + LMV during the first month of therapy led us to suggest that the free virus production might consist of two phases: the first one is described by the term $1-\varepsilon$ used in the standard model, and the second by an exponential function described by the following equation: $\Psi(t) = (1-\varepsilon) \cdot [(1-\gamma) \cdot \Psi_0 \cdot e^{-\varphi \cdot t} + \gamma \cdot \Psi_0]$, where $1/\varphi$ represents the time constant of the second phase decline of virus production and $(1-\varepsilon)\gamma \cdot \Psi_0$ is the asymptotic

value (Ψ_{asym}) of the free virion production rate.

We then applied this multiphase model to 72 HBeAg-negative patients treated with LMV monotherapy and with Peg-IFN2a or with the two drugs combined in an international phase III study[25]. Applying the new model, we obtained a better fitting of the serum HBV-DNA multiphasic decline, as compared to the standard biphasic model (Figure 4), in 95% of the patients, and we could identify one additional phase of decline of viral production between days 4 and 14 in all LMV-treated patients.

We can hypothesize that two main biological mechanisms form the basis of this phase: a further reduction of virus production rate combined with an initial reduction in the number of infected cells. The additional antiviral effect of LMV inhibiting HBV replication during the second phase could be explained in several ways. One reason could be the decline of the cccDNA or viral minichromosome, provided that LMV blocks its production, as some authors have hypothesized in an animal model of hepadna-virus infection[26].

However, the half-lives determined for duck hepatitis B virus[26] and woodchuck hepatitis virus[21] in animal models and for HBV DNA in a chimpanzee experimental infection[27] were much longer than that computed for the above patients. Whalley *et al*[28] have reported an average HBV-DNA half-life of 3.7 ± 1.2 d compared with the 2 d found in the second phase of HBV-DNA decline during spontaneous resolution in patients with acute hepatitis B. Another hypothesis is that the block of virus production caused by LMV may restore some specific cytotoxic lymphocyte immune-mediated responses[29], and may also activate antiviral effects *via* cytokines,

such as IFNγ and tumor necrosis factor α, which either reduce transcription or increase cccDNA degradation. It has been proven that such mechanisms inhibit HBV replication before hepatocellular damage in transgenic mice and chimpanzee acute hepatitis models[17,22].

However, further studies are needed to understand better the biological reasons for this viral load decline. It is interesting to notice how Peg-IFN2a-treated patients had declines in serum HBV DNA much different from those observed in LMV-treated patients[20], given that the classic biphasic pattern was present during the first month of Peg-IFN2a monotherapy in the majority of patients. In the group of patients treated with Peg-IFN2a, however, the first slope of viral load decline was much lower than in the LMV-treated group with a mean HBV-DNA half-life of 1.6 ± 1.1 d and 9.5 ± 3.0 h, respectively.

The slower HBV-DNA decline during the first phase in patients treated with Peg-IFN2a monotherapy may have been caused by a decrease in virus production, similar to that induced by LMV with different kinetics, or to increased free virus clearance. Under the latter assumption, we noticed that the simulation of viral load decline did not fit with the experimental data, therefore, it appears more reasonable to accept the theory that Peg-IFN2a inhibits HBV replication inside the infected cells at a slower rate than LMV does.

The overall extent of inhibition of viral production induced by Peg-IFN2a was slightly higher (88%) than that reported by Sypsa et al[19] for Peg-IFN2b (82.6%). Such a difference emerged using our model, which allowed us to compute and study the antiviral effects of Peg-IFN during its whole period of action and not only during the first 4 d, as in the model of Sypsa et al[19].

Consistently, we could also prove that the extent of inhibition of viral production, in patients treated with LMV and Peg-IFN2a combination therapy, was comparable to that with LMV monotherapy, but the viral load decline was faster in the first phase (1/HBV-DNA decay constant: 2.79/d vs 1.91/d in LMV, P < 0.005) than in the second phase (1/HBV-DNA decay constant: 0.44 vs 0.34, P = 0.023).

In agreement with the fact that the molecular targets of LMV and IFN are different, these findings suggest that the mechanisms of IFN to inhibit HBV replication could be complementary and additive to those of LMV.

The experimental data reported in our study[20] proved also that the serum HBV-DNA decline after 4-5 wk of antiviral therapy tends to flatten in a large group of patients regardless of the treatment arm. If we assume that the viral load decline observed from day 14 onward depends uniquely on infected cell clearance, we can explain the slow decline in HBV-DNA levels after the first month of therapy, only accepting the reduction in the initial clearance rate of infected cells.

In the past, many efforts have been made to model variations in the immune response during viral infections[30], but they have led to a very complex system of differential equations without any effective result. Thus, with our model, we simply hypothesized a negative feedback on the immune clearance activity caused by a

reduction in the number of infected cells, which is one major factor that induces cytotoxic immune responses.

The strength of the negative feedback, as modeled by the parameter "k", was computed by fitting the HBV-DNA serum decline, which is usually detectable up to the third month of therapy. This allowed a more realistic simulation of the decline in HBV DNA and infected cells during the remaining period of therapy. It is noteworthy that, at the end of therapy, the mean logarithmic reduction in the HBV-infected hepatocyte fraction, computed by our model, was comparable in patients treated with Peg-IFN2a and LMV monotherapy (-3.30 log10 vs -3.31 log10, P > 0.05), but significantly higher in patients treated with combined Peg-IFN2a + LMV as compared to LMV monotherapy (-5.02 log10 vs -3.31 log10, P = 0.028).

These findings suggest that Peg-IFN2a, in spite of a lower inhibition of HBV replication, has an equivalent, if not higher, impact on infected cell clearance than that of viral polymerase inhibitors. This could be the direct consequence of PEG-IFN2a immunomodulatory activity that polymerase inhibitors are lacking.

CONCLUSIONS AND PERSPECTIVES

Using our new multiphasic model, we could describe for the first time the second phase decrease in viral production that occurs mainly between days 4 and 14 in patients receiving LMV, alone or in combination.

Using the new model, we could prove that both IFN and LMV have inhibitory activities on HBV replication, but different kinetics. Their different mechanisms of action appear to work in synergy and cause faster declines in viral production during the first 2 wk of therapy in patients treated with both drugs.

The new model successfully describes the HBV infection dynamics far beyond the third month of antiviral therapy, under the assumption that the sum of infected and non-infected cells in HBeAg-negative chronic hepatitis B patients remains roughly constant during therapy, and both target and infected cells concur in hepatocyte turnover. These findings suggest that the ongoing production of new HBV-infected cells may occur after the division of already infected cells via transmission of the mini-chromosome-like cccDNA, when their immune-mediated clearance is reduced during long-term therapy. This might explain experimental data that report the persistence of high cccDNA levels even after 1 year of treatment with adefovir[31].

In the future, it will be very important to develop new models for a better simulation of HBV dynamics during various antiviral treatments, in order to predict the outcome of the infection after treatment discontinuation in every single patient, as is already available for hepatitis C patients[32]. The introduction of additional parameters that describe the HBV intrahepatic condition, related to infected hepatocytes and cccDNA copies, together with immune response markers in terms of immunoactivation and immunocompetence, could improve significantly the comprehension of the various profiles of response during

and after antiviral treatment. In clinical practice, these new models could allow the development of simulators of treatment response that will be used as an "automatic pilot" for tailoring antiviral therapy in chronic hepatitis B, as well as chronic hepatitis C patients.

Abstract

By modulating hepcidin production, an organism controls intestinal iron absorption, iron uptake and mobilization from stores to meet body iron need. In recent years there has been important advancement in our knowledge of hepcidin regulation that also has implications for understanding the physiopathology of some human disorders. Since the discovery of hepcidin and the demonstration of its pivotal role in iron homeostasis, there has been a substantial interest in developing a reliable assay of the hormone in biological fluids. Measurement of hepcidin in biological fluids can improve our understanding of iron diseases and be a useful tool for diagnosis and clinical management of these disorders. We reviewed the literature and our own research on hepcidin to give an updated status of the situation in this rapidly evolving field.

INTRODUCTION

Hepcidin is a circulating peptide hormone that regulates the entry of iron into plasma. It is primarily, but not exclusively, secreted by hepatocytes and is highly conserved among different species. The mature bioactive form of hepcidin is a peptide of 25 amino acids that derives from a precursor (pre-prohepcidin) of 84 amino acids that undergoes two enzymatic cleavages. Other isoforms of 20 and 22 amino acids are detectable in human serum and urine, although the biological significance of these isoforms is uncertain[1-3]. There is evidence that hepcidin is also expressed in the heart, kidney, adipose tissue, pancreas and haematopoietic cells, although the biological relevance of extra-hepatic hepcidin is not well defined yet (see below).

Targeted deletion of the *HAMP* gene in mice or mutations in the human *HAMP* gene result in the most severe forms of iron-overload disease. Conversely, increased expression of hepcidin leads to decreased iron absorption and iron deficient anaemia. Hepcidin, therefore, is a negative regulator of iron transport into plasma. It acts by binding to ferroportin, the only known cellular iron exporter, causing ferroportin to be phosphorylated, internalized, ubiquitylated, sorted through the multivesicular body pathway and degraded in lysosomes[4,5]. The interaction between hepcidin and ferroportin can explain the systemic regulation of iron metabolism. In fact, hepcidin is mainly targeted to duodenal enterocytes, where it regulates dietary iron absorption, and to macrophages, where it inhibits the

release of iron derived from senescent erythrocytes. By modulating hepcidin production, an organism controls intestinal iron absorption, iron uptake and mobilization from stores to meet body iron need[6,7].

REGULATION OF HEPATIC HEPCIDIN PRODUCTION: *IN VITRO* STUDIES AND ANIMAL MODELS

Hepcidin is modulated by different stimuli, which act as positive or negative regulators. There are four main active regulation pathways (erythroid, iron store, inflammatory and hypoxia-mediated regulation) that control hepcidin production through different signalling pathways (Table 1). These pathways must be closely coordinated to match iron supply to erythropoietic demand and, in turn, to maintain adequate plasma iron concentrations.

Positive regulation of hepcidin transcription
Under normal conditions, iron store and inflammatory regulation activate hepcidin transcription in the hepatocytes through the bone morphogenetic proteins (BMPs)/SMAD4 and signal transducer and activator of transcription-3 (STAT-3) pathways, respectively[6]. Binding of specific BMPs by hepatocyte BMP receptors results in phosphorylation of receptor SMADs (R-SMADs) within the cytosol. These phosphorylated R-SMADs complex with SMAD4, and the complex of phosphorylated R-SMAD and SMAD4 then activates transcription of *HAMP*[8]. Accordingly, *in vivo* and *in vitro* experimental studies showed that specific BMPs can activate *HAMP* transcription[9] and a liver-specific *Smad4*-knockout (KO) abrogates hepcidin gene transcription in mice leading to massive iron overload[10]. The hemochromatosis protein HFE, transferrin receptor 2 (TfR2) and the membrane isoform of hemojuvelin (mHJV) are all positive modulators of *HAMP* transcription and, when defective, lead to hemochromatosis (HH) in humans and HH-like phenotype in knock-out animal models[7].

HFE: Recent studies *in vitro* and in animal models clarified the crucial role of HFE as a hepatocyte iron sensor and upstream regulator of hepcidin[11,12]. Several mechanisms have been proposed by which HFE regulates iron metabolism. HFE competes with transferrin for binding to transferrin receptor (TfR)-1, lowering iron uptake into cells[13,14]. Alternately, there is more recent evidence supporting a role for HFE as an important component of a larger iron-sensing complex that involves interactions with diferric transferrin, TfR1 and TfR2 at the plasma membrane of hepatocytes[15-17]. Defective HFE protein prevents formation of a functional iron sensor and signal transduction effector complex leading to dysregulated hepcidin expression as observed in human hereditary hemochromatosis[18-20] and mouse models of this disease[21]. Recent findings also support other HFE-dependent mechanisms

of regulation of iron homeostasis through post-transcriptional regulation of Zip14, a metal transporter that mediates non-transferrin-bound iron into cells[22].

TfR2: Homozygous mutations of *TfR2* have been linked to type 3 HH[23]. Animal models of mutated or knock-down *TfR2* confirmed human findings indicating that TfR2 plays an important role in iron metabolism[24-26]. It has been shown that diferric transferrin levels may increase the stability of TfR2 protein and it has been postulated that TfR2 is a sensor of serum iron levels and works to modulate iron absorption through the induction of the iron regulatory hormone hepcidin[27,28]. Accordingly, mutated or absent TfR2 is associated with reduced hepcidin expression either in animal models or in humans[18,24]. TfR2-induced regulation of hepcidin synthesis likely occurs through interaction with HFE to form an iron-sensing complex that modulates hepcidin transcription through the activation of a still unclear signalling pathway upstream or independent of SMAD4[7,29]. Interestingly, hepatic *HJV* mRNA level was lower in complete TfR2 knock-out[25] than in controls suggesting an interaction between TfR2 and HJV in the regulation of hepcidin expression. This finding has been recently confirmed to also occur in humans (Pelucchi *et al*, Haematologica in press).

HJV: As BMP co-receptor, HJV is strongly involved in the regulation of hepcidin transcription through the BMP/SMAD4 pathway[9,30,31]. Accordingly, *Hjv*-mutant mice exhibit iron overload as well as a dramatic decrease in hepcidin expression[32]. HJV is synthesized as a membrane-GPI-linked protein by hepatocytes but is also abundant in muscle. HJV exists in 2 forms: a membrane-bound form (m-HJV) and a soluble one (s-HJV), which *in vitro* reciprocally regulate hepcidin expression in response to opposite iron changes[33].

IL-6 and cytokines: Under inflammatory conditions, IL-6 and other cytokines induce *HAMP* transcription by activating STAT3 signalling to the hepcidin gene promoter[2,34,35]. The inflammatory regulatory pathway is thought to have a dominant effect on the other regulatory pathways as shown by the fact that inactivation of HFE does not affect the increase of hepcidin expression and the hypoferremia induced by inflammation. However, STAT3 activation requires the presence of SMAD4 because absence of SMAD4 prevents STAT3-mediated hepcidin gene expression[10].

Negative regulation of hepcidin transcription
Hypoxia, anemia, increased erythropoiesis and reduced iron stores all negatively regulate hepcidin expression. Hypoxia and anemia regulate the production of erythrocytes through synthesis of erythropoietin (EPO) and are the two main signals that increase iron absorption independently of iron stores to meet the need of iron for erythrocyte production[36,37].

Anemia could mediate hepcidin suppression

Table 1 Positive and negative regulators of hepcidin production, signalling pathways involved and human diseases either caused by defective function of the regulatory protein (Hemochromatosis, IRIDA) or inducing activation or suppression of the regulatory pathway

Positive regulators	Signalling pathway	Human disease	Negative regulators	Signalling pathway	Human disease
Inflammation [IL-6, IL-1α]	STAT-3	Anemia of chronic disease	Hypoxia [HIF1, sHJV, ROS]	HIF-1, BMPs/SMAD Oxygenases inhibition	--
Iron stores [mHJV]	BMPs/ SMAD4	Hemochromatosis	Iron stores [Matriptase2, s-HJV, GDF15]	BMPs/SMAD inhibition	IRIDA, iron deficiency
Iron stores [HFE, TfR2]	BMPs/ SMAD4	Hemochromatosis	Erythropoiesis [GDF15, others?]	BMPs/SMAD inhibition others?	Thalassemia, CDA1
Liver metabolic activities	C/EBPα		Erythropoietin?	C/EBPα block	
Oxygenases	?		Oxidative stress [ROS]	C/EBPα, STAT3 block; Oxygenases inhibition HDAC activation	Hepatitis C viral and alcoholic liver disease

IRIDA: Iron refractory iron deficiency anemia; CDA1: Congenital dyserythropoietic anemia type 1; Oxygenases: Family of 2-oxoglutarate-dependent oxygenases including prolyl and aspariginyl hydroxilases, PHDs and FIH. References: Andrews[6], De Domenico et al[7], Braliou et al[42], Choi et al[43], Nemeth[38], Pinto et al[39], Pak et al[40], Tanno et al[41], Lakhal et al[54], Tamary et al[55], Silvestri et al[57], Silvestri et al[59], Miura et al[101], Harrison-Findik[46].

through multiple mechanisms including increased EPO or erythropoietic activity, increased iron demand or liver hypoxia[38]. Pinto et al[39] found that EPO at high concentration is able to inhibit hepcidin expression *in vitro*, *via* signalling through EPO receptor and C/EBPα regulation. This finding contrasts with that previously reported by Pak et al[40] who showed that hepcidin regulation depended on erythropoietic activity and was not directly mediated by anemia, tissue hypoxia, or EPO in murine models and that secondary changes in plasma and tissue iron would also be expected to contribute to hepcidin regulation. The nature of the erythropoietic regulator of hepcidin is still uncharacterised, but may include one or more proteins released during active erythropoiesis. Recent observations in thalassemia patients has suggested that one of these regulators could be the cytokine growth differentiation factor-15 (GDF15)[41].

Hepcidin is suppressed in human cultured hepatoma cells exposed to hypoxia[42] but the physiological relevance and the mechanisms of hepcidin regulation by hypoxia are still uncertain and conflicting. Hypoxia-inducible factor (HIF)-1 and reactive oxygen species (ROS) have been both implicated in hepcidin regulation either directly or through modulation of 2-oxoglutarate-dependent oxygenases, respectively[42-44].

Studies *in vitro* and *in vivo* in animals[45,46] have recently shown an alcohol-dependent decrease of hepcidin expression possibly through ROS-induced down-regulation of C/EBPα. Two other studies analysed the effect of 7 d alcohol exposure in HFE KO mice and results were discrepant, one showing an additive effect of alcohol on hepcidin down-regulation[47] and the other not[48]. There remains however a major discrepancy between these experimental findings and the absence of increased iron deposits in alcohol-fed animal models[45,49], and clinical data in humans indicate a generally mild effect of chronic alcohol consumption on iron stores even in patients with hemochromatosis[50-53].

GDF15: GDF15 is a divergent member of the transforming growth factor-β superfamily that is secreted by erythroid precursors and other tissues. It has been identified as an oxygen-regulated transcript responding to hypoxia and as a molecule involved in hepcidin regulation[41,54]. This is intriguing considering the strong interaction between iron and oxygen and indicates that some homeostatic systems for iron and oxygen are responsive to both stimuli. Tanno et al[41] showed that serum from thalassemia patients suppressed hepcidin mRNA expression in primary human hepatocytes and depletion of GDF15 reversed the hepcidin suppression. They suggested that GDF15 overexpression arising from an expanded erythroid compartment contributed iron overload in thalassemia syndromes by inhibiting hepcidin expression, possibly by antagonizing the BMP pathway. Very high levels of serum GDF15 were also observed in patients with congenital dyserythropoietic anemia type 1 (CDA I) suggesting that GDF15 contributes to the inappropriate suppression of hepcidin with subsequent secondary hemochromatosis in these patients[55]. Very recently Lakhal et al[54] partially elucidated some of the mechanisms regulating GDF15 and demonstrated robust and sensitive up-regulation of GDF15 mRNA and secreted protein in response to iron depletion in a range of human cell lines and *in vivo* in humans. They also demonstrated that this up-regulation was independent of HIF providing support for the involvement of a novel iron and oxygen-sensing pathway. Whether regulation of GDF15 by intracellular iron provides a mechanism by which intracellular iron might directly influence hepcidin production is unclear and requires further analysis.

HIF, ROS and Oxygenases: Hypoxia is primarily sensed in vertebrates by the HIF family of transcription factors. Under normal conditions, hydroxylation of HIF results in its recognition by the von-Hippel–Lindau (VHL) ubiquitin ligase, which targets it for degradation. In the absence of oxygen, HIF proteins

are stabilized and function as transcription factors[37]. Mice with a liver-specific deletion of HIF1α, even if they are maintained on a low iron diet, show increased hepcidin expression because they have an impaired hypoxic response and cannot normally down-regulate hepcidin gene transcription[44]. In contrast, mice with a liver-specific deletion of the *Vhl* gene show extremely low levels of hepcidin expression[44]. The same authors showed that HIF1α can bind to the mouse and human *HAMP* promoter suggesting that HIF-family members can directly and negatively regulate hepcidin expression[6,44]. Thus, the VHL/HIF pathway could be an essential link between iron and oxygen homeostasis and hepcidin regulation *in vivo* that through coordinated down-regulation of hepcidin and up-regulation of erythropoietin and ferroportin, mobilizes iron to support erythrocyte production. Conflicting data were, however, obtained in hepatoma cell lines in which over-expression, knockout and chromatin immunoprecipitation (Chip) assays failed to demonstrate the involvement of HIF-1 in the regulation of hepcidin promoter[42,43]. Choi *et al*[43] found that hypoxia-induced hepcidin suppression was related to ROS levels which prevented the binding of transcription factors, CCAAT/enhancer-binding protein alpha (C/EBPα) (a liver enriched transcription factor that accounts for developmental changes in liver metabolism after birth) and STAT-3, to the *HAMP* promoter. More recently, Braliou *et al*[42] showed that 2-oxoglutarate-dependent oxygenases (which include prolyl and asparagine hydroxylases, PHDs and FIH) were important to maintain high hepcidin mRNA expression in a HIF-1-independent manner These enzymes depend on molecular oxygen, 2-oxoglutarate and Fe^{2+} and act on their main substrate HIF-1α causing its inactivation and degradation by protein hydroxylation. Hypoxia and generation of ROS inhibit protein hydroxylation and cause stabilization and activation of HIF-1α[37]. Braliou *et al*[42] demonstrated that hypoxia and chemical agents inhibiting the 2-oxoglutarate-dependent oxygenases repress hepcidin expression in hepatoma cell lines opening the way for further experimental studies to identify downstream factors mediating hepcidin regulation.

Soluble HJV: It has been shown that s-HJV can bind BMP and function as a competitive antagonist of m-HJV, leading to decreased hepcidin expression[33] and that chronic s-HJV injection in mice causes iron overload[56]. Silvestri *et al*[57] demonstrated that s-HJV is the product of a furin cleavage at the C-terminus of the protein that occurs mainly in the endoplasmic reticulum and that it is up-regulated in conditions of iron deficiency and hypoxia. They suggested that hypoxia and iron deficiency activate furin to release s-HJV and to rapidly reduce the amount of m-HJV, inhibiting hepcidin production[33,57]. These events may occur in the same cells (hepatocytes) that produce hepcidin in order to suppress hepcidin up-regulation by an autocrine mechanism.

Transmembrane serine protease 6: Recently, Du *et al*[58] described *mask*, a recessive, chemically induced mutant mouse phenotype, characterized by progressive loss of body, but not facial, hair and microcytic anemia. The *mask* phenotype results from reduced absorption of dietary iron caused by high levels of hepcidin. High *Hamp* mRNA levels were in fact observed in the liver of *mask* homozygotes despite anemia, a finding consistent with insensitivity to low iron stores and failure to suppress hepcidin synthesis. A splicing defect was found in the transmembrane serine protease 6 gene *Tmprss6* in the *mask* mutant. This gene is expressed in a limited number of tissues, but the major site of expression is the liver in both mice and humans. Du *et al*[58] demonstrated that TMPRSS6 cotransfection strongly inhibited *Hamp* reporter gene activation by each stimulus (IL-1α, IL-6, BMP2-4-9) in HepG2 cells, whereas the *mask* mutant version of TMPRSS6 showed a modest inhibitory effect. This indicates that TMPRSS6-dependent pathway predominates over all known *Hamp*-activating pathways and that TMPRSS6-mediated *Hamp* suppression is determinant for acquiring adequate iron uptake from dietary sources. They hypothesized that TMPRSS6, also known as matriptase-2, participates in a transmembrane signalling pathway triggered by iron deficiency and independent to the known *Hamp* activation pathways and demonstrated that the proteolytic activity of matriptase-2 is determinant to hepcidin suppression activity. Recent experiments provided evidence that this serine protease inhibits hepcidin by cleaving HJV from the plasma membrane and has no cleavage activity on s-HJV[59]. The tissue-restricted, strong liver expression of matriptase-2 is logical if we consider that its activity responds to iron deficiency, in order to suppress the mHJV-BMPs pathway of hepcidin activation. The authors suggest that the pathway may still be modulated by s-HJV, further increasing the inhibition of hepcidin transcription induced by matriptase-2 alone.

HEPCIDIN MEASUREMENT IN HUMAN DISORDERS: PAST, PRESENT AND FUTURE

Since the discovery of hepcidin and the demonstration of its pivotal role in iron homeostasis, there has been a substantial interest in developing a reliable assay of the hormone in biological fluids. Measurement of hepcidin in biological fluids can improve our understanding of iron diseases and be a useful tool for diagnosis and clinical management of these disorders. However, this has proven to be a very challenging task.

Hepcidin assay in biological fluids
Inherent problems: The development of traditional immunochemical methods based on the production of specific anti-hepcidin antibodies has been hampered by several factors, including: (1) the small size (25 amino acids) and the compact structure of the peptide,

Figure 1 Typical mass spectra of human serum (A) and urine (B) samples by SELDI-TOF-MS in a control subject. In addition to hepcidin-25, two isoforms truncated at the N-terminus are detectable. The 20 aa isoform is detectable in both urine and serum, while the 22 aa isoform is found only in urine.

with few antigenic epitopes; (2) the high degree of conservation between animal species[60], with ensuing difficulties in elicitation of an appropriate immune response in host animals; (3) the limited availability of the antigen. Indeed, the production of synthetic hepcidin in its hairpin native conformation determined by four disulfide bonds among the eight cysteine residues (near one fourth of the molecular weight)[61] is a complex procedure, as well as the isolation of hepcidin from urine[62]. A further problem is represented by hepcidin tendency to aggregate and to stick to laboratory plastic tubes, necessitating the need for careful handling and for standardized pre-analytical procedures.

"First generation" methods: Early after hepcidin discovery, an ELISA kit able to detect serum pro-hepcidin became commercially available[63], based on an antibody recognizing an epitope outside the 25 amino acid sequence of the bioactive peptide. With few exceptions, this assay generally failed to give clinically useful information, since no correlation was reported with iron status and/or absorption[64,65]. Most of the human studies published so far have relied on an immunodot assay for urinary hepcidin based on selective extraction of the peptide from urine by cation-exchange chromatography and its subsequent quantification by chemiluminescence using rabbit anti-human hepcidin primary antibodies[66]. Although this method provided very useful information on hepcidin regulation in human diseases[18-20,67,68], it was quite laborious, and suitable only for relatively small series of patients. To circumvent inherent limitations of immunochemical methods, several research groups have focused on novel technologies, particularly on Mass Spectrometry (MS)-based methods, that rely on direct determination of the molecule of interest without the need for specific antibodies. Among these techniques, Surface-Enhanced Laser Desorption/Ionization Time-Of-Flight Mass Spectrometry (SELDI-TOF-MS) has emerged as a proteomic technique

particularly promising for rapid direct detection of small sized biomarkers[69], like hepcidin. SELDI-TOF-MS combines matrix assisted laser-desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) to surface chromatography. Depending on their chemical characteristics, peptides/proteins of interest are captured by specific interactions with protein surfaces ("chip-arrays") that are used as a laser desorption ionization target. After the enriching step, proteins that do not bind to the surface are removed by a simple wash step, while bound proteins are analyzed by MS. Good preliminary results in hepcidin measurement were reported by several groups[70-73]. In particular, the SELDI-TOF-MS assay was able to discriminate different clinical conditions on the basis of the expected variations in hepcidin levels[70,72], and correlated well with the immunodot assay in head-to-head comparison[70]. An important advantage of the SELDI-TOF-MS technique is the potential to evaluate not only the predominant 25 amino acid form, but also the forms with two peptides shorter at the amino terminus, i.e. hepcidin-22 and hepcidin-20 (Figure 1; also see below). Nevertheless, an inherent limitation of first generation SELDI-TOF-MS hepcidin assays (and in general, of all MS-based methods) is that peak heights in mass spectra do not always reflect absolute concentrations in clinical samples, because of competition during binding steps, and variations in ionisation efficiency. This implies that results can be expressed only in semi-quantitative arbitrary units, unless the use of a proper internal standard is implemented. But this again is a difficult task. Ideally, an internal standard is represented by a synthetic hepcidin-related peptide with no overlap with the endogenous peptide or other common peaks in serum/urine mass spectra, so that it could be spiked at known concentration to the clinical sample and co-analysed. Quantification of endogenous peptide is then obtained through the ratio internal standard: endogenous peptide. Murphy et al[74] first described a MS-based quantitative assay for either human or mouse

Method	Reported normal range in serum (No. of controls)	Intra-assay precision (CV[1]) (%)	Internal standard	Note	LLOD[2]	Reference
Table 2 Recently published methods for hepcidin quantification in biological fluids						
C-ELISA	29-254 ng/mL (males) 17-286 ng/mL (females) (*n* = 114)	5-19	n.a.	Also used to quantify hepcidin in urine	5 ng/mL	Ganz[76], 2008
Quantitative SELDI-TOF-MS	9-45 ng/mL (males) 7-15 ng/mL (females) (*n* = 23)	5.7-11.7	Des-Asp Hepcidin-24 (deletion of aspartate residue at position 25)	Also used to quantify hepcidin in urine	3 ng/mL	Swinkels[77], 2008
Quantitative SELDI-TOF-MS	50 ng/mL (average in females) (*n* = 24)	8-9	Stable isotope labelled hepcidin ($^{13}C/^{15}N$ phenylalanine at position 9)		10 ng/mL	Ward[79], 2008
Micro-HPLC tandem tandem MS	1-19.5 ng/mL (males) 1-6.5 ng/mL (females) (*n* = 10)	4.8-21	Stable isotope labelled hepcidin ($^{13}C/^{15}N$ isoleucines at position 6-8)		1 ng/mL	Kobold[78], 2008
Liquid Cromatography tandem MS	n.a.	8.7-12.5	Stable isotope labelled hepcidin ($^{13}C/^{15}N$ glycines at position 12-20)	Only used in urine for the moment	n.a.	Bansal[75], 2008
Hepcidin binding domain based test	39-88 ng/mL (*n* = 40)	< 5	n.a.	Potential for measuring true biologically active hepcidin (e.g. able to bind ferroportin)	n.r.	De Domenico[1], 2008

n.a.: Not applicable; n.r.: Not reported; [1]Coefficient of variation. CV ranges refer to samples with different hepcidin concentrations. With all methods, variations in repeated assays were higher at the lower hepcidin concentration; [2]Lower limit of detection.

hepcidin in serum using liquid chromatography tandem MS (LC-MS/MS) and calcitonin gene-related peptide (CGRP) as the internal standard. While a good accuracy was reported, the suitability of CGRP as non-hepcidin internal standard cannot be considered ideal because of its differences from the endogenous peptide in terms of mass, hydrophobicity, p*I*, and net charge[75].

Recent advances by "second generation" assays: This year has witnessed substantial advances in quantitative methods for hepcidin measurement in serum and/or urine. A variety of different approaches have been used by several research groups, summarized in Table 2. One of the most innovative was described by De Domenico *et al*[1]. They first identified the hepcidin binding domain (HBD) on the ferroportin molecule, and then synthesized a 19 amino acid corresponding peptide (spanning from amino acids 324 through 343 of the fourth extracellular loop of ferroportin). This peptide was then used in a competitive assay, i.e. by determining the ability of serum samples to compete with radioactive hepcidin for binding to the HBD peptide. In mice with targeted deletions of either *HAMP* or *HFE* gene, serum hepcidin measured by this method was found to vary as expected, as it did in a small group of healthy volunteers. This assay looks promising as an effective measure of true biologically active hepcidin, but needs further validation.

Ganz *et al*[76] were successful in obtaining sufficient amount of anti-hepcidin antibody to develop the first competitive enzyme-linked immunoassay (C-ELISA) for human hepcidin in a simple format (96-well plates) applicable to a relatively large series of patients. On the

other hand, Swinkels *et al*[77] reported good quantification of hepcidin in both serum and urine updating the SELDI-TOF-MS protocol with the use of a proper internal standard clearly distinguishable from the endogenous peptide, i.e. a synthetic hepcidin-24 lacking the amino-terminal asparagine residue. Moreover, other groups working on MS-based methods reported reliable hepcidin quantification using stable isotope labelled 25 amino acid peptides with masses different from endogenous hepcidin because of the introduction of $^{13}C/^{15}N$ at different amino acid positions[75,78,79]. Interestingly, the C-ELISA and the updated SELDI-TOF-MS protocol were used to measure hepcidin in series of serum/urine pair samples from healthy donors[76,77], yielding quite similar results in terms of fractional excretion of the peptide (3%-5%). A preliminary direct head-to-head comparison of these two methods in split serum samples from the same individuals showed a high degree of correlation (Spearman's rho up to 0.94; (Girelli D, unpublished observation)). Moreover, similar comparative analyses in rigorously selected healthy subjects without any potential confounder of iron status (e.g. subclinical inflammation or iron depletion) showed that the two methods were almost equally effective in reflecting the expected subtle physiologic variations of serum hepcidin as a function of established indices of body iron stores, with Spearman's rho ranging from 0.7 to 0.8 (Girelli D, unpublished observation). In perspective, the two methods may be of complementary implementation in clinical and/or research setting. SELDI-TOF-MS has the disadvantage of relying on relatively expensive equipment and the need of dedicated skilled personnel. On the other

hand, it has the positive advantage of being able to detect the two isoforms truncated at the N-terminus, i.e. hepcidin-22 and hepcidin-20. At present, the actual biological significance of these post-translational modifications is uncertain. Studies by Nemeth et al[3] have demonstrated that the five N-terminal amino acids are essential for the interaction with ferroportin, and thus for modulation of iron homeostasis. On the other hand, the 20 amino acid isoform has been demonstrated to possess greater antimicrobial activity than hepcidin-25[1,62]. Thus, the smaller forms may not simply reflect the catabolism of the "iron active" hepcidin-25 as postulated by some authors[80], but rather the generation of more potent defensins with antimicrobial peptides[1]. Further studies are needed in this direction, as it appears that we are just starting to know the complex role of hepcidin at the crossroads between iron homeostasis and infectious/inflammatory conditions.

In contrast, the C-ELISA method has the potential for a more widespread diffusion into clinical/hospital settings, since it does not need any specific equipment. However, the specificity of the antibody used with respect to various hepcidin isoforms remains to be verified.

Hepcidin in human diseases

Until recently, most of the studies of hepcidin in humans have relied on a human urinary hepcidin assay and on comparisons between patients and small groups of normal subjects without distinction between gender and age, all factors that might influence hepcidin concentrations. Very recently, Ganz et al[76] reported data on 114 healthy subjects, showing that the medians of hepcidin concentrations, measured by C-ELISA, significantly differed between men and women (112 and 65 ng/mL, respectively), likely due to difference in iron stores. They also showed a trend for age-related increase in serum hepcidin in both genders needing further confirm, and that there was a direct correlation between serum hepcidin and ferritin concentrations within the range of normality for ferritin.

Iron overload: In most cases iron overload results from inadequate hepcidin production relative to body iron stores[6,7,81]. However, the causes that lead to reduced hepcidin production are different and include: hereditary defects that disrupt one or another protein involved in the normal pathway of positive regulation of hepcidin transcription (HFE, TfR2, HJV) and hepcidin itself; hereditary defects of proteins involved in iron transport (hypo-transferrinemia); ineffective erythropoiesis leading to increased and endless iron need by the erythroid marrow independent of iron stores (iron loading anemias)[38]. Exceptions are the iron overload due to hereditary defects of ferroportin, in which urinary hepcidin was found to be variably increased[19,82,83] and pure transfusional iron overload in which the increased iron stores stimulate hepatic hepcidin production and

can reach into the thousand of ng/mg creatinine[84]. In both these conditions, however, the cases tested are few and not homogeneous, and results need confirmation. There are no available data on aceruloplasminemia.

Hemochromatosis: Based on the current knowledge of the pathophysiological mechanisms of hepcidin regulation and on hepcidin measurement at either protein or mRNA level, hemochromatosis (HH) can be divided into two groups: primary iron overload disorders associated with defective or suppressed HAMP expression and ferroportin diseases.

The first group includes HH type 1, 2 and 3, which are determined by defects in four different genes (HFE, TfR2, HJV and HAMP). Since all these proteins are involved in the same pathway, the physiopathological mechanism leading to iron overload in all these forms of HH depends on absent or defective synthesis, or the inability to up-regulate hepcidin production appropriately in response to increased iron stores[6,7,11]. This in turn induces increased iron absorption in the plasma which exceeds the binding capacity of transferrin, causing the production of non-transferrin-bound iron and the accumulation of iron in parenchymal tissues. Thus, the differences among these forms of primary iron overload is quantitative (the amount of iron overload and the severity of iron-related damage), rather than qualitative (similar alterations of serum iron indices, similar iron distribution in the liver, same targets of iron deposition and damage). It can be hypothesised that the more important a defective protein is in the regulatory pathway of hepcidin transcription, the stronger is its suppression and the higher is the rate and amount of iron accumulation and, consequently, the severity of iron-related damage. In fact, in juvenile hemochomatosis (JH), hepcidin concentrations are lower than in adult forms of hemochromatosis, despite massive iron overload[19]. Figure 2 shows the concentration of urinary hepcidin measured by the same method in different forms of HH derived from personal and unpublished observations and on available data in the literature. For HFE-related HH patients we report only data collected at baseline. For the rare forms of HH, the available data on hepcidin are very limited in number and in most of these patients hepcidin measurement was not done at baseline. Thus, we took care, as far as possible, to select those still not fully iron depleted and sampled some time from phlebotomies, to limit the effect of phlebotomy-induced erythropoiesis and iron depletion on hepcidin synthesis.

Due to the higher prevalence of HFE-related HH, most of the data available on hepcidin measurements concern this form of HH. At diagnosis, when C282Y homozygous patients are iron overloaded, hepcidin values either at mRNA, urine or serum levels are only slightly lower than in controls[20,67,85-87]. Interestingly, in only one study hepcidin was measured also in the C282Y/H63D genotype, showing that it was higher

Figure 2 Mean (SE) values of urinary hepcidin (U-hepc), measured as described[20], in patients with different forms of hemochromatosis (A) and in patients with thalassemia major and intermedia (B) compared with healthy controls. Data collected from personal unpublished results and from Barisani *et al*[67], Cremonesi *et al*[82], Kattamis *et al*[90], Matthes *et al*[116], Nemeth *et al*[18], Origa *et al*[91], Papanikolau *et al*[117], Papanikolau *et al*[19], Piperno *et al*[20]. (*P* < 0.05: Controls *vs* C282Y +/+) (*P* < 0.01: Controls *vs* others; C282Y +/+ *vs* C282Y/H63D, HJV and Fp; HJV *vs* Fp; Thalassemia Major *vs* Intermedia). Statistical analysis was not performed for TFR2 and HAMP due to the small number of patients.

than in controls at diagnosis[20]. In both genotypes, however, the hepcidin/ferritin ratio (a derived parameter used to normalize hepcidin levels by the amount of iron overload) was significantly lower than in controls[20]. When analysed after iron depletion, patients of both genotypes, even at a time remote from the last phlebotomy, showed hepcidin concentrations significantly lower than that observed in iron overloaded patients and in controls. These findings allowed two considerations to be made: first, assuming that after normalization of iron stores HH patients return to their inborn status, van Dijk *et al*[87] concluded that hepcidin levels are innately low in HFE-HH; second, that patients with HFE-HH can modulate, although inappropriately, the chronic hepcidin increase in response to iron stores[20]. This impairment is less evident when the defect is mild as observed in patients with the C282Y/H63D genotype[20]. Based on the evidence that genetic background influences iron overload in HFE knockout mice and on recent findings in humans showing that some polymorphisms in the BMPs/SMAD4 signalling cascade can influence the iron phenotype in C282Y

homozygotes[88], it can be hypothesised that phenotype variability in HFE-HH depends on the whole effect of major disease locus (HFE) together with genetic polymorphisms and modifiers on hepcidin production that can protect or aggravate the effect of the defective protein. Acquired factors may contribute to phenotype variability through modulation of hepcidin production in HFE-HH[89], but no data are available yet.

Recently, we demonstrated that in contrast to healthy subjects, hepcidin response after acute oral iron challenge was blunted in most patients with HFE-HH at diagnosis and after iron depletion[20]. This supports a role of HFE in the iron-sensing pathways regulating hepcidin synthesis. Interestingly, we also found a blunted response to acute oral iron challenge in a severe iron overloaded patient affected by type 3 HH due to a novel splicing defect of *TFR2* (Pelucchi *et al*, *Haematologica* in press). Although this single observation needs caution, it provides the first evidence *in vivo*, in humans, that TFR2 may act as a sensor of serum iron levels to modulate hepcidin production[27,28].

A handful of data is available for ferroportin disease (type 4 hemochromatosis) and these data are reported in Figure 2. The high concentration of urinary hepcidin has been ascribed to response to iron overload, but also to "hepcidin resistance" that may vary according to different mutations of ferroportin. However, there are not enough data to define how hepcidin is regulated in the two different forms of ferroportin disease (types A and B) and if hepcidin measurement can be of some help in distinguishing one type from the other.

Iron loading anemias: The erythroid regulator exerts a negative effect on hepcidin production that overwhelms the store regulator as shown by the marked iron overload which develops in hypotransferrinemia and iron loading anemias[38].

Thalassemia intermedia and thalassemia major are the best studied human models of hepcidin modulation by ineffective erythropoiesis alone and the combined and opposite effect of both ineffective erythropoiesis and transfusion dependent iron overload, respectively. Regular transfusions, in fact, induce a huge tissue iron accumulation, but also inhibit erythropoietic drive. As shown in Figure 2, hepcidin levels are markedly reduced in thalassemia intermedia, due to the erythropoietic drive and despite systemic tissue iron overload[90,91]. Similar results were observed in not transfused hereditary diserythropoietic and acquired sideroblastic anemias[19] that share common pathogenetic mechanisms of iron overload with thalassemia intermedia[36,38]. In thalassemia major, hepcidin production is higher than in thalassemia intermedia although still inappropriate to the massive transfusional iron loading that partially counteracts the erythropoietic-dependent hepcidin down-regulation[90-93]. However, there is a large variability in thalassemia major probably dependent on several factors that might influence hepcidin production: time of transfusion[93], iron chelation therapy, amount of iron overload.

Very few data are presently available for other iron loading anemias that share pathogenetic mechanisms of iron overload with thalassemic syndromes, such as sideroblastic and congenital dyserythropoietic anemias. As expected, hepcidin either at mRNA level in the liver or at protein level in the urine was found to be suppressed despite marked iron overload[19]. There are scanty and discrepant results in sickle cell disease where iron status and hepcidin regulation are influenced by various factors that may act in opposite directions: anemia and hypoxia that lead to suppression of hepcidin production, transfusional iron overload and inflammation that stimulate hepcidin synthesis by different pathways[93,94].

Due to the rarity of congenital hypo-transferrinemia in humans, most data on hepcidin regulation comes from studies in hypotransferrinemic mice which recapitulate the human disorder, showing very low hepatic mRNA levels that support the notion of a dominant erythroid signal in hepcidin regulation and the importance of low hepcidin levels in the development of iron overload[93-95]. There is a single study in a child with congenital hypo-transferrinemia which describes the modulation of urinary hepcidin during plasma transfusions[96]. The study suggests that hepcidin production is regulated by the balance between iron requirements of the erythroid marrow and iron supply by transferrin, in agreement with the concept that iron supply to the erythron is the most important factor influencing iron absorption and iron release from stores[36,96].

Transfusional iron overload: The majority of studies relate to thalassemic patients in which ineffective erythropoiesis and transfusions frequently cooperate to produce iron overload and induce opposite effects on hepcidin transcription as extensively described. In contrast, very few and sometimes contradictory data are available for patients with pure transfusional iron overload. Nemeth et al[84] showed that hepcidin can reach into the thousands of ng/mg creatinine in two polytransfused patients with myelodysplastic syndrome (MDS), suggesting that the ranges of variation for urinary hepcidin and serum ferritin induced by iron overload are actually very similar. A recent study in 20 patients with MDS and myelofibrosis reported different results, mostly suggesting suppression rather than induction of hepcidin synthesis[97]. However, the group was not homogeneous and included patients with different MDS subtypes and alterations of iron status such as iron deficiency, iron overload secondary to transfusions or ineffective erythropoiesis. Overall, these findings indicate that the causes of hepcidin down-regulation in patients with MDS and myelofibrosis are much more heterogeneous than in thalassemia and need to be defined in more selected series[98].

Other acquired iron overload disorders: Preliminary data are available for some common chronic liver diseases frequently associated with slight to moderate

iron overload. Aoki et al[99] measured hepatic mRNA expression in patients with chronic hepatitis C showing that hepcidin expression did not correlate with markers of inflammation, but correlated with hepatic iron stores, suggesting that iron overload in chronic hepatitis C is not due to inappropriate hepcidin production. In contrast, Fujita et al[100] found that patients with chronic hepatitis C had serum hepcidin-to-ferritin ratios significantly lower than HCV negative controls and that this relative impairment of hepcidin production was fully reversible after successful HCV eradication by PEG-IFN plus ribavirin. The hypothesis that HCV might suppress hepcidin expression is also supported by recent experiments in HCV replicon cells and in HCV core-expressing Huh7 cells. Miura et al[101] found that hepcidin expression was inversely correlated with the amount of reactive oxygen species (ROS) production and that HCV-induced oxidative stress caused hypoacetylation of histones and inhibited binding of two positive regulators (C/EBPα and STAT3) of hepcidin transcription. Interestingly, anti-oxidants restored hepcidin expression in these cell lines and reduced HDAC activity in a dose-dependent manner. Hepatic hepcidin mRNA expression correlated with hepatic iron in advanced chronic liver disease and may also be affected by hepatic dysfunction[68]. A reduced hepcidin synthesis indeed might be one of the mechanisms leading to iron overload in advanced liver disease of any origin, but no further studies have clarified this issue.

Increased hepatic iron deposits have been frequently described in association with obesity and alterations of lipid or glucose metabolism, insulin resistance and non-alcoholic fatty liver (NAFLD) and variably named dysmetabolic or insulin-resistance hepatic iron overload syndrome (IR-HIO). Urinary hepcidin levels, although inappropriate for the iron overload, were indeed significantly higher in patients with dysmetabolic iron overload than in controls[67]. This finding has been also confirmed by others, as recently reviewed by Deugnier et al[89]. Hepcidin resistance or increased extra-hepatic production have been hypothesised[67,89] to explain these findings. Another explanation is that IR-HIO might be the result of an association of a mild-moderate, maybe polygenic, defect of hepcidin production and insulin resistance or metabolic syndrome (MS). These patients may retain some ability to increase hepcidin production in response to iron load as observed in subjects carrying the low expressing C282Y/H63D HFE genotype[20]. In IR-HIO patients, NAFLD and MS might induce hepcidin production through cytokine-mediated pathways[102] leading to the typical phenotype[103]. Further studies are needed to clarify this issue and the role of dysmetabolism in dysregulating iron regulatory pathways.

Iron deficiency: Urinary hepcidin levels were undetectable or low in patients with iron deficiency anemia[76,84], in agreement with the suppressive effect of deficient iron stores and iron deficient erythropoiesis

on hepcidin production. Very recently, the *TMPRSS6* gene has been identified as the hepcidin negative regulator required to sense low iron stores[104]. TMPRSS6 mutations cause the rare iron-refractory iron deficiency anemia (IRIDA)[105,106] and, in accordance with the suppressive effect of TMPRSS6 protein on hepcidin production, IRIDA patients show inappropriately elevated urinary hepcidin levels. This may explain the failure to absorb dietary iron despite systemic iron deficiency as well as the partial failure to respond to parenteral iron, which must be processed and then released by macrophages before being driven to the erythroid marrow[105,106].

EXTRA-HEPATIC PRODUCTION OF HEPCIDIN

Although the liver is the main site of hepcidin synthesis, recent studies demonstrated the presence of measurable amounts of hepcidin mRNA and protein in cells and tissues other than liver in humans and animals: heart, kidney, retina, monocytes and macrophages, splenocyte and alveolar cells, adipocytes and pancreatic β-cells[102,107-113]. In all these tissues the basal expression rate of hepcidin is lower than in the liver, suggesting a local role for hepcidin regulating iron homeostasis in these organs and tissues in an autocrine and paracrine fashion. On the other hand, it has been hypothesised that pancreatic hepcidin may contribute to the systemic hepcidin pool since it is exclusively synthesized by β-cells that secrete their product into the blood[108]. Nonetheless, this seems unlikely since expression of hepcidin in the pancreas is lower than in the liver and β-cells represent only a small portion of the total pancreatic parenchyma, in contrast to hepatocytes.

A major limitation of these studies is that they analysed hepcidin expression in response to only one of the major hepcidin regulators (iron, inflammation or hypoxia). In addition, only few evaluated the coupled modifications of hepcidin and ferroportin expression in response to such stimuli. There is emerging evidence, in fact, that hepcidin and its molecular target ferroportin may be expressed in the same cells, suggesting that ferroportin may be regulated by hepcidin generated within these cells independent of hepcidin in the circulation[107,108,113,114].

Most studies showed that hepcidin responds to an acute phase reaction caused by either LPS, turpentine, group A *Streptococcus* strain or *Pseudomonas aeruginosa*. They can induce a 20-80 fold increase of hepcidin expression in murine macrophages, splenocytes and retinal cells by a Toll-like receptor 4 (TLR-4) dependent pathway[107,110,112], and in human monocytes *via* IL-6 induction, which is TLR-4 independent and involves STAT-3 dependent activation[114]. It is suggested that formation of hepcidin may locally contribute to the development of iron retention as part of the innate defensive mechanism generally aimed at reducing the availability of the essential nutrient iron from pathogens. This may be important for tissues such as the retina and the brain, which are protected by blood barriers or at inflammatory sites with poor perfusion where circulating hepcidin is scanty. In particular, it has been proposed that hepcidin formation by activated monocytes/macrophages may result in biologically significant accumulation of this peptide in the inflammatory environment[114]. Hepcidin produced by monocytes targets membrane bound ferroportin primarily as a secreted peptide in an autocrine way, but hepcidin also affects, although to a much lesser extent, ferroportin expression within the cell, suggesting two pathways of hepcidin trafficking within macrophages.

Further studies are needed to understand the function of hepcidin in extrahepatic tissues and to evaluate possible influences at the systemic level. In fact, it has been hypothesised that in massively obese patients hepcidin production by adipocytes might contribute to the development of iron deficiency anemia in some patients[102]. Other authors, based on the co-localization of hepcidin with insulin-storing secretory granules, suggested that regulation of iron and glucose metabolism are distinctly coupled at the pancreatic level by the co-release of insulin and hepcidin[108].

CONCLUSIONS

Despite these recent important advances, much work still needs to be done. For example, the presence in blood of pro-hepcidin at concentrations greater than the iron active peptide remains puzzling. Huang *et al*[115] recently suggested that pro-hepcidin conversion into hepcidin may occur in the circulation as part of an iron-dependent regulation at the post-translational level, but this needs to be confirmed in larger studies. Other issues to be clarified are fluctuations of hepcidin related to circadian rhythm and/or meals[72,76], and if urinary hepcidin quantification can give information that might be complementary to single point serum measurement, similar to many other hormones. Since hepcidin is directly implicated in the regulation of iron homeostasis, its measurement might turn out to be a useful tool in the differential diagnosis of iron overload disorders and iron deficiency. The definition of the biological value of the hepcidin/ferritin ratio will be important to understand the appropriateness of hepcidin production in the clinical setting. Similarly the response of hepcidin to oral iron might prove to be a useful test to evaluate iron absorption in iron deficiency and the iron-sensing pathway in iron overload and in targeting phlebotomy treatment in patients with hemochromatosis[20]. Finally, of special importance are collaborative studies among various laboratories aimed at comparing the analytical performance of different methods, as well as for promoting standardization of hepcidin assay. In this regard, the results of the ongoing first international round robin for quantification of urinary and plasma hepcidin (Kroot *et al*, *Blood Suppl*. in press) are eagerly awaited.

Abstract

AIM: To elucidate the interaction between non-parenchymal cells, extracellular matrix and oval cells during the restituting process of liver injury induced by partial hepatectomy (PH).

METHODS: We examined the localization of oval cells, non-parenchymal cells, and the extracellular matrix components using immunohistochemical and double immunofluorescent analysis during the proliferation and differentiation of oval cells in N-2-acetylaminofluorene (2-AAF)/PH rat model.

RESULTS: By day 2 after PH, small oval cells began to proliferate around the portal area. Most of stellate cells and laminin were present along the hepatic sinusoids in the periportal area. Kupffer cells and fibronectin markedly increased in the whole hepatic lobule. From day 4 to 9, oval cells spread further into hepatic parenchyma, closely associated with stellate cells, fibronectin and laminin. Kupffer cells admixed with oval cells by day 6 and then decreased in the periportal zone. From day 12 to 15, most of hepatic stellate cells (HSCs), laminin and fibronectin located around the small hepatocyte nodus, and minority of them appeared in the nodus. Kupffer cells were mainly limited in the pericentral sinusoids. After day 18, the normal liver lobule structures began to recover.

CONCLUSION: Local hepatic microenvironment may participate in the oval cell-mediated liver regeneration through the cell-cell and cell-matrix interactions.

Hepatic non-parenchymal cells and extracellular matrix participate in oval cell-mediated liver regeneration. *World J Gastroenterol* 2009; 15(5): 552-560 Available from: URL: http://www.wjgnet.com/1007-9327/15/552.asp DOI: http://dx.doi.org/10.3748/wjg.15.552

INTRODUCTION

The capacity of hepatocytes and cholangiocytes to contribute to their own maintenance has long been recognized. They transiently enter the cell cycle and proliferate to restore the lost liver mass after parenchymal damage[1,2]. If the proliferation of hepatocytes is inhibited or blocked (such as by viral infection or chemicals), or if liver damage is extensive and chronic, putative liver progenitor cells are activated to proliferate into mature liver cells[3-7]. Liver progenitor cells are evident in both human pathologic ductular reactions and experimental animal models during hepatocarcinogenesis or as a part of the restituting response to liver injury[8-10]. After liver injury was induced by N-2-acetylaminofluorene (2-AAF)/partial hepatectomy (PH) in rodent models, the best candidate for liver progenitor cells would be the "oval cell" population, which is oval in shape, with a darkly staining nucleus and scant, basophilic cytoplasm. These cells radiate out from terminal biliary ductules, proliferate and migrate from portal regions into the parenchyma until liver regeneration is completed.

In recent years, attention has focused on the influence of the hepatic microenvironment on hepatic oval cell activation and proliferation[11-13]. The microenvironment comprises the extracellular matrix, epithelial and non-

epithelial resident liver cells, and recruited inflammatory cells as well as the variety of growth-modulating molecules. It is conceived as a restricted locale in an organ that regulates liver progenitor cell division through microenvironmental signaling, supporting their self-renewal, inhibiting or maintaining normative baseline differentiation in normal physiological states, and promoting proliferation and differentiation in response to injury[14-16]. The modulation factors for oval cell proliferation and differentiation are now being identified. Although great progress has been made in the research of multiple growth modulators (priming factors, growth factors, inflammatory cytokines, chemokines and growth inhibitory factors) involved in oval cell regulation[13], the role of individual non-parenchymal cells and hepatic extracellular matrix in oval cell-mediated liver regeneration remains unclear.

In the present work, we present a detailed immuno-histochemical analysis of the involvement of non-parenchymal cells, hepatic extracellular matrix components and the interaction of these elements with oval cell and hepatocytes in oval cell-mediated liver regeneration induced by partial hepatectomy after 2-AAF treatment. To obtain detailed morphological assessment, the samples were analyzed under traditional light microscopy and confocal microscopy. The results indicated that different non-parenchymal cells and extracellular matrix component proliferation and migration were accompanied with the "ductular" periportal oval cell response. The local hepatic microenvironment may influence the oval cell response through the production of growth factors, expression of growth factor receptors and remodeling the hepatic extracellular matrix during the restitution process.

## MATERIALS AND METHODS

Animal models
Male Sprague Dawley (SD) rats (8-9 wk of age; 120-150 g of body weight) were used. They were fed standard pelleted chow and had access to water *ad libitum*. Rats were maintained in a temperature-controlled room with a 12-h light/dark illumination cycle. To inhibit hepatocyte proliferation, all rats received daily oral gavage of 2-AAF (Sigma Chemical Co) at a dosage of 15 mg/kg body weight for 4 d before and up to 7 d after PH. 2-AAF was dissolved in dimethyl sulfoxide (DMSO, Sigma Chemical Co). After the first four daily gavages, all rats were anesthetized, and two-thirds partial hepatectomy was performed by surgical removal of the left and median liver lobes; no dosing was performed on the day of surgery. Three rats were killed at 2, 4, 6, 9, 12, 15, 18 and 21 d after PH. Formalin-fixed and paraffin-embedded serial liver tissue sections (4 μm) were used for immunohistochemical and double immunofluorescent analysis. All procedures were conducted in accordance with the Guide for the Care and Use of Laboratory Animals and approved by the Institutional Animal Care and Use Committee.

Immunohistochemistry
Paraffin sections of formalin-fixed liver tissues were stained with mouse monoclonal antibody to ov-6 (MAB2020, R&D Systems, Inc), a marker of hepatic oval cells in ductular reaction; mouse monoclonal antibody to desmin (DE-R-11, DAKO Denmak), a marker of stellate (Ito) cells, smooth muscle cells, periportal fibroblasts; mouse monoclonal antibody to ED1 (MCA341GA, Serotec Ltd) recognizing the cytoplasmic antigen in circulating monocytes and small Kupffer cells in the liver; and polyclonal rabbit anti-laminin (Z0097, DAKO, Denmark) or polyclonal rabbit anti-fibronectin (A0245, DAKO Denmark). Tissue sections were rehydrated at descending concentrations of ethanol and endogenous peroxidase activity was blocked with 3% hydrogen peroxide in methanol. Tissues used for ov-6 and desmin immunohistochemistry were microwaved to boiling for 15 min in 10 mmol/L Tris buffer, 1 mmol/L ethylenediamine tetra-acetic acid (EDTA), pH 9.0, for antigen retrieval. The sections labeled ED1, laminin or fibronectin were digested with Proteinase (10 μg/L, 5 min, 37℃). After antigen retrieval, the tissue sections were blocked with 10% normal serum from the donor species of the secondary antibodies for 15 min at room temperature, followed by incubation with primary antibodies overnight at 4℃. Primary antibody dilutions were as follows: anti-ov-6, 1:10; anti-desmin, 1:50; anti-ED1, 1:50; anti-laminin, 1:100 and anti-fibronectin, 1:50. After rinsing with phosphate buffered solution (PBS), primary antibodies were detected by incubation for 30 min with biotinylated rabbit anti-mouse or goat anti-rabbit immunoglobulins. After further rinsing with PBS, sections were incubated with horseradish peroxidase conjugated streptavidin/biotin complex (85-9843, Histostain Plus Kits, Zymed Laboratories Inc.). Peroxidase activity was developed with 0.05% diaminobenzidine and 0.03% H_2O_2. Finally, sections were counterstained for 5 min in hematoxylin, dehydrated through graded alcohols, and mounted under glass coverslips.

Double immunofluorescent analysis
After deparaffinization and hydration, liver sections were microwaved for 15 min in 10 mmol/L Tris buffer, 1 mmol/L EDTA, pH 9.0, for antigen retrieval. Proteinase digestion was added if the second primary antibodies were laminin, ED1 or fibronectin. Five pairs of double labeling (ov-6/desmin, ov-6/laminin, ov-6/ED1, ov-6/fibronectin, desmin/laminin) were performed. We used a vector Mouse-On-Mouse (MOM) immunodetection kit (FMK2201, Vector Laboratories Inc.) when both primary antibodies came from mice. After rinsing with PBS, tissue sections were incubated for 5 min in working solution of MOM™ diluent, followed by incubation with primary antibodies overnight at 4℃. Working solution of MOM biotinylated anti-mouse IgG was used as secondary antibodies. Then, sections were incubated with fluorescein avidin DCS for 5 min. Before incubating

Figure 1 Ov-6 immunoreactivity of ductular cell reaction following PH of rats treated with AAF. A: Oval cells (short arrow) close to hepatocytes at limiting plates on day 2 after PH show much lighter labeling than pre-existing bile duct cells (long arrow) (× 200); B: On day 4 after PH, strongly stained cells are beginning to move into the parenchyma (× 200); C: On day 9 after PH, apparent long cords of ductular oval cells are fanning outward from each portal area (× 100); D: On day 15, the ov-6 (+) ductular structures are restricted to the periphery of small hepatocyte nodus (× 100).

the second primary antibodies, both the avidin/biotin blocking step and the mouse Ig blocking step must be done to prevent the interaction of the second set of labeling reagents with the first set of labeling reagents if the two mouse monoclonal primary antibodies were used. If two primary antibodies came from different species, only the avidin/biotin blocking step was necessary. After the protein blocking step, sections were incubated with the second primary antibodies for 1 h at 37℃, followed by incubation with working solution of MOM biotinylated anti-mouse or anti-rabbit IgG (BA-1000, Vector Laboratories Inc.) for 10 min, then Texas Red Avidin DCS (A-2016, Vector Laboratories Inc.) for 10 min. All samples were analyzed by confocal laser-scanning microscopy using the Nikon Digital ECLIPSE C1 system (Nikon Corporation, Japan).
RESULTS

Ductular oval cell response

In the normal liver, ov-6 strongly labeled pre-existing intraportal bile ducts, ductules and terminal duct cells. There was no change from normal in the distribution and the expression pattern of the ov-6 (+) cells on day 1 after PH. On day 2 after PH, small cells with high nuclear/cytoplasmic ratio (oval cells) were evident in and around the portal area. Oval cells were close to hepatocytes at limiting plates (Figure 1A). On day 4 after PH, ov-6 positives cells could be seen protruding into the parenchyma. Pre-existing ducts stained more strongly than new ducts (Figure 1B). By day 6, there is further extension of ductular structures across the hepatic lobule. On day 9 after PH, multiple strings of ductular cells spread further into the midzone (Figure 1C). By

day 12 and beyond, the periportal areas were colonized by small hepatocyte nodus, though small strings of ductular cells could still be discerned at the periphery of hepatocytes. Many ductular profiles exhibited what looked like clear intestinal differentiation. On day 15 after PH, there was a significant decrease in the ductular structure and increase in the new small hepatocyte nodus (Figure 1D). From day 18 to 21 after PH, small ov-6 (+) cells further decreased or disappeared. The normal liver lobule structures recovered.

Non-parenchymal cell response and interaction with oval cells

Desmin stained smooth muscle cells of the blood vessels and dendritic cells around the bile ducts and vessels, but not sinusoidal cells as in normal rat liver. However, by day 2 after PH, hepatic stellate cells (HSCs) were activated and expressed desmin. At this moment, a few oval cells began to proliferate from the portal areas. Most desmin (+) cells were located in the portal areas and minority of the HSCs were small interlobular sinusoidal cells (Figure 2A). There were no desmin (+) cells in the central zone. From day 4 to 6 after PH, desmin (+) cells could be seen protruding into the parenchyma and formed the organized meshwork arrangement (Figure 2B). As time elapsed, HSCs spread further into the parenchyma and reached the mid zonal parenchyma. The number of desmin (+) periportal stellate cells peaked on day 9 and 12 after PH and decreased afterward. During the course of proliferation, HSCs appeared to be closely associated with the oval cells. They appeared to admix with oval cells in the periportal zone and tightly surrounded the long strings of ductular oval cells (Figure 2C). Along with the formation of the small

Figure 2 HSCs response and correlation with oval cell following PH of rats treated with AAF. A: Increase in number of desmin positive stellate cells in the portal areas. Very few of HSCs were small interlobular sinusoidal cells on day 2 after PH (× 200); B: Further increase in number of stellate cells at the periphery of the portal areas at day 6 after PH (× 200); C: Double immunofluorescent labelling for ov-6 (red) and desmin (green) on day 9 after PH. The strings of ductular oval cells are closely surrounded by the mesh-like desmin (+) stellate cells (× 400); D: On day 12 after PH, dash line marks the edge of a regenerative small hepatocyte focus. Desmin (+) cells are present around the focus, and occasionally in the focus (× 200); E: Double immunofluorescent labelling for ov-6 (red) and desmin (green) on day 12 after PH. Desmin (+) cells accompany the ductular structure around small hepatocytes focus. There are few HSCs in the focus negative for ov-6 (× 200); F: By day 18 after PH, the number of desmin (+) portal stellate cells is further decreased (×100).

hepatocyte nodus, most of the desmin (+) cells were located around the nodus. There were few activated HSCs in the nodus (Figure 2D). In addition, increasing numbers of desmin (+) cells were seen in the interlobular sinusoidal zone. On day 15 after PH desmin (+) cells became far less prominent and accompanied with the ductular structure around small hepatocyte nodus (Figure 2E). The number of stellate cells decreased more significantly than the ductular oval cells. On day 18 after PH, the number of desmin (+) stellate cells further decreased or vanished completely (Figure 2F).
ED1 stained the small rounded or spindle-like macrophages in the sinusoids with a cytoplasmic staining pattern in normal liver (Figure 3A). The number of ED1 (+) cells sharply increased not only in the pericentral zone but also in the periportal zone by day 2 after PH. At this time, no obvious ductular structures spread into the parenchyma (Figure 3B). On day 4, ED1 (+) cells began to decrease in both portal and central zones with an increase of the ductular oval cells. Infiltration of ED1 labelled macrophages into the ductular structures was seen in the periportal areas. A few scattered ED1

(+) cells around the portal zone appeared to admix with oval cells (Figure 3C and D). From day 6 to 9, there appeared to be different fate for central zone and portal zone macrophages. The number of ED1 (+) cells in the periportal zone decreased more markedly than in the pericentral zone as the ductular oval cells spread further into the mid zone (Figure 3E). On day 12, ED1 staining was limited to a few pericentral sinusoidal macrophages. There were very few ED1 (+) cells in the expanding ductular cells (Figure 3F). After day 15, ED1 (+) cells were seen mainly located between the central veins and small hepatocyte nodus as oval cells differentiated into small hepatocyte-like cells.

Extracellular matrix changes and interaction with oval cells

Laminin normally stained around the bile ducts, blood vessels, and in the sinusoids. On day 2 after PH, laminin appeared along the hepatic sinusoids in the peirportal areas and in the cytoplasm of few nonparenchymal cells, as well (Figure 4A). During the course of oval cell proliferation, laminin-containing basement membrane
Figure 3 Kupffer cell response and correlation with oval cells following PH of rats treated with AAF. A: Normal rat liver. Small round or spindle-like cells in the sinusoids are labelled (× 200); B: On day 2 after PH, there is marked increase of ED1 (+) cells in periporal and interlobular sinusoids. No oval cells are seen in the poral areas (× 200); C: on day 4 after PH, number of pericentral and periportal ED1 (+) cells decreased along with the ductular oval cells(arrows) (× 100); D: double immunofluorescent labelling for ov-6 (green) and ED1 (red) at day 4 after PH. A few scattered ED1 (+) cells around the portal appeared to admix with ov-6 (+) oval cell (× 400); E: on day 9 after PH, very few ED1 (+) cells are visualized in the periportal ductular oval cells (× 200); F: double immunofluorescent labelling for ov-6 (green) and ED1 (red) on day 12 after PH. Dash line marks the edge of a regenerative small hepatocyte nodus. ED1 (+) cells are situated around the small hepatocte nodus and ductular ov-6 (+) cells (× 100).

surrounded the undifferentiated oval cells (Figure 4C). The cylinder formed by the basement membrane had an open end plugged by hepatocytes (Figure 4B), and desmin-positive stellate cells were accompanied with the ductular structures outside the basement membrane. In addition, laminin was found in the cytoplasm of many desmin (+) fusiform stellate cells (Figure 4D). No cells penetrating through the basement membrane could be observed. The maximum laminin staining was from day 9 to 12 after PH and decreased afterwards. The paucity or complete lack of laminin staining was characteristic of nodus as oval cells differentiated into small hepatocyte nodus on day 12 after PH. Numerous undifferentiated oval cells located outside nodus were still outlined brightly by laminin staining. After day 15, the ductular oval cells further decreased and the small hepatocyte-vascular relationship and hepatic architecture began to be restored. Straps of laminin were present in the periportal hepatocyte cluster in which there was no intervening sinusoids or extracellular matrix (ECM) in the early stage of regeneration (Figure 4E).

In normal liver, fibronectin is present in the perisinusoidal space and codistributed with collagens in the ECM of the subcapsular region, portal triad, and central vein regions. In general, the cellular staining for fibronectin in the normal liver is very similar to that of ED1. On day 2 after PH, fibronectin staining became more prominent in sinusoidal cells and in the periportal and pericentral regions (Figure 5A). By day 4, fibronectin (+) cells increased further in the periportal areas accompanying with ductular oval cells as oval cells began to spread into the parenchyma, and there was a marked decrease of fibronectin staining in the sinusoids of the mid zone and the pericentral areas (Figure 5B). From day 6 to 9, fibronectin admixed with the proliferating ductual oval cells expanded further into the pericentral areas. The clumps of oval cells were closed associated with desmin, and fibronectin as well (Figure 5C). On day 12, fibronectin (+) cells were seen around the small hepatocyte nodus in the periportal areas and very little fibronectin was detected within the hepatocyte clusters (Figure 5D). The number of fibronectin (+) cells among the expanding ductules decreased as oval

Figure 4 Laminin distribution and correlation with oval cell following PH of rats treated with AAF. A: On day 2 after PH, laminin is present along hepatic sinusoids in peirportal areas and in the cytoplasm of few nonparenchymal cells in the lobule (arrows) (× 200); B: On day 6 after PH, laminin positivity around the ductular oval cells. The proximal part of the ductule has continuous laminin staining, whereas distally the basement membrane is fragmented or absent (arrows) (× 400); C: Periportal area stained for OV-6 (green) and laminin (red) 12 d after PH. The bifurcating ductule strongly positive for OV-6, is surrounded by continuous basement membrane (× 200); D: Portal area 15 d after PH, stained for laminin (red) and desmin (green). Some of the desmin-positive cells are positioned closely to the laminin (+) basement membrane of ductules (long arrows). Some of the laminin-positive ductules also stained positively for desmin (short arrows). The focus (dash line marks the edge) is negative for laminin except some oval cell ductules enclosed in the focus (arrow head) (× 400); E: On day 15 after PH, most laminins are present around the focus, some laminins invading the hepatocyte clusters (arrows) (× 100).

Figure 5 Fibronectin distribution and correlation with oval cell following PH of rats treated with AAF. A: On day 2 after PH, there is a marked increase of fibronectin in the periportal, pericentral areas and interlobular sinusoids (× 100); B: On day 4 after PH, there is a decrease in number of fibronectin in pericentral zone and increase of fibronectin in periportal areas (× 200); C: Double immunofluorescent labelling for ov-6 (green) and fibronectin (red) on day 9 after PH. The ductular oval cells fanning outward from portal area were closely surrounded by fibronectin (× 200); D: On day 12 after PH, dash line marks the edge of a regenerative small hepatocyte focus. Fibronectin was present around the focus, very few in the nodus (× 200); E: On day 15 after PH, there is notable decrease of fibronectin during recovery of normal hepatic architecture (× 100).

cells differentiated into the hepatocytes on day 15 (Figure 5E). Recovery of normal sinusoidal fibronectin expression occurred after day 18.

DISCUSSION

In this paper, we describe the proliferation of non-parenchymal cells and extracellular matrix components in the oval cell-mediated liver regeneration in a 2-AAF/PH rat model. In addition, the interaction of these elements with oval cell and hepatocytes was studied through confocal double immunofluorescent labeling. Our results show that the reconstitution of the liver parenchymal following 2-AAF/PH treatment involves not only the ductular oval cells but the Kupffer cells, hepatic stellate cells and ECM components (laminin and fibronectin). A close anatomical relationship among the hepatic oval cells, non-parenchymal cells and ECM was observed during the restituting process. These results suggest that ECM remodeling and production of growth factors and expression of growth factor receptors by non-parenchymal cells play an important role in the oval cell-mediated liver regeneration.

The effect of HSCs on oval cell proliferation and differentiation is complex, including elaboration and secretion of specific paracrine stimuli to proliferation in the early phase after partial hepatectomy, inhibition of proliferation in the later phase and matrix remodeling. During oval cell growth and ductule formation, HSCs are closely associated with oval cells, as suggested by Alison et al[17]. Both HSCs and oval cells produce and have receptors for a variety of overlapping growth factors[18]. Liver stem-like cells can differentiate into hepatocytes induced by coculture with hepatic stellate cells. These results suggest that, besides growth factors, cell-cell interaction through extracellular matrices produced by HSCs is also important for the induction of hepatocytic differentiation[19]. Another important role of HSCs is matrix remodeling by combination of proteolytic degradation of ECM and extracellular matrix synthesis. HSCs exhibit collagenase, stromelysins, metalloelastase and gelatinase A activity. Tissue inhibitors of metalloproteinases, also HSC derived, balance these activities. Matrix components, including laminins, fibronectins, collagens and proteoglycans, are largely but not exclusively HSC derived[20]. Our results show that after ductular oval cells differentiate into small hepatocyte nodus, the HSCs extend into the hepatocyte clusters without intervening sinusoids or ECM. HSCs gradually disappear as the normal liver lobule structures are restored. These results indicate that HSCs may play an important role in the restoration of normal hepatocyte-vascular relationships and overall hepatic architecture in the later stages of regeneration.

Concomitant with periportal oval cell proliferation, there is an increase in ED1 (+) Kupffer cells. Kupffer cells are mainly phagocytic cells also synthesize and secrete a number of cytokines, including tumor necrosis factor-α (TNF-α), IL-1 and IL-6[20-22]. Inhibition of TNF signaling results in a reduced progenitor cell response and impaired liver regeneration[23]. In our study, there was a quick increase in ED1 (+) Kupffer cells in the whole hepatic lobule by day 2 after PH, before obvious ductular structures were observed. From these results, we can speculate that Kupffer cells may play a crucial role in priming the oval cells and inducing DNA synthesis by secreting the priming factors (TNF-α and IL-6) in the early phase of oval cell-mediated liver regeneration. After 4 d, as the oval cells spread further into the liver parenchyma, Kupffer cells appeared to admix with the expanding oval cell population. The structural relationship of the interaction of the responding cells implies that there may also be a functional interaction. Takeishi et al[24] demonstrated that Kupffer cells play a stimulatory role in liver regeneration by enhancing hepatocyte growth factor (HGF) expression. In addition, studies indicate that HGF accelerates the proliferation of hepatic oval cells and promotes the differentiation to hepatocytes[25,26]. Apart from secreting growth factors, Kupffer cells may also produce metalloproteases, elastase, collagenase and fibronectin[27]. Thus, Kupffer cells and HSCs may act together to contribute to the dissolution of basement membrane around small ductules, perhaps allowing ductular oval cells to move into the adjacent hepatic lobe, providing mitogenic growth factor and remodeling ECM during the proliferation and differentiation of oval cells. Kupffer cells also play a role in terminating the surge of replication after partial hepatectomy[20]. One of powerful inhibitors of hepatocyte replication is TGF-β, produced most prominently by hepatic stellate cells and Kupffer cells. TGF-β has been proposed to play similar modulatory roles in oval cell-mediated liver regeneration[28].

The extracellualr matrix is a dynamic complex of macromolecules and plays a role not only in structural support, but also in cell proliferation, migration, and differentiation[29]. The morphological observations described above suggest a link between stroma in the hepatic microenvironment and the oval cell response. We speculate that ECM (laminin and fibronectin) may affect the oval cell response by: (1) Providing the growth factors for oval cells in the early stage of regeneration. The upregulation of urokinase-type plasminogen activator (uPA) mRNA accompaning oval cell proliferation has been reported, and infusion of uPA enhanced the mitogenic response of cells located near bile ducts[30]. uPA has been shown to initiate the degradation of the ECM through activation of metalloproteinase and the degradation leads to the release of bound HGF with a subsequent increase in serum HGF concentration[31]. Several growth factors involved in oval cell regeneration may be also regulated by this system[18]. Together, these findings support the overall concept of ECM remodeling as an important step in the growth phase of oval cell-mediated liver regeneration. (2) Influencing the differentiation state of the oval cell. Our results show that there is a distinct

continuous laminin staining around the oval cells, and the disappearance of the basement membrane (BM) that surrounds the oval cell ductules is closely associated with initiation of the differentiation into hepatocytes. Yin *et al*[32] reported that isolated hepatic stem cells expressed biliary or hepatocytic phenotypes in culture, depending on the presence or absence of basement membrane matrix (Matrigel). Matrigel was also found to play an important role in maintaining the biliary phenotype in tissue culture in other experimental systems[33,34]. Recently Leite *et al*[35] demonstrate that fibronectin and laminin can induce expression of islet cell markers in hepatic oval cells in culture. (3) Affecting the migration, proliferation and attachment of oval cells. Sánchez *et al*[36] demonstrate that fibronectin might regulate morphology, cell organization and gene expression of rat fetal hepatocytes in primary culture. Other studies show that the apparent affinity of hepatocytes to laminin increases during the prereplicative phase of rat liver regeneration and laminin is one of the most effective substrates in supporting the responstiveness of hepatocytes to the growth stimulus[37,38]. (4) Playing a role in the development of the hepatic sinusoidal vasculature. We observed that both laminin and fibronectin are present in the periportal hepatocyte cluster and when the maturation of the sinusoidal vasculature is complete, the expression is repressed. A resynthesis of the previously degraded perisinusoidal ECM is required for full regeneration. Epithelial cells require contact with ECM to inhibit detachment-induced apoptosis, and the reconstitution of a perisinusoidal ECM therefore will stabilize the newly formed hepatocyte population[39].

In summary, our results indicate that there is a close relationship between the non-parenchymal cells (HSCs and Kupffer cells), ECM components (laminin and fibronectin) and oval cells during the restitutive repair in 2-AAF/PH model, providing evidence that the local hepatic microenvironment may participate in the oval cell-mediated liver regeneration through the cell-cell and cell-matrix interactions. Furthermore, our results also suggest that the production of growth factors and extracellular matrix remodeling may be required to regulate the migration, proliferation and differentiation of oval cells and the process of liver regeneration. Further studies should focus on providing the direct evidence of hepatic microenvironment in regulating to oval cells *via in vitro* experiments and elucidating the molecular mechanisms.

COMMENTS

Background
Oval cells are thought to be the progeny of stem cells in adult liver, which are able to differentiate bipotentially into mature hepatocytes and biliary epithelial cells when the proliferation of mature hepatocytes is inhibited or blocked. In recent years, attention has focused on the influence of the hepatic microenvironment on hepatic oval cell activation and proliferation.

Research frontiers
Although great progress has been made in the research of multiple growth modulators involved in oval cell regulation, the role of individual non-parenchymal cells and hepatic extracellular matrix in oval cell-mediated liver regeneration remains unclear.

Innovations and breakthroughs
The current study demonstrated that the local hepatic microenvironment may influence the oval cell response through the production of growth factors, expression of growth factor receptors and remodelling the hepatic extracellular matrix during the restitution process.

Applications
By observing the interaction of hepatic microenvironment with oval cells in oval cell-mediated liver regeneration, the existence and importance of liver stem cell niche have been further confirmed. This study has laid a foundation for researchers to elucidate the molecular mechanisms of hepatic microenvironment in regulating oval cells.

Terminology
Stem cell niche is conceived as a restricted locale in an organ that regulates stem cell division through microenvironmental signaling, supporting their self-renewal, inhibiting or maintaining normative baseline differentiation in normal physiological states, and promoting proliferation and differentiation in response to injury.

Peer review
The authors reported a close anatomical relationship between the hepatic oval cells, non-parenchymal cells and extracellular matrix (ECM), and they suggested that ECM remodeling and production of growth factors and expression of growth factor receptors by non-parenchymal cells may play an important role in the oval cell-mediated liver regeneration. Overall, the data are well presented, although some conclusions could not be supported as this is only a immunohistochemical and a double immunofluorescent analysis.

Abstract

AIM: To investigate the effects of Tat-NEMO-binding domain (NBD) peptide on taurocholate-induced pancreatitis and lipopolysaccharide (LPS)-stimulated AR42J acinus cells inflammatory response in rats.

METHODS: Sodium taurocholate (5%) was used to induce the pancreatitis model. Forty-eight rats from the taurocholate group received an intravenous bolus of 13 mg/kg Tat-NBD (wild-type, WT) peptide, Tat-NBD (mutant-type, MT) peptide, NBD peptide or Tat peptide. The pancreatic histopathology was analyzed by hematoxylin staining. LPS was added to the culture medium to stimulate the AR42J cells. For pretreatment, cells were incubated with different peptides for 2 h before LPS stimulation. Expression of *IL-1β* and *TNF-α* mRNA was analyzed using a semi-quantitative reverse-transcript polymerase chain reaction (RT-PCR) method. IL-1β and TNF-α protein in culture medium were detected by enzyme linked immunosorbent assay (ELISA). NF-κB DNA-binding in pancreas was examined by electrophoretic mobility shift assays. P65 expression of AR42J was determined by Strept Actividin-Biotin Complex (SABC) method.

RESULTS: Pretreatment with Tat-NBD (WT) peptide at a concentration of 13 mg/kg body wt showed beneficial effect in pancreaitis model. LPS (10 mg/L) resulted in an increase of *IL-1β* mRNA, IL-1β protein, *TNF-α* mRNA and TNF-α protein, whereas significantly inhibitory effects were observed when cells were incubated with Tat-NBD (WT). Consisting with p65 expression decrease analyzed by SABC method, NF-κB DNA-binding activity significantly decreased in Tat-NBD (WT) pretreatment group, especially at the largest dose. No significant changes were found in the control peptide group.

CONCLUSION: Our result supports that active NF-κB participates in the pathogenesis of STC-induced acute pancreatitis in rats. Tat-NBD (WT) peptide has anti-inflammatory effects in this model and inhibits the inflammation of acinus simulated by LPS.

INTRODUCTION

Because of the systematic inflammatory response syndrome (SIRS) in severe acute pancreatitis (SAP), the mortality rate of SAP is very high, reported to reach about 30%[1,2]. Though it is known that several kinds of proinflammatory mediators, such as lipopolysaccharide (LPS), cytokine, *etc.*, are closely related to the

development of systematic complications, the exact mechanism of acute necrotic pancreatitis is still unclear. Therefore, it is very important to develop an effective therapy. Nuclear factor kappa B (NF-κB) is a member of the Rel family of transcriptional regulatory proteins including p50, p52, p65, c-Rel and Rel B[3]. It has been proved that in many inflammatory diseases, including rheumatoid arthritis, inflammatory bowel disease and SIRS, NF-κB is highly activated while the inflammatory mediators, such as LPS, can intermediate the activation of NF-κB[4]. Once activated, NF-κB is translocated into the nucleus from the cytosol. It binds the consensus sequence to promoter or enhancer region of related genes and regulates gene transcription.

Activation of NF-κB dimers is regulated by the inhibitory proteins, IκBα, IκBβ, and IκBε. The phosphorylation sites of IκBα have been identified, and the kinases have been found involved in the process, namely the IκB kinase (IKK)[5,6]. The IKK complex comprised primarily three IKKs, α, β, and γ. IKKγ, the third protein within the IKK complex, which is also named NEMO (NF-B essential modulator), was deemed regulatory of the other IKKs. NEMO is critical for pro-inflammatory activation of the IKK complex[7,8]. Although the precise mechanism of NEMO action is poorly understood, it was speculated that it recruits the IKK complex to ligate cytokine receptors and facilitate transphosphorylation events. More intriguingly, NEMO may facilitate the recruitment of upstream IKK activators such as kinases that specifically target the activation loops within the catalytic domains of the IKK subunits. NEMO interacts with a COOH-terminal sequence within the both IKKs termed the NEMO-binding domain (NBD)[9]. Importantly, short cell-permeable peptide spanning the IKKβ NBD disrupted the association of NEMO with IKKβ, blocked NF-κB activation, and ameliorated responses in animal models of inflammation. These observations defined the IKK NBD as a viable target for the development of anti-inflammatory drugs[7,10,11]. Such peptide interacting the NBD had been confirmed to attenuate the severity of cerulein-induced mouse pancreatitis which ameliorated inflammation in the pancreas, reduced hemorrhage in the lungs, and lowered the myeloperoxidase activity in both pancreas and lung. It indicates that this novel compounds that selectively target NF-κB may be useful in the treatment of AP and AP-associated lung injury[12]. In rat pancreatitis induced by taurocholate, activation of NF-κB in pancreas has been reported[13]. It was not clear whether or not the peptide could have anti-inflammatory effects in taurocholate-induced SAP model and inhibited the inflammation of acinus stimulated by LPS directly. In this paper, we report the effects of Tat-NBD peptide on STC-induced pancreatitis and LPS-stimulated AR42J acinus cell inflammatory response in rats.

MATERIALS AND METHODS

Materials and animals
Sodium taurocholate and LPS were purchased from Sigma Company (America); AR42J cells, from American Type Culture Collection (ATCC N.O: CRL-1492); agarose, inhibitor of RNase and M-MLV retroviridase, from Promega Company (America); F12 culture medium, from Gibco Company (America); DNA marker, from Beijing Huamei Biological Company (China); primers for reverse transcription-polymerase chain reaction (RT-PCR) from Shanghai Boya Biological Company (China); TRIzolTM Reagent from Invitrogen Company (America); and EX Taq enzyme from TaKaRa Company (Japan). Peptide was synthesized by Xian Meilian Biological Company (China). TNF-α kit for enzyme-linked immunosorbent assay (ELISA) is a product of Guangzhou Jingmei Biological Company (China). Immunohistochemistry (IH) kit of steptavidin-biotin complex method (SABC) was obtained from Wuhai Boshide Company (China). Anti-rat monoclonal antibody of p65 is from Santa Crutz Company (America). All other chemicals were obtained from either Sigma or Beijing Dingguo Company. Female and male Sprague-Dawley (S-D) rats (200 ± 10 g) were from specific pathogeny free unit in the Animal Center of Guangdong Medical College.

Peptide synthesis
According to Dai et al[7], the wild Tat-NBD peptide was synthesized with a 23-amino acid sequence (YGRKKRRQRRR-G-TTLDWSWLQME). A mutant peptide was called Tat-NBD (MT) with TrpAla mutations (YGRKKRRQRRR-G-TTLDASALQME). NBD sequence (TTLDWSWLQME) and Tat sequence (YGRKKRRQRRR) were synthesized respectively as controls. The peptide concentrations of 0.1, 1, 10 and 100 mg/L were prepared with F12 culture medium (no serum and antibody).

Induced rat pancreatitis model
Seventy-two Sprague-Dawley rats were randomized into different groups. All rats were maintained at 23℃ on a 12 h light/dark cycle and allowed free access to water and standard laboratory chow. From 12 h before start of the experiments, the animals were deprived of food, except access to water. Acute taurocholate pancreatitis was induced according to Aho et al[14]. Under anesthesia with a combination of xylazine (10 mg/kg) and ketamine (100 mg/kg), a midline laparotomy was performed and a PE-50 catheter (inside diameter 0.58 mm, outside diameter 0.96 mm) was inserted in the pancreatic duct through a puncture of the duodenum. The biliopancreatic duct was occluded transiently by a silk ligature at the liver hilus to prevent regurgitation into the liver. Sodium taurocholate solution (1 mL/kg of 5%; STC group, n = 60) or the same volume of saline (sham-operated group, n = 12) was retrogradely infused in the pancreatic duct at a flow rate of 0.07 mL/min by a microinfusion pump. Upon the completion of the infusion, the catheter and hilar ligature were removed and the abdomen was closed with suture. For pretreatment with peptide, 48 rats from the TC group

received an intravenous bolus of 13 mg/kg Tat-NBD (WT) peptide [Tat-NBD (WT) group, *n* = 12], Tat-NBD (MT) peptide [Tat-NBD (MT) group, *n* = 12], NBD peptide (NBD group, *n* = 12) or Tat peptide (Tat group, *n* = 12). Peptide in F12 culture medium was incubated 2 h before intraductal infusion of taurocholate, followed by a continuous intravenous infusion. Controls received an intravenous saline infusion. These groups of rats were killed 6 and 12 h after taurocholate administration.

At 6 or 12 h after taurocholate infusion, animals were killed and blood was obtained with heparinized tubes for amylase and TNF-α determinations. Portions of the gland were saved for morphological examination, which were fixed in 10% zinc-buffered formalin, embedded in paraffin, and cut into 3 to 5 μm thick sections. The microscopic damage score was calculated according to Spormann *et al*[15].

Cell culture
The AR42J cell line was obtained from American Type Culture Collection. Cells were grown in 75-cm^2 flasks containing 12 mL medium, consisting of Ham's F-12 nutrient medium (F12K) with 2 mmol/L *L*-glutamine, 1% antibiotic, 1.5% sodium bicarbonate, and 10% FBS. Flasks were placed into an incubator maintained at 37℃ and a 5% CO$_2$-95% air atmosphere. Cells were plated at a density of 10^5 cells/mL in 12-well plates. LPS was added to culture media at a dose of 10 mg/kg for 2 h to stimulate the cells. For pretreatment, cells were incubated with different peptides [Tat-NBD (WT), *n* = 3; Tat-NBD (MT), *n* = 3; NBD, *n* = 3; Tat, *n* = 3] for 2 h before LPS stimulation.

AR42J, IL-1β and TNF-α mRNA detection by RT-PCR
Analysis of *TNF-α* mRNA expression was conducted by a semiquantitative RT-PCR method. Total RNA from cells was extracted using the TRIzol reagent (Invitrogen Life Technologies). One microgram of total RNA was used for amplification using the Invitrogen One Step RT-PCR System according to the manufacturer's instructions. The following primers were used for: *IL-1β* (307 bp) forward: 5'-GGATGATGACGACCTGCT AGTGT-3', reverse: 5'-CTTCTTTGGGTGTTTG GGA-3'; *TNF-α* (231 bp) forward: 5'-GAACTCCAG GCGGTGTCT-3', reverse: 5'-TCTGCTTGGTGGTTT GC-3'. Fragments were amplified using 25-30 cycles of PCR; each cycle consisted of 15 s at 94℃, 30 s at 55℃, and 1 min at 72℃. The resulting RT-PCR products were electrophoresed on 2% agarose gels with DNA markers, stained with ethidium bromide, and visualized under UV light. *Beta-Actin* (701 bp) was used as an internal control for stable expression (housekeeping gene) in all experiments. The forward primer was 5'-GCCAACCGT GAAAAGATGA-3', and the reverse primer was 5'-GCCAGGATAGAGCCACCAAT-3.

Electrophoretic mobility shift assays (EMSAs) of NF-κB
The activity of NF-κB DNA-binding was detected by EMSA as descried by Molloy[16] with the following

modifications. The double-stranded oligonucleotide sequence of 5'-AGTTGAGGGGACTTTCCCAGGC-3, 3'-TCAACTCCCCTGAAAGGGTCCG-5', which corresponds to the κB binding site, was end-labeled with [γ-^{32}P] ATP by T4 polynucleotide kinase (Promega). Labeled probes were purified and CPM detected with Whatman DE81 (> 5000 cpm/min). The nuclear extract equivalent to 15 μg was mixed with 5 $\times$ binding buffer 2 μL (room temperature, 10 min), then labeled probe (0.0175 pmoL) added for incubation (room temperature, 20 min). The mixture was subjected to electrophoresis on 4% polyacrylamide gel at 150 V in 0.5 $\times$ TBE buffer for 40 min at 4℃. After being dried, the gel was exposed to imaging system of FX P screen (Bio-Rad, America) for 24 h.

P65 expression of AR42J by SABC method
In immunohistochemical monitoring of NF-κB-p65 subunit to determine p65 expression, AR42J cells were incubated in coverslips overnight at 37℃ under 5% CO$_2$ in air. Cells were treated first with peptides or saline for 2 h, then LPS was added to the culture medium for 2 h. Cells were fixed with 4% formaldehyde in phosphate-buffered saline for 20 min at 4℃ and permeabilized with 0.1% Triton in phosphate-buffered saline for 5 min at room temperature. Saturation was obtained by incubating cells with 5% bovine serum albumin in phosphate-buffered saline for 30 min at room temperature. Cells were stained with anti-p65 NF-κB antibody (Santa Cruz). Staining step was referred to the SABC kit description. Slides' staining degree was scanned by imaging system (BIO-RAD) and semi-quantitated by software package of quantity.

IL-1β and TNF-α protein detection by ELISA
The detection was performed according to the manufacturer's instructions.
Statistical analysis
Parametric data were presented and statistical analyses were performed using two-way ANOVA with SPSS8.0. Results were considered significant when $P < 0.05$.

RESULTS
Pancreas histology
Histomorphology after sodium taurocholate-induced acute pancreatitis was analyzed semiquantatively using the Spormann score. Pancreatitis without treatment was characterized by severe interstitial edema formation, considerable necrosis of fatty tissue, distinct sublobular and lobular parenchymal necrosis, as well as hemorrhage, resulting in a Spormann score of 8.71 ± 0.45 at 6 h and 10.31 ± 1.23 at 12 h, which reflects severe, acute, necrotizing pancreatitis (Figure 1A and C). Pretreatment with Tat or Tat-NBD (MT) peptide at a concentration of 13 mg/kg body weight had no beneficial effect in the pancreatitis-associated tissue injury, whereas the same
Figure 1 Tat-NBD attenuates STC-induced pancreatitis (HE, × 200). A: STC group at 6 h; B: Tat-NBD (WT) group at 6 h; C: STC group at 12 h; D: Tat-NBD (WT) group at 12 h.

Table 1 Pancreas histopathologic scores (mean ± SD)

Group	Histopathologic scores	
	6 h	**12 h**
Sham-operated	0	0
STC	8.71 ± 0.45	10.31 ± 1.23
Tat	9.84 ± 0.73	10.61 ± 1.62
NBD	6.76 ± 0.26[a]	8.31 ± 0.53[e]
Tat-NBD (WT)	5.04 ± 0.41[a]	5.45 ± 0.34[c]
Tat-NBD (MT)	8.85 ± 0.59[e]	10.13 ± 0.36[g]

[a]$P < 0.05$ vs STC group at 6 h; [c]$P < 0.05$ vs STC group at 12 h; [e]$P < 0.05$ vs Tat-NBD (WT) group at 6 h; [g]$P < 0.05$ vs Tat-NBD (WT) group at 12 h.

Figure 2 Pancreas histopathologic scores. The pretreatment of NBD peptide and Tat-NBD (WT) resulted in a significant reduction of the tissue damage score and more beneficial effect can be seen in the latter group at the two time points. Pretreatment with Tat or Tat-NBD (MT) peptide showed no therapeutic effect.

cell necrosis (Figure 1B and D). The histological scores in different groups are shown in Table 1 and Figure 2.
Cytokine change of AR42J

We used LPS (10 mg/L) to stimulate AR42J and explore whether the peptide could play a direct role in pancreatic acinus cells. Cells were cultured as previously stated.

IL-1β: LPS (10 mg/L) resulted in an approximately 10-fold increase of *IL-1β* mRNA, whereas significant inhibitory effects were observed when cells were incubated with Tat-NBD (WT) at a dose of 0.1 mg/L (Figure 3). The Tat-NBD (WT) peptide decreased IL-1β mRNA expression in a dose-dependent manner and its peak role appeared at a dose of 100 mg/L (Figure 4). We next determined whether Tat-NBD (WT) peptide attenuated IL-1β protein, which was activated by LPS. Culture medium was analyzed by ELISA. Results confirmed that IL-1β protein was inhibited by Tat-NBD (WT) at different doses, which also presented in a dose-dependent manner. Finally, we investigated whether the control peptide of NBD, Tat or Tat-NBD (MT) could block LPS-induced *IL-1β* mRNA or protein increasing in AR42J cells. Cells were preincubated for 2 h at a concentration of 10 mg/L of Tat-NBD (WT) or control prior to stimulation with LPS. Cells were harvested 120

concentration of NBD peptide caused a significant reduction of the tissue damage (Table 1). More beneficial effect can be seen in Tat-NBD (WT) group. The Spormann score was lowered to 5.04 ± 0.41 at 6 h and 5.45 ± 0.34 at 12 h, which was mainly due to a decrease in degree and amount of fatty tissue and parenchymal

decreased TNF-α protein in a dose-dependent fashion over a range of 0.1-100 mg/L (Figure 7). We determined whether Tat-NBD (WT) peptide attenuated TNF-α protein, which was activated by LPS. Culture medium was analyzed by ELISA. Result confirmed that TNF-α protein was inhibited by Tat-NBD (WT) at different doses, which also presented in a dose-dependent manner (Figure 8). Finally, we investigated whether the control peptide of NBD, Tat or Tat-NBD (MT) could block LPS-induced TNF-α mRNA or protein increasing in AR42J cells. Cells were preincubated for 2 h at a concentration of 10 mg/L of Tat-NBD (WT) or control prior to stimulation with LPS. Cells were harvested 120 min after addition of LPS. RT-PCR and

Figure 13 NF-κB activity was obviously activated after LPS induced AR42J (line 1). After cells were pretreated with Tat-NBD (WT), the activity of NF-κB was markedly inhibited in a dose-dependent manner (line 5-8). No change in control peptide group (line 2-3); Lane 1-8: NF-κB activity in LPS group, Tat-NBD (MT) group, Tat group, NBD group, Tat-NBD (WT) group (0.1 mg/L, 1 mg/L, 10 mg/L and 100 mg/L respectively).

ELISA were performed as stated. Only Tat-NBD (WT), not the control peptides, inhibited TNF-α expression (Figures 9 and 10).

NF-κB change in AR42J: To know the role of p65 in the cytokine change in AR42J cells stimulated by LPS and whether the peptide interfered with p65 expression and nucleus transposition, we stained the AR42J cells by IH method. First, we performed experiments to

demonstrate that AR42J cells can successfully express p65 under silence condition. Figure 11 shows the increasing histochemical staining of AR42J cells for p65 after stimulation with 0.1 mg/L of LPS. The data indicated that LPS increased p65 in a dose-dependent fashion over a range of 0.1-100 mg/L. We studied the effects of different doses of Tat-NBD (WT) in p65 expression. Cells were preincubated for 2 h at concentrations ranging from 0.1 mg/L to 100 mg/L. After pretreatment of Tat-NBD (WT), weakened immmunocytochemical staining of p65 in AR42J cells was observed, especially in larger dosage. Finally, we investigated whether the control peptide of NBD, Tat or Tat-NBD (MT) could block LPS-induced p65 increasing in AR42J cells. The results showed that only Tat-NBD (WT), not the control peptide inhibited p65 expression. EMSA demonstrated that the NF-κB DNA-binding activity was similar to the IH results (Figures 12 and 13).

DISCUSSION

It is known that a "cascade" induced by recruitment of inflammatory cells and release of inflammatory mediators is an important pathogenesis in the development of acute pancreatitis[17]. Inflammatory mediators, such as LPS and cytokines, may play a critical role in the development of murine acute pancreatitis. NF-κB formed dimeric complex that controls the expression of a variety of inducible genes involved in inflammation and proliferation[13]. It was reported that a selective inhibitor of NF-κB activation, NBD, demonstrated a significant decrease in pancreatic inflammation and lung hemorrhage associated with acute pancreatitis[11]. Here, rats were pretreated with the peptide at a dose larger than that used by Ethridge *et al*[12]. The Tat-NBD or NBD peptide resulted in tissue damage, including edema, hyperemia, necrosis, hemorrhage, and infiltration of inflammatory cells, decreased. Neither mutant Tat-NBD nor Tat peptide had preventative effects. It is suggested that treatment with Tat-NBD or NBD may be effective in this kind of pancreatitis model.

Inflammation and acinar cell death are the hallmarks of both human and experimental pancreatitis[18]. It is not clear whether peptides can have such direct anti-inflammatory effects in acinus cells. LPS stimulates cells by interaction with CD-14 in the context of Toll-like receptor, whose activation leads to NF-κB nuclear translocation through degradation of IκB and subsequent release of NF-κB[19]. The AR42J cell line is the only currently available cell line that maintains many characteristics of normal pancreatic acinar cells, such as the synthesis and secretion of digestive enzymes[20]. AR42J cell receptor expression and signal transduction mechanisms parallel those of pancreatic acinar cells. Thus, this cell line has been widely used as an *in vitro* model to study cellular secretion, growth, proliferation, and apoptosis of the exocrine pancreas[21]. So, we used LPS and AR42J as tools to explore peptide effects

in present study. Further studies showed that in the early stages of LPS-stimulated inflammation in AR42J cells, consisting with sharp increasing expression of cytokine mRNA, such as *IL-1β* and *TNF-α*, which is confirmed as critical factors related to acinus injury[22]. The level of IL-1β and TNF-α protein also were increased in the culture medium. Our data, obtained from parallel studies, demonstrate that pretreatment with different doses of Tat-NBD peptide had constitutive inhibitory effects in acinus cells, resulting in reduced inflammatory cytokines IL-1β and TNF-α. These results are in agreement with previous reports[7,10,11]. We found that the effects of peptide had a dose-dependent manner ranging from 0.1 to 100 mg/L. The largest anti-inflammation effects were found at a dose of 100 mg/L. We used the same concentration of control peptide, NBD, mutate Tat-NBD or Tat, and compared effects with those of Tat-NBD (WT). The results suggest that no control peptide had a preventive role. It has been confirmed that the Tat protein of human immunodeficiency virus 1 (HIV-1) can enter cells efficiently when added exogenously in the tissue culture[23,24]. Also, Tat-mediated uptake may allow the therapeutic delivery of macromolecules previously thought to be impermeable to living cells[23]. Our data show that the sequence of Tat plays an intensive role in NBD sequence, and only the NBD sequence had a therapeutic role in STC-induced rat model as stated previously. The degree of permeability of Tat-NBD and NBD sequences in acinus cells must be confirmed in further studies.

The NBD peptide is a novel six-amino acid cell-permeable peptide that selectively inhibits NF-κB activation *in vitro* and *in vivo* by blocking the interaction of the regulatory protein NEMO with the IKK complex. In the present study, we detected AR42J cell NF-κB activity by EMSA at 24 h after LPS stimulation. During the parallel time course, the DNA-binding of NF-κB markedly inhibited Tat-NBD (WT) peptide (Figure 12), especially at the dose of 100 mg/L. Mutant Tat-NBD, NBD or Tat sequence had no significant effect on NF-κB activity. Consistent with the changes of NF-κB activity, the cell expression of p65 was also attenuated by Tat-NBD (WT) peptide in a dose-dependent manner (Figure 13). Like other studies, our results suggests that the Tat-NBD (WT) peptide plays a part in NF-κB activating pathway.

In conclusion, our results support the idea that active NF-κB participates in the pathogenesis of STC-induced acute pancreatitis in rats. Tat-NBD (WT) peptide has anti-inflammatory effects in this model and inhibits the inflammation of acinus simulated by LPS directly. Inhibition of NF-κB activity may be a protective measure in the treatment of acute pancreatitis.

COMMENTS

Background

The Tat-NEMO-binding domain (NBD) confirmed that it could attenuate the severity of cerulein-induced pancreatitis in mice which improved the inflammation in the pancreas, reduced hemorrhage in the lungs, and lowered myeloperoxidase activity in both pancreas and lung.

Research frontiers

In rat pancreatitis induced by taurocholate, activation of NF-κB in pancreas has been reported. It is not clear yet whether peptide has anti-inflammatory effects in taurocholate-induced severe acute pancreatitis (SAP) model and inhibits the inflammation of acinus stimulated by lipopolysaccharides (LPS).

Innovations and breakthroughs

Tat-NBD peptide is able to inhibit the inflammation of AR42J cells. Further studies are needed to prove its mechanism of action in pancreatic acinar cells.

Applications

Tat-NBD (WT) peptide has anti-inflammatory effects in STC-induced pancreatitis model and inhibits the inflammation of acinus simulated by LPS directly. Inhibition of NF-κB activity may be a protective measure in the treatment of acute pancreatitis.

Peer review

This is an interesting study in which the authors used an alternate approach to demonstrate the influence of inflammatory cytokines involvement in acute pancreatitis.

Abstract

AIM: To determine the inhibitory effect of Astragalus memebranaceushas on gastric cancer cell supernatant-induced apoptosis of human peritoneal mesothelial cells.

METHODS: Human peritoneal mesothelial cell (HPMC) line HMrSV5 was co-incubated with gastric cancer cell supernatant (MKN45) and/or Astragalus memebranaceushas. Morphological changes in gastric cancer cells were observed under phase-contrast microscope. Quantitative cell damage was determined by MTT assay. Apoptosis was determined under transmission electron microscope and quantified by detecting acridine orange/ethidium bromide-stained (AO/EB) condensed nuclei under fluorescent microscope or by flow cytometry. Expressions of Bcl-2 and Bax were evaluated with immunostaining.

RESULTS: Morphological changes and exfoliation occurred and naked areas appeared in cultured HMrSV5 cells 24 h after they were treated with gastric cancer cell supernatant. Cell supernatant from MKN45 gastric cancer cells induced apoptosis of HMrSV5 cells in a time-dependent manner. Obvious morphological changes were observed in cell apoptosis, such as condensation of chromatin, nuclear fragmentations and apoptotic bodies. Astragalus memebranaceus could partly suppress these changes and regulate the expressions of Bcl-2 and Bax in HMrSV5 cells.

CONCLUSION: Gastric cancer cells induce apoptosis of HPMCs through the supernatant. Astragalus memebranaceushas inhibits this phenomenon and can be used an adjuvant chemothera-peutic agent in gastric cancer therapy.

INTRODUCTION

Peritoneal dissemination is one of the most important factors for human gastric cancer and stands in the way of its successful surgical treatment[1]. It appears in the terminal stage and significantly worsens the prognosis of gastric carcinoma. However, the mechanisms underlying this propensity for metastasis are not yet clearly understood.

Peritoneal carcinomatosis can be considered a series of events that form a peritoneal metastatic cascade. Peritoneal stromal tissue appears to be a friendly host for tumor proliferation, providing a rich source of growth factors and chemokines involved in tumor metastasis. At present, our understanding of the molecular mediators that orchestrate this cascade is poor[2]. It has been reported that mesothelial cells prevent cancer invasion and undergo morphologoc changes in response to the factors released by cancer cells[3]. Before invading tumor cells and gaining firm adherence to the submesothelial monolayer, mesothelial cells must penetrate the mesothelial monolayer. Buck *et al*[4] have illustrated the protective effect of mesothelium in a rat model. When Walker 256 tumor cells are injected into the peritoneal cavity of rats, in which the parietal

peritoneum has been stripped of its mesothelial lining leaving the basement membrane intact, rapid implantation occurs in denuded areas[4]. However, in un-operated rats with an intact mesothelium, peritoneal implantation is a rare event. Findings suggest that, prior to gastric cancer cell adhesion to the peritoneum, mesothelial cells become hemispherical, exfoliation occurs, and the naked areas of submesothelial connective tissue are exposed to the peritoneal cavity[5,6]. Invasion of the mesothelial monolayer appears to occur by tumor-induced mesothelial apoptosis[7,8]. In this study, we examine the effects of factors released by gastric cancer cells on peritoneal mesothelial cell apoptosis *in vitro*.

Astragalus memebranaceus is a traditional Chinese herbal medicine used in treatment of common cold, diarrhea, fatigue, anorexia and cardiac diseases[9-11]. It also has been used as an immunomodulating agent in treatment of immunodeficiency diseases, to alleviate the adverse effects of chemotherapeutic drugs[12-14], such as significantly reduced myelosuppression in cancer patients[15,16]. The active pharmacological constituents of radix Astragalus memebranaceus include various polysaccharides, saponins and flavonoida as well as L-arginine or L-canavanine[17]. Moreover, studies also showed that Astragalus polysaccharides have effects on colon cancer, mammary tumor, urological tumor, gastric cancer, *etc*.[18,19]. In recent years, it has been proposed that Astragalus may possess anti-apoptosis potential in peritoneal mesothelial cells[20,21]. In spite of this, the anti-apoptotic effects of Astragalus saponin extract on human peritoneal mesothelial cells during peritoneal carcinomatosishas have not been extensively studied. This study was to observe the anti-apoptosis effects of Astragalus saponin extract on human peritoneal meso-thelial cells during peritoneal gastric cancer metastasis.

MATERIALS AND METHODS

Reagents

Astragalus injection was obtained from Chiatai Qingchunbao Pharmaceutical Co. Ltd (China). 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl-tetrazoliumbromide (MTT) and acridine orange/ethidium bromide (AO/EB) were obtained from Fluka (USA). Propidium iodide (PI) was obtained from Biosharp (USA). Bcl-2, Bax and actin primary antibodies, as well as second antibodies goat anti-mouse IgG were obtained from Santa Cruz Biotechnology Inc (CA, USA). Dulbecco's modified Eagle's medium (DMEM) and fetal calf serum (FCS) were obtained from GIBCOBRL (Grand Island, NY, USA). Other laboratory reagents were obtained from Sigma (USA). Phase-contrast microscope (Japan, Nikon), fluorescence microscopy (Japan, Olympus), transmission electron microscopy (Japan, Hitachi H-6001), flow cytometry (FACScalibur; Becton Dickson, USA), were also used in this study.

Cell line and cell culture

Human peritoneal mesothelial cell line HMrSV5 was kindly provided by Professor You-Ming Peng, Second

Hospital of Zhongnan University (Changsha, China) and Professor Pierre RONCO, Hospital TENON (Paris, France). Human gastric carcinoma metastatic liver cell line, MKN-45, and normal gastric epithelial cell line, GES-1, were obtained from Beijing Cancer Research Institute, China. The cells were placed into 75 cm^2 tissue culture flasks and grown at 37℃, under a humidified atmosphere containing 50 mL/L CO_2 and 950 mL/L air, in DMEM supplemented with 10% fetal calf serum (FCS), 100 U/mL penicillin and 100 μg/mL streptomycin, 2 mmol/L L-glutamine, 20 mmol/L hydroxyethyl piperazine ethanesulfonic acid (HEPES). The medium was changed every two or three days. The cells were dislodged using 0.25% trypsin and 0.02mol/L EDTA in PBS for subculture.

Preparation of serum-free conditioned media

Serum-free conditioned media (SF-CM) from gastric cancer cells or normal gastric epithelial cells were prepared as previously described[1]. Briefly, $5.0 × 10^5$ cells were seeded into 100 mm tissue culture dishes with 10 mL DMEM supplemented with 10% FCS and incubated at 37℃ for 3 d. To obtain SF-CM, the cells were washed twice with PBS and then incubated for 2 d with 3 mL of serum-free DMEM. SF-CM were eluted and centrifuged at 1000 × *g* for 5 min, passed through filters (pore size, 0.45 μm) and stored at -20℃ until use.

Human peritoneal mesothelial cell line HMrSV5 was cultured to sub-confluence in a 50 cm^2 dish with 10% FCS containing DMEM. The medium was changed to 4 test solutions: (1) serum free DMEM, (2) SF-CM from gastric cancer cell line MKN45, (3) SF-CM from gastric cancer cell MKN45 + 200 μg/mL Astragalus injection, (4) DMEM + 200 μg/mL Astragalus injection.

Morphologic evaluation under a phase-contrast microscope

Mesothelial cells in 24-well chambers were exposed to test solutions for 24 h, gently washed with PBS, and then examined under a phase-contrast microscope for the size, shape, and integrity of cell membrane, cytoplasm, and nuclei.

Transmission electron microscopy

After incubation in test solutions for 24 h, the cells were trypsinized and then fixed in PBS (pH 7.3) containing ice-cold 2.5% glutaraldehyde. The specimens were rinsed with PBS, post-fixed in 1% osmium tetroxide containing 0.1% potassium ferricyanide, dehydrated through a graded series of ethanol (30%-90%), and embedded in Epon. The specimens were cut into semi-thin (300 nm) sections with a Reichart ultra-cut, stained with 0.5% toluidine blue, and examined under a light microscope. The ultra-thin sections (65 nm) were stained with 2% uranyl acetate and Reynold's lead citrate, and examined under a transmission electron microscope (× 5000 or × 8000 magnification).

Quantitative determination of cell damage by MTT assay

Tests were performed to assess mesothelial cell viability

after treatment with SF-CM for gastric cancer cell MKN45 and Astragalus injection. After exposure to the control or test solutions for a specific period (observed at 12 h, 24 h, 48 h), the cells in 96 well plates were incubated with 50 μg/mL MTT at a dilution of 1:10 based on the volume of culture medium, for 3 h at 37℃. At the end of incubation, MTT solution was removed, 150 μL DMSO was added to each well and stirred to dissolve the dark-blue formazon crystals formed. The proportion of viable cells was determined by measuring the optical density of each sample at 480 nm with a spectrophotometer. The cells were exposed three times to each solution for the same period of time. The means for the groups of cultures were compared. Control wells with no Astragalus injection and SF-CM were added. The same test was performed to assess the MKN45 viability after treatment with Astragalus injection.

Flow cytometry

After incubation in test solutions for 12, 24 and 48 h, the cells were harvested by trypsinization, resuspended in PBS at a concentration of 1×10^6/mL and fixed in 2 mL methanol for 30 min at 4℃. After mesothelial cells were fixed, the mixture was incubated in 0.5 mL propidiumiodide (PI) solution (0.05 mg/mL in 3.8 mol/L Na citrate) and 0.5 mL RNAse A (0.5 mg/mL) at room temperature for 30 min. Finally, the cells were resuspended in 1 mL PBS and analyzed by flow cytometry according to the manufacturer's instructions. The cells in the subdiploid peak were considered apoptotic.

In situ detection of apoptosis

Human peritoneal mesothelial cells were cultured to sub-confluence in a 24-chamber slide with 10% FCS containing DMEM. The medium was changed to (1) serum free DMEM, (2) SF-CM from gastric cancer cell MKN45, (3) SF-CM from MKN45 + 200 μg/mL Astragalus injection, (4) DMEM + 200 μg/mL Astragalus injection, and (5) SF-CM from normal gastric epithelial cell line GES-1, respectively. After incubation for 48 h, apoptosis was quantified with fluorescent staining method by detecting AO/EB condensed nuclei with fluorescent microscopy. AO/EB staining could identify alive, early and late apoptotic cells and necrotic cells. Sub-confluent cells (70%-80% confluent) in 24 well uncoated plates were exposed to apoptotic stimuli for 48 h. Mesothelial cells in 24 well plates were gently washed with PBS and immediately treated with acridine orange (100 μg/mL) for 5 min and ethidium bromide (100 μg/mL) for 5 min. Each well was then examined under an epifluorescence microscope. An excitation wavelength of 455 nm was used to evaluate apoptosis under a fluorescence microscope. Apoptosis was defined by morphological criteria. Cells containing normal nuclear chromatin exhibited green nuclear staining. Cells containing fragmented nuclear chromatin exhibited orange to red nuclear staining.

Western blot

Human peritoneal mesothelial cells were cultured to sub-confluence in a 50 cm² dish with 10% FCS containing

DMEM. The media were then changed to test solutions for 24 h. The cells were lysed in an ice-cold lysing solution containing 154 mmol/L NaCl, 1 mmol/L EDTA, 1% octylphenoxy polyethoxyethanol, 1 mmol/L phenylmethanesulfonyl fluoride, 1 mg/mL pepstatin, 1 mg/mL aprotinin, and 0.25% nadeoxycholate. Samples were rotated for 15 min at 4℃ and then centrifuged at 12 000 r/min for 5 min at 4℃. The supernatant was recovered, and protein concentration was measured by bicinchoninic acid assay (Bio-Rad), with bovine serum albumin as the standard. Samples were incubated for 5 min at 95℃ in a loading buffer (12 mmol/L Tris-HCl, pH 6.8, with 25% glycerol, 2% sodium dodecyl sulfate, 14.4 mmol/L 2-mercaptoethanol, and 0.1% bromophenol blue), and 50 mg of protein was loaded on different percentages different percentages of SDS-polyacrylamide gels (exclusion limits) corresponding to the molecular weight of target proteins. After electrophoresis, the proteins were transferred to a polyvinylidene difluoride membrane by electro-blotting. The membrane was blocked in 1% BSA, 0.05%Tween and PBS solution overnight at 4℃. Mouse antihuman monoclonal antibodies to Bcl-2 and Bax were used as primary antibodies. Horseradish peroxidase-labelled goat anti-mouse IgG was used as a secondary antibody. Blots were developed by incubation in a chemiluminescence substrate and exposed to X-ray films.

Statistical analysis

All data were expressed as mean ± SE. Student's t-test was used to compare drug effects. $P < 0.05$ was considered statistically significant.

RESULTS

### Morphologic evaluation under a phase-contrast microscope

A typical polygonal cobblestone was found in untreated mesothelial cells in SF-CM (Figure 1A), but morphological changes occurred in treated mesothelial cells in SF-CM. The most obvious morphological changes in mesothelial cells was exfoliation and naked areas (Figure 1B). Astragalus injection could partly suppress such morphological changes (Figure 1C).
Transmission electron microscopy

Twenty-four hours after treatment of MKN45, the apoptotic features (such as condensation of nuclear chromatin, wrinkling of nuclear membrane, dilation of endoplasmic reticulum, and relatively normal structure of mitochondria) were verified by electron microscopy (Figure 2). Under transmission electron microscope, the membrane of nuclei was complete, and the chromatin concentrated into masses on the boundary of the membrane or formation of arch (Figure 2C). Phenomena of budding and formation of apoptotic bodies were also observed (Figure 2D).

MTT assay

Anti-apoptotic effects of Astragalus injection were observed in SF-CM and apoptosis of gastric cancer cells

Figure 1 Morphological changes in human peritoneal mesothelial cells under phase contrast microscopy (× 40). A: Morphology of mesothelial cells cultured in serum free DMEM; B: Exfoliation and naked areas of mesothelial cells after treatment with Astragalus injection; C: Morphological changes in mesothelial cells after treatment with 200 μg/mL Astragalus injection; D: No typical morphological changes in mesothelial cells after treatment with DMEM + 200 μg/mL Astragalus injection.

Figure 2 Mesothelial cells under electron microscope after incubation with and without SF-CM. A: Normal nuclei and endoplasmic reticulum of control cells; B: Condensation of nuclear chromatin (arrow in Figure 2B); C: Wrinkling of nuclear membrane of cells after treatment with Astragalus injection (arrow in Figure 2C); D: Dilated endoplasmic reticulum (arrow in Figure 2D).

shared the common intracellular signaling pathways. To evaluate the potential anti-apoptosis effects of combined SF-CM and Astragalus injection on mesothelial cells, we examined the cytotoxic effect of SF-CM and Astragalus injection on human mesothelial cell line HMrSV5. SF-CM could effectively inducing apoptosis of mesothelial cells in a time-dependent manner (Figure 3). Astragalus injection could effectively suppress mesothelial cell apoptosis in SF-CM at 0, 12, 24 and 48 h, respectively.
To evaluate the potential effects of Astragalus injection on MKN45 cells, we examined the cytotoxic effect of Astragalus injection on MKN45 cells. No significant effect of Astragalus injection on MKN45 cell viability was observed ($P = 0.995$, Table 1).

Flow cytometry assay (FCA)

After incubation for 12 h, flow cytometry showed that the apoptosis peak occurred ahead the diploid peak when mesothelial cells were incubated with SF-CM for MKN45 (9.51% ± 0.71%). In contrast, the apoptosis peak value was not increased in the serum free DMEM group (0.70% ± 0.16%). The apoptosis peak value of was 1.65% ± 0.09% in the serum free DMEM group after treatment with Astragalus injection. The percentage of apoptosis was less than 0.5% (0.3% ± 0.07%) in the serum free DMEM group after treatment with DMEM + 200 μg/mL Astragalus injection. The data demonstrate that Astragalus injection could augment anti-apoptosis effects on MKN45 cells (Figure 4) and could effectively

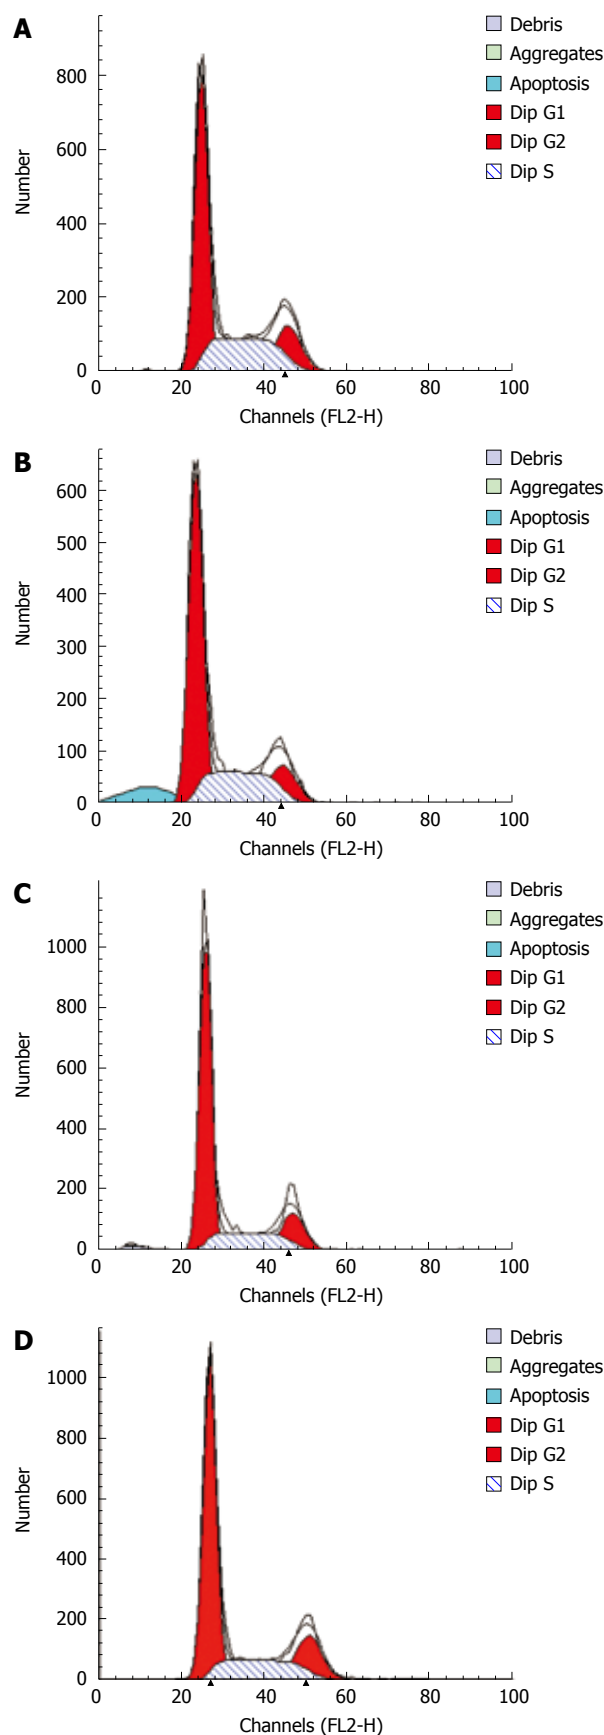
Table 1 MKN45 viability after treatment with 200 μg/mL Astragalus injection

Group	Optical density
Control (MKN45)	2.096 ± 0.834
MKN45 + Astragalus 200 μg/mL	2.183 ± 0.844

Figure 3 Viability of mesothelial cells after treatment with SF-CM and Astragalus injection. Mesothelial cells (5 × 10³ cells/well) were treated with SF-CM, 200 μg Astragalus injection, and SF-CM plus 200 μg Astragalus injection for 12, 24 and 48 h, respectively. Mesothelial cells cultured in serum free DMEM served as controls. MTT assays were performed in triplicate for each data point.

suppress mesothelial cell apoptosis induced by MKN45 as detected by MTT (Figure 5).

In situ detection of apoptosis

After mesothelial cells were treated with SF-CM from gastric cancer cell line MKN45 for 48 h, marked morphological changes in cell apoptosis occurred, such as condensation of chromatin, nuclear fragmentation and apoptotic bodies (Figure 6). Compared with the other three groups, the number of apoptotic cells significantly increased after treatment with SF-CM from gastric cancer cell line MKN45.


The number of apoptotic cells decreased significantly, while the number of green cells increased (Figure 6B and C). Astragalus injection inhibited the apoptosis of mesothelial cells induced by gastric cancer cells, while normal gastric epithelial cell line GES-1 could not induce apoptosis of mesothelial cells (Figure 6E). The number of apoptotic cells decreased after treatment with Astragalus injection (Figure 6B and C).

Western blot

We further delineated the underlying mechanisms of Astragalus injection by which apoptosis of mesothelial cell apoptosis is induced. We examined the effects of Astragalus injection on the expression of Bcl-2 and Bax. Bcl-2 expression was increased and Bax expression was reduced in mesothelial cells 24 h after treatment with Astragalus injection (Figure 7).

DISCUSSION

It has been reported that mseothelial cells can prevent cancer invasion and undergo morphologic changes

Figure 4 Effect of MKN45 and/or Astragalus injection on cell-cycle distribution in mesothelial cells treated for 12 h. DMEM with an apoptotic rate of 0.52% (A), SF-CM with an apoptotic rate of 10.03% (B), SF-CM plus 200 μg Astragalus injection with an apoptotic rate of 1.57% (C), DMEM + 200 μg/mL Astragalus injection with an apoptotic rate of 0.25% (D). Samples were analyzed by flow cytometry as described in "Materials and methods" section. Apoptotic peak is shown in green.

in response to factors released by cancer cells[22]. This phenomenon can be explained by the "seed and soil" theory: metastases occur when some tumor cells only live and grow in a congenial environment. Peritoneum might be a congenial environment for scirrhoid gastric cancer cells. Mesothelial cells can prevent cancer cell infiltration into sub-mesothelial connective tissue. It was reported that abdominal cavity cancer cells release early inflammatory factors and induce apoptosis of peritoneal mesothelial cells[23,24]. When mesothelial cells

Figure 7 **Western blotting analyses of Bcl-2 and Bax proteins.** Mesothelial cells were treated for 24 h with serum free DMEM, MKN45, MKN45 + 200 μg/mL Astragalus injection (MKN45 + A), DMEM + 200 μg/mL Astragalus injection, respectively.

become hemispherical, exfoliation occurs, and naked areas of sub-mesothelial connective tissue are exposed to the peritoneal cavity, and this injured peritoneum is a congenial environment for peritoneal metastasis[25].

In the present study, gastric cancer cell supernatant could significantly affect mesothelial cell viability, whereas normal gastric epithelial cell line GES-1 could not. Under contrast phase microscopy, mesothelial cells became hemispherical and exfoliation occurred when serum-free conditioned media were added into cultured mesothelial cells. Furthermore, cytoplasmic atrophy, nuclear shrinkage, and formation of extracellular and/or intracellular apoptotic bodies were observed under a transmission electron microscope. Astragalus injection could partly suppress these morphological changes. Moreover, apoptosis was also quantified by fluorescence microscopy and flow cytometry, showing that factors released by gastric cancer cells in the abdominal cavity induce apoptosis of mesothelial cells, cause exfoliation, and eventually result in metastasis. These may be the mechanisms by which cancer cells adhere to sub-mesothelial connective tissue. More tests will be conducted to better characterize the apoptotic signaling induced by gastric cancer cells.

Our study demonstrated that Astragalus injection could inhibit apoptosis of human peritoneal mesothelial cells induced by gastric cancer cell supernatant, suggesting that morphological changes in human peritoneal mesothelial cells are significantly decreased when human peritoneal mesothelial cells are exposed to both Astragalus injection and gastric cancer cells. Moreover, Astragalus injection could regulate the expression of Bcl-2 and Bax.

Bcl-2, an inhibitor of the mitochondrial apoptosis pathway, exerts its action by blocking proapoptotic counterparts, which in turn prevents release of cytochrome C and activation of caspases[26,27]. The results of this study show that treatment of mesothelial cells with Astragalus injection significantly increased Bcl-2 expression in mesothelial cells, indicating that Astragalus injection exerts its antiapoptotic effects by maintaining the expression of Bcl-2 (Figure 6).

Bax is a death promoter, which is neutralized by heterodimerization with Bcl-2. When Bax translocates

into the outer mitochondrial membrane, a leakage of cytochrome C from the mitochondria into the cytosol occurs[28]. Caspases-9 and -3 are activated sequentially, leading to breakdown of chromosomal DNA. In the present study, MKN45 significantly increased the Bax expression in mesothelial cells, while Astragalus injection partly suppressed the expression of Bax, indicating that there is a great possibility that Astragalus injection-mediated antiapoptosis of mesothelial cells is due to the regulation of Bcl-2 and Bax activation. Hence, identification of target compounds is imminent.

In general, investigation of the application of Astragalus injection in protecting human mesothelial cells is lacking. Astragalus injection has only been used in peritoneal dialysis therapy[29]. Studies on Astragalus injection were mainly concentrated on its immuno-modulating functions. Recently, Astragalus injection has been shown to have anticancer activity. In this study, we demonstrated the apoptotic effects of gastric cancer cell supernatant on human peritoneal mesothelial cells during peritoneal gastric cancer metastasis.

In conclusion, Astragalus injection can suppress apoptosis of mesothelial cells and can thus be used in treatment of gastric cancer.

ACKNOWLEDGMENTS

COMMENTS

Background

Peritoneal carcinomatosis is a common form of disease progression in gastrointestinal cancer. Gastric cancer-induced apoptosis of peritoneal mesothelial cells has been assumed to be an important part in gastric cancer peritoneal metastatic cascade. Astragalus extract, an active component isolated from Astragalus Root, has recently been reported to have anti-apoptosis activities.

Research frontiers

In general, investigations on the application of Astragalus injection in protecting human mesothelial cells are lack. Astragalus injection has only been used in peritoneal dialysis therapy. Studies on Astragalus injection were mainly concentrated on its immunomodulating functions. Recently, Astragalus injection has been shown to have anticancer activity. The objective of this study was to determine the inhibitory effect of Astragalus memebranaceushas on apoptosis of human peritoneal mesothelial cells induced by gastric cancer cell supernatant.

Innovation and breakthroughs

The inhibitory effects of Astragalus injection on apoptosis of human peritoneal mesothelial cells during peritoneal gastric cancer metastasis were investigated in this study.

Applications

Astragalus injection could suppress apoptosis of mesothelial cells and can thus be used in treatment of gastric cancer.

Terminology

Human peritoneal mesothelial cells (HPMC) are sentinel cells that can sense and respond to signals within their microenvironment. Calycosin is a vasorelaxant with no competitive Ca^{2+} release.

Peer review

This is a very excellent work. The authors demonstrated the anti-apoptosis

effects of Astragalus on human peritoneal mesothelial cells during peritoneal gastric cancer metastasis.

Abstract

AIM: To evaluate and confirm the low incidence of hepatocellular carcinoma (HCC) in patients with autoimmune hepatitis (AIH). At present only very few cases of HCC in patients with AIH and definite exclusion of chronic viral hepatitis have been published, suggesting that HCC due to AIH is rare.

METHODS: In order to further investigate the incidence of HCC in patients with AIH, we reviewed our large cohort of 278 patients with AIH.

RESULTS: Eighty-nine patients (32%) were diagnosed with liver cirrhosis, a preneoplastic condition for HCC. We studied a total of 431 patient years of cirrhosis in these patients, an average 4.8 years per patient. During this period none of the patients of our own study cohort developed HCC. However, three patients with HCC due to AIH associated liver cirrhosis were referred to our department for further treatment of HCC. In all three patients chronic viral hepatitis was excluded.

CONCLUSION: We conclude that HCC may under rare circumstances develop due to chronic AIH dependent liver cirrhosis. Compared to other causes of liver cirrhosis such as chronic viral hepatitis, alcohol, or hemochromatosis, the incidence of HCC is significantly lower. Pathophysiological differences between AIH and chronic viral hepatitis responsible for differences in the incidence of HCC are yet to be further characterized and may lead to new therapeutic concepts in prevention and treatment of liver cancer.

Key words: Autoimmune hepatitis; Hepatocellular carcinoma; Hepatic C virus; Hepatic B virus; Liver cirrhosis

INTRODUCTION

Hepatocellular carcinoma (HCC) is among the most common malignancies world wide and its incidence is rising, especially in Asia and Sub-Saharan Africa, but also in Western countries[1,2]. Most HCCs develop on the basis of liver cirrhosis due to chronic liver disease, making it a prerequisite for development of the disease. HCCs in non-cirrhotic livers are rare and mostly due to aflatoxin B or hepatitis B. Although HCC may develop as a consequence of all entities of underlying liver disease, it has been noticed before that the incidence of primary liver cancer varies significantly between different forms of chronic liver disease leading to cirrhosis and subsequent liver cancer. In hepatitis C patients suffering from liver cirrhosis, the average yearly incidence of HCC has been published as being approximately 1%-4% in Western countries[3-6]. An even higher rate of up to 8% was reported in Asia[1]. Similarly, the corresponding cumulative incidence rates of HCC in patients with chronic

viral hepatitis B were 1.3% and 14.9% per person-year, respectively, depending on HBV DNA levels[7,8]. The risk for HCC in decompensated alcohol-induced cirrhosis approaches 1% per year[9] and was demonstrated to be less in patients without co-infection of chronic viral hepatitis. Furthermore, the rate for HCC developing on the basis of hemochromatosis was reported between 2% and 6% per patient year[10,11]. Finally, HCC due to late stage primary biliary cirrhosis (PBC) was also reported as up to 2% per patient year in late stage (stage IV) PBC[12,13].

For patients with liver cirrhosis due to autoimmune hepatitis (AIH), only very few patients with HCC have been reported, mostly as single case reports. In addition, since in most earlier studies hepatic C virus (HCV) co-infection was not excluded, only very few data exist on the incidence and occurrence of HCC solely on the basis of AIH and subsequent liver cirrhosis[14,15] (Table 1).

However, confirmation of a low incidence of HCC in patients with AIH would point towards a (patho-)physiological mechanism in patients, preventing a much higher incidence as compared to patients with chronic viral hepatitis C. Further characterization of this phenomenon and patient collectives with HCC due to AIH may subsequently lead to identification of protective mechanisms against liver cancer and open new therapeutic perspectives.

MATERIALS AND METHODS

Study cohort

Two hundred seventy-eight patients satisfied the international criteria for the diagnosis of AIH[16]. They had been enrolled in our chronic liver disease program from 1970 until present and were reviewed for evidence of HCC. All patients had been followed in a uniform fashion for a total of 1951 years (0-34 years). On the basis of immunoserological assessment for autoantibodies, 207 patients were assessable for subtypes of AIH. Of these 195 patients (94%) were classified as type-1 AIH due to positive ANA, SMA, or anti-SLA/LP autoantibodies[17,18]. Eleven (6%) patients had elevated LKM autoantibodies, characteristic for type Ⅱ AIH[19]. Seventy-two patients had no detectable autoantibodies. Follow-up was usually maintained at three-month or six-month intervals during treatment discontinuation and for at least one year after treatment. Thereafter, follow-up assessments were performed at annual intervals, if the clinical condition was stable. Hepatic ultrasound and serum α-fetoprotein determinations were usually repeated every 6-12 mo. Follow up on patients with diagnosed liver cirrhosis was documented for 431 patient years. Follow up on patients not suffering from liver cirrhosis accumulated to 1183 patient years. The diagnosis of HCC required histological documentation.

Immunoserological assessments

SMA, ANA, and LKM were analyzed by indirect immunofluorescence on murine tissue sections as described previously. Anti-SLA/LP were analyzed by

Table 1 Summary of the incidence of HCC in patients with liver cirrhosis due to different underlying diseases. Incidence of HCC was demonstrated to be by far the lowest in autoimmune hepatitis

Patients with liver cirrhosis		
Underlying disease	HCC incidence per year (%)	Reference
Chronic hepatitis C	1-8	[1,3-6]
Chronic hepatitis B	1-15	[7,8]
Alcoholic liver disease	1	[9]
Hemochromatosis	2-6	[10]
Primary biliary cirrhosis (PBC)	2	[12,13]
Autoimmune hepatitis	< 0.2	

inhibition ELISA[18]. A serum titer of 1:80 or higher was considered positive for ANA[17]. A titer of 1:40 or higher was considered positive for SMA. A titer of 1:40 or higher was considered positive for anti-LKM-1[19]. All patients were tested for SMA and ANA, and 193 patients (91%) were tested for anti-LKM-1. Patients with SMA and/or ANA in the absence of anti-LKM-1 were classified as type-1 AIH. Patients with anti-LKM1 were classified as type-2 AIH[19].

Virological assessments

Antibodies to anti-HCV were detected by a second-generation enzyme linked immunosorbent assay (ELISA) and HCV RNA was assessed in serum by PCR. Hepatitis B surface antigen (HBsAg) was determined by ELISA.

HCC patient 1

A 59-year-old male presented at our institution with hydrops decompensated cirrhosis (Child-Pugh Score C) and suspected HCC due to previously diagnosed AIH (SMA positive, anti-SLA/LP positive) and overlap syndrome to primary biliary cirrhosis. The patient had previously been treated at an external hospital over 25 years for cryptogenic hepatitis. Through the course of disease, the patient had been intermittently treated with prednisolone, and at presentation at our department treatment consisted of prednisolone 15 mg/d. For 5 years prior to his presentation at our department, the patient had intermittently been treated with lactulose, pointing to presence of decompensated liver cirrhosis and thus, retrospectively, liver cirrhosis must be assumed to have existed several years prior to presentation. Esophageal varices were known at least 2 years prior to presentation at our department. An accompanying chronic viral hepatitis was excluded by means of serological testing.

After presentation at our department a large liver tumor measuring 9.8 cm × 8 cm × 7.5 cm was found by ultrasound and CT scan. Histology confirmed the diagnosis of HCC. Due to the lack of surgical options, the patient underwent transarterial chemoembolization as palliative treatment. Initially, the intervention was performed without complications and the patient was released from the hospital in good condition. However, three weeks later, the patient was re-admitted to our emergency department with abdominal pain and signs

of subileus. Splenic rupture was identified. The patient died the following day.

HCC patient 2

A 78-year-old female was admitted to our hospital with a confirmed longstanding course of AIH under immunosuppressive therapy. ANA and SMA autoantibodies were positive with high titers. Liver cirrhosis (Child-Pugh-Score A) had previously been diagnosed. Initial diagnosis of AIH was made 12 years prior to presentation at our department and the patient was treated with an immunosuppressive regimen. At presentation at our department medication consisted of prednisolone 2.5 mg/d and azathioprine 100 mg/d. An accompanying chronic viral hepatitis was excluded by means of serological testing. Shortly after presentation, HCC was diagnosed by means of ultrasound and CT scan in addition to elevated tumour marker AFP (1000 ng/mL). The patient declined all therapeutic options and decided for best supportive care near her hometown. Thus, no follow up on the patient's condition or course of HCC was available.

HCC patient 3

A 46-year-old female was admitted to our department for histologically confirmed HCC and liver cirrhosis (Child-Pugh-Score C) due to AIH. Sixteen years prior to presentation, the patient had already been treated for "non-A/non-B" hepatitis. Thus, retrospectively, a longer course of AIH must be assumed. Throughout the course of disease, treatment had been extended to prednisolone and azathioprine. An accompanying chronic viral hepatitis was excluded by means of serological testing. A CT scan demonstrated two nodes of 8.8 cm × 7.7 cm and 2.3 cm × 1.8 cm, confirmed to be HCC. Due to tumour size and lack of sufficient size of the potentially remaining liver after surgical resection, surgery was declined and the patient was offered palliative chemotherapy. However, the patient declined chemotherapeutic treatment and was lost in follow up.

RESULTS

In order to investigate the incidence of HCC in patients with AIH, we retrospectively examined our large cohort of 278 patients with AIH. Twenty-nine patients (10%) had been under treatment for AIH for less than one year. Thirty-two patients in the study cohort (11%) had cirrhosis at presentation. Of the remaining 255 patients, fifty-seven (22%) developed cirrhosis despite treatment at our department. Together, the total number of patients with cirrhosis and thus at risk for developing HCC was 89 (32%).

For these patients, a total of 431 patient-cirrhosis-years were evaluated. Median follow up time in patients with cirrhosis was 4.8 years (58 mo). Twenty-seven of these patients had a follow up with cirrhosis of more than five years. Overall, these patients were observed for an average of 8.6 years. Twenty-nine patients (10%) were under treatment for less than one year. During this period, none of the 278 patients developed HCC. Three more patients with HCC on the basis of liver cirrhosis due to AIH were referred to our department for treatment of HCC. However, the HCC did not develop during treatment or follow up within our study group. None of those patients seen for HCC in cirrhosis due to AIH tested positive for HCV or HBV or showed any signs of other chronic liver disease. Thus, these patients were excluded from our cohort for calculation of the incidence of HCC per patient-cirrhosis-years.

The 189 patients not developing liver cirrhosis during follow up were observed for a total of 1183 patient years, an average of 6.3 years. None of these 189 patients lacking histological evidence of cirrhosis developed HCC during the time of observation.

DISCUSSION

HCC is among the most common cancers worldwide and its incidence is rising. However, the incidence of HCC in patients with liver cirrhosis varies due to the underlying chronic liver disease. The risk of developing HCC due to chronic hepatitis was estimated to be approximately 1%-8% per patient year in patients with Hepatitis C[4-6,20,21] and 1%-15% in patients with hepatitis B[8]. Incidence in patients with alcoholic liver disease or hemochromatosis was reported to be somewhat lower, but still at the lower margin of the risk of patients with chronic viral hepatitis[9-11]. Finally, HCC incidence due to late stage primary biliary cirrhosis (PBC) was also reported to be up to 2% per patient year in late stage (stage Ⅳ) PBC[12,13].

Contrary to the number of reports on patients with chronic viral hepatitis, only very few cases of patients with HCC developing due to AIH have been reported. Furthermore, most of these patient reports were published before the era of HCV screening and thus, many of these may be accounted for by a HCV co-pathogenesis[15]. At present, besides individual case reports, only a single larger patient cohort has been published, definitely excluding HCV co-pathogenesis[14]. Park et al[14] demonstrated a low incidence of HCC in patients with AIH and cirrhosis. They observed only one HCC in 88 patients with cirrhosis due to AIH and in a total of 212 patients, pointing towards an incidence of HCC in patients with liver cirrhosis of about 0.1%. Comparing these numbers to patients with cirrhosis due to chronic viral hepatitis, a significant difference in the occurrence of HCC in cirrhotic livers due to these different entities becomes obvious.

In our cohort of 278 patients with AIH, 89 (32%) patients suffered from liver cirrhosis. During the period of follow up, none of the patients of our own cohort developed HCC. Three more patients with HCC on the basis of cirrhosis due to AIH were referred to our department for treatment of HCC (tertiary referral center for treatment of HCC). However, these patients were referred to our department already with the definite diagnosis of HCC or suspected liver cancer and reason for referral was treatment for HCC. Thus, the existence

of these three patients further confirmed the potential occurrence of HCC in patients with AIH-associated liver cirrhosis. Nevertheless, the patients were not included for the calculation of the incidence of HCC per patient-cirrhosis-years. Therefore, incidence of HCC in patients with cirrhosis due to AIH must be estimated to be less than 0.2% per patient-cirrhosis-year, since HCC was not observed in our cohort in 431 patient years.

Most importantly, all three patients seen for HCC in cirrhosis due to AIH tested negative for HCV or HBV. In two patients no signs of chronic liver disease other than AIH were diagnosed. However, patient 1 was known to suffer from overlap to PBC. Thus, we confirmed that development of HCC may occur independently of co-infection with any form of chronic viral hepatitis or other common causes for liver cirrhosis.

Our results were in accordance with the results published by Park *et al*[14], which primarily demonstrated a significantly lower incidence of HCC in patients with AIH. Although our total patient number was larger than the Park study[14], we had comparable numbers of cirrhosis in our patients, i.e. 89. These patients were observed for a total of 431 years. Median follow up was 4.8 years, which was less than the Park study. Since to our knowledge, the study by Park *et al*[14] still remains the only data on a comparably large cohort, evidence for an altered pathomechanism for HCC development in cirrhosis due to AIH must be considered.

Although the pathogenesis behind this significant difference in HCC development remains to be further elucidated, it may hold important insight into the pathomechanism of HCC differentiation. The lower incidence of HCC in AIH patients is even more surprising since AIH patients are commonly treated with immunosuppressants such as steroids and azathioprine, potentially increasing the risk of malignant transformation. However, immunosuppressants such as steroids act through suppressing cytokines, important for inflammation. An increased production of some these cytokines, IL-1β and TNF-α, have been demonstrated to coincide with the presence of liver cancer[22]. Thus, downregulation of these cytokines by immunosuppressive therapy[23,24] may be speculated to contribute to protection from the development of HCC.

In conclusion, we characterized our large collective of patients with AIH and were able to demonstrate and confirm a low incidence of HCC in these patients. The further characterization of patients with HCC due to autoimmune hepatitis may finally lead to the identification of new therapeutic targets preventing the development of liver cancer and thus novel therapeutic strategies.

COMMENTS

Background
At present only very few cases of hepatocellular carcinoma (HCC) in patients with autoimmune hepatitis (AIH) and definite exclusion of chronic viral hepatitis have been published, suggesting that HCC due to AIH is rare.

Research frontiers
Compared to other causes of liver cirrhosis such as chronic viral hepatitis,

alcohol, or hemochromatosis, the incidence of HCC due to AIH is significantly lower. From our data it was estimated to be less than 0.2% per patient-cirrhosis-year.

Innovations and breakthroughs
This study confirms that AIH patients have a lower risk of HCC than patients with other chronic liver disease, despite their often long term treatment with immunosuppressants.

Applications
Immunosuppressants such as steroids act through suppressing cytokines, essential mediators in inflammation. An increased production of some of these cytokines, IL-1β and TNF-α, has been demonstrated to coincide with the presence of liver cancer. Thus, downregulation of these cytokines by immunosuppressive therapy may be speculated to contribute to protection from the development of HCC. Identifying the differences in patients with AIH and other chronic liver diseases may lead to the identification of protective mechanisms against liver cancer.

Peer review
Compared to other causes of liver cirrhosis such as chronic viral hepatitis, alcohol, or hemochromatosis, the incidence of HCC due to AIH is significantly lower. From our data it was estimated to be less than 0.2% per patient-cirrhosis-year. This study confirms that AIH patients have a lower risk of HCC than patients with other chronic liver disease, despite their often long term treatment with immunosuppressants.

Abstract

AIM: To retrospectively collect inpatient and outpatient data and to assess the use of endoscopic procedures during the years 1991, 1997 and 2003 to analyse for trends.

METHODS: This retrospective survey was conducted in a University-associated Gastroenterology Unit offering secondary and tertiary health care services for a population of approximately 182 000 people in Southern New Zealand. Data collected included patient contacts (in- and outpatients), gastroscopic and colonoscopic investigations.

RESULTS: We observed a significant increase in the absolute numbers of patient contacts over the years (1991: 2308 *vs* 1997: 2022 *vs* 2003: 2783, $P < 0.0001$) with inflammatory bowel disease, other diseases of the colon, anus and rectum and iron studies related disorders decreasing significantly but liver disease and constipation increasing linearly over time. The use of endoscopy services remained relatively stable but colonoscopic investigations for a positive family history of colorectal cancer increased significantly while more gastroscopies were performed for unexplained anaemia.

CONCLUSION: The whole spectrum of gastroenterology contacts was studied. A substantial proportion of colonoscopies and outpatient consultations were undertaken to screen for colorectal cancer. This proportion is likely to grow further. Our findings have implications for the recruitment and training of the next generation of gastroenterologists.

INTRODUCTION

The worldwide demand for gastroenterological services is growing. In order to adapt a training curriculum for future gastroenterologists and to allocate health resources, disease trends and the workload of gastroenterologists need to be monitored closely[1-3]. The literature on this topic is sparse. In 1973, Switz first described the practice of gastroenterologists in Virginia, USA[4] but only a few studies followed, mainly focussing on specific procedures or diagnoses. Manning *et al* (1980) surveyed the practice of a single gastroenterologist[5] and in 1984 an analysis of the working patterns of 500 members of the American Gastroenterological Association was published, focussing mainly on functional disorders[6]. A more general profile of a district hospital gastroenterology service in the United

Kingdom was obtained by Holmes *et al* in 1987; there was little change over a 12 year period[7]. The most recent survey of practice patterns was conducted in the USA by Russo *et al* and was published in 1999[8].

However, each of these surveys had limitations and was therefore not suitable for generalisation. The Southern Island of New Zealand is mostly rural with approximately 182 000 people scattered over an area of about 32 000 sq km and is therefore comparable to many other regions outside the large population centres of Asia, Europe and the Americas. A difficult and often unmet task is to ringfence health resources (funding, staffing and facilities) prospectively so that the health needs of the population can be met. Long distances and a borderline population size make the justification for investments difficult. Projected data for disease and demand trends are of utmost importance. There is no published New Zealand data on the workload of gastroenterologists and the use of endoscopy procedures.

The goals of this study were (1) to retrospectively collect inpatient and outpatient data and (2) to assess the use of endoscopic procedures during the years 1991, 1997 and 2003 to examine the demographics of patients seen by the service and to analyse trends in diseases seen during these periods.

MATERIALS AND METHODS

Study population

This survey was conducted in the Dunedin Public Hospital Gastroenterology Unit. The hospital serves as the only secondary and tertiary public referral centre for a population of approximately 182 000 people mainly in the Otago Region of the South Island of New Zealand. The majority of people in this area identify themselves as European in ethnic origin, with 5.9% identifying themselves as Maori, 3.1% as Asian, and 1.5% as Pacific Islanders[9]. These numbers were relatively stable over the observed period. The next advanced public health care centres are to the north or to the south and approximately 4 h by car.

The Gastroenterology Unit is usually staffed by one full-time consultant, two part time (0.5) consultants and one full-time registrar. Patients have access through referrals from local general practitioners and hospital specialists. The unit offers in- and outpatient specialist consultations and diagnostic procedures such as upper and lower diagnostic and therapeutic endoscopies, endoscopic retrograde cholangio-pancreatico-graphy (ERCP), trans-abdominal ultrasound, liver biopsy, and pH telemetry. Patients in general have the possibility to access private services but transfer to a public centre out of area is not possible.

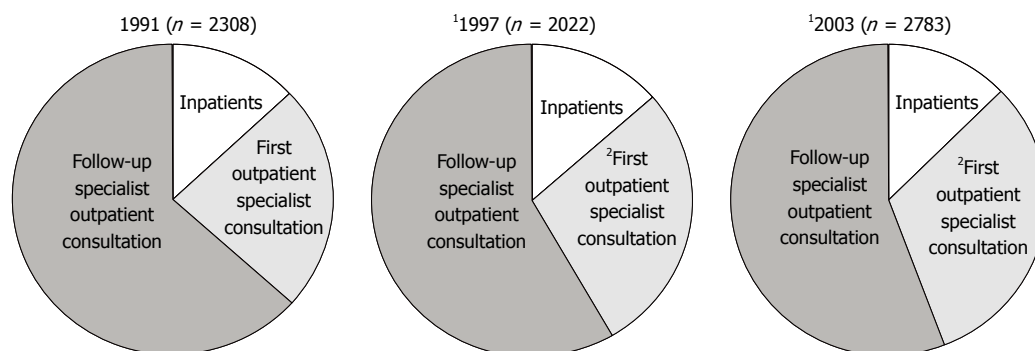
Prior to the commencement of this study, ethical approval was obtained from the Lower South Regional Ethics Committee. The data collection was performed in two phases by two separate groups of final year medical students as part of their health-care evaluation projects during their attachment to the Department of Preventive and Social Medicine. Each phase included data from the same years: 1991, 1997 and 2003.

Data collection

The absolute number of patient contacts (i.e. individual patients might have been seen more than once) including inpatients (IP; first and subsequent admissions) and outpatients (OP; as new or follow-up visits) was determined for the years concerned. Disease trends were determined based on the diagnosis on first presentation of the disease. Excluded from analysis were deceased patients as their files had been destroyed, and those with missing files. At the time of our analysis in 2005/2006, 23.9% of all patients first seen in 1991 were deceased, compared to 10.4% and 4.1% first seen in 1997 and 2003, respectively. The proportion of missing data ranged from 1% to 4% for the three years combined.

Data was obtained via the hospital computerised patient management system. In addition, OP diagnoses were obtained by retrieving the relevant clinic letters from the hospital's medical record filing system.

Diagnostic data were in the form of International Classification of Disease Version 9 (ICD-9) codes (1991 and 1997) and ICD-10 codes (2003), providing all the diagnoses recorded during each admission. The ICD-9 codes were matched electronically to the ICD-10 codes so as to simplify analysis. When more than one gastrointestinal diagnosis was present in the raw data, it was ranked numerically by clinical coders but not necessarily in order of relevance to the clinical presentation (primary *vs* secondary diagnosis). Therefore, two investigators went through all the diagnoses listed for each admission, and chose the most likely primary and secondary diagnoses for that presentation. This resulted in more diagnoses than patients or patient contacts. If numbers for an entity were too small for analysis, codes were combined into broader diagnosis groups.

Endoscopic data were collected for all patients using the gastroenterology database and the computerised patient management system. Data on ERCP ($n = 309$), abdominal ultrasound and pH telemetry were not included in this analysis due to the small numbers of these procedures.


Statistical analysis

Differences between years for qualitative variables were tested using a chi-squared test or, in the case of small expected counts, Fisher's exact test. If the chi-squared test was statistically significant, linear trends were investigated using the Cochrane-Armitage (C-A) test for trend. Quantitative data was compared using analysis of variance (ANOVA). The level of significance for all tests was set at 5% and all tests were 2-sided. All statistical analyses were performed in STATA (Version 9.2) or XLSTAT (Version 2008).

RESULTS

In- and outpatient demographic features

There was a statistically significant increase in the absolute numbers of patient contacts (IP-first admissions and subsequent admissions and OP-new patients and

1991 (*n* = 2308)   [1]1997 (*n* = 2022)   [1]2003 (*n* = 2783)

Figure 1 Total numbers of patients seen as in- and outpatients. There is a significant increase in the total number of patients ([1]C-A *P* < 0.0001) and in the number of new patients seen ([2]C-A *P* < 0.0001). The number of follow-up patients and inpatients remained statistically unchanged.

Table 1 Patient numbers and demographics

	Yr		
	1991	**1997**	**2003**
Inpatients			
No. of admissions[1]	173	310	391
Rate per 10 000 population[2]	9	16	20
Age mean (SD)[3]	54.1 (19.7)	55.9 (18.9)	53.4 (19.1)
Female *n* (%)	97 (56)	196 (63)	210 (54)
Outpatients			
No. of admissions[1]	553	469	756
Rate per 10 000 population[2]	30	25	39
No. of patients with information available	399	404	716
Age mean (SD)[3]	49.0 (19.3)	47.0 (18.0)	50.1 (18.5)
Female *n* (%)	246 (62)	256 (63)	421 (59)

[1]First hospital admissions and first specialist consultations showed a statistically significant linear increase over the years (*P* < 0.001 for both); [2]Estimates of the Otago population obtained from the Ministry of Social Development website: http://www.socialreport.msd.govt.nz/regional/r-councils/otago.html; [3]There was a statistically significant difference in the mean age of inpatients and outpatients (*P* < 0.001).

follow-up visits) over the years (Figure 1: 1991: 2308; 1997: 2022; 2003: 2783; C-A test *P* < 0.0001). Also, first hospital admissions and first specialist consultations (patients not seen before by this service) showed a statistically significant increase over the thirteen years between 1991 and 2003 (C-A test *P* < 0.001 for both, Table 1). For the three years combined, more females were seen as both in- and outpatients (58% inpatients and 61% outpatients were female, *P* < 0.001 for both). Overall, there was no statistically significant difference in the percentage of females seen in the in- and outpatient setting (*P* = 0.123). The mean age of inpatients was higher than that of outpatients (*P* < 0.001).

Diagnoses of in- and outpatients
In the IP (Table 2) setting, the top 5 diagnostic groups over all the years studied were: liver disease and abnormal liver function tests (LFTs; 20.8%), biliary disease (16.1%), inflammatory bowel disease (IBD; 11.7%), malignancy (8.7%) and other diseases of the colon/anus/rectum (5.0%). In comparison, the top 5 diagnoses in OP (Table 2) were: liver disease and abnormal LFTs (11.4%), other functional disease (11.1%), abdominal pain of unknown cause (10.0%), constipation (7.3%) and

oesophagitis/gastro-oesophageal reflux disease (GORD; 6.5%). The detailed results are presented in Table 2. The data excludes patients referred by open access for endoscopy.

Disease trends
The number (percentage) of diagnoses seen in the inpatient setting is presented in Table 2. Disease trends in IP showed a statistically significant linear decline over time for inflammatory bowel disease, other diseases of the colon, anus and rectum and for iron studies related disorders as a proportion of all diagnoses (C-A tests *P* = 0.015, 0.040 and < 0.001, respectively). Conversely, liver disease and constipation increased linearly over time (C-A tests *P* = 0.010 for both). The proportion of patients seen with biliary disease spiked in 1997 but then decreased again in 2003 to levels similar to those seen in 1991, therefore, the difference across the years for biliary disease was not statistically significant (chi-square test *P* = 0.502). There was no statistically significant difference in the proportions of malignant disease (chi-squared test *P* = 0.457).

The number (percentage) of diagnoses seen in the OP setting is presented in Table 2. The OP diagnosis of abdominal pain of unknown cause and other functional disease showed a statistically significant linear decrease over the years (C-A tests *P* < 0.001 for both). Conversely, liver disease and abnormal LFTs, family history of bowel cancer, constipation and iron studies related disorders showed a statistically significant linear increase (C-A tests *P* = 0.001, < 0.001, 0.003 and 0.002, respectively) (Table 2). All other diagnoses in the in- and outpatient settings showed no statistically significant linear trend over the years studied.

Use of endoscopies
The number of procedures and the patient demographics are presented in Table 3. Over the three years studied, a total of 6705 procedures were performed; 4795 (71.5%) were gastroscopies and 1910 (28.5%) were colonoscopies.

There was no statistically significant linear trend across the years for either procedure (C-A tests *P* = 0.379 and 0.392, respectively). Overall, there were no gender differences for both colonoscopies and gastroscopies (*P* = 0.132 and 0.078, respectively). The age distribution

Table 2 Number (percentage) of diagnoses seen in the inpatient and outpatient setting[1]

Diagnosis	1991	1997	2003	Total
Inpatient				
Liver disease (including Hepatitis)and Abnormal LFTs[4]	33 (15.1)	90 (20.3)	124 (23.5)	247 (20.8)

for colonoscopies changed over time ($P = 0.027$) while the age distribution for gastroscopies did not change ($P = 0.527$).
Indications and findings

The patient indications and findings following the colonoscopies are illustrated in Figures 2 and 3, respectively. The indications and findings following the gastroscopies are illustrated in Figures 4 and 5, respectively. Some patients had more than one finding so the percentages added up to more than 100% for each of the years.

### Indications for colonoscopy

Most colonoscopies were performed to investigate rectal bleeding or as part of the surveillance for colorectal cancer and polyps in patients with a positive family history. Interestingly, while there was a further statistically significant increase in colonoscopies performed for cancer surveillance and for patients with a family history of cancer (C-A tests $P = 0.014$ and $P < 0.001$, respectively), there was a statistically significant decrease in the frequency of colonoscopies performed for rectal bleeding (C-A test $P < 0.001$), change in bowel habit (C-A test $P < 0.001$), and IBD surveillance/ulcerative colitis (C-A test $P = 0.018$) over the years studied. There was a tendency towards an increase in colonoscopies for unexplained anaemia (chi-squared test $P = 0.057$). The remaining indications showed no statistically significant linear trend (Figure 2).

Colonoscopy findings

Most colonoscopies were either reported as normal or showed polyps or diverticulae. Over the study timeframe, statistically significant increases in cancer (C-A test $P = 0.007$) and diverticulae (C-A test $P < 0.001$) were seen. In contrast, IBD decreased (C-A test $P < 0.001$), and there was a tendency towards an increase in polyps (C-A test $P = 0.057$). The proportion of normal findings did not change across the years (chi-squared test $P = 0.493$) (Figure 3).

Figure 2 Indications for colonoscopies over the three years studied. There was a significant increase in colonoscopies in patients with a past medical history of colorectal cancer ([a]P = 0.015) and in patients with a positive family history of colorectal cancer and/or polyps ([d]P < 0.001). But there was a significant decrease in colonoscopies for rectal bleeding ([f]P < 0.001), change in bowel habit ([h]P < 0.001), and IBD surveillance ([i]P < 0.019).

Figure 3 Colonoscopic findings. Over the 13 years studied, significant increases in cancer ([a]P = 0.008) and diverticulae ([b]P < 0.001) were seen. In contrast, findings of inflammatory bowel disease decreased ([f]P < 0.001).

Indications for gastroscopy

Over the study timeframe, significantly more gastroscopies were performed for unexplained anaemia and heartburn (C-A test P < 0.001 for both), GI bleeding (C-A test P = 0.034), dysphagia (C-A test P = 0.014) and cancer surveillance (C-A test P = 0.010). Conversely, the frequency of gastroscopies carried out for nausea/vomiting, abdominal pain and healing surveillance decreased (C-A test P < 0.001 for all). There were no significant changes in the proportion of gastroscopies performed for dyspepsia (chi-squared test P = 0.114) (Figure 4).

Gastroscopy findings

Most gastroscopies showed only inflammatory changes. The number of ulcers, healed ulcers and scarring/strictures (C-A test P < 0.001 for all) and the proportion of normal findings (C-A test P = 0.005) decreased significantly over the years. There was no significant difference in Barrett's oesophagus (chi-squared test P = 0.313) and cancer (chi-squared test P = 0.424) observed over time. Findings of inflammatory changes and hiatus hernia differed significantly across the years

(chi-squared P < 0.001 and 0.005, respectively), but there was no significant linear trend across the years (C-A test P = 0.148 and 0.478, respectively) (Figure 5).

DISCUSSION

Our retrospective analysis over 13 years (1991-2003) aimed to collect data on in- and outpatient demographics, disease trends and endoscopic procedures in a secondary and tertiary but rural referral centre in southern New Zealand. This analysis has produced data which can be used for prospective planning in order to allocate health resources and in curriculum development for the future gastroenterological workforce.

Our study has several interesting findings, demonstrating that the working pattern for gastroenterologists over the last 13 years has changed dramatically in several aspects. This was not only true for absolute numbers of patient contacts, but also for indications and findings. These results may permit speculation on possible trends. However, this analysis was not aimed at explaining observed disease trends in the wider context as this is very complex and needs to take both contractual arrangements as well as local characteristics into account.
The absolute numbers of patient contacts by this service increased significantly over time, despite a stable workforce both inside and outside the hospital (e.g. consultants and general practitioners). This was mainly seen for in- and outpatient contacts, while the number of investigations remained stable over the years studied. Our results show distinct differences in the types of conditions seen in inpatient versus outpatient settings (Table 2). The gastroenterology service continues to see consistently more females (60%) than males (inpatients and outpatients; P < 0.001), in contrast to the 50:50 ratio seen in the study by Bohra in Ireland[10]. Age distributions have also remained stable over the thirteen year observation period, with a mean age of 48.9 years for outpatients and 54.4 years for inpatients (P < 0.001).

Excluding endoscopies, the gastroenterology service sees approximately 660 patients for a first specialist

Figure 4 Indications for gastroscopies over the three years studied. There was a significant increase in gastroscopies performed for unexplained anaemia and heartburn ($^{b}P < 0.001$), as well as for suspected upper gastrointestinal bleeding ($^{c}P < 0.034$), dysphagia ($^{e}P = 0.014$) and cancer surveillance ($^{h}P = 0.01$).

Figure 5 Gastroscopic findings. The number of ulcers, healed ulcers and scarring/strictures ($^{b}P < 0.001$) for all) and the proportion of normal findings ($^{d}P = 0.006$) decreased significantly over the years. Findings of inflammatory changes and hiatus hernia fluctuated significantly across the years (chi-squared $^{f}P < 0.001$ and $^{h}P < 0.005$, respectively) ($^{f}P = 0.148$ and $^{h}P = 0.478$, respectively).

assessment each year. The top five OP diagnoses (liver diseases, functional disorders, abdominal pain, constipation and reflux) were similar across the three years studied. This is largely in agreement with statistics published by Russo et al ranking abdominal pain, reflux, gastroenteritis, gastritis, haemorrhoidal disease and irritable bowel disease first but with liver disease in 16th place[11]. A survey among 376 members of the American Gastroenterological Association revealed Irritable Bowel Syndrome (19%) as the most common diagnosis, followed by oesophageal reflux and peptic disorders (17% and 10%, respectively), IBD (14%) and liver diseases (11%)[8]. If we summarise abdominal pain and constipation as a likely presentation of a functional disorder, this indication made up 27.3% and is therefore very much in agreement with the above survey by Russo et al[8]. However, in contrast to the view by Powell[1], but in agreement with others[5-7], there were significantly fewer patients with functional disorders compared with the beginning of the period. It is difficult to speculate on a reason for this finding, however, due to long waiting times of up to 6 mo for non-urgent referrals it is likely that only treatment-resistant cases are seen by this service.

Patients with liver disorders made up 8.5% of our outpatients and over 20% of the inpatient population with a significant increase seen over time. This might be

a reflection of treatment options for Hepatitis C (testing available since 1992 in NZ), and the understanding of the significance of non-alcoholic fatty liver disease (NAFDL). However, most of these patients are admitted as day cases for liver biopsies and are therefore not truly reflecting inpatients. Such a trend was suspected by Powell[1] and in part confirmed by Russo et al[8].

We found that the absolute number of endoscopies (gastroscopies and colonoscopies) performed in our centre remained largely the same over the study period, approaching 80/10 000 gastroscopies and 36/10 000 colonoscopies in 2003 with 77/10 000 and 34/10 000 in 1991, respectively. This was largely due to contractual constraints. Scott and Atkinson in their 5-year review found that the annual number of gastroscopies doubled in the early 80's and was expected to reach 120/10 000 in the 90's with a similar trend expected for colonoscopies[2,12]. The Working Party of the Clinical Services Committee of the British Society of Gastroenterology stated in 1991 that an annual requirement of 100/10 000 gastroscopies and 20/10 000 colonoscopies were needed for a district general hospital[13].

In a study by Westbrook, gastroscopies were recorded at 179/10 000 population in 1997/98 in New South Wales, Australia[14]. Our almost stable lower numbers for endoscopic services can have several explanations and

might not necessarily reflect the actual demand. Due to a strictly limited budget, the service in Dunedin can offer open access for gastroscopy but not for colonoscopy. Colonoscopy referrals undergo rigorous evaluation before an investigation is granted. Throughout the years the percentage of normal colonoscopies remained stable at approximately 35%. While it is relatively easy to judge the appropriateness of an investigation retrospectively, prospectively this task is difficult. It has been reported that the indication for up to 24.5% of colonoscopies[15] and 15-39% of gastroscopies[16-18] might not be appropriate. In contrast, we observed a significant increase in the number of cases of colorectal cancer at colonoscopy. This has to be seen on the background of more than a doubling of the incidence of colorectal cancer between 1956 and 1996 from 32/100 000 to 80/100 000 in male New Zealanders[19]. A significant relative increase in colonoscopies performed for cancer surveillance and for a positive family history of colorectal cancer (from 20 in 1991 to 168 in 2003) and also for unexplained anaemia was also observed reflecting our increasing understanding of preventative measures in medicine.

The relative increase in gastroscopies performed for unclear anaemia is probably a result of our greater understanding of the changing face of coeliac disease[20,21]. The awareness of the significance of Barrett's oesophagus in the development of oesophageal cancer[22] is possibly reflected in the increased number of endoscopies performed for dysphagia and cancer surveillance. However, we did not find an increased incidence of Barrett's oesophagus (approximately 5.5%-6.8%)[16] or cancer of the upper gastrointestinal tract (1.5%-1.2%) over the years.

In summary, we have presented data that reflect changes in the working pattern of a rural tertiary gastroenterology service over 13 years. Most of our findings are in agreement with those of previous studies. However, this analysis is unique in that we studied the whole spectrum of gastroenterology contacts in a hospital providing secondary and tertiary services. This study provides dynamic information to aid allocation of health resources and emphasises the importance of preventive medicine and also workforce development. A substantial proportion of colonoscopies and outpatient consultations are already undertaken to screen for colorectal cancer in an at-risk population. This proportion is likely to grow further, and New Zealand is no exception. In the United States, about 13% of the population is over 65 years, and projections estimate this figure may rise to 20% over the next twenty years[23]. Our study showed that the median age of patients undergoing endoscopy in Dunedin Public Hospital was almost 60 years, and our aging population means that more patients will require endoscopic procedures in the coming years.

A larger workforce will probably be necessary to meet these increasing demands. A recent review of the gastroenterology workforce available in the United States suggests that there will be a significant shortfall in gastroenterologists by 2010[24]. The baby boom generation is not only providing more patients, but those gastroenterologists who are also part of that era are now nearing retirement. In 1997, about 30% of American gastroenterologists were within 5-10 years of retirement[23]. All of this has huge implications for the recruitment and training of the next generation of gastroenterologists.

ACKNOWLEDGMENTS

COMMENTS

Background

The field of gastroenterology in line with other areas in medicine is rapidly changing. New insight into disease progression and pathomechanisms translate into daily medicine. In order to obtain a high standard of patient care, gastroenterological training as well as recruitment has to adapt to these changes.

Innovations and breakthroughs

This analysis is unique in that the whole spectrum of gastroenterology contacts in a hospital setting providing secondary and tertiary services was studied. The Dunedin Public Hospital is located in the Otago region which is in general, sparsely populated. Nevertheless, advanced gastroenterological services are expected to meet the demand of the people. Most data is provided by large specialised centres, not suitable for units based in rural settings. However, it is these centres that need to consider trends to carefully plan training and staffing.

Applications

This study provides dynamic information to aid allocation of health resources and emphasises the importance of preventive medicine and also workforce development. Our findings have implications for the recruitment and training of the next generation of gastroenterologists and a larger workforce will be necessary to meet these increasing demands.

Peer review

This clinical study gives a well structured survey about gastroenterological diagnoses in the University-associated Hospital in Southern New Zealand. The manuscript is well written and all data are statistically verified.

Abstract

AIM: To evaluate different biochemical markers and their ratios in the assessment of primary biliary cirrhosis (PBC) stages.

METHODS: This study included 112 patients with PBC who underwent a complete clinical investigation. We analyzed the correlation (Spearman's test) between ten biochemical markers and their ratios with different stages of PBC. The discriminative values were compared using areas under receiver operating characteristic (ROC) curves.

RESULTS: The mean age of patients included in the study was 53.88 ± 10.59 years, including 104 females and 8 males. We found a statistically significant correlation between PBC stage and Aspartate aminotransferase (AST), Alanine aminotransferase (ALT) to platelet ratio (APRI), ALT/platelet count, AST/ALT, ALT/AST and ALT/Cholesterol ratios, with the values of Spearman's rho of 0.338, 0.476, 0.404, 0.356, 0.351 and 0.325, respectively. The best sensitivity and specificity was shown for AST/ALT, with an area under ROC of 0.660.

CONCLUSION: Biochemical markers and their ratios do correlate with different sensitivity to and specificity of PBC disease stage. The use of biochemical markers and their ratios in clinical evaluation of PBC patients may reduce, but not eliminate, the need for liver biopsy.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a slowly progressive autoimmune disease of the liver that primarily affects women. Its peak incidence occurs in the fifth decade of life, and it is uncommon in persons under 25 years of age. PBC is diagnosed more frequently than it was a decade ago because of its greater recognition by physicians, the widespread use of automated blood testing and the antimitochondrial antibody test, which is relatively specific for the diseases[1,2]. Histologically, PBC is characterized by portal inflammation and immune-mediated destruction of the intrahepatic bile ducts. These changes occur at different rates and with varying degrees of severity in different patients. The loss of bile ducts leads to decreased bile secretion and the retention of toxic substances within the liver. This results in further hepatic damage, fibrosis, cirrhosis, and eventually, liver failure[3].

Liver biopsy is necessary to assess the extent of liver damage in an anicteric patient, e.g. in a patient in whom a transplantation is considered because of heavy symptom load. A liver biopsy may also be desirable to detect cirrhosis indicating a need for esophagogastroscopy for the detection of oesophageal varices or it may reveal a relative contraindication for treatment with

ursodeoxycholic acid, which is effective only in early stages of PBC[4,5].

For both, the physician and the patient, the decision to proceed with a liver biopsy is not trivial one. Furthermore, many patients are reluctant to experience repeated biopsies, which limits our ability to monitor disease progression and the effects of treatments. Significant complications, defined as requiring hospital admission or prolonged hospital stay, occurs in 1%-5% of patients who have a liver biopsy, while the reported mortality rate varies between 1:1000 and 1:10 000[6,7]. Most, but not all, studies have shown that the incidence of complications is related to both the presence of relative contraindications and the number of biopsies taken[6,8]. Despite these reservations, needle liver biopsy has been used as the "gold standard" for the assessment of liver fibrosis. However, a review of the available data on the accuracy of needle liver biopsy to define the stage of fibrosis reveals that the assessment of liver fibrosis is affected by significant sampling and interpretative errors. Therefore, while liver biopsy remains the "gold standard", both the clinician and the researcher should view the result of liver biopsy with some reservation and should interpret the findings in the broader clinical context. These problems must be considered when assessing the performance of other non-invasive tests for fibrosis when needle biopsy is used as the "gold standard". Many fibrosis experts would therefore consider serum fibrosis tests with an ROC area of 0.85-0.90 to be as good as liver biopsy for staging fibrosis.

The aim of our study is to evaluate different biochemical markers and their ratios in assessment of various stages of PBC[9].

MATERIALS AND METHODS

This study includes 112 patients investigated and treated for primary biliary cirrhosis in Clinic for Gastroenterology and Hepatology, Clinical Centre of Serbia during 2006. The diagnosis was based on clinical features, laboratory test, imaging diagnostics, and whenever possible, on liver histology.

The following information was collected for each patient: age, gender, biochemical parameters [aspartate aminotransferase (AST), alanine aminotransferase (ALT), albumin, ALT to platelet ratio (APRI), AST/ALT ratio, ALT/AST ratio, ALT/alkaline phosphatase (AF) ratio, ALT/gamma glutamyl transferase (GGT) ratio, ALT/cholesterol (Chol) ratio], and the histological stage of the disease.

Stage I -IV classification of the disease was applied by an experienced pathologist who assessed the liver biopsies. Stage I is defined by the localization of inflammation to the portal triads. In stage II, the number of normal bile ducts is reduced, and the inflammation extends beyond the portal triads into the surrounding parenchyma. Fibrous septa link adjacent to portal triads in stage III, while stage IV represents the end-stage liver disease, characterized by obvious cirrhosis

with regenerative nodules[10].

Laboratory testing and needle biopsy of livers were performed within a maximum of one week.

The Ethics Committee of our institution approved the study and all patients gave informed consent prior to inclusion in this investigation.

All collected data were analyzed and correlated. Statistical analysis was performed using the Statistical Package for Social Sciences (SPSS®, version 14.0). Basic descriptive statistics included means, standard deviations, ranges and percentages. For correlation analysis, we used Spearman's test. Differences were considered statistically significant if the two-tailed P value was less than 0.05. Confidence intervals and the best cut-off values for the assessment of disease stage were calculated using ROC curves.

RESULTS

The study included 112 patients with PBC who underwent a complete clinical investigation. The mean age of patients included in the study was 53.88±10.59 years. (range 29-76), 104 females and 8 males. There were 58 (51.8%) patients in PBC stage I, 20 (17.9%) in stage II 20, 24 in stage III (21.4%), and the remaining 10 patients (8.9%) were in stage IV, characterized by liver cirrhosis. In fact, 78 patients (69.7%) had a mild form of PBC (stages I and II), while 34 patients (30.3%) showed an advanced form of the disease (stages III and IV). Values of analyzed biochemical markers, as well as results of statistical analyses are presented in Table 1. We found a statistical significant correlation between PBC stage and AST, APRI, ALT/platelet, AST/ALT, ALT/AST and ALT/Chol ratio, with the values of Spearman's rho of 0.338, 0.476, 0.404, 0.356, -0.351 and 0.325, respectively. The best sensitivity and specificity was shown for AST/ALT, with the area under ROC of 0.660.

DISCUSSION

During the last decade many studies have been designed to identify non-invasive markers capable of providing accurate information about liver fibrogenesis activity and stage of liver fibrosis in patients with chronic, potentially progressive hepatic diseases. The ideal characteristics of such markers are: (1) Specific for liver fibrosis; (2) Providing measurement of: (a) stage of fibrosis, (b) fibrogenesis activity; (3) Not influenced by comorbidities (e.g. renal, reticulo-endothelial); (4) Known half-life; (5) Known excretion route; (6) Sensitive; and (7) Reproducible. Two quite different approaches have been followed. Many studies have evaluated "direct" markers of fibrogenesis, i.e. of biochemical parameters, measurable in the peripheral blood as a direct expression of either the deposition or the removal of ECM in the liver. These direct markers of liver fibrosis include several glycoproteins (hyaluronan, laminin, human cartilage glycoprotein 39 (YKL-40), the collagens family (procollagen III, type IV collagen and type IV collagen 7s domain), the collagenases and

Table 1 Values of biochemical markers and results of statistical analyses for differentiation of disease stage in patients with PBC

their inhibitors (metalloproteinases and tissue inhibitors of metalloproteinases) and a number of cytokines connected with the fibrogenetic process (TGF-β1, TNF-β). A second and easier approach in the search of non-invasive markers of liver fibrosis has been choosing single or combined hematological and/or biochemical parameters that reflect the stage of liver disease, and assessing and comparing the accuracy of their diagnostic performance. This approach, using routinely performed blood tests, has led to the identification of sets of markers able to define the stage of liver fibrosis with accuracy very similar, if not superior, to that of the more sophisticated and difficult to test direct markers. The diagnostic performance of most direct and indirect markers of liver fibrosis has been investigated in all the common etiological forms of chronic liver diseases, including hepatitis C, hepatitis B and alcoholic and non alcoholic fatty liver disease and steatohepatitis, although some of them have been more extensively tested in patients with chronic hepatitis C[11].

There are many published articles on non-invasive assessment of fibrosis in patients with chronic hepatitis C infection, but only one published article[12] analyzed the value of AST/ALT ratio as an indicator of cirrhosis in patients with PBC. This study included 160 patients with PBC and for 121 they had laboratory data and liver histology. The authors of the study analyzed the clinical and laboratory data, as well as follow-up outcomes: liver-related death, liver transplantation and survival. The AST/ALT ratio was also used for assessment in alcohol-induced liver cirrhosis prediction of oesophageal varices and ascites presence. It is suggested that the AST/ALT ration increases in patients who develop liver cirrhosis, regardless of its cause. The reason for the increased AST/ALT ratio is unknown. It is suggested that the sinusoidal clearance of AST decreases in cirrhotic patients[13-15]. Nyblom *et al*[14] reported the use of this ratio for discrimination between cirrhotic and non-cirrhotic patients with sensitivity of 82% and specificity of 79%, for a cut-off value 1.1. The explanation for such high sensitivity is that a large number of cirrhotic patients were included, while sampling variability in the liver biopsies contributed to low specificity. The study concluded that the AST/ALT ratio is of clinical value as a predictor of cirrhosis in patients with PBC, but not as a prognostic factor.

Our study explored the value of different biochemical markers in the assessment of a range of disease stages in PBC patients. The sensitivity and specificity was calculated to discriminate early (stages I and II) *vs* advanced (stages III and IV) stages of PBC. We showed that several biochemical markers could be successfully used for staging the disease. Our results are, to some extent, comparable with the results of the previous similar studies, while the observed lower sensitivity (47.5%) and specificity (75%) for the AST/ALT ratio (Figure 1) could be explained by different study design.

New technology has been developed based on the fact that liver stiffness (LS) increases as liver fibrosis progresses[16]. The FibroScan 502 (FS, EchoSens, Paris, France) for transient elastography is a new modality developed for non-invasive evaluation of LS. LS correlated well with the histological stage of fibrosis. Changes in liver fibrosis stage may thus be estimated non-invasively using transient elastography[17,18]. Nevertheless, further studies are needed to confirm the value of this technique in different chronic diseases of liver.

In our opinion, the potential predictive value of aminotransferase and platelet count ratios in prediction of PBC stage may be used in evaluation of PBC evolution, despite their limited sensitivity and specificity, especially when considering their availability and cost effectiveness. Combination panels of non-invasive biomarkers may improve the accuracy of the single tests.

COMMENTS

Background

The main goal of this study was to evaluate different biochemical markers and their ratios in assessment of various stages of primary biliary cirrhosis (PBC).

Research frontiers

Despite liver biopsy remaining the "gold standard", there is great clinical interest in the use of non-invasive methods to assess disease stage in primary biliary cirrhosis.

Innovations and breakthroughs

This study explored the value of different biochemical markers in assessment of a range of disease stages in PBC patients. The sensitivity and specificity was calculated to discriminate early (stages Ⅰ and Ⅱ) vs advanced (stages Ⅲ and Ⅳ) stages of PBC. We showed that several biochemical markers could be successfully used for staging the disease.

Applications

Use of biochemical markers and their ratios in clinical evaluation of PBC patients may reduce, but not eliminate, the need for liver biopsy. The potential predictive value of aminotransferase and platelet count ratios in prediction of PBC stage may be used in evaluation of PBC evolution, despite their limited sensitivity and specificity, especially when considering their availability and cost effectiveness.

Peer review

This is a simple and elegant study that increases our knowledge of the non-invasive evaluation of biliary cirrhosis staging.

Abstract

AIM: To assess the usefulness of bispectral index (BIS) monitoring in order to carry out endoscopic submucosal dissection (ESD) safely and with patients' satisfaction.

METHODS: Three hundred sixty-six patients with an early-stage neoplasm of the digestive tract were enrolled. The BIS monitor (A-1050: Aspect medical systems/NIHON KOHDEN, Tokyo, Japan) was used. The appropriate sedative condition was set at 55 to 75 BIS levels (BIS value) during the endoscopic procedures.

RESULTS: Among 366 cases, 13 were accompanied by adverse events during and/or after ESD. All episodes occurred in cases with BIS value between 56 and 65. Hypotension was observed in four cases, and bradycardia in six. Respiratory distress was observed in two cases with chronic pulmonary obstructive disease. All patients with adverse events were able to leave the hospital without extension of the hospitalization.

CONCLUSION: BIS monitoring is useful to safely perform ESD. A BIS value of 70 to 75 is suitable for ESD.

INTRODUCTION

Endoscopic submucosal dissection (ESD) has recently been developed for *en bloc* resection of gastric cancer, which results in high tumor eradication rates, as well as a modality for the precise histological evaluation of the entire lesion[1,2]. Furthermore, recent studies have reported that ESD is useful for selected localized neoplasms of the esophagus and the colon[3,4]. However, ESD is a highly complex endoscopic technique and sometimes needs long time to be performed. So, conscious sedation is the standard of care for the majority of ESD cases to perform a safe procedure and to minimize complications.

The bispectral index (BIS) is a quantitative parameter of the hypnotic effects of anesthetic drugs on the central nervous system (CNS)[5,6]. BIS is not an instrument just for the frequent analysis of electroencephalogram, but it analyzes the relationship among the different components of the electroencephalogram in various phases. BIS also takes into account the correlation between the electrocardiogram and the CNS suppression. BIS is a dimensionless number ranging from 0 to 100, with 0 representing no cortical activity and 100 representing fully awake state. BIS has been utilized in guiding dosing of anesthetics, including decreasing the amounts of drug use and enhancing faster emergence and recovery[5]. To avoid excessive administration of propofol, we introduced the monitoring of the sedation depth by BIS, which enables the objective evaluation of the sedation.

It is desirable to make an objective judgment of the depth of the conscious sedation during ESD and to maintain a sedation that does not affect the cardiorespiratory dynamics. BIS monitoring is expected to avoid excessive administration of anesthetic drugs

during ESD. In this study, we investigated the usefulness of BIS monitoring while using propofol in the course of ESD. Propofol has been reported to afford a higher comfort and satisfaction to patients and to reduce the time to recovery, compared to previously reported drugs such as benzodiazepines and opiates[7,8].

MATERIALS AND METHODS

Patients

Three hundred sixty-six patients with early-stage esophagus cancer, gastric cancer and/or colorectal cancer, treated with ESD from May, 2004 to April, 2007 at the Hospital of the Shiga University of Medical Science (Otsu, Japan), were enrolled into the study. The baseline features and history of these patients are reported in Table 1.

Anesthesia

An anesthesist or a specialist in endoscopy trained in anesthesiology performed the procedure, including the administration of a sedative drug during operation. Two BIS sensors were put on the forehead of each patient and another sensor was placed on the outer side of an eyebrow. The BIS monitor (A-1050: Aspect medical systems/NIHON KODEN, Tokyo, Japan) was used. As soon as the sedative drug started its effects, oxygen (2 L/min) was given through a nasal cannula. Three-lead electrocardiogram, pulse oximetry and blood pressure were monitored.

Just before the sedation started, intravenous drip infusion of pentazocine (15 mg/body) was given. An initial 40-mg bolus of propofol was administered intravenously to all patients, followed by continuous infusion of propofol (3 mg/kg per hour). The appropriate sedative condition during endoscopic procedures was set at 55 to 75 BIS levels (BIS value). From May, 2004 to September, 2005, the BIS level was set between 56 and 65, while later on (i.e. from October, 2005 to April, 2007) it was set between 70 to 75. In order to maintain suitable BIS levels, the dosage of continuous infusion of propofol was adjusted.

Adverse events during and after ESD were recorded. We observed delayed awakening (i.e. the patient failed to awake 15 min after the stop of propofol administration), hypotension (systolic blood pressure < 90 mmHg), bradycardia (heart beats < 50/min) and respiratory failure (patient needing a mandatory ventilation).

RESULTS

Among the 366 cases, 13 were accompanied by adverse events during and after ESD (Table 2). The adverse events occurred during the period in which BIS value was set between 56 and 65 (12 cases out of 139 cases, 9%), but no adverse events occurred as long as the BIS value was set between 70 and 75.

Hypotension was observed in four cases. One of them occurred immediately after the administration of propofol, but in the other three it occurred at a later phase

Table 1 Backgrounds of patients (number of cases)

BIS value	56-64 (May/2004 -Sep/2005)	70-75 (Oct/2005 -April/2007)	Total
Esophageal cancer	13	36	49
Gastric cancer	100	149	249
Colon cancer	26	42	68
Total	139	227	366

Table 2 Adverse events (number of cases)

BIS value	56-64 (May/2004 -Sep/2005)	70-75 (Oct/2005 -April/2007)	Total
Delayed awakening	1	0	1
Decreased blood pressure	4	0	4
Bradycardia	6	0	6
Respiratory depression	2	0	2
Total	13	0	13

during ESD. These four patients recovered quickly when propofol was decreased or stopped, together with an adjustment of infusion of fluids.

Respiratory depression was observed in two cases, both of which had chronic obstructive pulmonary disease (COPD.) One patient had a history of chronic bronchial asthma, the other of pulmonary emphysema. During ESD, 2 to 5 L/min of oxygen was given and adjusted at a timely basis in order to maintain a $SpO_2 > 92\%$. The latter case developed CO_2 narcosis after ESD, but gradually recovered.

Bradycardia was observed in six patients. All of them recovered with an adjustment of fluid infusion.

All patients with an adverse event were able to leave the hospital without extending the duration of the hospitalization.

DISCUSSION

The standard protocol of conscious sedation is generally determined by the experience of doctors at the respective medical institutions. Ideal conditions of conscious sedation are as follows: (1) rapid and short acting, (2) no accumulation and rapid recovery after operation, (3) no modulation of respiratory and cardiovascular dynamics, and (4) no hepatic or renal toxicity. In Japan, midazolam is widely used, while flumazenil is given as an antagonist after the operation[7]. However, because of the different half-life of these two drugs (midazolam, approximately 120 min; and flumazenil, approximately 50 min), there is a high risk of a new period of unconsciousness after the treatment.

Propofol is the most frequently used intravenous anesthetic in the field of intensive cares. The most important feature of propofol is its short half-life. Thus, even after prolonged administration, it does not bring about the repeated sedation once the administration is stopped. In a controlled study of propofol versus

midazolam, it has been reported that patients showed a higher level of satisfaction with propofol than with midazolam[7-9]. In the guidelines of endoscopy under sedation issued by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), it is recommended to use propofol for endoscopic treatments of long duration, due to its dual advantage of a deep sedation and a quick awakening, compared to benzodiazepines and narcotic drugs. However, propofol may cause cardiorespiratory suppression. Since there are no appropriate antagonists available, it is necessary, in case of cardiorespiratory suppression induced by excessive propofol administration, to carry out cardiorespiratory supportive care with a ventilator until propofol is fully metabolized.

To avoid excessive administration of propofol, we introduced monitoring by BIS, which enables the objective evaluation of the sedation depth. BIS is not an instrument just for the frequent analysis of electro-encephalogram, but it also analyzes the relationship among the different components of the electroencephalogram at various stages. BIS is equal to 100 when the patient is fully awake and 0 when an isoelectric electroencephalogram is observed. It has been reported that BIS is useful to evaluate the sedation depth during digestive endoscopy or treatment[10].

During surgical operations under general anesthesia, the BIS value is usually set at 45 to 65[11]. Thus, we also set the target BIS during ESD at 56 to 64, at least during the initial period. However, since we experienced cases with adverse events during ESD, we slightly increased the BIS values. Thus, after October 2007, we set a BIS value at 70 to 75. Propofol has sedative effects but it does not possess analgesic properties. Therefore, we added pentazocine (15 to 30 mg) and in most cases we could carry out the ESD without impediments, using these BIS values.

There were four cases of decreased blood pressure during the first period. In one case, this occurred because of the bolus infusion of propofol at the time of induction of sedation. After this case, propofol was given through a syringe pump with constant speed. Also, we administrated propofol from the port which is located close to the peripheral intravenous indwelling needle, in order to minimize the lag time between the start of injection and the actual appearance of a sedative effect. By doing this, we did not experience any additional case of decreased blood pressure after the infusion.

Regarding the other three cases, decreased blood pressure occurred in the second half of ESD. Each of these patients had a history of elevated blood pressure and therefore they had been taking antihypertensive drugs until the day of ESD. Decreased blood pressure might be attributed to the interaction of propofol with antihypertensive drugs. However, all patients recovered quickly when propofol was decreased or stopped, or when the fluid infusion was adjusted. In addition, no additional case of decreased blood pressure was experienced in the later period, i.e. when the BIS value was set higher.

Two cases of respiratory depression were confirmed and one of the patients had a history of chronic bronchial asthma. Respiratory depression was due to accidental aspiration during ESD. This is not considered as an adverse event of propofol, and could be prevented by placing an aspirating cannula in the stomach. The other patient had a history of pulmonary emphysema and developed CO_2 narcosis because of the excessive infusion of oxygen during ESD. Therefore, based on this case, the oxygen infusion was started at 1 liter per minute when dealing with patients with COPD. Also, we made it a rule to carry out an arterial blood gas analysis at least once during ESD. As a consequence, we have not experienced any additional cases of respiratory depression.

Recent studies have reported that ESD is useful for localized esophagus and colon neoplasms[3,4]. ESD for such neoplasms is a much more complex endoscopic technique than that used for gastric neoplasms. So, BIS monitoring with conscious sedation may be useful for safely performing ESD of esophageal and colonic neoplasms.

In conclusion, BIS monitoring of conscious sedation with propofol is considered a very effective method for safe implementation of ESD. A BIS value between 70 to 75 is suitable for monitoring sedation depth during ESD.

COMMENTS

Background
Endoscopic submucosal dissection (ESD) is a highly complex technique for *en bloc* resection of localized neoplasms of the digestive tract, and conscious sedation is the standard of care to perform safe procedures. During ESD conscious sedation is required, but the usefulness of sedation monitoring has not been reported.

Research frontiers
The bispectral index (BIS) is a quantitative parameter of the hypnotic effects of anesthetic drugs on the central nervous system. In this study, we present data supporting the usefulness of BIS monitoring for safely performing ESD with patients' satisfaction.

Innovations and breakthroughs
This is the first study to report that conscious sedation by BIS monitoring is useful for ESD.

Applications
BIS monitoring may be useful during ESD of gastric, esophageal or colonic tumors.

Terminology
Endoscopic submucosal dissection (ESD) is a highly complex technique for *en bloc* resection of localized neoplasms of the digestive tract. BIS is a quantitative parameter of the hypnotic effects of anesthetic drugs on the central nervous system. BIS is not an instrument just for the frequent analysis of electroencephalogram, but it also analyzes the relationship among the different components of the electroencephalogram at various phases.

Peer review
This paper describes a novel method of assessing sedation during endoscopy and as such it should be published.

Abstract

AIM: To determine if disruption of the *cagA* gene of *Helicobacter pylori* (*H pylori*) has an effect on the expression of other proteins at proteome level.

METHODS: Construction of a *cagA* knock out mutant *Hp27_ΔcagA* (*cagA⁻*) *via* homologous recombination with the wild-type strain *Hp27* (*cagA⁺*) as a recipient was performed. The method of sonication-urea-CHAPS-DTT was employed to extract bacterial proteins from both strains. Soluble proteins were analyzed by two-dimensional electrophoresis (2-DE). Images of 2-DE gels were digitalized and analyzed. Only spots that had a statistical significance in differential expression were selected and analyzed by matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF-MS). Biological information was used to search protein database and identify the biological function of proteins.

RESULTS: The proteome expressions between wild-type strain and isogenic mutant with the *cagA* gene knocked-out were compared. Five protein spots with high abundance in bacteria proteins of wild-type strains, down-regulated or absently expressed in bacteria proteins of mutants, were identified and analyzed. From a quantitative point of view, the identified proteins are related to the *cagA* gene and important antioxidant proteins of *H pylori*, including alkyl hydroperoxide reductase (Ahp), superoxide dismutase (SOD) and modulator of drug activity (Mda66), respectively, suggesting that *cagA* is important to maintain the normal activity of antioxidative stress and ensure *H pylori* persistent colonization in the host.

CONCLUSION: *cagA* gene is relevant to the expressions of antioxidant proteins of *H pylori*, which may be a novel mechanism involved in *H pylori cagA* pathogenesis.

INTRODUCTION

Helicobacter pylori (*H pylori*), a spiral-shaped bacterium that colonizes the human gastric mucosa, is estimated to inhabit at least half of the world's human population[1]. Infection with *H pylori* is associated with development of peptic ulcer, gastric carcinoma and gastric mucosa-associated lymphoid tissue lymphomas[2-4]. However, little is known about the molecular mechanisms of pathogenesis induced by *H pylori* and the fundamental causes of diversity in infection outcomes. Cytotoxin-associated gene A protein (CagA) is a *H pylori* immuno-

dominant antigen with its gene residing in the cag pathogenicity island, which is a 40-kilobase insertion containing genes involved in virulence[5]. Recent studies indicate that CagA is delivered from *H pylori* into the cytoplasm of *H pylori*-attached gastric epithelial cells via the type-IV secretion system[6]. Upon membrane localization, translocated CagA interacts with a number of host proteins involving cell signaling in a tyrosine phosphorylation-dependent and -independent manner[7,8]. Epidemiological studies have shown that *cagA* positive *H pylori* strains are associated with higher grades of gastric mucosal inflammation as well as severe atrophic gastritis and gastric carcinoma[9,10]. CagA is considered a marker of increased pathogenic potential and may play an important role in the pathogenesis induced by *H pylori*.

China is one of the nations with the highest *H pylori* infection incidence[11]. More than 90% isolated strains possess *cagA* gene[12]. However, the biological activity of *cagA* gene still remains unclear. In the present study, we analyzed two related *H pylori* strains, *Hp27* and *Hp27_ΔcagA*, through a proteomic approach. Wild type strain *Hp27* is a *cagA* gene possessor, while strain *Hp27_Δ cagA* is an isogenic *cagA* knock out mutant. Proteins with altered expressions can be separated by two-dimensional electrophoresis (2-DE) and conclusively identified by matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS) analysis of the peptide digests. This study was to determine if disruption of the *cagA* gene has an effect on the expression of other proteins of *H pylori* at proteome level.

MATERIALS AND METHODS

Bacterial strains

Hp27 (*cagA*[+]) isolated from a patient with chronic atrophy gastritis was grown on Brucella agar plates containing 10% sheep blood supplemented with 10 mg/L vancomycin, 2500 U/L polymyxin B, 2 mg/L amphotericin and 5 mg/L trimethoprim, in an anaerobic jar consisting of 50 mL/L O$_2$, 100 mL/L CO$_2$, and 850 mL/L N$_2$ at 37℃ for 3 d. Kanamycin (25 mg/L) was added for mutated strains selection.

Construction of Hp27_ΔcagA isogenic mutant

Isogenic *Hp27_ΔcagA* mutant was obtained from strain *Hp27* as follows. In brief, we produced a *Hp27_Δ cagA* isogenic mutant harboring a total *cagA* deletion as previously described[13]. *H pylori* were grown on blood agar plates under microaerophilic conditions for 3 d and genomic DNA was extracted with a genomic DNA purification kit (Takara). An upstream (U fragment) and a downstream region (D fragment) of the *cagA* gene were amplified over the genomic DNA as homologous arms using the *P1/P2* and *P3/P4* primer pairs, respectively. A kanamycin-resistant gene was amplified as a screening marker from *pEGFP-N2* vector (Clontech) using the *P5/P6* primer pair. The primer sequences are as follows (restriction sites are underlined): *P1-Xho* I : 5'-GCGCTCGAGACTTTCTTGTAGCTGTC-3'; *P2-HindIII*: 5'-GGCAAGCTTTGTTTCTCCTTTACT-3'; *P3-Pst* I : 5'-GGCTGCAGAGGATTGAGGAATAC-3'; *P4-Xba* I : 5'-CGTCTAGATTTTAGCGATCAAACAA C-3'; *P5-HindIII*: 5'-GCAAGCTTATGATTGAACAAG ATGGATTG-3'; *P6-Pst* I : 5'-GGCTGCAGTCAGAAG AACTCGTCAAGAAG-3'.

After digestion of PCR products with *Xho* I /*HindIII* (U fragment) and *Pst* I /*Xba* I (D fragment), the kanamycin resistance gene digested with *HindIII*/*Pst* I was introduced between the U and D fragments. The resulting chimera was cloned into the *Xho* I /*Xba* I -digested *pBluescript SK II* (-) vector (Stratagene) to obtain the construct targeting vector: *pBSKΔcagA_kan*. *Hp27* served as a recipient strain was electrotransformated with *pBSKΔcagA_kan*. Bacteria were grown on blood agar plates for 48 h and then streaked on fresh selective plates supplemented with 25 μg/mL of kanamycin. A real *cagA* isogenic mutant (*Hp27_ΔcagA*) was selected from kanamycin-resistant colonies and the corresponding insertional DNA region was checked by PCR to confirm the exact recombination.

Protein extraction

A wild-type strain of *Hp27* and an isogenic mutant of *Hp27_ΔcagA* were harvested from Brucella agar plates and then washed 3 times with ice-cold PBS. Total protein was extracted with an appropriate volume (300 μL) of lysis buffer containing 8 mol/L urea, 65 mmol/L DTT, 2% CHAPS, 2 mmol/L PMSF, 0.5% IPG buffer, and protease inhibitor mixture. The extraction mixture was sonicated with parameters of 120 W, 5 min, pulse: 1S, 2S. The protein mixture was centrifuged at 12 000 r/min for 40 min. After transferred to a clean tube, the supernatant was stored at -70℃ as aliquots. The protein concentration was determined by Bradford dye-binding assay with bovine serum albumin as the standard.

Two-dimensional electrophoresis

Two-dimensional electrophoresis was carried out as follows. Precast IPG strips (pH 3-10 linear, 18 cm, Amersham Pharmacia Biotechnology Inc.) were used in the first dimension. A total amount of 1000 μg protein was diluted to a total volume of 350 μL with the buffer containing 8 mol/L urea, 20 g/L CHAPS, 5 g/L IPG buffer 3-10, 20 mol/L DTT and a trace of bromophenol blue. After loaded on IPG strips, IEF was carried out on IPGphor (Bio-Rad,USA) according to the following protocol: rehydration for 16 h at 50 V, 1 h at 200 V, 1 h at 500 V, 1 h at 1000 V , 5 h at 10 000 V and 60 000 V h at 10 000 V (total 112.5 kVh). The current was limited to 50 μA per gel. After IEF separation, the strips were immediately equilibrated for 2 × 15 min with an equilibration solution containing 50 mmol/L Tris-HCl (pH 6.8), 6 mol/L urea, 300 g/L glycerol and 20 g/L SDS. Then, 20 mmol/L DTT was included in the first equilibration solution, and 20 g/L iodoacetamide was added in the second equilibration step to alkylate thiols. Electrophoresis in the second dimension was carried out

on 15% SDS-PAGE gels (18 cm × 20 cm × 0.1 cm). The strips were held in place with 5 g/L agarose dissolved in a SDS/Tris running buffer and electrophoresis was carried out at a constant power (2.5 W/gel for 40 min and 15 W/gel for 5 h) using a Protean Ⅱ xi cell gel SDS-PAGE system (Bio-Rad, USA).

Image processing and analysis

After electrophoresis, gels were stained with Coomassie brilliant blue, equilibrated in a solution containing 500 mL/L methanol, 50 mL/L acetic acid and 25 g/L Coomassie brilliant blue R-250 for at least 2 h, and rinsed in 300 mL/L ethanol containing 70 mL/L acetic acid. Digitalized images were obtained by ImageScanner GS-800 (Bio-Rad, USA) scanning of the gels, and analyzed qualitatively and quantitatively by the PDQuest gel image analysis software 7.1 (Bio-Rad, USA). To determine variation, three gels were prepared for each sample. The computer analysis allowed automatic detection and quantification of protein spots as well as matching. The normalized volume of protein spots was used to analyze the differential level of protein expression. Only those spots that had a statistical significance in differential expression were selected for further investigation.

Protein identification by MALDI-TOF-MS

Differential protein spots were cut out from the gel. After being washed with 300 μL milliQ water for 15 min, each protein spot was decolorized with the successive action of 50 μL of 15 mmol/L potassium ferricyanide and 50 mmol/L sodium thiosulphate for 5-10 min. Faded gel pieces were dried in a vacuum centrifuge tube for 5 min. Cysteine reduction and alkylation were performed and incubated with 10 mmol/L DTT, 100 mmol/L NH₄HCO₃ at 56℃ for 1 h in the dark. Gel pieces were dried again and incubated with 50 mmol/L fresh iodoacetamide in 100 mmol/L NH₄HCO₃ at room temperature for 30 min and rehydrated in digestion buffer containing 20 μL of 12.5 μg/mL modified trypsin and 20 mmol/L NH₄HCO₃ for 30 min in ice. Excess liquid was removed and the gel pieces were digested continuously at 30℃ overnight (> 16 h). The resulting peptide mixture was extracted from the digested solution by centrifugation and resuspended in 10 μL of 50% CH₃CN and 0.1% trifluoroacetic acid (TFA) for 10 min at 30℃ on a shaking platform. Peptide mass maps were generated by Applied Biosystems Voyager System 6192 MALDI-TOF-mass spectrometry (ABI, USA). Peptide masses were analyzed using the MS-Fit search program (http://prospector.ucsf.edu/ucsfhtml4.0u/msfit.htm). The searching parameters were set up as follows: acquisition mass ranges 900-3500 Da, the mass tolerance was ± 0.5 Da; the number of missed cleavage sites was allowed up to 1; the minimum number of matched peptide was four; species was set as bacteria; and the searching range was within the experimental pI value ± 0.5 pH unit and experimental Mr ± 20%.

Figure 1 Differential two-dimensional maps of wild-type strain *Hp27* (A) and mutant strain *Hp27_ΔcagA* (B) stained with Commassie blue.

RESULTS

The proteome maps of *H pylori* strains *Hp27* and *Hp27_ΔcagA* were produced and compared (Figure 1). After spot detection, background subtraction, volume normalization, differentially expressed proteins were detected in wide-type strain versus isogenic mutant. The arrows indicate five protein spots whose expression levels were significantly differently represented in strain *Hp27* as compared to strain *Hp27_ΔcagA*.

Expression levels of the two proteins were obtained by calculating the relative spot volume of each protein *versus* the total amount of protein in the gel. Segments of 2-DE gel map for five proteins derived from strains *Hp27* and *Hp27_ΔcagA* are shown in Figure 2.

Five protein spots differentially expressed in strains *Hp27* and *Hp27_ΔcagA* were excised from 2-DE gels and identified by peptide mass fingerprinting (Figures 3 and 4).

Mascot searches using the peptide mass fingerprinting data indicated that the differentially expressed proteins were alkyl hydroperoxide reductase (Ahp), superoxide dismutase (Sod) and modulator of drug activity (Mda66) (Table 1). These three proteins are all important antioxidant proteins of *H pylori*. From a quantitative point of view, these proteins are novel, and have not been reported previously in relation to *cagA* gene.

DISCUSSION

A comparative proteome analysis was carried out between the two *H pylori* strains: *Hp27*, a wild-type

Table 1 Mascot search results of PMFs in 5 protein spots

Spot	Accession No.	MW	PI	Description	MOWS E score	Sequence coverage (%)
H1	gi|2313748	21591	6.59	Modulator of drug activity (Mda66)	62	46
H2	gi|2314747	22221	5.88	Alkyl hydroperoxide reductase (AhpC)	111	67
H3	gi|2314747	22221	5.88	Alkyl hydroperoxide reductase (AhpC)	140	76
H4	gi|2313490	24602	5.77	Superoxide dismutase (SOD)	86	62

Figure 2 Magnified segments of 2-DE gel map of protein spots including H1~H5.

strain and *Hp27_ΔcagA*, a *cagA*⁻ isogenic mutant. Five differential protein spots, which are abundant in bacteria proteins of wild-type strains and are down-regulated or absently-expressed in bacteria proteins of mutants, were selected to perform in-gel trypsin digestion and MALDI-TOF-MS-based PMF analysis. The three identified proteins are Ahp, Sod and Mda66. Of the 5 position identifications, spots H2 and H3 were identified as the same protein Ahp, and spots H4 and H5 were

also identified as the same protein Sod, indicating that these gene products are present as isoforms with post-translational modification[14].

Alkyl hydroperoxide reductase (AhpC), a thioredoxin (Trx)-dependent AhpC, is a member of the 2-Cys peroxiredoxins family (2-Cys Prxs). A group of thiol-specific antioxidant enzymes, which catalyze the reduction of hydrogen peroxide and organic hydroperoxides, are ubiquitous proteins that protect organisms from damage by reactive oxygen species[15]. *H pylori* are oxygen-sensitive microaerophilic bacteria, and contain many antioxidant proteins, among which AhpC is most abundant. The function of AhpC is to protect *H pylori* from a hyperoxidative environment by reducing toxic organic hydroperoxides[16].Wang *et al*[17] reported that mutant cells defective in AhpC are more sensitive to oxidative stress conditions, accumulate more free (toxic) iron, and suffer more DNA fragmentation compared to wild type cells. Olczak *et al*[18] tested the ability of strains with mutation in *ahpC* (encoding alkyl hydroperoxide reductase) to colonize the stomachs of mice, and showed that the mutant is clearly more sensitive than the parent strain to both oxygen and cumene hydroperoxide and unable to colonize mouse stomachs, whereas 78% of the mice inoculated with the parent strain become *H pylori* positive. Recently, Chuang *et al*[19] revealed that AhpC of *H pylori* acts as a peroxide reductase in reducing organic hydroperoxides and as a molecular chaperone in preventing protein misfolding under oxidative stress. Besides, AhpC could also influence the activity of other proteins. Catalase in *ahpC* mutant partially inactivated (approximately 50%) in comparison with the parent strain, indicating that organic hydroperoxides (the substrate of AhpC), which accumulate in *ahpC* mutant cells, are responsible for the inactivation of catalase[20]. In this study, the expression of AhpC was down-regulated in the *cagA* gene knocked-out mutant (Hp27_ΔcagA), suggesting that AhpC, one of the most important anti-oxidative stress proteins of *H pylori*, is related with the *cagA* gene.

Superoxide dismutase (SOD), a nearly ubiquitous enzyme in organisms exposed to toxic environments, is able to catalyze the conversion of superoxide radicals to hydrogen peroxide and molecular oxygen. Single SOD in *H pylori*, encoded by the *sodB* gene, has been suspected to be a virulence factor for this pathogenic microaerophile[21]. Seyler *et al*[22], who first isolated mutants with interruptions in the *sodB* gene, found that the *sodB* mutants are devoid of SOD activity, and more sensitive to O_2 and H_2O_2 for both growth and viability.

Figure 3 Mass spectrometry (MS) maps of one protein spots. A: MS of H1; B: MS/MS of H1.

Since oxidative stress is correlated with DNA damage, they studied the frequency of spontaneous mutation to rifampin resistance. The frequency of mutagenesis of the *sodB* mutant strain is about 15-fold greater than that of the wild-type strain. Wang *et al*[17] also reported that mutant cells defective in SOD are more sensitive to oxidative stress conditions and suffer more DNA fragmentation compared to wild type cells, and that a significant proportion of cells of *sodB* mutant strains develop into stress-induced coccoid form or lysed as well as that they also contain a significantly higher amount of 8-oxo-guanine associated with their DNA, compared to wild type cells. Seyler *et al*[22] observed that only 1 out of 23 mice inoculated with a SOD-deficient mutant of a mouse-adapted strain became *H pylori* positive, while 15 out of 17 mice inoculated with the wild-type strain harbored the organism, in a mouse colonization model, indicating that SOD is a virulence factor affecting the ability of *H pylori* to colonize the mouse stomach and is important for the growth and survival of *H pylori* under oxidative stress conditions.

Mda66, identified in the *ahpC napA* double mutant by two-dimensional gel electrophoresis combined with N-terminal protein sequencing, is another possible antioxidant protein[23]. Single bacterial homologue is a MdaB protein of *Escherichia coli* (*E. coli*), first identified as a modulator of drug activity (named *mda66*) because the gene is mapped at 66 min on the *E. coli* chromosome[24]. Wang *et al*[25] demonstrated that, like its homologue in *E. coli*[26], Mda66 protein is a NADPH quinone reductase and able to reduce quinone to quinol. Quinone metabolism within cells has a direct effect on the cell's ability to deal with oxidative stress[27]. Therefore, the reduced status of *H pylori* Mda66 protein plays an important role in the management of oxidative stress. Wang *et al*[25] reported that the wild-type strain could tolerate 10% oxygen, but the growth of *mdaB* mutant was significantly inhibited by 10% oxygen. The *mda66* mutant was also more sensitive to H_2O_2, organic hydroperoxides, and paraquat, an agent generated by superoxide. Although the wild-type strain survived more than 10 h after air exposure, exposure of the mutant strain to air for 8 h resulted in no recovery of viable cells. It was reported that oxidative stress sensitivity of *mda66* mutant can reduced the ability of *mda66* mutant to colonize mouse stomachs[25]. *H pylori* were recovered from 10 of 11 mouse stomachs inoculated with the wild-type strain, with about 5000-45 000 CFU/g of stomach, while only 3 of 12 mice inoculated with the *mdaB* mutant strain did not harbor any *H pylori*, and contained less than 2000 CFU/g of stomach[25]. Therefore, the physiological function of *H pylori* Mda66 protein is similar to that of NADPH quinone reductase that plays an important role in the management of oxidative stress and contributes to successful colonization of the host.

Oxidative stress resistance is one of the key properties enabling pathogenic bacteria to escape the effects of reactive oxygen produced in the host.

Figure 4 Mass spectrometry (MS) maps of 4 protein spots. A: MS of H2; B: MS of H3; C: MS of H4; D: MS of H5.

Therefore, proteins (enzymes) involved in oxidative stress resistance are the important factors for bacterial colonization and pathogenesis[28]. Microaero philic organisms, such as *H pylori*, are particularly vulnerable to the detrimental effects of oxygen and oxidative stress. Nevertheless, enzymes including AhpC, catalase (KatA), SOD, thioperoxidase (Tpx), *etc.*, can maintain persistent infection by using a variety of protective enzymatic systems that eliminate or minimize toxic oxygen-derived products.

In this study, three important antioxidant proteins of *H pylori* including AhpC, SOD and Mda66 were identified from the 2-DE maps showing differentially expressed proteins between the wild-type strain (*Hp27*) and isogenic *cagA* knock out mutant (*Hp27_ΔcagA*), indicating that the *cagA* gene is relevant to the expressions of antioxidant proteins of *H pylori*. Disruption of the target gene was found to have a certain effect on the expression of other genes that its encoded protein was shown to play a direct or indirect role in the regulation of protein biosynthesis, suggesting that *cagA* gene quantitatively influences *ahpC*, *sodB* and *mda66* transcription or their subsequent translation and correct folding.

Regulatory genes are usually located in the genome upstream of genes. With reference to the genomic sequence of *H pylor 26695*, *cagA* is only located in the upstream of *mda66*, and it is difficult to explain how CagA regulates other antioxidant proteins. Since there are no DNA-binding motifs or motifs suggestive of a two-component regulatory system in CagA, the protein may act as a signal transducer by means of other proteins[8,29]. It was recently reported that a ferric uptake regulator (Fur) and a post-transcriptional regulator CsrA play a key role in the regulation of antioxidative stress enzymes[21]. We presumed that *cagA* might be related to Fur and/or CsrA, through which *cagA* influences the expression of antioxidant protein. However, the correlation between *cagA* and Fur and/or CsrA needs to be further studied.

In this study, *cagA* was found to be correlated with the three stress-resistant enzymes, suggesting that *cagA* gene may be of importance for *H pylori* to maintain the normal activity of antioxidative stress and to keep long-term persistence in the host, which is a novel mechanism involved in *cagA* pathogenesis. Based on our results and the reported linkage between *cagA* and motility[30], our conclusion is that *cagA* has virulence effects and may play a specific role in *H pylori* pathogenesis by influencing the expression of other proteins (enzymes).

COMMENTS

Background

Helicobacter pylori (*H pylori*) is a causative agent of gastritis, peptic ulcer and gastric cancer. CagA, a major virulence factor of *H pylori*, is considered a marker of increased pathogenic potential and may play an important role in the pathogenesis of *cagA* gene. However, little is known about the molecular mechanism and multiple biological functions of *cagA*.

Research frontiers

CagA is a *H pylori* immunodominant antigen whose gene resides in the *cag* pathogenicity island, a 40-kilobase insertion containing genes involved in

virulence. A previous study showed that *cagA* is related with the motility of *H pylori*. However, its exact mechanism still remains unclear. In this study, a proteomic approach was employed to determine if disruption of the *cagA* gene has some effects on the expression of other proteins of *H pylori*, through which various functions of the *cagA* gene can be recognized.

Innovations and breakthroughs

A proteomic approach combined with MALDI-TOF-MS was employed to investigate changes in expression of the wild-type strain of Hp27 (*cagA*+) and the *cagA* gene knock out isogenic mutant. Three antioxidant proteins were identified, including alkyl hydroperoxide reductase (Ahp), superoxide dismutase (SOD) and modulator of drug activity (Mda66), respectively. It is implied that *cagA* is essential to maintain the normal activity of antioxidative stress and ensure *H pylori* persistent colonization in the host, which may be a novel mechanism involved in *cagA* pathogenesis.

Applications

These results provide a novel mechanism involved in *H pylori cagA* pathogenesis. The *cagA* gene may be of importance for *H pylori* to maintain the normal activity of antioxidative stress and keep long-term persistence in the host.

Terminology

CagA: Cytotoxin-associated gene A protein encoded by cytotoxin-associated gene pathogenicity island, a major virulence factor of *H pylori*. Two-dimensional electrophoresis: A two-step method to separate soluble proteins. Soluble proteins were first separated by isoelectric focusing (IEF) electrophoresis, and then according to the difference in molecular weight by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Antioxidant protein: Proteins (enzymes) involved in oxidative stress resistance, which are important factors for bacterial colonization and pathogenesis.

Peer review

The results of this study are interesting. The findings are novel. However, how the absence of antioxidant proteins should be further studied.

Abstract

AIM: To explore the role of color Doppler flow imaging (CDFI) in visualization of spleen vessels and to define its value for spleen micro-invasive operation.

METHODS: A total of 36 patients requiring laparoscopic splenectomy (LS) for various hematopathies and autoimmune diseases were randomly selected from April 2005 to May 2008. Anatomic types of spleen pedicle, adjacent relations between spleen vessels and pancreas, diameters of spleen artery and vein were detected and recorded by preoperative CDFI. Different operative procedures were performed according to different anatomic frameworks. The parameters were recorded by telerecording during LS and compared with those by preoperative CDFI using Chi-square test.

RESULTS: Two anatomic types of spleen pedicle and four different adjacent relations between spleen vessels and pancreas were detected by CDFI. The diameters of spleen artery and vein detected by CDFI were 0.46 ± 0.09 cm and 0.85 ± 0.35 cm, respectively. There was no statistical difference between the parameters recorded by CDFI and by telerecording (χ^2 = 0.250, 0.677, P > 0.05). LS was successfully performed following the anatomic information provided by preoperative CDFI.

CONCLUSION: Different anatomic frameworks of spleen vessels can be provided by preoperative CDFI, which instructs micro-invasive operation of spleen and increase the safety of operation.

INTRODUCTION

Laparoscopic splenectomy (LS) can relieve refractory hematopathies and autoimmune diseases[1]. However, LS is performed safely and effectively only by surgeons who are familiar with the anatomy of spleen vessels because it is vital to manage spleen pedicle successfully during LS[2-6].

With the advances in ultrasound techniques, color Doppler flow imaging (CDFI) has become one of the major diagnostic methods for vascular diseases especially for localization of target vessels. Furthermore, CDFI plays an important role in selecting the operational procedures for hematopathies[7]. In this study, the applicable anatomy of spleen vessels was examined in detail by CDFI before operation on patients requiring splenectomy in order to explore the value of CDFI in micro-invasive operation of spleen.

MATERIALS AND METHODS

Patients

Thirty-six consecutive patients (21 males and 15 females) with a mean age of 9.21 ± 4.06 years (range, 1.5-25 years) were randomly selected from April 2005 to May 2008. The indications for splenectomy were idiopathic thrombocytopenic purpura (*n* = 8), hereditary

spherocytosis (n = 19), portal hypertension and hypersplenia (n = 5), hemolytic anemia and hypersplenia (n = 3), and splenic neutropenia (n = 1). The study was approved by the institutional review board. All patients provided their informed consent.

Examinations of CDFI

All patients were carefully examined by an experienced ultrasonic physician with HDI-5000 color Doppler ultrasonograph (Philips Corporation). C_{5-2} abdominal probes were used with a 3.5 MH$_z$ mean frequency. Ultrasonic images were independently evaluated by one chief physician with 15-year experience in abdominal vascular imaging.

Patients were placed in a supine or lateral decubitus position and kept their stomach empty for 6-8 h before examination. Anatomic type of the spleen pedicle end, adjacent three-fourths of the distal segments of spleen vessels and pancreas, diameters of spleen artery and vein were measured, classified and recorded.

Surgical procedures

Accessory spleens were resected according to the preoperative ultrasonic examination. After splenculus ligament was separated by ultrasound shear, retinula cavity was opened. The surgeon separated and ligated the trunk of spleen artery directly if CDFI showed that all or parts of the segments of spleen artery were located at the anterosuperior border of pancreas or else, the surgeon separated the anadesma tissue around the pancreatic tail, then revealed and ligated the spleen artery if CDFI showed that most spleen artery segments were located behind the pancreas. The spleen pedicle was revealed and ligated. If the spleen pedicle was distributed, the surgeon cut off the secondary vessels. However, the trunk of spleen pedicle was cut off directly if it was magistral. Finally, all ligaments around the spleen were cut off and the whole spleen was resected. There were no intra-operative complications. Anatomic parameters of spleen were recorded.

Comparisons

Imaging findings were used to assess the preoperative strategy and retrospectively compared with operative findings.

Statistical analysis

The number and constituent ratio of anatomic parameters recorded by preoperative CDFI were compared with those by intra-operative telerecording. $P < 0.05$ was considered statistically significant.

RESULTS

Imaging results of CDFI

By adopting cross section below left costal margin, CDFI detected four different adjacent relations between three-fourths of the distal segments of spleen vessels and pancreas and two anatomic types of spleen pedicle end. The number and constituent ratio of the

Table 1 Comparison of parameters recorded by preoperative CDFI and intra-operative telerecording n (%)

Anatomic parameters	CDFI	Intra-operative telerecording	χ^2	P
Anatomic types of the end of spleen vessels				
Distributed type	23 (63.9)	25 (69.4)	0.25	0.617
Magistral type	13 (36.1)	11 (30.6)		
Adjacent relationships between the distal three-fourths segments of spleen vessels and pancreas				
Type I	16 (44.5)	17 (47.2)		
Type II	8 (22.2)	6 (16.7)	0.677	0.879
Type III	5 (13.9)	4 (11.1)		
Type IV	7 (19.4)	9 (25.0)		

different anatomic parameters are listed in Table 1. The appearance of each anatomic parameter on CDFI was described and classified as types 1-4 (Figure 1A-D) and distributed and magistral types (Figure 2A-B). In type I, the limpid spleen arterial blood stream signal was detected constantly in front of the distal pancreatic body or tail and eventually the signal increased and distributed into spleen like a tree (Figure 1A). In type II, the color blood stream signal put forth from the rear of the pancreatic body passed by the pancreatic tail and went up or down to the hilum of spleen (Figure 1B). In type III, the blood stream signal was detected in front of the pancreatic body and suddenly disappeared in the rear of pancreatic tail (Figure 1C). In type IV, the obvious blood stream signal was not detected in front of pancreas although the probe was completely removed. Nevertheless, the vague color signal was found leading to spleen behind pancreas (Figure 1D). In distributed type, two or three color signals of scattering blood stream were detected leading to the hilum of spleen beside the pancreatic tail without signal of main blood stream (Figure 2A). In magistral type, the limpid color signal of main blood stream led to the hilum of spleen beside the pancreatic tail but the evident signal of branches was hard to be detected (Figure 2B).

The diameters of spleen artery and vein detected by CDFI were 0.46 ± 0.09 cm (range, 0.40-0.60 cm) and 0.85 ± 0.35 cm (range, 0.50-1.60 cm), respectively.

Comparison of parameters recorded by preoperative CDFI and intra-operative telerecording

To compare the number and constituent ratio of the parameters recorded by CDFI and telerecording during LS; there was no significant statistical difference between them (Table 1).

DISCUSSION

CDFI is the latest diagnostic technique for the detection of heart and blood vessels without trauma by using Doppler principle combined with B model imaging and M model echocardiogram. Furthermore, CDFI can display the direction and relative velocity of blood stream and provide temporal and spatial information of blood vessels[7]. With a higher sensitivity and accuracy of

Figure 1 Sonogram and conceptual diagram of relationships between spleen vessels and pancreas. A: All spleen artery segments were located at the antero-superior border of pancreas (Type Ⅰ); B: One-fourth of the distal spleen artery segments were located at the antero-superior border of pancreas (Type Ⅱ); C: Two-fourths of the distal spleen artery segments were located behind or in the pancreas (Type Ⅲ); D: Three-fourths of the distal spleen artery segments were located behind or in the pancreas (Type Ⅳ).

Figure 2 Sonogram and conceptual diagram of the spleen pedicle showing three isolated branches of spleen artery (A) (the distributed type) and the main stem of transparent spleen vessels (B) (the magisterial type).

diagnosis, CDFI can display 2-dimentional blood stream images directly and quickly[7,8]. CDFI has been used to prospectively assess resectable carcinoma in the head of pancreas and peri-ampulla since it can detect the tumor and blood vessels around it[9-11].

The spleen artery originates from the celiac artery and is divided into a segment upon the pancreas, a segment in the pancreas, a segment in front of the pancreas and a segment before the hilum of the spleen. One-fourth of the sub-terminal spleen artery segment keeps away from the pancreas. On the contrary, three-fourths of the distal pancreatic and spleen vessel segments are close to each[12-14]. In this study, the adjacent relations between spleen vessels and the pancreas were detected by preoperative CDFI. Four types of segment were found on CDFI. In type Ⅰ, three-fourths of the distal segments walked along the superior border of the pancreas constantly from celiac artery to hilum of spleen. In type Ⅱ, two-fourths of the middle segments were located behind or in the pancreas while one-fourth of the distal segments were located at the antero-superior border of the pancreas. In type Ⅲ, two-fourths of the distal segments walked behind or in the pancreas. In type Ⅳ, three-fourths of the distal segments were located behind or in the pancreas. Most adjacent relations belonged to type Ⅰ (approximately 45%), but the other types are consistent with those reported in the latest literature[13,14].

The anatomy of the spleen artery can be divided into magistral type and distributed type according to Michels' classification[15,16]. In this study, CDFI revealed that the anatomy of the spleen pedicle could also be divided into magistral type and distributed type. About 70% belonged to distributed type and 30% belonged to magisterial type. The overall categorization accuracy

of spleen arterial geography was perfect according to Michels' classification.

Since hemorrhage is the major reason of conversion during LS, which is closely related to trauma of spleen pedicle and segment[17-20], operation can be performed safely and effectively if the surgeon fully understands the anatomic information of the spleen vessels[21]. In this study, the anatomic types of spleen pedicle and the adjacent relations between spleen vessels and pancreas were detected by preoperative CDFI and compared with the actual anatomy during LS. The results showed that their constituent ratio had no significant statistical difference and the coincidence rate almost reached 92% (23/25), suggesting that preoperative CDFI provides significant anatomic information of the spleen, thus operative procedures can be performed for type I and type II spleen artery segments, the trunk of spleen artery can be ligated to control intra-operative hemorrhage and megalosplenia[5,22-24]. For type III and type IV spleen artery segments, surgeons should elevate the anus perineum of spleen, separate anadesma tissue around the pancreatic tail and reveal the spleen pedicle.

In regard to the anatomic types of spleen pedicle, CDFI may lead surgeons to hilar approach strategy, particularly during the learning curve time. Surgeons may use the vascular stapler to ligate the trunk of spleen pedicle directly when a magisterial type of vascularization is present, and use clips to separate and ligate the secondary vessels of spleen pedicle when the distributed type is present, which prevents damage to the pancreatic tail and decreases the incidence rate of spleen fever[25]. In addition, surgeons can judge the trunk or the branches of spleen vessels to be ligated according to the diameters of spleen vessels shown by CDFI.

In our study, CDFI was limited to the body corresponded to the caudal extension of the spleen, which prevented a complete assessment of the remote spleen vessels.

Individual operation procedure can be formed according to the anatomic parameters of spleen provided by preoperative CDFI which can increase the safety and shorten intra-operative hemorrhage rate.

ACKNOWLEDGMENTS

COMMENTS

Background

Laparoscopic splenectomy can be performed safely and effectively only when surgeons are familiar with the anatomy of spleen vessels. Color Doppler imaging plays an important role in location of target vessels. The value of color Doppler flow imaging (CDFI) for spleen micro-invasive operation was explored in this study.

Breakthroughs

Conversion often occurs during laparoscopic splenectomy which is closely related to trauma of pancreas and intra-operative hemorrhach. Since methods such as magnetic resonance angiography may result in additional traumas and heavy economic burden on the patients, they are often not used. However, color Doppler flow imaging (CDFI) can provide anatomic information of spleen vessels not leading to trauma, thus make laparoscopic splenectomy more safe and effective.

Applications

Individual operative procedures can be formed according to the anatomic parameters of spleen provided by preoperative CDFI. As a commonly used examination, CDFI may have an application prospect in micro-invasive surgery of spleen.

Terminology

CDFI is the latest diagnostic technique for the detection of heart and blood vessels without trauma by use of Doppler principle combined with B model imaging and M model echocardiogram. Furthermore, CDFI can display the direction and relative velocity of blood stream and provide temporal and spatial information of blood vessels.

Peer review

In this manuscript, the authors evaluated and classified the anatomy of spleen vessels into four types and two large categories based on the preoperative CDFI and compared the results with intra-operative recordings. The results are acceptable and helpful. The statistical analysis and all figures are adequate.

Abstract

Endometriosis is the ectopic growth of viable endometrium outside the uterus, affecting approximately 7% of females. It commonly affects pelvic structures including the bowel. Perforation of the colon by endometriosis is very rare and the patients generally present with an asymptomatic or painful pelvic mass, often in the left iliac fossa. Our patient presented acutely unwell and her symptoms were more suggestive of pyelonephritis or diverticulitis. We therefore report an unusual cause of acute abdomen. The purpose of the following case report is to elucidate certain diagnostic and therapeutic problems of the disease, concerning both surgeons and gynaecologists. In summary, intestinal endometriosis should be considered in the differential diagnosis of all post-menarche women with episodic gastrointestinal symptoms. A past history of endometriosis or co-existent gynaecological symptoms should increase the index of suspicion, and laparoscopy prior to formal laparotomy should be considered. Our patient, in retrospect, had a history of mild endometriosis, but we feel that this case serves as a reminder of a rare, but important, differential diagnosis of acute abdomen in females.

INTRODUCTION

Endometriosis is the ectopic growth of viable endometrium outside the uterus, affecting approximately 7% of females. It commonly affects pelvic structures including the bowel. Perforation of the colon by endometriosis is very rare and the patients generally present with an asymptomatic or painful pelvic mass, often in the left iliac fossa. Our patient presented acutely unwell and her symptoms were more suggestive of pyelonephritis or diverticulitis. We therefore report an unusual cause of acute abdomen. The purpose of the following case report is to elucidate certain diagnostic and therapeutic problems of the disease, concerning both surgeons and gynaecologists.

CASE REPORT

The patient, a previously fit and well 44 years old female, presented with a 10 d history of worsening colicky pain in the left flank and iliac fossa. She had suffered form mild endometriosis in the past. On examination, she was pyrexial (39℃) with guarding over a mass in the left iliac fossa. Initial investigations revealed a white blood cell count of $22\,000$ per mm^3 and a urine dipstick weakly positive for blood, proteins, ketones and negative for beta-human chorionic gonadotropin. An urgent ultrasound suggested mild pelvicalyceal dilation on the left but a subsequent intravenous pyelography (IVP) was normal. A provisional diagnosis of a diverticular abscess was made and an emergency laparotomy was performed.

At surgery, a large endometriotic mass arising from the left fallopian tube and ovary, which had adhered to the sigmoid colon and then perforated it, was found. A left hemicolectomy with a proximal colostomy was performed and the endometriotic mass resected. The distal lumen of the bowel was closed with staples. Due to the large amount of peritoneal contamination, the wound was initially left open and underwent a delayed primary closure 9 d later. Postoperatively, the patient

made a steady recovery, initially requiring total parenteral nutrition. The distal part of her wound broke down and was allowed to heal by secondary intention. Colostomy was closed after three months and was referred to the gynaecologists for further management.

Following review by the gynaecologists, the patient was placed on the gonadotrophin releasing hormone agonist nafarelin, which is administered as a nasal spray, and placed on hormone replacement therapy with Premique [conjugated oestrogens (equine) 625 mg and medroxyprogesterone acetate 10 mg]. A combined procedure of hysterectomy and bilateral salpingo-oophrectomy (BSO) was planned for definitive management.

PATHOLOGY

The segment of excised sigmoid colon measured about 22 cm in length and up to 5 cm in external diameter. The colonic mucosa was oedematous with haemorrhagic mottling. An elongated fusiform cystic lesion or abscess was noted in the pericolic fat, measuring approximately 12.5 cm in length and 4 cm in transverse diameter, with a haemorrhagic lining. Approximately 6 cm away from this area was another cystic space, about 0.6 cm in diameter, which appeared to extend from the serosal surface of the specimen into at least the submucosa of the colon. Mucinous material was present within the latter area.

On histological examination, the smaller of the pericolic cavities was found to be an abscess communicating with the colonic lumen *via* a narrow channel. This was lined mainly by oedematous and acutely inflamed granulation tissue and degenerated endometriod type epithelium, together with macrophages filled with brown pigment, consistent with haemosiderin, scattered along the wall. Further areas of endometriotic glands and stroma were present in the adjacent pericolic fat. These features confirmed the clinical suspicion of a colonic perforation caused by endometriosis (Figure 1).

The section of the much larger pericolic abscess showed only acutely inflamed granulation tissue lining its cavity. Endometriotic tissue was not identifiable in the wall of this abscess, although, based on the features of the other abscess cavity, it is likely that also this larger abscess was the result of endometriosis. The overlaying colonic submucosa and mucosa were markedly oedematous and acutely inflamed. Extensive endometriosis was also present within the muscularis propria at the site of, and adjacent to, one of the colonic mucosal resection margins.

DISCUSSION

Endometriosis refers to extrauterine location and growth of endometrial tissue. Intestinal endometriosis occurs in 12% to 15% of cases, most often affecting those segments located within the pelvis, such as the terminal ileum, the appendix, the sigmoid colon and the rectum, both above and below the peritoneal reflection. The most common sites are the rectosigmoid (up to 73% of

Figure 1 Histology findings. A: A low-power image of the colonic wall, with a few endometrial glands and stroma embedded in the muscular layer; B: A high-power view of the colonic wall, with endometrial glands and stroma embedded in the smooth muscle of the colon.

cases) and rectovaginal septum (13%). It predominantly involves the extra mucosal layers[1].

Intestinal endometriosis usually takes the form of asymptomatic, small and superficial serosal implants. However, under cyclical hormonal influences, these implants may proliferate and infiltrate the bowel wall. Cyclical haemorrhage from the endometrioma causes an intense localised fibrotic reaction in the bowel wall and the formation of strictures. Serosal involvement results in the formation of adhesions to neighbouring pelvic structures and bowel loops. This may result in intestinal obstruction with recurrent abdominal pain and alteration in bowel habits.

Endometriosis has also been reported in more distant locations, such as lungs, pleura and the umbilicus. Although the aetiology is uncertain, several hypotheses have been proposed concerning how the ectopic tissue reaches these locations, the most widely accepted being retrograde menstruation, although metaplastic change or metastatic spread may also occur[2].

Despite extensive serosal and intramural involvement, the intestinal mucosa usually remains intact and the endometrial perforation of the affected bowel is a very rare complication, which generally occurs in pregnant females. Haufler[3] first reported it in 1931 and, overall, we could find only seven cases of bowel perforation due to intestinal endometriosis in the literature. Six of them concerned pregnant women and in three cases the perforation involved their sigmoid colon.

Haufler[3] described a jejunal perforation due to

rupture of an endometriotic cyst during the sixth month of pregnancy in a 30-year old woman. In 1955, Henriksen[4] briefly mentioned a case of sigmoid perforation in his series of 1000 cases of endometriosis. Clement[5] in 1977, Rud[6] in 1979, and, most recently, Schweitzer[7] also reported similar cases of sigmoid colonic perforation secondary to endometriosis during pregnancy. Gini et al[8] in 1981, reported a case of appendiceal rupture through endometriotic tissue during the 35th wk of gestation. Most recently, Floberg et al[9] reported a 41-wk pregnant woman who perforated an endometriotic area of the sigmoid colon immediately postpartum.

A review of these reports reveals that most of the bowel wall, particularly the muscular layers, was replaced by endometriotic tissue. The most commonly reported symptom was intermittent crampy abdominal pain. These symptoms may not coincide with the menstrual cycle. McArthur and Ulfelder[10] observed that the area of endometrium had become decidualized and enlarged during the first trimester, and had undergone decidual necrosis with contraction during the third trimester. After pregnancy, there usually was a continued reduction in the size of the endometriotic lesions. This shrinkage may weaken the affected tissues and lead to rupture, particularly in the third trimester. This corresponds to the time of rupture in most of the previously reported cases.

Our present case differs from the previous reports in that the perforation occurred in a nonpregnant woman.

The treatment of uncomplicated intestinal endometriosis depends on the patient's age and intention to conceive. Bowel resection is indicated if there are symptoms of obstruction or bleeding, and if malignancy cannot be excluded. In patients of child-bearing age, resection of the involved colon followed by hormonal treatment may be sufficient; otherwise, hysterectomy and bilateral oophorectomy is the treatment of choice.

In summary, intestinal endometriosis should be considered in the differential diagnosis of all post-menarche women with episodic gastrointestinal symptoms. A past history of endometriosis or co-existent gynaecological symptoms should increase the index of suspicion, and laparoscopy prior to formal laparotomy should be considered. Our patient, in retrospect, had a history of mild endometriosis, but we feel this case serves as a reminder for a rare but important differential diagnosis of acute abdomen in females.

Abstract

We report a case of primary localized malignant biphasic mesothelioma of the liver in a 66-year-old man associated with asbestosis. The tumor was detected as a hepatic nodule, 4 cm in diameter, in the right lobe (S8 segment) on CT scan. Histopathological examination demonstrated an intrahepatic tumor with central necrosis consisting of a papillary epithelioid pattern on the surface of the liver, microcystic (microglandular or adenomatoid) pattern mainly in the subcapsular area and sarcomatoid pattern intermingled with microcystic pattern in the major part of the hepatic nodular tumor. Tumor cells, especially of epithelioid type, showed distinct immunoreactivity for mesothelial markers (WT-1, calretinin, D2-40, CK5/6, mesothelin, thrombomodulin) and no immunoreactivity for epithelial (adenocarcinoma) markers (CEA, CD15, BerEP4, BG8, MOC31). P53 immunoreactivity was detected focally in papillary epithelioid tumor cells and extensively in microcystic and sarcomatoid components, suggesting that the papillary epithelioid mesothelioma arose on the surface of the liver, and tumor cells showing microcystic and sarcomatoid patterns invaded and grew into the liver. To date, this is the first case of primary localized malignant biphasic mesothelioma of the liver, since all three primary hepatic mesotheliomas reported so far were epithelioid type.

INTRODUCTION

Malignant mesothelioma is a rare neoplasm of mesothelial cells arising most frequently in the parietal or visceral pleura and much less commonly in the peritoneum and pericardium[1-3]. In about 80%-90% of these patients, malignant mesothelioma is related to occupational exposure to asbestos in the air. The latent development period is long, about 25-40 years after initial exposure[3]. The disease is more common in men with a mean age of 58 years, with a male to female ratio of 4:1[1,4]. Mesothelioma occurring at various sites other than pleura, peritoneum and pericardium has been reported previously[4-7]. The mesothelial nature of the lesions is supported by immunohistochemical or electron microscopic evidence[3]. Most malignant mesotheliomas grow widely over the serosal membrane surfaces and tumors in the later stages eventually encase organs surrounding the involved site. Diffuse malignant mesothelioma typically has a poor clinical course with death occurring in most patients within 2 years of diagnosis[3]. In contrast, Allen *et al*[8] have recently reported a series of localized malignant mesotheliomas as uncommon sharply circumscribed tumors of the serosal membranes with the microscopic appearance of

diffuse malignant mesothelioma. They proposed that localized malignant mesotheliomas should be separated from diffuse malignant mesotheliomas because of their localized presentation, quite different biological behavior, and far better prognosis[8].

Primary malignant mesothelioma arising in the liver is very rare and there have been only 3 adult cases in previous reports[9-12], to our knowledge. In addition, there is one reported case of malignant cystic mesothelioma in an infant[11]. Although several primary hepatic tumors termed "localized fibrous mesotheliomas" have been reported[2,13-17], this type of tumor is better classified as a solitary fibrous tumor rather than mesothelioma retrospectively, because of the characteristic CD34 immunoreactivity[16] and limited evidence of a mesothelial nature[18].

In this report, we describe a case of primary localized malignant biphasic mesothelioma of the liver showing a nodular hepatic tumor and histologically sarcomatoid and epithelioid patterns in a 66-year-old man associated with asbestosis, and review the literature on primary malignant mesothelioma of the liver.

CASE REPORT

Clinical Findings

The patient (66-year-old man) had been followed up for hypertension and pulmonary asbestosis caused by occupational exposure to asbestos. At the age of 66, CT revealed a hepatic nodule, 4 cm in diameter, in the S8 segment of the liver (Figure 1) on periodic examination for pulmonary asbestosis. The hepatic nodule was located just under the diaphragm, wedge-shaped and slightly low density compared to the surrounding hepatic parenchyma on plain CT. Peripheral staining of the hepatic nodule was seen on enhanced CT (Figure 1). Cholangiocarcinoma or inflammatory pseudotumor was suspected from CT findings. The findings signifying pulmonary asbestosis showed on chest X-ray and chest CT as previously detected, but there were no new lesions suggesting lung cancer or pleural mesothelioma (Figure 1). There was no finding suggesting peritoneal mesothelioma or a primary mesothelioma of the tunica vaginalis testis. Examination using [18F]-fluoro-deoxy-D-glucose positron emission tomography (FDG-PET) revealed no additional lesions other than the hepatic tumor. At that time, the serum levels of ALT, AST, Al-P, r-GTP and LDH were within the normal range. AFP, CEA and CA19-9 were negative. Viral markers related to hepatitis B virus (HBV) and hepatitis C virus (HCV) infection were negative. The patient was not a drinker. The needle biopsy revealed that the hepatic tumor was a sarcomatoid malignant tumor with immunoreactivity for cytokeratin and vimentin, and with faint and focal immunoreactivity for calretinin and D2-40. The papillary and microcystic components were not included in the biopsy. The patient underwent a hepatic segmentectomy (S8). A few sclerotic nodules attached to the diaphragm were also removed during the operation. Recurrence and metastasis of the tumor have not been detected by 6 mo after the operation.

Figure 1 Radiological findings. A: Plain CT showed a low-density mass (asterisk) in S8 segment of the liver; B: The periphery of the mass (asterisk) was enhanced in the early phase of enhanced CT, suggesting abundant blood supply; C: Chest X-ray showed pulmonary asbestosis and pleural thickening, but there were no new lesions suggesting lung cancer or pleural mesothelioma.

Gross pathology examination

The resected specimen consisted of a 12.8 cm × 17 cm × 7 cm portion of the liver (445 g). On the surface faced to the diaphragm, a firm, white and slightly depressed lesion measuring 4.2 cm × 3 cm was identified (Figure 2). On sectioning of the liver, a yellowish-white tumor of 4.4 cm × 3.8 cm was identified just under the hepatic capsule. The tumor had well-defined borders and contained central necrosis (Figure 2). The tumor mainly grew within the hepatic parenchyma, not in the surface of liver, and therefore adhesion did not occur between the diaphragm and hepatic capsule. There were no daughter nodules in the liver and the surgical margin was free from tumor. The background liver appeared normal macroscopically.

Histologic findings

Hematoxylin and eosin stained sections showed a

Figure 2 Gross appearance of the tumor. A: A firm, white and slightly depressed lesion (asterisk) measuring 4.2 cm × 3 cm was identified on the liver surface. B: Cross section of the tumor in the liver. A yellowish-white tumor of 4.4 cm × 3.8 cm was identified just under the hepatic capsule (asterisk). The tumor had well-defined borders and an area of central necrosis. Bar indicates 1 cm.

tumor composed of three main components: (1) sarcomatoid, (2) papillary epithelioid and (3) microcystic (microglandular or adenomatoid) (Figure 3). The sarcomatoid component was predominant and was composed of tumor cells showing trabecular structures separated by bands of fibrous tissue (Figure 3A). The tumor cells had abundant eosinophilic or clear cytoplasm, indistinct cytoplasmic borders, round and atypical nuclei with vesicular fine chromatin and variably sized nucleoli (Figure 3A). There were many mitoses and atypical mitoses in tumor cells. The tumor contained broad coagulation necrosis. Although the tumor had well-defined borders, there was no fibrous capsule and hepatocytes and bile ducts were entrapped in infiltrating tumor cells. In the white lesion on the surface, papillary proliferation of epithelioid tumor cells was identified. Epithelioid cells had eosinophilic cytoplasm with bland nuclei and distinct nucleoli. Near the surface, tumor cells showed microcystic structures with a lace-like, adenoid cystic or signet ring appearance (microcystic, microglandular or adenomatoid component). The microcystic component was located adjacent to the papillary epithelioid component (Figure 3B). Furthermore, microcystic component was also intermingled with the sarcomatoid component even in the deeper area adjacent to the surrounding hepatic parenchyma (Figure 3C). The background liver showed mild steatofibrosis and there was no intrahepatic metastasis of the tumor. The biopsy site could not be identified by gross and histological examination in the surgical specimen.

A few sclerotic nodules attached to the diaphragm were composed of dense hyalinized fibrous tissue resembling pleural plaques. There were no tumor cells in the nodules.

Immunohistochemical and special stains
Formalin-fixed, paraffin-embedded sections were stained with periodic acid-Schiff (PAS) with and without diastase digestion, and alcian blue (pH 2.5) with and without hyaluronidase digestion. Immunohistochemical stains were performed using the Envision methods

Figure 3 Histologic features of the tumor. A: Sarcomatoid component was predominant and was composed of tumor cells with abundant eosinophilic or clear cytoplasm, indistinct cytoplasmic borders, round and atypical nuclei with vesicular fine chromatin and variably sized nucleoli; B: Papillary proliferation of epithelioid tumor cells was identified on the surface of the tumor. Epithelioid cells had eosinophilic cytoplasm with bland nuclei and distinct nucleoli. Arrows indicate microcystic (microglandular or adenomatoid) component; C: In the area near the surface, a microcystic (microglandular or adenomatoid) component showing microcystic structures with lace-like, adenoid cystic or signet ring appearance was detected (arrows) (HE × 400).

(Dako, Carpinteria, CA, USA) and antibodies as described previously[19]. The antibodies included WT-1 (6F-H2, Dako), calretinin (polyclonal; no dilution; Nichirei, Tokyo, Japan), D2-40 (D2-40; dilution 1/100; Dako), CK5/6 (D5/16B4, dilution 1/50; Dako), mesothelin (5B2, dilution 1/20; Lab vision, Fremont, CA, USA), thrombomodulin (1009, dilution 1/20; Dako), vimentin (3β4, dilution 1/600; Dako), CD34 (Immu133, dilution 1/200; Immunotech, Fullerton, CA, USA), p53 (DO-7; dilution 1/100; Dako), epithelial membrane antigen (EMA) (E29; dilution 1/200; Dako), MUC1 (DF3, Toray-Fuji Bionichs, Tokyo, Japan), Ber-EP4 (Ber-EP4; no dilution; Neomarkers, Fremont, CA,

USA), cytokeratin (polyclonal; dilution 1/600; Dako), MOC-31 (MOC-31; dilution 1/50; Dako), CK7 (OV-TL 12/30; dilution 1/50; Dako), CK19 (RCK108; dilution 1/50; Dako), CEA (II-7, dilution 1/100, Dako), CA19-9 (C241:5:1:4, dilution 1/100; Novocastra, Newcastle, UK), CD15 (C3D-1; dilution 1/50; Dako), BG-8 (F-3; dilution 1/200, Signet, Dadham, MA, USA), HepPar1 (OCH1E5, dilution 1/100; Dako). Heat-induced epitope retrieval was used for all antibodies except CD34, MUC1, CA19-9 and BG-8. Appropriate positive and negative controls were used throughout.

Alcian blue showed positive staining on the surface of papillary epithelioid cells and the lumen of microcystic component, and this positive staining was sensitive to digestion with hyaluronidase. Neutral mucin stained by PAS stain was not detected on the surface of papillary epithelioid cells or the lumen of the microcystic component. Immunohistochemical stains confirmed the mesothelial features of the tumor showing membranous D2-40, mesothelin and thrombomodulin and nuclear WT-1, in addition to nuclear and cytoplasmic calretinin immunoreactivity, mainly in the papillary epithelioid and microcystic components (Figure 4). Sarcomatoid tumor cells showed focal immunoreactivity for WT-1, D2-40 and calretinin. When we examined the immunoreactivity for D2-40 and calretinin in 23 intrahepatic cholangiocarcinoma samples for comparison, none of the cholangiocarcinoma showed nuclear immunoreactivity for calretinin or immunoreactivity for D2-40. Four cholangiocarcinomas showed weak cytoplasmic immunoreactivity for calretinin. The tumor cells showed focal immunoreactivity for CK5/6. The tumor cells showed strong immunoreactivity for vimentin, CK7, CK19 and polyclonal cytokeratin (Figure 4). Strong EMA and MUC1 immunoreactivity was seen on the surface of papillary epithelioid cells, the lumen of the microcystic component and part of the sarcomatoid component (Figure 4). Sarcomatoid and microcystic components showed strong nuclear immunoreactivity for p53 (Figure 4). A few positive cells were also seen in the papillary epithelioid component. The tumors showed no immunoreactivity for CEA, Ber-EP4, MOC-31, CA19-9, CD15, BG-8, CD34 and HepPar1.

DISCUSSION

Primary malignant mesothelioma arising in the liver is rare and is currently not listed in the World Health Organization classification of hepatic tumors[20]. Review of the literature disclosed only three previously reported adult cases of primary malignant mesothelioma[9,10,12]. The previously reported cases were two men[9,10] and a woman[12], ranging in age from 54 to 64 years old (mean: 60 years old). Two patients had no history of asbestos exposure[9,10] and there was no indication in one patient[12]. One case was associated with cirrhosis due to hepatitis C viral infection[9]. All tumors arose in the right hepatic lobe, located in the subcapsular area of the liver and were 3.2 to 12 cm in diameter (mean: 7 cm).

Histologically malignant mesotheliomas conform to one of three patterns: epithelial (the most common type), sarcomatoid and biphasic (mixture of epithelioid and sarcomatoid) types[1,3,4]. All three reported mesotheliomas arising in the liver were of the epithelioid type[9,10,12]. One tumor was composed of sheets of cytologically bland polygonal cells containing multiple gland-like spaces and microcysts lined by cuboidal to columnar epithelium[12]. The other tumors displayed the tubular[9,10] and papillary proliferation[10] of epithelioid cells with a desmoplastic stroma[9] or surrounded by a densely mixed inflammatory infiltrate[10]. A panel of immunohistochemical markers was applied for differential diagnosis in all three tumors as discussed below and electron microscopic findings suggested a mesothelial cell origin in two tumors[10,12]. One tumor was speculated to originate from mesothelial cells of Glisson's capsule[12]. However, no tumors were exposed to the peritoneal cavity on the hepatic capsule[9,10,12] and were thought to be localized mesothelioma of the liver, not to be localized mesothelioma of the peritoneum with hepatic invasion[9,10,12].

In this report, we have described for the first time a malignant mesothelioma of biphasic type arising in the liver in a 66-year-old man with a history of asbestos exposure. The tumor was detected as a hepatic nodular lesion in a follow-up examination for asbestosis and there was no other lesion suggesting primary tumor in the pleura and peritoneum. The tumor arose in the right lobe (S8 segment) of the liver in accordance with the reported cases[9,10,12]. In the major part of the hepatic nodular tumor, the tumor cells showed a sarcomatoid pattern and a microcystic pattern was intermingled with the sarcomatoid pattern. Tumor cells showed a papillary epithelioid pattern on the surface of the liver and a microcystic pattern was also seen in the subcapsular area near the surface. Since these tumor cells show the profile of mesothelioma even in the deeper area, this tumor is diagnosed as a malignant mesothelioma, not as another type of tumor with reactive mesothelial hyperplasia. The tumor in the present case may be categorized into the entity of localized malignant mesothelioma because of localized presentation[8], and better prognosis may be expected in the patient.

The origin of tumor cells showing mesothelial features in the liver is not clear, since mesothelial cells are not present in livers under normal physiological conditions. The mesothelioma cells might originate from other types by transition, although there has been no evidence of transition to mesothelial cells, so far. In contrast to the reported cases in which tumor cells did not expose to the peritoneal cavity, a papillary epithelioid component was also seen on the surface of the hepatic capsule adjacent to the hepatic nodular tumor. This finding suggests that the present tumor may originate from mesothelial cells of the Glisson's capsule which subsequently invaded into the liver. A reported tumor was also speculated to originate from mesothelial cells of the Glisson's capsule, although there was no evidence[10]. From a standpoint of p53 immunoreactivity, a few

Figure 4 Immunohistochemical and special stains. Alcian blue (pH 2.5) showed positive staining on the lumen of adenomatoid tumors (A). This positive staining was sensitive to digestion with hyaluronidase (B). Nuclear WT-1 immunoreactivity (arrows) was detected focally in sarcomatoid (C), papillary epithelioid (D) and microcystic (E) components. Immunostaining for WT-1 and methyl green. Sarcomatoid tumor cells showed focal membranous immunoreactivity for D2-40 (F). Membranous D2-40 immunoreactivity was detected in the papillary epithelioid (G) and microcystic (H) components. Immunostaining for D2-40 and hematoxylin. Sarcomatoid tumor cells showed focal and rather weak immunoreactivity for calretinin (I). Nuclear calretinin immunoreactivity (arrows) was detected in the papillary epithelioid (J) and microcystic (K) components. Immunostaining for calretinin and hematoxylin. Immunoreactivity for CA19-9 was not detected in sarcomatoid (L), papillary epithelioid (M) and microcystic (N) components. The apical surface of the entrapped bile duct showed immunoreactivity for CA19-9 (L, upper right corner). Immunostaining for CA19-9 and hematoxylin. Sarcomatoid (O) and microcystic (P) components showed strong nuclear immunoreactivity for p53. A few papillary epithelioid cells showed nuclear immunoreactivity for p53 (Q). (Immunostaining for p53 and hematoxylin, × 400).

cells showed faint p53 immunoreactivity in papillary epithelioid components, whereas most tumor cells showed strong p53 immunoreactivity in microcystic and sarcomatoid components. Therefore, it is conceivable that the mesothelioma of papillary epithelioid type initially arose on the surface of the liver and tumor cells showing microcystic and sarcomatoid patterns invaded and grew into the liver with more aggressive features originating from p53 mutation in the present case. Since this tumor was located on the hepatic capsule just under the diaphragm and compressed, it may be easier for tumor cells to grow into hepatic parenchyma than spreading in the surface of the liver, and therefore adhesion did not occur between the diaphragm and hepatic capsule. Taken together, a localized mesothelioma of the liver may arise as a localized mesothelioma of the Glisson's capsule (peritoneum) and may subsequently show an intrahepatic nodular growth.

The differential diagnosis of primary malignant mesothelioma of the liver includes primary liver cancers and metastases from pleural malignant mesothelioma. In particular, it is important but may be difficult to distinguish from intrahepatic cholangiocarcinoma. Since both malignant mesothelioma of epithelioid type and cholangiocarcinoma show a tubular and papillary structure[3,20], a similar panel of immunohistochemical markers may be useful in the differential diagnosis between pleural mesothelioma and pulmonary adenocarcinoma, which is sometimes difficult[3,21-23]. There is no single absolute marker for mesothelioma, so far[3]; therefore, a combination of two or more positive immunohistochemical mesothelial markers (CK5/6, calretinin and Wilms tumor gene-1 (WT1)) with negative epithelial (adenocarcinoma) markers (CEA, CD15, BerEP4, B72.3, BG8, MOC31) is recommended for a diagnosis of pleural mesothelioma[3,21,23]. Since both malignant mesothelioma and cholangiocarcinoma show immunoreacitivity for CK7, CK19, polyclonal cytokeratin, EMA (a glycosylated form of MUC1) and unglycosylated form of MUC1 detected by DF3, these markers are not helpful for differential diagnosis. Recently, D2-40 was reported to be a sensitive marker for cells of mesothelial origin, and useful in the differential diagnosis of epithelioid malignant mesothelioma vs adenocarcinoma[22]. In previous reports[9,10,12], the diagnosis of primary hepatic mesotheliomas has been made based on positive immunoreactivity for calretinin[9,10,12], HBME-1[9], D2-40[10], thrombomodulin[10], vimentin[10,12] and cytokeratins[9,10,12] and negative immunoreactivity for CEA[9,10], LeuM1 (Lewis X)[9], CD34[9,10,12], CA19-9[10] and Ber-EP4[10]. There have been no reports regarding immunoreactivity for calretinin and D2-40 in intrahepatic cholangiocarcinoma, so far. In our preliminary study, cytoplasmic, but not nuclear calretinin immunoreactivity was detected in some intrahepatic cholangiocarcinomas and D2-40 imunoreactivity was not detected in any intrahepatic cholangiocarcinomas examined. Since the expression of CEA and LeuM1 (Lewis X) is less frequent in poorly differentiated intrahepatic cholangiocarcinoma[24] and

the specificity of HBME-1 for mesothelioma is rather low (45%)[21], a combination of calretinin, HBME-1, CEA and LeuM1 may not be enough for a definite diagnosis of mesothelioma in the previously reported primary hepatic mesothelioma arising in a patient with cirrhosis and chronic hepatitis C[9]. The possibility of cholangiocarcinoma associated with cirrhosis and chronic hepatitis C[25] should be excluded in the reported case[9].

In the present case, tumor cells, especially of epithelioid type, showed distinct immunoreactivity for mesothelial markers (WT-1, calretinin, D2-40, mesothelin, thrombomodulin) and no immunoreactivity for epithelial (adenocarcinoma) markers (CEA, CD15, BerEP4, BG8, MOC31). Markers suggesting other types of tumor such as CD34, CD31, HepPar1 were totally negative; therefore the tumor fulfills the immunohistochemical diagnostic criteria for mesothelioma. However, it was quite difficult to reach a final diagnosis from a needle biopsy specimen including only the sarcomatoid component with immunoreactivity for cytokeratin and vimentin, and faint and focal immunoreactivity for calretinin and D2-40. It is reported that intrahepatic cholangiocarcinoma shows only occasional sarcomatous change[20,26]. In this type, tumor cells show immunoreactivity for both epithelial markers (cytokeratins and EMA) and vimentin[20,26]. Clinical information about asbestos exposure was important to raise the possibility of mesothelioma.

In summary, we presented for the first time a localized malignant biphasic mesothelioma arising in the liver in a 66-year-old man with a history of asbestos exposure. A panel of immunohistochemical markers to distinguish pleural mesothelioma from pulmonary mesothelioma was useful for diagnosis. Malignant mesothelioma should be included in the differential diagnosis of primary hepatic tumor, especially in patients with a history of asbestosis exposure. Because of unusual localization of the tumor, a very careful histological and immunohistochemical examination was required to reach the final diagnosis in the present case. Accumulation of more cases similar to the present case is important to characterize the features of mesothelioma of the liver, including the biological behavior and the prognosis.

Abstract

Diagnostic criteria for autoimmune pancreatitis (AIP) have been proposed and used clinically because, despite its unique clinicopathological features, AIP does not have disease-specific serological tests for confirmation. However, diagnosis of a patient with pancreatic lesions mimicking cancer who deviates from these diagnostic criteria is still difficult. We present herein a patient with a variant form of AIP successfully diagnosed by fine-needle biopsy, whose response to steroid therapy was excellent. A 55-year-old Japanese man was admitted to hospital because of jaundice and pancreatic head mass. AIP was considered as one of the differential diagnoses; however, as the patient showed neither pancreatic duct narrowing nor immunological abnormalities, he did not meet the Japanese diagnostic criteria for AIP. Histopathology of the pancreatic mass demonstrated abundant infiltration by lymphocytes and interstitial fibrosis, which suggested AIP. Immunoreaction to IgG4, which is supposed to be specific to AIP, was not observed; however, response to subsequent prednisolone therapy was good, with dramatic pancreatic head mass regression. Aside from the pancreatic head mass, diffusely spreading small lesions were observed throughout the liver. The likelihood of a potential association with extrapancreatic lesions of AIP was considered and led us to carry out a liver biopsy, which revealed biliary hamartoma, also called von Meyenburg complex (VMC). As IgG4-positive plasma cell infiltration was not demonstrated in the hamartomatous regions, the hepatic condition was thought to have occurred incidentally; however, to the best of our knowledge, this is the first report in which the association between AIP and VMC was investigated and discussed.

A variant form of autoimmune pancreatitis successfully treated by steroid therapy, accompanied by von Meyenburg complex. *World J Gastroenterol* 2009; 15(5): 622-627 Available from: URL: http://www.wjgnet.com/1007-9327/15/622.asp DOI: http://dx.doi.org/10.3748/wjg.15.622

INTRODUCTION

Clinically unique chronic pancreatitis, in which autoimmune mechanisms are supposed to be involved, has been focused upon and investigated intensively over the last decade[1-3], and is now recognized as a clinical entity worldwide, autoimmune pancreatitis (AIP)[4-6]. Since disease-specific serological tests for determining AIP remain unavailable, diagnostic criteria for AIP have been proposed by incorporating characteristic clinical aspects of the disease[7-11]. Japanese criteria were established first in the world in 2002 by the Japan Pancreas Society (JPS)[7]; however, with the accumulation of clinical investigations of AIP, the JPS criteria were modified in 2006 by the Research Committee of Intractable Pancreatic Diseases (RCIPD)[9], because the concept of AIP has changed gradually with the detection of additional new clinicopathological aspects,

such as a high concentration of serum IgG4[12], a variety of extrapancreatic involvement relevant to IgG4-positive lymphoplasmacytic infiltration[13-15], and morphologically atypical localized AIP[16-19]. On revision, these new clinical findings were included in the criteria, enabling more cases to be diagnosed. However, because Japanese criteria mandate first identification of characteristic imaging, namely, narrowing of the main pancreatic duct demonstrated by endoscopic retrograde cholangiopancreatography (ERCP) and enlargement of the pancreas, in order to exclude absolutely pancreatic or biliary cancer rather than picking-up suspicious AIP patients[9], some AIP patients remain undiagnosed as a result of being unmatched with the Japanese criteria for AIP. Yet, because AIP has a favorable prognosis if steroid therapy is administered appropriately[20], we should also pay attention to atypical forms of AIP before a patient undergoes an operative procedure.

We describe herein a case of the variant form of AIP diagnosed by fine-needle aspiration biopsy, and the subsequent successful response to steroid therapy, whose primary presentation was obstructive jaundice caused by the pancreatic head mass alone, without other specific features outlined in the Japanese diagnostic criteria for AIP. In addition, the patient was found to concomitantly have biliary hamartoma (von Meyenburg complex; VMC), the initial clinical appearance of which first led us to consider them as possible extrapancreatic lesions of AIP.

CASE REPORT

A 55-year-old Japanese man was referred and admitted to our hospital for the evaluation of jaundice and a pancreatic head mass on 2 May 2007. One week before admission, the patient had visited another hospital because of body weight loss and a 1-wk history of epigastralgia, and was found to have obstructive jaundice caused by pancreatic head swelling, upon abdominal ultrasongraphy (US). Upon admission, he was 170 cm tall and weighed 57.0 kg, blood pressure was 112/62 mmHg, and temperature was 37.1℃. There was no history of drug or alcohol abuse.

Physical examination revealed no abnormal findings except for jaundice of the conjunctiva and skin. Laboratory findings on admission are shown in Table 1. Abdominal US showed obstructive jaundice caused by a hypo-echoic pancreatic head mass that measured 43 mm in diameter, which compressed the lower portion of the bile tract, and resulted in intra- and extra-hepatic dilatation of the bile duct. In addition, many irregular hyperechoic spots and comet-like tails were found to spread diffusely in the bilateral liver parenchyma (Figure 1). Upon dynamic contrast-enhanced computed tomography (CT), the pancreatic head tumor was slightly less enhanced than the other portion of the pancreas, together with irregular dilatation of the main pancreatic duct distal to the tumor, which suggested pancreas cancer. However, the distal area of the pancreas was not atrophied (Figure 2A and B).

Figure 1 Abdominal US. A: Pancreatic head mass with hypo-echogenicity, 43 mm in diameter, which compressed the lower portion of the bile duct, and resulted in upstream bile tract dilatation; B: Many tiny, diffuse hyperechoic patches or comet-like tails that suggested the presence of certain intrahepatic abnormalities, but the reason could not be elucidated.

Magnetic resonance cholangiopancreatography (MRCP) performed subsequently demonstrated intensive stenosis of the pancreatic head portion and peripheral dilatation of the common bile duct, as well as the skipped stenotic lesions of the main pancreatic duct (Figure 3). Simultaneously, on MRCP imaging, numerous hyper-intense round nodules of small diameter, presumably correlating with the US imaging of the liver, were found to be diffusely scattered throughout the liver (Figure 3). We could not perform ERCP because of the lack of an expert ERCP endoscopist in the hospital. Upon MRCP, skipped stenotic lesions of the main pancreatic duct, which was suggestive of AIP was observed; however, irregular narrowing of the pancreatic duct seen in typical AIP was not observed. The levels of tumor markers, carbohydrate antigen (CA 19-9, DUPAN-2) and carcinoembryonic antigen (CEA), were normal. Immunologically, antinuclear antibody was absent and the serum level of total IgG as well as IgG4 was within the normal range (Table 1). As we could not obtain diagnostic confirmation from these sequential atypical clinical features of AIP or pancreatic cancer, we performed US-guided percutaneous aspiration biopsy using a 21G fine needle that targeted the pancreatic head mass on 15 May 2007. Histopathological examination demonstrated marked infiltration of pancreas parenchyma by mononuclear cells and fibrosis adjacent to the lesion, which suggested a diagnosis of AIP (Figure 4A). There were no malignant cells indicating

Figure 2 Abdominal enhanced CT imaging with contrast medium in May 2007. A: Swelling of the pancreatic head like a solid tumor was shown. B: The distal portion of the main pancreatic duct was found to be irregularly dilated; however, the pancreatic body and tail were not atrophied as seen in pancreatic cancer.

Figure 3 MRCP showed proximal stenosis of the bile duct as well as the main pancreatic duct; however, narrowing of the pancreatic duct, as seen in AIP, was not demonstrated at all. A simultaneous finding was that there were many round high-intensity nodules scattered throughout the liver.

Table 1 Laboratory data			
	Normal value	May 2, 2007	July 14, 2007
WBC (White blood cell)	4000-9000/μL	10210	15350
RBC (Red blood cell)	410-530 × 10^4/μL	504	471
Hb (Hemoglobin)	14-18 g/dL	15.5	15.0
Plt (Platelet)	12-36 × 10^4/μL	33.9	23.4
TP (Total protein)	6.5-8.0 g/dL	6.8	6.9
Alb (Albumin)	3.9-4.9 g/dL	3.5	4.3
IgG (Immunoglobulin G)	870-1700 mg/dL	919	843
IgG4 (Immunoglobulin G4)	4.8-105 mg/dL	20.3	-
AST (Aspartate aminotransferase)	10-33 IU/L	49	19
ALT (Alanine aminotransferase)	4-30 IU/L	57	28
LDH (Lactate dehydrogenase)	100-230 IU/L	146	132
ALP (Alkaline phosphatase)	167-345 IU/L	992	265
γ-GTP (γ-glutamyl transpeptitase)	10-75 IU/L	140	51
TB (Total bilirubin)	0.2-1.2 mg/dL	4.6	0.7
DB (Direct bilirubin)	0-0.4 mg/dL	2.6	0.1
Amylase	30-120 IU/L	105	36
BUN (Blood urea nitrogen)	8-20 mg/dL	13	13
Cr (Creatinine)	0.6-1.1 mg/dL	0.6	0.7
CRP (C-reactive protein)	0-0.4 mg/dL	0.0	0.0

pancreatic cancer. These infiltrated cells were revealed to be mainly T lymphocytes by subsequent immuno-histochemistry (Figure 4B), which was more compatible with AIP. However, plasma cell infiltration was scarce and immunoreaction to anti-IgG4 antibodies was not seen (Figure 4C).

The patient did not fulfill the JPS diagnostic criteria for AIP. However, as the presence of pancreatic cancer cells was histopathologically ruled out and the likelihood of spontaneous regression of obstructive jaundice seemed to be poor, we started oral prednisolone (PSL) therapy on 18 May 2007. Once PSL at an initial daily dose of 30 mg was introduced, prompt regression of the pancreatic head mass and improvement of bile and pancreatic duct dilatation was achieved (Figure 5A and B).

Apart from the pancreatic head mass, the presence of intrahepatic anomalies was suspected from the US and MRCP imaging. As AIP is known to show frequently a variety of extrapancreatic involvements, we carried out liver biopsy in order to elucidate the identity of the diffusely spreading aberrant echoes on US and small nodules seen on MRI, in addition to investigating the possible association with AIP. Histopathological examination of the hepatic parenchyma revealed aggregation of irregular-shaped cystic dilated bile ducts embedded in fibrous stroma, with minimal inflammatory reaction (Figure 6), and biliary hamartoma, also called VMC. Additionally, we performed immuno-histochemistry using anti-IgG4 antibody, which resulted in negative interactions in those areas.

All laboratory abnormalities seen upon admission were normalized by 14 July 2007 (Table 1), and the patient remains in a good condition without recurrence at the present time, under maintenance therapy with 5 mg/d PSL.

DISCUSSION

This case report presents notable clinical information for dealing with AIP patients. First, the existence of a variant form of AIP not meeting the diagnostic criteria was verified by fine-needle aspiration biopsy, together with a subsequent dramatic good response to steroid therapy. Second, concomitant development of AIP and VMC was investigated and discussed for the first time, even though this condition might occur incidentally.

Sets of diagnostic criteria for AIP have been proposed by integrating several known unique morphological, immunological and histopathological characteristics of AIP. Currently, four major sets of diagnostic criteria for AIP have emerged from Japan[9], Italy[8], Korea[10] and the

Figure 4 Histopathology of a specimen taken from the pancreatic head mass showed no malignant cells that indicated cancer. A: Marked infiltration of pancreatic parenchyma by lymphocytic mononuclear cells, as well as interstitial fibrosis suggested a diagnosis of AIP (HE, × 200). B: These infiltrated cells were revealed to be mainly T lymphocytes (T-cell staining, × 200). However, the histopathology was not diagnostic without so-called LPSP with scarce plasma cell infiltration. C: Immunohistochmistry using antibody against IgG4 resulted in a negative study (IgG4 staining, × 200).

Figure 5 Abdominal enhanced CT scan with contrast medium in July 2007. As compared with CT imaging taken in May 2007, swelling of the pancreatic head had significantly regressed (A). Irregular dilatation of the main pancreatic duct had improved with the whole body bulk being reduced (B).

Figure 6 Histopathology of specimens taken from the hepatic parenchyma (PAS, × 200). Distribution of many irregular, angulated duct structures was observed. Ductal epithelium was comprised of monolayered columnar epithelium, morphologically identical to biliary epithelium, surrounded by fibrous connective tissues with minimal inflammatory change. The sequential histopathological features were considered to be bile duct hamartoma (VMC). Subsequent immunohistochemistry of the region by anti-IgG4 antibody was negative.

United States[11], and have been used clinically in each setting. However, there are some differences between each criterion for AIP that make it difficult to compare data in studies from different centers. Recently in 2008, Asian diagnostic criteria for AIP have been proposed by RCIPD and the Korean Society of Pancreatobiliary Diseases to reach an international consensus, thus enabling more cases to be accurately diagnosed and restraining the routine use of steroids for the diagnosis of AIP[21]. In the JPS criteria established in 2002[7], on the basis of the minimum consensus features of AIP required to avoid misdiagnosing malignancy, but not to pick-up suspicious cases of AIP, the demonstration of diffuse swelling of the pancreas and diffuse and irregular narrowing of the main pancreatic duct by

ERCP is stressed and is required first of all. On revision of the JPS criteria in 2006[9], more cases of AIP have been correctly diagnosed. However, in the present case, since pancreatic swelling was located in only the head portion, which resembled a solid tumor, and there were neither pancreatic duct narrowing nor immunological abnormalities including IgG4, AIP could not be definitely diagnosed even with application of the revised Japanese criteria.

There are an increasing number of reports dealing

with atypical cases of AIP with focal swelling mimicking pancreatic cancer, as well as cases that begin with focal mass and progress to diffuse swelling, which results in a typical AIP appearance[16-19]. However, the most important issue when dealing with localized mass-forming AIP is that we should differentiate it absolutely from pancreatic or biliary cancer, in order to prevent too ready use of steroids, and leaving cancer untreated under a mistaken diagnosis. With this in mind, we performed US-guided percutaneous fine-needle aspiration biopsy, which targeted the pancreatic head mass and showed massive inflammatory cell infiltration, as well as interstitial fibrosis, and denied the presence of malignant cells. Subsequent steroid therapy resulted in an excellent clinical course of the patient. As AIP is known to show favorable prognosis, as in the present case, when steroid therapy is adequately administered[20], we should also detect suspicious variant forms of AIP before a patient undergoes invasive surgery.

It is debatable whether the diagnosis of AIP can be made from pancreatic core biopsy specimens, because they often do not show the complete spectrum of diagnostic change of lymphoplasmacytic sclerosing pancreatitis (LPSP) seen in typical AIP by routine histology alone[22]. In addition, certain types of pancreatic cancer exhibit a reaction that resembles LPSP[21]. However, we think that the purpose of fine-needle aspiration biopsy is to rule out the presence of malignant cells, and to provide a basis for the introduction of steroid therapy, rather than to establish a diagnosis of AIP, when we encounter a patient with a pancreatic mass, in whom differential diagnosis is difficult. Therefore, when a patient presents with uncertain clinical features of a pancreatic tumor, the presence of AIP and pancreatic fine-needle aspiration biopsy should be considered as one of the diagnostic modalities.

As awareness of AIP increases and more cases are reported and clinically investigated, high serum IgG4 concentration has been recognized as a notable characteristic and a marker of AIP disease activity[12]. Moreover, as the presence of a variety of extrapancreatic lesions related to IgG4-positive plasma cell infiltration, such as sclerosing cholangitis[23], sialadenitis[24] and retroperitoneal fibrosis[25], becomes evident, AIP has been proposed as one of the clinical aspects of generalized autoimmune IgG4-related sclerosing disease[13-15]. Therefore, we should consider the presence of extrapancreatic lesions of AIP when encountering unexplained manifestations outwith the pancreas. In the present case, the initial features of diffusely scattered intrahepatic lesions demonstrated on US and MRCP first led us to consider them to be possible extrapancreatic lesions of AIP. However, subsequent liver biopsy showed the presence of a unique group of cystic and dilated bile ducts surrounded by a dense fibrocollagenous stroma, which was revealed to be biliary hamartoma. Biliary hamartomas, also referred to as VMC, are benign liver malformations that histopathologically include a cystic dilated bile duct, typically 0.1-0.3 cm in diameter,

embedded in abundant fibrous stroma[26]. As a result of its asymptomatic nature, this relatively rare entity is usually detected incidentally in 5.6% of reported autopsies[27]. In view of the results of histopathological investigation of the liver, including negative IgG4 staining, it seems unlikely that a common pathogenesis underlies AIP and VMC. However, as far as we know, this is the first presentation dealing with both AIP and VMC.

In conclusion, we reported herein a variant form of AIP accompanied by VMC, which did not fulfill the Japanese diagnostic criteria. When we encounter a patient with atypical presentation of a pancreatic disease and find it difficult to make a diagnosis, despite applying diagnostic criteria, fine-needle aspiration biopsy of the pancreatic lesion should be considered as a diagnostic modality.

Abstract

Cystic neoplasms of the pancreas are relatively rare, comprising 10 percent of pancreatic cysts and only 1 percent of pancreatic cancers. Cystic neoplasms include mucinous cystic neoplasms, serous cystadenomas, papillary cystic tumors, cystic islet cell tumors and intraductal papillary mucinous neoplasms of the pancreas (IPMNs). IPMN was first described in 1982. It has been most commonly described in 60 to 70 years old males, and represents a relatively "new" but increasingly recognized disease. The improvement and widespread use of modern imaging equipments and heightened awareness of physicians contribute to the increasing incidence of IPMN. The majority of IPMNs are located in the pancreatic head (75%) while the rest involves the body/tail regions. Multifocal IPMNs have been hypothesized, but the true presence of multifocality is unknown. Here we present a 72-year-old male diagnosed with IPMN (carcinoma *in situ*) in the pancreatic head and a branch duct type IPMN (duct atypia) in the pancreatic body and tail. The patient underwent a Whipple intervention and a distal pancreatectomy. A three-year disease-free survival has been observed so far.

INTRODUCTION

Cystic neoplasms of the pancreas are relatively rare, comprising 10 percent of pancreatic cysts and only 1 percent of pancreatic cancers. Cystic neoplasms encompasses mucinous cystic neoplasms, serous cystadenomas, papillary cystic tumors, cystic islet cell tumors and intraductal papillary mucinous neoplasms of the pancreas (IPMNs)[1,2].

IPMN was first described in Japan in 1982, when four patients, diagnosed with pancreatic carcinoma with favorable outcomes, were reported sharing three distinct clinical features: dilated main pancreatic duct, patulous ampullary orifice and mucus secretion[3]. Since then, several reports have described mucus-producing pancreatic tumors with different stages of carcinogenesis, referred to by a variety of names[4-10], but mostly as mucinous ductal cancers. IPMN has very clear malignant potential and exhibits a broad histological spectrum, ranging from minimal mucinous hyperplasia to adenoma to invasive carcinoma[11-13].

The criteria used to classify IPMNs and to discriminate them from other mucin-producing cystic neoplasms of the pancreas have been established by the WHO in 1996[14]. The WHO gave a clear definition for IPMNs as intraductal mucin-producing neoplasms with tall, columnar, mucin-containing epithelium, with or without papillary projections. This type of neoplasm involves the main pancreatic duct and/or major side branches.

The majority of IPMNs are located in the pancreatic head (75%), while the rest involves the body/tail regions[15]. Multifocal neoplasms have been hypothesized[15], but the real prevalence of multifocality is unknown. Here, we present a 72-year-old male diagnosed with non-invasive

Figure 1 Abdominal ultrosonograpy showing multiple cystic tumors over the pancreatic head area with P-duct dilatation.

Figure 2 Abdominal computed tomography showing pancreatic head and body cystic tumors (arrow) with no evidence of regional lymphadenopathy or distant metastases.

mixed type IPMN (carcinoma *in situ*) in the pancreatic head together with a branch duct type IPMN (duct atypia) in the pancreatic body and tail.

CASE REPORT

A 72 years old male presented in 2005 with abdominal fullness after meals, general weakness, and body weight loss of about 2-3 kg occurred during the previous 3 mo. He had had diabetes and hypertension under regular medical control for the past 8 years. He was first admitted as outpatient, and an upper panendoscopy was performed, which showed chronic duodenal ulcer and gastric erosions. Antacids were prescribed but symptoms were not relieved.

Figure 3 The endoscopic ultrasonogaphy showed that the papilla of Vater was grossly normal without mucin discharge. However, a cystic tumor (arrow) measuring 4.0 cm x 4.2 cm in size was seen over the pancreatic head. The lining of cysts showed no definite projectile mass and the pancreatic duct was dilated about 0.6 cm in the head and 0.4 cm in the body and tail area.

Abdominal ultrosonography was then carried out (Figure 1) and a pancreatic head cystic tumor with pancreatic duct dilatation (0.75 cm) was found. He was then hospitalized for further treatment. The physical examination revealed a soft abdomen without palpable mass. No lymphadenopathy was found over his neck or the axillary and inguinal areas. Digital examination showed nothing abnormal. The following laboratory tests were performed: white blood cell count 9000/mm^3, hemoglobin 13.5 g/dL, platelet count 257 000/mm^3, albumin 4.1 g/dL, aspartate aminotrasferase (AST) 16 U/L, alanine aminotransferase (ALT) 14 U/L, alkaline phosphatase 47 U/L, total bilirubin 0.6 mg/dL, creatinine 0.7 mg/dL, amylase 117 U/L, lipase 48 U/L. Tumor markers, including carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9), were also checked and their results were 0.92 ng/mL (normal < 5 ng/mL) and 27.2 U/mL (normal < 37 U/mL), respectively. Then abdominal computed tomography (CT) was performed (Figure 2), which showed two cystic tumors at the level of the pancreatic head and body, measuring 4.8 cm and 1.2 cm, respectively. To further investigate the nature of the tumors, endoscope ultrosonography (EUS) and magnetic resonance imaging (MRI) were carried out. The EUS (Figure 3) disclosed a cystic tumor, 4 cm × 4.2 cm, without obvious internal projective mass in the pancreatic head. The papilla of Vater was grossly normal without mucin discharge. The MRI (Figure 4) showed three cystic lesions in pancreatic head (4.9 cm), body (1.8 cm) and

Figure 4 Magnetic resonance imaging showing three cystic lesions in the pancreatic head (4.9 cm), body (1.8 cm) and tail (1.2 cm), with P-duct dilatation. Mild common bile duct and common hepatic duct dilatation without definite tumor was observed in the liver upon MRI.

Figure 5 Histopathologic findings (HE × 200). A: Histopathological examination showed the presence of cystically dilated ducts with formation of papillary growth lined by mucin-secreting columnar epithelium at the level of the pancreatic head; B: The mucin-secreting epithelium reveals stratification of atypical nuclei. No obvious stromal invasion was seen and the features suggested a diagnosis of intraductal papillary mucinous carcinoma, noninvasive type; C: The section of the pancreatic body showed that it was focally involved by the lesion (arrow); D: The section of the pancreatic tail showed the focal presence of atypical ducts.

tail (1.2 cm) with pancreatic duct dilatation. Given the presence of pancreas cystic neoplasms, which may be malignant IPMNs, cystic adenocarcinomas or cystic adenomas, affecting the pancreatic head, body and tail, an extended Whipple operation (including the partial resection of the pancreatic body, about 2 cm away from the portal vein) together with a distal pancreatectomy were performed. Intraoperative findings revealed three tumors as described in the MRI. Intraoperative pancreatic US revealed no additional cystic mass in the residual pancreas, measuring about 7 cm in length, after resection. The proximal and distal margins were all negative for malignancy demonstrated by intraoperative histopathologic examination. The regional lymph nodes were grossly normal.

Histopathologic examination revealed that the pancreatic head showed the presence of cystically dilated ducts, encompassing the main and branch ducts, with formation of papillary growth lined by mucin-secreting columnar epithelium. The mucin-secreting epithelium had stratification of atypical nuclei. No obvious stromal invasion was seen. The features suggested a diagnosis of intraductal papillary mucinous carcinoma, non-invasive type (Figure 5A, B). The pancreatic body was focally involved by the lesion (Figure 5C), in the branch duct, not contiguous to the lesion of the pancreatic head. The pancreatic tail displayed focal presence of atypical ducts (Figure 5D), located in the branch duct. The final pathological diagnosis was non invasive mixed (involving both the main and the branch duct) type IPMN (carcinoma *in situ*) in the pancreatic head and branch duct type IPMN (duct atypia) in the body and tail. The postoperative course was uneventful and a three-year disease free survival has been achieved so far.

DISCUSSION

An enormous increase in the diagnosis of IPMN has occurred in recent years[16-18], which is due both to the improvement and widespread use of modern imaging equipments and to a heightened awareness among physicians.

IPMN usually occurs in 60 to 70 years old males, most of whom have a long-standing history of recurrent acute pancreatitis or symptoms suggestive of chronic obstructive pancreatitis, similarly to our patient, due to intermittent obstruction of the pancreatic duct with mucus plugs[19]. Other symptoms are nonspecific[20,21] and no signs or symptoms are pathognomonic of primary cystic neoplasms of the pancreas, including IPMN. Furthermore, many patients with no symptoms have their tumors detected incidentally at imaging studies performed for unrelated indications. Thus, there is often a several months delay in the diagnosis of IPMN, due to the insidious nature of this disease and to the lack of awareness of this entity among physicians[13,20,22-24]. Some patients may have elevations of pancreatic enzymes with episodes of pain (with or without biliary obstruction), but in most cases routine laboratory tests are normal. Similarly, tumor markers, such as CA 19-9 and CEA, are elevated in less than one-fifth of cases only, and are not always indicative of a malignant transformation of the tumors[19]. In this case, there were normal routine laboratory tests and tumor markers.

IPMN is a precancerous lesion with a well described adenoma-carcinoma sequence. However, the rate of progression appears to be extremely slow (approximately 15 to 20 years)[25].

The IPMN has been classified as main duct type (MDT-IPMN) or branch duct type (BDT-IPMN), based upon the anatomic involvement of the pancreatic duct[26,27]. The majority of IPMNs are located in the pancreatic head (75%) whereas the rest involves the body/tail regions[15]. Multifocal neoplasms have been hypothesized[15], but the real prevalence of multifocality is still unknown. The final diagnosis of this case proved the existence of this rare entity.

The majority of patients with IPMN does not have invasive cancer, and usually have a prolonged course without the development of cancer. In one series, the ten-year actuarial risk of high grade dysplasia and invasive cancer were 49% and 29%, respectively[28]. The five-year actuarial risk of progression was significantly higher in patients with main duct type compared with those with exclusively the branch duct type (63% *versus* 15%). Surgery is the only treatment option in patients who do have high grade dysplasia or cancer detected by endoscopic or cytological examination. Preoperative staging, using a combination of ERCP, pancreatoscopy, EUS and intraductal ultrasonography, may be beneficial to determine the indication to surgery[29-32]. However, accurate prediction of malignancy is not possible preoperatively. Sugiyama *et al*[33] proposed some predictive factors of malignant IPMN, including (1) tumor size, since an IPMN > 4 cm and a branch duct

IPMN > 3 cm suggest malignancy; (2) a mural nodule of a size > 5 mm; (3) a dilatation of main pancreatic duct > 10 mm; (4) the patient age, the mean age for adenomas being 64, whereas that of invasive cancers is 67; and (5) symptoms, especially jaundice.

Selection of a surgical procedure for treating IPMN remains controversial, because IPMNs show a wide spectrum of histologic changes, ranging from hyperplasia to invasive carcinoma and because of the so far unresolved question of multifocality. As demonstrated in this patient, the aim of surgery is to achieve complete resection with negative margins for invasive and noninvasive disease and to minimize the incidence of recurrence in the pancreatic remnant. However, an extended resection of the pancreas may pose the risk of inducing a severe pancreatic functional insufficiency, both exocrine and endocrine.

Another difficult question is the management of patients with suspected IPMNs who do not have high grade dysplasia or cancer detected during initial evaluation, and of patients with small (< 3 cm) branch-duct IPMNs. Our opinion is that management should be based upon the confidence in the diagnosis, the presence of symptoms and a discussion with the patient regarding the possible risk of subsequent malignant transformation. Surgery can be reasonably offered to patients who are good surgical candidates in order to confirm the diagnosis and to prevent the subsequent development of cancer. In contrast, patients who are poor surgical candidates can be treated conservatively with an imaging test performed every six to twelve months to evaluate the stability of the lesion. Our case fared very well despite the fact that he was 72 years old. Originally, we suggested the resection of pancreatic head with close follow-up of the other two tumors, considering the tiny risk of malignant transformation, but both the patient and his family preferred a complete resection of the three tumors. Finally, we performed an extended Whipple operation (including the partial resection of the pancreatic body) with a distal pancreatectomy. The postoperative course was uneventful without deterioration of the diabetes and exocrine insufficiency.

The final pathologic diagnosis was noninvasive mixed (involving both the main and the branch duct) type IPMN (carcinoma *in situ*) affecting the pancreatic head and a branch duct type IPMN (duct atypia) of the pancreatic body and tail. This confirmed the occurrence of multifocality of IPMNs of the pancreas. The patient has until now achieved a three year disease free survival.

Abstract

Pulmonary and cerebral lipiodol embolism after transcatheter arterial chemoembolization (TACE) of hepatocellular carcinoma is rare. To our knowledge, only 7 cases have been reported in the literature. We present a case of pulmonary and cerebral lipiodol embolism, and analyzed retrospectively the imaging and clinical data of the patient and conclude the most probable mechanism of pulmonary and cerebral lipiodol embolism, which is different from that of the cases reported previously.

Wu JJ, Chao M, Zhang GQ, Li B, Dong F. Pulmonary and cerebral lipiodol embolism after transcatheter arterial hemoembolization in hepatocellular carcinoma. *World J Gastroenterol* 2009; 15(5): 633-635 Available from: URL: http://www.wjgnet.com/1007-9327/15/633.asp DOI: http://dx.doi.org/10.3748/wjg.15.633

INTRODUCTION

Transcatheter arterial chemoembolization (TACE) has been widely used in the treatment of primary hepatocellular carcinoma (HCC). The reported rare or serious complications associated with TACE mainly include: acute hepatic failure, liver abscess, hepatic infarction, hepatic artery occlusion, spontaneous rupture of tumor, gallbladder infarction, perforation of duodenum, acute renal failure, gastrointestinal mucosal ulceration, *etc*[1,2]. Cerebral lipiodol embolism is a rare complication of TACE. To our knowledge, only 7 cases of cerebral lipiodol embolism after TACE have been reported so far[3-7]. We herein report a case of pulmonary and cerbral lipiodol embolism after TACE in HCC, and discussed the possible mechanism, which is different from the cases reported previously.

CASE REPORT

A 36-year-old man who complained of right upper abdominal pain for one week was admitted to our hospital. He had a history of hepatitis B for 10 years. Hepatic computed tomography (CT) revealed a massive HCC in the right liver and tumor thrombosis in the right branch of portal vein. The concentration of blood α-fetoprotein (AFP) was 2.5 ng/mL, while hepatic function was classified as A according to Child-Pugh classification. The surgical resection cannot be performed because of inadequate residual liver volume. So the patient underwent the first TACE.

As revealed by angiography, a huge hypervascular tumor located in the right liver was only supplied by the right hepatic artery (RHA) without arteriovenous shunt. TACE was performed *via* the RHA using a mixture of 40 mg pirarubicin, 40 mL lipiodol, 20 mg hydroxycamptothecine and 150 mg Oxaliplatin. Gelatin sponge particles (560-710 μm) were used to reduce the flow of tumor feeding artery. After the operation, the patient had a sustained high fever in the afternoon with a maximum of 39.6℃ for 10 d. A follow-up non-contrast hepatic CT showed incomplete lipiodol retained in the hepatic tumor and hyper-attenuating lipiodol deposition only in the right collapsed basal lung (Figure 1). The patient recovered and was discharged from hospital two weeks after TACE. Four weeks later, a follow-up hepatic CT demonstrated that incomplete lipiodol deposited in

Figure 1 Ten days after the first TACE, a non-contrast hepatic CT revealed incomplete lipiodol retained in hepatic tumor (white arrow) and hyper-attenuating lipiodol deposition only in the right collapsed basal lung (black arrow).

Figure 2 During the second TACE, hepatic angiography revealed the residual tumor fed by RHA and no arteriovenous shunt was found.

Figure 4 A 36-year-old man with cerebral lipiodol embolism. A: Axial T2-weighted imaging (T2WI); B: Biffusion-weighted imaging (DWI); C: Apparent diffusion coefficient (ADC); D: Follow-up DWI. A, B and C obtained 57 h after the second TACE, and D obtained 5 wk after the second TACE. T2WI and DWI (A, B) demonstrated multiple high-signal lesions on the bilateral frontal and parietal lobe. The corresponding lesions showed a low signal area on the ADC map (C). A follow-up DWI revealed no obvious abnormal signal (D).

Figure 3 Fifty-three hours after the second TACE, a non-contrast head CT showed multiple high-attenuating spots and patch-like lesions in bilateral parietal and frontal cortex, suggesting the lipiodol desposition.

Figure 5 A follow-up head CT obtained 5 wk after the second TACE showed no abnormality and the previously observed lipiodol deposition cleared entirely.

the tumor, so the second TACE was performed. During the second procedure, the hepatic artery angiography revealed that the residual tumor was supplied by RHA, but no arteriovenous shunt was found (Figure 2). A mixture of 40 mg pirarubicin, 40 mL lipiodol, 20 mg hydroxycamptothecine and 150 mg Oxaliplatin was infused the RHA. The embolism process was monitored with fluoroscope and no abnormal flow of the lipiodol was found. Postoperative abdominal X-ray plain film showed dense lipiodol deposition in the tumor. The patient felt transitory numbness in the right hand at the end of the procedure. Two hours after the 2nd TACE, the patient had a numbness and weakness in the right hand and the right fingers could not carry out fine motor activities (such as writing, holding chopsticks, finger's diadochokinesia, *etc*.), no symptom of chest tightness and dyspnea occurred. A non-contrast head CT obtained

in 53 h after the second TACE showed multiple high-attenuating spots and patch-like lesions in bilateral parietal and frontal cortex (Figure 3). At the same time, a non-contrasted thoracic CT demonstrated small doses of hyper-attenuating lipiodol deposition in the bilateral basal lungs. Cerebral magnetic resonance imaging (MRI) was performed 57 h after TACE by 1.5 T magnetic resonance imaging (Siemens), diffusion-weighted imaging (DWI) and T2WI demonstrated multiple high-signal lesions on the bilateral frontal and parietal lobe (Figure 4A and B); the corresponding lesions showed a low signal area on the apparent diffusion coefficient (ADC) map (Figure 4C). Pulmonary and cerebral lipiodol embolism with acute cerebral infarction after TACE was considered. After the intervention of positive dehydration, diuresis and nutrition of nerve for 10 d, the right hand resumed normal function. Four weeks later, a follow-up head CT showed no abnormality and the previously observed

lipiodol deposition had been cleared entirely (Figure 5). Follow-up MRI revealed no obvious abnormal signal on the DWI (Figure 4D). After the patient underwent TACE, the volume of the normal left liver had a marked compensatory hyperplasia, which was sufficient for safe resection. Surgical tumor resection was performed. During the procedure, the right hepatic massive tumors were seen invading into the diaphragm. Pathological diagnosis revealed primary HCC with large necrosis, surrounded by nodule hepatic cirrhosis. The patient is still living in good health.

DISCUSSION

Cerebral lipiodol embolism rarely occurs after TACE in HCC. There are only seven reported cases and its possible mechanism was analyzed in detail in three cases. Wu *et al*[5] thought the link between systemic vessels and pulmonary vessels may occur *via* the adhesive pleurae or tumor invasion into the thoracic cavity. The lipiodol injected *via* the inferior phrenic artery may enter the pulmonary circulation, and then entered the systemic circulation *via* these pathways, resulting in cerebral lipiodol embolism. Matsumoto *et al*[6] concluded that communication between tumor feeding artery and pulmonary vein might occur *via* adhesive pleural or tumor invasion into the diaphragm. Therefore, a small dose of lipiodol could enter the systemic circulation quickly and caused cerebral embolism. Choi *et al*[7] concluded that a large dose of lipiodol and communication between right inferior phrenic artery and pulmonary vessels were contributed to cerebral lipiodol embolism. In this report, we analyzed retrospectively the features of the case as follows. (1) The tumor is huge and was adhered to the diaphragm, suggesting the tumor invading into the diaphragm, which was confirmed during the surgery. (2) The repeated hepatic angiography did not reveal any arteriovenous shunt. (3) The pulmonary lipiodol embolism was found only in the right collapsed basal lung and no neurological signs or symptom of cerebral lipiodol embolism appeared after the first TACE, which suggested that the communication between the tumor feeding artery and the branch of the right pulmonary artery might occur and congenital intrapulmonary arteriovenous shunt did not exist in the field at that time. Given the communication between the tumor feeding artery and pulmonary vein, cerebral lipiodol embolism may occur directly and pulmonary lipiodol embolism in both lung fields. Due to the communication between the tumor feeding artery and hepatic vein, pulmonary lipiodol embolism might be found in both lung fields. So these two possibilities were excluded. (4) The symptom of cerebral lipiodol embolism appeared immediately after the second TACE. According to the features mentioned above, we conclude the most probable mechanism of pulmonary and cerebral lipiodol embolism as follows: Since the tumor invaded into the diaphragm, the communication between the tumor feeding artery and the branches of the right pulmonary artery were presented, and the lipiodol went into the branches of the right pulmonary artery through the communication,

resulting in pulmonary lipiodol embolism during the first TACE. While there was no congenital intrapulmonary arteriovenous shunt, the cerebral lipiodol embolism did not form after the first TACE. However, the second intrapulmonary arteriovenous shunt appeared during the pulmonary lipiodol embolism because of increasing pulmonary artery pressure or hypoxia. Therefore, the cerebral lipiodol embolism occurred immediately after the second TACE.

In this case, the head CT revealed multiple hyper-attenuation spots and patch-like lesions in the bilateral frontal and parietal cortex, which suggested hyper-attenuating lipiodol deposition. Cerebral MRI demonstrated multiple ischemic lesions in the bilateral frontal and parietal lobe but not lipiodol deposition. In CT and MRI embolism is observed mainly in the gray matter and the pathological changes are predominant in the white matter[8]. Therefore, CT is considered useful to the diagnosis of cerebral lipiodol embolism, and DWI can help detect lesions and evaluate the therapeutic effect.

Pulmonary and cerebral lipiodol embolism is a rare and serious complication. In this case, pulmonary lipiodol embolism only occurred in the right lung, suggesting the communication between tumor feeding artery and branch of the right pulmonary artery. The risk of pulmonary and cerebral lipiodol embolism should be considered in the tumor treated with TACE again. To prevent the pulmonary and cerebral lipiodol embolism, it is important to consider an individualized therapeutic plan, including the dose of lipiodol and evaluation for the presence of shunt prior to TACE.

Global Collaboration for Gastroenterology
For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1212 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: Introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Leader Frontier: Comment on excitement and existing problems of core fields, and offer suggestions for the future research; (3) Topic Highlight: Experts in gastroenterology and hepatology to focus on certain individual hot topics and try to provide answers to the clinical questions on the topics; (4) Observation: Which updates the development of old and new questions, highlights unsolved questions, and provides strategies on how to solve the questions; (5) Guidelines for Basic Research: Which provides Guidelines for basic research; (6) Guidelines for Clinical Practice: Which provides guidelines for clinical diagnosis and treatment; (7) Review Articles: Summarize the representative progress in core scientific disciplines, comment on the research status, and make suggestions for the future work; (8) Original Articles: Originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: Briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: Report a rare or typical case; (11) Letters to the Editor: Discuss and make reply to the contributions published in *WJG*, or introduce and comment on a controversial issue of general interest; (12) Book Reviews: Introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: Guidelines or common understanding for gastroenterology and hepatology from international academic committee.

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials. gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http:// www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori*, *E coli*, *etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Hepatitis C virus (HCV) infection is highly prevalent among patients on hemodialysis (HD). The prevalence of HCV infection in HD patients varies markedly from country to country. Some factors are especially related to these high prevalence rates, such as blood transfusions and length of dialysis time. Nosocomial routes of transmission including the use of contaminated equipment and patient-to-patient exposure is considered more important. Several prophylactic measures have been suggested to avoid infection by HCV in the HD environment.

INTRODUCTION

Hepatitis C virus (HCV) infection is considered a major public health problem worldwide. Patients with chronic renal failure who are on hemodialysis (HD) have a high prevalence of HCV. They are among the highest risk groups for the acquisition of HCV infection[1-3]. Prevalence of HCV infection has decreased in this group in recent years[4], but still remains a significant public health concern. HCV-infected patients on HD have significant liver disease and a decreased life expectancy[5,6]. The relative risk for death in HCV-infected patients on HD compared with non-infected patients is greater than 1.4[6-8]. In addition, HCV infection leads to decreased graft and patient survival in renal transplant recipients[9,10]. On the other hand, due to the increased prevalence of non-communicable diseases such as diabetes mellitus and hypertension, and their complications, chronic renal failure has become a more serious health issue throughout the world[11]. Therefore, the clinical importance of HCV has been increasingly recognized in the dialysis community.

PREVALENCE AND INCIDENCE

HCV prevalence in HD varies geographically, both within and between countries[12]. The reported anti-HCV seropositivity since 1999 ranges from low (1.9%) in the Slovenian 2001 Annual Report[13] to high (80%) in Senegal[14]. HCV seroprevalence in the HD population was 59% in Bosnia and Herzegovina[15], 6.8% in Belgium[16], 16.3% in France[2], 6.1% in Germany[17], 10%-29% in Greece[18-20], 22.5%-32.1% in Italy[21,22], 75% in Moldavia[23], 3.4% in the Netherlands[24], 1.9% in Slovenia[13], 11% in Sweden[25], 7%-23.3% in the USA[26-30], 4% in the UK[31] 20.5% in Libya[32], 71% in Kuwait[31] 80% in Senegal[14], 23.7% in Sudan[33], 19%-41.7% in Tunisia[34,35], 8.4%-43.2% in Brazil[36-39], 6.7% in Mexico[40], 59.3% in Peru[41], 3.5% in Puerto Rico[42] and 13.2% in Iran[43]. Some investigators have suggested a decline in HCV prevalence among HD patients in recent years, mostly attributable to strict adherence to universal precautions with[16,44-49] or without[50,51] observing isolation measures. This decrease is more significant in the USA and European countries[4,16,47,52]. Studies that have prospectively followed HD patients for their HCV serostatus have yielded annual incidence rates of de novo HCV infection of 0.4% in France[53], 0.5% in Tunisia[54], 0.5% in the Netherlands[24], 0.83% in Italy[55], 1.38%[56] and 2.1%[57] in the USA, 0.33%[58], 2.59%[59], 3.1% in Japan[60], 3.7%[61] 5.5% in Brazil[62], and 6.2% in Greece[20]. This variation in different countries and different centers underlines the importance of infection

control. New infection was evidently more frequent at centers that had higher anti-HCV prevalence and failure in infection control measures. In some countries, both prevalence and incidence remain very high, indicating major ongoing nosocomial transmission, probably due to the limited resources available to treat a rapidly growing HD population[63,64].

RISK FACTORS FOR HCV TRANSMISSION

The high prevalence of HCV seropositivity among HD patients was initially attributed to blood transfusions for the treatment of uremic anemia in this population, which were often necessary[41,65-68]. Historically, the number of blood transfusions received was consistently reported in the literature to be associated with an increased prevalence of HCV-positive dialysis patients[31]. However, several recent reports have failed to recognize blood transfusion as an independent risk factor in HCV spread among HD subjects[2,20,23,24,30,33,62,69-74]. Indeed, from the late 1980s onward, the prescription of erythropoietin reduced the need for blood transfusion in HD patients. Furthermore, the introduction of sensitive tests for screening blood donors has markedly reduced the risk of HCV transmission through blood product transfusion. These two reasons may explain recent findings on the lack of association between blood transfusion and HCV infection. Nonetheless, considering the fact that new HCV infections do still occur in patients without a history of transfusion, the duration of HD is increasingly being considered as a risk factor for HCV infection[75,76]. Almost all recent surveys on the subject have congruently suggested that the length of time on HD is a risk factor for HCV seropositivity[17,20,23,29,30,33,36,39,43,60,69-71,77-80]. Nosocomial patient-to-patient transmission of HCV infection among HD patients has been suggested by several investigators who performed phylogenetic analysis of HCV viral isolates[24,25,53,54,81-84]. Lack of strict adherence to universal precautions by staff and sharing of articles such as multidose drugs might be the main mode of nosocomial HCV spread among HD patients[54,82,84-86]. Although some studies found that nosocomial spread of HCV declined when HCV-infected patients were treated in dedicated HD units[44-49,87,88], other investigators could control nosocomial spread of HCV among HD patients by the strict application of hygienic precautions, without isolation of HCV-infected subjects or machine segregation[12,50,89]. Indeed, the observed efficacy of isolation might simply be due to the prevented sharing of articles between patients and might reflect a better implementation of other hygienic precautions.

The spread of HCV infection in HD units is mainly due to nosocomial transmission between patients[53,88,90-94]. The importance of this route of transmission is demonstrated by the high HCV prevalence in some HD units and by the lower infection rate in patients on peritoneal dialysis compared with those on HD. A high prevalence of patients with HCV infection in HD facilities has been considered a risk factor for

transmission of the infection. However, there is no consensus on the necessity for infection control isolation of HCV-positive patients for at least two reasons: firstly, the infectivity of HCV is lower than that of the hepatitis B virus; and secondly, the criteria for patients to be isolated remain to be defined. On the contrary, some HD patients are infected with HCV but do not have antibodies. Detection of viral RNA by reverse-transcription polymerase chain reaction (RT-PCR) is the only method to confirm HCV infection, however, this technique is not available at all centers.

PREVENTIVE STRATEGIES

Several prophylactic measures have been suggested to avoid infection by HCV in the HD environment, and range from isolating patients with HCV infection[44,47,48,88,95], to adopting a series of biosafety measures specific for HD, such as preparing medications in a separate area, cleaning and disinfecting dialysis station surfaces, washing hands and changing gloves between patient contacts, and items dedicated for use only with a single patient[12,39,50,96]. Strict adherence to universal infection control precautions seems to be enough to control the spread of disease in HD units[12,50,89,97-99]. Some reports have recommended the adoption of infection control isolation measures at centers with a high HCV prevalence[47,87,100,101] or if the staff/patient ratio at the center is lower than 28/100[102]. At centers with a high prevalence of HCV infection and in developing countries, universal precautions may not always be possible to implement. Thus isolation measures for HCV-positive patients should be implemented[47]. The CDC recommends that special precautions be observed in dialysis units including the wearing and changing of gloves and water-proof gowns between patients; systematic decontamination of the equipment, circuits, and surfaces after each patient treatment; no sharing of instruments (e.g. tourniquets) or medications (e.g. multiuse vials of heparin) among patients; and the assignment of patients to specific HD units[97]. Clearly, it is necessary to attempt, one step at a time, to minimize intradialytic or intracenter HCV transmission.

CONCLUSION

In summary, despite the marked decrease in anti-HCV prevalence in HD patients in many countries, the disappearance of HCV from HD units should not be expected for decades. Universal infection control precautions are the keystone in the prevention of nosocomial HCV transmission in HD units; however, isolation measures, including health care monitoring of infected patients and providing care in a dedicated section of the unit, improve prevention results. Those HD units with a high HCV prevalence or in which there is no fulltime infection control personnel dedicated to the infected patients during HD sessions may have a greater risk of seroconversion. Therefore, isolation in

special units or dialyzing patients in specific sessions must be considered[44]. As HCV-infected HD patients serve as a reservoir of infection for other patients, HD staff, and the transplant team[28,103,104] at HD centers must be aware of new HCV infections in order to review their practices and increase vigilance. Public health authorities should be aware about the prevalence and incidence of HCV infection in HD patients in different cities in their respective countries, so that changes can be proposed and the risks of infection among patients can be assessed. Implementation of surveillance systems and continuing education of the unit's personnel on recommended infection control measures in HD units are necessary. The treatment of most HCV-infected patients with interferon alpha can significantly contribute to decreasing HCV infection in this group in the future[105]. Successful control of infection requires further studies to assess the effectiveness of different preventive policies.

Editorial statement

Salvatore Gruttadauria, Bruno G Gridelli

In the following four articles, we will provide an overview of the current clinical work in different areas of liver transplantation.

For many decades, this transplantation has been the treatment choice for patients suffering from chronic and acute liver diseases.

Understanding of the complexity of this procedure can be read only through a multidisciplinary approach.

Liver transplantation has become a clinical reality thanks to the pioneer Thomas E Starzl, MD, PhD, who at the University of Colorado was one of the first to test cyclosporine in humans. Considered the father of liver transplantation, he performed the world's first liver transplant at the University of Colorado in 1963. Upon his arrival in Pittsburgh in 1981, when the university's liver transplant program began, Dr. Starzl continued research on the drug, which was approved by U.S. Food and Drug Administration (FDA) in November 1983.

Now, after many thousands of liver transplants have been successfully accomplished worldwide, the main problems to be solved remain the chronic shortage of organs and the need to investigate alternative and less aggressive forms of therapy, for the cure of end-stage liver disease.

The authors would like to thank Domenico Biondo for his help in editing these papers.

Pediatric liver transplantation

Abstract

In previous decades, pediatric liver transplantation has become a state-of-the-art operation with excellent success and limited mortality. Graft and patient survival have continued to improve as a result of improvements in medical, surgical and anesthetic management, organ availability, immunosuppression, and identification and treatment of postoperative complications. The utilization of split-liver grafts and living-related donors has provided more organs for pediatric patients. Newer immunosuppression regimens, including induction therapy, have had a significant impact on graft and patient survival. Future developments of pediatric liver transplantation will deal with long-term follow-up, with prevention of immunosuppression-related complications and promotion of as normal growth as possible. This review describes the state-of-the-art in pediatric liver transplantation.

Key words: Pediatric liver transplantation; Indications; Surgical techniques; Complications

INTRODUCTION

Liver transplantation has been very successful in treating children with end-stage liver disease, and offers the opportunity for a long healthy life. Organ scarcity, which is the main limitation to the full exploitation of transplantation, is being overcome thanks to innovative surgical techniques, and all children in need, even the youngest, today have the chance of being transplanted, with almost no waiting list mortality. Split-liver and living-donor transplantation have contributed to reversing a situation in which, during the 1980s and 90s, children had greater waiting list mortality compared to that of adult patients.

Several years ago, the main focus of care of children with end-stage liver disease was to find a liver transplant, but today, the main interest is in long-term follow-up, with prevention of immunosuppression-related complications and promotion of as normal growth as possible. The history of pediatric liver transplantation has clearly shown that success is dependent on strict and integrated collaboration between referring pediatricians, pediatric transplant hepatologists, transplant surgeons, nurses, transplant coordinators, psychologists and social workers. Everybody involved has the task of bringing a cure to a population of pediatric patients who present some of the most challenging clinical problems in modern medicine.

INDICATIONS FOR LIVER TRANSPLANTATION

The main indications for liver transplantation in the pediatric population are as follows: (1) Extra-hepatic cholestasis: biliary atresia. (2) Intra-hepatic

cholestasis: sclerosing cholangitis; Alagille's syndrome; non-syndromic paucity of intrahepatic bile ducts; and progressive familial intrahepatic cholestasis. (3) Metabolic diseases: Wilson's disease; α_1-antitrypsin deficiency; Crigler-Najjar syndrome; inborn error of bile acid metabolism; tyrosinemia; disorders of the urea cycle; organic acidemia; acid lipase defect; oxaluria type I; and disorders of carbohydrate metabolism. (4) Acute liver failure. (5) Others: primary liver tumor and cystic fibrosis.

Cholestatic liver diseases

Typically, the child referred to a liver transplant center is a small baby with cholestatic liver disease. Out of 1187 children transplanted in North America between 1995 and May 2002, 33.5% were $\leqslant$ 12 mo old at the time of transplantation, 55.6% had cholestatic disease, and 41.6% had biliary atresia. Of the children transplanted at < 1 year of age, 65.6% had biliary atresia[1]. Most of these children have undergone a Kasai procedure that failed to re-establish effective biliary flow, which caused rapid evolution to secondary biliary cirrhosis. When intrahepatic cholestatic diseases (Alagille's syndrome, progressive familial intrahepatic cholestasis, and sclerosing cholangitis) or sclerosing cholangitis are diagnosed, liver transplantation is indicated to eliminate severely debilitating symptoms, such as pruritus. Children affected by these diseases are also at high risk for the development of liver cancer[2].

Metabolic diseases

Metabolic diseases are the second most common indication for liver transplantation[3]. Metabolic diseases can be divided in two groups on the basis of the presence or absence of structural damage of the liver. To the first group belong α_1-antitripsin deficiency, tyrosinemia and Wilson's disease, which have the potential to progress to end-stage liver failure, liver cancer (Figure 1) and acute liver failure, while diseases such as Crigler-Najjar syndrome type I and ornithine transcarbamylase (OTC) deficiency belong to the second group. In primary hyperoxaluria type I, liver and kidney transplantation is considered when irreversible kidney damage from oxalic acid accumulation has developed. Different transplantation timings have been tested, combined liver and kidney transplantation (simultaneous or sequential) and pre-emptive liver transplantation (before end-stage renal failure occurs)[4,5]. Liver transplantation has been suggested recently for the treatment of organic acidemia (propionic aciduria, methylmalonic aciduria). In patients affected by these diseases, liver transplantation does not correct the enzyme deficiency in other organs beside the liver. Although quality of life is generally improved, patients remain at risk of severe extrahepatic disease complications[6-8]. Liver cirrhosis with severe portal hypertension develops in an about 25% of the patients affected by cystic fibrosis. Liver transplantation should be considered before the development of end-stage liver failure and when pulmonary function is still preserved (FEV_1 > 50%).

Figure 1 Adolescent affected by tyrosinemia who developed hepatocellular carcinoma, despite 2-(2-nitro-4-fluoromethylbenzoyl)-1,3-cyclohexanedione therapy. A: Magnetic resonance imaging displays a 26-mm lesion. B: After liver transplantation, the resected liver showed multiple nodules in the left lobe. C: Histological sections from the nodule revealed hepatocellular carcinoma. D: Microvascular invasion.

Acute liver failure

Acute liver failure is a rare event in children; recovery without transplantation occurs in 15%-20% of patients with severe hepatic encephalopathy. A prospective study from the Pediatric Acute Liver Failure Study Group

Figure 2 Non-resectable hepatoblastoma.

has indicated that in 49% of patients (54% of children aged 1 year), the cause of acute liver failure cannot be determined and that total bilirubin $\geq$ 5 mg/dL, international normalized ratio (INR) $\geq$ 2.55 and hepatic encephalopathy are risk factors predictive of death or liver transplantation[9]. In a large retrospective United Network for Organ Sharing (UNOS) data analysis, it has been shown that 5-year patient and graft survivals of children with acute liver failure are significantly lower than the survival of children transplanted for biliary atresia (73% and 59% vs 89% and 78%, respectively)[10].

Liver tumors

Hepatoblastoma is the most common liver tumor in children and, when non-resectable, should be treated with total hepatectomy and liver transplantation (Figure 2). Children with hepatoblastoma should first be treated with chemotherapy and then be evaluated for resection or transplantation[11]. Hepatocellular carcinoma in children is rare and is often secondary to congenital liver disease. The development of hepatocellular carcinoma has been reported in biliary atresia, Alagille's syndrome, progressive intrahepatic cholestasis (recently also hepatoblastoma has been reported in a child with this condition). In children with tyrosinemia, there is a 33% incidence of hepatocellular carcinoma before 2 years of age that seems to be reduced if not eliminated by 2-(2-nitro-4-3 trifluoromethylbenzoyl)-1,3-cyclohexanedione (NBTC) therapy.

CONTRAINDICATIONS TO LIVER TRANSPLANTATION

Current contraindications to liver transplantation in children are: (1) non-resectable extrahepatic malignant tumor; (2) concomitant end-stage organ failure that cannot be corrected by a combined transplant; (3) uncontrolled sepsis; and (4) irreversible serious neurological damage. Whereas in adults there are limitations to access to liver transplantation waiting lists for patients with primary liver tumors, in children, the approach is much more liberal and the indication should be discussed on a case by case analysis with pediatric oncologists.

EVALUATION OF THE TRANSPLANT CANDIDATE

The primary goal of the evaluation process is to identify appropriate candidates for liver transplantation and to establish a pre-transplantation plan. The following steps are usually considered: (1) confirm the indication for transplantation; (2) determine the severity of the disease; (3) consider alternative treatments to transplantation; (4) exclude contraindications to transplantation; (5) identify active infections and assess the immunological status of the child; (6) rule out cardiac malformations that might need to be corrected before transplantation; (7) establish a pre-transplant therapeutic plan: immunizations, when possible, nutritional support to optimize growth, dental care, prevention or treatment of drug-induced side effects (e.g. osteopenia secondary to prolonged steroid intake); (8) inform parents, and the patient if possible, on the transplantation procedure and on the post-transplantation period in order to motivate and prepare them to accept and deal with all issues and possible complications of the procedure; and (9) evaluate social status and logistic issues.

PRIORITIZATION

In the early 1980s, waiting time and severity of illness expressed by patient location (home, hospital, ICU) were the primary factors used to stratify patients. Later on, it was shown that waiting time had no relationship to mortality, except for urgent acute liver failure patients, and therefore, that an allocation policy based on objective medical criteria was needed. Based on data derived from the Studies of Pediatric Liver Transplantation research group, a pediatric end-stage liver disease score (PELD) was created, using bilirubin, INR, serum albumin, age > 1 year, and growth failure to predict waiting list mortality[12]. Additional PELD points are awarded for specific risk factors not taken into account in the PELD equation, such as hepatopulmonary syndrome, metabolic diseases, and liver tumors. The adoption of the PELD score in the USA has improved the access and accountability of the allocation system. However, the PELD score has not proven to be a successful predictor of outcome following transplantation[13,14].

THE TRANSPLANT OPERATION

The first liver transplant was performed by Thomas Starzl, in 1963, on a 2-year-old child affected by biliary atresia[15]. The patient died in the operating room of uncontrolled hemorrhage. After this first case, and up to the early 1980s, the only technical option for pediatric liver transplantation was to transplant the whole liver of a donor with a weight as close as possible to that of the recipient. Given the low number of pediatric donors, up to 50% of the children on the waiting list would die before they could receive a transplant[16]. The development of techniques that allow surgeons to transplant portions of livers from adult donors has

completely changed the fate of liver transplantation in pediatric patients.

Whole-liver transplantation

The procedure of whole-liver procurement in pediatric donors can be performed exactly as in adults, applying a technique that is a combination of the initial procurement technique described by Starzl *et al*[17], and the most recently described rapid flush technique[18,19]. Whole-liver pediatric transplantation can be performed with two different techniques: the classic technique with inferior vena cava replacement, and the piggyback technique[20] with preservation of the native inferior vena cava. The present authors routinely use the classic technique in the vast majority of whole liver transplants. Veno-venous bypass is generally not used in pediatric liver transplantation, given that patients generally tolerate explantation well, provided that volume replacement has been adequate. Adopted techniques are almost identical to the ones used in adults recipients. In cases in which the liver is encased in adhesions, as it is in biliary atresia, we recommend that surgeons first approach the hepatic hilum from the right posterolateral aspect, identifying the Roux-en-Y jejunal limb, which is transected with a linear stapler or between ligatures. This allows better exposure and dissection of the hilum. If the portal vein is small and sclerotic, it has to be dissected proximally to the confluence of the splenic and superior mesenteric vein, dividing the coronary vein of the stomach. The portal vein anastomosis will then be performed by means of a donor interposition vein graft. In difficult dissections, the vena cava can be clamped above and below the liver before completing the mobilization of the liver itself.

Several methods of arterial reconstruction have been proposed. It is our preference to anastomose the small arterial vessels encountered in pediatric whole liver transplantation in an end-to-end manner by using the magnification loops (3.5 ×) and interrupted or running 8-0 polypropylene sutures. We generally do not use the branch patch technique, and in the case of aberrant arterial anatomy, the supraceliac aorta is the inflow vessel of choice. The use of arterial conduits anastomosed to the infrarenal aorta is avoided if possible.

In theory, biliary tract continuity can be restored through direct anastomosis between the new liver's hepatic duct and the recipient's common bile duct. However, the most common type of biliary reconstruction adopted in pediatric patients is hepaticojejunostomy. In biliary atresia patients, the reconstruction uses the previous Roux-en-Y limb of the hepatic portoenterostomy, if suitable; otherwise a 40-cm Roux-en-Y jejunal limb is created. The authors' attitude is not to use a T tube, because no randomized trial so far has demonstrated any advantages in using it, and there are often biliary leaks when the T tube is pulled.

Occasionally in children, abdominal-wall closure may be impossible because of the large size of the transplanted liver. This may be remedied by creating a silo on the abdominal wall such that a temporary closure can be made[21].

Reduced-size liver transplantation

This procedure was first described by Bismuth *et al*[22] and consists in the procurement of the whole liver from an adult cadaver donor, which is reduced in its size on the back-table. In the original description, a right hepatectomy was performed on the back-table: the right lobe of the liver was discharged, while the left lobe (Couinaud liver segments 1 to 4), including the vena cava, was transplanted in a child. This technique of parenchymal reduction, very seldom used today, allows surgeons to overcome differences in size between the donor and the recipient of up to four or five times[23,24].

Following these first experiences, a more aggressive reduction that allows transplanting the liver from donors with a body weight up to 12 times the recipient's was introduced. On the back-table, the graft undergoes an extended right hepatectomy, including segment 4 and the caudate lobe. The resulting left lateral segment graft comprises segments 2 and 3, without the vena cava. The graft is transplanted retaining the recipient's vena cava, anastomosing the graft left hepatic vein to the recipient's vena cava.

Reduced-size liver transplantation shows outcomes in line, if not superior, to whole-liver transplantation, and has become an essential part of the technical expertise of pediatric transplant centers[25-30] (Table 1). The development of this technique has led to almost total elimination of child mortality on the waiting list, through the utilization of an adult liver cadaver donor. Its main limitation is that it withdraws organs from the larger adult recipient pool. For this reason, after the development of living-related and split-liver transplantation, reduced-size live transplantation is used increasingly less, and should not be considered an option anymore for pediatric liver transplantation.

Living-related liver transplantation

The first description of the procedure in which segments 2 and 3 were procured from a living donor (the mother), and transplanted in a child affected by biliary duct atresia, dates back to 1988[31,32]. Living-related liver transplants soon came to account for a substantial number of pediatric cases performed in many centers throughout the world, and the only possibility for liver transplants in countries where cadaveric organ procurement was not allowed until just a few years ago[33].

Living-donor procurement involves performing a left lobectomy during which segments 2 and 3 are separated from the remaining liver, and dissecting the parenchyma along a section running to the right of the round ligament. After the parenchyma dissection, the left branch of the portal vein, the hepatic artery, and the left suprahepatic vein are quickly clamped and dissected, and the left lobe perfused on the back-table. The recipient's procedure is similar to the one described for the transplant of segments 2 and 3 from a cadaver donor, except for the fact that the arterial anastomosis can be performed only in the left branch of the hepatic artery. The branch is small and usually anastomosed directly to the recipient's hepatic artery using the operative

microscope.

Living-related liver transplantation has been widely debated with regard to the ethics of performing major surgery on a healthy person. The validity of this procedure is broadly recognized, and over 1200 cases have been performed worldwide, with a donor mortality and morbidity of approximately 0.2% and 10%, respectively. Morbidity relates mainly to biliary fistulas, incisional hernias, and bleeding. In the majority of cases, living-related transplants register an excellent outcome for pediatric recipients, thanks to the possibility of performing the transplant before the child's clinical condition deteriorates. Centers with most experience in this area report survival rates between 80 and 90% after 1 year[34-39] (Table 2).

Split-liver transplantation

Split-liver transplantation, as described originally by Pichlmayr, involves procuring a whole liver from a cadaver donor and dividing it into two sections along the round ligament, leaving the vascular structures for the two portions of hepatic parenchyma intact[40]. In this way, two partial organs are obtained from a single liver: the left lateral segment (segments 2 and 3), which can be transplanted in a child, and the extended right liver (segments 1 and 4-8), which can be transplanted into an adult. This procedure involves a much longer ischemia time, which, at the beginning of its adoption, led to unsatisfactory results, with a high incidence of primary dysfunction and technical complications[41-55] (Table 3). In 1994, Rogiers described a technical variation in the split-liver technique, derived from the living-related transplant experience that consisted in dividing the liver *in situ*

during the procurement procedure[56]. The technique has shown outcomes comparable to those obtained with conventional techniques[57-62] (Table 4).

The donor operation

A section of the liver is made along the falciform ligament to obtain a left graft, composed of segments 2 and 3, including the left hepatic vein, the left branch of the portal vein, and the left branch of the hepatic artery, along with the common hepatic artery and the celiac tripod, and a right graft, composed of segments 1 and 4 to 8, including the vena cava, the right branch of the hepatic artery, and the portal vein along with the origin of the mesenteric and splenic veins (Figure 3).

At the beginning of the split procedure, the hepatogastric ligament is inspected to detect an accessory left hepatic artery originating from the left gastric artery, which must be preserved. When this vessel is not detected, the ligament is sectioned. The common hepatic artery is then identified and dissected from the gastroduodenal artery up to its division into the right and left hepatic arteries. The left hepatic artery is then encircled (Figure 4A). If present, branches for the fourth segment originating from the left hepatic artery should be identified and divided. The base of the round ligament is exposed by dividing the small bridge of parenchyma that connects the lower portion of segment 4 to the left lateral section of the liver. The round ligament is dissected and completely mobilized with isolation and division of its venous connections to the fourth segment. Once the round ligament is dissected, the extrahepatic portion of the left branch of the portal vein can be identified just below the left hepatic artery.

Figure 3 Spit liver allows for the procurement of two separate grafts of different size. A section of the liver is made along the falciform ligament and divides the left lateral segment from the extended right liver. The left graft, composed of segments 2 and 3, and representing 20%-25% of the total liver volume, includes the left hepatic vein, the left branch of the portal vein, and the left branch of the hepatic artery, along with the common hepatic artery and the celiac tripod. The right graft composed of segments 1 and 4-8, and representing 75%-80% of the total liver volume, includes the vena cava, the right branch of the hepatic artery, and the portal vein.

This vein must be carefully dissected and encircled (Figure 4B). The left lateral section is rotated laterally on the right side and the ligamentum venosum is dissected up to left lateral hepatic vein, which can be isolated and encircled (Figure 4C). The bile ducts of the left lateral segment are included in the porta hepatis and should not be dissected. On the contrary, the porta hepatis must be encircled and divided sharply (Figure 4D).

The section of the parenchyma can now be performed along the falciform ligament (Figure 4E). It is helpful when identifying the plane of the dissection to pass the cotton tape, which encircles the left hepatic vein on the posterior surface of the liver in the fossa of the ductus venosus, laterally to the left branch of the hepatic artery and of the portal vein (Figure 4F and G). Pulling up on this tape, the dissection of the parenchyma is usually easy. At this point, the procedure continues as a standard donor operation with heparinization, cannulation and cross-clamping of the aorta, perfusion, and cooling of the abdominal cavity. The left hepatic vein is then sectioned close to the vena cava. Care must be taken to identify a distal bifurcation of this vein. A double left hepatic vein significantly increases the technical difficulty of the implantation of the graft. In this case, the vessel should be removed with a cuff of vena cava to allow a single vascular anastomosis with

Figure 4 Main phases of split liver procurement. the recipient vena cava. The left branch of the portal vein is sectioned close to the parenchyma. The right hepatic artery is sectioned close to its origin, and the hepatic artery is dissected up to the celiac trunk, which is removed along with an aortic cuff.

The recipient operation

Recipient hepatectomy is performed, as previously described for whole-liver transplantation, with the piggy-back technique[63]. Implantation of the left lateral segment is substantially different from a whole-sized graft. Assuring an adequate venous outflow requires a careful technique of anastomosis between the left hepatic vein of the graft and the inferior vena cava of the recipient and a proper positioning of the graft itself, which is rotated clockwise 45° on a transversal plane and slightly on a frontal plane. The final position of the cut surface of the parenchyma, including the new hilum of the graft, is high and posterior, so that the portal vein and hepatic artery have a course that is curved and longer than usual.

The outflow anastomosis is end-to-side between the left hepatic vein of the graft and the inferior vena cava of the recipient, with the triangulation technique described by Emond et al[64]. The bridge between the ostia of the right and middle hepatic veins is cut to obtain a single opening. The ostium of the left hepatic vein may be treated in the same fashion, to obtain a further enlargement of the opening, or suture-closed. The opening is then enlarged by cutting the anterior face of the vena cava to obtain a wide reversed triangular orifice. The cuff of the left hepatic vein of the graft is trimmed as short as possible, to avoid kinking. Three 5/0 vascular monofilament sutures are placed, taking the three corners of the graft and recipient orifices (Figure 5). The graft is then placed in the hepatic fossa of the recipient and the triangular anastomosis performed with three running sutures.

The second anastomosis is the portal one, performed in an end-to-end fashion with running sutures of 6/0 or 7/0 vascular monofilament. Both the length and the section of the vessels are crucial. As already mentioned, the length should be sufficient for the vessel to make a gentle curve that reaches the hilum of the graft; as for

Figure 5 **Anastomosis between the left hepatic vein of the graft and the inferior vena cava of the recipient, performed with the triangulation technique.** A: The bridge between the ostia of the right, middle, and left hepatic veins is cut to obtain a single opening; B: The opening is further enlarged by cutting the anterior face of the vena cava to obtain a wide triangular orifice; C: Three 5/0 vascular monofilament sutures are placed, taking the three corners of the graft and recipient orifices.

the section, the limiting factor is the size of the graft cuff. In the majority of cases, the recipient's vessel matches this size rather well. If not, it can be cut at its bifurcation, to obtain a branch patch. In case of real hypoplasia of the recipient's portal vein, the confluence of the mesenteric and splenic vein can be clamped, the vessel sectioned at this level and a venous graft from the donor (usually the splenic or the external iliac vein) interposed between the confluence and the portal vein of the new liver. After completion of the anastomosis the graft is reperfused.

The arterial anastomosis comes next. The arterial axis of the graft usually includes the proper and common hepatic artery, in continuity with the celiac artery, and a patch of the aorta. The level of the anastomosis is chosen at any place along the recipient's arterial axis, and

the two vessels are trimmed to obtain a similar section and an adequate length, according to what has already been stated concerning the portal vein. The anastomosis is performed end-to-end with a running suture of 7/0 or 8/0 vascular monofilament. If the recipient's arterial axis is deemed inadequate, the aorta can be clamped at the origin of the celiac artery or just below the renal arteries, and an end-to-side anastomosis can be performed at one of these sites. In the latter case, the interposition of an arterial graft from the donor, usually represented by an iliac artery, may be necessary.

The final stage is biliary reconstruction, which is always a hepaticojejunostomy with a Roux-en-Y loop. The bile duct of the graft may be single or double, although in the latter case two different anastomoses are performed (Figure 6).

Childhood hepatic malignancies have been considered a contraindication to the use of split-liver transplantation, since the need for the retention of the recipient's inferior vena cava potentially precludes obtaining a tumor-free margin[65]. A technical variation, which has allowed us and others to successfully use left lateral segment grafts to transplant children affected by hepatic malignancies, involves the replacement of the recipient's inferior vena cava using an iliac vein graft from the donor[66]. On the back-table, a wide V-shaped opening on the wall of the common iliac vein graft from the donor is made. The left hepatic vein of the left lateral segment graft is anastomosed end-to-side to the V-shaped opening on the common iliac vein with two 5/0 polypropylene running sutures (Figure 7). On the recipient, a total hepatectomy is usually performed using the standard technique of removing the liver together with the retrohepatic vena cava. At this point, the left lateral segment graft with the iliac vein graft is anastomosed to the suprahepatic vena cava in an end-to-end fashion with a 4/0 polypropylene running suture. The inferior edge of the iliac graft is then anastomosed to the infrahepatic vena cava with a 5/0 polypropylene running suture.

Donor selection
The following factors must be considered when a donor is evaluated for a specific patient.

Dimensional matching: The selection of a graft with an adequate parenchymal mass is critical to success. The minimal hepatic mass necessary for recovery is not clearly established, and its calculation must take into account the temporary loss of hepatocytes caused by the donor's injury or treatment, as well as preservation injury, acute rejection, or technical problems. Several formulas have been proposed to estimate adult and pediatric normal liver volume[67-72].

Considering that preservation injury is greater in organs from deceased donors, the hepatic mass of a graft procured from a cadaver donor should be greater than the calculated mass necessary using a living-donor liver segment. In the authors' experience, a donor weight range 20%-30% above or below that of the recipient is

Figure 6 Biliary reconstruction performed by means of hepatico-jejunostomy. The bile duct of the graft can be single or double, although in the latter case, two different anastomoses are performed (B) or, if the two ducts are closed sufficiently, a common orifice can be created and anastomosed to the bowel loop (C).

Figure 7 Use of left lateral segment grafts to transplant children affected by hepatic malignancies, with replacement of the recipient's inferior vena cava using an iliac vein graft from the donor. On the back table a wide V-shaped opening on the wall of the common iliac vein graft from the donor is made (A), and the left hepatic vein of the left lateral segment graft is anastomosed end-to-side to the V-shaped opening on the common iliac vein (B).

ideal for whole-organ donors, however these values can be extended down to 50% below and 100% above, taking into consideration body habitus and factors that would increase recipient abdominal size, such as ascites and hepatosplenomegaly. When selecting donors of partial grafts, a graft fraction of 1%-3% of the recipient body mass is optimum, while a graft-to-recipient weight ratio < 0.7 is usually associated with inferior overall allograft and patient survival. In the authors' experience, a liver is procured and transplanted as a whole graft when the donor-to-recipient body weight ratio is ≤ 2. When the donor-to-recipient body weight ratio is between 2 and 12, the graft is considered for split liver[60,61].

Donor characteristics: Donor-organ suitability is assessed by evaluating clinical information and by biochemical tests. Particular attention is paid to donor age, intensive care hospitalization time, infections, hemodynamic stability. Biochemical tests do not serve as good benchmarks of functional capability, even if severe electrolyte disturbances and deteriorating trends identify increased risk. In questionable cases, biopsy of the donor liver at the time of organ harvest or during evaluation of live donors is helpful to identify pre-existing liver disease or steatosis. Quite extended criteria can be used in donors of whole allografts, especially when ischemic time is limited, without compromising the outcome. On the contrary, restricted selection criteria have been proposed when split-liver transplantation is considered. Commonly accepted donor selection criteria for split-liver procurement are: (1) age 15-50 years; (2) weight > 40 kg; (3) no past history of liver dysfunction/damage; (4) liver function tests within 2-5-fold of normal values; (5) normal macroscopic appearance of the graft; and (6) hemodynamic stability[73]. Nevertheless, the authors have adopted a liberal policy of liver splitting. The decision of whether or not to split a graft is based mainly on recipient, rather than on donor, criteria. Children requiring re-transplantation or who have fulminant hepatic failure are not excluded. Donor evaluation does not require special or additional invasive or non-invasive tests. Using these extended criteria for donor selection, we have been able to transplant all the children in need with no mortality on the waiting list and good overall patient and graft survival rates[60,61].

No consistent data exist on the effect of donor age on the long-term results of pediatric liver transplantation. Data from multicenter registries have shown that pediatric patients receiving livers from pediatric-age donors have significantly better graft survival compared to those receiving livers from donors aged > 18 years[74,75]. These data strongly support the primary use of pediatric donors for pediatric recipients, but are not to be considered a contraindication to the use of adult donors in pediatric transplantation. The limited availability of pediatric donor organs does not allow us to satisfy the need of an increased waiting list population. Moreover, the results obtained using adult donors are biased by the policy to use older donors only in high-risk urgent cases. For split-liver transplantation, the authors used donors over the age of 50 years without affecting the 3-year patient and graft survival[76]. In addition, pediatric donors can be safely used for split-liver procurement and transplantation: left lateral segment is transplanted in a small child, while the extended right lobe can be used in larger children, adolescents or adults[77,78].

Living-donor selection: In living-donor transplantation, the evaluation and selection of a donor, usually a parent or first-degree relative is performed on the assumption that donor safety can be assured and that the donor's liver function is normal. Donors should be 18-55 years of age, and have an ABO-compatible blood type. Following a satisfactory medical and psychological examination by physicians who are not directly involved with the transplantation program, vascular imaging is performed to assess the hepatic arterial anatomy. Donor safety has been excellent in all living donor series.

EARLY POSTOPERATIVE PERIOD

The early postoperative period consists of managing problems related to technical complications and to the prevention, diagnosis, and treatment of acute rejection and infection episodes. Postoperative complications usually present with a combination of cholestasis, rising hepatocellular enzyme levels, and variable fever, lethargy and anorexia. This non-specific symptom complex requires specific diagnostic evaluation before establishing treatment, and empiric therapy may result in misdiagnosis, morbidity and mortality.

Primary non-function

The lack of graft functional recovery can be seen in the first hours following transplantation, with high lactate levels, increased prothrombin time and partial thromboplastin time, and failure of the patient to wake despite sedation suspension. This extremely serious complication must be treated aggressively and immediately by infusing prostaglandin E_1, adopting the necessary measures to prevent a brain edema (mannitol infusion, hyperventilation), and addressing the effects of the liver failure by infusing plasma and glucose. If the signs of lack of functional recovery persist for more

than a few hours, the patient needs a new transplant as soon as possible. Lesser degrees of allograft dysfunction occur more frequently but are usually reversible. The status of the donor liver contributes significantly to the potential for primary non-function because of ischemic injury secondary to anemia, hypotension, hypoxia, or direct tissue injury. A possible cause of primary non-function is hyperacute rejection, a rare phenomenon characterized by rapid intraparenchymal vascular thrombosis, mediated by pre-formed antibodies that bind to the vascular endothelium and trigger the complement system. Antibodies are generally directed against protein alloantigens such as foreign MHC molecules or less differentiated alloantigens expressed on endothelial cells.

Vascular complications

The hepatic artery anastomosis carries the highest risk of thrombosis (5%-18%) and leads to massive graft necrosis in cases of early onset. Hepatic artery thrombosis occurs in children three to four times more frequently than in adult transplant patients, and occurs most often within the first 30 d after transplantation and in small babies transplanted with whole livers[62,79]. When hepatic artery thrombosis is identified early (Figure 8), reconstruction can be attempted to avoid allograft necrosis[80]. When allograft failure develops, urgent re-transplantation is the only option. Late thromboses (occurring some weeks after the transplant) can manifest with biliary complications (stenosis or dehiscence of the biliary anastomosis, intrahepatic bilomas) or sepsis. Rarely, allograft necrosis occurs. Stenosis of the hepatic artery usually occurs at the anastomosis and in many cases may progress to complete thrombosis. Clinical manifestations include cholestasis or graft failure caused by diminution in hepatic blood flow. Non-invasive diagnosis relies on Doppler ultrasound with calculation of resistive indices and systolic acceleration time. Treatment modalities include revision of the anastomosis or balloon angioplasty (Figure 9).

A typical complication of a left lateral segment graft is stenosis at the level of the anastomosis between the left hepatic vein of the graft and the native vena cava, which in the worst cases can lead to acute Budd-Chiari syndrome. However, since the introduction of the triangulation technique, this complication has become quite rare[68]. When present, outflow venous obstruction can be treated by cavography and balloon angioplasty (Figure 10).

Finally, portal vein thrombosis occurs in 5%-10% of recipients. It is more frequent in children transplanted for biliary atresia, because of pre-existing portal vein hypoplasia, which requires replacing the entire portal vein down to the confluence of the superior mesenteric vein with the splenic vein to avoid low-flow-related thrombosis. Early thrombosis following transplantation, detected by ultrasound screening, requires immediate anastomotic revision and thrombectomy[81]. Later thrombosis is usually detected by decreased platelet counts and increasing spleen size or gastrointestinal bleeding (Figure 11). Interventional radiographic stent

Figure 8 Selective celiac angiography showing early hepatic artery thrombosis after left lateral segment transplantation. A: Conventional angiography is the gold standard for radiographic diagnosis of hepatic artery thrombosis. B: Nowadays, the sensitivity of multiphase, multislice computed tomographic angiography with multidetector reconstruction approaches that of conventional angiography.

placement or balloon dilation has been successful in patients who have portal anastomotic stenosis but is less successful when complete thrombosis has occurred[82]. Portal venous shunting may be needed in patients who have progressive portal hypertensive complications.

Biliary complications

Biliary complications occur in approximately 10%-30% of pediatric liver transplant recipients, depending on the type of allograft used[62,83-85]. In the early postoperative period, the presence of bile-like fluid in the abdominal drainage is strongly suggestive of a bile leak. Ultrasound evidence of intrahepatic biliary ducts dilatation, elevated alkaline phosphatase and γ-glutamyl transferase (GT), and/or recurrent cholangitis suggest anastomotic or intrahepatic biliary stricture or small bowel obstruction at or distal to the Roux-en-Y anastomosis. Sometimes, non-specifically elevated liver function tests may be caused by a biliary stricture; in these cases a liver biopsy showing biliary duct proliferation and portal tract enlargement may help in differential diagnosis (Figure 12). Complications after duct-to-duct biliary reconstruction can be treated by dilation and internal stenting. With recurrent stenosis or persistent postoperative leak, Roux-en-Y choledochojejunostomy is the preferred treatment. In small children and in all patients transplanted for biliary atresia or with a partial graft, Roux-en-Y choledochojejunostomy is the reconstruction method of choice. In these patients,

Figure 9 A case of hepatic artery stenosis. Figure 11 Portal vein thrombosis. Computed tomographic angiography with evidence of portal vein thrombosis and cavernomatous degeneration with collateral drainage through the left gastric vein (A), and evidence of intrahepatic portal flux restoration (B).

Figure 12 Liver biopsy performed in a left lateral segment recipient because of non-specifically elevated liver function tests. Histology shows biliary duct proliferation and portal tract enlargement suggestive of mechanic cholestasis.

dilatation and stenting are performed by percutaneous transhepatic cholangiography (Figure 13). The presence of multiple bile ducts has a documented increased risk for biliary complications[86].

Reoperation and re-transplantation

Early second-look reoperation is commonly used in several centers for the best diagnosis and treatment of bile leakage, hemorrhage, bowel injury secondary to multiple intra-abdominal adhesions, and sepsis. Infants and small children who have had only initial skin closure require secondary laparotomy for musculofascial closure in 5-7 d[87].

The overall incidence of re-transplantation ranges from 8% to 29%. The incidence of re-transplantation is similar for whole-organ allografts and partial allografts. The majority of re-transplantations result from acute allograft damage caused by either hepatic artery thrombosis or primary non-function; chronic rejection and biliary complications are uncommon causes. When re-transplantation for acute organ failure is undertaken in a timely manner, patient survival exceeds 80%. When re-transplantation is performed after prolonged immunosuppression for chronic allograft failure, often complicated by multiorgan insufficiency, the survival is only 50%.

Acute rejection

About 20%-50% of patients develop at least one episode of acute rejection in the first weeks after liver transplantation. The clinical picture of rejection

Figure 13 A case of biliary stenosis. Percutaneous transhepatic cholangiography performed in a left lateral segment recipient demonstrating intrahepatic biliary tree dilatation with stenosis of the hepaticojejunostomy (A), balloon bilioplasty (B), and transanastomotic percutaneous transhepatic biliary drainage positioning (C). Resolution of the stenosis after three sessions of bilioplasty (D).

Figure 14 Acute cellular rejection: histopathological findings and grading. A: Mild acute cellular rejection, portal tracts are mildly expanded because of a predominantly mononuclear, but mixed portal inflammation. Rejection infiltrate is composed of blastic and small lymphocytes, eosinophils, macrophages, and occasional plasma cells. Lymphocytes are also present inside the basement membrane of the small bile ducts and in the subendothelial space of small portal vein branches. B: Moderate acute cellular rejection, all the portal tracts are markedly expanded by a predominantly mononuclear, but mixed inflammation. Centrilobular inflammation and hepatocyte necrosis and dropout are absent. C: evere acute cellular rejection, severe expansion of the portal tracts because of inflammation with focal portal-to-portal bridging; perivenular inflammation with hepatocyte necrosis and dropout; inflammation and damage to small bile ducts.

and transaminases. A liver biopsy is required to confirm rejection. Acute rejection is characterized by the histological triad of endothelialitis, portal triad lymphocyte infiltration with bile duct injury, and hepatic parenchymal cell damage[88] (Figure 14). Severity of acute rejection is scored according to the Banff scheme, which includes the descriptive grades indeterminate, mild, moderate, and severe, and a semi-quantitative rejection activity index (RAI) scoring on a scale from 0 to 3 the prevalence and severity of portal inflammation, bile duct damage, and subendothelial inflammation[89] (Tables 5

includes fever, irritability, malaise, leucocytosis, often with eosinophilia, and increased γ-GT, bilirubin,

Table 5 Banff grading of acute liver allograft rejection

Assessment	Criteria	RAI
Indeterminate	Portal inflammatory infiltrate that fails to meet criteria for the diagnosis of acute rejection	1-2
Mild	Rejection infiltrate in a minority of the triads that is generally mild and confined within the portal spaces	3-4
Moderate	Rejection infiltrate expanding most or all of the triads	5-6
Severe	As above for moderate, with spillover into the periportal areas and moderate to severe perivenular inflammation that extends into the hepatic perenchyma and is associated with perivenular hepatocyte necrosis	> 6

Table 6 Rejection activity index (RAI)

Category	Criteria	Score
Portal inflammation	Mostly lymphocytic inflammation involving, but not noticeably expanding, a minority of the triads	1
	Expansion of most or all of the triads by a mixed infiltrate containing lymphocytes with occasional blasts, neutrophils, and eosinophils	2
	Marked expansion of most or all of the triads by a mixed infiltrate containing numerous blasts and eosinophils with inflammatory spillover into the periportal parenchyma	3
Bile duct inflammation damage	A minority of the ducts are cuffed and infiltrated by inflammatory cells and show only mild reactive changes such as an increased nuclear-to-cytoplasmatic ratio of the epithelial cells	1
	Most or all of the ducts infiltrated by inflammatory cells. More than an occasional duct shows degenerative changes such as nuclear pleomorphism, disordered polarity, and cytoplasmatic vacuolization of the epithelium	2
	As above for the 2nd criterion, with most or all of the ducts showing degenerative changes or focal luminal disruption	3
Venous endothelial inflammation	Subendothelial lymphocytic infiltration involving some, but not a majority, of the portal and/or hepatic venules	1
	Subendothelial infiltration involving most or all of the portal and/or hepatic venules	2
	As above for the 2nd criterion, with moderate or severe perivenular inflammation that extends into the perivenular parenchyma and is associated with perivenular hepatocyte necrosis	3

and 6).

The primary treatment of rejection is a short course of high-dose steroids. Bolus doses administered over a 3-6-day period with a rapid taper to baseline therapy are successful in the majority of cases. When refractory or recurrent rejection occurs, conversion from cyclosporine to tacrolimus, or antilymphocyte therapy using the monoclonal antibody, ornithine-ketoacid transaminase orthoclone, have been successfully used[90,91].

INFECTIONS

Immunosuppressive drugs used to prevent rejection inhibit activation of T lymphocytes, medullar cell proliferation and macrophage function, therefore creating an optimal environment for the development of infections. Infectious complications now represent the most common source of morbidity and mortality after transplantation.

Bacterial infections occur in the immediate post-transplantation period and are most often caused by Gram-negative enteric organisms, enterococci, or staphylococci. Sepsis originating at sites of invasive monitoring lines can be minimized by replacing or removing all of the intraoperative lines soon after transplantation. The use of prophylactic antibacterial antibiotics is discontinued as soon as possible to avoid the development of resistant organisms.

Fungal infection is a potential problem in the early post-transplantation period. To prevent fungal infection, aggressive protocols for pre-transplantation prophylaxis have been proposed[92]. Fungal infection most often occurs in high-risk patients requiring multiple operative procedures, re-transplantation, hemodialysis or continuous hemofiltration, pre-transplant chemotherapy, and multiple antibiotic courses. The authors use antifungal postoperative prophylaxis with liposomal amphotericin B only in high-risk patients undergoing liver transplantation.

Early and severe viral infections are caused by viruses of the herpes family, including Epstein-Barr virus (EBV), cytomegalovirus (CMV), and herpes simplex virus[93]. The risk of developing either CMV or EBV infection is influenced by the preoperative serological status of the transplant donor and recipient[94,95]. Seronegative recipients receiving seropositive donor organs are at greatest risk. Various prophylactic protocols, including intravenous IgG and hyperimmune anti-CMV IgG, associated with acyclovir or ganciclovir have been used to decrease the incidence of symptomatic CMV and EBV infection, although seroconversion in naive recipients inevitably occurs[94,96]. The suspicion of CMV infection is suggested by the presence of fever, leukopenia, maculopapular rash and hepatocellular abnormalities, respiratory insufficiency, or gastrointestinal hemorrhage. Hepatic biopsy or endoscopic biopsy of colonic or gastroduodenal sites allows early diagnosis with immunohistochemical recognition. Nowadays, the availability of specific antiviral drugs like ganciclovir, foscarnet and more recently valaciclovir, have radically modified the prognosis of CMV infection. At the start of the 1990s, the concept of pre-symptomatic therapy

was introduced as a strategy to prevent the incidence of CMV-related disease, based on the principle of not administering antiviral medications up to the point when these will have maximum effect, and monitoring CMV antigenemia (pp65) or viremia (CMV DNA)[97,98].

Herpes simplex virus infections, similar to those seen in non-transplant patients, require treatment with acyclovir when diagnosed.

EBV infection represents a potential risk for the pediatric transplant recipient. EBV infection has a variable clinical picture including a mononucleosis-like syndrome, hepatitis-simulating rejection, extranodal lymphoproliferative infiltration, peritonsillar or lymph node enlargement, or encephalopathy. Monitoring of EBV blood viral load by quantitative polymerase chain reaction (PCR) is the best predictor of risk. When evidence of active infection exists, an acute reduction in immunosuppression is mandatory. The authors recommend monthly EBV-DNA PCR counts and more frequent monitoring in case of increasing viral load levels. As a result of the lack of a standardized EBV DNA count methodology, no common cutoff exists. In the authors' experience, more than 500 genomes/10^5 peripheral blood leukocytes identify patients who benefit from reduction in primary immunosuppression[99]. Antiviral therapy with ganciclovir and CMV-IgG is also used, although no definitive data support their use[100,101].

Other post-transplantation infectious complications include adenovirus hepatitis, varicella, and enterovirus-induced gastroenteritis. *Pneumocystis carinii* infection has been nearly eliminated by the prophylactic administration of sulfisoxazole and trimethoprim or aerosolized pentamidine.

MANAGING IMMUNOSUPPRESSIVE THERAPY

The immune system recognizes the graft as foreign and begins a destructive immune response mediated principally by the T lymphocytes. In order to avoid destruction of the graft, immunosuppressive drugs must be administered. Progress in transplant surgery in the last 20 years has been characterized in large part by the introduction of calcineurin inhibitors that today represent the keystone of most immunosuppressive protocols[102,103]. In the last decade, new drugs that selectively target various cellular activation pathways have been proposed and used. The following are the most commonly used drugs in pediatric liver recipients.

Corticosteroids

Corticosteroids were the first drugs to be used to control rejection and are still an essential element of the immunosuppressive regimen; they are effective in both the prevention and treatment of graft rejection. They act through intracellular receptors expressed in all cells of the body. Their immunosuppressive action mechanism, not fully clarified yet, is linked to the suppression of antibody production; inhibition of synthesis of

cytokines such as interleukin-2 (IL-2) and interferon-γ; reduction in the proliferation of helper and suppressor T cells, cytotoxic T cells, and B cells; and the migration and activity of neutrophils.

Long-term clinical experience with steroid use has documented a host of adverse effects. Over-immunosuppression is associated with increased incidence of bacterial, fungal and viral infections. In addition, patients taking steroids carry an increased risk for developing malignancies, especially lymphomas and skin cancers[104]. Detrimental metabolic effects of steroids are wide ranging and are of particular concern for the pediatric transplant patient[105-107]. In terms of hospital costs, the calculated 10-year cumulative expense for steroid-related complications in adult kidney recipients has been shown to be 5300 $ per patient per year[108]. Efforts are underway to develop immunotherapy regimens in which steroids can be withdrawn early, or not used at all.

The experience of steroid weaning after pediatric liver transplantation was summarized in 2000 by Reding[109]. There are a total of nine recent studies, not all of which were non-randomized and uncontrolled. Steroid treatment could be successfully stopped in 21%-100% of the transplanted patients. The risk of rejection was not significantly increased, and varied from 7% to 29%. Chronic rejection did not seem to be increased[110-118] (Table 7). The conclusions of this review are the following: (1) weaning of steroids after pediatric liver transplanatation is safe and, most of the time, beneficial; and (2) in many patients, calcineurin inhibitor monotherapy can be achieved, suggesting that the next step could be the adoption of steroid-free immunosuppressive protocols.

In a non-randomized study, Reding *et al*[119] compared pediatric liver transplantation under steroid-free immunosuppression in children who received combined tacrolimus and antibody to the IL-2 receptor of T cells (basiliximab), with matched historical recipients taking tacrolimus and steroids. Twelve-month rejection-free survival was similar in the steroid-free group compared with the corticosteroid group. The authors performed the first prospective, controlled, randomized study designed for children undergoing liver transplantation to test the possibility of avoiding the use of corticosteroids under baseline tacrolimus immunosuppression plus basiliximab induction, which confirmed no harmful effect of steroid avoidance on graft acceptance[120].

Corticosteroid withdrawal or avoidance can be difficult in patients with autoimmune hepatitis, primary biliary cirrhosis, or primary sclerosing cholangitis. In these patients it might be desirable to include steroids in the immunosuppressive protocol as a principle, although definitive and convincing data are not available.

Calcineurin inhibitors

Cyclosporine and tacrolimus are classified as calcineurin inhibitors because they inhibit T-cell responses and bind to intracellular proteins called immunophilins.

Table 7 Literature review of immunosuppressive protocol with steroid weaning after pediatric liver transplantation

CsA: Cyclosporine; CsA-ME: Cyclosporine microemulsion; Aza: Azathioprine; TAC: Tacrolimus. [1]In 53% of the weaned children; [2]Some patients received antilymphocyte globulin or OKT3 induction.

The immunophilin-drug complex competitively binds to and inhibits the phosphatase activity of calcineurin. Calcineurin inhibition indirectly blocks the transcription of cytokines, particularly IL-2, which regulate the proliferative T-cell response[121]. Calcineurin inhibitors have similar side-effect profiles, which include dose-dependent nephrotoxicity, neurotoxicity, and hypertension. Most adverse effects are reversible after dose reduction or discontinuation of the drug[122,123]. Tacrolimus has not been associated with cosmetic adverse effects such as hypertrichosis and gingival hyperplasia observed in cyclosporine-immunosuppressed children. Moreover, tacrolimus is associated with less hyperlipidemia and a lower adverse cardiovascular risk profile than cyclosporine[124], but with slightly more *de novo* diabetes and gastrointestinal symptoms[125]. In some studies, tacrolimus has been described to cause a higher incidence of post-transplant lymphoproliferative disease[126,127], but this has not been confirmed in other authors' experiences[128]. Hypertrophic cardiomyopathy has been reported with prolonged use of tacrolimus at unusually high levels[129].

Calcineurin inhibitors are mainly absorbed from the small intestine and are metabolized in the liver and small intestine by the cytochrome P4503A enzyme system[130]. The majority of their metabolites are excreted in bile[131]. The most important interactions are with enzymes or drugs that induce or inhibit the cytochrome P4053A, which results in reduced or increased calcineurin inhibitors levels.

Tacrolimus or cyclosporine usually represents the primary drug of most immunosuppressive regimens. Over the last 10 years, the use of tacrolimus has increased, being nowadays preferred to cyclosporine[132]. Tacrolimus and cyclosporine have been compared in large multicenter trials that showed similar 1-year patient and graft survival, with a significantly reduced incidence of acute rejection as well as steroid-resistant rejection in children treated with tacrolimus. Moreover, tacrolimus is superior to cyclosporine for the treatment of rejection episodes that may resolve when patients are switched from cyclosporine to tacrolimus therapy[97,133].

Table 8 Desired trough concentrations of calcineurin inhibitors after pediatric liver transplantation

Time post-transplant (mo)	Target level (mg/L)	
	Cyclosporine	Tacrolimus
0-3	200-250	10-15
4-12	150-200	8-10
> 12	50-100	5-8

Cyclosporine: The microemulsion form of cyclosporine, Neoral, is the formulation mainly used, which has replaced the original formulation Sandimmune because of its greater and more consistent bioavailability. Pharmacokinetics features of cyclosporine that are to be considered in children are the following: (1) cyclosporine bioavailability correlates with age, being lower in younger patients; and (2) cyclosporine is metabolized in children at a higher rate than adults, and appears to be inversely related to age[134]. The type of biliary anastomosis (e.g. Roux-en-Y biliary anastomosis for biliary atresia) and concomitant disease (e.g. cystic fibrosis) may affect absorption and bioavailability[135,136]. The recommended starting dose of Neoral is 5 mg/kg twice daily, which should be administered orally within the first 12 h of abdominal closure. Intravenous cyclosporine can be administered at a dose of 2 mg/kg per day in two divided doses by continuous infusion over 2-6 h in case of poor absorption or inadequate trough concentrations. After the first administration, the dose is adjusted in order to keep trough concentrations within a recommended target range (Table 8). Trough levels are poor predictors of rejection episodes or outcome of graft recipients[137], therefore, drug concentration in blood drawn 2 h post-dose has been proposed recently to be a superior estimate of the subsequent 12 h cyclosporine exposure[138,139].

Tacrolimus: The recommended tacrolimus starting dose is 0.05-0.1 mg/kg, administered orally within the first 12 h after abdominal closure. Subsequently, doses are adjusted in order to maintain trough concentrations

within a recommended target range (Table 8). The trough level is widely accepted for routine tacrolimus drug level monitoring. Large inter- and intra-individual differences in pharmacokinetics exist. The elimination half-life of tacrolimus in children is 50% of that in adults, and clearance is correspondingly two to four times faster[140,141]. Therefore, children require higher doses to achieve similar tacrolimus concentrations.

Mycophenolate mofetil

The active metabolite of mycophenolate mofetil, mycophenolic acid, is a selective inhibitor of the enzyme inosine monophosphate dehydrogenase, which is essential for the *de novo* pathway of purine synthesis[142]. Inhibition of the *de novo* pathway results in the depletion of guanosine nucleotides and arrested lymphocytes replication because they are unable to use the alternative pathway for nucleotide production[143].

Mycophenolate mofetil has been used successfully as an alternative immunosuppressive agent in patients with chronic rejection, refractory rejection, or severe calcineurin inhibitor toxicity[144,145]. Mycophenolate mofetil has also been used in calcineurin-inhibitor and corticosteroid-sparing immunosuppressive protocols, without increasing the risk of rejection[146,147]. The suggested dose for pediatric liver transplant recipients is 15 mg/kg twice daily[148]. Pharmacokinetic studies showed large inter-individual variations in mycophenolic acid parameters[149,150], which indicates the need for therapeutic drug monitoring and individualized dosing. The most relevant adverse effects of mycophenolate mofetil are dose-dependent gastrointestinal symptoms and bone marrow suppression[147,151]. Acyclovir and ganciclovir increase mycophenolic acid efficacy, whereas cholestyramine, oral antibiotics, antacids, cyclosporine, and high tacrolimus concentrations reduce its concentration[148-150].

Sirolimus

Sirolimus (rapamycin) is a macrolide antibiotic with potent immunosuppressive properties that acts by blocking T-cell activation by way of IL-2R post-receptor signal transduction[152]. Sirolimus has been used in small, uncontrolled studies in liver transplant recipients (Table 9) and reduces rate of acute rejection, when used in combination with calcineurin inhibitors, even at low doses, or facilitates early steroid withdrawal, while maintaining low rates of acute rejection[153-157].

Sirolimus has also been used as rescue treatment in chronic rejection and calcineurin inhibitor toxicity[157-159], whereas attempts to use sirolimus as a single primary immunosuppressive agent have resulted in a high rate of acute rejection[160]. Sirolimus has not yet been approved by the US Food and Drug Administration for use in liver transplantation. One trial to evaluate sirolimus in liver transplant recipients was halted because of an increased incidence of hepatic artery thrombosis. In contrast, other studies have not confirmed this finding[154,161,162], and a possible benefit of sirolimus in the prevention of coronary artery restenosis after percutaneous coronary revascularization has been described[163]. Sirolimus has shown antineoplastic activity, inhibiting angiogenesis in malignant tissue through reduction of vascular endothelial growth factor secretion, which may provide a specific indication for using of the drug in patients transplanted for primary liver malignancy[164].

Sirolimus drug interactions are similar to those of calcineurin inhibitors. It has a long half-life (40-86 h) and intra- and inter-individual variation[152,165]. Therefore, daily sirolimus monitoring is not necessary and monitoring trough level twice weekly for the first month and weekly for the next month is recommended, targeting a 5-15 mg/L range. Sirolimus levels increase during simultaneous administration of cyclosporine[166]. The most relevant dose-related side effects of sirolimus are hyperlipidemia, thrombocytopenia and leukopenia[153,157].

IL-2 receptor antibodies

T cells involved in acute rejection act by exposing activation markers such as the IL-2 receptors. Therefore, anti-IL-2 receptor therapy appears to be a promising option for specific immunosuppression. IL-2 receptor antibodies have been used primarily in children as induction agents in double or triple immunosuppression protocols. Preliminary experience in pediatric liver recipients is encouraging: pooled data from the available papers from the literature encompassed 79 patients treated with daclizumab, 165 with basiliximab, and 209 no-induction controls; incidence of acute rejection was lower in the induction groups[119,120,167-172] (Table 10).

A multicenter trial studied basiliximab pharmacokinetics and pharmacodynamics in children. It demonstrated that to achieve efficacious results, pediatric patients less than 35 kg in weight should receive two intravenous 10-mg

doses, and those weighing $\geqslant$ 35 kg should receive two 20-mg doses of basiliximab. The first dose should be given within 6 h after organ reperfusion, and the second on day 4 after transplantation. A supplemental dose may be considered for patients with a large volume of drained ascitic fluid relative to body size[173]. For daclizumab, various different dosing regimens have been used[169,174]. A dual regimen of 1 mg/kg on days 0 and 4 provides receptor saturation for up to 21 d.

POST-TRANSPLANT LYMPHOPROLIFER-ATIVE DISORDERS (PTLDS)

PTLDs are a heterogeneous group of diseases, ranging from benign lymphatic hyperplasia to lymphomas. PTLD is the most frequent tumor in children following transplantation, and occurs in the majority of the cases within the first 2 years after transplantation[175]. Late forms have usually an aggressive clinical course and severe prognosis. The development of PTLD in pediatric liver transplant recipients is favored by the intensity of the immunosuppression, its lifetime duration, and the absence of prior exposure to EBV infection in 60%-80% of patients. Risk factors for PTLD development are: (1) high total immunosuppression load; (2) EBV-naive recipients; and (3) the intensity of active viral load[176,177]. No single immunosuppressive agent has been directly related to PTLD. An important pathogenic feature favoring PTLD development is EBV infection.

Treatment of PTLD is based on the immunological cell typing and clinical presentation. Documented PTLD requires an immediate decrease or withdrawal of immunosuppression, taking into account the increased risk of organ rejection[100,101]. If a tumor expresses the B-cell marker CD20, the anti-CD20 monoclonal antibody rituximab has been successfully used. In some studies, the combination of cyclophosphamide, predni-

sone and rituximab has shown a response rate of 100%, with minimal toxicity[178,179]. Patients who have aggressive monoclonal malignancies have poor prognosis even with immunosuppressive reduction, acyclovir, surgery, and conventional chemotherapy or radiation therapy. Recently, autologous EBV-specific cytotoxic T-lymphocytes have proved effective in enhancing EBV-specific immune responses and reducing viral load in organ transplant recipients with active infection, and have been successfully used as first-line treatment of EBV-related PTLD[180].

LATE LIVER ALLOGRAFT DYSFUNCTION

There are several potential causes of late liver allograft dysfunction and differential diagnosis can be difficult because of overlapping clinical, serological and histopathological features. Recurrence of the native liver diseases after transplantation is a less significant problem in the pediatric population in comparison to adults. Recurrent infections and immune-based diseases are the most difficult diagnostic challenges. Most late causes of liver allograft dysfunction are detected because of abnormalities in routinely monitored liver tests; clinical signs and symptoms are much less common. When signs or symptoms do occur, liver biopsy is indicated. Common causes of late dysfunction in the pediatric population are shown in Table 11.

Late-onset acute rejection
Late-onset acute rejection may show slightly different features than typical acute rejection episodes seen early after transplantation, and is commonly characterized by: (1) predominantly mononuclear portal inflammation; (2) venous subendothelial inflammation of portal or central veins or perivenular inflammation; and (3) bile duct inflammation and damage. Late-onset acute rejection can

Table 11 Common causes of late dysfunction in the pediatric population

	Incidence at 5 yr (%)	Risk factors
Acute rejection	Variable (< 30)	Inadequate immunosuppression
		Treatment with immune activating drugs (e.g. interferon)
		History of autoimmune liver disease
Chronic rejection	-3	Inadequate immunosuppression
		Treatment with immune-activating drugs (e.g. interferon)
		Refractory acute rejection
		Chronic rejection in a previous failed allograft
Recurrent AIH	-30	Suboptimal immunosuppression
		AIH type I
		Severe inflammation in native liver
		HLA DR3 or DR4
De novo AIH	< 5	
Recurrent PBC	20-30	Tacrolimus as baseline immunosuppression

		Steroid and other immunosuppression withdrawal
Recurrent PSC	20-30	Male sex; donor-recipient gender mismatch
		Intact colon at time of transplantation
Idiopathic post-transplant hepatitis	5-60	

AIH: Autoimmune hepatitis; PBC: Primary biliary cirrhosis; PSC: Primary sclerosing cholangitis.

Figure 15 Histological findings in chronic rejection: Little portal inflammation in conjunction with bile duct loss affecting > 50% of the portal tracts and moderate or severe perivenular fibrosis.

also manifest as so-called central perivenulitis [181-183], or may resemble chronic hepatitis[184,185]. Mild cases may resolve spontaneously[183], but more severe forms warrant more aggressive treatment.

Chronic rejection

Chronic rejection develops in 5%-10% of transplanted patients. The primary clinical manifestation is progressive cholestasis. This course can occur within weeks from transplantation or later, and can be asymptomatic or follow persistent and/or unresponsive acute rejection and/or inadequate immunosuppression. Two clinical forms have been described[186]. In the first, named vanishing bile duct syndrome, the biliary epithelium is primarily injured with changes ranging from senescence (early stage) to severe ductopenia in at least 50% of the portal tracts (late stage)[187]. This form can be successfully treated by conversion from cyclosporine to tacrolimus immunosuppression protocols. Re-transplantation is necessary in non-responding children. The second subtype is characterized by the development of progressive ischemic injury to bile ducts and hepatocytes, which causes ductopenia and ischemic necrosis with fibrosis (Figure 15). In this setting, the diagnosis is rarely based on histology alone, because arteries with pathognomonic changes are rarely present in needle biopsy specimens. Bile duct injury and ductopenia, however, can be caused by biliary strictures, hepatic artery pathology, adverse drug reactions, and CMV. Selective hepatic angiography showing pruning of the intrahepatic arteries with poor peripheral filling and segmental narrowing supports a diagnosis of chronic rejection[188,189]. This form nearly always requires retransplantation.

Recurrent and new-onset or de novo autoimmune hepatitis

Theoretically all forms of autoimmune hepatitis after transplantation can be classified as rejection[190-192]. No conventional clinical tests differentiate an autoimmune response from rejection. The diagnosis of autoimmune hepatitis is established by a combination of serological, molecular biological and histopathological findings. Non-organ-specific autoantibodies are a requisite for the diagnosis, and they typically include smooth muscle antibodies (SMAs), antinuclear antibodies (ANAs), and antibodies to liver kidney microsome (anti-LKM)[193]. Minimal diagnostic criteria for recurrent or *de novo* au-

Figure 16 Histological appearance of recurrent or new-onset autoimmune hepatitis characterized by moderate portal inflammation, prominent interface activity, relative sparing of the bile ducts, and perivenular accumulation of inflammation.

toimmune hepatitis in an allograft are: (1) interface hepatitis with portal lymphocytic infiltrates (Figure 16); (2) presence of ANA, SMA or anti-LKM; (3) hypergammaglobulinemia; and (4) exclusion of virus-induced or drug-related hepatitis and late acute or chronic rejection. Most adult recipients respond to an increase in immunosuppression, whereas pediatric recipients often require the use of second-line immunosuppressive drugs (azathioprine, mycophenolate mofetil). A cautious approach to withdrawal of immunosuppression is warranted in all patients transplanted for autoimmune hepatitis, and the consequences of recurrent disease within the graft will require prolonged follow-up. A recent study, evaluating protocol liver biopsies performed in asymptomatic children 1, 5 and 10 years after transplantation, documented that chronic hepatitis is a common finding in children after liver transplantation, and is associated with a high risk of developing progressive fibrosis, which leads to cirrhosis, and with the presence of autoantibodies[194].

Idiopathic post-transplant hepatitis

Chronic hepatitis that cannot be ascribed to a particular cause is defined as idiopathic post-transplant hepatitis. Cases presenting with central perivenulitis probably represent centrilobular-based acute rejection or autoimmune hepatitis, if autoantibodies are also present[185], because allograft dysfunction usually responds to increased immunosuppression[185,195]. Some cases may represent a form of rejection with features of chronic hepatitis[195]. A diagnosis of idiopathic post-transplant hepatitis does not usually require treatment with increased immunosuppression. However, as some cases do show progressive fibrosis, the management of those with moderate to marked activity needs to be clarified.

Primary sclerosing cholangitis

Recurrent primary sclerosing cholangitis is nearly identical to that seen in native livers[196,197]. Most patients with suspected recurrent disease are asymptomatic after transplantation. An accurate diagnosis of primary sclerosing cholangitis recurrence requires well-defined cholangiographic and histological criteria. Other disorders that can

Table 12   UNOS pediatric liver Kaplan-Meier patient and graft survival rates for transplants performed between 1997 and 2004

produce biliary strictures after transplantation should be excluded. Graft with primary sclerosing cholangitis recurrence shows biliary strictures, acute and chronic pericholangitis, and centrilobular hepatocanalicular cholestasis periductal fibrosis[198].

OUTCOME FOLLOWING TRANSPLANTATION

The overall results following liver transplantation are rewarding. The European Liver Transplantation Registry (ELTR) reports liver transplantation activity in Europe, and represents 5895 children transplanted between 1988 and 2005. Overall 1-year patient and graft survival was 84% and 73%, respectively, in patients older than 2 years at the time of transplantation, and 81% and 71%, respectively, in children < 2 years of age. Ten-year patient and graft survival rates for the same age groups were 75% and 61%, and 74% and 60%, respectively. Similarly, UNOS reported survival rates of the 9064 pediatric patients transplanted between 1997 and 2004. One-, 3- and 5-year patient and graft survival rates stratified according to recipient age at the time of transplant are reported in Table 12. Overall 1-year patient and allograft survival reported to the Studies of Pediatric Liver Transplantation (SPLIT) registry, representing 1611 patients, reached 88% and 82%, respectively, while these were 83% and 74%, respectively, 4 years after transplantation. Specific factors influencing early survival include age, diagnosis, severity of illness, and possibly allograft type[199].

Age

Survival for infants < 1 year of age or weighing < 10 kg has been reported to be between 65% and 80% overall, an improvement over the previously reported rates of 50%-60%[200]. Experienced programs have described even better patient survival rates at 3 mo[201]. Improved survival in these recipients results from technical innovations, better graft preparation and avoidance of life- and graft-threatening complications such as hepatic artery thrombosis and primary non-function.

Diagnosis

Survival after transplantation is similar in patients who have cholestatic and metabolic liver disease. Early survival rates are worse for patients who have acute liver failure[9,202,203] and liver tumors[11], but their long-term survival rates are similar to those of other recipients. Asso-

ciated multiorgan failure and a limited organ-acquisition time frame influence this result. Similar decreased survival trends are seen in patients who have a PELD score > 20, in status 1 recipients, and in patients whose PELD scores deteriorate significantly before transplantation[204].

Graft type

Donor factors influencing patient and graft survival include a donor age < 6 mo or > 50 years, even if some studies have demonstrated that elderly donors can be used safely[76]. The impact on the outcome of graft type (whole, reduced, split, or living-donor) is less clear. In the SPLIT registry, recipients of whole organs had better patient and graft survival than recipients of reduced, split, or living-donor allografts[205]. The US Scientific Registry of Transplant Patients database review has reported significantly lower risk of graft failure for patients aged < 2 years who received living-donor grafts compared to whole- and split-liver recipients. Older recipients showed a higher risk of graft loss and mortality after living-donor transplantation[206]. These conflicting results may have been influenced by the diverse experience accumulated in the transplant centers. Reports of whole-organ, living-donor, and split-liver outcomes from experienced centers showed no difference in patient and graft survival, and in biliary and vascular complications[53,60-62,207,208]. Successful transplantation of very small recipients with monosegments has been reported[209]. Overall, the best results can be achieved at centers that have extensive experience with all age groups and allograft types, allowing transplantation according to the needs of the recipient. The most important prognostic factor is the severity of the patient's illness at the time of transplantation[210]. The good survival rates obtained in patients receiving living-donor transplantation are positively influenced by the possibility to schedule transplantation before the development of life-threatening complications or severe malnutrition[211]. Children with acute liver failure, PELD > 20, and severe growth retardation have significantly lower overall survival than other groups. Previous major surgery influences the incidence of complications, especially bowel perforation, but do not negatively impact overall patient or graft survival. Long-term survival is mainly influenced by the consequences of prolonged immunosuppression such as infection, PTLD, renal insufficiency, hypertension, diabetes mellitus, and coronary artery disease[212].

Abstract

The aim of this study was to illustrate the role of non-invasive imaging tools such as ultrasonography, multi-detector row computed tomography, and magnetic resonance imaging in the evaluation of pediatric and adult liver recipients and potential liver donors, and in the detection of potential complications arising from liver transplantation.

INTRODUCTION

In liver transplantation (LT) candidates, the goal of imaging is to evaluate the intra- and extra-hepatic anatomy, identify conditions that can complicate LT, and stage the neoplastic disease.

Preoperative assessment of potential living liver donors requires the evaluation of liver parenchyma to identify steatosis or lesions; the accurate evaluation of intra and extrahepatic biliary and vascular anatomy to identify congenital variants and, overall, to detect the dominant arterial branch to segment 4 to prevent accidental removal at surgery; and an accurate estimation of the volume of both liver lobes to exclude complications related to graft volume [small-for-size grafts or large-for-size grafts, characterized by a graft-to-recipient weight ratio (GRWR) less than 1%, and more than 3%, respectively].

In the post-transplant period, the goal of imaging is to identify vascular and biliary complications. The long-term follow-up also allows clinicians to identify recurrence of the primary disease and/or detect disease related to long-term immunosuppression.

In the pediatric recipient a wide spectrum of diffuse and focal diseases are indications for LT. Biliary atresia represents at least 50% of all pediatric transplantation, while the most common hepatic malignancy leading to LT is hepatoblastoma[1-5]. Other indications for LT in pediatric patients are Alagille syndrome, cystic fibrosis, tyrosinemia type 1 (associated with a high risk of hepatocellular carcinoma (HCC) development), Wilson's disease, Langerhans' cell histiocytosis, HCC, infantile hepatic hemangioendothelioma type Ⅱ (IHE), and hemangiomatosis[5-10].

In the adult recipient the most common indication for LT is still hepatitis-related liver cirrhosis with or without HCC. HCC is the fifth most common neoplasm in the world, and the third most common cause of cancer-related death. In adults it typically occurs within the cirrhotic liver. Non-alcoholic post-hepatitic cirrhosis is the most common association, but any condition that causes cirrhosis may potentially lead to HCC, including conditions such as inborn errors of metabolism. Exposure to chemical carcinogens can also cause the development of HCC. LT based on the Milan criteria is considered the optimal treatment for HCC, especially in patients with underlying chronic liver disease, because it offers a potential cure for both HCC and the underlying

liver disease. The prognosis of cirrhotic patients depends on the occurrence and progression of HCC. α-feto protein (AFP) alone shows low predictivity and sensitivity for the screening of HCC, and so imaging plays a key role in the surveillance of the cirrhotic patient[11-14].

Other focal diseases that require LT in adult patients are metastasis of neuroendocrine tumors, adenomatosis, giant angiomas, hepatic epitheloid hemangioendothelioma, and cholangiocarcinoma in selected cases, while the most common diffuse liver diseases in adults that require LT are primary biliary cirrhosis, primary sclerosing cholangitis, polycystic liver disease, Caroli's disease and Budd-Chiari Syndrome[15]. Fulminant hepatic failure can occur in both pediatric and adult patients[16].

RADIOLOGICAL ASSESSMENT OF LIVER TRANSPLANT RECIPIENTS

Ultrasonography (US)

US is usually the first imaging modality in the evaluation of a transplant candidate, independent of the disease, because it is easy to perform, widely available, relatively inexpensive, and is cost effective. US can detect morphological changes in the liver, hepatic focal lesions (cystic or solid) or abdominal masses, and signs of portal hypertension such as hypersplenism, perihepatic or perisplenic varices, and ascites.

US plays a specific role in the diagnosis of biliary atresia and in the screening of HCC in cirrhotic patients[17-20].

In biliary atresia, US may show the absence, or reduction in size, of the gallbladder and the presence of a triangular cord (TC) sign (thickness of 4 mm or more of the anterior wall of the right portal vein, seen near the portal bifurcation). The identification of a TC sign results in a sensitivity of 80%, a specificity of 98%, a positive predictive value of 94%, a negative predictive value of 94%, and an accuracy of 94% for diagnosing biliary atresia[17].

US is the most common examination for the screening of HCC in cirrhotic patients, usually performed at either 3-, 6- or 12-mo intervals, although the sensitivity and specificity reported in the literature show a wide heterogeneity, ranging from 58% to 89%, and from 75% to 94%, respectively[18-20].

On gray-scale US, HCC is predominantly hypoechoic and sometimes isoechoic, with a thin hypoechoic halo corresponding to the tumor capsule. In diffuse HCC, there is subtle disruption of the normal echo pattern, with anechoic areas due to necrosis. Color Doppler and power Doppler modes permit a real-time evaluation of the hemodynamics in liver tumors. There are, however, many limitations that can affect the assessment of tumor hemodynamics[21].

For the diagnosis of HCC, contrast-enhanced US (CEUS) is recommended by the European Association for the Study of the Liver (EASL) as the modality for evaluation of the vascularity of hepatic nodules in cirrhotic patients. Two dynamic imaging studies that show arterial hypervascularity and washout in the portal venous phase for diagnosis of HCC ranging from 1 cm to 2 cm in diameter are required. For a mass greater than 2 cm, the coincident findings of characteristic arterial vascularization that is seen on at least two imaging techniques, or hypervascularity in one imaging technique associated with washout in the portal venous and/or delayed phase, may be used to confidently establish the diagnosis without biopsy[22-26].

However, there is currently no indication for the use of microbubble contrast agents to increase the detection rate of HCC in patients undergoing US surveillance. In fact, with CEUS one can only observe the perfusion in selected lesions identified with other imaging modalities, and not in the whole liver[23-25].

US also shows a high sensitivity and specificity for excluding portal vein thrombosis (PVT). In patients with hypervascular tumors such as HCC, it is important to establish the nature of the thrombus because tumoral vascular invasion worsens prognosis and may result in exclusion from the LT program. The presence of pulsatile arterial signals inside the thrombus at color Doppler ultrasound (CDUS) is reported to be a highly sensitive and specific sign of malignant PVT[27]. CEUS, using sulfur hexafluoride microbubbles (SonoVue, Bracco SpA), seems to increase sensitivity (88%) and accuracy (92.5%) when distinguishing between benign and malignant PVT[28].

Multi-detector row computed tomography (MDCT)

In liver recipients, MDCT provides important information about liver morphology (normal or cirrhotic), intrahepatic and extrahepatic malignancy, venous benign and/or malignant thrombosis, patency of main portal vein, portosystemic collateral due to portal hypertension (spleno-renal spontaneous shunt, gastroesophageal and/or paracaval varices, and paraumbilical and caput medusae), celiac stenosis, splenic artery aneurysm, congenital arterial variants, patency, and anomalies of the inferior vena cava[29]. These findings may influence the decision to transplant, or the surgical planning of arterial and venous reconstruction. In addition, combined arterial, portal venous, and delayed-phase imaging improves the sensitivity of MDCT in detecting hypervascular neoplasms such as HCC or neuroendocrine metastases, and can also detect other tumors that enhance in a delayed phase, such as cholangi-ocarcinoma[30-33].

In pediatric candidates, the studies are usually performed with and without isosmolar or lower osmolar contrast media intravenous (c.m.i.v.) injection (Iodixanol 320 mgI/mL, Optiray 320, respectively) at a dose of 1.5 mL/kg, and at a rate that depends on the age of the patient (0.5-4 mL/s). When needed, the patient is anesthetized with intravenous propofol (0.5-1 mg/kg), without intubation. Images of the liver are acquired in the cranium-caudal direction, with slice thickness 1.25 mm or 0.625 mm, collimation 2.5 mm and table

speed 7.5 mm per gantry rotation. Usually only three phases are acquired: unenhanced phase, arterial phase, and portal venous phase. Postprocessing of the dataset offers a variety of advanced three-dimensional models of the hepatic artery and vein using multi-planar reconstruction (MPR), maximum intensity projection (MIP), and volume rendering (VR) reconstructions. The volume of the liver is usually calculated, using dedicated software, in pediatric recipients as a guide in the donor-to-dimensional matching[34,35].

In adult candidates, MDCT studies are usually performed with and without iodinated c.m.i.v. with a dose ranging from 1.5 mL/kg to 1.8 mL/kg of body weight, at a rate of 4-5 mL/s. Images of the liver are acquired in the cranium-caudal direction, during a single breath-hold acquisition, with slice thickness 1.25 mm or 0.625 mm, collimation 2.5 mm and table speed 7.5 mm per gantry rotation. A triple or quadruple-phase protocol is used: unenhanced phase, arterial phase, and portal venous phase, without and with late phase, respectively. Before the study, patients receive 500 mL of water as an oral contrast agent. Bolus tracking or test bolus technique (10 mL of contrast material at 5 mL/s) is used to calculate the correct time of the arterial phase. The portal venous phase and late phase acquisitions are generally obtained after 60 s and 180 s from the beginning of contrast injection, respectively. MIP and MPR reconstructions are usually made[30-33].

Magnetic resonance imaging (MRI)

MRI is a non-invasive and sensitive technique that is devoid of ionizing radiation. For this reason, MRI is the preferred modality in the assessment of pediatric recipients. MRI examinations are usually performed using a head coil for small infants, or body coils for larger children. All images are acquired in the axial plane in breath-hold, or with suspended respiration if under general anesthesia. If necessary, contrast medium is injected. Using Gadobenato dimeglumina 0.1 mL/kg (Bracco, SpA) it is possible to obtain information about perfusion of the liver, changes in the parenchyma and the vasculature related to cirrhosis and portal hypertension (PVT, varices, ascites), and to detect vascular congenital anomalies. In addition, the multiphasic contrast enhancement study can detect malignancy in the liver, and locoregional involvement.

Mangafodipir trisodium (MnDPDP, Teslascan, GE) is a contrast agent composed of a water-soluble chelate complex salt that is between a paramagnetic manganese (Mn^{2+}) ion and the ligand dipyridoxyl diphosphate, a vitamin B6 analogue; 50%-60% of the contrast administered is excreted through the gastrointestinal tract. For this reason, Teslascan has recently been used for the early diagnosis of biliary atresia, based on the absence of the bowel excretion of contrast material[36].

In adult recipients, especially in cirrhotic patients, MRI plays a role in detecting and differentiating HCC from other regenerative or dysplastic nodules, because it is more sensitive than multiphasic contrast-enhanced MDCT. However, it is still unclear whether MRI is more

sensitive than MDCT in detecting HCC[19,20,26].

MR cholangio-pancreatography (MRCP) using single shot fast spin echo (SSFSE) single and multisection, parallel and radial acquisition can well depict disease (such as sclerosing cholangitis, Caroli's disease) of the biliary tree in adults, while in pediatric recipients, it is limited by the small caliber of the duct, thus rarely visible in neonates. In biliary atresia, it can help to demonstrate the absence of the gallbladder.

RADIOLOGICAL ASSESSMENT OF POTENTIAL LIVER DONORS

US

US is usually the first imaging modality for the evaluation of potential donors because it can identify hepatic lesions, obtain important information on the anatomy of the great vessels, such as hepatic veins and portal system, and evaluate the presence of steatosis. Due to a lack of accepted methods for quantification of steatosis on imaging, in many hospitals a biopsy is incorporated in the work-up, while in other centers, a biopsy is performed only in cases of suspicion based on clinical or imaging grounds[37].

MDCT

MDCT is the most important tool in the assessment of potential donors. MDCT can precisely depict congenital variants, if present, that can influence the surgical technique, identify focal lesions (hemangiomas, focal nodular hyperplasia, adenomas) or diffuse liver diseases (steatosis, hemocromatosis), and calculate the volume of the two liver lobes.

Congenital arterial variants are frequent, and are found in approximately 45% of donors. The identification of the dominant arterial branch to segment 4 is very important because its integrity is indispensable for the regeneration of the residual left hemiliver. This artery usually arises from the left hepatic artery (LHA), while in 25% of cases it arises from the right hepatic artery (RHA) or from both the LHA and RHA (Figure 1).

Anatomical variants of the portal system occur in 20% of the donor population; although the anomalies are not a contraindication to surgery, they must be known because they may require multiple portal anastomoses during the implantation of the right lobe into the recipient (Figure 2).

Identifying the hepatic venous anatomy is a fundamental step because it determines the hepatectomy plane that runs 1 cm to the right of the middle hepatic vein (MHV). Both accessory hepatic veins of the right inferior lobe (68% of the donor population), and large branching veins (> 5 mm) draining into the MHV from the right lobe require separate anastomosis to prevent venous congestion in the graft[37-41] (Figure 3).

Accurate volume of both liver lobes needs to be estimated to ensure that the hepatic mass is adequate for both liver donor and recipient.

MDCT scan studies are performed with and without

Figure 1 MDCT. VR reconstruction images. A: 35-year-old male, potential living liver donor. Normal anatomy of hepatic artery. CHA: Common hepatic artery; GDA: Gastroduodenal artery; PHA: Proper hepatic artery; LHA: Left hepatic artery; RHA: Right hepatic artery; S4: Artery to segment 4; B: 29-year-old female, potential living liver donor. Early bifurcation of hepatic artery. Two large arterial branches to segment 4 arising from LHA and RHA; C: 25-year-old male, potential living liver donor. LHA arising from left gastric artery. The artery to segment 4 arising from the gastroduodenal artery.

Figure 2 Thirty-two-year-old male, potential living liver donor. VR reconstruction shows a right anterior branch arising from left portal branch. SMV: Superior mesenteric vein; SplV: Splenic vein; LPV: Left portal vein; RAPD: Right anterior portal vein; RPPV: Right posterior portal vein.

Figure 3 Forty-one-year-old male, potential living liver donor. VR reconstruction shows normal anatomy of hepatic veins. The right lobe and right hepatic vein are blue, the left lobe and the MHV and left hepatic veins are red. A cut-plane runs 1 cm to the right of the MHV.

iodinated c.m.i.v. at a dose ranging from 1.5 mL/kg to 1.8 mL/kg of body weight, and at a rate of 4-5 mL/s. Images of the liver are acquired in the cranium-caudal direction, during a single breath-hold acquisition, with slice thickness 1.25 mm or 0.625 mm, collimation 2.5 mm and table speed 7.5 mm per gantry rotation. Before the study, patients receive 500 mL of water as an oral contrast agent. Usually, a triple-phase protocol is used: unenhanced phase, arterial phase, and portal venous phase. Bolus tracking or test bolus technique (10 mL of contrast material at 4/5 mL per second) is used to calculate the correct time of the arterial phase. The peak enhancement plus 2 s is deemed as the start of the arterial acquisition to depict the arterial system. The portal venous phase is generally taken 70 s after the contrast agent has been injected to determine the exact delineation of the portal and hepatic veins. MIP and VR image reconstruction of the artery and portal venous system are usually created in the post-processing stage. The portal-venous acquisition is used for the volumetric evaluation, using dedicated software, in the postprocessing of the right and left lobe[37-39].

Some authors have proposed an all-in-one protocol to depict the biliary system, using a biliary contrast agent (Biliscopin; Schering, Berlin, Germany). However, a high incidence of adverse reactions to the biliary contrast agent, ranging from mild and self-resolving to severe systemic adverse reactions (shock-syndrome and death), has been observed[38].

Magnetic resonance cholangio-pancreatography (MRCP)
MRCP is currently considered the primary imaging tool for biliary anatomy evaluation in potential living liver donors. In fact, it is performed with new generation units equipped with high performance gradient and phased-array coils, allowing for high quality heavily T2-weighted images with increased spatial resolution in a few seconds or with respiratory triggering, eliminating most motion-related artifacts.

Only 57% of donors have a conventional biliary anatomy (Figure 4). Although the congenital variants of biliary anatomy do not represent a contraindication to liver donation, they must be identified before surgery to prevent ligation of major branches of the right lobe in the recipient and/or of the liver lobe in the donor. Multiple biliary anastomoses during the implantation of the right lobe into the recipient can be required to avoid atrophy due to biliary obstruction.

Improvements in hepatocyte-specific contrast

Figure 4 Normal anatomy of biliary drainage: Right posterior duct (RPD) and right anterior duct (RAD) drain, respectively, S6-S7 and S8-S5; right hepatic duct (RHD) is formed by confluence of RPD and RAD. Left hepatic duct (LHD) drains S2-S3. S1-S4 can be drained by LHD or by RHD. The common hepatic duct (CHD) arises from the confluence of RHD and LHD.

Figure 5 MRCP. VR reconstruction images. A: Twenty-two-year-old male, potential living liver donor. VR image using MRCP acquisition shows congenital anomalies of biliary drainage: RPD (1) draining in LHD (2), accessory LHD (3) and accessory RPD (4) draining in MHD (5); B: 24-year-old female, potential living liver donor. VR image after Teslascan injection shows congenital anomalies of biliary drainage: RPD draining in LHD. The finding is confirmed with intraoperative cholangiogram.

agents with biliary excretion (mangafodipir trisodium and gadobenate dimeglumine) seem to have increased the accuracy of MRI in depicting the biliary system[41,42] (Figure 5).

Some studies propose MRI as a single imaging modality for the preoperative assessment of potential donors to depict the arterial, portal and venous anatomy using MR-angiography with 3D sequence after the administration of extracellular c.m.i.v. However, MR-angiography can rarely depict the artery supplying segment 4[40,43].

RADIOLOGICAL ASSESSMENT OF POST-TRANSPLANT COMPLICATIONS

US

US and CDUS are the most important tools in the follow-up of LT patients because they show high sensitivity and specificity in detecting vascular complications.

During transplantation, CDUS is usually performed to detect the intraparenchymal flows (arterial, portal and venous), and to evaluate the velocity of flow and

Figure 6 Fifteen-year-old male underwent orthotopic LT (OLT) for biliary atresia. A: Ten days after OLT, CDUS shows a pathologic resistance index (< 0.5) and pathologic acceleration time (> 0.08), strongly suspicious for stenosis; B: AngioMDCT confirms a stenosis of the hepatic artery after the anastomosis (arrow).

waveform to detect very early complications such as hyperacute hepatic artery or PVT[44].

After LT, CDUS is usually performed once a day during the first week, and once a week in the following 2 mo, and is key in the suspicion or identification of vascular or biliary complications.

Hepatic artery thrombosis (HAT) occurs more frequently in pediatric recipients (9%-42%) than in adult recipients (4%-12%). It frequently leads to graft failure, due to biliary wall necrosis with bilomas, biliary leakage, and hepatic infarction[45].

CDUS is able to identify up to 92% of cases of HAT, demonstrating the absence of flow in the common hepatic artery and in the intrahepatic branches. In younger subjects, in the event of complete hepatic artery thrombosis, intrahepatic flow can be sustained by small collateral neoformed vessels from the superior mesenteric artery. In these cases, the flow has a *tardus parvus* waveform. In adults, the formation of collateral vessels is almost never sufficient to prevent ischemic biliary complications. Ultrasound findings can be false positive if the hepatic artery is small or stenotic, if the flow is very slow, or if there is coexistent systemic hypotension. If US does not show an arterial flow, administration of contrast media (microbubble) can help to improve the flow visualization in the HA, differentiating between thrombosis and a patent artery in patients without HA flow on conventional Doppler US[46-49].

Hepatic artery stenosis is reported in 5%-10% of transplant recipients and can be anastomotic (in 70% of cases), perianastomotic or intrahepatic. It is most frequently caused by an error in surgical technique or by arterial damage during explantation. Near the stenosis, the Doppler ultrasound shows a focal velocity greater than 2 mL/s, and turbulence; more distally, it detects a *tardus parvus* arterial waveform with a resistance index lower than 0.5 and a systolic acceleration time (between the end of the diastole and the first systolic peak) greater than 0.08 s[46-49] (Figures 6 and 7).

Post-transplant PVT is extremely rare in adults. In children, particularly with biliary atresia, post-transplant PVT, although not usual, is not rare. The underlying

Figure 7 Fifty-four-year-old male underwent living related liver transplant (LRLT) for HCC in HCV-related cirrhosis. A and B: 3 mo after LRLT, a lumen stripe reconstruction (A) and VR reconstruction (B) show irregularities (arrow) of aortohepatic by-pass. Six months after LRLT, the patient was admitted to hospital with fever; C: US shows a hypoechoic and inhomogeneous lesion in the right lobe (arrow); D: MR T2W images show a hyperintense lesion, confirming an abscess in the right lobe (arrow). The left lobe appears inhomogeneously and diffusely hyperintense, showing a large abscess (head of arrow).

Figure 8 Fifty-one-year-old male underwent OLT for HCC in HCV-related cirrhosis. A and B: Eight days after OLT, CDUS shows a high velocity gradient between the subhepatic (A) and suprahepatic (B) segments of the inferior vena cava, with a velocity of 32 cm/s and 237 cm/s, respectively, strongly suspicious for stenosis; C: MDCT with MPR image confirms stenosis of the suprahepatic segment of the inferior vena cava (arrow).

problems in small children are not only due to smaller caliber vessels but also due to hypoplastic and sclerotic vessels brought about by pre-transplant recurrent cholangitis[50]. Color Doppler ultrasound shows the absence of flow in the portal vein, and whether it is anechogenic (recent thrombosis) or echogenic (old thrombosis). If the thrombosis is recent, it can be treated with local thrombolysis and mechanical thrombectomy.

Portal vein stenosis is more frequent in partial liver transplants than in whole liver transplants. The suspicion of stenosis arises if color Doppler shows a turbulent flow with focal aliasing in the stenotic tract, and a velocity gradient of > 4-fold[46-49].

Post-liver transplant stenosis of the inferior vena cava is rare and generally secondary to technical issues. CDUS shows an increased trans-anastomotic velocity gradient (> 4 times) and the loss of the tracing's normal phasicity[44,46,49] (Figure 8).

In partial liver transplants, hepatic vein stenosis is a frequent complication. CDUS of the hepatic veins reveals a slow (< 10 cm/s) and monophasic flow[44,46,49].

All the vascular complications described, when suspected on US and CDUS, need confirmation with contrast-enhanced MDCT, contrast-enhanced MR or with angiography.

US shows low diagnostic accuracy in identifying biliary complications, particularly in early anastomotic stenosis without a significant intrahepatic biliary duct dilatation. US is, however, an accurate tool for evaluating necrosis, bilomas, or abscess of the graft.

MDCT
MDCT angiography is the best option for confirming the ultrasonographic suspicion of early and late vascular complications (HAT, main portal vein or inferior vena cava (IVC) stenosis or thrombosis)[51]. In addition, it permits a good assessment of liver parenchyma and other abdominal organs, and the evaluation of bilomas (Figure 9), bleeding, abdominal or hepatic abscesses (Figure 7), adrenal infarction, and intestinal perforation or obstruction. MDCT can identify biliary duct dilatation, even if the anastomosis is not easy to depict.

MDCT also plays a key role in detecting late complications, such as recurrence of the primary disease, post-transplant lymphoproliferative disease (PTLD), Kaposi's sarcoma or other malignances related to long-term immunosuppression.

MRI
MRCP after LT is the modality of choice for the

Figure 9 Sixty-one-year-old male underwent OLT for primary biliary cirrhosis, with bilio-enteric anastomosis. MRCP shows a severe anastomotic stricture (arrow) and multiple intrahepatic biliary leakages (head of arrows).

diagnosis and management of biliary complications, and shows a sensitivity ranging from 87.5% to 95.3%, a positive predictive value ranging from 92.3% to 97.6%, and an accuracy ranging from 90.4% to 95.2%[52-54]. The T2W images easily identify fluid collection (bilomas, bile leakage, biliary duct dilatation) that appear strongly hyperintense, while MRCP using SSFSE single and multisection, parallel and radial acquisition can finely depict filling defects, anastomotic or non-anastomotic stenosis, or irregularities of the biliary duct.

Bile duct complications in the various series vary from 7% to 50%. In partial liver transplants, biliary complications are more frequent because the diameters of the bile ducts to be anastomosed are smaller, and multiple biliary anastomoses are often necessary. Most of these complications occur within the first 3 mo, even though biliary stenoses and gallstones can occur months and years after transplantation.

Bile extravasation has an incidence ranging from 5% to 19%, and may occur in the T-tube insertion site, in the region of the anastomosis, or intrahepatically.

Intrahepatic bile leakage (biloma) entails the suspicion of bile duct necrosis secondary to HAT. In these cases, a new transplant is almost always necessary. However, the percutaneous drainage of a biloma can prevent sepsis and increase the likelihood of graft survival. In partial liver transplants, bile can also leak from a large bile duct damaged at the time of liver "splitting," or from the surface of the resection margin, which exposes thousands of small bile ducts (Figure 9).

Stenoses can be classified as anastomotic or non-anastomotic. Anastomotic stenoses are the result of postoperative fibroses or of errors associated with surgical technique (Figure 9). Non-anastomotic stenoses can be intra- or extrahepatic, single or multiple, and are often due to ischemic damage. In these cases, it is necessary to assess the patency of the hepatic artery. Rarely are they due to prolonged graft ischemia time, chronic rejection or cytomegalovirus infections. In transplants related to sclerosing cholangitis, intrahepatic stenosis can indicate disease recurrence.

Rare causes of bile duct obstruction are the dislocation/obstruction of the T-tube, biliary sludge,

gallstones or an excessive choledochus length after the choledochocholedochostomy. The mucocele of the residual cystic duct can cause bile duct stenosis resulting from extrinsic compression.

Enhancement with mangafodipir trisodium improves the performance of MRCP for the detection and exclusion of biliary abnormalities after orthotopic LT[55].

CONCLUSION

Imaging plays a primary role in LT. It is used in the assessment of the recipient, the assessment of the potential living liver donor, and the detection of early and late complications. US, MDCT and MRI have different roles, depending on accuracy, in depicting the different goal in each period of the orthotopic LT.

Abstract

Interventional radiology has acquired a key role in every liver transplantation (LT) program by treating the majority of vascular and non-vascular post-transplant complications, improving graft and patient survival and avoiding, in the majority of cases, surgical revision and/or re-transplantation. The aim of this paper is to review indications, technical consideration, results achievable and potential complications of interventional radiology procedures after deceased donor LT and living related adult LT.

INTRODUCTION

Liver transplantation (LT) in patients with end-stage liver diseases has become an accepted treatment. Advances in the field of percutaneous, radiological, minimally invasive techniques have increased the importance of interventional radiology in the management of patients after LT[1]. In this article, we discuss the possible applications of interventional radiology in the management of adult recipients after deceased donor LT or living related LT (LRLT), including diagnosis of graft disease, treatment of vascular complications and treatment of biliary complications. Techniques used, results and possible complications of interventional radiology procedures are described by reviewing our experience and other protocols present in literature.

DIAGNOSIS OF GRAFT DISEASE

Random liver biopsy is frequently requested after LT. Any alteration of liver function tests, not explained by diagnostic imaging, requires a liver biopsy to exclude rejection and/or other pathologies. Liver biopsy can be performed by a percutaneous approach (blind or ultrasound guided) or, in selected patients, with a transjugular approach. In our practice, in patients without ascites, percutaneous core liver biopsies are performed with an 18-Ga needle under ultrasound guide to avoid entering the bowel or other adjacent organs, and to avoid the perforation of main intra-hepatic vascular structures. If coagulation defects are present (platelets $< 50\,000$ mm^3 and/or prothrombin activity $< 50\%$) patients receive infusion of platelets and/or fresh frozen plasma. No antibiotic prophylaxis is performed before the procedure. Complications are

infrequent, most of them being minor (pain, decrease in hematocrit value not necessitating treatment). Possible major complications of percutaneous liver biopsies are bleeding, emobilia, arterio-portal fistula and infections, and are reported in up to 3% of cases[2]. Controlled studies have shown that blind percutaneous biopsy carries a higher risk for major complications compared to ultrasound guided liver biopsy[3]. Although it has been reported by Little *et al*[2] that the presence of perihepatic ascites does not statistically affect the major or minor complications rate of image-guided percutaneous hepatic biopsy, in our center, the transjugular approach is preferred if perihepatic ascites are present. The transjugular approach is considered mandatory if a severe coagulopathy and/or massive amounts of perihepatic ascites are present. This technique reduces the risk of hemorrhage, because a biopsy specimen is acquired through the hepatic vein and any bleeding from the puncture site remains in the vascular space. In addition, if a clinical suspicion of portal hypertension is present, hepatic vein pressure gradient (HVPG) can be measured during the same procedure. The right internal jugular vein approach is usually preferred, but in selected cases, if the right jugular vein is not usable (thrombosis or difficult catheterization), the left internal jugular vein can be used[4]. In our experience, there are no major complications related to transjugular liver biopsies performed in adult liver transplant recipients. Despite transjugular liver biopsy being effective and safe for patients with contraindications to percutaneous liver biopsy, in patients with small liver or in patient with partial LT (from a living donor or deceased donor), subcapsular or intraperitoneal bleeding due to accidental perforation of the capsule is possible. Hemobilia, accidental puncture of kidney, transient dysrhythmias, and hematoma at the puncture site are the most common complications reported in other studies[5-7].

TREATMENT OF VASCULAR COMPLICATIONS

Vascular complications following LT are associated with high morbidity, graft lost and mortality rate. The majority of vascular complications develop within 3 mo of the transplant and possible complications should be considered in any LT patient with alteration of liver function tests. The clinical presentation of vascular complications is often indistinguishable from other post-transplantation complications (biliary complications, rejection, graft dysfunction, infections). Color Doppler ultrasonography (US), multidetector-row computed tomography (MDCT), and magnetic resonance are useful for diagnosis. Vascular complications can affect the hepatic artery, hepatic vein, portal vein and inferior vena cava (IVC).

Hepatic artery thrombosis (HAT)

HAT is a dramatic, potentially life-threatening, complication of LT occurring in 3%-9% of adult liver-

Figure 1 Status post right lobe LRLT in 18-year-old male. A: Celiac arteriogram showed acute HAT. Local thrombolysis with TPA was performed by placing a microcatheter in the hepatic artery stump; B: Celiac arteriogram after TPA infusion showed patent hepatic artery. In this patient, splenic artery embolization was performed by coils and PVA in order to increase the flow in hepatic artery. Although a good and early flow restoration was achieved, the patient underwent re-transplantation 2 d later for graft failure.

transplanted patients[8,9]. Risk factors for HAT are considered to be surgical technique, small donor vessels, slow flow secondary to hepatic artery stenosis (HAS), ischemia-reperfusion injury, coagulation abnormalities, ABO blood group incompatible transplantation, use of aortic jumping graft and multiple rejection episodes. Ischemia caused by HAT results in severe biliary and parenchyma damage and is associated with high rates of graft loss and mortality. Urgent thrombectomy and revascularization or re-transplantation is currently considered the treatment of choice in case of early diagnosis of HAT[10]. If Doppler US and/or computed tomograghy (CT) suspicious of HAT are present, an arteriogram is usually performed to confirm the imaging finding and, in very early diagnosis of HAT, to try to restore the hepatic flow with selective thrombolytic therapy and eventual treatment of concomitant HAS with balloon angioplasty and/or stent placement. In our practice, selective catheterization of the hepatic artery stump is performed with a microcatheter and an infusion of thrombolytic drugs. In selected patients with concomitant steal syndrome from splenic and/or gastroduodenal arteries, percutaneous splenic and/or gastroduodenal artery embolization can be performed in the same session in order to increase the flow in the hepatic artery (Figure 1). Surgical thrombectomy and/or re-transplantation should be reserved for cases in which percutaneous techniques fail. Saad *et al*[11] reported successful in re-establishment of arterial

Figure 2 Status post deceased donor LT. Doppler US performed 5 mo after the transplant showed low intrahepatic resistive index 0.50 and prolonged systolic acceleration time 0.113 s, suspected for HAS. A: MDCT volume rendering 3D reconstruction showed a severe stenosis in the hepatic artery anastomosis; B: Digital subtraction angiography (DSA) celiac arteriogram confirmed the stenosis, trans-stenotic pressure gradient measured by a microcatheter was 50 mmHg; C: DSA percutaneous transluminal angioplasty performed by 4 mm diameter balloon catheter; D: DSA final arteriogram showed good patency of the arterial anastomosis with trans-stenotic pressure gradient reduced to 4 mmHg. Doppler US performed 4 mo later showed regular resistive index 0.70 and systolic acceleration time 0.100 s. Patient currently in good general condition and without biliary tree impairment after 6 mo of follow-up.

flow and uncovered underlying arterial anatomical defects in four out of five patients treated, but none were treated definitively by endoluminal procedures, due to the inability to resolve the underlying arterial stenosis, showing that the treatment of the underlying arterial defect is mandatory. Several cases of successful thrombolytic treatment of HAT in adult transplanted recipients are reported, usually if the diagnosis of HAT is performed a few hours after LT[12-15], but further analysis is needed to understand the correct timing of a possible thrombolysis and if endovascular procedures can be safely considered, a viable option to prevent re-transplantation after HAT. Possible complications of endovascular therapies are dissection and/or rupture of the hepatic artery during the arterial manipulation (requiring the placement of a covered stent) and bleeding from the arterial anastomosis[16].

Hepatic artery stenosis (HAS)

HAS is an insidious complication of LT occurring in approximately 5% of patients[17] leading to graft ischemia and possible hepatic artery occlusion as a result of slow flow with high incidence of morbidity and mortality due to hepatic insufficiency, biliary damage and possible sepsis. The majority of HAS arises at the anastomosis site and usually occurs within 3 mo after transplantation. The etiology of HAS can be due to small caliber of arteries or vascular clamp injury. Non-anastomotic stenosis can be present in cases of rejection or hepatic necrosis. The most common complication seen on cholangiography of recipients with HAS is non-anastomotic biliary strictures (BSs) seen in up to 49% of patients[18]. Early detection of HAS is fundamental because many of the stenoses are suitable for percutaneous treatment with angioplasty

and/or stent placement or surgical revision, allowing good long-term graft function. In adult recipients with HAS that underwent percutaneous transluminal angioplasty, a 60%-80% patency rate at 1 year is reported[19]. Percutaneous transluminal angioplasty has also been reported to be an effective treatment of HAS after living donor LT, with a success rate of 94% and a complication rate of 6%, with possible HAS recurrence in 33% of patients[20]. In our practice, in a case of suspicious Doppler US or MDCT scan of HAS, a hepatic arteriogram is performed, from a transfemoral approach, with a 5F Cobra 2 or SOS catheter. A coaxial microcatheter is then advanced through the stenosis and the trans-stenotic pressure gradient measured. If a significant pressure gradient is present (> 10 mmHg) then an angioplasty is performed. Before angioplasty, 0.2 mg of nitroglycerine and 2000 UI of heparin are infused into the hepatic artery to reduce the risk of spasm or thrombosis. A 6F guiding catheter is advanced and a balloon catheter advanced over a 0.018 inch or 0.014 inch stiff wire. The diameter of the balloon used varies according to the diameter of the hepatic artery, ranging from 3 to 6 mm. Procedural success is determined by reduction or absence of the stenosis in a final arteriogram with significant reduction of the trans-stenotic pressure gradient (Figure 2). If a good patency is not restored, a metallic stent is deployed. The use of low-profile coronary stents in the treatment of HAS, as a first therapeutic approach, also showed good results with a 1-year patency rate of 45%-53%[21,22].

Portal vein stenosis (PVS)

PVS is a postoperative complication reported in 3% of patients after LT[23]. Clinical symptoms of hemodynamically significant PVS are related to portal

Figure 3 Status post right lobe LRLT in 60-year-old female. A: MDCT, MIP reconstruction showed a stenosis in portal vein anastomosis. The stenosis is very near the bifurcation of anterior and posterior branches; B: DSA, portogram performed from transjugular approach confirmed the PVS, 15 mmHg trans-stenotic pressure gradient was measured; note large patent coronary vein with filling gastro-oesophageal varices; C: DSA, final portogram performed after the deployement of a 10-mm diameter WallStent; note good filling of intrahepatic branches and no more evidence of the coronary vein, trans-stenotic pressure gradient reduced to 6 mmHg. Patient currently in good general condition with 1 year of follow-up.

hypertension and are bleeding from varices, splenomegaly and ascites. The portal vein is usually accessed by a transhepatic approach or by a transjugular approach. Percutaneous transhepatic angioplasty is considered an effective treatment and is usually considered as a first, non-surgical, therapeutic approach. Shibata *et al*[24] in a large series of patients, reported a success rate of 74% with a single session of balloon dilatation and a mean follow up of 24 mo. Recurrent stenoses were detected in 28% of patients and a maximum of three sessions of dilatation were necessary to resolve the stenosis. Funaki *et al*[25] reported metallic stent placement to treat recurrent and/or non-responsive, elastic stenosis with good long-term patency. Ko *et al*[26] reported a series of patients following living donor LT with early occurrence of PVS that were treated with transhepatic primary stent placement and showed good patency of the stents after a mean follow up of 66 mo in six out of nine patients. In the same paper, three post-procedural major complications were reported, two cases of hemoperitoneum and one case of intrahepatic pseudoaneurysm. In our practice, when a transhepatic approach is preferred, the procedure is performed under monitored anesthesia care. Transhepatic puncture of the portal vein is performed under ultrasound guide with a 21-Ga needle. An Accustik system (Boston Scientific) is advanced in the portal branch, over a nitinol wire, and then exchanged, over a 0.035 inch wire, for a 6F or 7F vascular sheath. The hemodynamic trans-stenotic pressure gradient measurement is performed using a 5F hydrophilic catheter. Before the dilatation, a bolus of heparin is administered (2000 UI) to reduce the risk of thrombosis during the balloon occlusion. The dilatation can be performed with balloon catheters up to 10 mm in diameter or more, according to the size of the vessel. Technical success is considered the resolution of the stenosis in a final portogram and a significant reduction of the trans-stenotic pressure gradient. In our practice, we embolize the transhepatic tracks with a coil to reduce the risk of bleeding, but in other series[25], transhepatic track embolization is not performed routinely without

evidence of perihepatic bleeding. In patients with severe coagulopathy and/or ascites, the transjugular approach can be chosen, reducing the risk of bleeding[27,28]. The procedure is performed with monitored anesthesia care from the right internal jugular vein approach using the standard Colapinto set. Balloon dilatation and/or metallic stent placement are performed with the same technique as the transhepatic approach. Note that when the stenosis is very near the intrahepatic branches bifurcation, it is mandatory to use a non-covered metallic stent because the use of a covered stent, such as a Viatorr, would cause the occlusion of one branch (Figure 3).

IVC stenosis (IVCS)

IVC anastomosis stenosis after orthotopic LT is a rare complication occurring in approximately 1% of patients but more frequently in the superior anastomosis of IVC[29,30]. Clinical manifestations are usually refractory ascites and/or pleural effusion associated with renal insufficiency, lower extremities edema and alterations of liver function tests. IVCs is usually related to technical problems during surgery or fibrous scar development at the anastomosis, and concomitant stenosis at hepatic vein anastomosis can be present. For this reason, hepatic vein catheterization is recommended during the same procedure. Donor-recipient size mismatch can also be responsible for IVCS. Transluminal angioplasty is the first-choice treatment for this complication[31] (Figure 4). Trans-stenotic metallic stent deployment is reserved for resistant stenoses or those with elastic recoil not responsive to angioplasty[32]. A transfemoral approach is preferred for a diagnostic cavogram, as is trans-stenotic pressure gradient measurement. Filling of collateral peri-caval vessels is possible in case of hemodynamically significant stenosis. Balloon dilatation is performed with large-sized catheters. Due to the large size of the IVC, simultaneous inflation of multiple balloons has been described[1]. In our practice, during the procedure, radial or femoral artery pressure measurement is performed to continuously monitor changes in systemic hemodynamics during balloon dilatation, and consequent

Figure 4 Status post deceased donor LT. Patient with refractory ascites in association with renal insufficiency and lower extremities edema 4 years after the transplant. A: DSA, cavogram showed a stenosis of IVC upper anastomosis, 12 mmHg trans-stenotic pressure gradient was measured. In the same session hepatic veins catheterization was performed showing no concomitant stenoses in hepatic vein anastomosis; B: DSA percutaneous transluminal angioplasty performed by 16-mm diameter balloon catheter; C: DSA final cavogram showed good patency of the caval anastomosis with trans-stenotic pressure gradient reduced to 2 mmHg. From 2001 to 2007, four other trans-luminal caval angioplasties were performed in the same patient. The patient is currently in good general condition after 15 mo and has avoided re-transplantation.

IVC occlusion, deflating the balloon before an excessive drop of systemic pressure. Repeat dilatations may be necessary for long-term patency. In patients with IVCS recurrence and severe renal insufficiency, trans-anastomotic pressure gradient measurement and balloon dilatation can be easily performed without injection of iodinate contrast.

Hepatic vein stenosis (HVS)

HVS, inducing outflow insufficiency, is a major postoperative complication of LT, especially in patients with partial liver graft transplantation producing graft failure with a reported incidence of 1%-4%[33-35]. Hepatic congestion can cause refractory ascites, refractory hydrothorax and alteration of liver function tests. HVS usually occurs at the anastomosis site; less frequent is the presence of an intrahepatic stenosis in the HV, likely due to previous venous injury during surgery or during previous percutaneous procedures, such as biopsy or biliary catheter placement. If a clinical and/or imaging suspicion of HVS is present, selective catheterization of all the HVs is mandatory to confirm the stenosis and measure the trans-stenotic pressure gradient (Figure 5). A pressure gradient greater than 3 mmHg between the HV and right atrium has been reported to be pathological[35]. Transjugular or transfemoral angioplasty or metallic stent placement is usually performed, as a first choice, to treat this complication[31,33-35]. In our experience, balloon dilatation is considered the preferred treatment choice because long-term patency of metallic stents is still unknown and metallic stent placement is reserved for persistent HVS not responsive to multiple angioplasties. Good technical and clinical success rates for percutaneous interventions are reported[33-36]. Long-term patency may require repeated interventions, especially if only trans-luminal angioplasty is performed. Better long-term patency results are reported in cases of stent deployment[36]. The primary percutaneous transhepatic approach for HVS treatment, has been reported[35] to have an easier negotiation through the stenosis, leading to shorter procedure time and ionizing radiation. In our experience, we use the percutaneous transhepatic approach only when the transjugular or the transfemoral approach fails. For the transhepatic approach, previous drainage of ascites and the embolization of the transhepatic tracks at the end of the procedure are, in our opinion, mandatory to reduce the risk of bleeding.

TREATMENT OF BILIARY COMPLICATIONS

Biliary complications occur in 10%-40% of patients after LT[37-40], with major incidence in patients with partial LT[41-42]. Complications include BSs, bile leakage (BL), biliary stones and bilomas. The majority of biliary complications develop during the first 3 mo, but strictures and stones may develop months or years after LT. The preferred methods for biliary tract reconstruction in LT are the duct-to-duct anastomosis between the donor and recipient common ducts and, less frequently, Roux-en-Y choledocojejunostomy. In right lobe split LT (from deceased or living related donor), a duct-to-duct anastomosis is usually performed between the donor right biliary duct and recipient bile duct, but due to possible anatomical variants of the donor biliary tree, two different biliary anastomoses, or less frequently three anastomoses, are performed with the recipient bile duct and the recipient cystic duct or with a Roux-en-Y limb, in up to 40% of patients[41,42]. Patients with multiple biliary reconstructions have a higher incidence of biliary complications[42]. Clinical presentation of biliary complications is often indistinguishable from other post-transplantation complications (vascular complications, rejection, graft dysfunction, infections). Ultrasonography is commonly used as screening test; however, due to the high rate of false-negative results, a negative test cannot exclude the presence of biliary complications.

Endoscopic retrograde cholangiopancreatography (ERCP) is usually the initial method of choice to

Figure 5 Status post deceased donor right lobe split LT in 65-year-old female. Three separates HV anastomoses were performed. One month after LT, patient developed refractory ascites and right pleural effusion with worsening of liver function tests. Doppler US was suspicious of HVs. A cavogram performed from the femoral approach showed widely patent IVC anastomosis. Selective catheterization of the three HVs (A, C and E) showed stenosis in the three anastomoses with trans-stenotic pressure gradient of 15, 20 and 16 mmHg, respectively. Balloon angioplasties were performed with balloon catheters ranging from 7 to 10 mm in diameter. Final venogram showed patent anastomoses (B, D and F). Trans-anastomotic pressure gradient reduced to 4, 2.5 and 8 mmHg. Eight months of follow-up without recurrence of refractory ascites and/or hydrothorax.

treat post LT biliary complications in patients with duct-to-duct anastomosis. Percutaneous transhepatic cholangiography (PTC) is the method to manage biliary complications in patients with choledochojejunostomy, in presence of intraepatic strictures and when endoscopic management fails.

Biliary strictures (BS)

BS is a common problem after LT with a reported incidence of 10%-35%[37-40]. Anastomotic BS is usually related to scar tissue and retraction at the suture site[41-42]. Intrahepatic BS is usually related to chronic rejection or arterial insufficiency due to HAS, thrombosis or ABO blood group incompatibility or infections. Single focal strictures and multiple/combined intrahepatic and anastomotic strictures can be present. Untreated BS is associated with high rate of morbidity and mortality. Endoscopic intervention is the preferred approach in patients with duct-to-duct anastomosis. PTC with biliary drainage placement and consequent percutaneous balloon dilatation is performed in patients with the Roux-en-Y reconstruction or in cases of endoscopic failure. In patients with partial LT, knowledge of the number of the anastomoses performed is mandatory before a possible percutaneous treatment. Possible complications of PTC are hemobilia, drop in hematocrit, intra or extrahepatic hematoma, fever with bacteremia, with a reported incidence of 3%-26% of cases[43,44]. Severe

injury to intrahepatic arteries with massive hemobilia and possible formation of intrahepatic aneurysm is reported in 2% of cases. In those cases, emergency arterial embolization is required[43]. Suspicion of BS is based on one or more findings: clinical picture (fever, cholangitis), biochemistry (elevation of alkaline phosphatase, direct bilirubin, and transaminases), ultrasound and/or CT scan and/or MR (biliary duct dilatation), and liver biopsy (with histology consistent for cholestasis due to biliary obstruction). BS can also be present in cases of non-dilated biliary ducts. An ultrasound sensitivity of 38% in the detection of biliary obstruction has been reported in transplanted patients[45]. Better results, with sensitivity in detecting biliary obstructions ranging from 80% to 100%, are reported with the use of magnetic resonance cholangiography (MRCP)[46]. Percutaneous treatment of BS is considered safe and effective, avoiding in most cases the need for surgical revision of the anastomosis. Multiple treatments are often necessary. Long-term patency of percutaneous bilioplasty in adult recipients is reported from 50% to 60% at 5 years[47,48]. Prolonged cold ischemic and operative times, multiple or peripheral strictures and the presence of hepatic artery disease, predispose to treatment failure or a lower patency of anastomotic BS after balloon dilation[48,49]. The use of cutting balloon catheters or combined cutting and conventional balloon protocol has been proposed in patients with refractory anastomotic stricture[50,51].

Figure 6 Status post deceased donor LT in 40-year-old man. Hepatico-jejunostomy was performed. A: PTC shows moderate biliary duct dilatation and suboccusive biliary anastomosis stricture; B: The stricture was crossed and trans-anastomotic. 6F Ring biliary catheter was placed; C: cholangiogram performed after four sessions of percutaneous bilioplasty shows no bile duct dilatation and patent anastomosis; D: Evidence of complete contrast transition from the bile ducts into the bowel loop within 2 min after the cholangiography. Three years of follow-up without clinical evidence of stricture recurrency.

Metallic stent deployment is reserved for patients who are refractory to repetitive balloon dilation of BS and who are poor surgical candidates[52]. In our practice, PTC is performed in an angiographic suite under monitored anesthesia care, with spontaneous respiration and additional local anesthesia. The patient is monitored continuously by electrocardiography, a pulse oximeter, and automatic blood pressure and pulse recordings. Intravenous antibiotic prophylaxis is administered before all procedures. Patients with coagulation defects (platelets < 50 000 mm^3 and/or prothrombin activity < 50%) receive infusions of platelets and/or fresh frozen plasma. PTC is generally performed through an intercostal approach, with an ultrasound- and fluoroscopy-guided 20-Ga needle inserted in a peripheral bile duct. If the cholangiography shows a stricture, the biliary tree is catheterized using an Accustick Introducer System (Boston Scientific, Natik, USA) over a Cope wire (Cook, Bjaeverskov, Denmark), the stricture crossed when possible with 0.035 or 0.038 inch hydrophilic guide wires, and a trans-anastomotic biliary catheter ranging from 6F to 8.5F with side holes placed above and below the stricture. The catheter is left to external gravity drainage for at least 1 d. If the patient has no fever and/or cholangitis the day after the procedure, the catheter is clamped for internal drainage. If, after the diagnostic cholangiogram, a guide wire cannot be passed through the stricture, an external drainage catheter is placed to allow for biliary decompression and to reduce the stricture's possible inflammatory component. A second attempt to cross the stricture is usually performed after 7 d. The first BS balloon dilatation session is never performed on the same day as the diagnostic cholangiogram, so as to reduce the risk of sepsis. It is generally performed after 1 wk, following a cholangiography performed with a 6F or 7F sheath and a balloon size ranging from 6 to 10 mm. Every dilatation session consists of three trans-anastomotic dilatations of 10 min each. Trans-anastomotic biliary catheters with sizes ranging from 6F to 14F according to the diameter of the anastomosis are placed after every dilatation session. An antibiotic infusion is re-administered 6 h after every procedure. At each dilatation session, the size of the balloon catheter is increased by 1 mm, up to a maximum diameter of 12 mm. Catheters are removed when the cholangiography performed through the sheath shows evidence of stricture resolution or of minimal residual stenosis of less than 20% of the expected lumen caliber. In all cases, catheters are removed only upon evidence of complete contrast transition from the bile ducts into the bowel loop within 3 min after the cholangiography (Figure 6), and if a significant reduction of cholestasis serum liver enzymes is achieved after bilioplasty. Our protocol envisages three BS dilatation sessions performed every 4-8 wk, followed by a cholangiographic evaluation 4 wk after the last session. If the stricture is resolved, the catheter is removed; if the BS persists, a supplementary balloon dilatation and follow up cholangiogram is performed, followed by potential catheter removal or balloon dilatation after 4-6 wk. In our experience, when a BS is crossed and a biliary catheter placed, percutaneous balloon dilatation gives good results, although multiple sessions over several months are necessary to obtain stricture resolution.

Bile leakage (BL)

Post-operative BL is a complication of LT that usually occurs within a few weeks from the transplant in 5%-20% of patients[37-39,53]. BL can arise from bile duct anastomosis of the resection margin in partial LT. Another possible site of leakage is the T-tube insertion in patients with choledocho-choledocho anastomosis. Small leakages usually close spontaneously, while large BLs are a serious complication and need to be treated because of possible associated complications such as fever, abdominal pain, fluid electrolyte depletion, fat malabsorption, possible sepsis or bleeding for hilar vascular erosion. The initial management should be non-operative. Percutaneous drainages, placed with a sonographic guide, are used to drain the bile collection. Endoscopic or percutaneous transhepatic management, with placement of large-size biliary catheters, allows achievement of good results in the treatment of large BL in adult patients, avoiding surgical repair in many cases[54-58]. In selected patients, when prior endoscopic or percutaneous transhepatic attempts to stent

Figure 7 Status post LRLT (right lobe) in 56-year-old woman. Two separate biliary anastomoses were performed. Approximately 300 mL of bile was drained every day from the existing perihepatic drainage catheter (JP) placed during the transplantation. ERCP was performed, revealing a BL from the anastomotic region. An endoscopic stent was deployed in the posterior duct anastomosis but endoscopy failed to place a stent in the anterior duct anastomosis. A: PTC of the anterior duct showed no bile ducts dilatation and a BL arising from the anastomosis; B: 12F external internal catheter without side holes was placed in the leak region. The bile output from the JP progressively reduced and stopped a few days later. The JP and the endoscopic stent were removed 1 mo later; C: Final cholangiogram performed 4 mo later showed no BL and patent biliary anastomosis. The catheter was removed. The patient is still in good condition after 12 mo of follow-up.

the biliary tree have failed, the combined transhepatic-endoscopic approach (rendezvous technique) can be successfully used to place large-size biliary catheters[59-60]. When minimally invasive treatments fail, operative intervention is mandatory. In our practice, in patients with anastomotic BL who undergo percutaneous trans-hepatic treatment, we do not use biliary catheters with standard side holes, but we prefer to modify multipurpose large-size drainages by adding holes only in the intrahepatic bile ducts and in the distal bile duct, so as to reduce bile contact in the duct lesion to favor the repair process (Figure 7).

CONCLUSION

LT, in patients with end-stage liver diseases, has become an accepted treatment. Advances in the field of percutaneous, radiological, minimally invasive techniques have increased the importance of interventional radiology in the management of patients after LT. Interventional radiology procedures are used in the treatment of vascular and non-vascular complications, improving graft and patient survival and avoiding, in the majority of cases, surgical revision and/or re-transplantation.

Abstract

An increasingly number of transplant centers have integrated a psychological assessment within their protocol for evaluation of patients being considered for transplantation. This paper highlights the psychological criteria for inclusion or exclusion for listing, briefly discusses the psychological dynamics of patients, and addresses possible psychotherapy and pharmacological therapy, before and after transplant.

INTRODUCTION

Orthotopic liver transplantation (OLTx) is a major surgical procedure that can precipitate distress, anxiety and depression. The experience of the last few years of many transplantation centers has highlighted the importance of a thorough and routine psychological assessment before considering the patient as a possible candidate for listing[1]. The importance of identifying psychological/psychiatric, and/or possible psychosocial problems is necessary in order to eliminate or prevent the insurgence of possible psychological problems post-transplant. Most transplant centers have included an initial psychological evaluation in their work-up protocol, to evaluate the psychological strengths and possible liabilities of the patient who is being considered for an OLTx, so as to provide interventions such as: smoking cessation therapy, drug/alcohol rehabilitation, and improvement of compliance; that is, behavior that needs to be resolved before surgery, in order to reduce possible behavioral liabilities after transplantation[2].

The transplant itself has deep psychological implications, which may exist within the affective, social and interpersonal realm of the individual's personality. In the postoperative phase, there may be manifestations of adjustment disorders, psychopathological disturbances, problems with compliance, as well as non-adherence to the therapeutic plan[3]. To reiterate, it is therefore necessary to carry out an accurate evaluation of the psychological and personality profile of each individual being considered for listing for possible OLTx.

PSYCHOLOGICAL ASSESSMENT OF THE POTENTIAL CANDIDATE FOR TRANSPLANT

During the initial interview, the psychologist's main goal is to determine how much the candidate knows or is aware of his/her medical status, or better yet, whether he/she has accepted his/her medical condition. The communication of the necessity of a liver transplant automatically induces the patient to think that conventional therapies and/or less invasive surgery are no longer an option. In such a case, the patients' psychological-emotional reactions take a course of their own, for example, they start experiencing: (1) sense of despair; (2) concerns for his/her medical status and sense of imminent death; (3) reactive and/or correlated psychopathology.

During the course of the psychological evaluation, then, patients may find themselves living two traumatic events (both real), at the same time: (1) sense of imminent death; or (2) rebirth through the transplant. During this phase, it has been observed that patients most often feel a sense of doubt, anxiety, ambivalence, fear and frustration,

which, if associated with a high level of psychological distress, can have consequences that can even lead to non-acceptance of the transplant. A careful psychological evaluation (cognitive, emotional and interpersonal) allows for an accurate course of psychotherapy[4].

The therapist must take into consideration those needs, deficits and assets that the patients possess in order to bring them step by step toward the final objective, which is the transplant. The specific, individualized treatment plan allows for an improvement of the quality of life (QOL) of the patient who will undergo a transplant and, specifically, during the postoperative period[4].

Ethically, the ability to give informed consent comprises three key elements: adequate information, adequate decision-making capacity, and freedom from coercion (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1982)[5]. Therefore, to this end, it appears fundamental to the psychologist's evaluation, whose goal is to evaluate the degree of the patient's knowledge and understanding of the various items on the informed consent. To this extent, it is fundamental that the patient's ability for decision-making is evaluated. If there is a suspected inability to do this (because of mental retardation or social deficits, *etc*), then, it is imperative that further testing be done using standardized tools for the evaluation of IQ (e.g. Wechsler Adult Intelligence Scale-Revision). If mental deficiency is found, then it becomes a legal issue, that is, it is necessary to assign a legal guardian who can represent the patient, in order to protect his/her rights. In the absence of a cognitive defect, if it is evaluated that the patient has not fully understood the context of such a document because of difficulty in perceiving such information, or in the event that there is resistance in accepting such information, then it becomes imperative that the patients undergo a psycho-educational process, in order to induce them to adjust their non-functional behavior or lifestyle in accordance with the expectations of the transplant team. For example, patients might need to be educated on topics such as maintaining adequate personal hygiene, given that they will be treated with immunosuppressant medication for the rest of their lives.

Table 1 outlines the absolute and relative contraindications for transplant listing. Although each item needs detailed discussion, for the purpose of this paper, the discussion will focus on alcohol/drug addiction and psychopathology, which are the two contraindications that need the most active intervention of the psychologist. The candidacy of patients who have an addiction has varied within each transplant center; however, in recent years, there has been an attempt to formalize the criteria for such patients. In Italy, the Director of the National Transplant Institute assigned a group of psychologists and psychiatrists to work on the guidelines to be applied in transplant centers across the country. This group (GLI PSI TO), of which the present author is a member, debated and focused a lot of time and energy in determining the criteria for listing patients

Table 1 Contraindications for OLTx
Absolute
Irriversible cognitive-neurological deficits
Active psychosis
Active addiction to drugs and/or alcohol
Relative
Personality disorder
History of psychiatric disorders
History of alcohol and/or drug addiction
Depression
Neurosis
History of use of psychotropic/neuroleptics
Limited family and social support
Limited ability to adhere to therapies
Inadequate motivation

with addiction. The consensus was, also following the lead of guidelines set forth by the United Network for Organ Sharing, that patients may be considered for listing after 6-12 mo abstinence, and that they have to be active participants in a rehabilitation center (even as an out-patient). With such patients, during this period of abstinence at our center (Istituto Mediterraneo per Trapianti e Terapie ad alta Specializzazione; ISMETT), the treatment is two-fold: patients are sent to a rehabilitation center closest to their residence, where the main focus is the toxicological component of the problem; while at ISMETT, the psychologists work in full synergy with such centers in an attempt to give patient support, in order to access those possible psychosocial resources that are needed for a positive, favorable prognosis.

With regard to psychopathology, it is important to note that it is not always a contraindication for transplantation *per se*. In fact, if patients manifest an active psychosis, not well compensated even with pharmacological therapy[6], it is obvious that this would be an absolute contraindication, especially since there is an absence of the necessary resources needed to undergo an OLTx. In other cases, however, such as in mood disorders and anxiety disorder, psychopharmacological therapy in conjunction with psychotherapy may ameliorate the disturbance to the point at which patients are placed in a condition in which they can reach a functional emotional, affective equilibrium that allows them to manage the eventual distress related to the transplant. Such patients, however, need constant support before, during and after transplantation. During the pre-transplantation phase, specifically for sensitivity to stress; in the post-transplant phase, most importantly because of immunosuppressant therapy that might precipitate mood swings, irritability, mania and anxiety. Psychotherapy and/or psychotherapy in conjunction with pharmacological treatment might be indicated during all the phases of the transplant process. Cognitive behavior therapy is the psychotherapeutic approach implemented at ISMETT, an approach which has been evaluated as being most beneficial with these patients, as they are individuals who tend to manifest traits such as depression, anxiety and phobia. Anxiety reduction techniques, autogenic training, systematic desensitization,

Table 2 Domains of the pre-transplant psychological evaluation

Informed consent
Personality profile
Psychopathology
Past/present psychiatric history
Effect of illness on daily life activities
Defense mechanism employed and coping skills
Motivation for surgery
Treatment compliance
Support from the family

Awareness of information regarding the actual surgical event and
future treatments
Use/abuse of alcohol and/or drugs (see paragraph on this topic)
QOL

relaxation techniques, guided imagery, pain management and hypnosis are techniques that might be implemented, and that normally bring more immediate results for the management of those symptoms already mentioned as those being manifested by patients during the transplant process (Table 2).

CONCLUSION

The role of the psychological assessment and monitoring during the pre- and post-transplant phases, as well as the ongoing follow-up intervention, is generally highly valued by organ transplant teams because of the significant health consequences of organ transplant failure. Identifying and reducing psychological risk factors can play an important role in overall long-term success of transplantation.

Abstract

AIM: To examine the expressions of N-cadherin and E-cadherin in specimens of 62 normal esophageal epithela, 31 adjacent atypical hyperplastic epithelia and 62 esophageal squamous cell carcinomas (ESCCs), and to investigate the roles of N-cadherin in the invasiveness of ESCC cell line EC9706 transfected by N-cadherin shRNA.

METHODS: PV immunohistochemistry was used to detect the expression pattern of N-cadherin and E-cadherin in specimens of 62 normal esophageal epithelia, 31 adjacent atypical hyperplastic epithelia and 62 ESCCs. The invasiveness of ESCC line EC9706 was determined by transwell assay after EC9706 was transfected by N-cadherin shRNA.

RESULTS: The positive rates of N-cadherin decreased in the carcinoma, adjacent atypical hyperplastic and normal esophageal tissues (75.8%, 61.3% and 29.0%, $P < 0.05$), respectively, while those of E-cadherin increased (40.3%, 71.0% and 95.2%, $P < 0.05$). The increased expression of N-cadherin and decreased expression of E-cadherin were related to invasion, differentiation, and lymph node metastasis ($P < 0.05$). The expression level of N-cadherin decreased in the N-cadherin knocked down cells, and the invasiveness of those cells decreased significantly as well. The number of cells which crossed the basement membrane filter decreased from 123.40 ± 8.23 to 49.60 ± 6.80 ($P < 0.05$).

CONCLUSION: E-cadherin and N-cadherin expression is correlated with the invasion and aggravation of ESCC. The down-regulation of N-cadherin lowers the invasiveness of EC9706 cell line.

Key words: Esophageal squamous cell carcinoma; RNAi; N-cadherin; EC9706

INTRODUCTION

The malignancy of cancer cells depends largely on their proliferative, invasive and metastatic activities, and invasive and metastatic activities are most closely associated with cell-to-cell and cell-to-extracellular matrix adhesion. As a class of transmembrane proteins, cadherins play an important role in cell adhesion. Among the members of cadherin family, E-cadherin and N-cadherin have been extensively studied about their biological activities and associations with cancer cell invasion. It was reported that the invasion and metastasis were present in the esophageal squamous cell carcinoma (ESCC) with a low level of E-cadherin[1,2]. Recent studies on prostate cancer and breast cancer proved that the up-regulated N-cadherin plays an important role in cell progression and metastasis[3,4]. In addition, N-cadherin is involved in angiogenesis and tumor growth regulation, and contributes to the invasive morphology in squamous tumor cells, and stimulates migration, invasion and metastasis[5]. However, the association of E-cadherin and N-cadherin expression with the malignancy of the ESCC is unknown.

In the current study, we analyzed the expression of E-cadherin and N-cadherin in the ESCC tissues, adjacent atypical hyperplastic epithelium and normal esophageal

epithelium. The roles of N-cadherin in the invasiveness were investigated in ESCC cell line (EC9706) transfected by N-cadherin shRNA.

MATERIALS AND METHODS

Tissue samples

In this study, we randomly selected 62 esophageal cancer patients who underwent potentially curative surgery without preoperative chemotherapy or radiotherapy between February 26 and March 16, 2006 in Anyang Tumor Hospital, Henan, China. Among them, 36 were men and 26 were women, ranging from 38-75 years of age with a mean age of 52.6 years. Overall, 22 cases were poorly differentiated, 25 were moderately differentiated, and 15 were well differentiated. For the lymphatic node metastasis, 20 cases were positive and 42 cases were negative. Seven cases were classified as T_1 and T_2, and 55 as T_3 and T_4 in terms of T stages. Surgically removed specimens were routinely fixed in buffered formalin and embedded in paraffin blocks for clinical diagnosis and reclassification for this study. The normal esophageal squamous tissues were taken from mucosae 3 cm away from carcinomas, and the adjacent atypical hyperplastic epithelium 2 cm away from the carcinomas. The final pathological diagnosis was based on the result of histological examination.

Expression of E-cadherin and N-cadherin in ESCC

Immunohistochemical analysis for E-cadherin and N-cadherin was performed on 5-µm sections made from tissue microarray blocks. The Envision Plus detection system (Dako, Carpinteria, CA, USA) was used for the immunostaining. The sections were deparaffinized in xylene and then were microwaved in 10 mmol/L citrate buffer (pH 6.0) to unmask the epitopes. Endogenous peroxidase activity was blocked by incubation with 0.03% hydrogen peroxide in methanol for 5 min. Slides were incubated with mouse anti-human E-cadherin antibody (microwaving retrieval in citrate buffer at 1:100 concentration, Abcam) and mouse anti-human N-cadherin antibody (microwaving retrieval in low pH buffer at 1:100 concentration; Abcam), respectively. Then, polyperoxidase anti-mouse IgG (Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd., China) was added for incubation for another 30 min followed by gentle rinsing with washing buffer for three times. Thereafter, the sections were stained for 5 min with 3,3-diaminobenzidine (DAB) (Beijing Zhongshan Golden Bridge Biotechnology), counterstained by hematoxylin, dehydrated, and mounted in Diatex. Expression of E-cadherin and N-cadherin in breast cancer was used as a positive control, while the same concentration of PBS was applied as a negative control for E-cadherin and N-cadherin.

Evaluation of staining for E-cadherin and N-cadherin

For both E-cadherin and N-cadherin, only membrane and cytoplasm staining was considered as positive. The intensity and percentage of immunostained carcinoma cells were all taken into consideration according to the previously published method with modification[6]. Briefly, the extent of positivity was scored as 0 when no positive cell was observed; 1 when the percentage of positive cells was < 30%; 2 when it was 30%-60%; and 3 when it was > 60%. The intensity was scored as 0 when no positive cells were identified; 1, weak; 2, moderate; and 3, strong staining. Multiplying the extent by intensity gave the following immunohistochemical staining grades as 0, 1, 2, 3, 4, 6 and 9. For statistical analyses, grades 0, 1 and 2 were considered as negatively stained, and grades > 2 were considered as positively stained.

Retroviral virus production and determination of viral titer

PT67 packaging cells were seeded onto a six-well plate at 1×10^5 cells per well and incubated for 24-48 h. The cells were allowed to grow to 60%-70% confluence and then rinsed with fresh DMEM medium. The control vector pEGFP-MSCVneo and recombinant retroviral vector pMSCVneo/N-cadherin plasmids (kindly provided by Dr. Ma Jie, Chinese Academy of Medical Sciences, China) (The former contained the enhanced green fluorescent protein and neomycin resistance genes, the latter contained the N-cadherin shRNA, U6-promotor, enhanced green fluorescent protein and neomycin resistance genes) were transfected into the packaging cell line PT67 by lipofectamine 2000 (Invitrogen Corp, UK) and incubated for 6 h following the manufacturer's instructions. The mixture was replaced with fresh medium to stop transfection and the transfected PT67 cells were further cultured with G418 (1000 mg/L) selecting medium for 2 wk. Viral supernatant of the drug-resistant clones was filtered through a 0.45-µm filter and condensed by ultracentrifugation at low temperature, then preserved at -80℃. The supernatant, from the fresh PT67 packaging cells containing recombinant retrovirus, was used to infect NIH3T3 cells to determine viral titer as previously described[7]. The highest titer clones were selected for further experiments.

Infection of EC9706 cells with viral supernatant

EC9706 cells were plated in a six-well plate at 5×10^4 cells/mL and cultured with 5% CO_2 at 37℃. Twenty-four hours later, the cells were exposed to 2 mL viral supernatant at a consecutive multiplicity of infection once for 12 h, in the presence of 8 µg/mL polybrene (Sigma). Subsequently, viral supernatant was replaced with fresh medium. After being incubated for another 24 h, the infected EC9706 cells were screened with G418 (600 mg/L) (Sigma) selecting medium for 2 wk. Drug-resistant clones were expanded with G418 (300 mg/L) (Sigma) selecting medium. Two days after culturing, the expression of EGFP in infected EC9706 cells was observed under fluorescence microscope.

Total RNA and protein isolation

Total RNA and protein isolation was performed using the Macherey-Nagel total RNA and protein isolation kit according to the user manual. About 5×10^6 EC9706

cells transfected with N-cadherin RNAi, control vector, or the untreated cells were collected and lysed. Through the NucleoSpin RNA/Protein column, RNA and DNA were bound to the column and protein was contained in the flow-through. After digestion of DNA, total RNA was isolated by washing the column. Protein was isolated from the flow-through and incubated for 3 min at 98℃ for dissolving and denaturation, and stored at -20℃ until used. All of the preparation and handling steps of RNA took place in a laminar flow hood under RNase-free conditions.

cDNA synthesis

RNA quality and quantity were determined by absorbance readings at 260 and 280 nm with the Nano Drop (ND-1000) spectrophotometer. RNA integrity was tested by PCR amplification of the GAPDH gene. Reverse transcription of RNA was performed using Transcriptor First Strand cDNA Synthesis Kit (Roche). cDNA was synthesized from 5 μg total RNA isolated from EC9706 cells transfected with N-cadherin siRNA, control vector, or the untreated cells according to the manufacturer's handbook.

Primer/probe design

The primer pairs and hydrolysis probes for N-cadherin, E-cadherin, matrix metalloproteinase-9 (MMP-9) and GAPDH were designed by Universal ProbeLibrary Assay Design Center (Roche). All primer sequences listed in Table 1 were synthesized by Shanghai Sangon (China). The hydrolysis probes were designed and synthesized by Roche Diagnostics.

Real-time PCR

Real-time PCR was performed with the ABI Prism 7500 Sequence Detection System (ABI) in a total volume of 20 μL in glasscapillaries containing 2 μL of cDNA, 0.5 μmol/L of each primer, 0.1 μmol/L of hydrolysis probe and 4 μL of LightCycler TaqMan Master Mix (Roche Diagnostics). PCR reaction was initiated with a 12-min denaturation at 95℃ and terminated with a 30-s cooling step at 40℃. The cycling protocol consisted of denaturation at 95℃ for 10 s, annealing at 54℃ for 10 s, and extension at 72℃ for 10 s, and was cycled 45 times. Fluorescence detection was performed at the end of each extension step. The housekeeping genes

GAPDH and DEPC-H$_2$O were set as internal control and negative control, respectively.

Western blot analysis

Twenty microliters of protein samples were separated on a 10% SDS-acrylamide gel (Bio-Rad) for 1 h at 150 V, and the proteins were transferred to nitrocellulose membrane (Whatman). After blocking in 5% fat-free milk, the membrane was treated with the dilution of the primary antibody overnight at 4℃ and the dilution of the secondary IgG-horseradish peroxidase (HRP) conjugated antibody for 1 h at room temperature. All dilutions were in PBS containing 5% Blotto (Santa Cruz) and 0.1% Tween-20. The stained membranes were visualized by enhanced chemiluminescence reaction using the ECL Plus (GE Healthcare). Western blot experiments were repeated at least three times on every sample, with similar results.

Transwell chamber migration assay

Matrigel-coated filter inserts with 8-μm pores that fit into 24-well invasion chambers were obtained from Becton Dickinson. EC9706 cells transfected with N-cadherin RNAi, control vector, or the untreated cells were detached from the tissue culture plates, washed, resuspended in conditioned medium (10^6 cells/mL), and then added to the upper compartment of the invasion chamber with or without plasmin (1.8 mg). Conditioned medium (500 μL) was added to the lower compartment of the invasion chamber. The Matrigel invasion chambers were incubated at 37℃ for 24 h in 5% CO$_2$. After incubation, the filter inserts were removed from the wells, and the cells on the upper side of the filter were removed using cotton swabs. The filters were fixed, mounted, and stained according to the manufacturer's instructions. The cells that invaded through the Matrigel were counted on the underside of the filter. Three to five invasion chambers were used for each experimental condition. The values obtained were calculated by averaging the total number of cells from three filters.

Statistical analysis

χ^2 test and Spearman rank correlation coefficient analysis were used to assess the univariate association between the immunohistochemical status and the clinicopathological characteristics. Results were expressed as mean ± SD. Statistical analysis was made using one way ANOVA or paired-samples t test of SPSS 11.0. $P < 0.05$ was considered statistically significant.

RESULTS

Immunoreactivity and clinicopathological correlations

For E-cadherin, positive immunostaining was observed on the membrane of cancer cells and the intercellular junctions. It was strongly expressed in the normal esophageal squamous tissues (95.2%), moderately expressed in the adjacent atypical hyperplastic epithelium (71.0%), and weakly expressed in the ESCC

+	25	12	13	-0.534	0.000
−	37	35	2		

and moderately expressed in the adjacent atypical hyperplastic epithelium (61.3%), but weakly expressed in the normal esophageal squamous tissues (29.0%) (Figure 1C, D and Table 2). The correlations between the clinicopathological features and the expressions of E-cadherin and N-cadherin in the primary tumors are summarized in Table 2. Higher level of N-cadherin expression was significantly associated with higher histological grade, deeper invasion and more lymph node metastasis, while E-cadherin expression was associated with totally opposite sides.

Correlation between E-cadherin and N-cadherin protein expression

In order to know whether the expression of E-cadherin and N-cadherin in these tumors was associated, a crosstable analysis was performed (Table 3), which showed that their expression was significantly negatively correlated.

PT67 cells producing retrovirus

After G418 selection for 30 d, the stable colonies of pEGFP-MSCVneo plasmid (control vector) with viral titer 1×10^7 cfu/L and colonies of pMSCVneo/N-cadherin (RNAi vector) with viral titer 3×10^7 cfu/L were picked up to infect EC9706 cells (Figure 2A).

Establishment of transfected EC9706 cells

EC9706 cells were infected with the concentrated viral supernatant and selected with G418 as described above. After screening with G418 for 2 wk, the isolated G418-

A: Strong expression (yellowish brown) of E-cadherin on the membrane of normal esophageal epithelial cells (PV, × 200); B: Weak expression (yellow) of E-cadherin on the membrane of ESCC cells (PV, × 200); C: Weak expression (yellow) of N-cadherin in the cytoplasm of normal esophageal epithelial cells (PV, × 200); D: Strong expression (yellowish brown) of N-cadherin in the cytoplasm of ESCC cells (PV, × 200).

tissues (40.3%) (Figure 1A, B and Table 2). Contrary to the E-cadherin, N-cadherin, which existed in the cytoplasm, was strongly expressed in the ESCC (75.8%)

Figure 2 EGFP expression in PT67 cells and EC9706 cells after pMSCV-neo/N-cadherin transfection. A: Selected by 1000 mg/L G418 for 15 d and 300 mg/L G418 for 15 d, the PT-67 cells transfected with pMSCVneo/N-cadherin plasmid expressed EGFP stably. The figure was taken under fluorescence microscope (× 400, at 488 nm); B: Selected by 600 mg/L G418 for 14 d and 300 mg/L G418 for 10 d, the EC9706 cells infected with pMSCVneo/N-cadherin viral supernatant expressed EGFP stably. The figure was taken under fluorescence microscope (× 400, at 488 nm).

Figure 3 E-cadherin, N-cadherin and MMP-9 gene transcripts detected by real-time PCR. 1: Positive control; 2: Untreated EC9706 cells; 3: EC9706 cells with control vector; 4: EC9706 cells with N-cadherin RNAi. $^aP < 0.05$ *vs* 2 and 3.

resistant clones (Figure 2B) were transferred into larger culture vessels to expand for further experiments.

N-cadherin depletion affected expression of E-cadherin and MMP-9 by EC9706

To investigate the expression phenotypes of E-cadherin and MMP-9 when N-cadherin was down-regulated, real-time PCR and Western blotting were employed to examine the expressions of the N-cadherin, E-cadherin

Figure 4 E-cadherin, N-cadherin and MMP-9 proteins detected by Western bloting. 1: Positive control; 2: Untreated EC9706 cells; 3: EC9706 cells with control vector; 4: EC9706 cells with N-cadherin RNAi. E-cadherin proteins were 0.247 ± 0.010, 0.252 ± 0.087, 0.249 ± 0.07 and 0.250 ± 0.006, respectively, from lane 1 to lane 4. $P > 0.05$. The N-cadherin proteins were 0.681 ± 0.003, 0.679 ± 0.004, 0.653 ± 0.009 and 0.342 ± 0.006, respectively, from lane 1 to lane 4. $P < 0.05$. The MMP-9 proteins were 0.624 ± 0.011, 0.628 ± 0.010, 0.623 ± 0.009 and 0.282 ± 0.010, respectively, from lane 1 to lane 4. $P < 0.05$.

and MMP-9 in ESCC cell line EC9706. Transfection of N-cadherin RNAi lowered N-cadherin mRNA level (0.397 ± 0.013) to less than 40%, compared with the untreated cells (1.000 ± 0.016) (Figure 3), and the N-cadherin protein (0.342 ± 0.006) to 50%, compared with the untreated cells (0.679 ± 0.004) (Figure 4).

The levels of MMP-9 mRNA and protein lowered by about 50% in the N-cadherin depleted cells compared with the untreated cells (Figures 3 and 4). The MMP-9 mRNA reduced from 1.241 ± 0.023 in the untreated cells to 0.566 ± 0.016 in N-cadherin RNAi cells, and the protein reduced from 0.628 ± 0.010 to 0.282 ± 0.010. However, it seems that N-cadherin shRNA did not affect the levels of E-cadherin mRNA and protein (Figures 3 and 4).

Knocking down N-cadherin decreased invasiveness of EC9706 in vitro

N-cadherin level was elevated with the malignancy in the ESCC tissues in a previous experiment. When N-cadherin was down-regulated, the migration of the cells was also reduced, compared with the untreated cells. Compared with the untreated EC9706 cells (Figure 5A) and the cells with control vector (Figure 5B), the N-cadherin negative-cells (Figure 5C) migration across the membranes decreased dramatically.

DISCUSSION

Cadherins are a class of type-1 transmembrane proteins. They are calcium dependent cell-cell adhesion glycoproteins. They play important roles in tissue formation and maintenance during embryonic development, and in the induction and maintenance of normal architecture and function in adult tissues. The most researched proteins of the cadherin family are E-cadherin and N-cadherin[8].

In the present research with ESCC, we found down-regulation of E-cadherin and increased N-cadherin. Normal E-cadherin expression contributes to the maintenance of epithelial integrity and polarized function[9,10]. Mutations in E-cadherin gene are correlated with gastric, breast, colorectal, thyroid and ovarian

Figure 5 Migration assay in transwell chamber. A: Untreated EC9706 cells; B: EC9706 cells with control vector; C: EC9706 cells with N-cadherin RNAi. They were 123.40 ± 8.234, 126.00 ± 10.295 and 49.60 ± 6.804, respectively, from A to C. $P < 0.05$. (HE, × 200).

cancer[11,12]. Much lower levels were found to be present in the poorly differentiated lung cancer, indicating the worse prognosis[13]. Unlike E-cadherin, which is inversely correlated with invasiveness, N-cadherin may promote motility and invasion in carcinoma cells. N-cadherin has been shown to enhance cell migration during epithelial-mesenchymal transformation[14]. Aberrant N-cadherin expression was also found in breast carcinoma cells and prostate carcinoma cells[3,4]. In epithelial carcinoma, E-cadherin is down-regulated in most cases, sometimes accompanied by the up-regulation of another cadherin, for example, N-cadherin[15,16]. For the present research with ESCC, less E-cadherin and more N-cadherin were expressed in the ESCC tissue with deep invasion, poor differentiation and lymph node metastasis than with superfacial invasion, well differentiated and negative metastasis tissues. The N-cadherin expression was increased in the advanced ESCC tissues where

E-cadherin was down-regulated, suggesting that they undergo a switch from E- to N-cadherin expression. The shift in expression from E- to N-cadherin and their mutually exclusive expression pattern in invasive tumor cell lines strongly reflect that the dedifferentiation from an epithelial to a mesenchymal phenotype was often associated with an increased invasive state[17]. The exact underlying mechanism has not been clear, but in many carcinomas, this "cadherin switch" was observed, especially in those where mild and non-progressive cells transformed into a more invasive phenotype[3,18,19]. Ras, Src, Rho, PI3K and Wnt signaling pathways were supposed to be involved in this switch[20-22].

We have proved that reduced E-cadherin and increased N-cadherin were present in advanced ESCC, and the following RNAi-mediated N-cadherin silence in EC9706 cell line further disclosed the correlation of E-cadherin and N-cadherin with ESCC progression. The down-regulation of N-cadherin did not change the expression of E-cadherin mRNA and its product. While N-cadherin and MMP-9 were reduced significantly in transcription level and translation level, less cells demonstrated invasiveness.

Local tumor invasion is characterized by at least two changes of function by the cancer cells. Firstly, these cells express higher levels of membrane-type and secreted proteolytic enzymes (e.g. the MMPs) in comparison with their normal epithelioid counterparts. Their contribution to invasion ranges from breakdown of the extracellular matrix, over-release of pro-invasive factors, to cleavage of cell-cell adhesion molecules[23]. Secondly, cancer cells are more motile than normal epithelial cells. Local tumor invasion is also made possible by disruption of epithelial cell junctions. E-cadherin, a part of the adherens junctions, plays an important role in maintaining the epithelioid cell organization and in preventing invasion[24]. Loss of function is thought to contribute to progression in cancer by increasing proliferation, invasion, and/or metastasis[5]. Forced expression of N-cadherin in well-differentiated breast cell lines did not change their E-cadherin expression as indicated, but stimulated marked increases in cell migration and invasion[25]. The ability of N-cadherin-expressing EC9706 cells to adhere to N-cadherin-expressing endothelial sheets may facilitate their transit through the vasculature and improve their ability to form metastasis. The present results also confirmed that the N-cadherin expression down-regulation did not affect E-cadherin mRNA and protein levels, but the invasiveness of all the EC9706 cells was weakened as compared with the untreated EC9706 cells. It might be postulated that N-cadherin, rather than E-cadherin, plays an important role in the cancer progression and metastasis.

Less invasiveness was shown in the N-cadherin-negative tumor cells. Therefore, knocking down N-cadherin can weaken the aggressiveness of cancer cells, by the mechanism involving more than a change in cellular adhesion. MMPs were thought to predominantly degrade structural components of the extracellular matrix

(ECM), thereby facilitating cell migration. In addition to cleaving structural ECM components, collagen type IV and the cell-adhesive molecules are also MMP substrates, increasing the invasive behavior of cells. Type I collagen is the predominant constituent of the perivascular ECM, and as mentioned previously, a variety of MMPs are capable of degrading collagen, including interstitial collagenase and neutrophil collagenase. The metastatic cells thus use these proteases to invade basement membrane and its underlying connective tissues and then subsequently through the basement membrane of the small blood vessels and lymphatics[26-30]. With RT-PCR and Western blotting, the level of MMP-9 mRNA and protein in the RNAi-mediated N-cadherin silencing EC9706 cells was found to be reduced as compared with untreated cells. It was supposed that the lower invasiveness of EC9706 cells was the consequence of down-regulation of N-cadherin, by the mechanism of decreasing the MMP-9 expression. The MMP-9 reduction resulted in less degradation of ECM, and thereby, the cancer cells were less aggressive. But which signaling pathway was involved in the N-cadherin to MMP-9 should be studied in the future researches.

In this study, decreased E-cadherin expression and increased N-cadherin expression were found more frequently in advanced ESCC than in low grade ESCC, confirming that the down-regulation of E-cadherin expression and up-regulation of N-cadherin expression were closely associated with the infiltration, invasion and metastasis of ESCC. *In vitro* experiments also demonstrated that even the E-cadherin mRNA and protein did not change much in the N-cadherin knocking down EC9706 cells, but the invasiveness of cancer cells was dramatically reduced. The decreased MMP-9 mRNA and its product were observed in the N-cadherin-negative cells, the majority of which lost their ability of migration *in vitro*. It was supposed that the N-cadherin played a role of facilitating cell invasion by MMP-9. In summary, our data suggest that N-cadherin is an important factor in the invasiveness of esophageal squamous cell carcinoma and N-cadherin may serve as a potential molecular target for biotherapy of esophageal squamous cell carcinoma.

COMMENTS

Background
Among the members of cadherin family, E-cadherin and N-cadherin have been extensively studied for their biological activities and associations with cancer cell invasion. Latest research on prostate cancer and breast cancer has proved that the up-regulated N-cadherin plays even more important roles in cell progression and metastasis.

Research frontiers
The shift in expression from E- to N-cadherin and their mutually exclusive expression pattern in invasive tumors strongly reflects dedifferentiation from an epithelial to a mesenchymal phenotype, often associated with an increased invasive state. This "cadherin switch" has been observed, especially in those where mild and non-progressive cells transformed into more invasive phenotypes. Therefore, many studies have focused on the exact underlying mechanism involved in this cadherin switch.

Innovations and breakthroughs
In the current study, the expression of N-cadherin and E-cadherin was first examined in esophageal squamous cell carcinoma (ESCC) specimens and the results revealed that increased expression of N-cadherin and decreased expression of E-cadherin were related to invasion, differentiation, and lymph node metastasis, the roles of N-cadherin in the invasiveness of ESCC were first investigated in the EC9706 cell line transfected by retroviral-mediated N-cadherin RNAi and the results revealed that N-cadherin knock-down significantly decreased the invasiveness of EC9706 cells.

Application
This study has indicated that N-cadherin is an important factor in the invasiveness of ESCC and N-cadherin may serve as a potential molecular target for biotherapy of ESCC.

Terminology
Cadherins are a class of type-1 transmembrane proteins. They are calcium-dependent cell-cell adhesion glycoproteins. They play important roles in tissue formation and maintenance during embryonic development, and in the induction and maintenance of normal architecture and function in adult tissues.

Peer review
The authors examined the expression pattern of N-cadherin and E-cadherin. They demonstrated that N-cadherin is an important factor in the invasiveness of ESCC and it may serve as a potential molecular target for biotherapy of ESCC.

Abstract

AIM: To examine the effects of ethanol-induced proteasome inhibition, and the effects of proteasome inhibition in the regulation of epigenetic mechanisms.

METHODS: Rats were fed ethanol for 1 mo using the Tsukamoto-French model and were compared to rats given the proteasome inhibitor PS-341 (Bortezomib, Velcade™) by intraperitoneal injection. Microarray analysis and real time PCR were performed and proteasome activity assays and Western blot analysis were performed using isolated nuclei.

RESULTS: Chronic ethanol feeding caused a significant inhibition of the ubiquitin proteasome pathway in the nucleus, which led to changes in the turnover of transcriptional factors, histone-modifying enzymes, and, therefore, affected epigenetic mechanisms. Chronic ethanol feeding was related to an increase in histone acetylation, and it is hypothesized that the proteasome proteolytic activity regulated histone modifications by controlling the stability of histone modifying enzymes, and, therefore, regulated the chromatin structure, allowing easy access to chromatin by RNA polymerase, and, thus, proper gene expression. Proteasome inhibition by PS-341 increased histone acetylation similar to chronic ethanol feeding. In addition, proteasome inhibition caused dramatic changes in hepatic remethylation reactions as there was a significant decrease in the enzymes responsible for the regeneration of S-adenosylmethionine, and, in particular, a significant decrease in the betaine-homocysteine methyltransferase enzyme. This suggested that hypomethylation was associated with proteasome inhibition, as indicated by the decrease in histone methylation.

CONCLUSION: The role of proteasome inhibition in regulating epigenetic mechanisms, and its link to liver injury in alcoholic liver disease, is thus a promising approach to study liver injury due to chronic ethanol consumption.

INTRODUCTION

A growing body of evidence indicates that specific histone modifications and modifying enzymes play essential roles in both global and tissue-specific chromatin organization[1]. Histone modifications, such as acetylation and methylation, play important roles in the regulation of gene expression, and impact many fundamental biological processes (i.e. in the cell cycle and cell proliferation). These modifications represent the inheritable epigenetic memory, which is transmitted with high fidelity to future cell generations.

Acetylation of histones is a major factor in

the regulation of chromatin remodeling and gene transcription. A sophisticated orchestra of proteins, such as histone acetyltransferases [HATs, gene activation (acetylation)], and histone deacetylases (HDACs), are required to regulate epigenetic mechanisms[2]. Acetylation of histone and non-histone protein is thus emerging as a central process in transcriptional activation, since nuclear HATs act as transcription co-activators, which have been shown to acetylate different transcriptions (i.e. p53, β-catenin, MyoD, SREBP-1)[3].

Alcohol consumption affects epigenetic mechanisms, and causes an increase in histone lysine acetylation, which has been associated with an increase in gene expression that may contribute to uncontrolled transcription[3]. These modifications are the results of changes in the activities of specific modifying enzymes that play essential roles in chromatin structure and specific gene expression. It has previously been shown that chronic ethanol feeding affects epigenetic mechanisms by causing an increase in the stability of histone-modifying enzymes, and thus, in histone modifications[4,5]. However, little is known about the mechanisms that control the life span of histone-modifying enzymes. For example, the consequence of proteasome inhibition in the nucleus, and its effects on epigenetic mechanisms, have not yet been investigated, and there is very little evidence on proteasome involvement in the turnover of the transcriptional factor and histone-modifying enzymes that regulate epigenetic mechanisms.

Our hypothesis is that proteasome inhibition, induced by ethanol feeding, is associated with histone modification, and is involved in the regulation of histone-modifying enzymes, such as the HAT p300.

The present study demonstrates the role of proteasome activity in epigenetic mechanisms, which significantly contribute to liver injury due to chronic ethanol feeding. Proteasome proteolytic activity regulates histone modifications by regulating the recruitment and stability of histone-modifying enzymes in the nucleus, and, therefore, regulates the chromatin structure, allowing easy access to chromatin by RNA polymerase and enhanced gene expression. The proteasome activity is also believed[6] to be critical for the expression of certain genes, such as those of the enzymes responsible for hepatic transmethylation reactions. In this study, microarray analysis showed up-regulation and down-regulation of a large number of genes, indicating that proteasome activity is essential for up-regulation, as well as down-regulation of specific gene expression. Proteasome inhibition caused a decrease in the gene expression of several enzymes involved in methionine metabolism, particularly betaine-homocysteine methyltransferase (BHMT), which was significantly down-regulated when the proteasome was inhibited[7]. These results indicated that DNA and histone methylation, which play important roles in the regulation of gene silencing, may be affected by proteasome inhibition, and, therefore, may impact many fundamental biological processes.

Previous reports have shown that gene expression changes were numerous at high levels of ethanol, when compared to their pair-fed controls. 1300 genes were changed[8-10]. Similarly, a preliminary microarray analysis of the livers of rats given the proteasome inhibitor PS-341, has shown marked changes in gene expression. Thus, a question arose: which mechanism is involved in this large number of gene expression changes? We believe that this mechanism is epigenetic in nature.

We believe that these modifications in gene expression are the result of a decrease in the activity of the proteasome in the nucleus, which would, for instance, increase the p300 HAT level and activity. Since p300 is responsible for a broad range of gene regulation, the activation of p300 acetylation in histones will increase and activate the expression of a large number of genes in a nonspecific and reversible manner.

The role of the proteasome in regulating histone methylation is also critical because the expression of several genes was changed when the proteasome was inhibited. We have previously demonstrated that proteasome inhibition causes a downregulation in the expression of several genes[8], particularly the gene involved in the remethylation pathway. The study of this remethylation, particularly, the reactional mechanism that regenerates S-adenosylmethionine (SAMe), the major methyl donor, is essential because this is the system that transfers the methyl group to DNA, histones and non-histone proteins *via* the methyltransferases, such as glycine N-methyltransferase (GNMT).

In this study, BHMT gene expression was markedly decreased by proteasome inhibition. BHMT is an essential enzyme in the remethylation pathway, and is involved in the recovery of SAMe. Betaine, a choline derivative which has been used clinically to treat, with some success, patients with methylenetetrahydrofolate reductase deficiency[11,12], acts as a substrate for BHMT, and serves as an alternative methyl donor for remethylation of homocysteine in the liver and kidney[13]. Therefore, betaine supplementation may cover the down-regulation of gene expression induced by proteasome inhibition, and correct the deregulation of hepatic transmethylation reactions due to the proteasome inhibition-induced decrease in BHMT activity.

MATERIALS AND METHODS

Animals
Male Wistar rats (Harleco, Hollister, CA, USA), weighing 250-300 g, were fed ethanol using the Tsukamoto-French intragastric model[14,15]. PS-341 was administered intraperitoneally, 24 h before sacrifice[16,17]. The rats were maintained according to the Guidelines of Animal Care, as described by the National Academy of Sciences and published by the National Institute of Health (1996).

Nuclei isolation
Histones were isolated from the nuclei, according to the method of Umlauf et al[18]. Liver tissues, frozen in isopentane and immersed in liquid nitrogen, were homogenized in a Dounce homogenizer with 10 strokes.

Homogenates were centrifuged for 10 min at 6000 × *g*. Pellets were resuspended, placed on ice for 10 min, and then centrifuged for 20 min at 9000 × *g* on a sucrose cushion. The pellets contained the nuclei. Histones were isolated from the nuclei, according to the method of Shechter *et al*[19]. Isolated nuclei were mixed with 0.2 mol/L H_2SO_4, and incubated on a rotator for 30 min at 4℃. Samples were spun in a microcentrifuge at 16 000 × *g*, for 10 min. Dissolved histones in the supernatant were precipitated with 33% TCA. After acetone wash, histones were dissolved in an appropriate buffer, and further analyses were carried out.

Proteasome chymotrypsin-like activity assay

Nuclei were isolated as mentioned above, and 1 μg of total protein was used. The reaction mixture contained 50 mmol/L Tris–HCl pH 8, 1 mmol/L DTT, and 40 μmol/L Suc-LLVY-AMC substrate for chymotrypsin-like activity. The mixture was incubated for 30 min at 37℃, and the reaction was then stopped by adding 100 μmol/L monochloroacetate and 30 mmol/L sodium acetate (pH 4.3). Fluorescence was determined by measuring the release of AMC (λ excitation: 370 nm, λ emission: 430 nm) using a Perkin Elmer LS 30 spectrofluorometer.

Western blot analysis

Proteins (50 μg) from isolated nuclei or isolated histones were separated by SDS-PAGE, and transferred to a PVDF membrane (Bio-Rad, Hercules, CA, USA) for 1 h in 25 mmol/L Tris-HCl (pH 8.3), 192 mmol/L glycine and 20% methanol. The membranes were stained using primary antibodies to the antigens. The appropriate species anti-polyclonal and anti-monoclonal HRP-conjugated antibodies were used as secondary antibodies. The membranes were subjected to chemiluminescence detection using luminal, according to the manufacturer's instructions (Amersham Pharmacia Biotech, Piscataway, NJ, USA).

Microarray analysis

Fast frozen rat liver tissue was subjected to microarray analysis. Total liver RNAs were extracted with UltraspecTM RNA Isolation Systemic (Biotecx Laboratories, Houston, TX, USA), and cleaned with Rneasy columns (Qiagen, Valencia, CA, USA). Five micrograms of total RNA were used for preparing biotin-labeled cRNA. Labeled and fragmented cRNA was subsequently hybridized to Mouse Genome 430 2.0 Array (Affymetrix, Santa Clara, CA, USA). Labeling, hybridization, image scanning, and initial data analysis were performed at the Microarray Core at Los Angeles Biomedical Research Institute. Sample preparation and loading, hybridization, staining, and microarray data analysis were then performed[8].

Quantitative RT-PCR

Total liver RNAs were extracted with Trizol Plus RNA Purification Kit (Invitrogen, Carlsbad, CA,

Table 1 List of primer sequences used in RT-PCR

p300	XM_576312	Forward	5GAGGTCACTGTTCGGGTTGTTC
p300	XM_576312	Reverse	5TGGTTCGATATGGAAAAGATTCTG
BHMT	NM_030850	Forward	5GGGCAGAAGGTCAATGAAGCT
BHMT	NM_030850	Reverse	5ACCAATGCATCCCCTTCGT

USA). Synthesis of cDNAs was performed with 5 μg total RNA, and 50 ng random hexamer primers using SuperScriptIII RNase H-Reverse Transcriptase (Invitrogen). PCR primers were designed using the Primer Express software (Applied Biosystems, Foster City, CA, USA). The primers for rat p300 are shown in Table 1.

Quantitative PCR was achieved using the SYBR Green JumpStartTM (Applied Biosystems). Thermal cycling consisted of an initial step at 50℃ for 2 min, followed by a denaturation step at 95℃ for 10 min, and then 40 cycles at 95℃ for 15 s and 60℃ for 1 min. A single PCR product was confirmed with the heat dissociation protocol at the end of the PCR cycles. Each data point was repeated three times.

Sense and anti-sense: quantitative PCR was achieved using the SYBR Green JumpStart™ Tag ReadyMix (Sigma, St. Louis, MO, USA) on an ABI PRISM 7700 Sequence Detector System (Applied Biosystems). The thermal cycling consisted of an initial step at 50℃ for 2 min, followed by a denaturation step at 95℃ for 10 min, then 40 cycles at 95℃ for 15 s and 60℃ for 1 min. A single PCR product was confirmed with the heat dissociation protocol at the end of the PCR cycles. Quantitative values were obtained from the threshold PCR cycle number (Ct) at which point the increase in signal associated with an exponential growth for the PCR product was detected. The target mRNA abundance in each sample was normalized to its 18S level as $\Delta Ct = Ct_{target\ gene} - Ct_{18S}$. For each target gene, the highest ΔCt was assigned as ΔCt_{max}.

Statistical analysis

Data were obtained from at least three animals in each group. Bars represent mean ± SE. *P* values were determined by one-way ANOVA and Student-Newman Keuls for multiple group comparisons (Sigma-Stat software, San Francisco, CA, USA). $P \leqslant 0.05$ was used to establish significant differences. Correlation of data was done by linear regression analysis using Pearson's period momentum method.

RESULTS

Microarray analysis of liver samples from rats fed ethanol showed that a large number of genes (about 1300) were up-regulated and down-regulated due to chronic ethanol feeding[8]. Microarray analyses of liver samples from rats given PS-341 (Bortezomib, Velcade®) also showed dramatic changes in gene expression (about 2082 genes changed) affecting several functional pathways (Figure 1).

Functional pathways of control *vs* PS-341 comparison

Figure 1 **Kegg functional pathway changes in gene expression induced by proteasome inhibition.** Both ethanol feeding and proteasome inhibition affected almost all pathways.

Figure 2 **Nuclear proteasome chymotrypsin-like activity.** 20S proteasome chymotrypsin-like activity was measured in isolated nuclei from the liver of rats fed ethanol chronically and from the liver of rats given PS-341.

The present study was based on the observation that the inhibition of proteasome, caused by chronic ethanol feeding, participated in the development of liver injury due to ethanol by altering the mechanisms through which normal epigenetic regulation occurs. The consequence of this was a marked change in the gene expression of several functional pathways in liver cells (Figure 1).

Data mining and gene specific pathway clustering showed that, similar to ethanol feeding, several transcriptional factors, such as cell cycle, histone modifying enzymes, and the remethylation pathway, were significantly changed by proteasome inhibition. Proteasome inhibition by PS-341 thus proved to be a powerful tool to investigate the role of proteasome activity in epigenetic mechanisms.

To verify the hypothesis that gene expression changes are regulated by nuclear proteasome activity, where inhibition is caused by chronic ethanol feeding[20], proteasome activity was measured in isolated nuclei

from the liver of rats fed ethanol chronically, and from the liver of rats given PS-341. Figure 2 shows that chronic ethanol feeding caused a significant decrease in proteasome chymotrypsin-like activity in isolated liver nuclei.

To further investigate the role of proteasome activity in regulating epigenetic mechanisms, histone acetylation was analyzed in the liver of rats given PS-341, and compared to histone acetylation in the liver of rats fed ethanol chronically. Figure 3A shows that acetylated histone 3 lysine 9 (AcH3K9) was increased in the liver of rats fed ethanol, and that acetylated histone 3 lysine 27 (AcH3K27) was increased in the liver of rats given PS-341 (Figure 3B).

Increased acetylation was concomitant with an increase in the level of HAT p300, which was linked to significant proteasome inhibition shown in the liver of rats fed ethanol chronically (Figure 3D), and in the liver of rats given PS-341 (Figure 3C). P300 was increased in the ethanol-isolated nuclear extract, which confirmed a previous report[4]. It is now well established that ethanol feeding increases histone acetylation[4,5], which correlates with an increase in the acetyltransferase CBP/p300, and a decrease in Sirt1 activity[3,21]. Under our experimental conditions, Sirt1 gene expression and protein level were up-regulated[22], or showed no significant changes[4]. However, the activity of the enzyme may be decreased due to the low level of NAD+, a Sirt1 cofactor[23].

The increased level of histone acetylation substantiated the increase in p300 activity in the liver of rats fed ethanol. In addition, proteasome inhibition by PS-341 caused a significant increase in histone acetylation, which substantiated our hypothesis that

Figure 3 Role of proteasome inhibition in histone acetylation. A: Proteasome inhibition caused a significant increase in histone acetylation as shown in the liver nuclear extracts of rats fed ethanol and in the liver nuclear extracts of rats given PS-341(B). C: p300 protein level was increased in the nuclear extract from the livers of rats fed ethanol chronically, and in the liver nuclear extracts of rats given PS-341, as shown by real time PCR (D), $P = 0.003$. (mean ± SE, $n = 3$).

ethanol induced-histone acetylation is associated with proteasome inhibition. The level of p300 was increased in the nucleus when ethanol was fed chronically, and may also have accumulated due to proteasome proteolysis slowdown in the nucleus.

Proteasome activity has also been found to be involved in the regulation of remethylation enzyme gene expression, thus affecting DNA and histone methylation when it is inhibited. Microarray data mining showed a down-regulation in gene expression of the remethylation enzymes when the proteasome was inhibited (Figure 4A), especially BHMT, which reconstitutes methionine, the major element in the methylation pathway (Figure 4B). Mat1a, Adm (S-adenosylmethionine decarboxylase), and Ahcy (S-adenosylhomocysteine hydrolase) were also down-regulated by proteasome inhibition (Figure 4A), indicating the role of proteasome activity in the methionine-metabolizing enzymes system. Figure 4C shows that proteasome inhibition significantly decreased the protein level of BHMT in the liver of rats given PS-341, and, to a lower extent, in rats subjected to chronic ethanol feeding. These findings demonstrated the role of the proteasome in regulating gene expression in the remethylation pathway, and the role of proteasome activity in the cellular remethylation pathway. Western blot analysis showed a significant decrease in H3K9 dimethylation in the liver of rats given PS-341. A decrease in H3K9 dimethylation (Figure 4D) was also observed in ethanol-treated cells[24], suggesting similar effects of proteasome inhibition and ethanol feeding. These results showed for the first time the role of proteasome activity in regulating the mechanisms of cellular remethylation, and is a promising approach in chemotherapy regimens which use proteasome inhibitor as an anti tumor drug.

DISCUSSION

Several studies have shown that the inhibition of the ubiquitin-proteasome pathway is a pathobiological mechanism associated with the development of liver disease, especially alcoholic liver disease[25,26]. We believe that ethanol-induced inhibition of proteasome activity may play a significant role in the deregulation of epigenetic mechanisms and the mechanism related to liver injury in alcoholic liver disease (ALD).

Many cellular signaling pathways are controlled by selective proteolysis of key regulatory proteins via the ubiquitin-proteasome system[4,12,27]. Proteasome is involved in RNA polymerase Ⅱ degradation[28], which is a key step in controlling the transcriptional mechanism, preventing uncontrolled transcription that may occur when ethanol metabolism generates oxidative stress, which causes DNA damage[29]. Reports have shown that proteasome dysfunction leads to apoptotic death of hepatocytes and sensitization to tumor necrosis factor (TNF) cytotoxicity, leading to direct hepatic injury[25]. Although it is now evident that inhibition of cytoplasmic proteasome function is consistently shown in ALD models, the way in which proteasome dysfunction may enhance hepatotoxicity is not well defined. In addition, the effects of ethanol feeding on the activity of nuclear proteasome and the consequences of proteasome inhibition on changes in epigenetic mechanisms have not yet been demonstrated. Most importantly, our previous investigations have repeatedly shown that chronic ethanol feeding causes significant proteasome inhibition in the cell[30,31]. The ubiquitin-proteasome pathway is the cellular proteolytic pathway dedicated to controlling protein stability, and understanding the link between the ubiquitin-proteasome pathway and the histone-

Figure 4 Role of proteasome inhibition in the remethylation pathway. A: Proteasome inhibition by PS-341 (PS) markedly decreased BHMT gene expression; B: Real time PCR analysis of BHMT expression; C: Western blot analysis of BHMT level in the liver of rats fed ethanol chronically and the liver of rats given PS-341. Note that the BHMT level was significantly reduced in the liver of rats treated with PS-341; D: Proteasome inhibition caused a decrease in histone methylation.

modifying machinery will define the link between proteasome proteolytic activity, epigenetic mechanisms, and the effect of toxic substances, such as ethanol and its metabolism generated end products, in the regulation and control of epigenetic mechanisms.

As predicted, our results showed an increase in acetylation of H3K9 in the liver nuclear extracts of rats fed ethanol chronically. This increase was associated with an increase in HAT p300, which confirmed a previous report[4]. In addition, p300 activation and histone acetylation were also obtained when proteasome activity was inhibited using PS-341, which supported the role of proteasome activity in regulating the stability of p300 in the nucleus and therefore supported the role of proteasome in regulating the acetylation mechanisms and thus gene expression. These results corroborate the findings of Marcu et al[32], which showed that p300 is a proteasome substrate, and that p300 is accumulated when the proteasome is inhibited.

The modification of histones mirrors the sophisticated protein machinery that controls gene expression and regulates transcription. Therefore, it would be naïve to suggest that, for instance, only H3K9 acetylation explained all the changes in the observed gene expression[11]. The balance between all histone lysine residue modifications accounted for the pattern of gene expression and further histone modifications are certainly involved in defining specific gene expression.

Histone methylation also plays a critical role in regulating gene expression and transcription. The cellular remethylation pathway is the major player in the methylation mechanism, because it produces the methyl donor SAMe. It is well known that chronic ethanol ingestion causes a serious deregulation of this pathway. Methionine adenosyltransferase 1-alpha, which

is responsible for the conversion of methionine to SAMe, is decreased in the liver of rats fed ethanol[33]. Since SAMe is thus decreased, the level of DNA and protein methylation is decreased[34], and the level of homocysteine is increased[35]. The ratio SAMe/SAH (S-adenosylhomocysteine) is critical in the cell because it controls most of the methyltransferase activity. BHMT, which hydrolyzes betaine, helps remove SAH and homocysteine with subsequent regeneration of the methyl group and a reduction in the level of SAH. Our results show that BHMT was significantly down-regulated when the proteasome activity was inhibited, either by chronic ethanol feeding or by treatment with a proteasome inhibitor. In addition, there was a decrease in histone methylation, reflecting the role of proteasome activity in regulating the methylation mechanisms in the liver cell. Proteasome inhibition plays a critical role in regulating the gene expression of key enzymes in the remethylation pathway, such as BHMT.

COMMENTS

Background
Alcohol ingestion causes alterations in several cellular mechanisms, and leads to inflammation, apoptosis, and fibrosis. These phenomena are associated with significant changes in epigenetic mechanisms and with a subsequent liver cell memory. The ubiquitin-proteasome pathway is a vital cellular pathway which undergoes dysfunction due to chronic ethanol consumption.

Research frontiers
Although inhibition of proteasome function has been widely reported in models of alcoholic liver disease (ALD), why proteasome dysfunction may enhance hepatotoxicity is not well defined. In addition, there is no evidence of the effect of ethanol feeding on the activity of nuclear proteasome and the consequences of proteasome inhibition in epigenetic mechanisms and DNA repair.

Innovations and breakthroughs
The present study focused on the role of proteasome activity in gene expression and the effects of proteasome inhibition in changing epigenetic mechanisms.

The model used to study the consequences of proteasome inhibition due to chronic intragastric tube ethanol administration was proteasome inhibition by PS-341, a dipeptide boronic acid currently used in clinical trials as an anti tumor drug, and is associated with profound side effects. Inhibition of proteasome activity occurred in the nucleus of liver cells taken from rats fed ethanol chronically and from rats given PS-341. This inhibition caused changes in the turnover of transcriptional factors, histone modifying enzymes, and, therefore, affected epigenetic mechanisms. Histone acetylation was increased following both treatments and gene expression was changed. Identification of DNA and histone modifications was critical in regulating gene expression, especially genes involved in the cell cycle and apoptosis, and those involved in the metabolism of ethanol. In addition, proteasome inhibition has been shown to significantly affect the hepatic remethylation pathway. In particular, proteasome inhibition caused a decrease in gene expression of the enzyme betaine-homocysteine methyltransferase (BHMT), which is involved in the recovery of s-adenosylmethionine (SAMe). Histone methylation was also decreased when the proteasome was inhibited suggesting that hypomethylation was associated with the decrease in proteasome activity.

Applications
The phenomenon of hypomethylation is currently corrected by diet supplementation with a methyl donor (betaine) to redirect methionine/homocysteine metabolism toward recovery of methionine, and SAMe regeneration.

Terminology
Chronic ethanol feeding causes proteasome inhibition, which leads to cellular dysfunction including the accumulation of damaged proteins which form Mallory bodies in the liver of severe alcoholic patients, immune response deficiency, cell cycle deregulation and incorrect gene expression. The mechanism of incorrect gene expression was the focus of this study, particularly the consequences of ethanol induced-proteasome inhibition in the nucleus and the role played by proteasome in regulating epigenetic mechanisms.

Peer review
The impact of this study is great because when epigenetic mechanisms associated with proteasome inhibition are fully identified, a therapeutic approach will be initiated to counteract the ethanol induced-epigenetic changes, and prevent any cellular memory for future cell generations.

Abstract

AIM: To investigate the efficacy and toxicity of systemic chemotherapy in a retrospective study of patients with hepatocellular carcinoma (HCC) occurring in normal or fibrotic liver without cirrhosis.

METHODS: Twenty-four patients with metastatic or locally advanced HCC in a normal or a fibrotic liver were given systemic chemotherapy (epirubicin, cisplatin and 5-fluorouracil or epirubicin, cisplatin and capecitabine regimens). Tumor response, time to progression, survival, and toxicity were evaluated.

RESULTS: There were 7 women and 17 men, mean age 54 ± 10 years; 18 patients had a normal liver and 6 had a fibrotic liver (F1/F2 on biopsy). Mean tumor size was 14 cm, 5 patients had portal vein thrombosis and 7 had metastasis. Patients received a median of 4 chemotherapy sessions. Overall tolerance was good. There were 5 partial responses (objective response rate = 22%), and tumor control rate was 52%. Second line surgical resection was possible in two patients. Median survival was 11 mo, and 1- and 2-year overall survival rates were 50% ± 10% and 32% ± 11%, respectively.

CONCLUSION: In patients with HCC in a non-cirrhotic

liver, chemotherapy was well tolerated and associated with an objective response rate of 22%, including two patients who underwent secondary surgical resection.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most frequent primary liver cancer, the fifth most common malignancy worldwide, and the third most common cause of cancer deaths[1]. Unfortunately, most patients are seen when the disease has reached a stage beyond curative treatment (surgery or percutaneous ablation), leaving palliative care as the only alternative. Based on the Barcelona-Clinic Liver Cancer (BCLC) staging classification[1] and treatment schedule, chemoembolization is the best option for intermediate stage patients, while for advanced stage patients, no standard treatment was established until 2007. Fortunately, after the positive results of the SHARP trial[2], a new treatment, sorafenib, was approved for advanced stage patients because of major improvements in overall survival and time to progression in comparison with placebo. In contrast to studies of most other malignancies, the efficacy of systemic chemotherapy has never been demonstrated in HCC. Despite the lack of demonstrated efficacy, doxorubicin is accepted by some physicians as a possible treatment for advanced HCC. In some recent trials using doxorubicin as a control arm, the investigational arms, a combination of platinum, doxorubicin, 5-fluorouracil and interferon in one trial[3] or nolatrexed[4], a novel thymidylate synthase inhibitor

in another trial, did not demonstrate any advantage or were associated with worse overall survival than doxorubicin alone. In one trial, this could have been partly due to toxicity, particularly because of hepatitis B virus reactivation[5]. Most likely, systemic chemotherapy lacks efficacy because of the frequently observed multidrug tumor resistance[6-8] (P-glycoprotein overexpression, p53 gene mutations), although greater drug toxicity related to the underlying cirrhosis might certainly have had an effect. In a search for clues to resolve this question, we retrospectively analyzed our records of cirrhosis-free HCC patients who received a standard chemotherapy regimen {ECF [epirubicin, cisplatin (CDDP) and 5-fluorouracil (5FU)][9] or ECC (epirubicin, CDDP and capecitabine)[10]}. Our goal was to determine whether chemotherapy was more effective in these patients than in HCC patients with cirrhosis.

MATERIALS AND METHODS

Between July 1999 and June 2006, we delivered standard chemotherapy regimens to 30 patients with HCC occurring in a non-cirrhotic liver. There was no indication for curative surgery or palliative treatment in these patients who had good performance status (ECOG PS 0 or 1), preserved liver function, normal blood cell counts (neutrophils > 15 000/mm^3, platelets > 100 × 10^9/L), normal renal function (serum creatinine < 110 μmol/L), and a measurable tumor target. Biopsy specimens, from the tumor and unaffected liver tissue, provided the diagnosis of HCC in non-cirrhotic liver in all 30 patients. None had a fibrolamellar cancer. The diagnosis of a normal liver was, however, less than certain in one patient since tumor cells had invaded most of the "normal liver" biopsy specimen. Five of the 30 patients had received a chemotherapy regimen other than ECF or ECC: capecitabine plus oxaliplatin ($n = 3$), and gemcitabine plus oxaliplatin ($n = 2$). Excluding these 6 patients, we thus retrospectively analyzed the records of 24 patients who received an ECF or ECC regimen for HCC occurring in a non-cirrhotic liver (normal liver or F1-F2 fibrosis); the ECF regimen was given from 1999 to 2002 and then we used the ECC regimen, which was much more convenient because it could be given orally.

The ECF treatment schedule was: epirubicin 60 mg/m^2 on day 1, CDDP 50 mg/m^2 on day 1, and 5FU 200 mg/m^2 administered in a continuous infusion from day 1 to day 21; in the ECC regimen, 5FU was replaced by capecitabine 1000 mg/m^2 twice a day from day 1 to day 14 followed by a 7-d off period. Courses were repeated every 21 d.

Tumor response was assessed with computed tomography performed before treatment onset and then every 9 wk (three chemotherapy courses). The tumor response (World Health Organization criteria) was considered as complete in the case of total disappearance of all tumors with normalization of α-fetoprotein (AFP) level, as partial for a decrease of tumor size less than 50%, and as stable disease with absence of progression and a decrease in tumor size less than 50%. Progression was an increase in tumor size greater than 25%. An objective

response was defined by achievement of a complete or partial response. Patient tolerance was assessed using NCI-CTC AE version 2.0. In some patients with an excellent general status, second line therapy was proposed in the event of disease progression. Patient survival could be precisely evaluated for all patients and was calculated using the Kaplan-Meier method. The cause of death was recorded when available.

RESULTS

The ECF protocol was given to 10 patients, and the ECC protocol to 14. There was no difference in disease status between these two groups. The population was composed of 17 men and 7 women, mean age 54.3 ± 10.7 years (range: 23-77 years). The liver tumors were revealed in all patients by tumor-related complications (pain, fever, constitutional syndrome). The tumor developed in a non-cirrhotic liver in 18 patients and in a fibrotic liver in 6 (classified as F1 or F2). The etiological investigation revealed that 6 patients drank more than 4 units of alcohol per day, one had serological markers of hepatitis C, 2 had steatosis and were overweight, and one had genetic hemochromatosis treated by phlebotomy and was without iron liver overload on liver biopsy; no contributory factor was recognized in 14 patients. Among the 6 patients with minor fibrosis, 3 were drinkers, one had hepatitis C virus infection, one had genetic hemochromatosis and one had steatosis.

There was a unique tumor in 14 patients, 2-4 lesions in 6 and multiple or diffuse tumors in 4. Mean tumor size was huge: 14 ± 7 cm (range: 6-29 cm). Portal vein thrombosis was found in 5 patients and metastases in 7 (bones, lungs, lymph nodes). In the BCLC staging, all these patients could be classified as having an "advanced HCC", and in cases of unique tumor, tumor size was > 75% of the liver volume and surgery or transarterial chemoembolization could not be considered. Following Child-Pugh classification, and despite the absence of cirrhosis, all these patients were considered as Child class A and, using the CLIP system, 8 patients had 4 points, 10 had 3 points, 5 had 2 points and only one had 1 point (but this patient was metastatic).

None of these patients had previously received treatment for HCC. The patients received from one to 12 courses of the ECF/ECC regimen (median = 4). As the best response, 5 patients had a partial response (objective response rate 22%; 95% CI: 6-38%), 8 patients had stable disease (30%) and 11 had tumor progression; the disease control rate was then 52%. The median time to progression was 6 mo. At the cut-off date of March 15, 2007, 18 patients had died due to progression of their tumor and 6 patients were still alive; median survival time was 11 mo (range 3-90 mo). Actuarial overall survival rates (mean ± SD) at 6 mo, 1 year and 2 years were 71% ± 9%, 50% ± 10% and 32% ± 11%, respectively (Figure 1). The 5 patients with an objective response achieved prolonged survival: 3 died 13, 27 and 48 mo after treatment onset and 2 were still alive at the cut-off date. Surgical resection was undertaken in one

Figure 1 Overall survival in the population of 24 HCC patients with non-cirrhotic liver treated by an ECC/ECF regimen.

Table 1 Adverse effects in this series of 24 patients with HCC in non-cirrhotic liver treated by chemotherapy (ECC regimen)

Adverse effets	Grade 1-2	Grade 3-4 (%)
Alopecia	8	-
Neutropenia	4	4 (17)
Mucositis	4	0
Diarrhea	2	0
Renal failure	1	0
Asthenia	2	0
Hand-foot syndrome	5	0
Nausea, vomiting	12	2 (4)
Anemia	2	0
Coronary spasm	0	1
Percentages not given in this column		

One patient died suddenly during the first course of chemotherapy.

patient 10 mo after treatment onset as a result of an objective response. This patient was alive at 90 mo with progression (the same chemotherapy was successfully resumed; she was subsequently treated with sorafenib). The other prolonged survivor had a 22-cm tumor; she underwent surgical resection when a minor response was observed after 9 courses of ECC. She was still alive and disease-free 36 mo after surgery. Initially, these 2 patients had a unique tumor involving more than 75% of the liver without portal vein thrombosis or extrahepatic metastases; both had an AFP level above 500 ng/mL; they were considered as CLIP 3.

Toxicity was graded using NCI-CTC criteria version 2.0. The main toxic effects are summarized in Table 1. Overall tolerance was good. Signs of grade 3-4 toxicity developed in 7 patients (29%), neutropenia in 4 (no cases of febrile neutropenia), gastrointestinal disorders (nausea, vomiting) in 2; one patient died suddenly after the first cycle and one presented with mild thoracic pain assumed to be related to 5FU. Among the other patients, 8 developed alopecia and renal function worsened in one, leading to discontinuation of the treatment.

DISCUSSION

Despite the lack of proof of efficacy, doxorubicin is commonly used as a first line therapy for HCC. Recent randomized studies with doxorubicin[3,4] have confirmed the minimal efficacy of this drug in HCC. Results obtained in phase II studies with different regimens using new cytotoxic drugs have not been very impressive. Thus, systemic chemotherapy cannot be considered as the standard of care for HCC patients. This situation could be related to a combination of poor efficacy and increased toxicity. Poor efficacy might result from intrinsic resistance caused by overexpression of multidrug resistance genes observed in most tumors. Obviously the underlying liver cirrhosis increases the risk of severe adverse events as many chemotherapeutic drugs are metabolized or eliminated via the liver. Moreover severe complications are certainly more likely if a cytotoxicity-related side effect occurs on a cirrhotic liver. Certain causes of the underlying cirrhosis, e.g.

hepatitis B virus infection[5], may be reactivated after chemotherapy-induced immunodepression, producing an additive toxic effect.

In this particular retrospective series of HCC developed in normal or fibrotic livers, we attempted to estimate the raw efficacy and toxicity of systemic chemotherapy, regardless of liver status. The objective response rate in these patients given the ECF/ECC regimen was 22%, with a disease control rate (objective response plus stable disease) of 52%. The median time to progression was 6 mo, that is to say, quite similar to that observed using sorafenib[2], In addition, despite the fact that most tumors were huge, the reduction in tumor size was sufficient to allow surgical resection in 2 patients having only one huge tumor. Toxicity was mild and most side effects were manageable; one patient died suddenly between two courses. These two regimens (ECF and ECC) are very similar: capecitabine is the oral form of 5FU and, in a randomized 2 × 2 study conducted in advanced esophagogastric cancers[11], these two regimens were demonstrated to be effective. Such results with objective response rates approaching 20% have been reported in some other phase II studies[12-14], including patients with or without cirrhosis: a similar ECC regimen gave, in a Korean series of 29 patients, an objective response rate of 24%[15]. Similar findings have been reported with the PIAF regimen (combination of CDDP, doxorubicin, 5FU and interferon)[16], where, in a series of 50 patients, 26% had a partial response including 9 who underwent surgical resection, and in 4, there were no viable cancer cells on resected specimens. Unfortunately, this did not translate into any difference in overall survival versus doxorubicin alone in a randomized phase III trial despite the fact that less than half of the patients had underlying cirrhosis (but 17% of the patients had Child B class cirrhosis). The response rate of 22% we have observed in this series is a little bit higher than that observed in a retrospective series of 21 patients we have previously published[17] (16 having underlying cirrhosis). Comparing the results of these two series, we suggest that efficacy was better in the non-cirrhotic group. In our first series of 21 HCC patients we observed 3 responders (objective response rate of 14.5%)

including one non-cirrhotic patient (among cirrhotic patients, 2/16 were responders); median survival was 10 mo and surgery was possible in one patient. Toxicity appeared to be more frequent in the whole population, as we described 18 cases of grade 3-4 toxicities versus 7 cases in the current 24 non-cirrhotic patients. This might suggest that an ECF/ECC chemotherapy regimen (particularly the ECC regimen which is more convenient, especially in cirrhotic patients) could be delivered to non-cirrhotic patients with a hope of the possibility of secondary resection.

As a result of the recent SHARP trial, which demonstrated the efficacy of sorafenib in advanced-stage HCC, sorafenib is now the new standard of care in that setting. Combinations of sorafenib plus doxorubicin[18] seemed to be well tolerated and have yielded promising results in a randomized phase Ⅱ trial. A combination of sorafenib with the ECC regimen deserves a phase Ⅱ trial particularly in patients with HCC in a non-cirrhotic liver.

COMMENTS

Background
Systemic chemotherapy is not usually considered as a standard treatment in hepatocellular carcinoma (HCC) developed in cirrhotic patients.

Research frontiers
New targeted agents, like sorafenib, are efficient in advanced HCC and could be associated with systemic chemotherapy.

Innovations and breakthroughs
When systemic chemotherapy is given to patients who develop HCC without liver cirrhosis, the tolerance and efficacy are better and can allow curative surgery in some cases.

Applications
In selected cases of HCC without liver cirrhosis, systemic chemotherapy can be safely given with promising results.

Peer review
The peer reviewer emphasized the differences between these two regimens; one (ECF) requires a continuous infusion of chemotherapeutic drug (5FU) while the other is given orally and is easier to use.

Abstract

AIM: To assess the value of widely used clinical scores in the early identification of acute pancreatitis (AP) patients who are likely to suffer from intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS).

METHODS: Patients (n = 44) with AP recruited in this study were divided into two groups (ACS and non-ACS) according to intra-abdominal pressure (IAP) determined by indirect measurement using the transvesical route *via* Foley bladder catheter. On admission and at regular intervals, the severity of the AP and presence of organ dysfunction were assessed utilizing different multifactorial prognostic systems: Glasgow-Imrie score, Acute Physiology and Chronic Health Evaluation Ⅱ (APACHE-Ⅱ) score, and Multiorgan Dysfunction Score (MODS). The diagnostic performance of scores predicting ACS development, cut-off values and specificity and sensitivity were established using receiver operating characteristic (ROC) curve analysis.

RESULTS: The incidence of ACS in our study population was 19.35%. IAP at admission in the ACS group was 22.0 (18.5-25.0) mmHg and 9.25 (3.0-12.4) mmHg in the non-ACS group (P < 0.01). Univariate statistical analysis revealed that patients in the ACS group had significantly higher multifactorial clinical scores (APACHE Ⅱ, Glasgow-Imrie and MODS) on admission and higher maximal scores during hospitalization (P < 0.01). ROC curve analysis revealed that APACHE Ⅱ, Glasgow-Imrie, and MODS are valuable tools for early prediction of ACS with high sensitivity and specificity, and that cut-off values are similar to those used for stratification of patients with severe acute pancreatitis (SAP).

CONCLUSION: IAH and ACS are rare findings in patients with mild AP. Based on the results of our study we recommend measuring the IAP in cases when patients present with SAP (APACHE Ⅱ > 7; MODS > 2 or Glasgow-Imrie score > 3).

INTRODUCTION

Acute pancreatitis (AP) remains a disease with an unpredictable clinical course, and significant associated morbidity and mortality[1]. Recently, the elevated intra-abdominal pressure (IAP) following the onset of AP has attracted growing attention, because it is increasingly recognized as an important risk factor for mortality in the early phase of the disease[2-4]. It was shown that intra-abdominal hypertension (IAH) is associated with higher mortality and morbidity rates, and prolonged ICU stay, in comparison to other patients who had normal IAP[5-8]. IAH has been recognized as a cause of organ dysfunction in critically ill patients, including those suffering from severe acute pancreatitis (SAP)[9-12]. Abdominal compartment syndrome (ACS) is defined as an increase of IAP > 20 mmHg, which is associated with occurrence of a new organ failure. A previously

reported incidence of ACS among patients with SAP ranges from 23% to 56%[11,13-15]. The mechanisms involved in the development of IAH and ACS include increased capillary permeability, hypoalbuminemia and volume overload, which produce a large retroperitoneal and visceral edema[6,16].

It has been shown that early recognition and treatment of IAH and ACS result in a significant improvement in patient survival and decreased morbidity. Due to its simplicity and minimal cost, the standard for intermittent IAP measurement is *via* the urinary bladder with a maximal instillation volume of 25 mL sterile saline[17]. Compared with bladder pressure measurements, clinical abdominal assessment showed poor sensitivity (56%) and accuracy (77%) for identifying elevated IAP[18]. It was shown that the essential approach to diagnosis and management of ACS is a timely IAP measurement. It is still not clear whether early IAP measurement should be routine for all AP patients and which patients would benefit most from the IAP monitoring.

This study aimed to assess the value of Acute Physiology and Chronic Health Evaluation Ⅱ (APACHE Ⅱ), Multiorgan Dysfunction Score (MODS) and Glasgow-Imrie clinical scores in early recognition of patients who are likely to suffer from IAH and ACS, and who would benefit from IAP monitoring and management. We also investigated the incidence of ACS, the role of its interventional management and clinical outcomes in patients with AP.

MATERIALS AND METHODS

Ethics
This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. The Regional Ethics Committee approved the study (protocols no. BE-2-47 and P1-113/2005) and all patients provided written informed consent.

Study design and patient population
The study population included 44 patients with AP admitted to the Department of Surgery, Kaunas University of Medicine Hospital, from May 2007 to February 2008. General inclusion criteria were defined as follows: (1) a time interval between onset of typical abdominal symptoms and study inclusion of 72 h and less; (2) at least 3-fold elevated serum amylase or lipase levels; (3) no previous history of acute or chronic pancreatitis. On the first day of admission, the severity of the AP and presence of organ dysfunction were assessed utilizing three different multifactorial prognostic systems: Glasgow-Imrie score, APACHE-Ⅱ score, and MODS. Later, the severity of disease and clinical status were repeatedly reassessed using the same prognostic tools every 7 d, and when the deterioration of clinical condition occurred and after interventional treatment of ACS. The contrast-enhanced CT scan was performed on day 4 to 7 after the onset of disease to demonstrate the presence of pancreatic necrosis. According to the clinical course and clinical severity scores (APACHE Ⅱ > 7;

Glasgow-Imrie > 2; MODS > 2; peak C-reactive protein value > 150 mg/L) patients were stratified into mild and severe AP groups. The data were prospectively recorded in a specially created database. All patients were treated according to our standard AP management protocol following the recent international guidelines.

Measurement of IAP and clinical assessment of patients
For IAP measurement, we used a standard two-way 16 Fr. Foley catheter inserted into the urinary bladder. The patient was placed in supine position. Twenty-five milliliters of 0.9% sterile NaCl were instilled and the catheter was connected to a tube from the urine collection bag. The pubic symphysis was considered level 0 and IAP was measured in cm H_2O, then recalculated in mmHg. IAP was measured every 24 h during a period of 3 d in all patients. For patients that developed IAH (IAP > 12 mmHg), the conservative treatment (according to the recommendations of international experts on IAH and ACS) was initiated and IAP was monitored every 12 h until the normal IAP was reached and sustained at least for 24 h. In cases when IAH > 18 mmHg was recorded, IAP was monitored every 4-6 h until IAP normalized or ACS developed. ACS was defined as an increase of IAP > 20 mmHg, which is associated with occurrence of a new organ failure[16,17].

Statistical analysis
Statistical analysis was performed using SPSS® for Windows release 16.0 (SPSS, Chicago, IL, USA). The quantitative variables are presented as mean ± SD or median (with interquartile range). For comparison between groups, the Mann-Whitney test, Student's *t* test or χ^2 test was employed where appropriate. The diagnostic performance of scores predicting ACS development, cut-off values and specificity and sensitivity of prognostic tools were established using receiver operating characteristic (ROC) curve analysis. Results with $P < 0.05$ were considered statistically significant.

RESULTS

A total of 44 patients with AP were included in the study. Demographic and clinical data of these patients are represented in Table 1.

All patients were divided into ACS and non-ACS groups. Median IAP in the ACS group at admission was 22.0 (18.5-25.0) mmHg and 9.25 (3.0-12.4) mmHg in the non-ACS group ($P < 0.01$) (Figure 1).

Differences of APACHE Ⅱ, Glasgow-Imrie and MODS median scores on admission and maximal scores (Max) during hospitalization period between ACS and non-ACS groups are presented in Table 2. The study revealed that patients in the ACS group had significantly higher multifactorial clinical scores on admission and higher maximal scores during hospitalization ($P < 0.01$). There were no significant differences between median admission and maximal scores of APACHE Ⅱ, Glasgow-Imrie and MODS within ACS or non-ACS groups ($P > 0.05$). The ACS group was characterized by

Table 1 Demographic and clinical variables of the whole series

Demographic and clinical variables	Values
Number of patents	44
Age (years ± SD)	49 ± 18
Gender male	70.4% (31/44)
SAP	70.4% (31/44)
Presence of necrosis	49.9% (18/44)
Extent (percentage) of necrosis	
< 30%	38.9% (7/18)
30%-50%	11.1% (2/18)
> 50%	50.0% (9/18)
IAH (IAP ≥ 12 mmHg)	43.2% (19/44)
ACS (IAP ≥ 20 mmHg + MOF)	13.6% (6/44)
Mortality	13.6% (6/44)
APACHE II score at admission[1]	6.5 (4.0-10.0)
Max APACHE II score during hospitalization[1]	8.0 (5.0-11.0)
Glasgow-Imrie score at admission[1]	3.0 (2.0-3.0)
Max Glasgow-Imrie score during hospitalization[1]	3.0 (2.0-4.0)
MODS score at admission[1]	2.0 (1.0-3.0)
Max MODS score during hospitalization[1]	2.0 (1.0-4.0)

[1]Values of clinical multifactorial scores is expressed as median (lower & upper quartiles).

Figure 1 The 1st IAP and maximal IAP value in ACS and non-ACS groups. All patients were divided in ACS (grey colour) and non-ACS (white colour) groups. Median IAP at admission was 22.0 and 9.25 mmHg in ACS and non-ACS groups respectively ($P < 0.01$). There was no significant difference between value of the 1st measurement and maximum observed value of IAP within each group.

a markedly higher incidence of severe and necrotizing AP, and by the presence of high volume pancreatic necrosis in comparison to the non-ACS group. Mortality rate in the ACS group was also significantly higher, when compared to the non-ACS group (Table 3).

SAP was diagnosed in 70.4% (31/44) of all cases in this study group. We believe such a relatively high incidence of SAP is associated with the concentration of patients with severe disease in our tertiary care center referred from other regional hospitals, and a special focus on the patients with systemic inflammatory response syndrome and multiorgan failure (MOF). Nevertheless, the incidence of ACS in our study population was 19.35% (6/31) and did not exceed the prevalence of IAH and ACS shown in other clinical studies. Interestingly, the prevalence of IAH was significantly lower in the mild AP group, with only 7.69% (1/13) when compared to 58.06% (18/31) in the SAP group ($P > 0.01$). Specifically, all cases of ACS occurred in the SAP group with an incidence of 19.35% (6/31), while there were no cases of ACS in the

Table 2 Clinical scores (on admission and max value) in relation to presence of ACS

Clinical scores	ACS group median (lower & upper quartiles)	Non-ACS group median (lower & upper quartiles)	P
APACHE II score on admission	12.0 (9.0-1.0]	6.0 (4.0-9.0)	< 0.01
Max APACHE score	14.0 (11.0-18.0)	7.0 (4.0-10.0)	< 0.01
Glasgow-Imrie score on admission	5.0 (4.0-5.0)	2.0 (2.0-3.0)	< 0.01
Max Glasgow-Imrie score	5.0 (4.0-5.0)	2.5 (1.0-3.0)	< 0.01
MODS score on admission	4.5 (3.0-8.0)	1.5 (1.0-3.0)	< 0.01
Max MODS score	4.5 (3.0-8.0)	2.0 (1.0-3.0)	< 0.01

Table 3 Clinical characteristics of patients with and without ACS

Clinical characteristics	ACS group (n = 6, %)	Non-ACS group (n = 38, %)	P
Severe AP	6 (100)	25 (65.8)	NS
Necrotizing AP	5 (83.3)	13 (34.2)	< 0.05
Necrosis > 30%	5 (83.3)	6 (15.8)	< 0.05
Deaths	4 (66.6)	2 (5.2)	< 0.01

Table 4 Areas under the ROC curves for prognostic factors of ACS

Variables	Area	Std. error	Asymptotic sig.	Confidence Interval	
				lower	upper
1st IAP on admission	0.932	0.065	0.001	0.805	1.059
Glasgow-Imrie score	0.921	0.054	0.001	0.816	1.026
APACHE II score	0.866	0.062	0.004	0.745	0.987
MODS score	0.829	0.098	0.010	0.636	1.022

Table 5 Cut-off points, sensitivity and specificity for prognostic factors of ACS

Variable	Cut-off	Sensitivity (%)	Specificity (%)
APACHE II score	> 7	100.0 (54.1-100.0)	60.5 (43.4-75.9)
Glasgow-Imrie score	> 3	83.3 (36.1-97.2)	86.8 (71.9-95.5)
MODS score	> 2	83.3 (36.1-97.2)	73.7 (56.9- 86.6)
1st IAP on admission	> 18	83.3 (36.1-97.2)	100.0 (90.7-100.0)

mild AP group (0/13).

The diagnostic performance of multifactorial clinical scores and the first IAP measurement in predicting development of ACS during the course of AP were assessed using ROC curve analysis. ROC analysis revealed that all the analysed clinical scores are of good prognostic value in determining patients who are likely to further develop ACS (Figure 2). The areas under the ROC curves, cut-off values, specificity and sensitivity of prognostic tools are presented in Tables 4 and 5.

DISCUSSION

Our study confirmed the earlier published observations that AP is a risk factor for development of IAH and ACS[13,14,19,20]. Overall, somewhat higher rates of SAP in our institution could be explained by the concentration

Figure 2 ROC curve analysis of prognostic factors for ACS development. ROC analysis revealed that clinical scores (APACHE Ⅱ, Glasgow-Imrie and MODS) and first IAP measurement on admission are good prognostic markers in determining patients who are likely to develop ACS. There was no significant difference between the areas under the ROC curves for these prognostic markers.

of the patients, because our hospital is a tertiary care center and many patients with suspected severe disease are referred to it from regional hospitals. However, the incidence of IAH and ACS in our study was similar to that observed in other studies, and as expected, it was associated with a higher incidence of MOF and higher mortality rates.

An early diagnosis of ACS and its adequate management is crucial[1,8,15,17]. The measurement and monitoring of IAP *via* urinary bladder catheter is a simple procedure, which requires virtually no technical skills and little resources. However, this procedure is invasive and is associated with significant discomfort for the patient[21,22]. It has also been shown that indwelling urinary catheters are associated with a higher incidence of infectious complications and prevalence of nosocomial pathogens[23-25]. Clearly, placement of a urinary catheter should not be routinely recommended for all patients, especially not for those who are unlikely to develop ACS. Therefore clinical assessment in selecting the patients that are likely to develop ACS is of particular importance. Our study demonstrated that development of IAH and ACS during the AP could be predicted by the use of clinical multifactorial scoring systems (APACHE Ⅱ, MODS, Glasgow-Imrie score), thus allowing a timely and appropriate selection of patients for this invasive procedure during the first hours and days of the disease. Clinical scores of patients who eventually suffered from IAH were higher during the first days in comparison to the group of patients with normal IAP. These findings are in accord with the observations of other groups[2,4,20,26]. The ROC analysis disclosed that APACHE Ⅱ, MODS, and Glasgow-Imrie scores have similar cut-off values to those used for the prediction of SAP. IAP > 18 mmHg on admission is also a valuable indicator that the patient has a higher risk for persistent IAH and development of ACS during the course of AP. All these prognostic markers had a good sensitivity, specificity and large area under

the curve. Furthermore, the use of a clinical scoring system in combination with the first IAP measurement (eg. APACHE Ⅱ + first IAP on admission) allows us to identify nearly 100% of patients who are likely to develop SAP and suffer from ACS.

Previously published studies do not provide us with any useful recommendations or criteria for the selection of the AP patients for the IAP measurement and monitoring, although it would be unnecessary in the majority of cases when patients have a mild and self-limiting disease.

Based on the results of our study we recommend measuring the IAP only in cases when patients present with SAP (i.e. APACHE Ⅱ > 7; MODS > 2 or Glasgow-Imrie score > 3). We advocate a continuous monitoring of IAP in all cases when the patient suffers from SAP and has an IAP > 18 mmHg on first measurement. We would recommend utilizing the simpler Glasgow-Imrie or MODS scores in daily clinical practice and a more complex APACHE Ⅱ score in the clinical trial setting.

CONCLUSION

Placement of a urinary catheter for the monitoring of IAP would be unnecessary in the majority of AP cases, when patients have a mild and self-limiting disease.

We recommend measuring the IAP only in cases when patients present with SAP (i.e. APACHE Ⅱ > 7; MODS > 2 or Glasgow-Imrie score > 3). We advocate a continuous monitoring of IAP in all cases when the patient suffers from SAP and has an IAP > 18 mmHg on first measurement.

COMMENTS

Background
Acute pancreatitis (AP) remains a disease with an unpredictable clinical course, and significant associated morbidity and mortality. Recently, the elevated intra-abdominal pressure (IAP) after onset of AP has gained growing attention, because it is increasingly recognized as an important risk factor for mortality in the early phase of the disease. Intra-abdominal hypertension (IAH) has been recognized as a cause of organ dysfunction in critically ill patients, including those suffering from severe acute pancreatitis (SAP).

Research frontiers
It has been shown that early recognition and treatment of IAH and abdominal compartment syndrome (ACS) result in a significant improvement in patient survival and decreased morbidity, however, clinical abdominal assessment showed poor sensitivity and accuracy for identifying the elevated IAP. The essential approach to the diagnosis and management of ACS is a timely IAP measurement. It is still not clear whether early IAP measurement should be a routine for all AP patients and which patients would benefit most from the IAP monitoring.

Innovations and breakthroughs
An early diagnosis of ACS and its adequate management is crucial. The measurement and monitoring of IAP *via* urinary bladder catheter is a simple procedure, which requires virtually no technical skills and little resources. However, this procedure is invasive and is associated with significant discomfort for the patient. It has also been shown that indwelling urinary catheters are associated with a higher incidence of infectious complications and prevalence of nosocomial pathogens. Clearly, placement of a urinary catheter should not be routinely recommended for all patients, especially not for those who are unlikely to develop ACS. For the first time, our study demonstrated that development of IAH and ACS during the AP could be predicted by the use of clinical multifactorial scoring systems [Acute Physiology and Chronic Health

Evaluation Ⅱ (APACHE- Ⅱ), Multiorgan Dysfunction Score (MODS), Glasgow-Imrie score], thus allowing a timely and appropriate selection of patients for this invasive procedure during the first hours and days of the disease.

Applications
Based on the results of our study, we recommend measuring the IAP only in cases when patients present with SAP (i.e. APACHE Ⅱ > 7; MODS > 2 or Glasgow-Imrie score > 3). They advocate a continuous monitoring of IAP in all cases when the patient suffers from SAP and has an IAP > 18 mmHg on first measurement.

Terminology
ACS is a severe increase in the pressure within the abdomen (IAP) such that a patient's internal organs begin to fail and malfunction. This is a medical emergency. Untreated, ACS has a high mortality rate. There are a number of different methods that your doctor may use to treat the ACS. These may include giving medications to sedate or temporarily paralyze you or your loved one, placing tubes through the nose and into the stomach to remove fluid and air, placing tubes into the abdomen to remove fluid or blood, or opening the abdomen to release the increased pressure. Most patients with IAH and/or ACS will be cared for in an ICU where doctors and nurses constantly monitor for signs of illness and treat patients to keep their heart, lungs, kidneys, liver, and intestines functioning as normally as possible.

Peer review
An important aspect of AP has been addressed in this paper, as not much has been written about IAP and ACS in relation to AP. The study design is simple and clear.

Abstract

AIM: To evaluate the outcome of laparoscopic cholecystectomy (LC) in patients aged 80 years and older.

METHODS: A total of 353 patients aged 65 to 79 years (group 1) and 35 patients aged 80 years and older (group 2) underwent LC. Patients were further classified into two other groups: those with uncomplicated gallbladder disease (group A) or those with complicated gallbladder disease (group B).

RESULTS: There were no significant differences between the age groups (groups 1 and 2) with respect to clinical characteristics such as age, gender, comorbid disease, or disease presentation. Mean operative time, conversion rate, and the incidence of major postoperative complications were similar in groups 1 and 2. However, the percentage of high-risk patients was significantly higher in group 2 than in group 1 (20.0% *vs* 5.7%, *P* < 0.01). Group A comprised 322 patients with a mean age of 71.0 ± 5.3 years, and group B comprised 51 patients with a mean age of 69.9 ± 4.8 years. In group B, mean operative time (78.4 ± 49.3 min *vs* 58.3 ± 35.8 min, *P* < 0.01), mean postoperative hospital stay (7.9 ± 6.5 d *vs* 5.0 ± 3.7 d, *P* < 0.01), and the incidence of major postoperative complications (9.8% *vs* 3.1%, *P* < 0.05) were significantly greater than in group A. The conversion rate tended to be higher in group B, but this difference was not significant.

CONCLUSION: Perioperative outcomes in elderly patients who underwent LC seem to be influenced by the severity of gallbladder disease, and not by chronologic age. In octogenarians, LC should be performed at an earlier, uncomplicated stage of the disease whenever possible to improve perioperative outcomes.

INTRODUCTION

The Korean population is steadily aging. The percentage of the population 65 years of age and older was 5.8% in 1995 and was 9.1% in 2005. This age group is expected to grow from 14.3% in 2018 to 20.8% in 2026[1]. The prevalence of gallstone formation increases with age[2]. The reported incidence of cholelithiasis in the very elderly (80 years and older) is as high as 38%-53%[3,4]. This age group has a high incidence of complicated gallstone disease, such as acute cholecystitis, choledocholithiasis, and gallstone pancreatitis[5]. Laparoscopic cholecystectomy (LC) is currently the

procedure of choice for the management of gallbladder disease[6]. Many reports have demonstrated the relative safety and efficacy of LC, with low conversion rates and low postoperative morbidity compared to open cholecystectomy (OC)[7,8]. Currently, LC is being used with increasing frequency in elderly patients. Advanced age may be associated with increased postoperative complications and high conversion rates[9]. However, as life expectancy continues to increase, octogenarians are becoming a growing proportion of the population undergoing LC. Therefore, the purpose of this study was to evaluate the outcome of LC in patients aged 80 years and older compared to patients aged 65 to 79 years.

MATERIALS AND METHODS

Study group

A retrospective analysis of patients aged 65 years and older who underwent LC from November 1991 to January 2006 at Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea was performed. A total of 353 patients aged 65 to 79 years (group 1) and 35 patients aged 80 years and older (group 2) underwent LC. According to disease presentation, patients were further classified into two other groups: one with uncomplicated gallbladder disease (group A) and one with complicated gallbladder disease (group B). The diagnosis of gallbladder disease was based on a combination of clinical, laboratory, and radiologic findings. The most common imaging techniques used were ultrasonography and computed tomography. The diagnosis was confirmed by pathologic evaluation and surgical inspection. Whenever choledocholithiasis was suspected, preoperative endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) was performed. Endoscopic sphincterotomy with stone extraction was performed as needed. Since March 2004, percutaneous transhepatic gallbladder drainage (PTGBD) has been performed at our institution for patients admitted with suspected complicated acute cholecystitis (gallbladder empyema, gangrenous cholecystitis, perforated acute cholecystitis, emphysematous cholecystitis, and pericholecystic abscess).

Surgical technique

All LC procedures were carried out by one surgeon who had previous experience of more than 3000 laparoscopic cholecystectomies, assisted by a resident. A 10-mm Visiport® trocar (Tyco, Norwalk, USA) was inserted at the subumbilical area as the first port site. Two additional laparoscopic cannulae were inserted; one in the right upper quadrant (5 mm) and the other in the epigastric area (12 mm). A soft silastic drain was used in all patients.

Statistical analysis

The clinical characteristics, duration of LC surgery, conversion rate, complication rate, and postoperative

hospital stay were analyzed using a statistical analysis program package (SPSS 15.0, SPSS Inc. Chicago, IL, USA). The results are expressed as mean ± SD. The statistical significance of observed differences was tested using the χ^2 test, Fisher's exact test, or Mann-Whitney test. A probability of 0.05 or less was $P < 0.05$ considered statistically significant.

RESULTS

Overview of patients

There were no significant differences among the age groups (group 1 and 2) with respect to clinical characteristics such as age, gender, additional disease, and disease presentation. However, the percentage of high-risk patients was significantly higher in group 2 (20.0%) than in group 1 (5.7%). High risk was defined as an American Society of Anesthesiologists (ASA) score of 3 or 4 (Table 1).

Perioperative outcomes

Three hundred and twenty-two patients (group A) underwent LC for uncomplicated gallbladder disease (recurrent biliary colic, gallbladder polyp, and chronic cholecystitis), 51 patients (group B) underwent LC for complicated gallbladder disease (acute cholecystitis, gallbladder empyema, gangrenous cholecystitis, perforated acute cholecystitis, emphysematous cholecystitis, pericholecystic abscess, biliary pancreatitis, and cholangitis), and the remaining 15 patients underwent LC for gallbladder cancer. Not all gallbladder

Postoperative hospital stay (d)	5.5 ± 4.2	5.1 ± 4.0	0.873

Table 3 Perioperative outcome according to disease presentation n (%)

	Group A (n = 322) Uncomplicated	Group B (n = 51) Complicated	P value
Age	71.0 ± 5.3	69.9 ± 4.8	0.125
Preoperative WBC count (/mm^3)	7048 ± 2166	11 928 ± 4269	< 0.001
Operative time (min)	58.3 ± 35.8	78.4 ± 49.3	< 0.01
Conversions	7 (2.2)	3 (5.9)	0.144
Complications	10 (3.1)	5 (9.8)	< 0.05
Postoperative hospital stay (d)	5.0 ± 3.7	7.9 ± 6.5	< 0.01

cancers were diagnosed before surgery. One patient in group 1 had a pT2 tumor and underwent complete radical surgery of the gallbladder bed with lymph node dissection. Preoperative PTGBD was performed for 12 patients in group 1 and for one patient in group 2. The timing of LC in patients with acute cholecystitis was variable (early, delayed, or scheduled after PTGBD) according to clinical factors such as specialist or operating theater availability and the patient's medical condition.

Mean operative time and the conversion rate to OC were similar for the two age groups. The reasons for conversion were difficulty in gallbladder exposure or dissection at the Calot triangle because of dense adhesions. The incidence of major postoperative complications was similar in the two groups; 15 patients in group 1 (4.2%) and 2 patients in group 2 (5.7%). Six patients in group 1 and one patient in group 2 developed bile leakage after surgery. All patients were treated conservatively and the leakage subsided spontaneously within 7 d. Three patients in group 1 and one in group 2 had intraabdominal fluid collection; all patients were treated by ultrasound-guided percutaneous catheter drainage and parenteral antibiotics. Two patients in group 1 presented with bloody discharge from the subhepatic silastic drain on the first postoperative day, but the bleeding was controlled conservatively without blood transfusion. Postoperative wound infection occurred in three patients in group 1. One patient in group 1 developed a subumbilical wound hernia (10 mm cannula wound), which was surgically treated. The length of postoperative hospital stay was similar in the two groups (Table 2).

Group A (uncomplicated gallbladder disease) comprised 322 patients with a mean age of 71.0 ± 5.3 years, and group B (complicated gallbladder disease) comprised 51 patients with a mean age of 69.9 ± 4.8 years. In group B, the mean operative time was 78.4 ± 49.3 min, and this was significantly longer than that in group A (58.3 ± 35.8 min, P < 0.01). The incidence of major postoperative complications was significantly higher (9.8% vs 3.1%, P < 0.05) and mean postoperative hospital stay was significantly longer (7.9 ± 6.5 d vs 5.0 ± 3.7 d, P < 0.01) in group B

compared to group A. The conversion rate tended to be higher in group B (5.9%) compared to group A (2.2%), but this difference was not significant (P = 0.144) (Table 3).

DISCUSSION

Gallbladder disease is the most common indication for abdominal surgery in the elderly[4,10,11]. In Korea, the age distribution of gallstones shows a peak incidence in the seventh decade and common bile duct stones show a peak incidence in the eighth decade[12]. Management of gallstones is important in the elderly because of a high rate of complicated biliary disease, increased postoperative morbidity, and prolonged hospital stay compared to younger patients[13,14]. However, recent reports have documented a mortality rate of 0% after LC in octogenarians[15,16]. In the present study, the mortality rate was 0% in octogenarians, with a 5.7% morbidity rate. This morbidity rate was comparable to that found in other studies (2.2-18.5%)[15-18]. Furthermore, there were no significant differences in operative time, conversion rate, complication rate, and postoperative hospital stay between the two age groups (group 1 vs group 2). The only difference observed was in the preoperative ASA score. Kwon et al[17] also found that there were no significant differences in the conversion rate, morbidity, mortality, and length of hospital stay between a group aged 65 to 79 years and a group aged ≥ 80 years. However, Pavlidis et al[16] reported that LC in the very elderly was associated with a higher conversion rate, increased morbidity, and longer hospital stay. Conversion to OC and postoperative complications may be associated with severe complicated gallbladder disease[19]. In the present study, operative time, postoperative complication rate, and postoperative hospital stay were also greater in patients who underwent LC for complicated gallbladder disease. In uncomplicated gallbladder disease, the overall conversion rate to OC was only 2.2% and the postoperative complication rate was also lower (3.1% vs 9.8%). These results may indicate that perioperative outcome is not influenced by chronologic age in the elderly, but is influenced by disease presentation.

When LC is performed in patients with severe cholecystitis, the rate of conversion to open surgery and postoperative complications is usually high. The

rate of conversion to open surgery in cases of severe cholecystitis is 8.7%-35%[20-23]. The complication rate associated with LC performed for acute cholecystitis ranges from 3% to 40%[19-22,24,25]. Therefore, since March 2004, we have adopted a protocol that includes PTGBD in patients admitted with suspected complicated acute cholecystitis (gallbladder empyema, gangrenous cholecystitis, perforated acute cholecystitis, emphysematous cholecystitis and pericholecystic abscess). Twelve patients in group 1 (3.4%) and one patient in group 2 (2.9%) underwent PTGBD before LC, and the conversion rate to OC was zero in both groups. Watanabe *et al*[26] reported that the combination of ultrasonography-guided PTGBD and LC was a safe and effective treatment for patients with acute suppurative cholecystitis. There were age no conversions to OC when LC was performed at a mean of 34.3 d after PTGBD. Moreover, a conversion rate of 3% was observed in patients who underwent surgery for acute cholecystitis 4 d after PTGBD[27]. In the present study, preoperative PTGBD may have had a positive effect on LC in complicated gallbladder disease.

Preoperative ERCP was performed in 33 patients in group 1 (9.3%) and 4 patients in group 2 (11.4%) who had clinical, laboratory, and radiological suspicion of choledocholithiasis, and 29 (87.9%) and 4 (100.0%), respectively, had common bile duct stones. All these patients underwent successful endoscopic sphincterotomy with stone extraction. The reported incidence of choledocholithiasis rises with age (26% and 43% in patients aged 65-79 years and 80-95 years, respectively)[10]. Therefore, preoperative ERCP in the elderly should be performed for patients with clinical, laboratory, and radiological suspicion of choledocholithiasis.

If elderly patients tend to have higher conversion and postoperative complication rates, and a longer postoperative hospital stay, this may be due to a higher incidence of complicated gallbladder disease[15]. In the present study, there was no difference in disease presentation between the two age groups; complicated gallbladder disease was 13.3% in group 1 and 11.4% in group 2. Therefore, despite higher ASA scores in group 2, perioperative outcomes might not be significantly different between the two groups.

In conclusion, perioperative outcomes in the elderly seem to be influenced by the severity of gallbladder disease, and not by chronologic age. In the very elderly, such as octogenarians, LC is also relatively safe, with acceptable morbidity compared to elderly patients younger than 80 years of age, if they have uncomplicated gallbladder disease. Therefore, in this age group, LC should be performed at an earlier, uncomplicated stage of the disease as often as possible to improve perioperative outcomes.

COMMENTS

Background

The Korean population is steadily aging. As life expectancy continues to increase, octogenarians are becoming a growing proportion of the population

undergoing laparoscopic cholecystectomy (LC).

Research frontiers

Perioperative outcomes in the elderly seem to be influenced by the severity of gallbladder disease, and not by chronologic age. LC is relatively safe in the very elderly, such as octogenarians.

Related publications

Many reports have demonstrated the relative safety and efficacy of LC, with low conversion rates and low postoperative morbidity compared to open cholecystectomy. Currently, LC is being used with increasing frequency in elderly patients. Advanced age may be associated with increased postoperative complications and high conversion rates.

Innovations and breakthroughs

If elderly patients tend to have higher conversion and postoperative complication rates, and a longer postoperative hospital stay, this may be due to a higher incidence of complicated gallbladder disease.

Applications

In the very elderly, LC should be performed at an earlier, uncomplicated stage of the disease as often as possible to improve perioperative outcomes.

Peer review

The authors reported that outcome of LC is not influenced by chronologic age. This result is interesting.

Abstract

AIM: To investigate the usefulness of anti-ulcer drugs for the prevention and treatment of low-dose aspirin-induced peptic ulcer.

METHODS: Upper gastrointestinal endoscopy was performed in 68 patients receiving daily low-dose aspirin (81 or 100 mg/day). The endoscopic findings were classified according to the Lanza score, and the scores were compared between groups categorized according to the concomitant use of anti-ulcer drugs and the types of drugs used. In another study, 31 hemorrhagic peptic ulcer patients who had been receiving low-dose aspirin were enrolled. The patients were randomly classified into the proton pump inhibitor (PPI)-treated group and the H2 receptor antagonist (H2RA)-treated group. The administration of low-dose aspirin was continued concomitantly, and endoscopic examinations were performed 8 wk later.

RESULTS: The Lanza scores (mean ± SD) of the gastro-mucosal lesions were 1.0 ± 1.9 and 1.9 ± 2.3 in 8 and 16 patients receiving prevention therapy with a PPI and an H2RA, respectively. Both scores were significantly smaller than the scores in 34 patients who were not receiving prevention therapy (4.7 ± 1.0) and in 10 patients receiving cytoprotective anti-ulcer drugs (4.3 ± 1.6). In the prospective study, 18 and 13 patients received a PPI and an H2RA, respectively. Endoscopic examinations revealed that the tissue in the region of the gastro-mucosal lesions had reverted to normal in all patients in the PPI-treated group and in 12 patients (92%) in the H2RA-treated group; no significant differences were observed between the groups.

CONCLUSION: H2RA therapy was effective for both the prevention and treatment of low-dose aspirin-induced peptic ulcer, similar to the effects of PPIs, while cytoprotective anti-ulcer drugs were ineffective in preventing ulceration.

Nakashima S, Ota S, Arai S, Yoshino K, Inao M, Ishikawa K, Nakayama N, Imai Y, Nagoshi S, Mochida S. Usefulness of anti-ulcer drugs for the prevention and treatment of peptic ulcers induced by low doses of aspirin. *World J Gastroenterol* 2009; 15(6): 727-731 Available from: URL: http://www.wjg-net.com/1007-9327/15/727.asp DOI: http://dx.doi.org/10.3748/wjg.15.727

INTRODUCTION

Two major causes of peptic ulcers are infection with *Helicobacter pylori* (*H pylori*) and the administration of non-steroidal anti-inflammatory drugs (NSAIDs). Recently, much attention has been paid to NSAID-induced peptic ulcers, since the trend toward *H pylori* eradication using proton pump inhibitors (PPIs) and antibiotics is likely to reduce the incidence of *H pylori*-induced peptic ulcers in the future. Moreover, the increasing proportion of elderly individuals among the Japanese population is likely to produce a simultaneous increase in the prescription

of NSAIDs for the treatment of pain arising from osteoporosis and/or osteoarthritis. This trend may highlight the significance of NSAID-induced peptic ulcers. Low-dose aspirin has also been shown to induce peptic ulcers, similar to the effects of regular-dose aspirin and other NSAIDs[1]; this finding suggests that NSAID-induced peptic ulcers may become more common among the elderly population, since many patients receive antithrombotic therapy using low-dose aspirin for the treatment of cardiovascular diseases. Previously, we reported that NSAIDs were associated with hemorrhagic peptic ulcers in 28% of the patients seen between 2001 and 2004; the rate of patients receiving low-dose aspirin in this population was 27%, while the rates of patients receiving regular-dose aspirin, loxoprofen, diclofenac and other NSAIDs were 6%, 16%, 10% and 21%, respectively[1]. These data suggest that among the various NSAIDs in use, low-dose aspirin is the most important drug provoking peptic ulcers in Japan.

Infection with *H pylori* is frequently found in patients with NSAID-induced peptic ulcers, including those with low-dose aspirin-induced ulcers. According to our previous survey[1], a total of 82% of patients with hemorrhagic peptic ulcers tested positive for *H pylori* infection; the positivity rate was higher among those not treated with NSAIDs (88.6%) than among those receiving NSAIDs (67.2%). Of note, 62.5% of the patients with hemorrhagic peptic ulcers induced by low-dose aspirin tested positive for *H pylori*[1]. However, whether *H pylori* eradication prevents the development of peptic ulcers induced by low-dose aspirin remains controversial[2]. Chan *et al*[3] reported that both *H pylori* eradication and PPI administration were effective in preventing peptic ulcers induced by low-dose aspirin. On the other hand, Lai *et al*[4] revealed that hemorrhage recurred in more than 10% of the patients with low-dose aspirin-induced peptic ulcers, even after *H pylori* eradication, whereas PPI administration was effective in reducing the risk of recurrence. A therapeutic strategy to prevent peptic ulcers induced by NSAIDs, especially low-dose aspirin, is needed.

In the present study, we evaluated the efficacies of various anti-ulcer drugs (PPIs, H2RA and cytoprotective drugs) for the prevention and treatment of peptic ulcers induced by low-dose aspirin, by comparing the endoscopic findings of the patients to establish a therapeutic strategy for low-dose aspirin-induced peptic ulcers in Japanese patients.

MATERIALS AND METHODS

Study-1

Patients receiving daily low-dose aspirin (81 or 100 mg/day) and undergoing an upper gastrointestinal endoscopy at Saitama Medical University Hospital between February 2001 and September 2006 were enrolled in the study. Patients receiving NSAIDs other than aspirin and/or receiving regular-dose aspirin (from 1.0 to 4.5 g/day) were excluded from the analysis. Patients with malignancies or those who had undergone

Table 1 Classification of endoscopic findings according to the Lanza score[5]

Score	Endoscopic findings
0	No lesion
1	Hemorrhagic erosion
2	One or two erosions
3	3-10 erosions
4	More than 10 erosions
5	Ulcer

a gastrectomy were also excluded. The endoscopic findings were classified according to the Lanza score, as show in Table 1[5]. The scores were compared between groups categorized according to the concomitant use of anti-ulcer drugs and the types of drugs used.

Study-2

The subjects comprised hemorrhagic peptic ulcer patients who had been receiving low-dose aspirin daily and who had been admitted to Saitama Medical University Hospital between February 2001 and March 2008. The exclusion criteria were similar to those used in Study-1: patients receiving NSAIDs other than aspirin and/or regular-dose aspirin and those with malignancies or who had undergone a gastrectomy at enrolment. Informed consent was obtained from all patients, and the subjects were randomly classified into two groups. The patients classified as the PPI-treated group were given either lansoprazole (15 or 30 mg, daily), rabeprazole sodium (10, 20 or 40 mg, daily) or omeprazole (20 mg, daily). In contrast, the patients in the H2RA-treated group were given famotidine (40 mg, daily). In all patients, the administration of low-dose aspirin was continued concomitantly with the PPI or famotidine therapy. Infection with *H pylori* was determined using a serum antibody test (AP-960; Scimed Life Systems/Boston Scientific Corp, Natick, MA, USA) or a culture of gastric mucosal specimens obtained during an endoscopic examination. *H pylori* eradication with the administration of lansoprazole (60 mg, daily), amoxicillin hydrate (1500 mg, daily) and clarithromycin (800 mg, daily) was performed for 7 d in patients with a positive infection status within 2 wk of the occurrence of peptic ulcer hemorrhage. The therapeutic efficacy of *H pylori* eradication was assessed by the urea breath test 8 wk later. An upper gastrointestinal endoscopy was performed 8 wk after the initiation of PPI or famotidine therapy. The ulcer was diagnosed as healed once scar formation at the site of the lesion was complete.

Statistical Analysis

The Mann-Whitney *U* test and the Fisher's exact test were used to analyze the data. Statistical significance was defined as $P < 0.05$.

RESULTS

Study-1

Sixty-eight patients (45 men and 23 women) between

Table 2 Anti-ulcer drugs used in patients enrolled in study-1

Type of drug	Drug name	Doses (/day)	Number of patients
None			34
PPIs			8
	Rabeprazole sodium	10 mg	3
	Lansoprazole	30 mg	2
	Lansoprazole	15 mg	1
	Omeprazole	20 mg	2
H2RAs			16
	Famotidine	40 mg	1
	Famotidine	20 mg	8
	Famotidine	10 mg	1
	Lafutidine	20 mg	2
	Nizatidine	300 mg	2
	Ranitidine hydrochloride	75 mg	1
	Cimetidine	100 mg	1
Cytoprotective anti-ulcer drugs			10
	Rebamipide	300 mg	2
	Rebamipide	200 mg	1

	Azulensulfonate sidium + L-Glutamine	2 g	2
	Teprenone	1.5 g	1
	Polaprezinc	150 mg	1
	Sofalcone	300 mg	1
	Alginate sodium	180 mL	1

the ages of 25 and 88 years were enrolled in the study. Thirty-four patients received no anti-ulcer drugs, while 8, 16 and 10 patients were given PPIs, H2RAs and cytoprotective anti-ulcer drugs, respectively. The types and doses of the anti-ulcer drugs are shown in Table 2. Duration of daily low-dose aspirin therapy ranged from 1 to 3650 d, however, therapy duration (days; mean ± SD) did not differ in patients receiving and not receiving anti-ulcer drugs (898 ± 1384 and 1165 ± 1389, respectively). In the case of patients receiving anti-ulcer drugs, the prevention therapies were initiated simultaneously with low-dose aspirin administration. Anti-platelet and anticoagulant drugs were used in 5 and 1 patients receiving and not receiving anti-ulcer drugs, respectively. No differences in age or sex were observed among the patients not treated with anti-ulcer drugs and those receiving PPI, H2RA or cytoprotective anti-ulcer drugs (Table 3). However, the endoscopic scores were significantly smaller in patients receiving PPIs and H2RAs, compared with those receiving cytoprotective anti-ulcer drugs and those not receiving anti-ulcer drugs. A grade 5 endoscopic score was observed in 31 of 34 patients (91%) not receiving anti-ulcer drugs and in 8 of 10 patients (80%) receiving cytoprotective anti-ulcer drugs, while the grades ranged between 0 and 3 in 11 of 16 patients (69%) receiving H2RAs and in 7 of 8 patients (88%) receiving PPIs. The scores in patients receiving PPIs and in those receiving H2RAs were statistically similar. In addition, no differences were observed between the scores in 5 patients receiving regular-dose H2RAs and in 11 patients receiving low-dose H2RAs. Moreover, the scores in patients receiving cytoprotective anti-ulcer drugs and in those not receiving anti-ulcer drugs were similar. One 72-year-old male patient had an endoscopic score of

grade 5 despite the use of a PPI. *H pylori* infection was not detected in this patient, but a coronary artery bypass grafting procedure had been performed 39 d prior to the endoscopic examination, and the patient had been receiving daily doses of warfarin in addition to low-dose aspirin since that time.

Study-2

Forty patients were enrolled in the study: 20 patients in the PPI-treatment group and 20 patients in the H2RA-treatment group. An endoscopic examination was performed at 8 wk in 18 patients (13 men and 5 women) aged 69.2 ± 13.4 years (mean ± SD) in the PPI-treatment group and in 13 patients (10 men and 3 women) aged 69.7 ± 9.5 years in the H2RA-treatment group; the 9 remaining patients were transferred to other hospitals prior to endoscopic examination. A positive *H pylori* infection status was seen in 12 and 10 patients (67% and 77%) in the PPI-treatment and H2RA-treatment groups, respectively; *H pylori* infection rate was similar in both groups. *H pylori* eradication was achieved in all patients who had a positive *H pylori* infection status. Endoscopic examinations performed at 8 wk revealed that the peptic ulcers had completely healed in 18 patients (100%) in the PPI-treatment group and in 12 patients (92%) in the H2RA-treatment group; no difference in therapeutic efficacy was seen between the two groups. The peptic ulcer in one patient with a positive *H pylori* infection status in the H2RA-treatment group had not completely healed at 8 wk. This patient had repeatedly received loxoprofen for the treatment of a headache 1 wk prior to the endoscopic examination, suggesting that peptic ulcers might recur in the presence of loxoprofen administration, even if the low-dose aspirin-induced ulcer had healed during famotidine therapy. There were 3 and 6 patients with a negative *H pylori* infection status in the H2RA-treatment and PPI-treatment groups, respectively. Peptic ulcers were completely healed in all these patients.

DISCUSSION

In the US and Europe, drugs such as PPIs[6], prostaglandins[7] and regular-dose H2RAs[8] have been reported to be effective in the prevention of NSAID-induced peptic ulcers, and PPIs and prostaglandins have been reported to effectively attenuate such ulcers[6]. In addition, studies conducted in Hong Kong and the US have revealed that both *H pylori* eradication[3] and PPI treatment[4] are useful in preventing the recurrence of hemorrhagic peptic ulcers induced by low-dose aspirin. In Japan, however, the administration of PPIs, H2RAs and prostaglandins for the prevention of peptic ulcers induced by NSAIDs and low-dose aspirin is not covered by medical insurance, although the use of these drugs for the treatment of peptic ulcers is covered. Among these drugs, PPIs and prostaglandins are widely accepted as the most effective therapeutic agents for NSAID-induced peptic ulcers, however, prostaglandins are seldom used due to their adverse effects such as abdominal pain and diarrhea. Thus, in Japan, many

Table 3 Endoscopic findings classified according to the Lanza score in patients receiving low-dose aspirin with or without anti-ulcer drugs

Less than regular doses									
11	5:6	66.9 ± 15.6	5	2	0	0	0	4	2.00[1]
PPIs									
8	6:2	62.0 ± 17.0	6	0	0	1	0	1	1.00[1]

[1]$P < 0.05$ *vs* both no anti-ulcer drugs and cytoprotective drugs, according to the Mann-Whitney *U* test.

physicians usually use PPIs for the treatment of peptic ulcers induced by NSAIDs and low-dose aspirin. For the prevention of peptic ulcers, cytoprotective anti-ulcer drugs other than prostaglandins are commonly used, although no evidence supporting this use has been reported in the medical literature. Therefore, a therapeutic strategy for the treatment and prevention of peptic ulcers induced by NSAIDs, especially low-dose aspirin, should be established for Japanese patients.

Thus, we performed a retrospective study (Study-1) to clarify the efficacy of various anti-ulcer drugs to prevent peptic ulcers induced by low-dose aspirin and a prospective study (Study-2) to compare the therapeutic efficacies of PPIs and H2RAs for treating such ulcers. The retrospective study revealed that H2RAs effectively prevented peptic ulcers induced by low-dose aspirin to a degree similar to that of PPIs, however, cytoprotective drugs were not effective in preventing peptic ulcers. To our surprise, H2RA administration at doses less than the regular dose was also effective in preventing low-dose aspirin-induced peptic ulcers. Furthermore, the prospective study demonstrated that the therapeutic efficacies of PPIs and H2RAs at regular doses were almost equivalent. The secretion of gastric acids from the gastric mucosa has been shown to be lower in Japanese patients than in European and American patients[9,10], since marked atrophy of the gastric mucosa is often found in many Japanese patients due to the prevalence of *H pylori* infection. Thus, low-dose H2RAs, such as famotidine 20 mg daily, seem to be effective in the prevention of peptic ulcers induced by low-dose aspirin, and regular-dose H2RAs, such as famotidine 40 mg, may be sufficient to treat such peptic ulcers in Japanese patients. However, it should be noted that grade-5 endoscopic findings were observed in a 72-year-old patient in Study-1 receiving both warfarin and low-dose aspirin despite concomitant prevention therapy with a PPI. In addition, peptic ulcer healing did not occur in one patient receiving loxoprofen as well as low-dose aspirin in the H2RA-treated group in Study-2. The usefulness of H2RAs for the treatment and prevention of low-dose aspirin-induced peptic ulcers should be further investigated, focusing on elderly patients and those receiving warfarin as well as NSAIDs[11]. Moreover, the therapeutic and prevention efficacy of H2RA should be studied in relation to *H pylori* infection status, therapeutic effect of *H pylori* infection, history of upper gastrointestinal diseases and the types of peptic ulcer such as acute and chronic disorders in future research.

In conclusion, H2RA therapy was effective for both the prevention and treatment of low-dose aspirin-induced peptic ulcers, similar to the effects of PPIs, while cytoprotective anti-ulcer drugs were ineffective in preventing peptic ulcers. Considering the cost and adverse effects of PPIs and prostaglandins, H2RA may be the most beneficial anti-ulcer drug for the prevention and treatment of peptic ulcers induced by low-dose aspirin in Japan.

ACKNOWLEDGMENTS

COMMENTS

Background

The incidence of low-dose aspirin-induced peptic ulcer seems to be increasing in Japan in conjunction with the increasing proportion of elderly individuals, in whom metabolic syndrome frequently develops. However, a therapeutic and prevention strategy for such peptic ulcers has not yet been established.

Research frontiers

The effect of *Helicobacter pylori* (*H pylori*) eradication in the prevention of peptic ulcers induced by low-dose aspirin remains controversial. Chan *et al*[3] reported that both *H pylori* eradication and proton pump inhibitor (PPI) administration were effective in preventing peptic ulcers induced by low-dose aspirin. On the other hand, Lai *et al*[4] revealed that hemorrhage recurred in more than 10% of patients with low-dose aspirin-induced peptic ulcers, even after *H pylori* eradication, whereas PPI administration was effective in reducing the risk of recurrence.

Innovations and breakthroughs

H2 receptor antagonist (H2RA) was effective in both the prevention and treatment of low-dose aspirin-induced peptic ulcers, similar to the effects of

PPIs, while cytoprotective anti-ulcer drugs were ineffective in preventing ulcers.

Applications

Considering the cost and adverse effects of PPIs and prostaglandins, H2RAs may be the most beneficial anti-ulcer drugs for the prevention and treatment of peptic ulcers induced by low-dose aspirin in Japan.

Terminology

Low-dose aspirin: aspirin at regular doses (from 1.0 to 4.5 g/day) is administered to patients with fever, headache and arthralgia. In contrast, daily low-dose aspirin (81 or 100 mg/day) is used as antithrombotic therapy for patients with cardiovascular diseases.

Peer review

The incidence of low-dose aspirin-induced peptic ulcers is increasing in Japan, but the evidence is still lacking. In this paper, the authors evaluated the efficacies of various anti-ulcer drugs for the prevention and treatment of low-dose aspirin-induced peptic ulcers. The author concluded that the efficacies of H2RAs and PPIs for the prevention and treatment of L-Asp-induced peptic ulcers.

Abstract

AIM: To explore a method to establish an animal model of ischemic type intrahepatic biliary lesion in rabbits.

METHODS: Forty Japanese white rabbits of clean grade were divided randomly into four groups (10 rabbits per group) including sham operation (SO) group, and artery-bile obstruction (ABO)-1 h group, ABO-2 h group and ABO-3 h group. All the rabbits in this study underwent the same initial surgical procedure in which the liver was prepared as for graft removal during liver transplantation. Subsequently in the SO group, no additional vascular intervention was performed, while in groups ABO-1 h, ABO-2 h and ABO-3 h, the animals underwent combined clamping of the hepatic artery and common bile duct with microvascular clips for 1, 2 and 3 h, respectively. After the scheduled occlusion time, the clip was removed to recover blood supply. The animals were killed 4 wk after operation. The survival rate, liver function, cholangiography and histopathological manifestation of the rabbits in each group were observed.

RESULTS: The survival rate was 100% in groups SO, ABO-1 h and ABO-2 h, while it was 60% in group ABO-3 h. At each observation time, the change degree of the indexes of liver function was proportional to the clamping time (ABO-3 h > ABO-2 h > ABO-1 h > SO, $P < 0.05$). Cholangiographical and histopathologic manifestations both showed that intrahepatic biliary lesion aggravated proportionally with the increase of the clamping time.

CONCLUSION: An animal model of ischemic type intrahepatic biliary lesion in rabbits is successfully established, which may provide a reliable technique for basic and clinical research into the etiology, development and prophylaxis of ischemic type intrahepatic biliary lesion after liver transplantation.

INTRODUCTION

Biliary complications, which occur at a rate of approximately 6%-35%[1], have long been recognized as a major cause of morbidity and graft failure in patients after orthotopic liver transplantation (OLT). The most troublesome is the so-called ischemic type biliary lesion (ITBL), with an incidence varying between 5% and 15%[2]. ITBL is a special biliary complication with non-anastomotic biliary tree destruction, which is one of the most important reasons for liver re-transplantation. For intrahepatic ITBL, especially in the presence of extensive intrahepatic ITBL, endoscopic and radiological techniques and surgical approaches are usually unsuccessful and re-transplantation is mostly unavoidable[2]. Therefore, it is urgent to establish an animal model of ischemic type intrahepatic biliary lesion to study the etiology, development and prophylaxis

of ITBL. In the present study, by combined clamping of the common bile duct and hepatic artery for 2 h, producing the biliary ischemia reperfusion injury, and raising the animals for 4 wk, an animal model of ischemic type intrahepatic biliary lesion in rabbits was successfully established.

MATERIALS AND METHODS

Animals and groups

Animal care and experimental procedures were carried out strictly in accordance with the guide for the care and use of laboratory animals (National Research Council of USA, 1996) and the related ethical regulations of our university. Forty Japanese white rabbits of clean grade, weighing 2.0-2.5 kg, were selected (provided by Institute of Laboratory Animal Science), irrespective of male or female gender. All of the rabbits were raised under the same condition including a temperature of 18-23℃, the relative humidity of 50%-60%, 12 h diurnal rhythm and freedom to eat and drink. The rabbits were divided randomly into four groups (10 rabbits per group) including sham operation (SO) group, and artery-bile obstruction (ABO)-1 h group, ABO-2 h group and ABO-3 h group.

Establishment of an animal model

The rabbits were prohibited to eat for 12 h and drink for 6 h before operation. They were anesthetized by injecting 1% pentobarbital (1-2 mL/kg) intravenously. The skin was prepared and disinfected routinely. Then, a median incision of the epigastrium about 6 cm in length was formed. All the rabbits in this study underwent the same initial surgical procedure in which the liver was prepared as for graft removal during liver transplantation. Upon the completion of this procedure, the liver was isolated from all vascular supply except for the main hepatic artery, the extra-hepatic peribiliary plexus and the portal vein. In the SO group, no additional vascular intervention was performed. In groups ABO-1 h, ABO-2 h and ABO-3 h, the animals underwent combined clamping of the hepatic artery and common bile duct with microvascular clips for 1, 2 and 3 h, respectively. After the scheduled occlusion time, the clip was removed to recover blood supply. All the animals from these groups were killed 4 wk after operation.

Observation indexes

Survival rate: The animals in each group were raised for 4 wk after operation, and the survival rates of each group were observed.

Examination of liver function: biochemical liver tests were monitored at different time points up to 4 wk including preoperation, and the 1 d, the 1, 2, 3 and 4 wk post-operation. Serum concentrations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), γ-glutamyl transpeptidase (GGT), total bilirubin (TBIL) and direct bilirubin (DBIL) were measured, using standard analytical methods.

Cholangiography: Four weeks after operation, all the rabbits in the four groups underwent cholangiography. Under routine anesthesia, the abdominal cavity was opened according to the former incision. Three to five milliliters of 30% meglucamine diatrizoate solution was injected slowly through the distal end of the common bile duct, and a X-ray photograph was taken to observe the intrahepatic biliary lesion.

Histopathologic examination: After cholangiography, the animals were killed to collect liver tissue samples at the hepatic hilum for histopathological examination. Serial 4-μm-thick sections of formalin-fixed, paraffin-embedded liver tissues were stained with hematoxylin-eosin.

Statistical analysis

Quantitative data were shown as mean ± SD. SPSS statistical software 13.0 was used to conduct analysis of variance of multiple means. For all analyses, a *P* value less than 0.05 was considered statistically significant.

RESULTS

Survival rates

The animals in groups SO, ABO-1 h and ABO-2 h lived throughout the period of the experiment with a survival rate of 100%. However, four rabbits in group ABO-3 h died on the days 5, 7, 12 and 14 after operation, respectively, with a survival rate of 60%. The causes of death included hepatic ischemic necrosis, bile leakage and abdominal infection, which was supported by autopsy and histopathological examination.
Examination of liver function

All the biochemical indexes (AST, ALT, ALP, GGT, TBIL and DBIL) in groups ABO-1 h, ABO-2 h and ABO-3 h increased with different degrees after operation. No biochemical abnormality was observed in group SO during the entire follow-up. The indexes reached a peak on the day 1 after operation, and then decreased gradually. At the end of the observation period (4 wk after operation), all biochemical abnormalities were spontaneously resolved except for the ALP and GGT in group ABO-2 h and ABO-3 h, which were still higher than that in group SO. At each observation time, the change in the indexes was proportional to clamping time (ABO-3 h > ABO-2 h > ABO-1 h > SO, *P* < 0.05) (Table 1).

Cholangiography

Four weeks after operation, all the rabbits in the four groups underwent cholangiography. The images of the intra-hepatic bile duct indicated that it was normal and no intrahepatic biliary lesion was visualized in groups of SO and ABO-1 h. However, a biliary lesion was observed obviously in groups ABO-2 h and ABO-3 h. It showed that intrahepatic biliary lesion aggravated proportionally with the increase in the clamping time (Figure 1).

Figure 1 Cholangiography of the four groups 4 wk after operation. A (SO): The image of the intra-hepatic bile duct was normal. No biliary stricture or dilation was observed; B (ABO-1 h): The image of the intrahepatic bile duct resembled that of SO, no intrahepatic biliary lesion was visualized either; C (ABO-2 h): All the branches of the intrahepatic bile duct appeared loose, with the "string beads manifestation" in part of them; D (ABO-3 h): The image of the intrahepatic bile duct was obviously abnormal, with a loose appearance and severe damage.

Histopathological examination

After cholangiography, the sample of liver tissues at the hepatic hilum was taken for histopathological examination. The results indicated that the morphology of the intrahepatic bile duct epithelial cells was normal and there was no cell necrosis in groups SO and ABO-1 h. However, epithelial cells were obviously damaged and sloughed into the bile duct lumen in groups ABO-2 h and ABO-3 h. It also showed that the intrahepatic biliary lesion was aggravated proportionally with the clamping time (Figure 2).

DISCUSSION

ITBL is defined as non-anastomotic destruction of the graft's biliary tree after OLT and characterized by the formation of sludge or stone, bile duct destruction, and even non-function of the allograft[3,4]. A classification of ITBL has been proposed based on the localization of the abnormalities, distinguishing type I (extrahepatic lesions), type II (intrahepatic lesions) and type III (intra- and extrahepatic alterations)[1]. For type II and type III, especially for multiple and diffuse ITBL, there is poor prognosis and graft survival, with the result of liver function failure and inevitable re-transplantation in most patients. Therefore, it is of clinical significance to establish an animal model of ischemic type intrahepatic

Figure 2 Histopathological manifestations of the four groups 4 wk after operation. A (SO): The intrahepatic bile duct epithelial cells were eumorphic and no cell necrosis was observed; B (ABO-1 h): The intrahepatic bile duct epithelial cells were almost normal. Small amounts of bile duct epithelial cells sloughed into the bile duct lumen; C (ABO-2 h): The intrahepatic bile duct epithelial cells were damaged obviously, and some of them were necrotic and sloughed into the bile duct lumen; D (ABO-3 h): The intrahepatic bile duct epithelial cells were damaged severely; many of them were necrotic and sloughed into the bile duct lumen. The normal epithelial structures disappeared (HE, × 200).

biliary lesion for studying the etiology, development and prophylaxis of ITBL.

Over the past years, several risk factors of this complication have been identified, strongly suggesting a multi-factorial origin, although the exact pathophysiological mechanism of ITBL is still unknown. The generally accepted risk factors include prolonged cold ischemic time warm ischemic time, reperfusion injury, disturbed blood flow in the peribiliary vascular plexus, ABO incompatibility, cytomegalovirus infection, chemokine polymorphism CCR5 delta 32, and bile salt-induced injury[2,5]. Obviously, ischemic injury is of vital importance for the occurrence of ITBL.

Several studies[6-8] have suggested that the peribiliary plexus (PBP) and hepatic artery branches are both the blood supply of the intrahepatic bile duct. Furthermore, it is demonstrated by scanning electron microscopy that there is no arterio-portal anastomosis in the liver of rabbits[9]. That is to say, the intrahepatic bile duct of rabbits do not receive their blood supply from portal vein. Therefore, in this study, by combined clamping of common bile duct and hepatic artery, as well as isolating the liver from all peripheral vascular connections, the blood supply of the intrahepatic bile duct was occluded nearly completely. After removing the clip, the intrahepatic bile duct underwent warm ischemia-reperfusion, which better simulated the clinical procedure of intrahepatic biliary warm ischemia and reperfusion injury in liver transplantation.

In this study, with the increase of the clamping time (1 h, 2 h, 3 h), it was found that intrahepatic biliary lesions were aggravated proportionally, as observed by biochemical indexes, cholangiography and histopathologicial examination. As for the clamping time, in group

ABO-1 h, biliary lesions were mild and no imaging and histopathological changes were found, while in group ABO-3 h, the success rate of the animal model was only 60%, in spite of the obvious intrahepatic biliary lesion. However, significant biliary lesions and a high success rate of the model (100%) were both observed in group ABO-2 h. Therefore, combined clamping of the common bile duct and hepatic artery for 2 h was considered the optimal clamping time to establish the model of ischemic-type intrahepatic biliary lesion in rabbits.

Generally, the time from biliary ischemic necrosis and fibrosis to stricture is about 30 d after clinical liver transplantation. Zhao *et al*[10] established an animal model of biliary ischemic stenosis with clamping in mice and observed the significant extrahepatic biliary ischemic stenosis on day 21 after operation. Therefore, the time interval of 4 wk was chosen in this study for the initial observation time. It was not confirmed that the animals in group ABO-2 h underwent more significant intrahepatic stricture when prolonging the observation time after operation.

Overall, the advantages of this animal model included the following. (1) By combined clamping of the common bile duct and hepatic artery, as well as isolating the liver from all peripheral vascular connections, the intrahepatic bile duct is in complete warm ischemia, which can better reflect the clinical procedure of intrahepatic biliary warm ischemia and reperfusion injury in liver transplantation. (2) Surgery with occlusion of the common bile duct and hepatic artery and without that of portal vein, is easy to perform, and has less trauma and higher survival rate. (3) The common bile duct and hepatic artery of all the animals are clamped by the same microvascular clip, which can control

the strength and time precisely. (4) The animal model excluded the influence of other surgical operations (biliary anastomosis, hepatic artery anastomosis, T tube detaining), rejection, biliary cold conservation and drug toxicity. (5) The intrahepatic biliary anatomy, structure and microcirculation of the rabbits are similar to those of humans. Moreover, this animal is cheap and easy to obtain sufficient samples[11].

In conclusion, in the present study, by combined clamping of the common bile duct and hepatic artery for 2 h, producing the biliary ischemia-reperfusion injury, and raising the rabbits for 4 wk, the animal model of ischemic-type intrahepatic biliary lesion in rabbits was successfully established, which may provide a reliable technique for basic and clinical research into the etiology, development and prophylaxis of ischemic type intrahepatic biliary lesion after liver transplantation.

COMMENTS

Background
Biliary complications are a major cause of morbidity and graft failure in patients after orthotopic liver transplantation (OLT). The most troublesome is the so-called ischemic type biliary lesion (ITBL), which is one of the most important reasons for liver re-transplantation. Therefore, it is of clinical significance to establish an animal model of ischemic type intrahepatic biliary lesion for studying the etiology, development and prophylaxis of ITBL.

Research frontier
ITBL, with an incidence varying between 5% and 15% after OLT, is defined as non-anastomotic destruction of the graft's biliary tree after OLT. Although the exact pathophysiological mechanism of ITBL is still unknown, several risk factors of this often cumbersome complication have been identified, strongly suggesting a multi-factorial origin. Therefore, the etiology, development and prophylaxis of ITBL have been research hotspots.

Innovations and breakthrough
This animal model of ITBL is easy to establish, and has less trauma and a higher survival rate. Moreover, it can better reflect the clinical procedure of intrahepatic biliary warm ischemia and reperfusion injury in liver transplantation. In addition, the model excluded the influence of other operations, rejection and biliary cold conservation.

Applications
This animal model of ITBL may provide a reliable technique for basic and clinical research into the etiology, development and prophylaxis of ischemic type intrahepatic biliary lesion after liver transplantation.

Peer review
The manuscript is of interest as a measure of assessing ischemia of the liver and bile ducts, and the methods appear acceptable. It is an interesting study.

Abstract

AIM: To investigate the anti-tumor effects of combined cytotoxic drug (gemcitabine) and photodynamic therapy (PDT) on human pancreatic cancer xenograft in nude mice.

METHODS: Human pancreatic cancer cell line SW1990 was used in the investigation of the *in vivo* effect of combined gemcitabine and PDT on human pancreatic cancer xenograft in mice. Sixty mice were randomly allocated into a control group (without treatment), photosensitizer treatment group (2 mg/kg photosan, without illumination), chemotherapy group (50 mg/kg gemcitabine i.p.), PDT group (2 mg/kg photosan + laser irradiation) and combined treatment group (photosan + chemotherapy), with 12 mice in each group. Tumor size was measured twice every week. Anti-tumor activity in different groups was evaluated by tumor growth inhibition (TGI).

RESULTS: No significant anti-tumor effect was observed either in photosensitizer treatment group or in chemotherapy group. PDT led to necrosis in cancer lesions and significantly reduced tumor volume compared with photosensitizer on day 6 and at the following time points after initialization of therapy (0.24 ± 0.15-0.49 ± 0.08 *vs* 0.43 ± 0.18-1.25 ± 0.09, *P* < 0.05). PDT significantly reduced tumor volume in combined treatment group compared with photosensitizer treatment group (0.12 ± 0.07-0.28 ± 0.12 *vs* 0.39 ± 0.15-1.20 ± 0.11, *P* < 0.05), small dose chemotherapy group (0.12 ± 0.07-0.28 ± 0.12 *vs* 0.32 ± 0.14-1.16 ± 0.08, *P* < 0.05) and control group (0.12 ± 0.07-0.28 ± 0.12 *vs* 0.43 ± 0.18-1.25 ± 0.09, *P* < 0.05). TGI was higher in the combined treatment group (82.42%) than in the PDT group (58.18%).

CONCLUSION: PDT has a significant anti-tumor effect, which is maintained for a short time and can be significantly enhanced by small doses of gemcitabine.

INTRODUCTION

Pancreatic cancer remains a lethal disease. Most pancreatic cancer patients are at advanced stage when apparent symptoms occur. Pancreatic cancer patients undergoing resection at the time of initial diagnosis account for less than 20%[1], and the 5-year survival rates after complete and partial pancreatic resection are 15%-25%[2-3] and 8%-14%[4-5], respectively. Treatment modalities for inoperable patients are largely limited to radiotherapy, chemotherapy, or their combination. Pancreas is a retroperitoneal organ, with stomach, intestine, and spinal cord around it. Since the sensitivity of pancreatic cancer to radiotherapy is poor, and the tolerant dosage of pancreas tissue is low, radiotherapy does not lead to a convincing beneficial effect on survival. Chemotherapy is the main therapeutic method for advanced pancreatic cancer. 5-fluorouacil is probably

the most useful single agent for symptomatic relief[6]. Gemcitabine may also have a value for palliation[7-9]. Overall, the prognosis of pancreatic cancer patients is poor with a 1-year survival rate of about 10%[10]. Therefore, new treatment modalities are urgently needed.

Photodynamic therapy (PDT) produces localized tissue necrosis with light (most conveniently from a laser), after administration of a photosensitizing agent in the presence of oxygen[10-12], based on the use of photosensitizing compounds that localize quite selectively in neoplastic/hyperplastic tissues and become cytotoxic when exposed to light[12-14]. In view of the antitumor effect of single treatment, PDT is local. PDT in combination with surgery[15], radiotherapy[16] or chemotherapy[17], has become a subject of research. New photosensitizers with improved spectroscopic, photochemical and tissue-localizing properties and improved laser instrumentation have stimulated attempts to establish clinical protocols for incorporation of PDT into multi-treatment modalities[18-24].

Most studies on PDT to date have been on lesions of the skin or in the wall of hollow organs, but recent interest is more in its potential for treating lesions of solid organs such as the pancreas[10,11,20]. We have undertaken experiments on treating pancreatic cancer of mice with different doses of gemcitabine[25]. The results indicate that the growth of transplanted tumors can be inhibited by gemcitabine at 100 mg/kg, which shows severe side effects such as diarrhea, dehydration and loss of weight[25]. When gemcitabine at 100 mg/kg is used, the growth of transplanted tumors could not be controlled[25]. On the other hand, combined angiogenetic inhibitors can decrease side effects of gemcitabine, meanwhile the growth and metastasis of transplanted tumors are effectively inhibited[25].

In this study, gemcitabine was used as a cytotoxic drug. The cytotoxic and antitumor effects of combined gemcitabine and PDT were evaluated. Human pancreatic cancer cell line SW1990 was used in experiments to assess the effect of gemcitabine or PDT, or their combination, on pancreatic cancer in accordance with institutional guidelines.

MATERIALS AND METHODS

Tumor line, animals and drugs
SW1990, a high transferred human pancreatic cancer cell line (ATCC, Kyriazis MD, USA), was maintained in Laboratory of Sun Yat-Sen Memorial Hospital and serially passed in nude mice. Five- to six-week-old male BALB/c nude mice were obtained from Animal Center Sun Yat-Sen University. Photosan, a second generation of photosensitizer, was provided by Diolitec Pharmaceutical Company (Germany). Gemcitabine was provided by Lilly Pharmaceutical Company (USA).

Animal model and therapeutic group
Two male nude mice (6 wk of age) were inoculated subcutaneously with 0.5×10^7 SW1990 cells. Tumors in subcutaneous tissue were excised and tumor tissue was implanted subcutaneously in 60 nude mice.

A tumor model was established and observed for 10-14 d after implantation of tumor tissue. Tumor-bearing nude mice were divided into control group (group A), photosensitizer group (group B), chemotherapy group (group C), PDT group (group D), and combined group (group E), with 12 mice in each group.

Forty-eight hours after the mice had photosan, tumor masses in mice of the PDT group and combined group were exposed to light (λ = 630 nm, 120 J/cm^2) from a PDT630 semiconductor laser (Diolitec Pharmaceutical Company) for 20 min. Gemcitabine (50 mg/kg) was injected into the peritoneal cavity of mice in the combined group 1 h prior to light exposure and on days 3, 6 and 9 after light exposure. The same dose of gemcitabine was given to mice in the chemotherapy group at the same time point as in the combined group.

Data collection
All experimental mice were weighed and tumor diameters were measured with vernier calipers before treatment and twice a week after treatment. On day 21 after treatment, all experimental mice were sacrificed with their tumors removed and weighed to obtain tumor weight (TW). Tumor volume (TV) was determined according to the formula: TV = $3/4 \times \pi \times (b/2)^2 \times a/2$, where a is the length and b is the height of the tumor. Antitumor activity was evaluated by tumor growth inhibition (TGI), calculated according to the formula: TGI = $(1 - TW_T/TW_C) \times 100\%$ in treated (T) and control (C) mice.

Statistical analysis
Data analysis was performed using SPSS11.0 statistical package (SPSS, Chicago, USA). Tumor response to treatment was compared using two-way ANOVA and Student-Neuman-Keuls test. $P < 0.05$ was considered statistically significant.
RESULTS

Tumor volume
Tumor volume increased with time after treatment in the photosensitizer group, small dose chemotherapy group and control group (Table 1 and Figure 1). Tumor volume had no significant difference at the same time point in three groups (ANOVA).

PDT led to necrosis in cancer lesions. Partial tumor necrotic tissue was exfoliated and a necrotic edge of volcano-like uplift was formed 1 wk after treatment. Tumor volume was significantly reduced in PDT treatment group compared with the photosensitizer treatment group and control group at different time points after initialization of therapy (ANOVA, $P < 0.05$). No significant difference in tumor volume was found on days 3, 6, 9 and 12, but tumor volume increased significantly on days 15, 18 and 21 ($P < 0.05$) in the PDT group after treatment.

Groups	Pre-therapy	3 d	6 d	9 d	12 d	15 d	18 d	21 d	P

Table 1 Tumor volume in different groups after treatment with PDT and/or gemcitabine (cm^3) (mean ± SE)

Variance-test, $P > 0.05$.

Figure 1 Tumor volume in different groups after treatment with PDT and/or gemcitabine (cm^3) (mean ± SE).

Tumor volume was significantly decreased in the combined PDT and gemcitabine treatment group compared with photosensitizer treatment group, small dose chemotherapy group and control group ($P < 0.05$). Tumor volume was significantly smaller in the combined treatment group than in the PDT group at different time points after treatment.

Tumor weight and TGI

Tumor weight and TGI of mice in five groups are listed in Table 2. Tumor weights of mice in the combination group (0.29 ± 0.20 g) and PDT group (0.69 ± 0.23 g) were significantly lower than those in the photosensitizer treatment group (1.62 ± 0.12 g), chemotherapy group (1.37 ± 0.19 g) and control group (1.65 ± 0.21 g) ($P < 0.01$). Tumor weights of mice in the combined group were obviously lower than those in the PDT group ($P < 0.01$). The mean tumor weight of mice in the two groups was significantly different ($P < 0.01$). Tumor weights were not significantly different in the photosensitizer treatment group, small dose chemotherapy group and control group. TGI (82.42%) was higher in the combined treatment group than in the PDT treatment group (58.18%).

Toxicity

The mice in four experimental groups had a loss of weight during the experiments. The weight in the four experimental groups was not significantly different from that in the control group.

Four treatment modalities did not induce signs of toxicity such as diarrhea and vomiting. No treatment-

related deaths occurred. Mice in the PDT group and combined treatment group had no skin photosensitivity to light.

DISCUSSION

PDT may be defined as a treatment based on an oxygen-dependent reaction between a photosensitizing dye and light, that is, the light combination of two absolutely non-toxic elements, drug and light, in the presence of oxygen, can result in selective destruction of tissue[11,26]. The technique consists of administration of a tumor-localizing photosensitizing agent, which most often requires metabolic synthesis followed by activation of the agent by light with a specified wavelength. Photosensitizing agents used in PDT are macromolecular materials, which contribute to preferential location in neoplastic tissues and delay clearance of neoplastic tissues[27]. Therefore, PDT aims at a sequence of photochemical and photobiological processes that cause irreversible damage to tumor tissues and little damage to connective tissues, and maintain the mechanical integrity of organs[12,24]. It was reported that PDT has a selective effect on malignant pancreas but no significant effect on normal pancreas, and could well match other treatment modalities, except for radical surgery[28]. In a pilot clinical trail, Bown *et al*[10] used PDT in the palliative treatment of 16 patients with cancers in the pancreatic head that could not be treated with surgery because of the advanced nature of the disease or the general condition of the patients, and they concluded that PDT may be of value for treating localized cancers in patients who are poor candidates for definitive surgery or in whom the location of tumor makes pancreatic resection inappropriate. Abulafi *et al*[29] and Tseng *et al*[30] reported that patients with pancreatic and ampullary carcinoma

who are not suitable for surgery should be treated with PDT, since PDT is both feasible and safe for small tumors.

PDT, on the other hand, has some disadvantages and limitations. Little information is currently available concerning the uptake of photosensitizer by pancreas or pancreatic cancer. Local spread of photodynamic agents to vital organs is common, and may cause perforation of the duodenum and jejunum, leading to death after treatment with PDT[11,31]. In addition, large tumor mass limits PDT to penetrate into the effective depth of tissue and needs multiple interstitial optical fibers to increase its volume[32]. Therefore, the ability of chemotherapeutic agents to enhance the effects of PDT in cell culture and transplantable mouse tumors has been studied by several groups[20-22]. Kirveliene et al[20] used murine hepatoma MH-22A to investigate in vitro and in vivo cytotoxic and anti-tumor effects of doxorubicin (Dox), a conventional anticancer drug, and PDT, showing that Dox potentiates therapeutic efficacy of PDT and vice versa, and that the degree of potentiation is influenced by Dox. Peterson et al[21] and Snyder et al[22] reported that combined treatment with PDT and Dox is more effective than treatment with either PDT or Dox alone. In vitro studies have revealed a significant effect of fluoropyrimidines[18] and mitomycin C[19] on the viability of mTHPC-photosensitized cells. Some studies focused on the effects of PDT on pancreas cancer[10,11]. As we know, no study about the effect of therapy with photodynamic-cytotoxic agents on pancreatic cancer has been reported.

Gemcitabine is an active nucleoside analogue against a wide variety of cancers, including non-small cell lung cancer and pancreatic cancer[7-9]. Gemcitabine, acting as an antimetabolite, can inhibit ribonucleotide reductase and DNA synthesis, and induce apoptosis[33]. Gemcitabine today remains a first-line drug for patients with advanced pancreatic cancer[7-9]. However, it has a narrow therapeutic index due to rapid enzyme deamination by deoxytidine deaminase into its corresponding inactive uracil derivative, and can also induce drug resistance[34,35]. Therefore, a high dose of gemcitabine is needed to achieve the desired therapeutic response with different adverse effects[36]. To overcome such drawbacks, based on the relation between quantity and effect of gemcitabine[25], we used photosan and gemcitabine as representatives of photosensitizing and cytotoxic agents to investigate the cytotoxic and antitumor effects of gemcitabine and PDT on pancreatic cancer in vivo. The results indicate that small dose gemcitabine or photosensitizer can not inhibit the growth of pancreatic cancer. PDT had a significant anti-tumor effect, but lasted a short time. Photodynamic-cytotoxic therapy (small dose gemcitabine) could significantly inhibit the growth of pancreatic cancer, and showed a relative long-duration anti-tumor effect compared with PDT. The inhibition rate of photodynamic-cytotoxic agents and PDT for tumors was 82.42% and 58.18%, respectively. The four treatment modalities did not induce any signs of toxicity such as diarrhea and vomiting. No treatment-related death occurred. Animals in the PDT group and combined treatment group had no skin photosensitivity to light.

In conclusion, low dose gemcitabine increases the anticancer effect of PDT with no obvious adverse effects. Combined PDT and gemcitabine can be used in treatment of pancreatic cancer in patients who are poor candidates for surgery.

COMMENTS

Background
Most patients with pancreatic cancer are at advanced stage when apparent symptoms occur. Treatment of pancreatic cancer remains a great challenge, and new treatment modalities are urgently needed. In this study, gemcitabine was used as a cytotoxic drug, and cytotoxic and antitumor effects of combined gemcitabine and photodynamic therapy (PDT) were evaluated.

Research frontiers
Gemcitabine may have a value in treatment of pancreatic cancer. Recently, more studies on PDT have been focused on solid pancreatic caner. The prognosis of pancreatic cancer is poor. This is the first report on the synergetic anticancer effect of combined gemcitabine and PDT on pancreatic cancer in vivo.

Innovations and breakthroughs
The results of this study indicate that PDT-cytotoxic therapy (small dose gemcitabine) could significantly inhibit the growth of pancreatic cancer, and showed a relative long duration of anti-tumor effect compared with PDT. This study first demonstrated that low dose gemcitabine could increase the anticancer effect of PDT with no obvious adverse effects.

Applications
Combined PDT and gemcitabine therapy can be used in treatment of patients who are poor candidates for surgery.

Terminology
PDT is a way to produce local tissue necrosis with light (most conveniently from a laser) after administration of a photosensitizing agent in the presence of oxygen. PDT is based on the use of photosensitizing compounds that localize quite selectively in neoplastic/hyperplastic tissues and become cytotoxic when exposed to light.

Peer review
The study revealed that PDT can significantly inhibit the growth of pancreatic cancer, and its effect could be significantly enhanced by a small dose of gemcitabine. The findings are of great interest and provide a foundation for its application in clinical practice. The data are reliable and valuable.

Abstract

AIM: To evaluate the diagnosis of chest pain with foregut symptoms in Chinese patients.

METHODS: Esophageal manometric studies, 24-h introesophageal pH monitoring and 24-h electrocardiograms (Holter electrocardiography) were performed in 61 patients with chest pain.

RESULTS: Thirty-nine patients were diagnosed with non-specific esophageal motility disorders (29 patients with abnormal gastroesophageal reflux and eight patients with myocardial ischemia). Five patients had diffuse spasm of the esophagus plus abnormal gastroesophageal reflux (two patients had concomitant myocardial ischemia), and one patient was diagnosed with nutcracker esophagus.

CONCLUSION: The esophageal manometric studies, 24-h intra-esophageal pH monitoring and Holter electrocardiography are significant for the differential diagnosis of chest pain, particularly in patients with foregut symptoms. In cases of esophageal motility disorders, pathological gastroesophageal reflux may be a major cause of chest pain with non-specific esophageal motility disorders. Spasm of the esophageal smooth muscle might affect the heart-coronary smooth muscle, leading to myocardial ischemia.

INTRODUCTION

Recent reports[1-2] have indicated that recurrent chest pain is often a result of esophageal motility disorders or gastroesophageal reflux diseases (GERD), which is known as esophageal chest pain. Esophageal chest pain is very similar to symptoms seen during myocardial ischemia. It is also observed in patients with coronary artery disease with similar incidence (i.e. linked angina)[3]. As a result, differential diagnosis is often difficult and many patients with esophageal chest pain are misdiagnosed as having coronary artery disease[4]. Hence, the percentage of patients that are correctly treated and cured is relatively low. It is well known that esophageal manometry and 24-h intra-esophageal pH monitoring provide accurate diagnoses of esophageal motility disorders. As an incentive, Holter electrocardiography is more economical for these patients from developing countries compared to coronary artery opacification.

Previous reports have focused on the diagnosis of unclear chest pain via both coronary artery 24-h intra-esophageal pH monitoring and coronary artery opacification, which is very expensive to the patient, particularly in developing countries. In addition, very few studies have shown the efficacy of combined esophageal manometry, 24-h intra-esophageal pH monitoring, and electrocardiograms from Holter

monitoring and the results have been inconclusive. Paterson *et al*[5] reported that there was no correlation between the incidence of chest pain and changes in esophageal manometry, 24-h intra-esophageal pH monitoring, and Holter electrocardiography. Wright *et al*[6] reported that physiologic gastroesophageal reflux does not induce electrocardiographic changes from Holter monitoring. However, Dobrzycki *et al*[7] and Patai *et al*[8] reported distinguishable alterations in 24-h intra-esophageal pH monitoring and Holter electrocardiography during chest pain. As a result, it was thought that simultaneous 24-h esophageal pH manometry and electrocardiograms from Holter monitoring could contribute to the diagnosis of atypical chest pain. However, up to now, many questions remain unaddressed. Can esophageal motility disorders affect myocardial ischemia? Can GERD affect myocardial ischemia? All of these diseases can cause chest pain, so it is unclear how to differentiate between cause and effect in these patients. Is there any clinical significance to the combination of these three types of monitoring in the differential diagnosis of unclear chest pain? Here, we present our experience in the combined application of monitoring over the past 6 years.

MATERIALS AND METHODS

Patients

From September 2001 to May 2007, 61 Chinese patients with chest pain from the thoracic surgery department were enrolled into this study. The patients were both male (27) and female (34), ranging in age from 18 to 69 years (average age: 45.5 years). All patients had complaints of varying degrees of chest pain and most had symptoms of retrosternal pain or backache, ranging in duration from 60 d to 5 years (average duration of pain: 14.5 mo). Twenty patients had intermittent dysphagia and 40 had other symptoms such as regurgitation. There were no abnormalities in their hemogram, chest X-rays, routine electrocardiograms or esophago-gastroscopy.

Methods

Esophageal motility was studied by standard water perfusion and stationary manometry (Medtronic DPT-6000, Smith Medical, Sweden) with computer-assisted analysis (Polygram 2.0, Smith Medical, Sweden) of the tracings according to a previously published protocol[9-10]. Briefly, a station pull-through technique was applied, and measurements were made at the pressure levels of the lower esophageal sphincter (LESP), the relaxation rate of the lower esophageal sphincter (LESRR), the esophageal body, the upper esophageal sphincter and the pharynx.

Twenty-four-hour intra-esophageal pH was monitored using the classical DeMeester criteria[11]. A single channel, nasoesophageal, antimony pH-probe (Synectics Medical, Sweden) was positioned 5 cm above the lower esophageal sphincter and was connected to a portable data acquisition system (Digitrapper Mark II Gold, Synectics Medical, Sweden). Following 24-h intra-esophageal pH monitoring, chest leads at CM1, CM5 and CMF of a digital ambulatory 24-h Holter monitor (Life Card CF, Reynolds Medical, England) were positioned. Holter studies and 24-h pH monitoring were performed simultaneously. Following 24-h monitoring, data from the two monitors were analyzed by software (supplied by Life Card CF, Reynolds Medical, England and Digitrapper Mark II Gold, Synectics Medical, Sweden).

RESULTS

Results interpretation

Esophageal contraction waves following swallowing were classified as (1) peristaltic, (2) simultaneous, (3) interrupted, or (4) dropped. Primary esophageal motility disorders were classified according to Chinese standards[12]: (1) Diffuse esophageal spasm; (2) Nutcracker esophagus; or (3) Non-specific esophageal motility disorders. Abnormal gastro-esophageal reflux was considered when the score was > 14.72. If the decreasing amplitude of the ST segment was above 0.1 mV, chest pain arousing from myocardial ischemia was considered, according to an electrocardiogram obtained from the Holter monitor.

Results of combined examination

In the present case report, 45 of 61 patients had different types of esophageal motility disorders (Table 1). The episodes of pain are shown in Table 1. Results of esophageal manometric studies and 24-h intra-esophageal pH monitoring are presented in Table 2.

Eight patients were diagnosed with myocardial ischemia and non-specific esophageal motility disorders. Two patients were diagnosed with myocardial ischemia and diffuse spasm of the esophagus. Of the above 10 patients, eight had myocardial ischemia, which occurred with simultaneous abnormal gastroesophageal reflux (GERD) (Figure 1).

DISCUSSION

Recurrent chest pain is typically general and difficult to identify. Shrestha *et al*[4] reported that 30% of non-cardiac chest pain was caused by esophageal diseases such as GERD. Since the innervation and location of the esophageal nervous system in the body overlaps with the cardiac nervous system, symptoms are often similar. As a result, patients with esophageal chest pain are often misdiagnosed as having coronary artery disease[13]. Therefore, it is important for physicians to pay particular attention to the differential diagnosis of inconclusive esophageal chest pain.

As for the differential diagnosis of chest pain, there are very few studies investigating combined 24-h intra-esophageal pH and electrocardiograms from Holter monitoring. Several studies[5-6] have found that there is minimal correlation between the incidence of

Table 1   Results of esophageal manometric studies, 24-h intra-esophageal pH monitoring and electrocardiograms from Holter monitoring in 77 patients

Diagnosis	Number cases and pain episodes		Cases combined with abnormal gastroesophageal reflux			Cases combined with myocardial ischemia

chest pain and changes in esophageal dysfunction and myocardial ischemia monitoring, while others have reported the opposite[7,8]. Therefore, in the present study, we reassessed the significance of the combined monitoring. In our study, 45 of 61 patients had esophageal disorders (the rate was 73.7%, which was rather high since the patients were recruited from the thoracic surgery outpatient clinic and some of them had pre-existing upper gastrointestinal symptoms such as dysphagia or regurgitation), and 10 (16.4%) patients had myocardial ischemia. We think that the main reason for the weak correlation between incidences of chest pain and changes in the combined monitoring reported by Paterson et al[5] and Wright et al[6] may be as follows: (1) the number of samples that were selected randomly was relatively small; and (2) there may have been an unknown heterogeneity of patient populations.

Esophageal motility disorders are the most common cause of esophageal chest pain[14]. Non-transmitted contraction waves appeared in all of the 39 patients with non-specific esophageal motility disorders, while 29 patients had abnormal gastroesophageal reflux. Among the total 235 pain episodes, 156 had changes in 24-h pH monitoring, indicating that abnormal gastroesophageal reflux may be the main cause of chest pain in these patients, confirmed by the observation by Patai et al[8] showing that proton pump inhibition with omeprazole alleviated gastroesophageal reflux as well as spontaneous chest pain. Interestingly, exercise potentiated the effect of intra-esophageal pH monitoring on electrocardiogram abnormalities (Badzynski et al[15]).
In the five patients with diffuse spasm of the

esophagus, 20% or more had simultaneous contractions in response to wet swallows. However, some degree of peristaltic function was retained and the differential diagnosis could be made between diffuse spasm of the esophagus and achalasia. All of the five cases were defined as secondary diffuse spasm of the esophagus due to abnormal gastroesophageal reflux[13]. Two patients were diagnosed as having simultaneous diffuse spasm of the esophagus, myocardial ischemia, and GERD. We hereby hypothesize that diffuse spasm of the esophageal smooth muscle might affect spasm of the heart-coronary smooth muscle, leading to myocardial ischemia. All of these could be caused by a disturbance of the nervous system controlling the esophagus and cardiovascular system. It is interesting that this presumption is supported by Manfrini et al[16], in which esophageal spasm was considered to be related to myocardial ischemia ($P < 0.05$). Bidirectional analysis of causal effects showed that the influence between esophageal and coronary spasms was mutual and reciprocal in seven patients with variant angina. In two patients in our study, 25 pain episodes occurred with eight episodes causing changes in 24-h pH and Holter monitoring. This fact indicates that myocardial ischemia may occur with GERD, especially in patients with diffuse spasm of the esophagus.

Amplitude of the contractive wave in the patients with nutcracker esophagus was 229.7 mmHg, consistent with the diagnostic criteria[17].

Hence, combined monitoring of esophageal manometry, 24-h intra-esophageal pH and electrocardiograms from Holter monitoring are very

Figure 1 Curves of 24-h intra-esophageal pH monitoring and Holter electrocardiography in a patient with abnormal gastroesophageal reflux show the decreasing amplitude of the ST segment. A: Ranged from 0.05 mV to 0.15 mV in 9 min. The results also indicate that abnormal gastroesophageal reflux occurred during this period; B: 0.1 mV to 0.3 mV in from 12:38:07 to 20:50:02. The results also indicate that abnormal gastro-esophageal reflux occurred during this period.

significant for the diagnosis of recurrent chest pain, particularly for patients with foregut symptoms. We therefore, suggest that the diagnostic procedures of cloudy chest pain should be undertaken as follows. Firstly, the patients with cloudy chest pain should undergo routine examination including hemogram, chest X-rays, routine electrocardiogram and esophago-gastroscopy, in order to exclude severe diseases such as tumor or myocardial infarction. Secondly, the combined examinations should be recommended to the patients without the positive results of the routine examinations and with foregut symptoms as the "final step" in the diagnostic procedures. The detection rate is satisfactorily high, as shown in our cases. In conclusion, as an added incentive, the combined monitoring is very cost-effective for the patients, with a total cost of approximately 50 US dollars.

COMMENTS

Background
Studies on unclear chest pain are timely and important with the growing age of the world's population. However, very few studies have been performed about esophageal manometric studies, 24-h intra-esophageal pH monitoring and a Holter electrocardiography for the differential diagnosis of chest pain caused by esophageal dysfunctional and/or myocardial ischemia. Interestingly, the results of published papers on the combined monitoring have been inconclusive.

Research frontiers
The aim of the present study was to evaluate the significance of combined monitoring in the diagnosis of chest pain with foregut symptoms in Chinese patients.

Innovations and breakthroughs
The study indicated that spasm of the esophageal smooth muscle might affect the heart-coronary smooth muscle, leading to myocardial ischemia. The combination of esophageal manometric studies, 24-h intra-esophageal pH monitoring and Holter electrocardiography are significant for the differential diagnosis of chest pain, particularly with foregut symptoms. As an added incentive, combined monitoring is very cost-effective for the patients, especially those from developing countries.

Peer review
The manuscript describes an interesting study that aimed to demonstrate the etiology of chest pain. In fact, it is well known that non-cardiac chest pain is associated with GERD in about 50% of cases and that spastic esophageal motility disorders are related to chest pain. This study revisits the conflicting situation concerning the precise primary cause of chest pain, especially in patients in whom myocardial ischemia, GERD and esophageal spastic motility

disorders are simultaneously found. As the authors pointed out, it has been suggested that spastic motility disorders may cause myocardial ischemia.

Abstract

AIM: To assess the efficacy of combined transcatheter arterial chemoembolization (TACE) and percutaneous microwave coagulation therapy (PMCT) for small hepatocellular carcinoma (HCC).

METHODS: Thirty-five patients with a total of 41 HCC nodules ($\leqslant$ 3 cm in diameter) were treated with TACE followed by computed tomograghy (CT)-guided percutaneous microwave coagulation therapy (PMCT) within 1-3 wk.

RESULTS: By biopsies and enhanced CT scans, complete necrosis of the tumor and 3-5 mm of the surrounding non-cancerous area were observed in 34 foci. In seven foci, incomplete necrosis of the surrounding parenchyma was observed. Serum alpha-fetoprotein (AFP) levels returned to normal 10 d after treatment in 25 patients who originally had high serum AFP levels. The follow-up period was 6-31 mo, and all patients remained alive. One patient had a recurrence in the subsegments of the liver, and another patient had a recurrence near the original lesion.

CONCLUSION: Combined therapy with TACE and PMCT is a safe and effective treatment without severe complications for small HCC.

Combined therapy with transcatheter arterial chemoembolization and percutaneous microwave coagulation for small hepatocellular carcinoma. *World J Gastroenterol* 2009; 15(6): 748-752 Available from: URL: http://www.wjgnet.com/1007-9327/15/748.asp DOI: http://dx.doi.org/10.3748/wjg.15.748

INTRODUCTION

Surgical resection[1], transcatheter arterial chemoembolization (TACE), and percutaneous ethanol injection (PEI)[2-4] are effective therapies for small hepatocellular carcinoma (HCC). However, for patients with poor liver functions, hepatectomy is not the first treatment choice. TACE is not effective for HCC with a poor blood supply[5], and PEI only yields incomplete necrosis of the tumor due to the uneven distribution of ethanol[6]. Although percutaneous microwave coagulation therapy (PMCT) can lead to complete necrosis of the hepatocarcinoma cells, the induced area of necrosis is small[7,8]. TACE has the advantage of reducing the local blood supply of the tumor foci, resulting in tissue necrosis and inflammatory edema. Therefore, it can decrease the cooling effect of blood flow on the heating action of microwaves, and enhance the coagulation action of microwaves[9]. In the present study, we investigate the therapeutic efficacy of the combied therapy of TACE and PMCT for the treatment of small HCC.

MATERIALS AND METHODS

Patient data

A total of 35 patients received the combined therapy of TACE and PMCT in our hospital between April 2005 and May 2007. These patients comprised 27 males

and eight females, with an age range of 27-78 years, and a mean age of 56.69 ± 14.02 years. All patients had a history of hepatitis B and liver cirrhosis, with liver functions categorized as class A by Child-Pugh classification. All of the cases met the diagnostic criteria of primary HCC. Twenty-eight cases were confirmed by pathological examination of puncture-biopsied specimens under the guidance of computed tomograghy (CT) before PMCT. Twenty-five cases had elevated levels of serum alpha-fetoprotein (AFP). The size of the tumor focus was determined by measurement of the largest and shortest diameters of the largest section. All tumor foci were less than 3 cm in diameter.

Therapeutic methods

All patients were initially treated with TACE. Hepatic artery angiography was performed using the Seldinger technique. Femoral arterial catheterization was conducted through the common hepatic artery or proper hepatic artery, and the location, number, size, and blood supply of the tumors were evaluated. Subsequently, a microcatheter was super-selectively inserted into the hepatic lobe or hepatic segmental artery branch, and mixed suspensions of iodized oil (3-6 mL) and epirubicin (20-30 mg) were infused into the artery through the catheter. Finally, gelatin sponge particles were infused to embolize the artery until the arterial blood flow supplying the tumor was completely blocked.

PMCT was initiated 1-3 wk after TACE. The microwave therapeutic device, FORSEA MTC-3 for inter-tissue tumor treatment, was produced by Nanjing Qinghai Microwave Electric Institute (Nanjing, China). The diameter of its electrode needle was 14 G, and the instrument was cooled by a cold water cycling system. To relieve pain in the patients, dolantin (100 mg) and valium (10 mg) were injected intramuscularly 5 min before the PMCT.

The puncture site and pathway were determined under the guidance of CT. After anesthetizing the puncture site with 2% lidocaine, a 12 G guide-needle was placed at its opposite side, across the tumor focus. The electrode needle of the microwave device was connected to the output machine of the microwave instrument via a flexible coaxial cable, and the cooling water tube was connected. The constant-flow pump was switched on to test the functioning of the cold water cycling system. The inner needle of the guide-needle was withdrawn, and the electrode needle of the microwave machine was inserted through the outer needle of the guide to place the electrode in the tumor area. The microwave power was set at 60-70 W. The coagulation time for each focus was 10-15 min, and the coagulation area covering the tumor focus and its surrounding area measured 5 mm or more. If a single needle coagulation treatment did not produce satisfactory results, a second PMCT therapy was conducted a week later.

After TACE and PMCT treatment, liver protection, anti-inflammatory and sedation therapies were prescribed. A follow-up study by repeat CT (plain and enhanced) and serum AFP level measurement was conducted once every 1-2 mo.

Figure 1 Pathological examinations of biopsied specimens and enhanced CT after PMCT showed complete tumor necrosis in 34 foci, together with complete ring-shaped necrosis of the surrounding non-cancerous hepatic parenchymal tissue, measuring 3-5 mm in width. A: CT scan of a primary HCC in the right anterior lobe of the liver, with a diameter of 1.6 cm × 1.4 cm; B: After TACE, the accumulation of iodized oil in the tumor area was satisfactory; C: PMCT was initiated 17 d later; D: One month after PMCT, an enhanced CT scan showed a complete non-enhanced area of the tumor, and a non-cancerous ring-shaped area surrounding the tumor (measuring 4-5 mm), indicating complete necrosis of the tumor lesion.

RESULTS

One to three weeks after all 41 foci were treated with TACE, these foci received PMCT treatment once. Among them, six foci were treated with a second PMCT within 1 wk.

Pathological examinations of biopsied specimens and enhanced CT after PMCT showed complete tumor necrosis in 34 foci, together with complete ring-shaped necrosis of the surrounding non-cancerous hepatic parenchymal tissue, measuring 3-5 mm in width (Figure 1). Seven other foci showed complete necrosis of the tumor, with incomplete necrosis of the surrounding non-cancerous hepatic parenchyma.

Among the 35 patients, serum AFP levels were elevated in 25; the AFP levels in these 25 patients returned to normal within 10 d after treatment.

Post-embolization symptoms included fever, pain, nausea, and vomiting after TACE, all of which were relieved by anti-inflammatory, liver protection, and sedation treatment. In the process of PMCT, most patients complained of local burning pain, which was generally tolerable, but in some patients, the microwave coagulation therapy had to be carried out intermittently.

After PMCT, some patients reported having fever and local pain, but these were not severe. Complications such as hemorrhage, subcapsular hematoma of the liver, or biliary duct damage were not found, nor was local dissemination of cancer cells along the puncture needle pathway.

All patients were followed up for 6-31 mo. No recurrence was found in 33 patients. One patient had a gradual increase of serum AFP levels 10 mo after the treatment, but repeat CT and magnetic resonance imaging (MRI) examinations revealed no recurrence. However, hepatic arteriography detected new tumor foci in the segments of the liver. Another patient showed an elevation of serum AFP levels 8 mo after treatment, and a CT scan showed recurrence in the lateral side of the original focus. The recurring foci were all treated with TACE and PMCT again. All patients remained alive during the follow-up period.

DISCUSSION

The mechanism of PMCT for HCC is based on the heating effect of microwaves and the sensitivity of the tumor to the heating action. The high temperature produced by the electrodes inserted into the tumor tissue results in the rapid coagulation and necrosis of the tumor tissue, thus achieving the goal of destroying the tumor. The area of PMCT is related to the diameter and number of the microwave electrode, the output power of the machine, coagulation time, and local blood circulation[7,10-13]. Increases in the diameter of the electrodes, the output power, and the coagulation time may enlarge the treatment areas of PMCT. However, increasing the diameter of the electrodes may also lead to increased rates of post-puncture hemorrhage, and an extension of the coagulation time may result in more pain for the patients. In practice, the diameter of the electrode and the output power of the microwave therapeutic machine are constant. Therefore, reducing the local blood supply is the only approach to achieving the goal of increasing the PMCT area.

It is well known that primary HCC possesses an abundant blood supply. TACE through the hepatic artery, especially the injection of iodine oil and gelatin sponge particles, blocks the artery supply to the tumor. The iodine oil can fill up the portal vein surrounding the tumor through the communication branches connecting the arterial and portal veins[14,15]. Thus, it can decrease the blood flow volume of the portal vein, and alleviate the adverse cooling effect induced by abundant blood flow[16,17]. In addition, TACE can result in ischemia of the tumor tissue and inflammatory edema, which accelerates tumor necrosis and enhances the coagulation effect of microwaves[18]. This forms the theoretical basis for the combined therapy of transcatheter hepatic artery chemoembolization with percutaneous microwave ablation for small HCC. Ishida et al[19] used hepatic artery embolization combined with a temporal block of the hepatic vein to reduce the segmental blood supply to the tumor. The therapeutic range of PMCT was increased;

however, the procedures were too complicated to be practiced often.

Primary HCC is a malignancy that usually develops from liver cirrhosis, and is likely to have multiple foci. Although modern advanced diagnostic imaging techniques (spiral CT and MRI) can detect tumor nodules smaller than 1 cm, the detection rate is quite low. TACE therapy prior to PMCT enhances the efficacy of the latter. In addition, TACE can also help detect nodules that are undetectable by conventional imaging techniques, because digital subtraction angiography and the so-called iodine oil-CT are still the best methods for the detection of small HCC. Another advantage of TACE therapy prior to PMCT is that TACE can quickly and effectively control the foci that are inaccessible to PMCT.

Seki et al[20] treated 18 cases of small HCC of less than 3 cm using PMCT, and achieved complete necrosis in 17 of them. After a follow-up of 12-31 mo, all the patients were still alive. Lu et al[21] treated 67 cases of small HCC of less than 3 cm using the microwave therapy device produced by Nanjing Qinghai Company (Nanjing, China), and achieved a complete necrosis rate of 94% (63 cases). We used a combined therapy of transcatheter hepatic artery chemoembolization with PMCT for 35 cases of small HCC, and achieved complete necrosis in all cases. After a follow-up of 6-31 mo, only one patient had a recurrence at the original tumor site. Liang et al[22] analyzed the correlative factors for the prognosis of 288 HCC patients who received PMCT. They concluded that HCC patients with a single focus of a diameter ≤ 4 cm, and a liver function of Child-Pugh class A can have long-term survival after PMCT. Therefore, PMCT is ideal for small HCC. It can completely substitute for surgical resection, especially for elderly patients or those with a poor general condition or poor liver function[23].

Pathological examinations indicate that HCC is very likely to invade the capsule or extracapsular tissues[24,25]. Therefore, to achieve the goal of complete necrosis of tumor tissue and to increase its overall therapeutic efficacy, PMCT must not only destroy the tumor cells in the center of the tumor, but also destroy the adjacent non-cancerous hepatic parenchyma tissue. The microwave therapy device used in our study could produce coagulative tissue necrosis with a diameter of 4-5 cm under the conditions of an output power of 60-70 W, and a coagulation time of 15 min. By TACE, the area of tissue necrosis using a single needle electrode was even larger, completely covering a liver cancer nodule of ≤ 3 cm, with a tumor-free margin of 5 mm. Among our patients, there was one case of recurrence at the original tumor site, with incomplete liver necrosis of the surrounding non-cancerous liver parenchyma. This was probably due to the invasion of the tumor into the capsule or subcapsular tissues, or an insufficient coagulation time, which resulted in the incomplete killing of the tumor cells.

Compared with ultrasound-guided treatment, the

present study was carried out under guidance of CT and has multiple advantages[26,27]. It allows for determination of the precise locations of the foci, especially after TACE because iodine oil accumulation in the tumor foci makes the identification of their location and range easier. Additionally, when a plain CT scan is unable to clearly show the location of a tumor due to its small size, CT-guided puncturing of the focus can be performed based on the result of the MRI scan, thus reducing the "blindness" of the therapy. Finally, CT-guided liver puncturing has almost no "blind area", and is not affected by the adjacent organ full of gas.

Only mild adverse reactions were reported by our patients treated by PMCT. Local pain, during and after the treatment, was not very severe. No internal bleeding, subcapsular hematoma, biliary duct damage, or spreading of the tumor along the puncturing pathway were found. This suggests that PMCT is a safe therapy. Our results show that the combined TACE and PMCT for small HCC (≤ 3 cm in diameter) is minimally invasive, simple and efficacious. Although further studies are needed, this combined therapy appears to be the first choice of treatment for small HCC that is unsuitable for surgical resection.

COMMENTS

Background
Surgical resection, transcatheter arterial chemoembolization (TACE), and percutaneous ethanol injection (PEI) are effective therapies for small hepatocellular carcinoma (HCC). However, for patients with poor liver functions, hepatectomy is not the first treatment choice. TACE is not effective for HCC with a poor blood supply, and PEI only yields incomplete necrosis of the tumor due to the uneven distribution of ethanol.

Research frontiers
TACE has the advantage of reducing the local blood supply of the tumor foci, resulting in tissue necrosis and inflammatory edema. Therefore, it can decrease the cooling effect of blood flow on the heating action of microwaves, and enhance the coagulating action of microwaves.

Innovations and breakthroughs
In the present study, the authors investigated the efficacy of the combined TACE and PMCT for small HCC.

Applications
The study shows that combined TACE and PMCT for treatment of small HCC (≤ 3 cm in diameter) is minimally invasive, simple and efficacious. Although further studies are needed, this combined therapy appears to be the first choice of treatment for small HCC that is unsuitable for surgical resection.

Peer review
This is an interesting study which shows the advantages of combined TACE and PMCT for small HCC. It may provide useful information for us.

Abstract

Anti-hepatitis B virus (HBV) therapy leads to the emergence of mutant viral strains during the treatment of chronic hepatitis B with nucleos(t)ides analogues. The existence of HBV variants with primary antiviral resistance may be important for treatment choice. We studied two patients with chronic HBV infection by sequencing the HBV polymerase gene. They had adefovir- and tenofovir-related mutations in the viral polymerase, although they had never been treated. These mutations were rtV214A/rtN238T in one patient and rtA194T in the other. Thus, mutations in untreated patients deserve cautious surveillance. These data indicate that mutations that can theoretically confer adefovir or tenofovir resistance may emerge in treatment-naive patients.

Hepatitis B virus mutations potentially conferring adefovir/tenofovir resistance in treatment-naive patients. *World J Gastroenterol* 2009; 15(6): 753-755 Available from: URL: http://www.wjgnet.com/1007-9327/15/753.asp DOI: http://dx.doi.org/10.3748/wjg.15.753

INTRODUCTION

Hepatitis B virus (HBV) infection is a major public health problem, with approximately 350 million individuals chronically infected worldwide. Chronic HBV carriers are exposed to the risk of complications, including chronic hepatitis, cirrhosis and hepatocellular carcinoma. Up to one million people die every year from complications of HBV infection[1].

The discovery and clinical use of antiviral agents, targeting in particular the viral reverse transcriptase, have revolutionized therapy for patients chronically infected with HBV[2]. While each nucleotide or nucleoside produces efficient viral suppression, they induce only modest rates of HBV surface antigen (HBsAg) seroconversion and require long-term administration to control disease in patients. The need for long-term therapy necessitates drug safety and the ability to delay or manage the emergence of resistant HBV strains[3-5]. The clinical benefit of these therapies has been compromised by the emergence of resistant viral strains that carry specific mutations in the polymerase gene[6,7]. Elsewhere, mutations can be observed in treatment-naive patients, but very little is known about the frequency and impact

of these HBV variants[8-11].

In this context, different treatment options for the optimal management of chronic hepatitis B deserve to be mentioned. According to the European Association for the Study of the Liver, interferon alpha or nucleos(t)ides analogues can be used[12]. The indications for treatment, for patients with HBe antigen (HBeAg)-positive or -negative chronic HBV infection, are based on three criteria: serum HBV DNA > 2000 IU/mL, serum alanine aminotransferase (ALT) above the upper limit of normal, and liver biopsy showing at least grade A2 or stage F2 by METAVIR scoring. As a summary of recommendations, interferon can be proposed in patients with high baseline ALT (> 3 times upper limit of normal) and HBV DNA < 2 × 10^6 IU/mL at baseline. Interferon gives higher rates of HBeAg and HBsAg seroconversion but has frequent side effects. The second option is treatment with nucleos(t)ides analogues with potent antiviral efficacy, good tolerance but lower rates of HBe and HBs seroconversion, possibly indefinite duration of treatment, and risk of HBV resistance.

In the context of the introduction of HBV sequencing in the Virology Laboratory of Strasbourg University Hospital, with the aim to explore genotypic viral resistance, 14 untreated patients with chronic HBV infection were investigated for the HBV polymerase gene. Two of 14 patients showed, in the absence of treatment pressure, mutations theoretically linked to adefovir and tenofovir pressure.

CASE REPORT

In December 2005, a 50-year-old Vietnamese man was diagnosed with chronic HBV infection, without co-infection by hepatitis delta virus, hepatitis C virus (HCV) or human immunodeficiency virus (HIV). This diagnosis was established by exploring asthenia associated with arthralgia. As mentioned during the medical investigation when the patient was admitted to the University Hospital of Strasbourg, the infection was acquired by vertical transmission, which is common in Asia[13,5]. At the time of diagnosis, HBsAg and HBeAg were positive and anti-HBc antibodies were detected. The patient's ALT and aspartate aminotransferase (AST) values were seven times the upper limit of normal. The viral load was 1.08 × 10^8 IU/mL (COBAS TaqMan HBV test; Roche Diagnostics). In March 2006, a liver biopsy confirmed the diagnosis of chronic hepatitis B with moderate activity and extensive fibrosis (Metavir score A2F3). Sequencing of the HBV polymerase (TRUGENE® HBV genotyping kit; Siemens Medical Solutions Diagnostics, France) revealed two mutations potentially linked to adefovir resistance: rtV214A and rtN238T (confirmed by a second sequencing).

The second patient, a 35-year-old Moroccan man, was diagnosed with HBV infection in May 2003, without co-infection by hepatitis delta virus, HCV or HIV. He presented no past history of hospitalization, transfusion or drug addiction. HBsAg was positive, HBeAg was negative, and anti-HBc antibodies were detected in the absence of anti-HBs antibodies. The viral load was 43 200 copies/mL (Amplicor HBV test; Roche Diagnostics). ALT and AST values were normal. A liver biopsy performed in July 2003 confirmed the diagnosis of chronic hepatitis B (Metavir score A1F0). Therefore, a simple follow-up was proposed to the patient. In December 2005, sequencing of the viral genome revealed an rtA194T mutation of the polymerase (confirmed by a second sequencing), possibly linked to tenofovir resistance.

DISCUSSION

In these two cases, viral variants with mutations that confer potential adefovir or tenofovir resistance were discovered in patients who had never been treated.

The rate of selection of adefovir resistance is around 30% after 5 years of treatment. Adefovir resistance is associated with a primary mutation in the D domain at rtN236T. In addition, a number of other mutations have been detected that cluster into three distinct regions of the polymerase: the D and A domains (rtP237H, rtN238T/D, rtV84M and rtS85A); the B domain at rtA181T/V; and the C-D interdomain (rtV214A, rtQ215S). These mutations may be regarded as secondary resistance mutations, as they are associated only with very low-level resistance *in vitro*. These secondary mutations have also been detected in the absence of rtN236T (both alone and in combination) in patients who have either not responded or have had a virological breakthrough during adefovir treatment[6]. The rtN238T mutation may be involved in disruption of triphosphate binding in viral polymerase. However, other authors have suggested that background polymorphisms including rtV214A and rtN238T could exist without any impact on antiviral treatment failure[8].

Tenofovir resistance conferred by rtA194T in association with the changes that cause lamivudine resistance, i.e. rtL180M and rtM204V, has been observed in individuals who are co-infected with HBV and HIV-1[14,15]. However, the analysis reported by other authors has not provided a clear association between rtA194T and viral load rebound[4]. Thus, the potential impact of this mutation on tenofovir susceptibility deserves further study.

Two hypotheses come to mind. The first one is that the mutations appeared in the course of the chronic infection. The probability of selecting antiviral resistance is usually proportional to the intensity of selection pressure and the diversity of HBV quasispecies[6]. In our cases, treatment was not the means of selection pressure that allowed the mutated clones to take over. In our study, the pressure may correspond to the patients' immune system, or the mutant clones that bear the rtV214A, rtN238T or rtA194T mutations may confer a replication advantage on the wild-type virus. This hypothesis suggests that there is a natural polymorphism in the population with chronic hepatitis B, which might predispose to resistance to certain antiviral agents. The second hypothesis is that the patients may have been

infected with strains from other patients who had been treated with the corresponding nucleotide analogues.

Although the fact that two treatment-naive patients were infected by HBV strains with mutations in viral polymerase is interesting, two limitations have to be considered. First, since only 14 patients were studied, the prevalence of these changes in treatment-naive patients cannot be safely established. Large-scale investigations in HBV-infected patients, before any anti-HBV treatment**,** should be conducted in order to determine this prevalence. Second, the changes observed in positions 194, 214 and 238 of HBV polymerase do not represent well-established HBV resistance mutations[4,8]. Based on *in vitro* results, with controversial data reported for the rtA194T change by Delaney *et al*[4] and for rtV214A and rtN238T by Borroto-Esoda *et al*[8], the clinical significance of these mutants remains questionable.

In conclusion, our results concerning HBV mutations in treatment-naive patients that potentially confer resistance suggest the need for studies on large cohorts. By analyzing HBV sequences before antiviral therapy with analogues in treatment-naive patients, the clinical impact of pre-treatment mutations on the efficacy of antiviral therapy may be better characterized[16].

Abstract

A 68-year-old man underwent laparoscopic low anterior resection for rectal carcinoma in December 2006. Nearly 19 mo after the operation, he developed recurrent rectal cancer with peritoneal metastasis. In September 2008, he subsequently underwent a laparotomy with a peritonectomy, omentectomy, splenectomy, and a Hartmann procedure. Hyperthermic intraperitoneal oxaliplatin 750 mg was administered. The patient was discharged with no postoperative complications and has been well with postoperative FOLFOX chemotherapy.

INTRODUCTION

Peritoneal carcinomatosis has a poor prognosis, and survival is generally less than 6 mo once diagnosed[1,2]. Recent advances in the treatment of this disease have resulted in improved, and even long-term, survival for select patients[3-5]. Optimal cytoreduction and adjuvant intraperitoneal chemotherapy have been credited with much of the recent success in the treatment of this cohort of patients. We would like to share our own experience with a complete peritonectomy and intraperitoneal chemotherapy for recurrent rectal cancer with peritoneal metastasis, and to review the relevant literature.

CASE REPORT

A 68-year-old man underwent laparoscopic low anterior resection (LAR) for upper rectal cancer. Histological examination revealed a poorly differentiated mucinous adenocarcinoma with a 4-cm distal margin and the TNM staging was T2N0M0. On routine follow-up, an anastomotic induration was felt on digital rectal examination 19 mo later, which was confirmed to be adenocarcinoma upon endoscopic biopsy. Abdominopelvic computed tomography and positron emission tomography showed multiple soft tissue infiltrations throughout the peritoneum. At laparotomy, a bulky mass around the previous rectal anastomosis and multiple peritoneal metastatic nodules were identified. A complete peritonectomy (Figure 1), complete omentectomy, splenectomy, and a Hartmann procedure were performed successfully with no visible gross disease at the completion of the procedure. Two catheters were inserted in the abdomen and secured: one on the left side aimed toward the pelvis and the other on the right directed up over the liver. The abdomen was closed, and the peritoneal cavity was filled with heated saline at 42℃. Continuous hyperthermic intraoperative intraperitoneal perfusion with 750 mg of heated oxaliplatin was then performed over 90 min. The operating time was 515 min with a moderate blood loss of 500 mL. Histopathology revealed a recurrent mucinous adenocarcinoma in the rectum with a clear resection margin and multiple metastatic nodules in the diaphragmatic, pelvic, and pericolic peritoneum and omentum. His postoperative course was uneventful, and he was discharged on the 25th postsurgical day. He had difficulty voiding, but this was managed conservatively. For 2 mo after the second

Figure 1 The peritonectomy.

operation, the patient has been well with postoperative FOLFOX chemotherapy.

DISCUSSION

Traditionally, there has been consensus in the oncology community that those patients with peritoneal carcinomatosis of colorectal origin were incurable. Neither systemic chemotherapy nor intraperitoneal chemotherapy alone had any significant impact on survival.

Recently, there has been increased interest in re-examining the management of peritoneal metastatic disease, and in utilizing cytoreductive surgery and hyperthermic intraperitoneal chemotherapy[6-9]. Aggressive cytoreductive surgery attempts to eradicate all residual tumor cells, or to significantly reduce the tumor burden, and the infusion of hyperthermic intraoperative intraperitoneal chemotherapy allows a favorable drug distribution to all surfaces at risk, without delay. A randomized trial by a Dutch group demonstrated superior survival with the combined approach over traditional 5-fluorouracil-based systemic chemotherapy, for peritoneal carcinomatosis of colorectal cancer[6]. Moreover, with proper patient selection, minimal morbidity can be achieved, with good overall survival and prolonged disease-free periods. The 11.1% rate of major perioperative complications and no perioperative mortality achieved in this cohort of patients compares favorably with the 27% quoted in the literature[10]. Elias *et al*[11] recently suggested that preoperative intraperitoneal chemohyperthermia with oxaliplatin is better tolerated than early postoperative intraperitoneal chemotherapy with mitomycin C and 5-FU, and is twice as efficient in

curing peritoneal carcinomatosis.

This report describes our initial experience with peritonectomy and hyperthermic intraperitoneal chemotherapy in a patient with recurrent rectal cancer. This combined approach can be a feasible treatment option for the traditionally inoperable recurrent rectal cancer patient with peritoneal metastasis.

Abstract

Pneumatosis intestinalis (PI) is an uncommon disease defined as gas-filled cysts that are found in the wall of the gastrointestinal (GI) tract. The exact causes of PI are still unclear, but it may associated with coexisting diseases, such as some GI disorders, connective tissue disease, some medication and drugs, and rarely malignancy. The most common localization is the small intestine. Gastric PI secondary to malignancy has been rarely documented. We report on a 94-year-old man with gastric PI associated with inoperable adenocarcinoma localized in the duodenum. Following the gastrojejunostomy and choledochojejunostomy bypass, his general condition improved and PI disappeared, but he died due to poor performance status and malignancy 6 mo later. We suggest that in patients presenting with PI, malignancy should be considered in the differential diagnosis.

INTRODUCTION

Pneumatosis intestinalis (PI) is a rare disorder characterized by multilocular gas-filled cysts localized in the submucosa and subserosa of the alimentary tract. It can occur in any part of the gastrointestinal tract (GI), from the esophagus to the rectum, but the small intestine is the most common localization[1-5]. PI may be primarily and secondarily associated with a coexisting disease. Eighty-five percent of patients have secondary PI[1,6,7]. Gastric PI, defined as air within the wall of the stomach, is an uncommon localization[8-12]. On the other hand, gastric PI, secondary to malignancy, has been very rarely reported in the literature[13]. We described here a case of gastric PI associated with adenocarcinoma localized in duodenum.

CASE REPORT

A 94-year-old man was admitted to our hospital with anorexia, nausea, vomiting, fatigue, constipation, weight loss, abdominal bloating and discomfort which started 1 mo previously, in May 2003. He had a prior history of peptic ulcer 15 years ago. He reported a history of upper GI bleeding in 1990. He had no the other systemic diseases, such as chronic obstructive lung diseases, connective tissue diseases, and no history of abdominal surgery. His family history was not contributory. On physical examination, he was dehydrated and afebrile. His blood pressure was 100/80 mm/Hg, pulse was 84/min, and heart sounds and jugular venous pressure were normal. No murmur was detected. Breath sounds were normal and there were no organomegaly or lympadenomegaly. Epigastric and periumblical sensitivity were noted. There was an abdominal distension and hypertympanism found on epigastric sites.

Initial laboratory results were as follows: blood urea nitrogen 23 mg/dL, creatinine 1.1 mg/dL, sodium 140 mEq/L, potassium 3.8 mEq/L, calcium 9.3 mg/dL, alanine aminotransferase 33 U/L, aspartate

Figure 1 Abdomino-pelvic CT scan showing big stomach and multilocular gas within the wall of the stomach (arrows).

Figure 2 Barium-enema study showing luminal obstruction of 80% in the bulber apex.

aminotransferase 27 U/L, γ- glutamyltransferase 428 U/L (N:7-49) alkaline phosphatase 317 U/L (N:38-155), lactate dehydrogenase 412 IU/L, glucose 105 mg/dL, erythrocyte sedimentation rate 40 mm/h, C-reactive protein 136.4 mg/L, total bilirubin 0.78 mg/dL, direct bilirubin 0.13 mg/dL, white blood cells (WBCs) 12 400/mm³, platelets 217 000/mm³, hematocrit 36.3%, mean corpuscular volume 84.9 fL, Fe 47 μ/dL, total iron binding capacity 214 μ/dL, and ferritin 55.4 ng/mL. Serum protein electrophoresis was normal. The patient's tumor marker profile was as follows: carbohydrate antigen 19-9 903.1 U/mL (0-37), carcinoembryonic antigen 12.3 ng/mL (0-3.4). Urine analysis revealed a urine specific gravity of 1010, protein negative, pH 5, and two WBCs per high-power field on urine sediment. Hepatitis B and C serology, and anti-HIV assays were negative. Fecal occult blood test was positive for the one stool sample. Other laboratory values were within normal limits.

The patient was treated with nasogastric intubation, parenteral fluids, ranitidine i.v. and broad-spectrum antibiotics. Because of elevated tumor markers, a diagnostic work-up for possible malignancy was initiated. The plain abdominal radiography (PAR) was normal. Abdominal ultrasonography (US) revealed sludge within the lumen of the gall bladder with findings of hydrops. The intrahepatic bile ducts were dilated (right, 5.3 mm; left, 4.5 mm). Abdomen and pelvic CT scans showed an enlarged stomach and multilocular gas-filled cysts localized in the wall of the stomach (Figure 1). The diagnosis of PI was made. Subsequent magnetic resonance cholangiopancreatography imaging demonstrated sludge with findings of hydrops and dilatation of intrahepatic bile ducts and choledochus. There was a calculius of 2 cm diameter at the neck of gall bladder.

A barium-enema study revealed luminal obstruction of 80% (Figure 2). As a result of these findings, gastroduodenoscopy and biopsy were performed. In the antrum, the ulcer had a 4-5 cm diameter, likely a malignant ulcer, and it was established that the lesion obstructed the lumen in the postbulbar duodenum. Malignancy was not detected in biopsy specimens. After the patient's general condition markedly improved, exploratory laporatomy was performed in the department of general surgery. An inoperable tumor originating from the duodenum

was detected. In addition, the tumor was infiltrated to extra-hepatic bile ducts and vascular structures. Gastrojejunostomy and choledochojejunostomy were carried out. The histopathological examination of biopsy specimens revealed adenocarcinoma infiltration originating from the GI tract. As a result of his age and performance status, we decided to treat with supportive management. Following the surgical procedure, the gas-filled cysts disappeared and his symptoms improved. After 6 mo of follow-up, he died from the the influence of malignancy and poor general condition.

DISCUSSION

PI is an uncommon entity in which gas-filled lesions are accumulated within the GI wall. In 42% of the cases with PI, the small intestine is the most common and the large intestine (36%) the second most common localization; in 22% of patients both small and large intestine are affected[1,2,6]. On the other hand, gastric PI has been rarely documented[8-12]. It can be classified as either idiopathic or of primary unknown etiology (15%) or the secondary type (85%)[1,6,7]. Fifty-five percent of secondary causes are peptic ulcer related to pyloric obstruction, and 3.3% of cases are GI malignancy[2]. In our patient, the gastric secondary type of PI associated with GI malignancy was detected. Gastric PI related to malignancy has been documented extremely rarely[13].

Although the pathogenesis of PI is not well understood, many theories have been proposed. First, the mechanical theory suggests that gas under pressure diffuses into the bowel wall from the intestinal lumen or the pulmonary airway. This theory is probably related to PI caused by trauma, surgery, endoscopy and bowel obstruction. The bacterial theory proposes that bacteria enter the bowel wall and produce gas within the intestinal wall[3,14]. The pulmonary theory proposes that alveolar rupture results in the diffusion of air through the mediastinum into the retroperitoneal space, through the diaphragm, along major vessels in the mesentery, and into the bowel wall. It may explain the occurrence of PI in patients with chronic obstructive pulmonary disease. Finally, there is the mucosal damage theory. It suggests that gas under pressure is forced into the bowel wall

by mucosal disruption. PI associated with peptic ulcer disease, pyloric stenosis and malignancy may probably be explained by this theory[2,3].

PI is usually asymptomatic, but patients can have gastrointestinal symptoms variying in severity, such as abdominal discomfort, distension and pain, rectal bleeding, constipation, meteorism and weight loss. The symptoms are dependent on the localization of PI and on the presence or non-presence of underlying disease[2,3,6]. Our patient also presented with gastrointestinal symptoms and elevated tumor markers. After PI was detected, we initialy started a diagnostic work-up to exclude malignancy as a cause of PI. The work-up revealed an inoperable adenocarcinoma originating from the duodenum. After gastrojejunostomy and choledochojejunostomy, the gas-filled cysts disappeared and the patient improved.

In two-thirds of patients with PI, PAR shows characteristic changes in the bowel. The PAR with our patient was normal, but an abdomino-pelvic CT scan revealed PI. In the literature, additional diagnostic procedures, such as US, CT, MRI, endoscopy and barium contrast studies, have been documented[1,2,5]. There is no special treatment for PI. If underlying diseases are present, it is necessary to treat them[6]. Conservative therapy can be causal or symptomatic. Causal treatments consist of normobaric or hyperbaric oxygen therapy, antibiotic treatment, especially metronidazole, endoscopic puncture and cysts sclerotherapy[6,15-17]. The aim of these therapies is to suppress the etiological mechanisms. Surgical treatments should be avoided unless there are serious diseases, such as malignancy, metabolic acidosis, portal venous gas and severe inflammation[18].

This report constitutes a rare case of gastric PI caused by duodenal adenocarcinoma. In patients with PI, especially localized in the stomach, who have serious GI symptoms and elevated tumor markers, malignancy-induced PI should be considered in the differential diagnosis.

Abstract

A major diagnostic challenge to the evaluation of an incomplete intestinal obstruction is to distinguish between infectious and malignant etiologies. We present a case of an elderly woman complaining of abdominal pain accompanied with nausea and vomiting, and failure to pass gas or stools. Anti-tuberculosis drugs were used to relieve her abdominal pain, and a needle biopsy of the peritoneal cavity showed evidence of primary papillary serous carcinoma of the peritoneum (PSCP). This is a rare description of tuberculosis in the setting of PSCP. This report illustrates the potential complex nature of malignancies, and emphasizes the need to consider coexistence of malignancy and infection in patients, especially in those with risk factors for malignancy who fail with antibiotic therapy.

Key words: Primary papillary serous carcinoma; Peritoneum; Tuberculous peritonitis

Hou XQ, Cui HH, Jin X. Coexistence of tuberculous peritonitis and primary papillary serous carcinoma of the peritoneum: A case report and review of the literature. *World J Gastroenterol* 2009; 15(6): 761-763 Available from: URL: http://www.wjgnet.com/1007-9327/15/761.asp DOI: http://dx.doi.org/10.3748/wjg.15.761

INTRODUCTION

A major diagnostic challenge to the evaluation of peritonitis is to determine whether it represents an infectious or malignant process. In the majority of cases, it is difficult to distinguish them from each other based on their clinical and radiographic data alone, and more invasive testing is usually required to reach a definitive diagnosis. In this report, we describe our experience with a case of peritonitis resulting from the coexistence of two distinct pathological processes.

CASE REPORT

A 59-year-old Chinese woman who was previously healthy presented to our clinic with a 2-mo history of intermittent abdominal pain accompanying general fatigue, subjective low-grade fever, weight loss and night sweats, which were not improved after treatment with over-the-counter antibiotics and traditional Chinese herbal drugs. Ten days before she visited our clinic, she felt her symptoms getting worse with nausea and vomiting, and weight loss of 10 kg within 2 mo. Thereafter, she failed to pass gas or stools which prompted her to seek medical care. She was admitted to 263 Hospital of PLA. A biochemical test showed 6500/mL white blood cells (WBCs), 78% N, 90 g/L hemoglobin, normal tumor markers (including carcinoembryonic antigen (CEA), carbohydrate antigen (CA) 19-9, CA125, alpha fetoprotein (AFP), erythrocyte sedimentation rate (ESR) 148 mm/h), and 135.8 mg/L CRP. Abdominal plain film displayed ascites and incomplete intestinal obstruction. Chest X-ray showed a high density of WBCs in the right middle outer lobe and lymph node calcification in the right trachea bifurcation. Abdominal paracentesis was arranged for further evaluation. Routine test of ascites showed that yellow fluid was translucent, 95% mononuclear cells, 5% polynuclear cells, 6400/μL erythrocytes and 210/μL WBCs, and 1.010 gravity. Protein concentration was 44.7 g/L, glucose was 1.82 mmoL/L, lactate

dehydrogenase was 334 U/L, and adenosine deaminase was 15 U/L. Acid-fast bacillus could not be found in the fluid. Culture of bacteria was negative. Cytology of the fluid was also negative. CEA and AFP of ascites were normal. Ten days after treatment with antibiotics, her abdominal pain was aggravated, and she was transferred to our hospital.

The patient was a cotton spinner prior to retirement and underwent appendectomy 30 years ago. She denied any history of hepatitis or alcohol, tobacco or recreational drug use and had no knowledge of sick contacts. Physical examination showed symptoms of tenacious abdominal wall, deep and rebound tenderness, decreased intestinal sound, but no actual palpable abdominal mass. Liver and spleen were not palpable, shifting dullness was negative.

After admission, tuberculin was positive. Ultrasonography and pelvic cavity computed tomography (CT) showed ascites and mesentery thickening and peritonitis could not be excluded. Blood test results were 100/mL WBCs, 83.8% N, 85 g/L hemoglobin, and 545 000/mL platelets. Routine urine and feces tests were normal. Feces occult blood tests was negative (140 mm/h ESR, 218 mg/L CRP, and 29.6 g/L albumin). Two-thirds of anti-tuberculosis test parameters were positive. Tumor markers (CEA, CA199, CA125, and AFP) were normal. CA, CYFRA, FRER, and TSGF were 153 100 U/mL, 21-1 16.44 ng/mL, > 2000 ng/mL, and 121.45 U/mL, respectively. LTA was positive. Autoimmune antibodies were negative. Abdominal ultrasound showed small encapsulated effusion in abdominal and pelvic cavity. Parietal peritoneum was thick. Ultrasound of the vagina showed metratrophia with no occupying lesions in the pelvic cavity. Chest X-ray showed old tuberculous foci on both lungs and mediastinum. Due to the suspicious appearance of the lesion, a positron emission tomography (PET) scan was performed along with induced peritoneal cavity CT. Diagnostic percutaneous needle biopsy was discussed with the patient and her family, but she denied any invasive tests. PET scan showed an increased metabolic activity in peritoneum, mesentery, and areas of omentum with thick and diffusive lesser tubercles. Local intestinal adhesions or distensions showed incomplete intestinal obstruction.

She began to cough and had a low fever, but biochemical tests could not identify any infectious bacteria in her sputum and feces. Since the patient remained symptomatic, we decided to treat her disease with oral isoniazid, rifabutin, ethambutol, and pyrazinamide. During the first 6 wk, she noticed significant clinical improvements, such as reduction in abdominal pain and ascites, and resolution of tenacious abdominal wall. Body temperature became normal. However, 8 wk after antibiotic therapy, as well as enteral and parenteral nutrition, her condition began to deteriorate. In addition to CT and ultrasonography, the patient underwent percutaneous CT-guided biopsy of the thick peritoneum, which revealed primary papillary serous carcinoma of the peritoneum (PSCP). Although subsequent staging suggested that it was amenable to chemotherapy, the patient was too weak to tolerate the treatment. Finally, therapy failed to improve her condition and she developed liver and kidney failure.

DISCUSSION

The main differential diagnostic considerations of diffuse peritoneal involvement associated with peritonitis include infectious processes (mainly tuberculosis) and malignant neoplastic conditions. Peritoneal involvement is a rare form of abdominal tuberculosis. Peritoneal tuberculosis occurs predominantly in patients aged 20-40 years and is always secondary to other tuberculous lesions and appears to be more common in females than in males. Tuberculosis in females commonly reaches the peritoneum through tubal infection and attacks the tubes during the sexually active period of life[1]. Diagnosis of any extrapulmonary forms of tuberculosis is quite difficult. For example, difficult diagnosis of peritoneal tuberculosis is due to its non-specific clinical manifestations, such as weight loss, abdominal pain, fever, ascites, and vomiting[2-3]. Positive culture of 7.8% *Mycobacterium. tuberculosis* has been reported[4]. Although our patient denied previous medical history of pulmonary or extra-pulmonary tuberculosis, tuberculous infection was diagnosed based on her positive tuberculin test and chest X-ray scan.

PSCP is a rare malignancy that predominantly affects postmenopausal women[5]. Reports suggest that approximately 10% of women diagnosed with ovarian, endometrial or sigmoid carcinoma actually have PSCP[6-8]. Multicentric peritoneal involvement is typical, and omental involvement is particularly common. Extensive calcification of omental caking present in many cases is a useful CT finding for excluding mesothelioma. The absence of ovarian mass is critical for excluding metastatic papillary serous ovarian carcinoma, which otherwise has a similar appearance at CT and is histologically identical to its primary peritoneal counterpart[9]. Some reports indicate a poor prognosis for women with peritoneal carcinomatosis[10-13]. Patients suffering from PSCP usually complain of abdominal distention, pain or pressure, associated with ascites and gastrointestinal symptoms (loss of appetite, nausea, vomiting, and change in bowel habits)[14]. On physical examination, the most common finding is ascites. The clinical presentation is usually indistinguishable from advanced ovarian cancer. Reports suggest that approximately 10% of women diagnosed with ovarian carcinoma actually have PSCP[15].

In this case, a moderate amount of ascites located between intestinal canals was observed by ultrasonography, and a thickened intestinal wall and pronounced enhancement of peritoneum were seen at CT scanning. Most nodules coalesced to form large omental plaques (omental cakes) (Figure 1). The largest plaque was located in the left lower quadrant of the

Figure 1 CT showing pronounced contrast enhancement of peritoneum and thickened intestinal wall. A: Most nodules coalesced to form large omental plaques (omental cakes); B: A moderate amount of ascites located between intestinal canals; C: No actual large abdominal masses.

abdomen, and extended to the pelvis, but did not involve the ovary. There was no calcification within the masses. The size of ovaries was normal. After treatment with anti-tuberculous drugs, the ascites decreased. Two months later, ascites stopped decreasing, suggesting that tissue biopsy is necessary to help its diagnosis. A delayed diagnosis or inadequate treatment, may promote progression to the malignant disease and the risk of life-threatening complications. To the best of our knowledge, this is the first report on the coexistence of PSCP and tuberculous peritonitis in humans.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1212 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: Introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Leader Frontier: Comment on excitement and existing problems of core fields, and offer suggestions for the future research; (3) Topic Highlight: Experts in gastroenterology and hepatology to focus on certain individual hot topics and try to provide answers to the clinical questions on the topics; (4) Observation: Which updates the development of old and new questions, highlights unsolved questions, and provides strategies on how to solve the questions; (5) Guidelines for Basic Research: Which provides Guidelines for basic research; (6) Guidelines for Clinical Practice: Which provides guidelines for clinical diagnosis and treatment; (7) Review Articles: Summarize the representative progress in core scientific disciplines, comment on the research status, and make suggestions for the future work; (8) Original Articles: Originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: Briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: Report a rare or typical case; (11) Letters to the Editor: Discuss and make reply to the contributions published in *WJG*, or introduce and comment on a controversial issue of general interest; (12) Book Reviews: Introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: Guidelines or common understanding for gastroenterology and hepatology from international academic committee.

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials. gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http:// www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: …; B: …; C: …; D: …; E: …; F: …; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that…"

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA, arg* 1, *c myc, c fos, etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www. wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

EDITORIAL

Anal transition zone in the surgical management of ulcerative colitis

Abstract

Preservation of the anal transition zone has long been a significant source of controversy in the surgical management of ulcerative colitis. The two techniques for restorative proctocolectomy and ileal pouch anal anastomosis (RPC IPAA) in common practice are a stapled anastomosis and a handsewn anastomosis; these techniques differ in the amount of remaining rectal mucosa and therefore the presence of the anal transition zone following surgery. Each technique has advantages and disadvantages in long-term functional outcomes, operative and postoperative complications, and risk of neoplasia. Therefore, we propose a selective approach to performing a stapled RPC IPAA based on the presence of dysplasia in the preoperative endoscopic evaluation.

INTRODUCTION

Restorative proctocolectomy and ileal pouch anal anastomosis (RPC IPAA) remain the standard of care in the surgical management of ulcerative colitis; however, controversy persists regarding preservation of the anal transition zone (ATZ). RPC IPAA is performed *via* either a stapled technique or a transanal mucosectomy and endoanal anastomosis, frequently referred to as a handsewn anastomosis. When the stapled technique is utilized, the ATZ is preserved; whereas a mucosectomy is usually performed from the level of the dentate line, therefore eliminating the ATZ and the proximal cuff of rectal epithelium. While the preservation of the ATZ has been shown to improve functional results and reduce operative time and complications, great debate persists regarding outcomes during recurrent or persistent disease and the theoretical risk of malignant transformation. Given the paucity of data in this realm, the long-term fate of the ATZ in the surgical management of ulcerative colitis has yet to be determined.

DEFINING THE ATZ

Defining the anatomy of the ATZ is difficult. Fenger first described the ATZ as "the zone interposed between uninterrupted crypt bearing colorectal-type mucosa above and uninterrupted squamous epithelium below"[1], which he characterized utilizing an Alcian dye technique. This technique is used for staining the ATZ macroscopically as the columnar epithelium stains dark blue, the squamous epithelium does not stain, and the ATZ stains pale blue. The Alcian dye technique delineates the margins of the ATZ from 6 mm below to 20 mm above the dentate line[1] with the median span from 0.73 to 0.89 cm[1,2]. Further studies by Thompson-Fawcett demonstrated that the Alcian dye technique overestimates the length of the ATZ when comparing this to computer mapping of the histological results[2]. Using computer histological mapping, the median upper and lower borders of the ATZ, measured from the

Figure 1 Retained rectal cuff after RPC IPAA.

lower margin of the internal sphincter, were 1.82 and 1.27 cm, respectively, with the dentate line measuring 1.05 cm by histology or 1.16 cm macroscopically above the lower margin of the internal sphincter. The median span was 0.45 cm *versus* 0.73 cm by the Alcian dye technique. This difference in length was accounted for by close examination of the histological specimens. The pale blue zone was due to staining of both superficial nuclei of thin squamous anoderm and the transitional epithelium that characterizes the ATZ. Fenger's technique for analyzing the ATZ did not exactly match the macroscopic Alcian blue specimens to the histological specimens, in comparison to Thompson-Fawcett's computer histological and Alcian dye mapping, and therefore likely overestimated the ATZ.

After careful measurements aided by computer mapping, the ATZ is now recognized to be smaller than previously considered. Significantly, columnar epithelium exists lower in the anorectal canal, and it is left behind when a stapled technique is utilized, which could be of consequence following RPC IPAA (Figure 1).

PRESERVATION OF THE ATZ: FUNCTIONAL OUTCOMES AND COMPLICATIONS

Duthie and Gairns in 1960 described a vast array of sensory nerve endings in the anal canal[3], which demonstrated sensitivity to temperature, touch, and pain, while the rectal mucosa lacked this innervation and sensation[3,4]. The rectum is able to sense distension, however, that results in a brief reflexive relaxation of the internal anal sphincter and contraction of the external anal sphincter, thus allowing the anal mucosa to sample the rectal contents. This sampling is thought to aid the ATZ in discrimination between gas, liquid, and solid stool. Anorectal sensation is abnormal in incontinent patients[5,6] and in patients following mucosectomy[7,8]. Thus, the extensive innervation of the ATZ is thought to play a very important role in maintaining fecal continence.

Following RPC IPAA *via* stapled or mucosectomy with endoanal anastomosis techniques, patients demonstrate decreased anal resting pressure (ARP)[9-13], thought to occur secondary to the extent of dissection, level of rectal transection, diameter of the stapling

device, and anal retraction. However, ARP is greater following RPC IPAA stapled anastomoses than following mucosectomy with endoanal anastomoses[8,10,11,14,15]. Controversy exists regarding improvement of ARP over time when comparing the two surgical techniques. ARP has been demonstrated to return to a normal value by 12 mo after the operation only in RPC IPAA *via* a stapled technique[9], whereas Tuckson *et al* demonstrated no significant improvement in ARP 13 mo after either technique[10]. Both these studies analyzed a very small group of patients, with relatively short follow-up.

Functionally, preservation of the ATZ *via* RPC IPAA stapled anastomosis improves clinically relevant outcomes. Three prospective randomized controlled trials were performed in the early 1990s with limited numbers of patients (between 23 and 41 in each study). The results showed only limited benefit for stapled anastomosis with no worse outcomes[15-17]. More specifically, Luukkonen *et al* demonstrated no statistically significant differences between the only two functional parameters measured: number of nocturnal bowel movements and frequency of mucous leakage[17]. Choen *et al* also argued that many functional parameters showed no differences including frequency of bowel movements, number of nocturnal bowel movements, ability to delay defecation, and full continence[16]. However, Reilly *et al* demonstrated trends towards improved functional outcomes in all parameters measured: nocturnal seepage, daytime continence, ability to differentiate stool and flatus, and pad usage[15].

Other studies more clearly outline the functional benefit of stapled anastomoses. Remzi *et al* showed that patients with stapled anastomoses had better outcomes in every functional category measured, including statistically significant differences in incontinence, daytime and night-time seepage, and pad usage[18]. Saigusa *et al* described an improved ability to discriminate between flatus and stool in the stapled *versus* handsewn group, 80% *versus* 33% ($P < 0.05$)[8]. Michelassi *et al* found that between 57% and 78% of patients were always able to delay a bowel movement until convenient; although this did not differ between the two groups[19]. These authors also demonstrated that stapled patients had improved rates of full continence, which persisted over time. Sagar *et al* studied stapled IPAA patients only for 12 mo postoperatively and compared parameters at 3 and 12 mo[9]. They showed that not only were functional outcomes better in the stapled IPAA group, but outcomes improved over time. Statistically significant improvements in the number of bowel movements ($P < 0.001$), number of nocturnal bowel movements ($P < 0.001$), frequency of loose stool consistency ($P < 0.001$), use of anti-diarrheal medication ($P < 0.01$), ability to defer defecation for more than 15 min ($P < 0.001$) and ability to discriminate flatus from stool ($P < 0.001$) were demonstrated. A single meta-analysis of 4183 patients (2699 handsewn and 1484 stapled IPAA) demonstrated no significant differences in the number of bowel movements, number of nocturnal bowel movements, daytime seepage, and use of anti-diarrheal

medication[14]. However, incontinence was more common in the handsewn group (P = 0.009) and the incidence of nocturnal seepage and nocturnal pad usage favored the stapled IPAA group (P < 0.001 and P = 0.007, respectively). Both groups were rated with a high quality of life with no statistically significant difference between the groups.

Early septic complications can occur following stapled or handsewn IPAA and may include anastomotic dehiscence with diffuse or localized sepsis, abscess, and fistula formation. These septic complications may require prolonged hospitalization, interventional procedures, reoperation, and pouch excision, therefore resulting in increased patient morbidity, prolonged recovery, and loss of bowel continuity. Risk factors for pelvic sepsis include ulcerative colitis, ulcerative colitis associated with toxic megacolon or fulminant colitis, male gender, and a handsewn anastomosis[20]. More than a two-fold increase in the rate of septic complications has been reported following handsewn versus stapled anastomoses[14,20,21], which results in increased rates of pouch failure requiring permanent diverting ileostomy[14,20,22] and more frequent pouch excision[14,21]. Pouch failure and pouch excision occur secondary to anastomotic dehiscence, poor functional results, pouchitis, perianal disease, and pouch leakage. Risk factors for pouch failure have been outlined and include handsewn anastomoses, anastomotic tension, use of diverting ileostomy, Crohn's disease, and postoperative anastomotic leak[22]. Further supporting the use of a stapled technique, when anastomotic leaks do occur, a better prognosis has been shown following a stapled anastomosis[20,22].

INFLAMMATION AND DYSPLASIA IN THE ATZ

It is well documented that chronic inflammation may lead to dysplasia and dysplasia may ultimately lead to neoplasia in patients with long-standing ulcerative colitis. The retained ATZ following stapled RPC IPAA is therefore at risk for chronic inflammation from recurrent or persistent disease, dysplasia, and possibly malignancy. The retained ATZ and potentially rectal mucosa is greater in length in the stapled anastomosis patient but can still be present in the handsewn patient due to the variation in location of the ATZ and incomplete transanal mucosectomy[2,23,24].

Inflammation within the ATZ is well documented. In early studies the incidence of endoscopic anal canal inflammation confirmed by biopsy was reported to be as high as 22% as estimated by Lavery et al, while the incidence of symptomatic inflammatory changes in the retained mucosa was 14.7%[25]. More recent prospective data document the incidence of inflammation following stapled RPC IPAA to be much higher: 4.6% with acute inflammation, 84.9% with chronic inflammation, and only 10.5% with normal mucosa[26]. The presence of inflammation, however, does not seem to negatively affect functional outcomes, as our group has reported in a large prospective study of 225 patients, with 96%

of them reporting perfect fecal continence, 5.3% using protective pads, and 93.2% being able to delay a bowel movement for more than 30 min[26]. Patients with chronic inflammation of the ATZ still report better functional parameters when compared to handsewn control patients, including statistically significant improved flatus versus stool discrimination, decreased protective pad usage, and decreased dietary modification regarding meal timing[27]. In addition, patients with chronic inflammation of the retained ATZ more commonly reported an improved quality of life than prior to surgery when compared to handsewn patients (P < 0.001)[27].

Several studies have published their experience with postoperative serial endoscopic surveillance and the risk of dysplasia following preservation of the ATZ via a stapled RPC IPAA. The principal risk factor for developing dysplasia in the ATZ was the presence of dysplasia or cancer in the proctocolectomy specimen, independent of the location; no other factors including age, sex, or duration of disease, appear to increase this risk[28-31]. Ziv et al reported eight cases of dysplasia in 254 patients with a mean postoperative follow-up of 2.3 years; however, repeat biopsy revealed dysplasia in only two of these patients, who underwent a transanal mucosectomy without evidence of cancer in the final specimen[28]. Remzi et al analyzed a total of 178 patients with a mean follow-up of more than 10 years and identified dysplasia in only eight patients (4.5%) and no evidence of cancer[30]. No dysplasia was identified by our group in 242 patients with a mean follow-up of 56 mo[27]. This small disparity in incidence may be explained by variation in patient selection. In our practice, we do not offer a stapled RPC IPAA to patients with documented, and confirmed by two independent pathologists, colorectal dysplasia, irrespective of degree and location. Instead, these patients will undergo a transanal mucosectomy with a handsewn anastomosis[27]. We believe that the presence of dysplasia irrespective of degree and location is an indication of "mucosal instability." Since the primary risk factor for developing dysplasia in the ATZ is the presence of dysplasia or cancer in the surgical specimen, we perform a complete mucosectomy in this patient population. Complete absence of dysplasia or cancer in the ATZ in our series after 56 mo of follow-up, supports this approach.

Overall, dysplasia within the ATZ is uncommon and the risk of developing cancer following RPC IPAA is even more unlikely with only 19 reported cases in the literature[31] (Table 1). Even following a mucosectomy with endoanal anastomosis, islands of rectal mucosa probably exist at or below the dentate line in at least 20% of patients[23,24], These islands of rectal tissue may not be easily visualized during endoscopic biopsy, and dysplastic or malignant transformation may ultimately be difficult to detect. In fact, of the 19 reported cases of adenocarcinoma, 13 occurred in patients who underwent transanal mucosectomy. Furthermore, six of these patients developed cancer within the pouch itself, raising concern for metaplasia of the pouch as a method for

[1]Excludes articles not in English and one study using Cavitron Ultrasonic Surgical Aspirator technique for rectal mucosal stripping; [2]Yr to presentation of carcinoma after RPC IPAA; HS: Handsewn anastomosis; Stapled: Stapled anastomosis; NR: Not recorded or unknown; UC: Ulcerative colitis, HGD: High grade dysplasia; CA: Carcinoma; LGD: Low grade dysplasia.

malignant transformation. Yet, Swedish research has demonstrated that although the pouch itself may undergo metaplasia, there has been no progression to carcinoma; dysplasia occurred in less than 4.4% of patients; no high-grade was observed; and experienced pathologists did not even agree on the presence of dysplasia itself[32]. None of these patients had documented dysplasia or carcinoma in the surgical specimen preoperatively. When reviewing the cases of carcinoma following RPC IPAA, it is important to note that all but three patients had documented dysplasia or carcinoma within the original surgical specimen[31]. Given these data and the extensive evidence for the development of carcinoma in ulcerative colitis patients following dysplastic changes of the colon, we believe that it is appropriate to label dysplasia as a marker for "mucosal instability." Therefore, it is our belief that the presence of dysplasia or carcinoma, irrespective of the severity or location, should preclude a stapled RPC IPAA.

The presence of dysplasia or malignancy within the ATZ raises concern regarding treatment. Invasive malignancy requires a complete IPAA excision and end ileostomy. On the other hand, clear data regarding management of dysplastic changes within the ATZ do not exist. Dysplasia may even sometimes be self-limiting. Interestingly, several studies have shown regression of low-grade and even high-grade dysplasia to normal mucosa in some patients by serial biopsies[28,30], which is consistent with findings seen in the colon and rectum[33].

Most authors recommend completion mucosectomy with pouch advancement for high-grade dysplasia and for recurrent or persistently positive biopsies of low-grade dysplasia[28,30]. Dysplastic changes may be a marker for mucosal instability and the risk of developing carcinoma in this setting should be eradicated.

CONCLUSION

Preserving the ATZ offers improved long-term function, clinical outcomes, and decreased postoperative complications and pouch failure; however, ATZ preservation carries a small risk for developing dysplasia or malignancy. As a result of the risk of developing dysplasia or cancer, a selective approach to stapled RPC IPAA should be undertaken, based on the presence of dysplasia, irrespective of the location and severity. Stapled RPC IPAA, and therefore preservation of the ATZ, should be reserved for those patients in whom multiple preoperative endoscopic biopsies rule out dysplasia or carcinoma in the entire colon. Transanal mucosectomy and handsewn IPAA should be performed in patients with biopsy-proven dysplasia, irrespective of the location and severity. Due to the significant inter-observer discrepancies noted, the presence of dysplasia should be confirmed by two independent pathologists. If these resection guidelines are utilized, it is believed that cancer risk can be further reduced, especially if postoperative endoscopic surveillance is employed.

INTRODUCTION

The intestine has an inherent ability to adapt morphologically and functionally in response to internal and external environmental stimuli. This process is called intestinal adaptation, or enteroplasticity. In fact, intestinal adaptation may be considered as a paradigm of gene-environment interactions. The array of phenotypic adaptations includes modification of brush border membrane (BBM) fluidity and permeability, as well as up- or down-regulation of carrier-mediated transport. Intestinal adaptation occurs following loss of a major portion of the small intestine (short bowel syndrome, SBS), following chronic ingestion of ethanol, following sublethal doses of abdominal irradiation, in diabetes, with aging, and with fasting and malnutrition[1-3].

Following intestinal resection, morphological and functional changes occur depending upon the extent and site of bowel removed, as well as external factors such as the lipid content of the diet (reviewed in Thiessen *et al*[4]). The increase in nutrient absorption from this process of enteroplasticity following resection compensates for the loss of mucosal absorptive surface area and minimizes the malabsorption that could otherwise occur. Therefore, intestinal adaptation has important implications in survival potential and welfare of the host[5]. In contrast, the adaptive process may be deleterious: for example, in diabetes this process enhances sugar and lipid uptake, exacerbating prevailing hyperglycemia, hyperlipidemia and obesity[6].

MECHANISMS

Mechanisms of intestinal adaptation occur at a variety of levels: physiological, cellular and molecular. Signals

Abstract

The process of intestinal adaptation ("enteroplasticity") is complex and multifaceted. Although a number of trophic nutrients and non-nutritive factors have been identified in animal studies, successful, reproducible clinical trials in humans are awaited. Understanding mechanisms underlying this adaptive process may direct research toward strategies that maximize intestinal function and impart a true clinical benefit to patients with short bowel syndrome, or to persons in whom nutrient absorption needs to be maximized. In this review, we consider the morphological, kinetic and membrane biochemical aspects of enteroplasticity, focus on the importance of nutritional factors, provide an overview of the many hormones that may alter the adaptive process, and consider some of the possible molecular profiles. While most of the data is derived from rodent studies, wherever possible, the results of human studies of intestinal enteroplasticity are provided.

of adaptation may relate to various hormone levels, transcription factors, ATP levels, or to changes in concentration of luminal solutes[3]. Signals for and mechanisms of the enteroplasticity process may be different for the jejunum and ileum, as well as in the intestinal crypt and villous tip, explaining site-specific alterations and differences between crypt and villous enterocytes[1-2].

Rodents are commonly used in well-characterized models for assessing the process of intestinal adaptation[7]. For example, following small bowel resection in the rat, the remnant intestinal mucosa undergoes compensatory alterations in an attempt to restore normal absorptive capacity[8]. Morphological and functional changes include increases in crypt depth and villous length, enterocyte proliferation, as well as increased electrolyte, glucose and amino acid uptake[7-8].

The adaptive process has been defined in terms of transport kinetics. Changes usually occur in the value of maximal transport rate (Vmax) rather than in Michaelis affinity (Km) constant of specific nutrient transporters (sugars and amino acids)[9-10]. Furthermore, there may be alterations in permeability coefficients of nutrients transported passively such as short-, medium- and long-chain fatty acids and cholesterol[1-2,11]. Increased Vmax results from either up-regulation of the total number of transporters per enterocyte, increased number of transporting mucosal cells, or increase in the intrinsic activity of the transporter[12-13]. Intestinal resection also selectively changes passive permeability properties of the BBM, as demonstrated by increased uptake of fatty acids, an increase that is not due simply to the changes in mucosal surface area or the effective resistance of the intestinal unstirred water layer (UWL)[14]. Indeed, this altered permeability is due to changes in the lipophilic properties of the BBM caused by variations in-lipid content of the BBM[15], which represents part of the adaptive process.

DIABETES AND INTESTINAL RESECTION AS EXAMPLES

Intestinal adaptation in the rodent model of chronic diabetes involves changes at the transcriptional as well as the post-transcriptional level, leading to increased Na^+-coupled sugar absorption[16]. After inducing acute hyperglycemia in rats, there is rapid up-regulation of glucose transport across the (enterocyte) basolateral membrane (BLM)[17]. In this model, both the vascular as well as luminal glucose infusion causes an increase in glucose transport capacity across the BLM[18]. No significant increase in BLM cytochalasin B binding or in GLUT2 protein abundance was observed, suggesting that there may be a post-translational event that increases the number of GLUT2 proteins available for transport, such as the movement of GLUT2 to the BLM from a preformed pool within the enterocyte. Alternatively, intrinsic activity of the transporter may be altered in the absence of changes in transporter protein abundance. Changes in intrinsic activity of glucose transporters have

been observed with hyperglycemia[19], diabetes[20], low luminal glucose concentrations[12], and following activation of mitogen-activated protein kinase (MAPK) and P13K[13].

Following extensive intestinal resection, there is hyperplasia of the remaining small intestine, which is often accompanied by enhanced uptake of nutrients[21]. Alterations in the cell kinetics that result in modification of nutrition status may be specific or non-specific. Non-specific mechanisms involve alterations that result in changes in intestinal mucosal mass and/or villous surface area, leading to modifications in uptake of all nutrients, including those that are absorbed passively[22]. Specific mechanisms involve up- or down-regulation of transporters responsible for uptake of nutrients, such as sugars or amino acids[1-2].

THE IMPORTANCE OF MORPHOLOGY

The observation that morphological modifications may accompany intestinal adaptation in the rodent small bowel resection model was first made by Dowling and Booth[21]. The remaining intestine after resection is hyperplastic, with greater villous height and crypt depth, leading to enhanced mucosal surface area. While increased nutrient absorption is observed, the morphological changes do not necessarily solely explain alterations in nutrient uptake. For example, 1 wk after 80% small bowel resection, the remaining intestine increased its mass to 50%-70% of its pre-resection level, yet uptake of glucose increased only to approximately 33% of the pre-resection level[8].

It is clear that dynamic morphological parameters of the intestine may also adapt. For instance, crypt cell production rates or enterocyte migration rates along the villi change in some situations of intestinal adaptation[23]. It is important that morphological alterations be considered when estimating kinetic parameters of absorption. Morphological modifications such as blunting of mucosal growth or mucosal hyperplasia after intestinal resection are observed when dexamethasone is given subcutaneously[24]. Both transporter kinetics and dynamic morphological parameters are altered in the adaptive process, and the influence of resection on nutrient uptake is due to integration of these processes. This may be due to altered cell kinetics changing the population of enterocytes along the villus, thereby leading to variations in the number of cells with transporters, or activity of the transporters[25-26].

OTHER EXAMPLES

Many models of intestinal adaptation have been described: glucose uptake has been found to be increased during pregnancy[27], and lactation[28], with ingestion of a high carbohydrate diet[29], hyperglycemia[30], with diabetes[15], high alcohol intake[31] and after intestinal resection[32]. Glucose uptake is decreased with aging[33], external abdominal radiation[34], and with use of total parenteral nutrition[35]. Most transporters are up-regulated by levels of dietary substrate levels, and yet toxic substances and

essential amino acids have the opposite effect[7,35-37]. These examples illustrate the diversity and variability of this enteroplasticity process.

Increases in nutrient absorption have been documented[38-40] in humans following intestinal resection. The role of morphological changes in this process, however, has not been conclusively demonstrated. Remnant small bowel lengthening and dilatation has been noted in patients with SBS, suggesting morphological mechanisms in human intestinal adaptation[41]. However, the morphological adaptation typical in rodent models[21,42] (hypertrophy or hyperplasia) is not necessarily observed in the human adaptive response[43-44]. Several studies have shown no increase in villous height or crypt depth among patients who underwent intestinal resection, compared to healthy controls[39,45]. With the existence of various anatomical, physiological and biochemical differences between the human and rodent gastrointestinal tracts[46], and a conspicuous lack of comparable human studies, the clinical adequacy of the rat as a model of intestinal adaptation remains to be determined. Accordingly, caution must be used when attempting to extrapolate findings from rodent studies to the human population. Is there a better model? The neonatal piglet has been used in short bowel studies[47-49], and has been used to determine the effects of insulin-like growth factor-1 (IGF-1) and dietary manipulations[48,50]. The degree to which the results obtained using this model reflect human findings has yet to be determined, and the rodent remains a popular model for studies of intestinal adaptation.

DIETARY REGULATION

The topic of dietary regulation of intestinal gene expression has been reviewed[29,51]. Dietary constituents provide continual environmental signals that elicit expression of a host of genes that influence intestinal adaptation[52]. Every day, enterocytes are exposed to different nutrients that vary according to the nutrient intake of the host. For this reason, the intestine must be able to adapt to variations in the dietary load and composition[29,53]. The intestine, like many other biological and engineered systems, is quantitatively matched to prevailing peak loads with modest reserve capacities. Indeed, physiological capacities are optimal and most economical if they ascribe to the adage "enough, but not too much"[53]. Therefore, intestinal enzymes and transporters are characterized by a "safety factor", a parameter that represents the ratio of its capacity to the load placed on it[54]. The maintenance of this reserve capacity is biosynthetically costly, but is necessary given the unpredictable nature of dietary contents.

Let us consider the process of enteroplasticity and parenteral vs enteral nutrition, dietary lipids, carbohydrates, proteins and polyamines.

Parenteral vs enteral nutrition

In rodent models using total parenteral nutrition (TPN), small bowel atrophy is well characterized[55-57].

Not surprisingly, the presence of luminal nutrients also contributes greatly to enteroplasticity[58].

Dietary lipids

The dietary fat content influences the uptake of hexoses and lipids into rabbit jejunum following ileal resection[14]. In using a rat model of SBS, early feeding of a high-fat diet increased lipid absorptive capacity of the intestinal remnant[59]. A high-fat diet decreased mucosal mRNA levels of the lipid binding protein FAT/CD36, and decreased oleic acid uptake by isolated enterocytes. Mice that were chronically fed a diet enriched in sunflower oil had increased liver fatty acid binding protein (L-FABP) mRNA levels in the small intestine[60]. The effect was specific to this gene, as the intestinal fatty acid binding protein (I-FABP) was unaffected.

Not only the amount of fat, but also the type of dietary fat may influence intestinal function. Keelan et al[61] tested the hypothesis that intestinal morphology and uptake of nutrients after resection of the distal half of the small intestine of rats responds to alterations in dietary content of saturated (SFAs) and polyunsaturated (PUFAs) fatty acids. Adult female Sprague-Dawley rats were subjected to a sham operation or to surgical resection of the distal half of the small intestine. Animals were fed chow for 3 wk, then either chow or isocaloric semisynthetic SFA or PUFA diets for a further 2 wk. The in vitro jejunal uptake of glucose was twice as high in animals that had undergone resection and were fed SFAs than in those fed PUFAs. Perhaps SFAs are necessary in the diet to ensure that adequate adaptation takes place.

Thiesen and colleagues examined the effect of dietary lipids on lipid uptake in rats post-resection. Intestinal resection had no effect on mRNA expression of early response genes (ERGs), proglucagon or the ileal lipid binding protein (ILBP), but was associated with reduced jejunal mRNA for ornithine decarboxylase (ODC) and for L-FABP[62]. These resection-associated changes in gene expression were not linked with alterations in intestinal uptake of long-chain fatty acids or cholesterol. In animals undergoing intestinal resection and fed SFA, there was a reduction in jejunal proglucagon mRNA expression as compared to those animals fed chow or PUFA. ODC mRNA expression in the jejunum of resected animals was reduced. Thus, dietary lipids modify uptake of lipids in resected animals, and ODC and proglucagon may be involved in this adaptive response[63].

The way by which dietary lipids alter gene expression and consequently change membrane composition and/or nutrient transport may be through activation of peroxisome proliferator-activated receptors (PPARs), hepatic nuclear factor-4 (HNF-4), nuclear factor κB (NFKB), and sterol response element binding protein-1c (SREBP-1c)[52]. By binding to these transcriptional factors, dietary lipids affect the rate of transcription and consequently the protein synthesis of nutrient transporters[51,64]. PPARs belong to the super-family of receptors that include the glucocorticosteroid receptor[65].

When the locally acting glucocorticosteroid budesonide was administered concomitantly with an SFA diet, jejunal uptake of glucose was increased but ileal uptake of fructose was reduced[66].

It has been suggested that dietary lipids participate in signal transduction involving activation of second messengers, such as cAMP, Ca^{2+} and diacylglycerol, thereby changing the mRNA expression[67]. Studies with glycosphingolipid have revealed the importance of these lipids and their metabolites in signaling pathways *via* the tyrosine kinase-linked receptors. This is a signal system mediated by protein kinase C (PKC), MAPK, other kinases, as well as by cytosolic Ca^{2+} concentration[68]. Additional new signals involved in adaptive intestinal response 3 d after 50% intestinal resection have been identified by cDNA microarray analysis. These include proline-rich protein 2, involved in wound healing; glutathione reductase, a gene involved in intestinal apoptosis; NF-2 family members, also involved in apoptosis; etoposide-induced p53-mediated apoptosis; basic Kruppe-like factor, a transcription factor that activates the promoter for IGF-1; and prothymosin-α, involved in cell proliferation[69,70]. These observations of altered expression of signals are useful to generate hypotheses that can be tested in future studies to establish whether these signals represent a primary or a secondary event in enteroplasticity.

The glycospingolipid, phospholipid, cholesterol and fatty acid composition of plasma membranes may be modified in mammalian cells[71]. For example, Keelan *et al*[72] demonstrated that alterations in dietary fatty acid saturation influence intestinal BBM phospholipid fatty acid composition in rats. The investigators proposed that previously reported diet-associated changes in active and passive intestinal transport are due at least in part to these alterations in the fatty acid composition in BBM phospholipids. A diet enriched with SFA is associated with increases in the saturation of BBM phospholipid fatty acids, while a diet enriched with PUFA is associated with an increase in the unsaturation of BBM phospholipid fatty acids[1-2].

Meddings[73] compared *in vivo* membrane lipid permeability within the same intestinal region, under conditions where membrane physical properties were radically altered by feeding rats an inhibitor of cholesterol synthesis. Marked reductions in membrane fluidity were observed due to replacement of membrane cholesterol with its precursor, 7-dehydrocholesterol. Associated with these alterations was a pronounced reduction in membrane lipid permeability. Therefore, BBM membrane lipid permeability, *in vivo*, appears to be correlated with the physical properties of the bilayer.

The degree of fatty acid unsaturation or saturation, as well as the cholesterol and ganglioside/glycosphingolipid content, are factors that influence fluidity of the BBM[74-75]. Changes in fluidity of the BBM may alter passive permeation of molecules and nutrients through this barrier, as well as conformation of binding sites on transporter proteins such as SGLT1, GLUTS[71,76]. For example, alterations in BBM fluidity influence passive uptake of lipids, as well as carrier-mediated D-glucose uptake[76,77]. While enhancement of fluidity increases the uptake of lipids, fluidization of BBM from enterocytes located on the villous tip decreases uptake of D-glucose to levels seen in the BBM from enterocytes located in the crypts[78].

While altered membrane lipid composition may act in part by changing viscosity or fluidity of the BBM, it may also alter the microenvironment surrounding the transporter and thereby modify transporter activity. Two types of specialized microdomains in the BBM have been identified: lipid rafts and caveolae. These regions are important in signal transduction as well as lipid and protein trafficking[79-81]. Lipid rafts are enriched in SFAs, cholesterol and gangliosides[80-82].

Feeding rats a diet containing gangliosides increases jejunal glucose uptake[83]. Feeding them a ganglioside-rich diet increases ganglioside content and decreases cholesterol content in the intestinal mucosa, plasma, retina and brain[84]. Similar changes in lipid composition of intestinal microdomains, or lipid rafts, occur following ganglioside feeding[85]. Although SGLT1 has been localized to these microdomains in renal epithelial cells[86], it is not known if sugar transporters reside in intestinal BBM microdomains. If this is the case, local changes in membrane fatty acids may affect the activity of transporter by altering the configuration of the protein, potentially exposing or masking transporter binding sites and thereby modifying nutrient uptake. Gangliosides may also influence intestinal sugar transport *via* alterations on pro-inflammatory mediators, many of which are known to influence intestinal sugar transport[87-89]. For example, in rats challenged with lipopolysaccharide, ganglioside feeding reduced the production of intestinal platelet activating factor, PGE2 and LTB4, as well as plasma levels of IL-1β and TNF-α[90].

Dietary carbohydrates

Dietary carbohydrate may induce the intestinal adaptive response by increasing the abundance of hexose transporters to facilitate a higher rate of sugar absorption[9]. In a murine model, intestinal glucose uptake was directly correlated with dietary carbohydrate load[29,36,91]. The effect of dietary carbohydrate on nutrient transporter abundance has been reported in several animal models. For instance, abundance of SGLT-1 in BBM and GLUT2 in the BLM was elevated in animals fed a high carbohydrate diet; associated with this enhanced level of protein was an increase in glucose absorption[17,92-93]. The GLUT5 transporter abundance was also elevated with enhanced consumption of dietary fructose, leading to increased fructose uptake[77].

Initiation of dietary glucose-induced adaptive response occurs in the intestinal crypts, where transport capacities of nutrient transporters are programmed[91,36-37,93]. Utilizing a mouse model, diet from a high to a low carbohydrate regimen reduced the amount of glucose transporter, as estimated from density of phlorizin binding. Enterocytes may adapt to the high carbohydrate diet by increasing

crypt cell turnover rate, enhancing enterocyte migration rate, as well as by reprogramming the capability of nutrient transporters in the crypts to accommodate to the requirement for higher monosaccharide transporters[93]. Alteration in the density of glucose transporters was first observed in the crypt cells, and over a 3-d period was subsequently seen in the villous tip cells. Thus, crypt enterocytes respond to the high carbohydrate diet by increasing glucose transportation density. These cells then migrate up the villus over the next 3 d, contributing to the adaptation process enhancing glucose uptake.

Animals fed a glucose-enriched diet have increased glucose uptake, resulting from up-regulation of both BBM and BLM glucose transporters[17,92,94]. During early development, precocious introduction of dietary fructose causes enhanced expression of fructose transporters and fructose transport, without changing glucose uptake[93]. The substrates glucose and fructose specifically up-regulate their own transporters, SGLT-1 and GLUT5. In contrast, increases in essential amino acids or other substances that are potentially toxic at high levels (such as iron, calcium or phosphorous) are associated with no changes, or even reductions, in transport[35,95].

In many cases, other nutrients may be equal, or even more potent, inducers of the transporter than the transporter's specific substrate. For example, young animals fed a diet enriched with PUFA have a decline in glucose uptake, as compared to animals fed an SFA-enriched diet[66,96,97]. Similarly, Vine et al[98] studied the effect of varying fatty acids on the passive and active transport properties of rat jejunum and found that an SFA-enriched diet increased Na$^+$-dependent glucose uptake when compared to a diet enriched with n6 PUFA. In contrast, in aged rats, glucose uptake is increased by PUFA and not by SFA[33].

Dietary fiber also modulates intestinal nutrient uptake. For example, in dogs, a diet enriched with fermentable fiber increases glucose uptake and GLUT2 transporter abundance[99]. In vitro studies, in which rat intestinal tissue was incubated with B-glucan isolated from barley or oats, show reductions in uptake of stearic and linoleic acids (Drozdowski et al, 2005, unpublished observations). Furthermore, many studies have investigated the effect of TPN supplemented with short-chain fatty acids, the products of fiber fermentation. Increases in glucose uptake, GLUT2 mRNA and protein, and intestinal morphology were observed in normal rats as well as in rats following intestinal resection[100-103].

Dietary proteins

Dietary proteins also have an impact on intestinal morphology and active amino acid transport[37,104]. Both in vitro[105] and in vivo[104] rat experiments have shown that a high-protein diet increases amino acid uptake in the jejunum. Alteration in the amount of dietary protein induces reversible adaptation of non-essential amino acid transport rate[106]. Feeding a high-protein diet to mice induces a 77%-81% increment in uptake of non-essential amino acids[35], yet only a 32%-61% increase

for essential amino acids. A protein-deficient regimen reduces uptake of non-essential amino acids, such as aspartate and proline, and maintains or increases uptake for essential amino acids and alanine.

Glutamine is a key metabolic fuel for enterocytes, mediating cellular nucleic acid synthesis and proliferation. Parenterally fed rats demonstrate decreased atrophy of the intestinal mucosa following glutamine supplementation[106]. Glutamine administration also normalizes the reduced levels of intestinal adaptation in rats receiving TPN following intestinal resection[107]. It is noteworthy that some studies of oral glutamine supplementation in the rat have failed to document more than temporary mucosal proliferation[108].

Other amino acids may inhibit intestinal adaptation. Sukhotnik et al[109] examined effects of parenteral administration of the nitric oxide precursor arginine to rats following 75% small bowel resection. Arginine supplementation was associated with lower cell proliferation and greater enterocyte apoptosis. Thus, the nature of the adaptive response depends upon the type of amino acid and the needs of the animal.

Polyamines

Polyamines are found in all eukaryotic cells[110], and they play an important role in growth and differentiation[111]. Polyamines are obtained either from the diet, or via synthesis from ornithine[112]. Luminal perfusions of polyamines rapidly (in less than 5 min) enhance intestinal glucose uptake in rats and increase BBM SGLT-1 protein[113].

Polyamine synthesis or uptake may be an important event that initiates adaptive hyperplasia observed in the intestinal remnant after partial small bowel resection. Enteral diets supplemented with ornithine alpha-ketoglutarate (OKG), a precursor for arginine, glutamine and polyamines, enhances intestinal adaptation in models of intestinal resection[114,115]. Indeed, studies by both Tappenden et al[116] and Thiesen et al[62] suggest that ODC, a key enzyme in polyamine synthesis, may mediate the adaptive process in rats that is stimulated by the administration of either glucocorticosteroids or short-chain fatty acids to rats following intestinal resection.

HORMONAL REGULATION

Glucocorticosteroids (GCs)

Numerous hormones modify the form and function of the intestine. It is not clear whether any of the dietary features that modify the intestinal adaptive process do so by way of hormonal alterations. In a model of extensive intestinal resection (50% enterectomy), the remaining proximal and distal intestinal remnants were adequate to assess the morphology and function at these sites[9,106]. The GC prednisone had no effect on intestinal uptake of glucose or fructose in these resected animals[62]. In contrast, the locally acting steroid budesonide increased by over 120% the value of the jejunal Vmax for the uptake of glucose, and increased by over 150% the ileal uptake of fructose. The protein abundance and mRNA

expression of SGLT-1, GLUT5, GLUT2 and Na$^+$/K$^+$ APTase α1 and β1 did not explain this enhancing effect of budesonide on glucose and fructose uptake. Budesonide, prednisone and dexamethasone reduced jejunal expression of the early response gene c-jun. In resected animals, the abundance of the mRNA of ODC in the jejunum was reduced, and GCs reduced jejunal expression of mRNA for proglucagon. These data suggest that enhancing influence of GC on sugar uptake in resected animals may be achieved by post-translational processes involving signalling with c-jun, ODC and proglucagon, or other as yet unknown signals.

In contrast, the uptake of D-fructose by GLUT5 was similarly increased with budesonide and with prednisone. Increases in the uptake of fructose was not due to variations in weight of intestinal mucosa, food intake, or in GLUT5 protein or mRNA expression. There were no steroid-associated changes in mRNA expression of c-myc, c jun, c-fos, of proglucagon, or of selected cytokines. However, the abundance of ileal ODC mRNA was increased with prednisone. Giving post-weaning rats budesonide or prednisone in 4-wk doses equivalent to those used in clinical practice increases fructose but not glucose uptake. This enhanced uptake of fructose was likely regulated by post-translational processes[62].

Growth hormone (GH)

GH has been suggested as possessing pro-adaptive properties[117]. In rats and piglets, GH administration results in an increase in small bowel length and function per unit length[118]. Hypophysectomized rats undergo mucosal hypoplasia of the small bowel, as well as a reduced adaptive response following resection that is restored by GH[119]. In contrast, transgenic mice expressing elevated levels of GH experience hypertrophy of the small intestine[118]. IGF-1 expression in the small bowel is regulated by GH and is believed to induce enterotrophic effects following resection[120,121]. In a rat model of SBS, acute IGF-1 treatment of TPN-fed rats produced sustained jejunal hyperplasia, and facilitated weaning from parenteral to enteral nutrition[122]. GH administration to normal rats has been reported to have positive effects on mucosal growth and intestinal adaptation following massive resection[123], although contradictory data exist[124,125]. Human and rabbit studies have indicated that increased nutrient transporter activity devoid of morphological changes may be the method of GH-induced intestinal adaptation[126].

GH administration inhibits liberation of glutamine from muscle during catabolic states in humans[127]. This suggests a possible role for combining GH and glutamine to achieve optimal adaptation. Trials investigating any such synergism in the rat have yielded conflicting results. Some studies have failed to demonstrate an additive effect of GH and glutamine in the enhancement of post-resection intestinal adaptation[128], while others have documented a positive synergistic effect[129]. For example, GH has been shown to enhance the absorption of amino acids using *ex vivo* human BBM vesicles[129]. An intestinal mucosal GH receptor has been described in rats and humans[130], and

GH promotes cell differentiation and clonal expansion of these differentiated cells[131].

Human studies have suggested that the efficacy of GH and/or glutamine therapy in the adaptive response of the small bowel may be based heavily upon the clinical status of the patient[132]. Evaluation of the effect of such may facilitate further understanding of the pathology and physiology of the bowel adaptation process, as well as more clearly defining positive predictive indicators of the bowel's ability to be rehabilitated. Existing human data indicate that administration of high concentrations of GH can actually increase patient morbidity and mortality[133].

In studies of home parenteral nutrition (HPN)-dependent patients with SBS, the use of high-dose recombinant human GH (0.4 mg/kg per day) in controlled[133,134] and uncontrolled studies[135] has led to variable results. Patients were given glutamine supplements by mouth or parenterally, and their diet was modified. In the randomized, placebo-controlled study of Scolapio *et al*[133], subjects ingested a standardized 1500 kcal/d diet, which is clearly different from the hyperphagic diet consumed by many SBS patients[136], and which may contribute to the physiological adaptation that occurs in the remaining intestine after extensive resection. It is unclear whether glutamine is beneficial for the adaptive response in humans. In rat models of SBS, it is unclear whether glutamine supplementation is efficacious for the adaptive process[137-138]. Furthermore, both a hyperphagic diet and absence of malnutrition are needed for humans to achieve optimal intestinal adaptation[41,139].

When HPN-dependent patients with SBS were provided a usual *ad libitum* hyperphagic diet, and given low doses of GH (0.05 mg/kg per day) for 3 wk, there was significant improvement in intestinal absorption of energy (15% ± 5%), nitrogen (14% ± 6%) and carbohydrate (10% ± 4%)[140]. Increased food absorption represented 37% ± 16% of total parenteral energy delivery. Body weight, lean body mass, D-xylose absorption, IGF-1, and IGF binding protein 3 increased, whereas uptake of GH binding protein decreased. During treatment with GH, improvement in net intestinal absorption compared with placebo was 427 ± 87 kcal/d, representing 19% ± 8% of the total energy expenditure required to obtain energy balance equilibrium in patients with SBS[136].

From a review of literature in this area, Matarese *et al*[140] noted that there were differences in gastrointestinal (GI) anatomy, dietary compliance, nutritional status, presence of mucosal disease, and diagnosis both within and between studies. These authors concluded that "administering recombinant human growth hormone alone or together with glutamine with or without a modified diet may be of benefit when the appropriate patients are selected for treatment".

IGF-1

IGF-1 proved to be efficient in increasing intestinal adaptation following resection in rats. IGF-l treatment
