Fructose is a natural component of many plants and is distributed widely among most fruits and vegetables. Fructose is metabolized primarily in the liver and to some extent in the kidney, small intestine and adipose tissue[6]. Deficiency in aldolase B in the liver, kidney and small intestine causes fructose intolerance[7]. After ingestion, fructose rapidly enters the hepatocytes where fructokinase phosphorylates it to fructose 1-phosphate. Fructose 1-phosphate accumulates in HFI because of deficiency of the enzyme fructose 1-phosphate aldolase, which splits fructose 1-phosphate into glyceraldehydes and dihydroxyacetone phosphate.

The accumulation of fructose 1-phosphate results in inhibition of other enzymes, namely phosphorylase, liver fructose 1-6 bisphosphate aldolase and fructokinase. This results in impaired glycogenolysis and glyconeogenesis, and may induce hypoglycemia[8]. Early exclusion of fructose and sucrose from the diet is accompanied by dramatic improvement; otherwise, growth is retarded and progressive liver and renal disease are likely, and may lead to death[9-11]. Diagnosis can be achieved by FTT and tissue diagnosis by direct assay of aldolase B activity in the liver, intestine or renal tissue. Recently, the use of PCR-based procedures has made the diagnosis simpler[12,13].

The infusion of fructose- or sorbitol-containing solutions in patients with unsuspected disease leads to potentially fatal hepatorenal failure. More than 20 cases have been reported in Germany where the use of fructose or sorbitol solutions is long established[14,15]. Our patient is alive at the age of 50 years with previously undiagnosed HFI, and did not have complications of the disease. This patient illustrates the importance of a careful dietary history and awareness of disease symptoms. In contrast, incorrect diagnosis and unawareness of possible pediatric problems in adult life may lead to catastrophic complications, while early recognition leads to effective management.

ACKNOWLEDGMENTS

We thank Professor Timothy M Cox from the Department of Medicine at University of Cambridge Clinical School, UK for performing DNA analysis from the blood samples.

Abstract

Taking herbal-extracts to lose weight is an underestimated health hazard. Often, these products contain active agents that can cause acute liver damage. In this case report, a 22-year-old female patient, who presented with a feature of cholestatic syndrome, was so sure that the "natural products" were not dangerous that she did not inform her physicians that she had taken them, making their task that much more challenging. Clinical presentation mimicked acute cholecystitis and the patient underwent a cholecystectomy. Surgery was without any consequences and complications, although it did not completely cure the illness. She later admitted to having taken herbal remedies and this led to the correct diagnosis of phytotherapy-related hepatotoxicity and a successful therapeutic approach. The true incidence of phytotherapy-related hepatotoxicity and its pathogenic mechanisms are largely unknown. It is important to increase the awareness of both clinicians and patients about the potential dangers of herbal remedies.

INTRODUCTION

The desire to lose weight using "natural products" and the availability of these items can induce pathologies, the causes of which are often overlooked. The main problem with "natural products" is that the exact quantity and purity of a given ingredient contained in extracts of vegetable origin (mainly herbs) are largely unknown. It can happen that patients deny taking these products, thinking that they are "safe" because they are "natural" and thus physicians do not have the key facts to interpret dangerous pathologies. Here we report a case of a patient who experienced jaundice and pruritus, not assuming the "natural products" was at fault, with a clinical presentation highly suggestive of cholecystitis whose final diagnosis turned out to be drug-induced liver injury (DILI).

CASE REPORT

A 22-year-old obese (BMI 32) woman presented to hospital in May 2007 with a cholestatic syndrome of unknown origin. Her only declared pre-existing medication was paracetamol (500 mg daily), used as an analgesic for menstrual pain. Pre-admission blood tests were normal.

Symptoms included jaundice, pruritus, right upper quadrant pain and epigastric tenderness, accompanied

by fever of low grade, nausea, vomiting, dark urine and pale stools. At the time of admission routine liver enzyme tests revealed bilirubin 128 μmol/L (< 20 μmol/L), alkaline phosphatase (ALP) 1229 U/L (40-110 U/L), γ-glutamyltransferase (GGT) 293 U/L (< 50 U/L), Aspartic-aminotransferase (AST) 1378 U/L (< 45 U/L) and Alanine-aminotransferase (ALT) 1686 U/L (< 40 U/L). She had never consumed alcohol and there was no recent travel history. Viral serology for hepatitis and HIV were negative. An infection screen was carried out because our country has an increasing incidence of exotic illnesses due to recent immigration that can cause transient liver enzyme derangement. This panel included cytomegalovirus, Epstein-Barr virus, Flavivirus, Dengue virus, Ross River virus, Barmah Forest virus, Spotted fever virus, Scrub Typhus, and Leptospirosis serology; all of them were unremarkable. Serum copper and caeruloplasmin, α-fetoprotein, α-1 antitrypsin, iron deposits were in the normal range. Anti-nuclear antibodies, perinuclear antineutrophil cytoplasmic antibodies, antibodies to liver kidney microsomal antigen type-1, anti-mitochondrial and anti-smooth muscle antibodies were negative. Her complete blood count was slightly abnormal. In fact, a modest increase in WBCs without left shift was present on admission, concurrent with an increase in eosinophils (7%) and a decrease in lymphocyte counts.

Abdominal ultrasound revealed the presence of microcalculi in the gallbladder. No clear dilatation of the common bile duct was seen, but the exam was performed in the presence of marked abdominal meteorism.

A magnetic resonance cholangio-pancreatography (MRC) indicated a dilatation of the choledocus with a likely interruption of its terminal tract, with some evidence of microstones in the gallbladder (Figure 1). Consequently, physicians empirically treated this illness by imipenem/cilastatin (500/500 mg every 6 h) for seven days.

A negative history of drug use, the physical findings (i.e. right upper quadrant and epigastric tenderness in the absence of peritoneal findings), laboratory data (i.e. elevated levels of bilirubin, alkaline phosphatase, ALT, and γ-glutamyltransferase) were consistent with extrahepatic obstruction, suggesting stones complicated by acute cholecystitis. Therefore, to gain access to and/or remove impacted common bile duct (CBD) stones at the ampulla of Vater, the patient was submitted to a preoperative endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy and extraction of sand-like stones.

Using this standard therapy, her laboratory data improved, with AST and ALT values of 1110 U/L and 1225 U/L, respectively. At this point, a laparoscopic operative CBD exploration with mini-invasive technique was planned.

The abdominal inspection showed the presence of extensive visceral adherences, as well as a general aspect of diffuse bowel inflammation. The gallbladder was reddish-colored with a thick wall and bled easily. This was suggestive of a complex abdominal pathology, therefore a conversion to an open procedure was chosen.

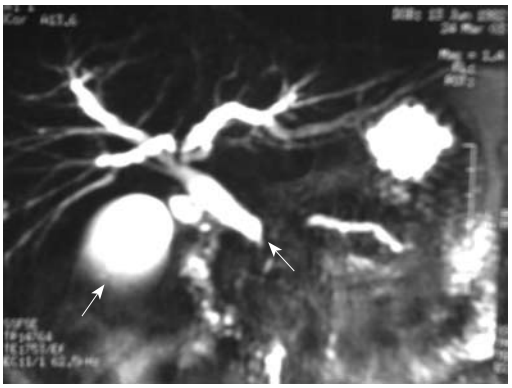

Figure 1 Magnetic resonance cholangio-pancreatography showing dilatation of the choledocus and mimicking an interruption of its terminal tract, with some evidence of microstones in the gallbladder (arrows).

Abdominal exploration and biliary manometry caused the surgeons to utilize an ante-grade trans-ampullary intra-operative endobiliary stenting. The macroscopic examination showed acute cholecystitis with moderate wall-thickening containing very dense bile and some small stones.

The postoperative course was pain-free and the patient was prematurely discharged with drastically reduced (though elevated compared to normal) enzymatic values of AST 108 U/L and ALT 156 U/L.

Four days later the patient underwent liver laboratory tests that underlined an elevation of the transaminases, with an AST level of 644 U/L, ALT of 810 U/L, AP of 806 U/L and bilirubin of 64 μmol/L, mainly unconjugated with a persistently draining T-tube.

An interrogation of the woman's relatives highlighted that the patient had taken several doses of a phyto-preparation in solution, bought from a store run by an herbalist, labeled as "herbal therapy for losing weight". Fortunately, the relatives found this preparation, containing "Lycopodium serratum and Chelidonium maius" at home. The Roussel Uclaf Causality Assessment Method, also known as Danan's international consensus criteria[1], was developed to quantify the strength of association between liver injury and herbal remedies and implicated the phyto-preparation as causing the injury. The case was adjudicated by three reviewers (DC, GT, MND) working independently and the patient was diagnosed as likely to be suffering from DILI. One month after given up taking the herbal remedy, all the liver parameters returned to normal values, without any apparent consequences. The case was re-adjudicated after a four-week follow-up by the same reviewers and the diagnosis was confirmed.

DISCUSSION

The "chelidonium majus" belongs to the family of papaveraceae; its roots contain the biologically active components chelerythrine and sanguinarine. The active "principia" are similar to those of opium, and have well-known hepatotoxic effects[2-4], although in animals an average daily oral dose of alkaloids up to 5 mg/kg has

been proven to be safe[5].

The herb "*Lycopodium serratum*" has several[6] active agents that can cause hepatotoxicity[7]. The hepatic damage caused by these agents, generally of a cholestatic type, is possibly mediated by an idiosyncratic or hypersensitivity reaction. Recently, a different hypothesis was proposed involving an impairment of mitochondrial respiration[8].

Although this is not the first case reported in the literature, its importance lies in the atypical presentation. Indeed, was this a case of misdiagnosis, the co-existence of two diseases or an uncommon manifestation of DILI with a clinical presentation mimicking an other disease? The results of liver laboratory tests and imaging studies were attributed to an earlier combination of symptomatic gallstones and cholangitis and the patient was treated accordingly. Unfortunately, a liver biopsy, which would have indicated the presence of canalicular cholestasis with bile plugs in dilated canaliculi, occasional portal tracts containing a prominent lymphocytic infiltrate with mild piecemeal necrosis, was not performed and consequently the opportunity for a definitive diagnosis was lost.

Gallstone disease remains one of the most common medical problems. The risk factors predisposing to gallstone formation include obesity, diabetes mellitus, estrogen and pregnancy, hemolytic diseases, and cirrhosis. Acute cholecystitis can carry the risk of complications, including empyema, perforation, abscess, peritonitis and sepsis. Acute cholecystitis also causes acute pain in the right upper quadrant (RUQ). However, cross-sectional imaging is essential, because more than one-third of patients with acute RUQ pain do not have acute cholecystitis. Today, laparoscopic cholecystectomy, laparoscopic common bile duct exploration, and endoscopic retrograde management of CBD stones play important roles in the treatment of gallstones, even though the treatment of choice remains cholecystectomy. However, when asymptomatic gallstones are detected during the evaluation of a patient, a prophylactic cholecystectomy is normally not indicated because of several factors. Only about 30% of patients with asymptomatic cholelithiasis will warrant surgery during their lifetime, suggesting that cholelithiasis is a relatively benign condition in some people.

The main question we should ask ourselves is: was surgery the right choice? Although the patient's symptoms and signs were extremely atypical for establishing the diagnosis of acute cholecystitis in this young immune-competent patient, her declaration of not having taken any other medications, including over-the-counter medications, herbal or traditional medicines, definitely misled physicians. The late admission by her parents allowed a correct diagnosis of DILI and not acute cholecystitis. Given the diagnosis of DILI, the patient took a further risk with anesthesia.

Should physicians have performed further studies before surgery? A CT cholangiogram would have shown contrast material being excreted by the renal tract, suggesting that the pathology concerned hepatocellular damage rather than a biliary obstruction.

Was the patient incautiously discharged from the surgery unit? The answer is probably yes, because the reduction of liver enzymatic activity caused surgeons to underestimate the pathology, with overconfidence in the previous diagnosis of cholecystitis.

There are many examples of hepatotoxicity induced by herbal remedies, which have been widely used in recent decades as weight loss agents. Germander (Teucrium chamaedrys) extracts cause DILI, probably mediated by furano neoclerodane diterpenoids[9]. Chaparral is a desert shrub traditionally used by Native Americans for treatment of several ailments. Recently, preparations of chaparral leaves have been marketed as weight loss agents. The mechanism of chaparral toxicity involves its active ingredient, nordihydroguaiaretic acid[10]. Kava (kava kava, awa, or kew), derived from the dried root and rhizome of Piper methysticum, has recently been marketed as an anxiolytic and mood enhancer. Recent studies from Europe have described cases of kava-associated hepatic injury. The mechanism of hepatic injury appears to be immune-mediated, with CYP2D6 deficiency perhaps being a risk factor[11]. *Herba Ephedrae* (from Ephedra sinica and other Ephedra species) is a traditional Chinese extract also used for treatment of asthma, nasal congestion, and fever. Although most adverse effects of *Herba Ephedrae* are cardiovascular or neurological, 4% of reports mentioned acute hepatitis. *Herba Ephedrae* contains phytochemicals, which are thought to strengthen its toxic activity[12].

In addition to the above supplements, liver injury has been attributed to other botanical agents. The pyrrolizidine alkaloids found in comfrey leaves and Heliotropium, Senecio, and Crotalaria species are known to cause veno-occlusive disease of the liver *via* a toxic effect[13]. Mixtures of valerian and skullcap (Valeriana officinalis and Scutellaria lateriflora) have induced hepatitis *via* alkylating agents. LipoKinetix was marketed as a dietary supplement for weight loss. Hepatic injury appears to be due to an idiosyncratic reaction, perhaps related to phenylpropanolamine[14]. Among other weight loss agents, Usnic acid should be suspected in case of severe hepatotoxicity[15].

In our case, the patient was sure the product was harmless and denied the use of a potentially dangerous product in her history, thus not allowing physicians to discover the etiology of the serious pathology from which she suffered. Only an accurate interrogation of relatives was able to discover the relationship between the herbal remedy and DILI.

The diagnostic approach was, in spite of the lack of a certain etiology, the most cautious possible; in fact, MRC and ERCP, perfectly framed into the clinical picture of this patient, are generally considered investigations of first level.

The prevalence of adverse drug reactions (ADR) in health care systems has generated immense interest in recent years. Some of these adverse events are completely unpredictable, but some result from medical errors, patient's negligence or ignorance, and may occur anywhere and at anytime in the health care processes. However, a majority of them may be preventable. The consequences of these ADRs might vary, from little or

no harm to ultimately being fatal to the patients.

Patient safety has received increased attention in recent years, but mostly with a focus on the epidemiology, rather than on practices that reduce (1) ADRs, (2) adverse events related to exposure to herbal remedies and dietary supplements and (3) invasive procedures in medical care involving a wide spectrum of diagnoses or conditions. Potential safety practices should be identified, based on preliminary surveys of the literature and expert consultation.

The misdiagnosis of DILI has many ramifications. These include medical and psychological implications for patients and their families, and financial and public health implications for health-care institutions.

The patient could have sued the health care practitioners (specifically the surgeons) if she felt she had been injured. However, successful medical malpractice lawsuits require proof of the following items: the care provided was below the ordinary standard of care that would be provided by similar health care practitioners under similar circumstances and the patient was harmed because of the deviation from the standard of care. In our case, concerns about lawsuits did not arise, because the physicians' actions were in the best interests of the patient. In fact, a good defence against malpractice lawsuits is to provide excellent medical care and to build close, trusting, and collaborative relationships with patients.

As a final consideration, patients should be especially cautious about using drugs, and should inform their doctor about any drugs or other substances they are taking, including prescription and over-the-counter medications, recreational drugs, herbal remedies, and nutritional supplements. Health care professionals are encouraged to report all ADRs, especially hepatotoxicity and to pay much more attention in prescribing and administering drugs.

For the vegetal abstracts, it should be mandatory to correctly describe their contents, taking in account the active ingredients, the real quantity per unit of product contained with the preparation, and to make clear any possible side effects.

In conclusion, the authors believe that a detailed, painstaking and meticulous history could have unveiled the underlying condition and the patient would not have been subjected to invasive and potentially harmful interventions. This is probably the most important learning point that emerged from this case report.

Abstract

Carcinoids are tumors derived from neuroendocrine cells and often produce functional peptide hormones. Approximately 54.5% arise in the gastrointestinal tract and frequently metastasize to the liver. Primary hepatic carcinoid tumors (PHCT) are extremely rare; only 95 cases have been reported. A 65-year-old man came to our attention due to occasional ultrasound findings in absence of clinical manifestations. His previous medical history, since 2003, included an echotomography of the dishomogeneous parenchymal area but no focal lesions. A computed tomography scan performed in 2005 showed an enhanced pseudonodular-like lesion of about 2 cm. Cholangio-magnetic resonance imaging identified the lesion as a possible cholangiocarcinoma. No positive findings were obtained with positron emission tomography. Histology suggested a secondary localization in the liver caused by a low-grade malignant neuroendocrine tumor. Immunohistochemistry was positive for anti chromogranin antibodies, Ki67 antibodies and synaptophysin. Octreoscan scintigraphy indicated intense activity in the lesion. Endoscopic investigations were performed to exclude the presence of extrahepatic neoplasms. Diagnosis of PHCT was established. The patient underwent left hepatectomy, followed by hormone therapy with sandostatine LAR. Two months after surgery he had a lymph nodal relapse along the celiac trunk and caudate lobe, which was histologically confirmed. The postoperative clinical course was uneventful, with a negative follow-up for hematochemical, clinical and radiological investigations at 18 mo post-surgery. Diagnosis of PHCT is based principally on the histopathological confirmation of a carcinoid tumor and the exclusion of a non-hepatic primary tumor. Surgical resection is the recommended primary treatment for PHCT. Recurrence rate and survival rate in patients treated with resection were 18% and 74%, respectively.

INTRODUCTION

Carcinoids are tumors of neuroendocrine origin, capable of producing functional peptide hormones. The literature has reported different classifications, mainly based on either anatomo-pathological and/or clinical criteria of neuroendocrine tumors of ubiquitous distribution. Several organs may be involved, such as the adrenal gland (pheochromocytoma), the thyroid (midollar carcinoma) and the lung, where microcytoma accounts

for 20%[1] while carcinoids represent 1%-2% of all pulmonary neoplasms in the typical variant (80%-90%) and atypical (10%-20%)[2,3].

About 54.5% of carcinoid tumors arise within the gastrointestinal system and frequently metastasize to the liver[4]. Primary hepatic carcinoid tumor (PHCT) is an extremely rare neoplasm affecting relatively young subjects with an average age of 45 years[5] and no gender predominance. Diagnosis of PHCT is mainly achieved through histological confirmation and exclusion of other sites of the disease[6].

Here, we report the case of an occasional finding of a hepatic lesion, which led to the diagnosis of PHCT after a complicated diagnostic process.

CASE REPORT

A 65-year-old man presented with hypertension, peripheral vascular disease, and statin treated dyslipidemia. His previous medical history, dating back to spring 2003, included an echotomography of the dishomogeneous parenchymal area with no focal lesions. A computed tomography (CT) scan showed no steatosis in the image area. In July 2005, a CT scan of the asymptomatic patient showed an enhanced a pseudonodular-like lesion of about 2 cm localized in hepatic segments Ⅱ-Ⅲ, with intra-hepatic biliary dilatation (Figure 1).

The patient was admitted to hospital for further clinical investigations. Blood chemical analyses showed no abnormalities, not even the presence of markers (CEA, CA 19-9, α FP). The laboratory results are shown in Table 1.

Due to the doubtful interpretations of the radiological findings, a magnetic resonance imaging (MRI) was carried out (Figure 2). The investigation revealed a pseudonodular mass of about 5 cm × 3 cm characterized by low signal intensity both on T1 and T1FS weighted images, as well as weak irregular high signal intensity on T2 and T2FS weighted images. Moreover, an intra-hepatic biliary dilatation was described at the source of the lesion, thus leading us to suspect a heteroplastic lesion similar to a cholangiocarcinoma.

The patient was therefore referred for an 18-fluorodeoxyglucose positron emission tomography (PET), which proved negative. This confirmed by histological examination of a biopsy sample from the lesion. The cytohistological and immunohistochemical picture proved to be consistent with a hepatic localization of a low-grade malignant neuroendocrine carcinoma (presence of anti-chromogranin and Ki 67 antibodies; positive for synaptophysin and S 100 protein) while serum markers were negative (CgA, NSE).

Octreotide scintigraphy using 111 In-pentetreotide (octreotide scan) confirmed the diagnosis as well as enhancing a marked hyperactivity near the lesion in the left hepatic lobe associated with adenopathy in the interaortocaval site (Figure 3A). The patient thus underwent further investigations to exclude metastases with extra hepatic lymph node involvement by endoscopic examinations of the gastroenteric tract (esophagus-gastro-duodenoscopy, colonoscopy, and capsular endoscopy) and analysis of the respiratory systema (bronchoscopy) which all proved negative.

Figure 1 Abdominal CT scan (July 2005) showing a low-density pseudonodular area (arrow) of 2 cm with biliary dilatation.

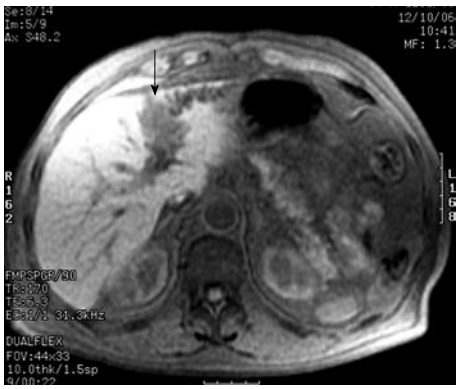

Figure 2 Abdominal MRI (August 2005) showing a pseudonodular mass (arrow) measuring about 5 cm × 3 cm of the hepatic segments Ⅱ-Ⅲ. At the bottom of the lesion, the biliary tree appears dilated.

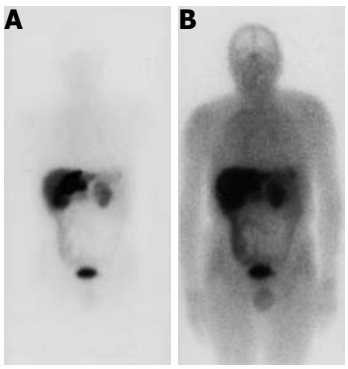

Figure 3 111 In-pentetreotide (octreotide) scintigraphy. A: Before hepatectomy: marked hyperactivity of the lesion is observed in the left hepatic lobe and interaortal adenopathy is observed; B: After hepatectomy; abnormal fluid accumulation of ligand in the epigastric region and dishomogeneous hepatic distribution.

The patient suffered no flushing, no abdominal pain, and no alvus alteration. Moreover, the patient only referred to some successive episodes of angioneurotic edema of the face in the previous 10 years, regardless of the disease in question. As a result, the patient underwent an uncomplicated left hepatic resection and appendectomy with an uneventful postoperative clinical course. Subsequently, octreotide therapy was

Table 1 Hematological values of the patient and normal range

Variable	Patient value	Normal value	Variable	Patient value	Normal value

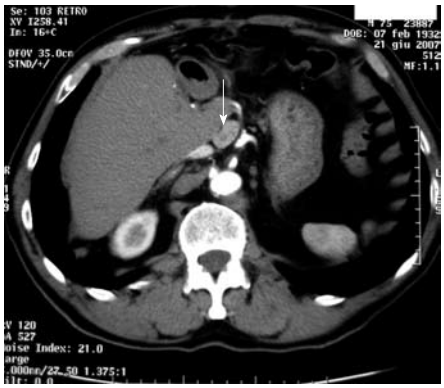

Figure 4 Abdominal CT scan. Results of left hepatectomy show an extended nodular mass measuring about 2.5 cm × 1.5 cm arranged on the back part of the caudate lobe, indicating a lymph node localization of disease.

administered subcutaneously *via* octreotide scan at 2 mo from resection which showed a dishomogeneous distribution of the radioactive drug in the liver site, without any focal images, which warranted further investigation (Figure 3B).

CT scan confirmed the presence of an extended nodular mass measuring about 2.5 cm × 1.5 cm on the back part of the caudate lobe, in close contact with the celiac tripod. The mass was attributable to lymph node recurrence of the disease (Figure 4). The patient showed no signs of evolutive chest disease or any other particular clinical signs.

After a strict clinical and instrumental follow-up period, jointly conducted by an oncologist and a surgeon, the patient's clinical and radiological picture remained stable, as demonstrated by the octreotide therapy. The patient then underwent a surgical lymph node exeresis. The histological finding was compatible with the lymph node metastasis of the neuroendocrine tumor (Figure 5). The postoperative clinical course was uneventful, with a negative follow-up for hematochemical, clinical and radiological investigations at 18 mo post surgery.

DISCUSSION

Neuroendocrine tumors cover a wide range of neoplasms that originate in the neuroendocrine cells that spread throughout the body. Recent studies have suggested an increase in the incidence of these tumors over time[7]. In particular, Maggard *et al*[4] reported a 6.3% increase in 1997 compared with 1973. This could be attributed to an enhanced classification of these tumors and better use of endoscopic techniques for screening purposes. In 1998, 90% of neuroendocrine tumors were reported to occur within the gastrointestinal tract, particularly at the level of the terminal ileum and appendix[8]. However, more recent studies have reported a less frequent gastroenteric involvement (54.%) followed, in decreasing order, by the lung (30.1%), pancreas (2.3%), reproductive system, (1.2%), biliary tract (1.1%), and head and neck (0.4%). As far as the gastrointestinal tract is concerned, a slighter greater involvement of the appendix has been reported compared other sites, such as the small bowel (44.7%) followed by the rectum (19.6%), appendix (16.7%) colon (10.6%) and stomach (7.2%)[4].

PHCTs are rare neuroendocrine tumors, representing 0.3% of all carcinoids, and were first described by Edmonson in 1958[9,10]. Recent studies reported a survey on 95 cases of PHCT[5,11]. The liver is the most frequently involved organ due metastatic disease from extrahepatic neuroendocrine tumors, thus justifying the physician's efforts in ruling out the presence of other diseases before confirming this organ as the primary nature of the tumor[5].

Indeed both the clinical exclusion criteria and the histological confirmation represent a diagnostic means to approach this rare disease.

The clinical onset of neoplasms is often aspecific and related to mass effect on the liver and adjacent organs. Likely symptoms include pain, weight loss, palpable mass, while less common is the classic carcinoid syndrome (skin flushing, abdominal pain and episodes

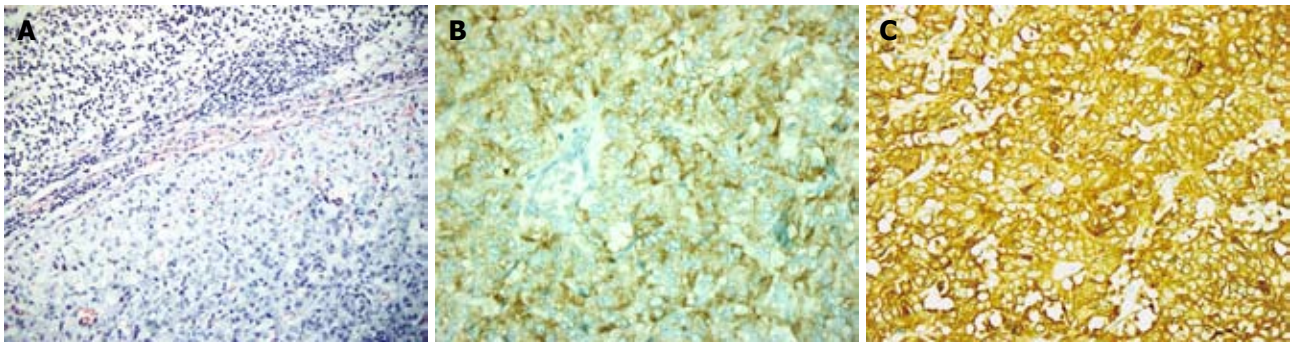

Figure 5 Histological and immunohistochemistry. Proliferation of average sized monomorphic epithelial cells collected in strings and glandular structures (A). Positive immunohistochemistry staining for CgA (B) and NSE (C).

of diarrhea) which are present in 5% of cases[5] and more frequently found in tumors which metastasize to the liver.

The clinical course of PHCT is generally painless compared to other neuroendocrine neoplasms with a more malignant progression. The latter may be characterized by varying degrees of pleomorphism, greater mitotic activity, vascular invasion and necrosis[12]. From the morphological point of view, in accordance with the literature, our patient presented well-differentiated PHCT with low-grade malignancy, minimum pleomorphism, low mitotic index and poor necrotic foci.

The first level diagnosis consisted of non-invasive imaging. A traditional ultrasound scan revealed a hyperecogenic mass containing multiple cystic lesions, while a CT scan confirmed a cystic pattern. Moreover, angiography might demonstrate multiple hypervascular and centrally located radiolucent areas[5]. Classical PET with fluorodeoxyglucose did not prove to be advantageous in neuroendocrine tumor imaging[13]. Thus, a serotonin precursor 11C-5 hydroxy tryptophan was developed as a tracer for PET-scanning, which can be concentrated within carcinoid tumors[13]. Findings using this application are encouraging, allowing the identification of the primary tumor in 84% of cases[14,15]. Primary carcinoid tumors and distant metastasis in patients affected by neuroendocrine tumors are better detected by otreoscan scintigraphy compared to the CT scan and the MRI[16].

The presence of somatostatin receptors within the tumoral cell is best suited for scintigraphy. There are five receptor subtypes (SSTR 1-5) each having different functional properties and binding specificity for the target tissue[16]. Octreotide binds with high affinity to the somatostatin subtype 2 receptor (SSTR 2), which is widely expressed on the cell surface with neuroendocrine characteristics. Certain diagnosis is, however, achieved by fine needle aspiration or biopsy. Immunohistochemistry confirms neuroendocrine origin of PHCT by detecting the markers CgA, NSE, chromostatin, CEA and synaptophysin[17]. Measurement of plasma CgA and repetition of the octreoscan scanning provide the basis for follow-up[5]. Although PHCT appears to be a low malignancy tumor with slow progression, treatment effectiveness and prognosis are difficult to establish owing to its rarity and subsequent lack of prospective data[18]. Surgical resection is the most commonly used therapy and it is considered the treatment of choice[19] in about 85% of primary hepatic carcinoids[18]. This procedure cannot be performed in the 10% of patients affected by metastatic hepatic carcinoid[20,21]. For these cases, as well as for non operable tumors, therapy with radionuclides and the somatostatin analog 177Lu-DOTA-Tyr3-octreotate, are the most modern and promising, not only in terms of stabilization but also with regard to disease regression with minimal toxicity[5,22]. Other therapeutic interventions have been tried for curative and palliative purposes, such as systemic chemotherapy, hepatic artery chemoembolization (only in cases of non resectable or recurrent disease), somatostatin hormone therapy or its analogs performed as a stand-alone therapy or as an adjunct to surgery[5,18]. Hormone therapy is indicated in carcinoids causing functional symptoms, however, no evidence is available as to the control of disease progression. Moreover, this therapy might only exert cytostatic effects[23-25]. Indeed, evidence does exist demonstrating that somatostatin analogs can inhibit tumour growth, at least for a certain period of time[26,27], but further studies are necessary to evaluate this effect.

Recent reports have demonstrated a favourable prognosis at 5 years in 74% of surgically treated cases with an 18% recurrence rate[19]. Post-resection perihepatic lymph node involvement has been infrequently reported in the literature without hepatic involvement, similarly to bone and lung metastasis[18,28].

In 2001, Iwao *et al*[18] analyzed 53 cases of PHCT reported in the English language literature. Accordingly, lymph node involvement occurs in 60% of cases. A case report of 2002[29] confirmed a case of metachrone lymph node metastasis after a 5-year follow-up in one case of surgically treated PHCT.

The case reported here is unique due to its discovery by chance during an abdominal scan which the patient was undergoing for other reasons.

The extremely long evolution, and the absolute lack of pathognomonic symptoms of the disease, resulted in successful diagnosis following a complex process lasting two years. Moreover, the diagnostic course was characterized by the physician's efforts to rule out

extrahepatic neoplasms with possible hepatic metastatic disease.

A diagnostic algorithm proposed by a study published in 2003[23] underlined the need for thorough research into neuroendocrine neoplasms of the small bowel (mid gut), large bowel (hind gut), bronchi (foregut) and pancreas (islet cell). In fact, a small sized lesion can metastasize extensively to liver tissues and might not be detected during a classic diagnostic approach.

In conclusion, a regular clinical and instrumental post surgical review is essential for identifying possible tumor recurrence as well as detecting previously unrecognised primary extrahepatic lesions.

Abstract

In this case report we present an elderly patient who was referred to our hospital with recurrent episodes of cholangitis that persisted after placement of five metal stents for a distal common bile duct (CBD) stenosis. All metal stents were endoscopically removed from the CBD by forceps after balloon dilatation of the papilla. A profoundly dilated CBD with sludge and concrements was seen. To ensure adequate bile drainage an enteral metal stent was inserted in the CBD. This case shows that proximally migrated uncovered metal stents in the CBD can be safely removed endoscopically under certain circumstances. We suggest that in the case of a CBD drainage problem due to an extremely dilated CBD, placement of an enteral metal stent in the CBD could be considered, especially in patients who are unfit for surgery.

Key words: Cholangitis; Dilated common bile duct; Endoscopic retrograde cholangiopancreatography; Enteral metal stent; Metal stent removal

INTRODUCTION

Biliary drainage of inoperable malignant bile duct obstruction by a metal stent is preferred over plastic stents due to longer patency[1]. Unfortunately, even metal stents can become dysfunctional[2]. Usually a second stent (metal or plastic) is placed[3] or an attempt to remove the stent endoscopically can be made[4]. We report a case of relapsing cholangitis after placement of 5 metal stents. Removal of the metal stents and insertion of an enteral stent in the common bile duct (CBD) regained adequate drainage.

CASE REPORT

An 84-year old woman was referred to our hospital with relapsing cholangitis since August 2007. Under the suspicion of a malignant distal CBD stricture with stones, a metal stent was placed. As drainage remained inadequate, the patient underwent several endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC) procedures with the subsequent placement of 5 uncovered metal 30 French 60 mm Wall stents (Boston Scientific Corporation, Natick, USA) and 2 externally draining PTC drains in the CBD, without clinical improvement.

The patient was referred to our centre in February 2008. Work-up by endoscopy and radiography showed five Wall stents in the CBD (four proximally and one was dislocated distally) and two externally draining 8 French percutaneous drains (Figure 1). To improve drainage the percutaneous drains were replaced by two internal/external 10 French drains. After endoscopic removal of the distally dislocated metal stent with the help of a snare, a large amount of biliary sludge with concrements was drained.

The patient recovered well, but two weeks later, she had to be re-admitted with bile leakage alongside the drains and a poor overall condition due to inadequate drainage (Figure 2).

During ERCP all metal stents were removed. We

Figure 2 After endoscopic removal of the distal metal stent. The distal CBD was visualized with 4 metal stents proximally in an abnormal position in relation to the CBD.

Figure 3 After placement of an enteral metal stent in the dilated CBD.

performed balloon dilatation (18 mm CRE balloon, Boston Scientific International S.A., Nanterre Cedex, France) of the sphincter and the relatively narrow distal CBD to 18 mm. We encountered four metal stents that had been overlapping. The stents were subsequently removed with foreign body forceps. With a balloon and crusher the majority of the concrements and debris was removed. Given the extreme dilatation of the CBD, up to 5 cm in diameter, with a profound angulation of the distal CBD and in retrospect no malignant stricture, an enteral metal stent was placed (WallFlex enteral duodenal stent 22 mm × 60 mm, Boston Scientific Corporation, Natic, USA) to prevent further obstruction by kinking[5] (Figure 3). Two internal/external drains were temporarily placed through the "enteral" stent to flush the bile ducts to remove the remaining debris.

Six months later our patient is still without signs of cholangitis.

DISCUSSION

In this case the following aspects were identified: After several interventions, the CBD drainage was still inadequate and the general condition of the patient excluded surgery as an option. To improve drainage, we removed all metal stents. The endoscopic removal of distal dislocated metal stents by forceps or a loop was previously described by Matsushita *et al*[4]. However, in our case we removed, in addition to the distally dislocated stent, a total of 4 metal stents that had migrated proximally in the CBD. To our knowledge, this has never been described. Usually these proximally migrated stents are fixed into their surroundings due to the radial expending force and ingrowth of bile duct epithelium. Secondly, these stents were located beyond the papilla which had to be dilated in order to reach the stents. Normally in the case of stent dysfunction, plastic stents or a second metal stent is introduced through the obstructing metal stent. However, the metal stents seemed to attribute to the increased angulation of the distal CBD and therefore had to be removed. In this particular case, safe removal was possible because the metal stents were free floating within an extremely dilated CBD. This left the patient with a widened CBD with a secondary distal angulation contributing to recurrent obstruction. Normally a hepaticojejunostomy would solve these problems, however, her general condition combined with her age forced us to look for other options. We chose to place a large diameter enteral metal stent in the distal CBD to avoid dislocation and kinking of the widened CBD. This procedure was successfully used by Diehl *et al*[5] to stent a wide CBD due to a choledochal cyst. In our patient we achieved adequate drainage, the stent remained in position and no recurrence of cholangitis has occurred for more than 6 mo.

Proximally migrated uncovered metal stents in the CBD can be safely removed endoscopically under certain circumstances. We suggest that in the case of a CBD drainage problem due to an extremely dilated CBD, placement of an enteral metal stent in the CBD could be considered, especially in patients who are unfit for surgery.

Abstract

Extramedullary plasmacytoma (EPM) is a plasma cell tumor arising outside of the bone marrow. Solitary EMP is an uncommon neoplasm and rarely occurs in the retroperitoneum and lacks distinctive clinical manifestations. We report a 26-year-old man with a solitary EMP in the retroperitoneum and discuss its clinical features, diagnosis and treatment.

Key words: Extramedullary plasmacytoma; Retroperitoneal neoplasm; Computed tomography; Histopathology

Solitary extramedullary plasmacytoma in retroperitoneum: A case report and review of the literature. *World J Gastroenterol* 2009; 15(19): 2425-2427 Available from: URL: http://www.wjgnet.com/1007-9327/15/2425.asp DOI: http://dx.doi.org/10.3748/wjg.15.2425

INTRODUCTION

Extramedullary plasmacytoma (EMP), accounting for approximately 3% of all plasma cell neoplasms, results from uncontrolled plasma cell proliferation and consists of monoclonal plasmacytic infiltration without bone marrow involvement[1]. Approximately 80%-90% of EMPs involve mucosa-associated lymphoid tissue of the upper airway and 75% of them involve the nasal and paranasal regions, while retroperitoneal infiltration is very rare[2]. We report a 26-year-old man with a solitary EMP in the retroperitoneum.

CASE REPORT

A 26-year-old man was referred to our hospital with a history of abdominal distention and effort intolerance persisting for the previous 2 mo. He had no history of fever, weight loss, bladder or bowel dysfunction, and back pain. Physical examination revealed an irregular, firm, non-tender mass occupying almost the whole abdomen. He had no icterus or lymphadenopathy with normal tests. An abdominal computed tomography (CT) scanning showed a large heterogeneous mass in the right retroperitoneal region, surrounding the posterior portion of the right kidney and compressing the right kidney (Figure 1A). The tumor tissue was slightly enhanced after injection of a contrast medium (Figure 1B).

Laboratory test revealed 2.8 × 10^9/L white blood cells (WBC) (normal range 4-10 × 10^9/L), 119 g/L hemoglobin (Hb) (normal range 120-160 g/L), 122 × 10^9/L platelets (PLT) (normal range 100-300 × 10^9/L), and normal serum levels of creatinine, blood urea nitrogen, amylase, hepatic enzymes, electrolytes including calcium and phosphorus. No erythrocyte or protein was observed in his urine.

Fine needle aspiration cytology of the mass was not done because of refusal of his parents who were afraid of needle track implantation. Thereafter, an extensive resection of the tumor including extirpation of the right kidney, and part of the liver was performed. Postoperative recovery was uneventful.

Histopathology revealed a 30 cm × 16 cm × 10 cm tumor surrounding the posterior portion of the right kidney with adherent liver. Microscopy showed diffusive infiltration of polygonal cells in the retroperitoneum.

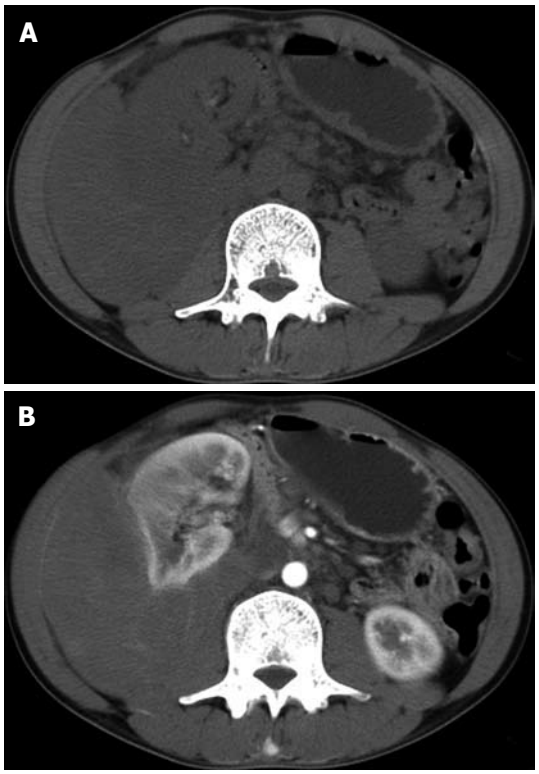

Figure 1 Abdominal computed tomography showing a large heterogeneous mass in the right retroperitoneal region, surrounding the posterior portion of the right kidney and compressing the right kidney (A), and slightly enhanced tumor tissue after injection of a contrast medium (B).

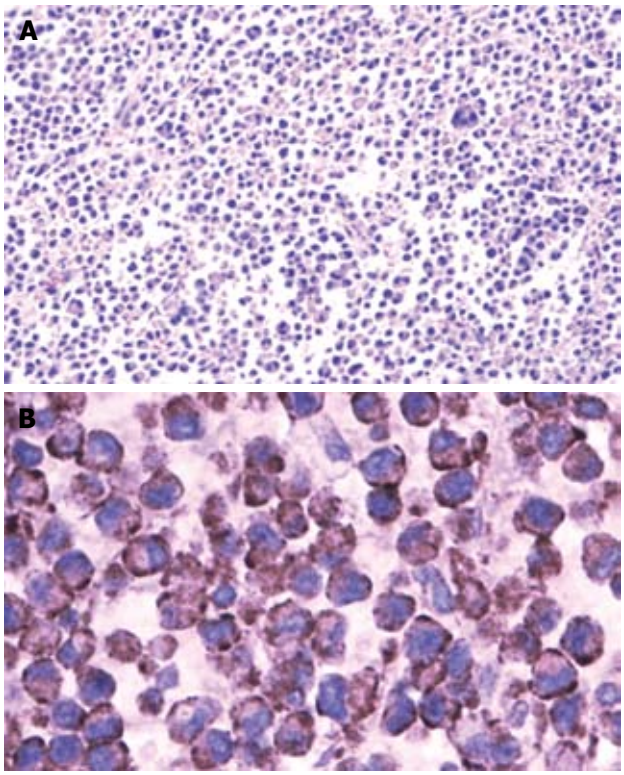

Figure 2 Tumor cells with homogenous amphophilic cytoplasm, whell-type and asymmetric nuclei, coarsely stippled chromatin, some acidophilic nucleoli, and occasional binucleate (A) (HE, × 100) and positive tumor cells for CD138 (B) (× 400) under microscope.

Homogeneous amphophilic cytoplasm, wheel-type and asymmetric nuclei, coarsely stippled chromatin, and some acidophilic nucleoli were observed in the tumor cells. Binucleate cells were also occasionally observed (Figure 2A). Immunohistochemistry demonstrated tumor cells were positive for CD138 (Figure 2B), Bcl-2 and VS38C, but negative for CD20, CD3, CD79a, CK, CD38, S-100, CD5, CK, myosin and CD10.

To confirm the diagnosis of EMP, further investigations were done after surgery. Serum IgG was 25.4 g/L (normal range 6.94-16.20 g/L). Serum IgA and IgM levels were within normal range. No Bence-Jones protein was detected in his urine. Iliac crest bone marrow aspiration and biopsy did not find any plasmacytic infiltration. A skeletal survey revealed no osteolytic lesions.

DISCUSSION

Solitary bone and extramedullary plasmacytomas are rare plasma cell proliferative disorders. Their diagnosis is based on the monoclonal plasma cell infiltration at a single disease site and the exclusion of systemic myeloma[3]. WBC and hemoglobin were slightly abnormal, and iliac crest bone marrow aspiration and biopsy showed no plasmacytic infiltration in our case. We ascribed these abnormalities to the fact that he worked as a painter for 8 years prior to surgery. Hematopathy can be found in workers exposed to benzene[4].

EMP occurs most commonly in the head and neck region, followed by gastrointestinal (GI) tract, central nervous system (CNS), thyroid, breast, parotid gland, testis, and lymph nodes[5].

Solitary EMP rarely occurs in the retroperitoneum. Cases of retroperitoneal EMP have different clinical manifestations, such as renal failure due to bilateral renal vein occlusion[6], flank pain, hematuria due to thrombosis of the renal vein[7], obstructive jaundice[8], abdominal distention and pain[9,10], and hyperamylasemia[11]. However, our patient presented with only abdominal distention and effort intolerance.

Retroperitoneal EMP should be differentially diagnosed from lymphoplasmacytic lymphoma and immunoblastic lymphoma[12]. Immunohistochemistry is used for its final diagnosis. In our case, microscopy showed that the tumor cells might be origined from plasmacytic cells confirmed by immunohistochemistry.

Preoperative CT scanning does not contribute to its differential diagnosis from other tumors, while preoperative angiography can indicate the vessels feeding the mass and the correlation to other vessels. Serum electrophoresis can help its diagnosis by finding the M band. However, we considered the mass as a common type of tumors, such as schwannoma, sarcoma before operation and serum electrophoresis was not done.

No clear guidelines for treatment of EMP are available due to its rarity and variable presentations. EMP is highly radiosensitive with excellent results (< 10% of local recurrences and about 50%-65% of patients remain free of disease for > 10 years)[13]. However, it is associated with a high morbidity particularly when

used for large retroperitoneal tumors. It was reported that there is no evidence that retroperitoneal EMP progresses one year after chemotherapy in combination with radiotherapy[14]. Chen *et al*[8] have reported a case of retroperitoneal EMP accompanying obstructive jaundice, who showed a complete response to sequential radiotherapy and chemotherapy.

Sharma *et al*[10] performed a complete surgical resection of a large bulky retroperitoneal EMP when the patient did not respond to chemotherapy, and found that the patient was symptom free 16 mo post surgery. Our patient did not receive chemotherapy or radiotherapy prior to operation. He was under observation 2 mo after surgery and remained asymptomatic when we wrote this paper.

In summary, EMP should be considered whenever a retroperitoneal soft tissue mass is identified.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systemically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H pylori*, *E coli*, *etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No.62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multidisciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

The clinical course of chronic liver diseases is significantly dependent on the progression rate and the extent of fibrosis, i.e. the non-structured replacement of necrotic parenchyma by extracellular matrix. Fibrogenesis, i.e. the development of fibrosis can be regarded as an unlimited wound healing process, which is based on matrix (connective tissue) synthesis in activated hepatic stellate cells, fibroblasts (fibrocytes), hepatocytes and biliary epithelial cells, which are converted to matrix-producing (myo-)fibroblasts by a process defined as epithelial-mesenchymal transition. Blood (non-invasive) biomarkers of fibrogenesis and fibrosis can be divided into class Ⅰ and class Ⅱ analytes. Class Ⅰ biomarkers are those single tests, which are based on the pathophysiology of fibrosis, whereas class Ⅱ biomarkers are mostly multiparametric algorithms, which have been statistically evaluated with regard to the detection and activity of ongoing fibrosis. Currently available markers fulfil the criteria of ideal clinical-chemical tests only partially, but increased understanding of the complex pathogenesis of fibrosis offers additional ways for pathophysiologically well based serum (plasma) biomarkers. They include TGF-β-driven marker proteins, bone marrow-derived cells (fibrocytes), and cytokines, which govern pro- and anti-fibrotic activities. Proteomic and glycomic approaches of serum are under investigation to set up specific protein or carbohydrate profiles in patients with liver fibrosis. These and other novel parameters will supplement or eventually replace liver biopsy/histology, high resolution imaging analysis, and elastography for the detection and monitoring of patients at risk of developing liver fibrosis.

Key words: Biochemical markers; Diagnostic validity; Liver fibrosis; Monitoring; Multiparametric algorithms; Non-invasive diagnostic tools

INTRODUCTION

Tissue fibrosis is characterized by the excess deposition of extracellular matrix (ECM) involving molecular and histological re-arrangement of various types of collagens, proteoglycans, structural glycoproteins and hyaluronan (Figure 1). It is a hallmark of liver cirrhosis and contributes significantly to the deleterious outcome of chronic liver diseases[1]. The deposition of ECM in the space of Disse (perisinusoidal fibrosis) between the sinusoidal surface of hepatocytes and the endothelial cell layer of liver sinusoids, the generation of (incomplete) subendothelial basement membranes, and the strangulation of hepatocytes by surrounding matrix impair not only the blood flow through the organ, but also the biosynthetic function of hepatocytes and the clearance capability of these and other cell types[2].

The molecular pathogenesis of the fibrotic transition of liver parenchyma turns out to be a muti-faceted process largely due to the activation of resting, vitamin A-storing stellate cells to matrix-producing myofibroblasts[3,4] in the immediate neighbourhood of hepatocytes, to the phenotypic switch of hepatocytes and bile duct epithelial

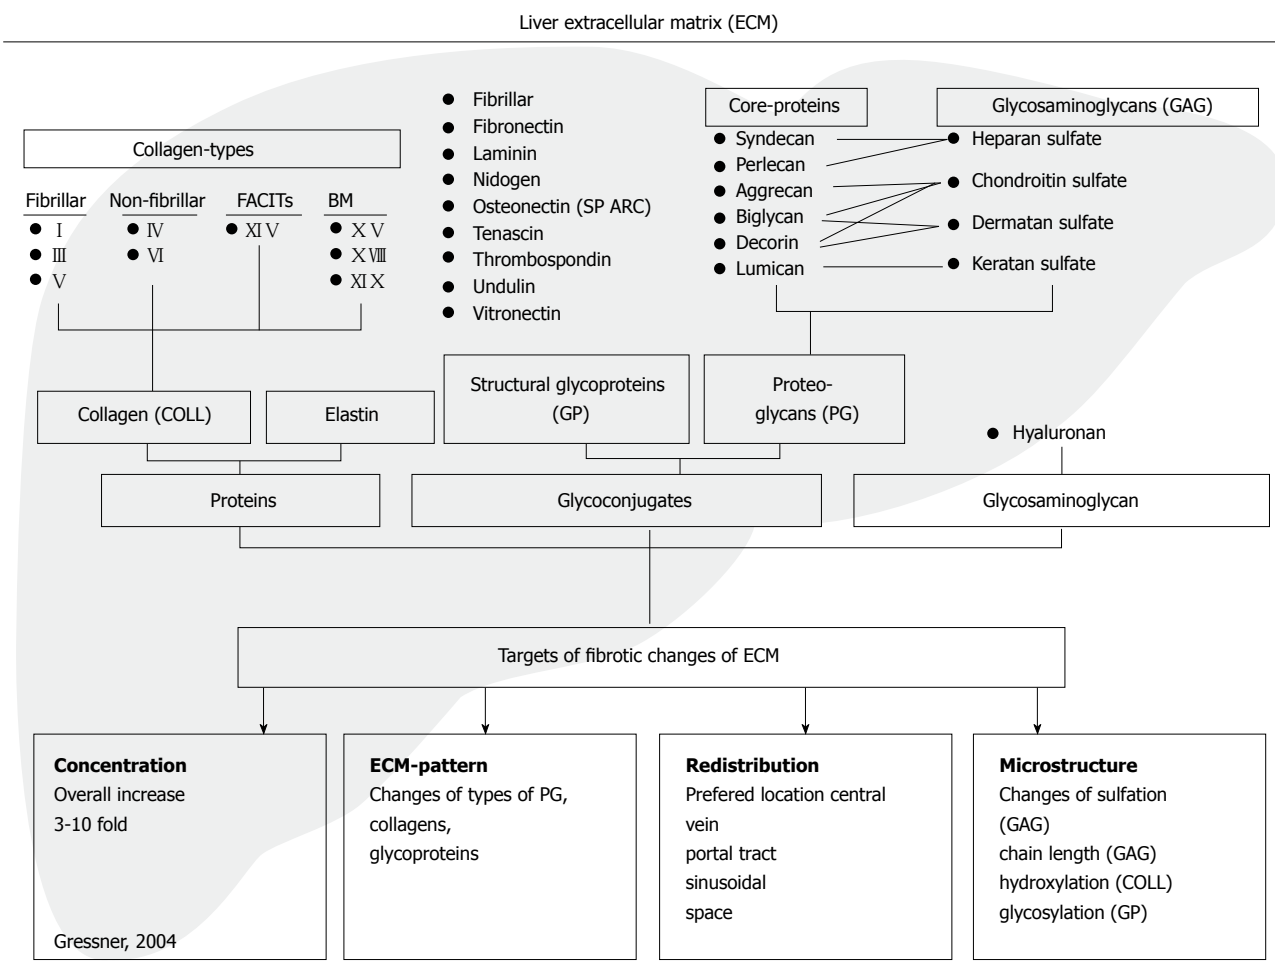

Figure 1 Components of the extracellular matrix (connective tissue) of the fibrotic liver and their major changes. The binding of glycosaminoglycans (GAG) to the respective core proteins (CP) of proteoglycans (PG) are shown. BM: Basement membranes; FACIT: Fibril-associated collagens with interrupted triple-helices.

cells to fibroblasts termed epithelial-mesenchymal transition (EMT)[5-7], and to the influx of bone marrow-derived cells (fibrocytes) reaching the liver via the systemic circulation[8,9] (Figure 2). The fractional contribution of these pathways to fibrosis depends on the underlying disease and probably on the stage of the fibrotic transition[2]. The activation of stellate cells results from interaction with damaged hepatocytes, activated Kupffer cells, disintegrated platelets and various subfractions of leucocytes. Among the cytokines involved in the pathogenetic processes, TGF-β plays a dominant role, but PDGF, endothelin-1, VEGF, and others also contribute significantly. Antagonistic (antifibrotic) mediators might also exist among which bone morphogenetic protein (BMP)-7 plays an important role, e.g. in the inhibition of EMT-derived fibroblasts[10].

The pathogenetic complexity is mirrored by multiple approaches of a clinical diagnosis and a follow-up of ongoing liver fibrosis.

The widely used diagnostic "gold standard" of liver biopsy has many draw-backs besides its invasiveness such as sampling error (around 1/50 000th of liver mass is obtained), irreproducible sample quality depending on length and size of the tissue specimen (coefficient of variation 45%-35%) and a histological evaluation strictly dependent on the experience of the pathologist (observer error)[11]. Therefore, the development of non-invasive, objective and quantitative serum- or plasma-based biomarkers of fibrogenesis is an important goal, which can be approached by the assessment of two, principally different lines of blood-borne (non-invasive) analytes: Class Ⅰ and class Ⅱ serum fibrosis markers.

CLASSIFICATION OF CIRCULATING BIOMARKERS OF FIBROSIS

Class Ⅰ fibrosis biomarkers are pathophysiologically derived from ECM turnover and/or from changes of the fibrogenic cell types, in particular hepatic stellate cells (HSC) and (myo-)fibroblasts[3]. They should reflect the activity of the fibrogenic and/or fibrolytic process and, thus, remodelling of ECM. These biomarkers do not indicate the extent of connective tissue deposition, i.e. the stage of fibrotic transition of the organ. Frequently, they involve costly laboratory tests and are the result of translation of fibrogenic mechanisms into clinical application. Thus, their selection is hypothesis-driven.

Class Ⅱ fibrosis biomarkers mostly estimate the degree of fibrosis (extent of ECM deposition). In general, they comprise common clinical-chemical tests (enzymes, proteins, coagulation factors), which do not necessarily

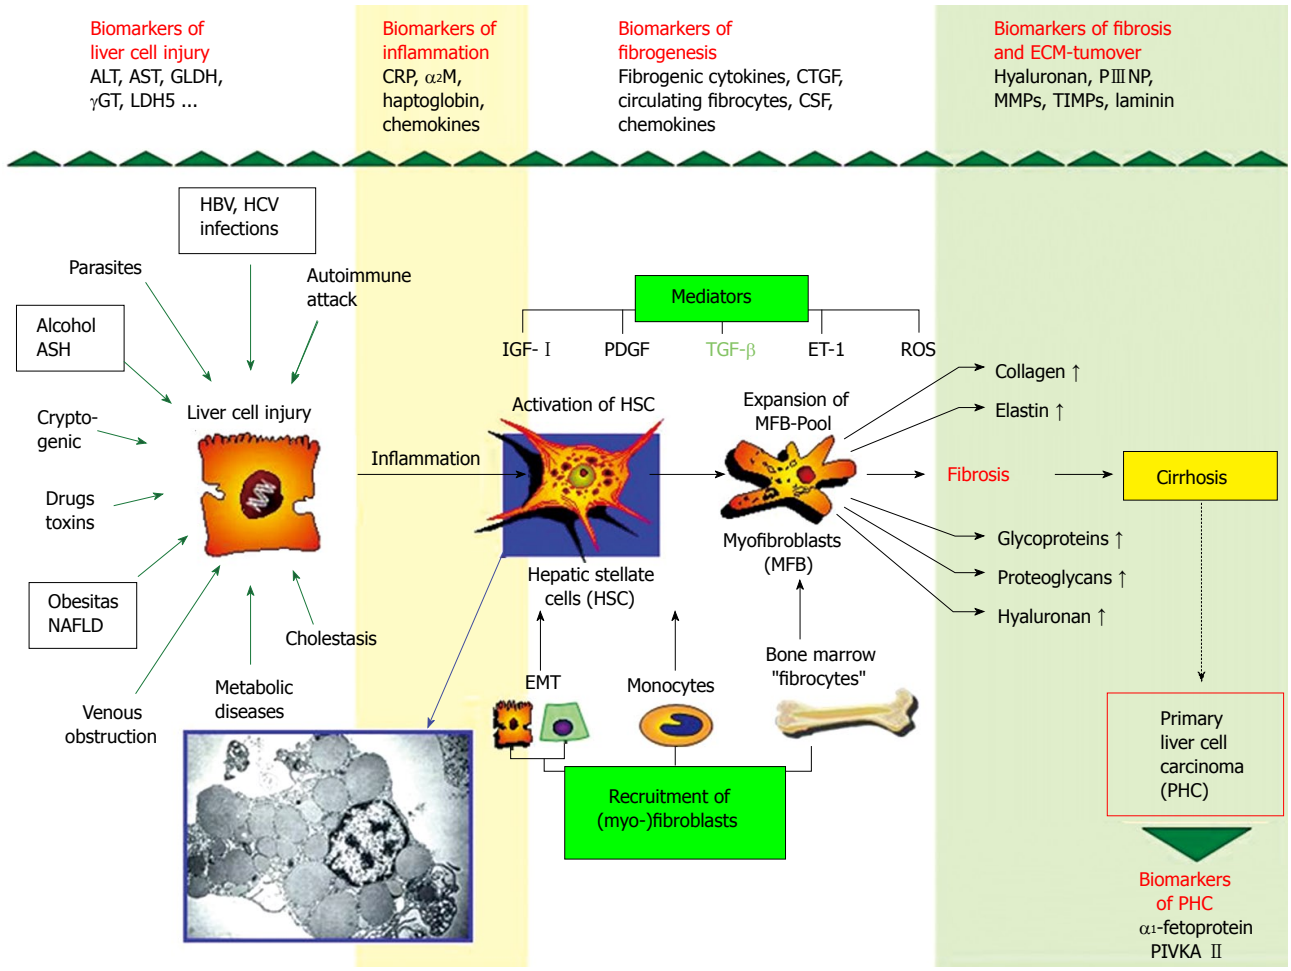

Figure 2 Synopsis of pathogenetic mechanisms of liver fibrosis (fibrogenesis). The cells produce an increase in extracellular matrix derived from activated hepatic stellate cells (HSC)/expended pool of myofibroblasts (MFB) produce various components of the extracellular matrix (fibrosis) leading to cirrhosis. Newly recognized pathogenetic mechanisms point to the (i) influx of bone marrow-derived cells (fibrocytes) to the liver, (ii) to circulating monocytes and to their TGF-β-driven differentiation to fibroblasts and (iii) to the epithelial-mesenchymal transition (EMT) of hepatocytes and bile duct epithelial cells to fibroblasts. All three complementary mechanisms enlarge the pool of matrix-synthesizing (myo-)fibroblasts. Some important fibrogenic mediators are transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), insulin-like growth factor I (IGF- I), endothelin-1 (ET-1), and reactive oxygen metabolites (ROS). Abbreviations: ASH: Alcoholic steatohepatitis; NAFLD: Non-alcoholic fatty liver disease. The insert shows an electron micrograph of hepatic stellate cells containing numerous lipid droplets.

reflect ECM metabolism or fibrogenic cell changes. Their pathobiochemical relationship with fibrogenesis is indirect if at all. Thus, their selection is not hypothesis-driven, but empiric. The markers are standard laboratory tests and are integrated into multiparametric panels.

In general, both types of serum biomarkers follow different pathophysiological concepts. Class I markers inform about "what is going on" (grade of fibrogenic activity), class II markers indicate "where fibrosis is" (stage of fibrosis).

Class I fibrosis biomarkers

These biomarkers are components of the connective tissue (matrix) increasingly expressed by activated hepatic stellate cells (HSC) and (myo-)fibroblasts[12], have a delayed clearance by Kupffer cells or sinusoidal endothelial cells in the liver due to metabolic dysfunction and/or hemodynamic bypasses, or are increasingly expressed mediators of fibrogenesis such as TGF-β. Taken together, of the several procollagen and collagen fragments proposed, only the N-terminal propeptide of type III procollagen (PIIINP) has reached a limited clinical application, but not widespread acceptance[13]. Sensitivities of about 76%-78% and specificities of 71%-81% have been reported, which can be increased up to 88%, if combined with additional collagen fragment markers. It should be emphasized that PIIINP is not a liver-specific biomarker. Similarly, structural glycoproteins (e.g. undulin, tenascin), biosynthetic (e.g. prolyl hydroxylase) or catabolic enzymes (e.g. matrix metalloproteinases) of collagen and other ECM-components have not been convincing in the detection, grading, and staging of fibrosis (Table 1). Several studies have shown that hyaluronic acid (hyaluronan) is currently the best class I biomarker of fibrosis having an area under the receiver operating characteristics (AUROC) of 0.97, a sensitivity of 86%-100%, and a specificity of about 88% in a recent investigation of cirrhosis due to non-alcoholic fatty liver disease[14] and other aetiologies. Since the negative predictive value of hyaluronan at a cut off value of 60 μg/L is much higher (98%-100%) than the positive predictive value (61%), the main utility of serum hyaluronan lies in its ability to exclude advanced fibrosis and cirrhosis. Its

Table 1 Class I biomarkers of liver fibrogenesis

	Specimen			Method
	Serum	Urine	Liver biopsy	
Extracellular matrix-related enzymes				
Enzyme				
Prolyl hydroxylase	+	-	+	Radioenzymatic, RIA
Monoamine-oxidase	+	-	(+)	Enzymatic
Lysyl oxidase	+	-	+	RIA
Lysyl hydroxylase	+	-	-	RIA

Marker				
Transforming growth factor β (TGF-β)	+	-	+	ELISA
Connective tissue growth factor (CTGF/CCN2)	+	?	+	ELISA

stimulated synthesis in activated HSC, secretion into the sinusoidal blood stream, and short half life of 2-9 min in the circulation are good suppositions for a valid fibrosis biomarker. Laminin was reported to be a predictor of portal hypertension since significantly elevated concentrations were found under these conditions[15]. TGF-β concentration in plasma is elevated in and correlates with the severity of liver disease and is suggested to be a non-invasive biomarker of fibrosis. However, the significant correlation with AST and ALT activity[16] and the pathobiochemical finding that substantial amounts of TGF-β are localized in hepatocytes and released into the medium if hepatocytes are permeabilized[17] suggest that the elevation of TGF-β is a marker of necrosis instead of fibrogenesis.

Preliminary studies point to connective tissue growth factor (CTGF/CCN2) in serum as an innovative class Ⅰ biomarker of fibrogenesis[18]. This 38 kDa protein is synthesized not only in HSC, but also in hepatocytes where the expression and secretion is strongly dependent on TGF-β[19,20]. Accordingly, the expression of the TGF-β down-stream mediator CTGF in fibrotic liver tissue is up-regulated and its concentration in blood is elevated if fibrogenesis is occurring. There is a correlation between CTGF levels and fibrogenesis, because the levels decrease in fully developed, end-stage cirrhosis, compared to fibrosis. The AUCs for fibrosis *vs* control and cirrhosis *vs* control were calculated to be 0.955 and 0.887, respectively, the sensitivities 100% and 84%, respectively, the specificities 89% and 85%, respectively[18]. These criteria suggest that CTGF is a potentially valuable class Ⅰ biomarker of active fibrogenesis.

Recently, the glycoprotein YKL-40 ("chondrex", molecular mass 40 kDa), which is likely a growth factor for fibroblasts and endothelial cells, was shown to be

Table 2 Class Ⅱ biomarkers of liver fibrogenesis

Index	Parameters	Chronic liver disease	Sensitivity (%)	Specificity (%)
PGAA-Index	Prothrombin time, γGT, apolipoprotein A1, α2-macroglobulin	Alcohol	79	89
Bonacini-Index	ALT/AST-ratio, INR, platelet count	HCV	46	98
Sheth-Index	AST/ALT (De Ritis)	HCV	53	100
Park-Index		HCV	47	96
PGA-Index	Prothrombin time, γGT, apolipoprotein A1	Mixed	91	81
Fortunato-Score	Fibronectin, prothrombin time, PCHE, ALT, Mn-SOD, β-NAG	HCV		94
Fibrotest (Fibro-Score)	Haptoglobin, α2-macroglobulin, apolipoprotein A1, γGT, bilirubin	HCV HBV	75	85
Pohl-Score	AST/ALT-ratio, platelet count	HCV	41	99
Actitest	Fibrotest + ALT	HCV		
Forns-Index	Age, platelet count, γGT, cholesterol	HCV	94	51
Wai-Index (APRI)	AST, platelet count	HCV	89	75
Rosenberg-Score (ELF-Score)	PⅢNP, hyaluronan, TIMP-1	Mixed	90	41
Patel-Index (FibroSpect)	Hyaluronan, TIMP-1, α2-macroglobulin	HCV	77	73
Sud-Index (fibrosis probability-index, FPI)	Age, AST, cholesterol, insulin resistance (HOMA), past alcohol intake	HCV	96	44
Leroy-Score	PⅢNP, MMP-1	HCV	60	92
Fibrometer test	Platelet count, prothrombin index, AST, α2-macro-globulin, hyaluronan, urea, age	Mixed	81	84
Hepascore	Bilirubin, γGT, hyaluronan, α2-macroglobulin, age, gender	HCV	63	89
Testa-Index	Platelet count/spleen diameter-ratio	HCV	78	79
FIB-4	Platelet count, AST, ALT, age	HCV/HIV	70	74
FibroIndex	Platelet count, AST, γ-globulin	HCV	38	97

GGT: γ-glutamyltransferase; PⅢNP: N-terminal propeptide of type Ⅲ procollagen; TIMP: Tissue inhibitors of metalloproteinases; MMP: Matrix metalloproteinases; β-NAG: N-acetyl-β-glucosaminidase; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; INR: International normalized ratio.

strongly expressed in human liver tissue[21]. In particular, HSC contain YKL-40 mRNA. Several studies have found elevated YKL-40 concentrations in sera of patients with liver diseases. A sensitivity and specificity of around 80% and an AUC of 0.81 for fibrosis have been reported for HCV-patients[22], for those with alcoholic liver disease, a specificity of 88% and a low sensitivity of 51% were calculated[23]. Serum concentrations of this protein correlated with other ECM products secreted by HSC and fibroblasts, e.g. PⅢNP, hyaluronan, MMP-2, and TIMP-1. It is claimed that YKL-40 concentrations reflect the degree of liver fibrosis but extensive clinical evaluation is still required and other inflammatory diseases as potential causes of YKL-40 elevations have to be excluded. In addition, the expression of this protein is not restricted to the liver, but occurs in chondrocytes (synovial fluid), bone cells, vascular smooth muscle cells and therefore non-specific to the liver[21].

Class Ⅱ fibrosis biomarkers

This category comprises a rapidly increasing, wide variety of biochemical scores and multiparameter combinations (biomarker panels), which are selected by various statistical models and mathematical algorithms, e.g. multiple logistic regression analysis. They fulfil the most appropriate diagnostic criteria for the detection and staging of fibrosis and to a lesser extent for grading of fibrogenesis. In general, the panels consist of rather simple (standard) laboratory tests, which are subject to changes in the serum or plasma of fibrotic and cirrhotic patients (Table 2). Several of the parameters included in the more than 20 scores currently available have no pathophysiological relation to fibrogenesis. Some of them have an indirect relation, and only a few parameters can be regarded as being directly related to fibrogenesis. The parameters measured comprise those of necrosis such as ALT and AST, coagulation-dependent tests, transport proteins, bilirubin and some ECM-parameters. Frequently, the reduction of platelet counts in cirrhotic patients is included. Most prevalent are the Fibrotest™ and for necro-inflammatory activity the Actitest™ (Biopredictive, Paris, France)[24]. These tests are based on γ-glutamyl-transferase (γ-GT), total bilirubin, haptoglobin, α2-macroglobulin, apolipoprotein A1, and for the Actitest additionally on alanine-aminotransferase (ALT)[25]. The data of Fibrotest and Actitest are calculated with a patented artificial intelligence algorithm to give measures of fibrosis stage and necro-inflammatory grade (activity), respectively. The Wai-score based on aspartate-aminotransferase (AST), alkaline phosphatase and platelet count[26], the ELF-test based on TIMP-1, PⅢNP, hyaluronan[27], and the Hepascore based on bilirubin, γ-GT, hyaluronan, α2-macroglobulin, age and gender[28] are further scores with up to now limited clinical application. The Fibrotest was shown to be a better predictor than biopsy staging for HCV complications and death[25]. Recently, Fibrotest™ and Actitest™ were included to detect biomarkers for the prediction of liver steatosis (Steato-test™), alcoholic steato-hepatitis (ASH-test™), and non-alcoholic steato-hepatitis (NASH-test™) by supplementation with serum cholesterol, triglycerides, glucose (and AST for NASH-test) adjusted for age,

Table 3 Future candidate biomarkers of non-invasive diagnosis and follow-up of liver fibrogenesis

Biomarker	Specimen	Assay technology	Pathobiochemical basis
CTGF	Serum	Immunoassay	TGF-β induced expression in and secretion by hepatocytes and hepatic stellate cells
Fibrocytes	Blood, buffy coat	Flow cytometry of $CD34^+$, $CD45^+$, Coll I^+ cells qPCR	Supplementation of local fibroblasts at site of liver injury by bone-marrow derived fibrocytes
BMP-7	Serum	Immunoassay	Antagonist of TGF-β, inhibitor of EMT
G-CSF GM-CSF M-CSF	Blood	Immunoassays	Mobilization of bone-marrow derived fibrocytes
Proteomics	Serum	Mass spectrometry (MS)	Fibrosis-specific serum protein profiles
Glycomics	Serum	Adaptation of DNA-sequencer/fragment analyzer technology to profiling of desialylated N-linked oligo-saccharides	Fibrosis-specific profiles of desialylated serum protein linked oligosaccharides (N-glycans)
Xylosyl-transferase (EC 2.4.2.26)	Serum	LC-MS/MS	Key enzyme in the biosynthesis of glycosaminoglycan chains in proteoglycans, e.g. in hepatic stellate cells and hepatocytes

gender, and body mass index (BMI)[29]. The diagnostic criteria elaborated in a large cohort of patients suggested that the Steato-test was a simple and non-invasive quantitative measure of liver steatosis and the NASH-test was a useful screening procedure for advanced fibrosis and NASH in patients with various metabolic syndromes[29]. FibroMax™ (Biopredictive) was recently developed as a method of combining calculations of these fibrosis-related tests in a single procedure. Comparative evaluation of class Ⅱ serum biomarker panels, however, did not highlight their clinical superiority if liver biopsy was used as the reference method[30]. Since only about 40% of the results were assigned to be correct, a fraction of about 50%-70% was inaccurate with regard to the staging of fibrosis severity and a small fraction of results was even incorrect[30]. Thus, currently suggested multi-parameter approaches with class Ⅱ fibrosis biomarker panels have to be used with caution in clinical practice. A successful approach to improve the diagnostic accuracy of the panel markers in chronic hepatitis C might be their stepwise combination[31]. By combining the sequential algorithms of APRI, Forns' index and Fibrotest (Table 2) the diagnostic performance could be significantly improved resulting in a 50%-70% reduction in the need for liver biopsy[31]. Recently, a comparison of the diagnostic power of up to five class Ⅱ biomarkers led to suggestions to strongly increase their overall accuracy which would, thus, reduce the need for a liver biopsy from 56% to 0% in chronic hepatitis C[32]. Additionally, an algorithm based on the AST-to-platelet-ratio-index (APRI) and liver surface ultrasound nodularity showed a strong diagnostic power making liver biopsy unnecessary[33].

It should be emphasized that the combination of individually assessed parameters necessarily creates a relatively high variance due to the imprecision of each separate measurement[34]. Coefficients of variation range from series to series and are usually between 3% and 6% for common clinical-chemical parameters and from 4% to more than 12% for hyaluronan, PⅢNP, and other matrix parameters. Furthermore, and even more important is the lack of standardized assays for many of these parameters, which excludes the general use of cut-offs and algorithms[34].

DEVELOPMENTS OF INNOVATIVE BIOMARKERS

A growing understanding of the pathogenesis of hepatic fibrosis has indicated potentially powerful non-invasive (blood) biomarkers of hepatic fibrogenesis and fibrosis (Table 3). CTGF/CCN2 was already mentioned as a pluripotent downstream modulator of TGF-β, and was found to be up-regulated by TGF-β in hepatocytes. Although most CTGF will only have a defined paracrine function in fibrogenic tissue, a certain fraction spills over into the circulation, resulting in elevated serum concentrations during active fibrogenesis[18]. The circulating level of CTGF might be an objective and sensitive measure of ongoing fibrogenesis in necro-inflammatory liver tissue.

Bone-marrow-derived fibrocytes might offer new approaches not only for understanding the pathogenesis, but also for the diagnosis of liver fibrosis. Fibrocytes are circulating progenitor cells (CD34 positive) of hematopoietic origin (CD45 positive) capable of differentiating into diverse mesenchymal cell types[35]. The additional markers of fibrocytes, i.e. positivity of type Ⅰ collagen and the CXCR4 chemokine expression can be used to quantitate this special sub-population of circulating leucocytes applying quantitative PCR and/or flow cytometry. The determination of the colony stimulating factors M-CSF, G-CSF, and GM-CSF, which are increasingly expressed in fibrotic liver tissue and elevated in serum[36], are possibly involved in the mobilisation of fibrocytes from the bone marrow and their homing in the liver during fibrogenesis. These factors may be further candidates for diagnostic evaluation.

A new, but currently still controversial aspect of fibrogenesis is epithelial-mesenchymal transition (EMT) of hepatocytes and biliary epithelial cells, respectively, to (myo-)fibroblasts[2]. EMT is governed by the balance of TGF-β (pro-EMT) and its antagonist, i.e. BMP-7 (anti-EMT). In addition to its anti-EMT effect, BMP-7 was shown to have anti-apoptotic and anti-inflammatory activities. Thus, the measurement of BMP-7 alone or even in relation to TGF-β in serum might reflect the activity of fibrogenesis and, hence, the velocity of

fibrotic organ transition[37].

Xylosyltransferase (XT), a key enzyme in the biosynthesis of glycosaminoglycans in proteoglycans, was shown to have increased activities in the serum of patients with connective tissue diseases. With HPLC-tandem mass spectrometry, measurements in large cohorts of liver fibrotic patients may to be possible[38]. Since HSC in fibrotic liver tissue (myofibroblasts) have a greatly stimulated proteoglycan synthesis[39], XT activity in serum might be a promising class I biomarker of fibrogenesis.

Further successful developments could emerge from serum proteome profiling[40] and from total serum protein glycomics, i.e. the pattern of N-glycans[41]. It was reported that a unique serum proteomic fingerprint is powerful enough (accuracy > 90%) to differentiate between various stages of fibrosis and to allow prediction of fibrosis and cirrhosis in patients with a chronic hepatitis B infection[40]. Specificities, sensitivities and accuracy of prediction of cirrhosis are around 89%. Similarly, N-glycan profiling can distinguish between compensated cirrhosis from non-cirrhotic chronic liver diseases with a sensitivity and specificity of 79% and 86%, respectively[41].

Supplementation of all these laboratory tests by modern high resolution or molecular imaging analyses would be extremely helpful in the consolidation of objective and valid non-invasive biomarkers of diagnosis and follow-up of fibrogenic (liver) diseases. In conclusion, currently available type I and II serum biomarkers should be used with caution, because neither single nor panel markers fulfil the requirements of an ideal non-invasive biomarker of fibrosis[42], i.e. analytical simplicity allowing performance in any laboratory, standardization of the test system and calibrators allowing comparison between laboratories over a long period, cost effectiveness, specificity for the liver and the disease, clear association with the stage of fibrosis or grade of fibrogenesis and independency of the aetiology of fibrosis. Even the best and most extensively evaluated type I (i.e. hyaluronan) and type II (i.e. Fibrotest, Actitest) serum biomarkers do not meet the criteria of an ideal marker. Further detailed insight into the mechanism of liver fibrosis and improvements in analytical techniques will result in new approaches for the non-invasive assessment of fibrosis with biochemical or physical means.

In addition, genetic markers linked with the progression rate of fibrosis will become important diagnostic and prognostic tools for patients with liver fibrosis.

CONCLUSION

Non-invasive evaluation of the fibrogenic response of the chronically injured liver has made considerable progress over the past few years, in particular over the last three years multiple algorithms based on a combination of more or less routine parameters have been suggested frequently. A rigorous, independent and widespread evaluation of the utility of these panels in the diagnosis and follow-up of chronic liver diseases is still needed for a final decision and the recommendation for use in routine clinical practice. Novel single biochemical markers have been suggested, but there putative diagnostic value in clinical practice is far from defined. The fundamental problem in the evaluation of existing and novel non-invasive parameters lies in the limited validity of the present diagnostic "gold standard", i.e. histology of liver biopsy specimens. Perhaps new developments in highly sensitive and tissue-specific scanning techniques of the liver will solve this problem. These procedures will then be suitable for the correct validation of effective antifibrotic treatments.

Abstract

This issue presents a symposium held in Messina talking about inflammatory bowel disease (IBD) and associated spondyloarthropathies. The topic covers epidemiology and clinical manifestations of IBD-related arthropathies, common genetic and immunologic features, combined therapies for gut and joint inflammation, and future biologic therapies *etc*. I believe this series of articles will deeply facilitate understanding of and the approach to IBD and associated arthropathies.

Key words: Inflammatory bowel disease; Spondyloarthropathies; Anti-tumor necrosis factor α

Fries W. Inflammatory bowel disease-associated spondyloarthropathies. *World J Gastroenterol* 2009; 15(20): 2441-2442 Available from: URL: http://www.wjgnet.com/1007-9327/15/2441.asp DOI: http://dx.doi.org/10.3748/wjg.15.2441

In January 2008, a symposium was held in Messina on inflammatory bowel disease (IBD) and associated arthropathies with the aim to improve cooperation between gastroenterologists dealing with IBD and rheumatologists. In an era of highly specialized medicine, it was felt that a better knowledge concerning the clinical features and pathogenic mechanisms of spondylarthritides would lead to an earlier recognition of such extra-intestinal complications among gastroenterologists and, finally, to a more appropriate therapeutic approach involving both specialists.

In the past decades, the relation between IBD and spondyloarthritides has been investigated mainly in epidemiologic studies and in studies concerning HLA-B27 associations. Most studies from the sixties through the eighties focused mainly on axial forms, like ankylosing spondylitis (AS) and sacroiliitis (SI) whereas peripheral manifestations were addressed very much later.

This apparent lack of interest is reflected also by the fact that guidelines on IBD up to 2005 did not mention IBD-associated arthritis. Only in 2006 with the publication of the European Crohn's and Colitis Organization (ECCO) evidence-based consensus on "special situations in Crohn's disease", articular manifestations are briefly discussed[1].

With the introduction of two new topics, genetics and especially biologic therapies, new efforts were made in combination of both kinds of pathology.

Until the end of the former century, only few therapeutic agents like salazopyrin, steroids, and methotrexate were available for the treatment of peripheral arthritis associated with IBD, whereas no disease modifying treatment did exist for axial forms.

With the introduction of the new biologic anti-tumor necrosis factor α (TNF α) therapies, a new chapter for combined treatment options has been opened. Whereas in arthropathies, all available anti-TNF strategies (receptors and antibodies) yielded positive results, in IBD only anti-TNF antibodies, chimeric (Infliximab) or human (Adalimumab), or their fragments (Certolizumab) were shown to effectively down-regulate mucosal inflammation. A possible explanation for the lack of a class effect of anti-TNF strategies may be found in their different mode of action (apoptosis of proinflammatory cells, binding to membrane-bound TNF, *etc*), may be dose-related, or due to immune-related effects from interference with TNF.

In a recent review of studies concerning patients with AS treated with different anti-TNF agents, the odds ratio of flares of an already diagnosed intestinal disease was calculated in comparison with infliximab (odds ratio 1) to be 4.2 for adalimumab and 18 for etanercept[2]. In this paper, a new onset of IBD was reported only for etanercept but not for infliximab or adalimumab.

This TOPIC HIGHLIGHT addresses these different aspects of IBD-associated spondyloarthropathies like epidemiology and clinical manifestations of IBD-related arthropathies, common genetic and immunologic features, diagnostic gastroenterological interventions in pa-

tients with arthritis and endoscopic findings, combined therapies for gut and joint inflammation, and future biologic therapies[3-8]. The papers are written by clinical experts in the field of IBD and experts in the field of gastrointestinal immunology together with their counterparts in the field of rheumatology. The symposium was organized under the auspices of the Italian Society of Gastroenterology (SIGE), the Italian Group for the Study of Inflammatory Bowel Diseases (IG-IBD), and the local academic authorities.

Abstract

Subclinical gut inflammation has been described in up to two-thirds of patients with spondyloarthropathies (SpA). Arthritis represents an extra-intestinal manifestation of several gastrointestinal diseases, including inflammatory bowel disease (IBD), Whipple's disease, Behcet's disease, celiac disease, intestinal bypass surgery, parasitic infections of the gut and pseudomembranous colitis. Moreover about two-thirds of nonsteroidal anti-inflammatory drug users demonstrate intestinal inflammation. Arthritis may manifest as a peripheral or axial arthritis. The spondyloarthropathy family consists of the following entities: ankylosing spondylitis, undifferentiated spondyloarthritis, reactive arthritis, psoriatic arthritis, spondyloarthritis associated with IBD, juvenile onset spondyloarthritis. This topic reviews the major gastrointestinal manifestations that can occur in patients with SpA and in nonsteroidal anti-inflammatory drugs users.

INTRODUCTION

Arthritis is a recognized extra-intestinal manifestation of several gastrointestinal diseases including inflammatory bowel disease (IBD). Arthritis occurs in 9%-53% of patients with IBD[1-3], and is more prevalent in patients with large bowel disease than in patients with small bowel involvement (42% *vs* 23%)[1]. It may manifest as a peripheral or axial arthritis. Peripheral arthritis includes two different patterns: a pauciarticular arthritis (type 1 arthropathy) striking large joints, which usually accompanies flares of IBD; and a polyarticular arthropathy (type 2 arthropathy) which involves the small joints and is less often associated with flares of IBD[4].

Subclinical gut inflammation has also been described in up to two-thirds of patients with spondyloarthropathies (SpA)[5-9]; histologic gut inflammation was found in SpA in 30%-60% of cases[9]. The observation that the extra-intestinal symptoms generally improve when the gastrointestinal disease is treated, suggests that the association between these two clinical entities is related. The mechanism by which this occurs is not fully understood[1,7].

This topic will review the major gastrointestinal manifestations which can occur in patients having SpA and other diseases with bowel and joint involvement, and in patients having nonsteroidal anti-inflammatory drugs (NSAIDs) related intestinal injuries.

It is useful to begin with a short review of the gastrointestinal function.

GASTROINTESTINAL FUNCTION

The human gastrointestinal tract is not a complete

barrier, being permeable to some macromolecules[10]. Permeability increases in pathologic conditions including IBD[4], celiac disease[11,12], and with the administration of NSAIDs[13,14]. When permeability is increased the gastrointestinal tract is exposed to bacterial and dietary antigens.

The epithelial lining of the gastrointestinal tract includes specialized cells (M cells) which permit transepithelial transport of foreign material from the lumen to mucosal lymphoid tissues; it is evident that some microorganisms use the M cell transport system as a means to infect the mucosa[10,15]. The human intestine harbours a complex microflora composed of aerobic and anaerobic bacteria. In normal individuals antigenic exposure results in tolerance rather than immunity, but this local tolerance is broken in inflamed intestinal tissue. Patients with active IBD lose tolerance to their own bacterial flora, whether this loss of tolerance is a cause or a consequence of the IBD is not known[16-18].

IBD represents a good model for the pathological events that may predispose a host to extraintestinal manifestations. Active IBD is characterized by the following features: (1) A breach of gastrointestinal wall integrity; (2) Increased permeability to macromolecules; (3) Increased exposure to microbial and dietary antigens; (4) Loss of tolerance to own bacterial flora; (5) Host susceptibility to the increased antigenic load. There is also data to suggest that patients with SpA often have subclinical inflammation that may progress to IBD[1].

SpA

The term SpA is used to refer to a family of diseases characterized by inflammation of axial joints, asymmetric oligoarthritis and enthesitis[19]. The SpA family consists of the following entities: ankylosing spondylitis (AS); undifferentiated spondyloarthritis; reactive arthritis (Reiter syndrome); psoriatic arthritis; spondyloarthritis associated with IBD; juvenile onset spondyloarthritis.

The prevalence of SpA in the Caucasian population is 0.5%-2%, with a significant variation worldwide[20].

The need for a standardized approach to classification led to the development of the European Spondyloarthropathy Study Group (ESSG) classification criteria for SpA. According to the ESSG criteria, for a patient to be classified as having SpA he has to show chronic inflammatory back pain before the age of 40 years, persistence for at least 3 mo or asymmetrical synovitis, predominantly of the lower limbs (Table 1). A patient is classified as having spondyloarthritis if he has one or both entry criteria plus one of the following additional criteria: positive family history, psoriasis, IBD, urethritis, cervicitis or acute diarrhea within 1 mo before arthritis, buttock pain alternating between buttocks, enthesopathy or plain film radiographic evidence of sacroiliitis.

The ESSG classification criteria for SpA have been validated in population studies and have a good sensitivity of 75% and a specificity of 87%[21].

An alternative to the ESSC classification criteria is that proposed by Amor and colleagues[22] and considers clinical and historical symptoms, radiologic findings, genetic background and response to treatment (Table 2). These classification criteria are more complicated due to the incorporation of common extra-articular manifestations of disease including gastrointestinal manifestation, but they give improved sensitivity (85%) and specificity (95%). Of these, each criterion is assigned a weight (one or two points) and the resulting points are summed. A patient is considered as having a spondyloarthritis if the sum of the criteria scores is at least six.

A high percentage of patients with SpA (90% of patients with AS and 70% of patients with undifferentiated spondyloarthritis) are HLA-B27 positive. However, this marker is not diagnostic of SpA because a significant percentage of the general population is also positive. In the presence of inflammatory back pain, a positive test for HLA-B27 increases the likelihood of SpA[23].

SpA are associated with several extra-articular manifestations, including acute anterior uveitis[24], genital and skin lesions[25] and inflammatory gut lesions[8].

Table 1 European Spondyloarthropathy Study Group (ESSG) classification criteria for spondyloarthritis

Inflammatory spinal pain, or synovitis (asymmetrical, predominantly in lower limbs), and any one of the following:
Positive family history
Psoriasis
Inflammatory bowel disease
Alternate buttock pain
Enthesopathy

Table 2 Amor classification criteria for spondyloarthropathy

Clinical symptoms or past history of
Lumbar or dorsal pain at night, or lumbar or dorsal morning stiffness = 1
Asymmetrical oligoarthritis = 2
Buttock pain (buttock pain = 1, alternating buttock pain = 2)
Sausage-like finger or toe = 2
Heel pain = 2
Iritis = 2
Non-gonococcal urethritis or cervicitis accompanying, or within 1 mo before, the onset of arthritis = 1
Acute diarrhoea accompanying, or within 1 mo before, the onset of arthritis = 1
Presence of history of psoriasis and/or balanitis and/or of inflammatory bowel disease (ulcerative colitis, Crohn's disease) = 2
Radiological findings
Sacroiliitis (grade > 2 if bilateral, grade > 3 if unilateral) = 3
Genetic background
Presence of HLA-B27 and/or family history of ankylosing spondylitis, reactive arthritis, uveitis, psoriasis or chronic inflammatory bowel disease = 2
Response to therapy
Definite improvement of musculoskeletal complaints with NSAIDs in less than 48 h or relapse of the pain in less than 48 h if NSAIDs discontinued = 2
A patient is considered as having a spondyloarthropathy if the sum of the scores is 6 or more

Table 3 Histologic types of gut inflammation in patients with SpA

Acute	Chronic
Architecture preserved	Architecture disturbed
PMN infiltration	Irregular, blunted and fused villi
Granulocytes, lymphocytes, plasma cells in lamina propria	Distortion crypts
	Basal lymphoid follicles
	Sarcoid-like granulomas

Two histologic types of gut inflammation in patients with SpA can be distinguished: acute and chronic inflammation (Table 3). This classification refers to the morphologic characteristics and not to the onset or duration of the disease.

The acute type mimics the acute bacterial enterocolitis: the mucosal architecture is well preserved, there is a polymorphonuclear infiltration of the ileal villi and crypts, and an increased number of inflammatory cells (granulocytes, lymphocytes and plasma cells) in the lamina propria.

Acute lesions are mainly seen in patients with reactive arthritis.

The chronic type is often indistinguishable from Crohn's disease (CD): the mucosal architecture is clearly disturbed, the villi are irregular, blunted and fused; the crypts are distorted and the lamina propria is edematous and infiltrated by mononuclear cells. In some cases aphthoid ulcers and sarcoid-like granulomas are present. Chronic lesions are more present in undifferentiated SpA and AS[9].

Similarities are present between the immune alterations in SpA and CD, suggesting that these are probably distinct phenotypes of a common immune-mediated disease, possibly being expressed in a genetically different host; in fact, the mutations of the CARD15/NOD2 gene that have been associated with CD have not been found in AS[26]. These similarities are: an increased expression of α-E-β-7 in T-cells from patients with SpA and in the intestinal lymphocytes of patients with CD; an increased expression of epithelial A-cadherin; an increased expression of CD 163 positive macrophages in CD and SpA; relative contribution of T-helper 1 cells; presence of IgA antibodies to Saccharomyces cerevisiae.

According to current knowledge, there is a clinical relationship between gut and joint inflammation in SpA, and the gut could have an important pathogenic role[9]: the prevalence of gut inflammation in AS is higher in patients with associated peripheral arthritis than in patients without arthritis[6]; chronic lesions in the gut are associated with more advanced radiologic signs of sacroiliitis and spondylitis and with more destructive peripheral arthritis[27]; remission of joint inflammation is usually associated with a disappearance of gut inflammation, whereas the persistence of locomotor inflammation is mostly associated with the persistence of gut inflammation[28-31].

Clinical, genetic, histopathologic and immunologic data suggest that SpA and CD probably should be considered as distinct phenotypes of a common immune-mediated inflammatory disease pathway rather than as separate disease entities[9].

Patients with peripheral arthritis and AS are often found to have endoscopic and histologic signs of small bowel inflammation, and a fraction of these patients go on to develop clinically overt CD. Moreover, some patients with SpA have a form of sub-clinical CD in which locomotor inflammation is the only clinical expression. In a prospective long-term study at first investigation about 6% of patients with SpA did not present any sign of CD, but demonstrated gut inflammation on biopsy. They developed CD 2 to 9 years later[32].

Ileal and colonic mucosal ulcerations in patients with SpA can be detected by endoscopy. Endoscopic lesions were found in 44% of patients with SpA versus 6% of patients with other inflammatory arthritis and the most common endoscopic diagnosis was early CD (26%)[5].

It has been highlighted that a capsule endoscopy can provide important information on upper gastrointestinal pathology in patients with SpA in which there is small bowel involvement. Eliakim *et al*[33] have compared the diagnostic yield of capsule endoscopy with that of ileo-colonoscopy in the finding of small bowel lesions in patients with SpA; significant small bowel findings (erythema, aphthous, erosions) were detected by capsule endoscopy in 30% and by ileo-colonoscopy in only 9% patients with SpA.

The association between SpA and clinical or subclinical intestinal association has rarely been described in children. Conti *et al*[34] investigated a group of 129 children for suspected IBD, 31 of whom had signs of axial and/or peripheral arthropathy, and after ileo-colonoscopy with biopsy, 7 children had classic IBD, 12 had indeterminate colitis, and 12 had lymphoid nodular hyperplasia of the distal ileum as the main feature. All were HLA-B27 negative. These patients may be a population at risk of developing a full IBD phenotype. SpA may be the initial manifestation of systemic disorders such as IBD.

Ankylosing spondylitis

AS is the most common disease among the SpA; it is a chronic inflammatory disease of the axial skeleton characterized by back pain and progressive rigidity of the spine. AS usually affects young adults and an association with the human leukocyte antigen HLA-B27 was observed. The association with HLA-B27 is weaker in IBD-associated AS than in idiopathic AS. Radiographic changes of the hips are present in roughly 10% of patients[35]. Other organs, such as eyes, lungs, gut and heart can be affected. Up to two-thirds of patients with AS have subclinical gut inflammations shown either by endoscopy or histology, between 5% and 10% of cases of AS are associated with IBD. Despite these observations, systematic screening of AS patients by ileo-colonoscopy is not indicated in the absence of gut symptomatology as only a small proportion of AS patients with subclinical gut inflammation will develop IBD in the future[2].

Reactive arthritis

Reactive arthritis may occur after an enteric infection due to *Salmonella*, *Shigella*, *Yersinia* or *Campylobacter species* with an incidence ranging from 2% to 33%. In particular an increased risk of arthritis is associated with a *Yersinia* infection and the presence of the HLA-B27 genotype. Joint symptoms develop within 2-3 wk of developing diarrhea and involve knee, ankle, wrist, and sacroiliac joints. To confirm the clinical suspicion of reactive arthritis it is useful to demonstrate a pathogenic organism by stool culture or a rise of antibody titres. Antibiotic treatment may be effective during the diarrheal phase but not when arthritis is present[8,27,36].

OTHER DISEASES WITH BOWEL AND JOINT INVOLVEMENT

In addition to ulcerative colitis and CD, other illnesses have intestinal involvement and arthritis as prominent clinical features. These include Whipple's disease, Behcet's disease, celiac disease, intestinal bypass arthritis, parasitic rheumatism, and pseudomembranous colitis. These disorders are also considered in the differential diagnosis of patients with suspected IBD and arthritis.

Whipple's disease

Whipple's disease is due to an infection with *Tropheryma Whippelii* and may cause diarrhea, malabsorption and weight loss. Systemic infection is often associated with joint manifestations, involving the knee, the ankle and the wrist and sometimes it is associated with spondylitis and sacroiliac joint involvement. In some patients the articular symptoms develop prior to symptomatic enteric involvement. A small bowel biopsy is usually diagnostic. Whipple's disease requires long term antibiotic therapy[37].

Behcet's disease

Behcet's disease is characterized by oral and genital ulceration, iritis and occasionally by central nervous system involvement; oligoarticular, asymmetric arthralgia and arthritis may develop in 50% of patients involving the knee, the ankle, the wrist and the elbow. Mucosal ulceration of the small bowel is a frequent manifestation of Behcet's disease and may cause nausea, diarrhea, abdominal pain and distension. It is often difficult to distinguish from IBD[38,39].

Celiac disease

Celiac disease may be associated with arthritis in some patients; articular involvement was peripheral in 10%, axial in 8% and combined in 9%. The arthritis is typically non erosive and can be either oligo-or-polyarticular. Joint symptoms may precede gastrointestinal manifestations and respond to a gluten-free diet[11,12].

Intestinal bypass surgery

Intestinal bypass surgery is a surgical technique used for the treatment of obesity in the past. Arthritis affecting knee, wrist, ankle, shoulder and finger joints was recognized as a postoperative complication of this technique. Polyarthralgia and sometimes arthritis has been reported to occur weeks or years following surgery in 8% to 36% of patients[2,36].

Parasitic infections

Parasitic infections of the gut due to *Strongyloides stercoralis*, *Taenia saginata*, *Endolimax nana* and *Dracunculus medinensis* have been associated with a form of reactive arthritis[36].

Pseudomembranous colitis

Arthritis associated with pseudomembranous colitis has been described following antibiotic therapy, often affecting the large joints of the lower extremity. In a report of four patients, arthritis developed 9-35 d after the onset of diarrhea[36].

NSAIDS RELATED INTESTINAL INIURY

The distal small bowel and colon are susceptible to the dangerous effects of NSAIDs; although the proportion of patients who develop clinically important NSAID-induced enteropathy or colopathy is small, the intestinal injuries induced by NSAIDs, including erosions, ulcers, strictures and perforations, are common[13]. About two-thirds of NSAID users demonstrate intestinal inflammation[13,14,40]. In a case control study, patients with small or large bowel perforation or bleeding were more than twice as likely to be NSAID users[41]. In an autopsy study nonspecific small intestinal ulceration was much more common in those who had taken NSAIDs (8.4% *vs* 0.6%)[42]. A randomized, controlled trial revealed more mucosal breaks in a group of patients who used NSAIDs plus omeprazole compared with a group of patients who used COX-2 inhibitors. This study suggests relative protection of the COX-2 inhibitors compared with non-selective NSAIDs plus omeprazole against small bowel injury[43]. By contrast a non-randomized cohort study found similar rates and types of small bowel injury with long-term use of COX-2 selective agents versus NSAIDs[44].

Most NSAID-induced injuries are subclinical and go unrecognized. When present, symptoms and signs are nonspecific and may include: anaemia, bleeding from ulcers, hypoalbuminemia, intermittent or complete bowel obstruction from broad-based or diaphragm-like strictures, watery or bloody diarrhea and acute abdomen. The typical patient is one taking a NSAID for a rheumatic condition and the duration of NSAID use to time of diagnosis is widely variable (days to years)[41].

A pathognomonic lesion of NSAID injury is the diaphragm-like stricture, which is likely to be due to a scarring reaction secondary to ulcerative injury. These lesions are thin, concentric, diaphragm-like septa which are usually multiple in the mid-intestine but may be also present in the ileum and colon. Histologically, they are characterized by sub-mucosal fibrosis with normal overlying epithelium, apart from the tip of diaphragm,

which may be ulcerated; the mucosa between diaphragms is normal[14,45].

Capsule endoscopy, double-balloon enteroscopy and colonoscopy may help in the diagnosis of NSAID-induced injury, although there is nothing endoscopically specific about NSAID-induced gut lesions[46,47]. Histology is also nonspecific; the differential diagnosis should include: Campylobacter, Yersinia, Cytomegalovirus, TB infections, IBD, ischemia, radiation enteritis, vasculitides and other drugs. The NSAIDs-induced lesions generally improve upon withdrawal of the drug.

CONCLUSION

An important role of the gut in the pathogenesis of SpA and for an overlap between SpA and CD is supposed. It is not clear if SpA and CD should be considered as distinct phenotypes of common immune-mediated inflammatory disease pathways or separate disease entities. Systematic screening of SpA patients by ileo-colonoscopy is not indicated in the absence of gut symptomatology but these patients may be a population at risk of developing a full IBD phenotype. It is important to know that there are other diseases with bowel and joint involvement like Whipple's disease, celiac disease and so on and that two-thirds of NSAID users demonstrate intestinal nonspecific inflammation.

Abstract

Inflammation of axial and/or peripheral joints is one of the most frequent extra-intestinal manifestations complicating the clinical course and therapeutic approach in inflammatory bowel diseases (IBD). The frequency of these complications seems to be similar for both diseases, Crohn's disease and ulcerative colitis. Arthritis associated with IBD belongs to the category of spondyloarthropathies. Axial involvement ranges from isolated inflammatory back pain to ankylosing spondylitis, whereas peripheral arthritis is noted in pauciarticular and in polyarticular disease. Asymptomatic radiological involvement of the sacroiliac joints is reported to occur in up to 50% of patients. Other musculoskeletal manifestations such as buttock pain, dactylitis, calcaneal enthesitis, and thoracic pain are frequently underdiagnosed and, consequently, are not treated appropriately. Several diagnostic approaches and criteria have been proposed over the past 40 years in an attempt to correctly classify and diagnose such manifestations. The correct recognition of spondylarthropathies needs an integrated multidisciplinary approach in order to identify common therapeutic strategies, especially in the era of the new biologic therapies.

Key words: Crohn disease; Ankylosing spondylitis; Ulcerative colitis; Spondylarthropathies; Arthritis; Enthesopathy

INTRODUCTION

Arthritis, belonging to the category of spondylarthropathy, is the most frequent extra-intestinal complication of inflammatory bowel diseases (IBD). The clinical spectrum of spondylarthropathies includes axial symptoms, peripheral arthritis, dactylitis and enthesopathy. Musculoskeletal manifestations occur in 20%-50% of patients with IBD[1-3].

Spondyloarthropathies (SpA), or spondyloarthritides as recently proposed[4], represent a group of distinct diseases with similar clinical features and a common genetic predisposition. The 5 major subtypes are ankylosing spondylitis (AS), psoriatic arthritis, reactive arthritis, IBD-associated SpA (IBD-SpA), and undifferentiated SpA. The main recognized genetic association is with HLA-B27, but it is clear that there are other genes involved.

According to the European Spondyloarthropathy Study Group (ESSG) criteria[5], IBD is a criterion of spondylarthropathy; psoriasis or enteric infections are 2 other manifestations included in the ESSG criteria for identifying patients with psoriatic arthritis and reactive arthritis. Thus, patients with IBD presenting with inflammatory back pain and/or synovitis (predominantly of the lower limbs) are diagnosed as having spondyloarthropathy (Table 1). The ESSG criteria, designed to be applicable without radiological examination and laboratory testing, have good sensitivity (75%) and specificity (87%), at least in established disease. An alternative classification scheme was put

forward by Amor *et al*[6] (Table 2), which is more complicated but gives improved sensitivity (85%) and specificity (90%) due to the incorporation of common extra-articular manifestations of disease, including enthesopathy, dactylitis, eye disease and HLA-B27 positivity. The basic concepts underlying each classification set are nevertheless similar.

CLINICAL FEATURES

The clinical picture of IBD-SpA is characterized by axial and/or peripheral joint involvement in the absence of rheumatoid factors and of typical extra-articular findings of rheumatoid arthritis (e.g. subcutaneous nodules)[7].

Axial joint disease

The spectrum of axial involvement ranges from inflammatory lower back pain with or without radiological evidence of sacroiliitis (SI), asymptomatic SI, and overt AS characterized by the "classical" clinical (spine stiffness, pain) and radiologic features (squaring, syndesmophytes, bamboo spine).

Inflammatory back pain (IBP)

IBP is usually difficult to localize, insidious in onset, frequently monolateral and intermittent at onset, more intense at rest, associated with stiffness but relieved by movement, exacerbated by cough or sneezing, and accompanied by fatigue. The diagnosis is clinical and defined according to Calin's criteria[8] (Table 3), based on morning stiffness, age and modality of onset, and duration. The diagnosis of IBP is based on the positivity of at least 4 out of 5 parameters. A modification of these criteria with a higher sensitivity has been recently proposed and, apart from the duration of pain and morning stiffness, also considers improvement with exercise, awakening because of pain, and the presence of alternating buttock pain[9].

According to this modification a 70% sensitivity and an 81% specificity are achieved if at least 2 parameters are fulfilled with a positive likelihood ratio 3.7; if at least 3 are fulfilled, the positive likelihood ratio raises to 12.4.

In the presence of IBP, the radiologic evaluation of the sacroiliac joints allows to make diagnosis of SI. SI is graded according to the radiologic criteria established since 1966[10] (Table 4). In the absence of findings with conventional X-ray examination, magnetic resonance imaging (MRI) evaluation may allow diagnosis and, thus, effective early treatment for axial spondyloarthritis[11]. The evidence of an increased signal in the bone and bone marrow (bone edema) with T1 post-gadolinium and STIR (short tau inversion recovery) techniques is a sign of active inflammation in the SI joints and/or spine (Figure 1).

The importance of an early diagnosis has been underlined in a study carried out on 25 HLA-B27 positive patients with IBP and a grade 2 (or lower) unilateral SI on conventional radiography. In these patients, when studied by MRI, 36/50 joints were diagnosed as having grade 2 or higher SI, and bone edema was found in 20/50. The same patients were studied 3 years later by conventional radiography and demonstrated grade 2 or more SI in 21/44 sacroiliac joints, with the conclusion that MRI is more sensitive than conventional radiography for the detection of SI in the early stages[12].

The diagnostic criteria for classic AS have been subjected to several changes over the past decades from the Rome Criteria[13] to the New York Criteria[7] and then to the Modified New York Criteria[14] in 1984 (for more detail concerning evolution of diagnostic criteria)[15]. This

Table 1 Diagnostic criteria according to the ESSG[2]

Inflammatory spinal pain or/and synovitis asymmetric or predominantly of the lower limbs
One or more of the following
Positive family history
Inflammatory bowel disease
Urethritis, cervicitis, or acute diarrhea within 1 mo before arthritis
Buttock pain alternating between right left gluteal areas
Enthesopathy
Sacroiliitis

Table 2 Amor diagnostic criteria for spondylarthropathy[3]

Clinical symptoms or past history of
Lumbar or dorsal pain at night, or lumbar or dorsal morningstiffness = 1
Asymmetric oligoarthritis = 2
Buttock pain (buttock pain = 1, alternating buttock pain = 2)
Sausage-like finger or toe = 2
Heel pain = 2
Iritis = 2
Non-gonococcal urethritis or cervicitis accompanying, or within 1 mo before, the onset of arthritis = 1
Acute diarrhea accompanying, or within 1 mo before, the onset of arthritis = 1
Presence or history of psoriasis and/or balanitis and/or of inflammatory bowel disease (ulcerative colitis, Crohn's disease) = 2
Radiological findings
Sacroiliitis (grade > 2 if bilateral, grade > 3 if unilateral) = 3
Genetic background
Presence of HLA-B27 and/or family history of ankylosing spondylitis reactive arthritis, uveitis, psoriasis or chronic inflammatory bowel disease = 2
Response to therapy
Definite improvement of musculoskeletal complaints with NSAIDs in less than 48 h or relapse of the pain if NSAIDs are discontinued = 2
A patient is considered as having spondylarthropathy if the sum of the scores is 6 or more

Table 3 Calin's criteria for the clinical diagnosis of inflammatory back pain[5]

Onset before age 45 yr
Insidious onset
Improvement with exercise
Morning stiffness
Persistence (at least 3 mo)
Coexistence of 4 out of 5 criteria allows the definition of inflammatory back pain

Table 4 Radiologic criteria for staging of inflammatory changes related to sacroiliitis[7]

Sacro-iliac joints	
Grade 0	Normal
Grade 1	Suspicious changes
Grade 2	Minimal abnormality-small localized areas with erosions or sclerosis without alterations in joint width
Grade 3	Unequivocal abnormality-moderate or advanced sacro-iliitis with one or more of the following: erosions, sclerosis, widening
Grade 4	Severe abnormality-total ankylosis

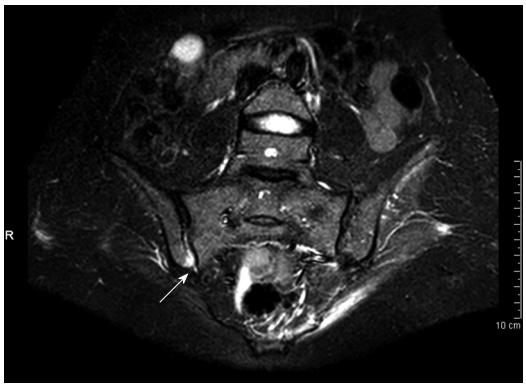

Figure 1 MRI of the sacroiliac joints of a 39-year-old patient with inflammatory back pain and ulcerative colitis (pelvis radiograph was negative for sacroiliitis): STIR MRI of the sacroiliac joints shows bone marrow edema (arrow) of the right sacroiliac joint.

Figure 2 Achilles tendonitis due to enthesitis of the tendon insertions.

Figure 3 Dactylitis with sausage-like appearance of the Ⅱ toe.

latter classification is based on: (1) lower back pain of at least 3 mo duration that improved with exercise and was not relieved by rest; (2) limited lumbar spinal motion in sagittal (sideways) and frontal (forward and backward) planes; (3) decrease of chest expansion, assessed at the Ⅳ intercostal space, relative to normal values for sex and age; and (4) bilateral SI grade 2-4 or unilateral SI grade 3 or 4. A definite diagnosis of AS is made if criterion 4 (radiology) and any one of the other criteria are fulfilled.

Apart from radiologic alterations, one of the key features of AS is the presence of IBP and/or alternate buttock pain. Other clinical signs to search for in order to assess reduced spine mobility include the Schober test, finger to floor distance, maneuvers for cervical spine assessment (occiput to wall, tragus to wall, cervical rotation), and investigation in order to establish a reduced chest expansion (for review see the INSPIRE study)[16].

Peripheral arthritis

The recognition of this entity is based on clinical diagnosis, e.g. joint swelling and tenderness but may be confirmed by ultrasound examination[17] or MRI[18], whereas conventional radiographs usually are not helpful.

Two subtypes of peripheral arthritis are recognized[1]. Type 1 involves less than 5 joints and is clinically characterized by acute self-limiting attacks of less than 10 wk duration often paralleling intestinal inflammatory activity. Moreover, it is strongly associated with other extra-intestinal manifestations of IBD such as erythema nodosum. Type 2 peripheral arthritis is polyarticular, involving 5 or more joints with symptoms that persist for months and years running independently from IBD flares. This type is associated with uveitis but not with other extra-intestinal manifestations. Both types are seronegative, usually non-erosive and non-deforming, but may become chronic and erosive in 10% of patients[19]. In addition, no significant association has been shown between peripheral arthropathies and HLA-B27 in IBD[1,19-21].

A type 3 peripheral arthritis has been proposed, which includes patients with both axial involvement and peripheral arthritis[22].

Other manifestations

Enthesitis is inflammation at the site of the tendon, ligament and joint capsule insertion to bone. The most frequent clinical expressions are Achilles tendonitis (Figure 2), plantar fasciitis and/or pain and swelling of the tibial tubercle[23]. Diagnosis is clinical but may be confirmed by ultrasound[24] or MRI[25].

Dactylitis (Figure 3) is characterized by the inflammatory swelling of one or more fingers (sausage fingers) or toes caused by tenosynovitis of the flexor tendons. Metacarpophalangeal or proximal interphalangeal arthritis may be associated.

Thoracic pain results from enthesitis of costovertebral,

[1]Modified New York criteria; [2]IBD-SpA according to ESSG criteria; [3]Calin's criteria; [4]Classification according to Gravallese[62]; [5]Only symptomatic SI, X-ray assessment; Undefined arthralgia group; no definitions are given for spondylitis or arthritis; [6]IBP and SI were considered excluding patients with AS; asymptomatic patients included in SI.

costosternal, manubriocostal articulations, exacerbates with cough and deep inspirations, limits respiratory expansion, and episodes are of variable duration.

Buttock pain is part of the IBP, irradiates to the sacrum and may be alternating; it is related to inflammation of sacroiliac joints.

Extra-articular features are represented by uveitis (25%), aortic insufficiency (4%-10%), and cardiac conduction disturbances 3%-9%[26]. These latter cardiologic complications seem to be related to disease duration and are associated with HLA-B27.

EPIDEMIOLOGY

With respect to the evolution of diagnostic criteria, studies on IBD populations from the 1960s, 70s and 80s include patients with axial joint involvement with application of restricted criteria substantially mirroring classic AS or SI together with peripheral arthritis. Table 5 summarizes the principal data from those early studies[20,27-33]. From these studies AS was found to be present in 2% to 16% of patients with higher numbers for Crohn's disease (CD) compared to ulcerative colitis (UC). Asymptomatic and symptomatic SI was found in 12% to 20% of patients and peripheral arthritis in 11% to 20%. Association with HLA-B27 ranged from 3.9% to 18.9%.

Studies on IBD populations after the introduction of the ESSG criteria or Amor criteria are summarized in Table 6[1,34-45]. A discrete number of papers reporting on IBD-associated joint disease were not included. Most of the excluded studies aimed to detect the frequency of every kind of extra-intestinal manifestation of IBD and were not specifically directed to identify IBD-SpA lacking exact definitions of diagnostic criteria. So, Maeda *et al*[46] found that out of 203 Japanese CD patients, 21 had arthritis (10.3%) and 3 had spondylitis (1.5%). Triantafillidis *et al*[47] reported a frequency of 30% of arthritis/arthralgias in a cohort of 155 Greek CD patients. The study by Bernstein *et al*[48] from Canada was based on the ICD code from hospitalized patients with IBD reporting a 4% prevalence of AS with male CD patients being more frequently affected than male UC patients. Souza *et al*[49], in a mixed Brazilian IBD population found a prevalence of 14.4%, with no difference between CD and UC. Al-Shamali *et al*[50] reported

an 8.9% prevalence of arthritis in UC patients from Kuwait with an overall prevalence of rheumatologic complaints of 31%.

Other studies aimed to identify the frequency of symptomatic or asymptomatic SI. Steer *et al*[51] found on CT examination 31/134 of CD patients, symptomatic for back pain, signs of SI (16 of these patients were missed by conventional X-ray). In another study carried out in 50 CD patients symptomatic for back pain, 28% fulfilled the modified NY criteria for AS on X-ray examination[52]. On the other hand, asymptomatic SI may be present in 10% to 50% of patients with IBD[19]. In a comparative study employing conventional X-ray and CT, changes compatible with SI were found in 29% of CD patients being symptomatic only 3%[53].

In the studies included in Table 6, overall prevalence of any manifestation ranged from 17% to 62%. AS ranged from 1% to 25.3%, SI from 1% to 45.7%, peripheral arthritis from 2.8% to 30.6%, IBD-SpA according to the ESSG criteria from 5% to 45.7%, and IBP in 5.2% to 42%. Other manifestations such as inflammatory enthesopathies, when present, were found in 7% to 50% of patients.

With regard to differences between CD and UC, most studies reported similar figures for peripheral and axial involvement in both pathologies. Concerning disease localization, most studies agreed that ulcerative proctitis is rarely complicated by joint inflammation and, concerning CD, that inflammatory joint disease occurs with increased frequency in Crohn's colitis compared to ileal involvement. A discrete percentage of patients will develop one or more spondylarthropathy-related manifestations (such as isolated calcaneal enthesitis and/or dactylitis)[39] without fulfilling any of the classification criteria.

Whereas type I peripheral arthritis is associated with intestinal disease activity[1], SI, especially in its asymptomatic form, is equally present in CD and UC[38,54], and seems more related to duration of IBD. Taken together, SI is one of the most frequent joint inflammations found in IBD patients[39]. The onset of axial symptoms may precede the diagnosis of intestinal disease by decades.

HLA-B27

The importance of HLA-B27 in conferring susceptibility to AS is well known, although the molecular basis is not completely understood. The HLA-B27 gene is located on the short arm of chromosome 6 and comprises 31 proteins with HLA-B*2705, 02, 04, and HLA-B*2707 as the major subtypes associated with disease. Several hypotheses are discussed on how HLA-B27 works on a molecular level in mediating joint inflammation. The arthritogenic peptide hypothesis postulates that HLA-B27 specific receptors on $CD8^+$ T-cells recognize antigenic peptides and subsequently elicit a cytotoxic T-cell mediated autoimmune response. The misfolding hypothesis states that an aberrant folding of HLA-B27 heavy chains occurs in the endoplasmic reticulum leading to a misfolded B-pocket of the peptide-binding groove and hyperaccumulation leading finally to cytokine and chemokine transcription. A third hypothesis suggests sharing of homing receptors on gut epithelium and synovium together with an impaired elimination of intracellular bacteria by HLA-B27 to represent the base for joint inflammation[55].

The prevalence of HLA-B27 varies greatly in the different ethnicities ranging from 0% in African Bantu and Australian Aborigines to 50% in Native Americans[56]. The prevalence in Western European countries varies from 3% to 18%. In Western European populations, HLA-B27 is found in 90% of patients with AS, in 30%-70% of patients with reactive arthritis, in approx 70% of undifferentiated SpA, in 50% of acute anterior uveitis and in 88% of patients with heart block associated with aortic insufficiency.

The association between axial involvement and HLAB27 in IBD patients is much less conclusive: only 25%-75% of patients with CD and AS present positivity for HLA-B27[34,57,58]. Pure asymptomatic SI in CD is not strongly associated with HLA-B27 and a very recent study indicates a prevalence of 7% (comparable to prevalence in the healthy population)[43], and it seems that evolution to AS is more likely to occur in HLAB27-positive patients[59]. This suggests that SI and AS in IBD patients are different entities. A similar distinction has been proposed for peripheral arthritis. Recently, Orchard *et al*[60] have observed an association with HLA-DRB1*0103, B*35 and B*27 in type 1 peripheral arthritis. Similar associations were observed in a control group consisting of patients with postenteric reactive arthritis. Neither HLA-B27 nor DR-4 associations were observed in type 2 arthropathy. These data indicate that type 1 and 2 arthropathies are immuno-genetically distinct entities and that type 1 is more similar to axial spondyloarthropathies

HLA-B27 testing as a tool for achieving diagnosis is useful only in patients with high pre-test probability and thus its use as a screening test is not recommended. In patients with clinically assessed presence of IBP (14% probability of axial SpA), HLA testing may follow and a positive test result would mandate a subsequent referral to a rheumatologist for further evaluation because the probability of axial SpA in such a patient would increase to 59%[61].

Abstract

The association between spondyloarthropathy and inflammatory bowel disease (IBD) is largely established, although prevalence is variable because of different population selection and diagnostic methodologies. Most studies indicate that as many as 10%-15% of cases of IBD are complicated by ankylosing spondylitis (AS) or other forms of spondylarthritis (SpA). Of note, ileal inflammation resembling IBD has been reported in up to two thirds of cases of SpA, and it has been suggested that the presence of ileitis is associated with the chronicity of articular complications. Although this observation is of interest to unravel the pathophysiology of the disease, systematic screening of patients with SpA by ileocolonoscopy is not indicated in the absence of gut symptoms, as only a small proportion of patients with subclinical gut inflammation will develop overt IBD over time. The existence of familial clustering of both IBD and AS, the coexistence of both conditions in a patient, the evidence of an increased risk ratio among first- and second-degree relatives of affected AS or IBD patients and finally, the increased cross-risk ratios between AS and IBD, strongly suggest a shared genetic background. So far, however, IL23R is the only identified susceptibility gene shared by both IBD and AS. Although functional studies are still needed to better understand its pathogenic role, great effort is being spent therapeutically targeting this pathway that may prove effective for both disorders.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are chronic relapsing inflammatory bowel diseases (IBDs) of unknown etiology that affect up to 1 in 250 of the adult population, with up to 25% of patients being diagnosed during childhood or adolescence[1]. Key features of UC include diffuse mucosal inflammation that extends proximally from the rectum. In CD, conversely, any site in the gastrointestinal tract may be affected with transmural inflammation, which is typically patchy and segmental[2]. Joint complications are the most common extra-intestinal manifestations of IBD, and were recognized as far back as the 1920s. Both axial and peripheral joint complications are recognized. This review mainly focuses on the so-called enteropathic spondyloarthropathy, and more specifically, on the possible pathogenic link which may lie in a common genetic background with IBD.

ANKYLOSING SPONDYLITIS (AS)

AS is a seronegative inflammatory arthropathy that affects

the vertebral column, and is characterized by sacroiliitis and progressive ankylosis (fusion) of the vertebral facet joints. It is defined classically by the modified New York Criteria[3], which include: low back pain for more than 3 mo; relieved by exercise and not improved by rest; limited spinal movement in two planes; and decreased chest expansion. If any of these clinical features is present in association with bilateral grade 2-4 or unilateral grade 3-4 sacroiliitis, then a definitive diagnosis can be made. However, there is some overlap with the more general term of sponyloarthropathy (SpA), as defined by the European Study Group on Spondyloarthropathy[4]. This involves a combination of inflammatory low back pain and a number of other factors including associated conditions, such as IBD or enteric infection, post-dysenteric reactive arthritis, psoriatic arthritis, and post-urethritis arthritis. The prevalence of AS in the general population is 0.25%-1%[5,6], but it is increased in IBD patients to 1%-6%, depending on the study population and the method of investigation[7,8]. In a recent population-based study in Italy[9], the prevalence of AS was 0.37%, while IBD-associated arthritis accounted for 0.09%. However, the clinical spectrum might be broader than that so far defined. In a population-based inception cohort of IBD patients evaluated in Italy and Netherlands, 18% satisfied the European criteria for SpA, 3.1% satisfied the modified New York criteria for AS, however, 14.4% patients developed one or more SpA-related manifestations, without fulfilling any of the classification criteria[10].

The traditional method of radiological assessment is by plain radiology of the sacroiliac joints. Magnetic resonance imaging has demonstrated a higher sensitivity[59], although in the absence of symptoms, its significance is sometimes unclear. Idiopathic AS is more common in male subjects, with an M:F ratio of 3:1, whereas in IBD, the M:F ratio is closer to 1:1. The main lesion of AS is sacroiliitis and this is associated with inflammatory low back pain. The symptoms are characterized by an insidious onset over several months, morning stiffness, and exacerbation of pain by rest. The evolution of AS is usually independent of the bowel disease, and more often runs a more benign clinical course than idiopathic AS[11].

ISOLATED SACROILIITIS

Isolated sacroiliitis may occur in association with IBD, without evidence of progressive spinal disease. Although some patients complain of low back pain, in many cases, they may be asymptomatic, therefore, prevalence is dependent largely upon the investigation. Radiographic surveys suggest a prevalence of 18%[7], but higher prevalence is estimated by means of scintigraphy, with radioisotope uptake found in up to 52% of patients with CD and 42% with UC[12]. However, given the large degree of inter- and intra-observer error, and the lack of follow-up information about possible progression to AS, the significance of these findings is unclear. In the majority of patients, it seems a non-progressive condition. In clinical practice, diagnosis is usually made by plain abdominal radiography, but more often it is detected incidentally.

PERIPHERAL ARTHRITIS

Articular manifestations have been reported in association with IBD for many years, but only in the late 1950s was arthritis proven to be inflammatory, and quite distinct from classical rheumatoid arthritis (RA), to be seronegative. Articular manifestations occur in 5%-20% of IBD patients, and more recently, a new classification proposes two distinct clinical forms with specific genetic associations[13].

Type I peripheral arthropathy, defined as acute, self-limiting inflammation that affects fewer than five joint, and is associated with IBD relapse and the presence of other extra-intestinal manifestations. More often, large weight-bearing joints are affected, particularly knees, wrists and ankles. The median duration of illness is 5 wk, however, 10%-20% of patients will develop persistent symptoms. One third of patients will report one episode over time.

Type Ⅱ arthritis is a symmetrical, seronegative, small-joint arthropathy, unrelated to disease activity. The onset may occur at any time during the course of IBD or before, and in CD, it is reported more commonly in colonic disease. It usually runs a more chronic course with a median duration of 3 years. The small joints of the hands are more commonly affected.

ROLE OF INTESTINAL INFLAMMATION

The role of intestinal inflammation and luminal factors in SpA is an area of debate. In a large series of ileocolonoscopy examinations with biopsies in patients with SpA[14,15], inflammatory lesions were found in two thirds of patients, with a similar proportion in those with AS and RA. Moreover, the clinical course of articular disease was independent of the presence of gut inflammation, and a minority of patients (3.7%) developed overt IBD. In another study[16], 123 patients with SpA at initial endoscopy were reassessed clinically, and follow-up endoscopy performed in 49 patients. Articular remission rates were independent of initial gut inflammation and associated with endoscopic and histological remission. In addition, initial chronic gut inflammation implies a high risk of evolution of AS. Nevertheless, a potential confounding factor of these studies is that most patients are treated with non-steroidal anti-inflammatory drugs (NSAIDs) which may promote enteropathy that is hardly distinguishable from primary inflammatory lesions of the gut. Furthermore, in a follow-up study[17] of some patients still taking NSAIDs, no inflammatory gut lesions were found in those in clinical remission from articular symptoms, while in contrast, half of the patients with articular inflammation had persistent inflammatory gut lesions, and one quarter developed overt IBD. This suggests that intestinal inflammation is important in idiopathic as well IBD-associated AS, possibly by determining an increased antigenic load across the inflamed gut mucosa.

Post-enteric reactive arthritis is associated with Gram-negative enterobacteria such as *Salmonella, Escherichia coli, Yersinia* and *Campylobacter*; in these circumstances, bacterial antigens have been isolated in the affected joints. These conditions are clinically very similar to type Ⅰ IBD arthritis, and it therefore seems likely that bacterial antigens may be important in the initiation of the inflammatory process. Furthermore, stronger support on the role of bacteria in initiating arthritis in the presence of gut inflammation has been gained from a study of HLA-B*27 transgenic animal models. These knock-out animals spontaneously develop colitis and axial and peripheral arthritis when reared under normal conditions[18,19]. Interestingly, when they are kept in a germ-free environment, gut and joint inflammation is prevented[19]. Furthermore, different bacteria induce gut and joint inflammation with different efficiency, with *Bacteroides vulgatus* being the most efficient and *E. coli* is ineffective[20]. Thus, it appears likely that similarly to IBD, bacteria are important in the pathogenesis of SpA, with an interaction with the immune system. The link between bacteria, gut/joint inflammation and the immune response, might result from a (common) genetic predisposition.

GENETIC PREDISPOSITION TO SPONDYLOARTHROPATHY

Idiopathic AS is strongly associated with possession of HLA-B*27, with a 94% prevalence in northern European patients, compared with 10% of healthy controls[21,22]. This association is considerably weaker in IBD-associated AS, ranging between 50% and 80% of patients[23-25]. Conversely, 50% of HLA-B*27-positive IBD patients have AS, compared with 1%-10% of B*27-positive individuals in the general population. Putative mechanisms include B*27 presenting peptide from luminal bacteria, or self proteins causing an inflammatory response, or peptides being presented to the immune system by other antigens such as HLA-DR. Central to these theories is the concept of a triggering bacterial antigen, although evidence is lacking. Patients with isolated sacroiliitis are less likely to be HLA-B*27-positive, and HLA-B*27 seems to be a marker of progressive axial disease rather than sacroiliitis, but long-term studies are needed. Other genes in the HLA region have also been implicated including HLA-DR1, TAP and LMP, but none of these findings have been conclusive. Moreover, subsequent studies have demonstrated other HLA associations in IBD arthritis. The association with HLA-DRB1*0103 is solely with type Ⅰ arthritis, which is also associated with HLA-B*27, whereas type Ⅱ is associated with B*44 and MICA[13,26] (Table 1).

A number of studies have demonstrated a striking overlap within patients and family members with rheumatological, dermatological and gastrointestinal diseases. The susceptibility genes of these disorders appear to overlap with each other[27]. In a study that explored the prevalence of secondary disorders in 3287 AS individuals[28], the sub-group of patients with IBD-AS had higher prevalence of iritis (OR = 1.4) or psoriasis (OR = 1.9) than the controls. Moreover, patients with multiple disorders predicted the highest prevalence of co-existing disease (i.e. psoriasis, IBD, iritis, or AS) within family members. These data suggest that susceptibility factors are additive or have a synergistic effect on each other, thus pointing to a shared gene hypothesis.

Table 1 HLA associations in IBD and IBD-associated arthropathy[11]

	HLA antigens investigated	Percentage in IBD + arthropathy affected patients	Percentage in IBD patients without arthropathy
AS	HLA-B*27	60	7
Type Ⅰ arthritis	HLA-B*27	26	7
	HLA-B*35	33	15
	HLA-DRB1*0103	35	3
Type Ⅱ arthritis	HLA-B*44	62	31

GENETIC PREDISPOSITION TO IBD

IBD is widely believed to originate from a dysregulated immune response to luminal bacteria in a genetically susceptible host[2]. The inheritance model is non-Mendelian but complex-polygenic, with several genes involved together with environmental factors. Of the other environmental factors thought to have an impact on disease susceptibility, only smoking and appendectomy have a substantive evidence base[29]. Concordance data in twins (36% for CD and 16% for UC, 4% for both CD and UC for monozygotic and dizygotic twins, respectively) and multiplex IBD families (relative risk to first-degree relative of proband up to 35 for CD and 15 for UC) have provided strong epidemiological evidence for a genetic contribution to IBD susceptibility[30]. These observations have led to the development of genetic investigations with two broad strategies: one has investigated candidate genes, and the other has used hypothesis-free methods of genome-wide scanning.

Overall, candidate gene strategies have not proved to be particularly fruitful in IBD, but one success has been the identification of an association between the major histocompatibility complex (MHC) region and UC susceptibility, initially in Japanese subjects[31] and later in Europeans[32]. The DRB1*0103 allele has been implicated in both severe UC and extra-intestinal (mainly articular) manifestations of IBD. Subsequently, 11 genome-wide scans by non-parametric linkage analysis were performed in the 1990s, and several susceptibility loci were identified in approximately half of the chromosomes[33].

The *NOD2* gene on chromosome 16q12 was the first susceptibility gene for CD to be identified successfully. It was detected by parallel strategies of positional cloning within a region of linkage and positional candidate gene investigation[34,35], and the finding was subsequently widely replicated in Caucasian, but not in Asian populations. NOD2 encodes an intracellular receptor that is expressed predominantly in monocytes and Paneth cells[33]. This has been implicated in the innate immune response to muramyldipeptide (MDP), a component of peptidoglycan

in bacterial cell walls. The CD-associated variants that are clustered in the C-terminal leucine-rich repeat part of the NOD2 protein significantly diminish responsiveness to MDP. On exposure to MDP, oligomerized NOD2 recruits RIP2 (the serine-threonine kinase RICK) and subsequently activates nuclear factor-κB transcription factor *via* NEMO ubiquitination and IκB degradation. This leads to production of cytokines and cryptidins/defensins, hence facilitating clearance of bacteria. In addition, there is evidence of cross-talk between NOD2 and toll-like receptor pathways. However, the precise mechanism by which NOD2 mutations lead to increased intestinal inflammation is unknown, but it may be that reduced ability to clear bacteria by innate immune mechanisms leads to dysregulation of adaptive immune pathways.

Following fine mapping of the IBD5 linkage region on chromosome 5q31, consistent evidence for association between CD and a haplotype of markers spanning 250 kb has been observed. More recently, the same locus has been associated also with UC[36]. However, because of the strong linkage disequilibrium (LD) across this region, it has been very difficult to identify the causal variant. Peltekova *et al*[37] have reported a two-locus risk haplotype in the region of the organic cation transporter (OCTN) genes and suggested that this accounts for the association. The two-locus haplotype comprises L503F (1672 C-T, missense substitution) and G207C (transversion) in the *SLC22A4* (OCTN1) and *SLC22A5* (OCTN2) genes, respectively. However, there remains significant debate as to whether these transcripts are truly implicated by the genetic evidence, and a number of other immunoactive candidates remain in the frame, including interferon regulatory factor 1 (IRF1) and a number of important cytokine genes (IL-3, IL-4, IL-5 and IL-13) located within the 250-kb risk haplotype.

Progress from the Human Genome Project and HapMap Project, combined with markedly decreasing genotyping costs, has made possible the performance of adequately powered genome-wide association studies (GWAs) in complex genetic disorders such as IBD. Several GWAs[38] and a meta-analysis[39] have already been performed in CD and more recently in UC[40] and pediatric IBD[41]. Genome scans have identified 11 susceptibility genes and loci and highlighted a number of new, previously unsuspected pathways as playing an important role in IBD pathogenesis, including the IL23 pathway in IBD overall and specific aspects of innate immunity (particularly the autophagy genes *ATG16L1* and *IRGM*) in CD. As expected, a number of genes such as IL23r, IL12B, MHC, STAT3, IBD5, MST1, PTPN2, NKX2-3 seem to be shared in the predisposition to both UC and CD (Table 2).

Table 2 Candidates genes and loci in CD and UC

	Genes and loci	Associated with CD	Associated with UC
1p31	IL23R	Yes	Yes
1q21	ECM1	-	Yes
2q37	ATG16L1	Yes	No
3p21	Several included MST1-BSN	Yes	Yes
5p13	Intergenic, PTGR4	Yes	No
5q31	Several included SLC22A5	Yes	Yes
5q33	IRGM	Yes	No
5q33	IL12B	Yes	Yes
6q21	HLA-DQ/DR	Yes	Yes
10q21	ZNF365	Yes	Yes
10q24	NKX2-3	Yes	Yes
16q12	NOD2	Yes	No
17q21	Several included STAT3	Yes	Yes
18p11	PTPN2	Yes	Yes

CD: Crohn's disease; UC: Ulcerative colitis.

COMMON GENETIC LINK BETWEEN IBD AND SPONDYLOARTHROPATHY

IBD and AS show familial clustering and may coexist in a patient. More intriguingly, healthy first-degree relatives of patients with AS (21%-60%) and CD (10%-54%) have increased permeability of the small intestine[42-44]. These changes might be a consequence of subclinical intestinal inflammation, and conform to the profile of an additive trait in both conditions[45,46]. Evidence from studies of twins and other first-degree relatives suggests that the genetic basis is somewhat stronger for IBD than for AS[47-50].

In the pre-GWA era, studies investigating a possible common genetic background in IBD and articular involvement were concentrated mainly on MHC and NOD2. It has been recognized that genes in the HLA region have a greater role for modifying IBD phenotype than in determining overall disease susceptibility. Within UC clinical subgroups, the uncommon DRB1*0103 allele is associated with both extensive and severe disease, with an early need for surgery[51]. Interestingly, the same allele has also been associated with CD colitis, thus suggesting the molecular basis of a colonic IBD phenotype. Furthermore, type I pauciarticular large-joint arthritis is also associated with this allele and other class I alleles (B*27 and B*35) in LD. However, the low frequency of this allele suggests that this association is unlikely to be clinically useful in predicting disease course. In addition, an increased prevalence of extraintestinal manifestations has been reported previously in colonic IBD, increasing the possibility that the association between DRB1*0103 and articular manifestations may merely mirror the association with colonic disease. Finally, recent evidence from GWA scans has at least refined the signal to the 400-kb haplotype block that contains DRB1*0103, and shows that this locus is common to UC and the colonic (but not small bowel) sub-phenotype of CD[52].

Crane *et al*[53] have investigated the hypothesis that the three major variants of the NOD2 gene are involved in AS. A case-controlled study was performed in 229 AS, 197 IBD-associated AS (78 with CD and 119 with UC), and 229 ethnically matched healthy controls. The Gly908Arg variant was associated with UC-associated AS (OR = 4.6, 95% CI = 1.3-16, $P = 0.016$), with a similar non-significant trend in CD-associated AS (OR = 3.9, 95% CI = 0.8-18, $P = 0.08$). In contrast, no association was found between

NOD2 variants and primary AS, or other variants with UC- or CD-associated AS. Moreover, carriage of the Pro268Ser variant was associated with greater disease activity. Similarly, in subsequent studies, variants of NOD2 do not appear to confer susceptibility to AS[54], but rather identify a subgroup of patient with CD-associated AS[55].

Recently, the Wellcome Trust Case Control Consortium and the Australo-Anglo-American Spondylitis Consortium have published the first association scan with 14 436 non-synonymous single nucleotide polymorphisms (SNPs) in 922 independent cases of AS, together with autoimmune thyroid disease, multiple sclerosis and breast cancer, against a common control dataset of 1500 healthy individuals[56]. The strongest association in AS was observed in the MHC region, centered around the HLA-B genes, but the association of $P < 10^{-20}$ was observed across about 1.5 Mb, probably reflecting the strong effect of HLA-B27, even over distant SNPs with modest LD. To validate less strong signals obtained at the first scan, a further 471 independent AS cases and 625 new controls were genotyped with additional SNPs. In the combined data set, a strong association ($P = 1.2 \times 10^{-8}$ to 3.4×10^{-10}) with SNPs of the ARTS1 gene (OR = 1.4) and IL23R gene (peak P value of 7.5×10^{-9} at the rs11209032 with an OR of 1.3) was found. The association with IL23R remained strong when considering individuals with AS not having IBD (n = 1066). These genes both represent excellent biological candidates, but more importantly, IL23R has been documented recently in CD and psoriasis[57], which suggests that this gene is a common susceptibility factor for the major seronegative diseases, at least partially explaining their co-occurrence. IL23R is a key factor in the regulation of a newly defined effector T-cell subset, T_H17 cells[33]. They express high levels of the cytokine IL-17 in response to stimulation, in addition to IL-1, IL-6, tumor necrosis factor α, IL-22 and IL-25. In animal models, blocking IL-23 reduces inflammation, which suggests that IL23R variants associated with disease are pro-inflammatory. No functional studies of IL23R variants are available to date, however a promising treatment of CD has been reported with anti-IL-12p40 antibodies, which block IL-12 and IL-23, as these cytokines share the p40 subunit[58].

A different perspective was employed in a study that explored the possible common genetic background of IBD and AS through a genealogical evaluation in Iceland[59]. Icelanders are relatively homogeneous with respect to the environment, cultural aspects and genetic factors; moreover, extensive genealogical records and diseases registries are available. By investigating the genealogical database and registry of subjects with AS (n = 205) and IBD (n = 1352), the risk ratios for relatives for each disease and the cross-risk ratios (AS *vs* IBD and *vice versa*) were estimated. First-, second- and third-degree relatives of patients with AS, had risk ratios of 94, 25 and 3.5, respectively, of developing AS (each $P < 0.0005$), while first-, second- and third-degree relatives of patients with IBD had risk ratios of 4.4, 2.2 and 1.4, respectively (each $P < 0.0001$). More intriguingly, the cross-risk ratio was 3.0 and 2.1 ($P < 0.0001$), respectively, in first- and second-degree relatives, with a comparable effect for UC and CD. This elevated cross-risk ratio between IBD and AS strongly suggests that there is a genetic component shared by these complex diseases, and should stimulate further molecular and functional studies.

CONCLUSION

The clinical association between spondyloarthropathy and IBD is well-established, with studies indicating that as many as 10%-15% of cases of IBD are complicated by AS or other forms of SpA[60]. Ileal inflammation that resembles IBD has been reported in up to two thirds of cases of SpA, and it has been suggested that the presence of ileitis is associated with the chronicity of articular complications. Moreover, evidence that there is familial clustering of IBD and AS, that both conditions may coexist in patients, that there is an increased risk ratio among first- and second-degree relatives of affected AS or IBD patients and finally, that there is an increased cross-risk ratios between AS and IBD, confirm the existence of a shared genetic predisposition. So far, IL23R is the only identified susceptibility gene shared by IBD and AS. Functional studies are still needed to better understand its functional role, but it is hoped that treatment that targets this pathway may prove effective in both disorders.

Abstract

Gut inflammation can occur in 30%-60% of patients with spondyloarthropathies. However, the presence of such gut inflammation is underestimated, only 27% of patients with histological evidence of gut inflammation have intestinal symptoms, but subclinical gut inflammation is documented in two-thirds of patients with inflammatory joint disease. There are common genetic and immunological mechanisms behind concomitant inflammation in the joints and intestinal tract. A number of blood tests, e.g. erythrocyte sedimentation rate, orosomucoid, C-reactive protein, and white cell and platelet counts, are probably the most commonly used laboratory markers of inflammatory disease, however, these tests are difficult to interpret in arthropathies associated with gut inflammation, since any increases in their blood levels might be attributable to either the joint disease or to gut inflammation. Consequently, it would be useful to have a marker capable of separately identifying gut inflammation. Fecal proteins, which are indirect markers of neutrophil migration in the gut wall, and intestinal permeability, seem to be ideal for monitoring intestinal inflammation: they are easy to measure non-invasively and are specific for intestinal disease in the absence of gastrointestinal infections. Alongside the traditional markers for characterizing intestinal inflammation, there are also antibodies, in all probability generated by the immune response to microbial antigens and auto-antigens, which have proved useful in establishing the diagnosis and assessing the severity of the condition, as well as the prognosis and the risk of complications. In short, non-invasive investigations on the gut in patients with rheumatic disease may be useful in clinical practice for a preliminary assessment of patients with suspected intestinal disease.

Key words: Biochemical markers; Fecal markers; Inflammatory bowel disease; Intestinal permeability; Serological markers; Spondyloarthropathies

INTRODUCTION

Gut lesions are relatively common in patients with rheumatic disease and approximately 30%-60% patients with spondyloarthropathies have occult intestinal inflammation, which may be related to their ingestion of non-steroidal anti-inflammatory drugs or associated with their rheumatic disease.

Spondyloarthropathies form a group of chronic autoimmune disorders of the joints which include ankylosing spondylitis, reactive arthritis, psoriatic arthritis, arthritis associated with inflammatory bowel disease (IBD), and undifferentiated spondyloarthropathies. The prevalence of gut inflammation in ankylosing spondylitis is higher among patients with associated peripheral arthritis than in those with axial involvement alone[1].

Gut inflammation has also been recorded in other spondyloarthropathies. In juvenile chronic arthritis, for instance, when colonoscopy with biopsies of the colonic mucosa and terminal ileum was performed in 12 patients less than 16 years of age, inflammation was observed in 9 patients (75%); gut inflammation could have a

role in the pathogenesis of the disease and persistent synovitis[2].

Two histological types of gut inflammation can be distinguished in spondyloarthropathies, i.e. acute and chronic, based on their morphological characteristics, not on the time of onset or duration of the disease[3]. The acute type resembles acute bacterial enterocolitis, with a well-preserved mucosal architecture. The chronic type resembles chronic ileocolitis and is generally indistinguishable from Crohn's disease, with a clearly disrupted mucosal architecture. While acute lesions are mainly seen in patients with reactive arthritis, chronic lesions are more prevalent in undifferentiated spondyloarthropathies and ankylosing spondylitis[4].

In a prospective study on 123 patients with spondyloarthropathies who initially underwent endoscopy, intestinal evolution was evaluated by ileocolonoscopy and an evolution to IBD was recorded in 7% of these patients[5].

Despite the high frequency of gut lesions in patients with joint diseases, only a few patients are symptomatic. In a series described by Cuvelier *et al*[3], only 27% of patients with histological gut inflammation had intestinal symptoms.

Non-invasive laboratory tests might therefore help to identify rheumatic disease patients with gastrointestinal symptoms who need further investigation. It would be helpful to have inexpensive and manageable tests to facilitate this selection.

GUT-RELATED GENETIC POLYMORPHISMS

There is clinical evidence of a correlation between gut and joint inflammation and the gut could have an important pathogenic role. Remission of joint inflammation has been associated with the disappearance of gut inflammation, and remission of persistent joint inflammation with the disappearance of persistent gut inflammation[4]. Ankylosing spondylitis affects 3%-10% of patients with IBD and is thought to have a genetic origin in these patients that differs from that of "classic" ankylosing spondylitis: while 90% of patients with "classic" ankylosing spondylitis have the human leukocyte antigen B27 phenotype, its prevalence drops to 30% in patients with ankylosing spondylitis associated with Crohn's disease. Polymorphisms of the CARD15 gene may act as a genetic trigger because 78% of patients with Crohn's disease and symptomatic or asymptomatic sacroileitis carry at least one mutation, as opposed to 48% of control patients with Crohn's disease alone[6]. Laukens *et al* confirmed a similar association, finding CARD15 variants in 42% of patients with spondyloarthropathy and asymptomatic gut inflammation, compared with 7% of patients with normal gut histology[7].

In a previous study, the frequency of HLA-Bw62 was found to be very high in patients with reactive arthritis and in those with active ankylosing spondylitis and Crohn-like lesions on gut biopsy[8].

BLOOD MARKERS

A number of proteins are up- or down-regulated in the acute phase of inflammation, and gut inflammation is associated with an acute-phase reaction and the migration of leucocytes to the gut lumen. Several blood tests are used to detect inflammation, however, these tests are unable to discriminate between inflamed joints and inflamed gut[9]. In a study on children with spondyloarthropathies, erythrocyte sedimentation rate (ESR) showed 63% sensitivity and 44% specificity in detecting gut inflammation[10]. Serum levels of human cartilage glycoprotein 39 (also called YKL-40) were recently found to be higher than normal in patients with IBD. More than 60% of Crohn's disease patients with extraintestinal manifestations have high serum YKL-40, as opposed to only 3% of ulcerative colitis patients[11]. We found significantly higher serum levels of YKL-40 in IBD patients with arthropathies than in those without arthropathies or controls ($P < 0.001$ and $P < 0.01$, respectively). The level of this protein also correlates with the number of joints involved, suggesting that this substance could be used as a disease activity marker in arthritis associated with IBD[12].

FECAL MARKERS

As serum markers may increase in various conditions, fecal markers might be more specific for gut inflammation. Barabino *et al*[10] compared a number of non-invasive tests for diagnosing intestinal inflammation in children with spondyloarthropathies. Forty-two children with IBD or rheumatologic manifestations associated with gastrointestinal symptoms were investigated by 99mTechnetium-HMPAO labeled white cell scanning, abdominal ultrasound, ESR, fecal occult blood and fecal alpha 1-antitrypsin tests. 99mTechnetium-HMPAO labeled white cell scanning was shown to be the most sensitive (85%) and specific (100%) in detecting gut inflammation. White cell scanning combined with the measurement of fecal excretion of labeled white cells was able to quantify inflammation accurately in an additional study: following intravenous administration of 111In-labelled leukocytes, fecal 111In granulocyte excretion correlated significantly with Crohn's disease activity index ($P < 0.001$), C-reactive protein (CRP) ($P < 0.001$) and ESR ($P < 0.001$)[13]. This technique is expensive and time-consuming, however, and involves the use of radiation. Moreover, leukocytes do not survive for long periods in feces due to bacterial degradation[14]. As an alternative, fecal leukocytes can be seen under the microscope, but again, such an evaluation is not practicable because it has to be carried out on fresh stools. Some leukocyte proteins, such as lactoferrin and calprotectin, are more durable and can be used as surrogate markers of the presence of leukocytes in stools. Fecal calprotectin levels have been shown to correlate with intestinal inflammation, as assessed by 111Indium-labeled leukocyte studies on 4-d-old fecal samples and the correlation was maintained, even when

a single stool specimen was examined[15,16].

A number of neutrophil-derived proteins have been studied in stools, including fecal calprotectin, lactoferrin, lysozyme, elastase and myeloperoxidase[17,18]. Experience with the analysis of fecal proteins has been gained mainly with calprotectin and lactoferrin. Calprotectin represents 60% of the cytosolic proteins in granulocytes, and is released from cells during cell activation or death, while lactoferrin is a component of the granules in the neutrophilic granulocytes, so their presence in feces is presumably directly proportional to neutrophil migration in the gut lumen[19,20]. Both calprotectin and lactoferrin are stable in stools for more than 7 d at room temperature[19,20].

Determining intestinal inflammation by means of fecal markers is of considerable interest to clinicians in various settings, e.g. to discriminate between patients with organic and functional processes, to monitor disease activity and response to treatment, and to predict relapses in IBD. Both calprotectin and lactoferrin have been found to correlate with intestinal inflammation in studies on patients undergoing colonoscopy for gastrointestinal symptoms or surveillance[21,22].

In a recent study, calprotectin and lactoferrin appeared to be equally recommendable as inflammatory disease markers in patients with lower gastrointestinal symptoms and both reflected inflammatory activity in IBD[23].

Fecal calprotectin and lactoferrin are equally useful in assessing disease activity: calprotectin correlated with endoscopic findings, lactoferrin with histology[23,24].

Fecal calprotectin also proved useful in predicting relapses in patients in clinical remission, probably reflecting subclinical activity. Tibble *et al*[25] found that fecal calprotectin levels greater than 50 μg/g were a sensitive and specific predictor of relapse in the short term in both ulcerative colitis and Crohn's disease (with 90% sensitivity and 83% specificity). More recently, Costa *et al*[26] found that ulcerative colitis patients with fecal calprotectin levels higher than 150 μg/g had a 14-fold relapse risk, while Crohn's disease patients had only a two-fold risk of relapse, which was not statistically significant. D'Incà *et al*[27] observed that calprotectin levels beyond 130 mg/kg correlated significantly with the probability of relapse in ulcerative colitis patients ($P = 0.000$) and colonic Crohn's disease patients ($P = 0.02$), but not in patients with ileal or ileocolonic disease.

INTESTINAL PERMEABILITY

Permeability refers to the property of a membrane that enables a solute to pass through it by unmediated diffusion due to the membrane's structure, the physical and chemical properties of the solute, and its interaction with the medium or solvent. Intestinal permeability is assessed non-invasively *in vivo* by measuring the urinary excretion of orally administered hydrosoluble, non-toxic and non-degradable probes, e.g. lactulose/mannitol, lactulose/rhamnose, ^{51}Cr-EDTA/rhamnose, or D-xylose.

Bjarnason *et al* postulated that a greater intestinal permeability to toxic "non-absorbable" compounds might be responsible for some of the extraintestinal tissue damage common in alcoholic patients[28]. An altered intestinal permeability may also represent the primary defect in patients with arthropathy. An increased antigenic load could result from an altered intestinal permeability, since higher levels of antibodies to *Klebsiella pneumoniae* have been found in the serum of patients with ankylosing spondylitis, rheumatoid arthritis and IBD[29]. Morris *et al*[30] found that small intestinal permeability increased in patients with ankylosing spondylitis taking non-steroidal anti-inflammatory drugs, suggesting that the increased permeability was probably not a primary mucosal lesion, but caused by the medication. De Vos *et al*[31] found both acute and chronic inflammation at the macroscopic (30%) and histological (61%) level in the terminal ileum of patients who were seronegative for arthropathy and were not taking non-steroidal anti-inflammatory drugs. Chronic inflammation predominated in ankylosing spondylitis patients, resembling Crohn's disease in one third of patients. Mielants *et al*[32,33] observed a greater gut permeability in rheumatic patients irrespective of whether they were taking non-steroidal anti-inflammatory drugs, indicating that the disrupted permeability is disease-related.

Altered gut permeability was also seen in juvenile chronic arthritides, which are frequently associated with IBD, despite the use of non-steroidal anti-inflammatory drugs ($P = 0.210$), disease activity ($P = 0.24$) and type of disease ($P = 0.28$)[34].

The same findings have been reported in various intestinal conditions, such as celiac disease[35], IBD[36], infectious gastroenteritis[37], and food intolerance or allergy[38,39]. We had the opportunity to study 261 consecutive patients referred with chronic diarrhea and found that the intestinal permeability test and CRP levels were independent predictors of the final diagnosis of an underlying organic small bowel disease. The test correctly identified the presence of organic disease in 80% of patients[40].

The permeability test is used in Crohn's disease to monitor disease activity and as a predictor of relapse in quiescent Crohn's disease. In active Crohn's enteritis, 95% of patients have an increased intestinal permeability, while in Crohn's colitis this is true of about 50% of patients[41]. Studies in patients with Crohn's disease in remission have shown that an increased intestinal permeability can pinpoint those at significant risk of disease relapse within the next few months[42,43].

SEROLOGICAL MARKERS

Serological tests focus on several antibodies, the most widely used being perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA) and anti-Saccharomyces cerevisiae antibodies (ASCA). p-ANCA were first described in ulcerative colitis patients in 1990, but the exact epitope remains unknown[44,45]. ASCA are directed against the cellular wall of baking yeast.

The specificity of both markers is very high, but their sensitivity is rather low and these tests are consequently

not suitable for screening purposes[46]. Combining the two (p-ANCA and ASCA) may be helpful, however, in the differential diagnosis between ulcerative colitis and Crohn's disease the combination of ASCA+/p-ANCA- is characteristic of Crohn's disease, while ASCA-/p-ANCA+ is characteristic of ulcerative colitis, with a sensitivity that ranges from 30%-64%, a specificity beyond 90% and a positive predictive value between 77% and 96%[47-49]. ASCA positivity has been related to disease severity[50], the risk of having to undergo surgery[51], and an ileal and/or right colonic localization of the disease[48,52].

The recent finding that p-ANCA and ASCA can be found in 25%-30% of patients some years before any IBD is diagnosed has shed some light on its pathogenesis[53].

Two studies documented a higher prevalence of ASCA IgA positivity in ankylosing spondylitis[54,55], adding proof to the conviction that spondyloarthropathies and IBD are immunologically related. Additional serum biomarkers include antibodies against outer membrane porin C (Anti-OmpC), the *Pseudomonas fluorescens* bacterial sequence I2 (anti-I2), bacterial flagellin (antiCBir1) and the anti-glycan antibodies, i.e. anti-chitobioside IgA (ACCA), anti-laminaribioside IgG (ALCA) and anti-mannobioside (AMCA)[46,56-58]. Although the data from independent studies vary, combining more than one serological marker has been shown to add clinical value, particularly in predicting a complicated disease behavior, including strictures, fistulas and the need for surgery.

CONCLUSION

Patients with spondyloarthropathies often have inflammation in the gut, especially in the terminal ileum, although only 30% of the patients involved have clinical symptoms.

The frequency of gastrointestinal disease remains poorly understood and should be investigated in all patients with chronic spondyloarthropathy. The early diagnosis and treatment of gut inflammation may make it unnecessary to use drugs that can damage the intestinal mucosa[59-61].

Biochemical markers are useful in managing gut inflammation, representing a valuable aid in the diagnosis of inflammatory processes and the evaluation of their prognosis.

The ideal marker should be easy to test, repeatable and inexpensive. Currently used blood markers are non-specific and reflect both joint and intestinal inflammation. The fecal markers calprotectin and lactoferrin, and intestinal permeability are more promising tests, as they have a good specificity for intestinal disorders and are straightforward to perform. This is very important, particularly to pinpoint those patients without intestinal symptoms who need to be selected for further, more invasive investigations, and to avoid medication-related complications.

Abstract

Inflammatory bowel diseases (IBDs), particularly Crohn's disease (CD) and ulcerative colitis (UC), are associated with a variety of extra-intestinal manifestations (EIMs). About 36% of IBD patients have at least one EIM, which most frequently affect the joints, skin, eyes and the biliary tract. The EIMs associated with IBD have a negative impact on patients with UC and CD, and the resolution of most of them parallels that of the active IBD in terms of timing and required therapy; however, the clinical course of EIMs such as axial arthritis, pyoderma gangrenosum, uveitis, and primary sclerosing cholangitis is independent of IBD activity. The peripheral and axial arthritis associated with IBD have traditionally been treated with simple analgesics, non-steroidal anti-inflammatory drugs, steroids, sulfasalazine, methotrexate, local steroid injections and physiotherapy, but the introduction of biological response modifiers such as tumor necrosis factor-α blockers, has led to further improvements.

Key words: Anti-tumor necrosis factor antagonists; Inflammatory bowel disease; Treatment; Arthropathies

INTRODUCTION

Inflammatory bowel diseases (IBD), particularly Crohn's disease (CD) and ulcerative colitis (UC), are associated with a variety of extra-intestinal manifestations (EIMs)[1]. About 36% of IBD patients have at least one EIM[2], and these have a negative impact on UC and CD patients. The most frequent EIMs affect the joints, skin, eyes and the biliary tract[3], but others give rise to small bowel dysfunctions (cholelithiasis, nephrolithiasis and obstructive uropathy) or are non-specific disorders (osteoporosis, hepatobiliary disease and amyloidosis)[1,2]. Although the association between EIMs and IBD has long been recognized, the underlying pathogenetic factors remain unclear. The reported incidence of peripheral and axial arthropathies ranges from 4% to 23%[4,5].

The Oxford group distinguished two types of peripheral arthropathy on the basis of their articular involvement[4]: (1) Type I is a large joint pauci-articular arthropathy that mainly affects the ankles, knees, hips, wrists, elbows and shoulders; is usually acute and self-limiting; occurs at times of IBD activity; and leaves no permanent joint damage. (2) Type II is a polyarticular arthropathy that mainly affects the small joints of both hands symmetrically; is characterised by pain that usually persists for months or years; and is largely independent of IBD activity.

Axial arthritis includes sacroiliitis and ankylosing spondylitis (AS)[5]: (1) Sacroiilitis may be asymptomatic or symptomatic[6]; asymptomatic sacroiilitis is common and up to 50% of CD patients show abnormal radiographic findings; symptomatic sacroiliitis is characterised by pain in the pelvis after rest, which improves with movement, and discomfort in the sacroiliac joints during bilateral pressure on the pelvic brim. (2) AS is characterised by persistent low back pain beginning before the age

of 30 years, and its clinical diagnosis is supported by characteristic radiological changes for which magnetic resonance imaging is the diagnostic tool of choice[7,8]. Although HLA B-27 is over-represented in IBD-related axial arthritis, it is of no diagnostic value[9].

THERAPEUTIC APPROACHES TO IBD AND ARTHROPATHIES

The treatment of IBD-associated arthropathies is almost entirely based on extrapolations from other forms of arthritis.

In the case of type I peripheral arthritis, treatment should concentrate on the active disease and include steroids, immunomodulators and anti-tumor necrosis factor-α (TNF-α)[10-12]; however, all forms of IBD-related arthritis seem to be treated with sulfasalazine (SSZ) despite the lack of supportive evidence[13]. The symptoms can be relieved using simple analgesics, rest and physiotherapy. Non-steroidal anti-inflammatory drugs may aggravate the underlying colitis[14], but the findings of a randomised study regarding the safety of celecoxib[15] indicate that its short-term use (< 2 wk) does not exacerbate colitis. A local steroid injection into the affected joints provides rapid but only temporary relief.

The treatment of AS should include intensive physiotherapy, together with the administration of disease-modifying drugs such as SSZ and methotrexate. However, since TNF-α has been shown to play a key role in the pathogenesis of AS and IBD, the treatment of this manifestation has changed[16].

The advent of biological response modifiers such as TNF-α blockers has improved the treatment of IBD and its associated peripheral and axial arthritides, and their safety and efficacy have been clearly established in the case of AS-related peripheral arthritis. IBD patients failing on immunomodulation therapy used to be recommended surgery, but are now treated with biological agents.

Table 1 lists the currently used treatments for IBD-related arthropathies.

Table 1 Therapy of spondyloarthropathies

Therapy	
Standard initial therapy	NSAIDs and anti-COX-2
	Physical activity
	Local steroids
Second line therapy	Sulfasalazine
	Methotrexate
	Gold
	Others (penicillamine, *etc*)
Biological therapies (TNFα-blockers)	Infliximab
	Etanercept
	Onercept
	Adalimumab
	Thalidomide

Anti-TNF antagonists

Infliximab is a chimeric IgG1 monoclonal antibody to TNF and represents a significant advance in the treatment of IBD with or without associated arthropathies[17]. There are anecdotal accounts of infliximab rapidly improving peripheral arthritis in IBD patients. Ellman *et al*[18] have reported the findings of an open-label study in which four patients with treatment-refractory peripheral arthritis responded to treatment with infliximab 5 mg/kg and, subsequently, a large-scale prospective, open-label trial demonstrated an improvement in peripheral arthritis in IBD patients who had previously been refractory to corticosteroids, 6-mercaptopurine, azathioprine or methotrexate[19]. Another small open-label study documented an improvement in the arthralgias of seven out of 11 IBD patients after a single infusion of infliximab 5 mg/kg[20].

On the basis of the available data, it seems that most IBD patients with active intestinal inflammation and concurrent peripheral arthritis are likely to experience an improvement in their joint symptoms upon receiving infliximab.

Adalimumab is a subcutaneously self-administered fully human monoclonal antibody against TNF-α that is efficacious in inducing and maintaining remission in patients with moderate-to-severe CD[21], but there are no published data concerning its efficacy in patients with concomitant IBD and arthritis.

Infliximab, etanercept and adalimumab have all been found to have positive short- and long-term effects on disease signs and symptoms in AS patients[22,23]. Braun *et al*[24] analysed the data from nine trials of anti-TNF agents (seven placebo-controlled and two open-label studies) and found that the treatment is efficacious in treating AS and IBD, and that the onset and flare of IBD are infrequent events in AS patients receiving anti-TNF therapy. Infliximab (but not etanercept) largely prevents IBD and AS activity but more data are required in the case of adalimumab.

The efficacy of adalimumab in the treatment of AS is mainly supported by the findings of the recent multicentre, randomized, double-blind and placebo-controlled trial conducted by van der Heijde *et al*[25] who observed that the response of most of the patients treated with adalimumab was better than that observed in the patients treated with placebo.

No published studies have yet addressed the effect of switching from infliximab to adalimumab in patients with CD-related spondyloarthropathy. We have recently evaluated the clinical response to adalimumab of 19 CD patients with associated spondyloarthritis who discontinued infliximab because of intolerance or loss of efficacy, and found that it successfully controlled both articular and intestinal disease activity[26].

In conclusion, about 36% of IBD patients have at least one EIM, especially articular involvement, and the introduction of anti-TNF therapy has improved the treatment of both. In particular, the subgroup of Crohn's disease patients with arthritic problems could be the one in which anti-TNF agents are most indicated.

Abstract

Spondyloarthropathies (SpA) are commonly observed extra-intestinal manifestations of both Crohn's disease (CD) and ulcerative colitis (UC), the two major forms of inflammatory bowel diseases (IBD). However, the immunological link between these two clinical entities is still poorly understood. Several lines of evidence indicate that SpA may originate from the relocation to the joints of the immune process primarily induced in the gut. The transfer of the intestinal inflammatory process into the joints implicates that immune cells activated in the gut-draining lymph nodes can localize, at a certain point of the intestinal disease, either into the gut or into the joints. This is indicated by the overlapping expression of adhesion molecules observed on the surface of intestinal and synovial endothelial cells during inflammation. Moreover bacterial antigens and HLA-B27 expression may be implicated in the reactivation of T cells at the articular level. Finally, accumulating evidence indicates that a T helper 17 cell-mediated immune response may contribute to IBD and IBD-related SpA with a crucial role played by tumor necrosis factor-α in CD and to a lesser extent in UC.

Key words: Cell adhesion molecules; Antigens; Th17; Helper T-cells; Tumor necrosis factor-α

INTRODUCTION

The term spondyloarthropathy (SpA) indicates a group of related diseases, including ankylosing spondylitis (AS), reactive and psoriatic arthritis (ReA and PsA), and undifferentiated spondyloarthritis (uSpA). All these forms of SpA share common clinical features which are sacroiliitis, inflammatory low back pain and oligoarticular asymmetric synovitis. SpA is a frequently observed extraintestinal manifestation in Crohn's disease (CD) and ulcerative colitis (UC), the two major forms of inflammatory bowel diseases (IBD). Indeed, the prevalence of SpA associated with CD and UC was 45.7% and 9.9%, respectively in a recent series[1]. Moreover a subtle gut inflammation is present in 25%-75% of patients with documented SpA[2], depending on the subtype, and among these, 6%-13% may evolve to overt IBD, suggesting common pathogenetic mechanisms between these two clinical entities[3-5].

The observation that SpA may occur during IBD has led to the hypothesis that IBD-related SpA originates from extraintestinal spreading of the immunologic process originating in the gut. Results from several studies suggest that the activation of the intestinal immune system may indeed lead, in certain conditions, to the generation of T cell clones which leave the gut compartment to home into the joints. These T cell clones would be able to replicate, in this site, the inflammatory process observed in the gut. However, to render this model plausible some conditions need to be met. Indeed the idea that joint inflammation is driven by T cell clones originating in the gut implies that these cells are able to leave the gut and to transfer into the joints. Secondly, gut-derived T cells need to encounter in the joint environment an adequate antigenic stimulus to

allow the reactivation of these cells. Finally, the immune response shaped in the gut must be responsible for the inflammation-related tissue damage observed in SpA.

FROM THE GUT TO THE JOINT: THE T CELL HOMING

A critical point for transfer of the inflammatory process from the gut to the joints is the possibility of redirecting the tissue-specific homing of inflammatory cells, mainly T cells, into the synovial compartment. In IBD, the abnormal reactivity of T cells against harmless antigens expressed by the commensal flora is thought to cause chronic intestinal inflammation[6,7]. In the gut-associated lymphoid tissue (i.e. Peyer's patches and lymphoid follicles) and mesenteric lymph nodes, professional antigen presenting cells (i.e. dendritic cells, DC) migrate from the intestinal lamina propria, prime naïve T cells which in turn differentiate into specialized T helper cells (e.g. Th1, Th2, Th17), thus acquiring the capacity to sustain a specific immune response. The profound changes observed in differentiated T cells in the secondary lymphoid organs include the expression of cell surface adhesion molecules and chemokine receptors which are responsible for the gut-specific T cell homing. Indeed, T cells activated in the Peyer's patches and mesenteric lymph nodes express the gut-addressing integrin $\alpha4/\beta7$ and the chemokine receptor CCR9[8]. Once activated, these cells reach the bloodstream through the efferent lymphatics and the thoracic duct. In the gut mucosa, the interaction between $\alpha4/\beta7$ integrin and its ligand, the mucosal addressin cell adhesion molecule 1 (MadCAM-1) expressed on the venular endothelial sheet[9,10] causes the initial rolling and subsequent arrest of activated T cells. MadCAM-1 is normally expressed on the intestinal mucosa and its expression is further enhanced during inflammation[11]. Once arrested on the surface of the intestinal venules, activated T cells transmigrate through the endothelial layer and move into the lamina propria following the gradient formed by the CCR-9-specific ligand CCL-25[12,13]. Therefore, the specific interaction between $\alpha4/\beta7$ integrin with MadCAM-1 and CCR9 with CCL-25 is pivotal for T cell homing into the gut. However it is worth noting that other molecules mediate the cell-to-cell interaction in this process. For instance CD44, the very late antigen-4 (VLA-4, $\alpha4\beta1$) and the lymphocytes function associated antigen-1 (LFA-1, $\alpha L\beta2$) expressed by activated T cells play a role in the recruitment of T cells into the gut. Moreover the expression of the vascular activated peptide-1 (VAP-1), intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and different subgroups of selectins (i.e. P- and E-selectins) which bind P-selectin glycoprotein-1 (PSGL-1) on T cells, is enhanced in endothelial cells of the inflamed intestine[14]. However, these molecules are not gut specific and they seem to contribute marginally to the specificity of T cell homing into the intestine. Nevertheless, many lines of evidence indicate that these molecules may be involved in the homing of gut-activated

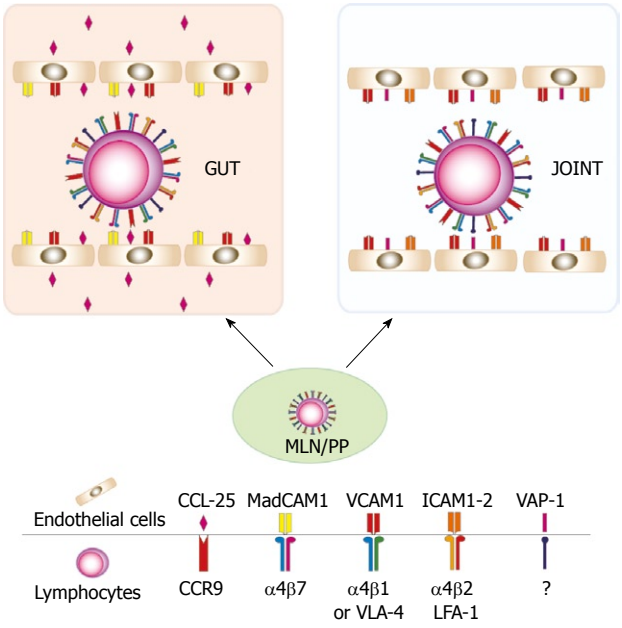

Figure 1 The heterogeneous expression of adhesion molecules allows T cells activated in the gut to home into the joints. CCR9: Chemokine receptor-9; CCL-25: Chemokine ligand-25; MadCAM1: Mucosal addressin cell-adhesion molecule-1; VCAM1: Vascular cell adhesion molecule-1; ICAM : Intracellular adhesion molecule; VLA-4: Very late antigen-4; LFA-1: Lymphocyte function associated antigen-1; VAP-1: Vascular adhesion protein-1.

T cells in other organs. Initial studies indicated that lamina propria lymphocytes (LPL) isolated from uninflamed gut were able to bind to uninflamed synovial vessels and that this interaction was critically mediated by CD44, VLA-4 and LFA-1[15]. In contrast, the adherence of lamina propria T cells to inflamed synovial vessels was dependent on VAP-1 and CD44[16]. When LPL were isolated from the inflamed gut of IBD patients, these cells bound more efficiently to synovial vessels than cells isolated from uninflamed gut[17]. This higher affinity could be explained by the observation that, in contrast with cells isolated from uninflamed gut, the binding of small, memory-like, T cells from IBD patients was, in addition to VLA-4, $\alpha4\beta7$-dependent, thus indicating a more varied use of adhesion molecules by IBD lamina propria T cells. By contrast, immunoblasts isolated from the lamina propria of IBD patients relied on CD44, LFA-1 and VAP-1 for their adhesion to synovial vessels, similar to immunoblasts from uninflamed gut.

Overall these data indicate that T cells primed in the gut-draining secondary lymphoid organs express a pattern of adhesion molecules that in part are responsible for the intestinal specific homing but that might, in particular conditions, mediate the entrance of activated T cells into extraintestinal compartments such as synovial tissue (Figure 1).

ROLE OF ANTIGEN MIMICRY AND HLA-B27 IN THE ANTIGENIC STIMULATION

As previously mentioned, intestinal commensal bacteria

are thought to sustain intestinal inflammation in IBD. Analogously, IBD-related SpA is thought to depend on the interaction between the host and the gut microbiota. This hypothesis is supported by the observation made in rat models of colitis and colitis-associated SpA. These rats, characterized by the over-expression of human HLA-B27, spontaneously develop intestinal inflammation and SpA. However, these animals did not develop inflammation when grown in germ-free conditions[18]. In contrast, both intestinal inflammation and SpA reappeared when they were transferred to a specific pathogen free environment[19,20], thus indicating that the intestinal and articular inflammatory processes depend on the presence of bacteria into the gut lumen.

Although many attempts to isolate living pathogens from the joint fluid during reactive arthritis failed, the presence of *Yersinia enterocolitica*-, *Salmonella enteritidis*- and *typhimurium*-, *Yersinia*- and *Shigella*-related antigens have been detected in the joints of these patients[21-23]. This observation suggests that the enteric antigens may be transported into the joints by monocytes. Accordingly, macrophages from the lamina propria of IBD patients were shown to adhere to the endothelial cells of synovial tissue[17]. It is therefore possible that recirculation of antigen-loaded macrophages may provide the antigenic stimulus necessary to sustain T cell activation and inflammation in the joints.

The crucial role of antigen stimulation in the pathogenesis of IBD-related SpA is also supported by the strong genetic association between SpA and the human leukocyte antigen (HLA) class I B-27 (HLA-B27). HLA-B27 was found in 75%-95% of patients affected by SpA[24,25] and in 25%-78% of IBD patients without SpA who developed this extraintestinal manifestation at a later stage of the disease[26,27]. Despite the strong genetic association, the pathogenetic role of HLA-B27 are still poorly understood. Activation of CD8+ T cells involved in the arthritic process by specific bacterial antigens exposed on HLA-B27 has been proposed[28,29]. Moreover, it has been shown that CD4+ T cells isolated from patients with reactive arthritis are activated by bacterial peptides presented in the context of HLA-B27[30]. These data draw a possible scenario in which activated CD4+ T cells migrate into the joints from the gut, in response to bacterial antigens presented by HLA-B27-expressing macrophages. Not necessarily in contrast with this hypothesis are data demonstrating the homology between HLA-B27 sequences and antigens derived from virus and enterobacteria. Indeed a certain level of antigen mimicry may contribute to the onset and/or maintenance of the inflammatory process initially induced by bacterial antigens. For instance, the nonapeptide, LRRYLENGK, derived from HLA-B27 (residues 168-176) shares the same sequence as peptides from enteric organisms (i.e. *Pseudomonas aeruginosa, Klebsiella nitrogenase, Escherichia coli, Bacillus megaterium, Salmonella typhimurium*). The same peptides originating from either bacteria or HLA-B27 endogenous turnover can be presented by HLA-B27, determining the activation of the same T cell repertoire[31]. Moreover, a dodecapeptide contained in the intracytoplasmic tail of HLA-B27 shows a strong homology with the sequence contained in the DNA primase of the arthritogenic bacteria *Chlamydia trachomatis*[32]. This fits well with the observation that high titers of antibodies anti-Saccharomyces cerevisiae (ASCA) and anti-neutrophils (pANCA) antibodies are present in IBD-related SpA[33]. Indeed pANCAs have been shown to cross-react with both neutrophil nuclear membrane and a *E. coli* proteins[34], while no self-antigens have been so far identified for ASCA. These data indicate that in the presence of HLA-B27 but also independently of this HLA antigen, an immune response initially evoked by a bacterial antigen may be further sustained by the cross-reactivity with self-antigens.

Recently, the process of folding and expression of the HLA-B27 heavy chain has received increasing attention as a potential mechanism involved in the pathogenesis of SpA. Under normal conditions, the peptide-loaded HLA class I heavy chain binds the β2-microglobulin (β2m). This assembling process takes place in the endoplasmic reticulum[35]. The folding process of the HLA-B27 heavy chain is slower than that of other HLA alleles thus leading to the generation of misfolded chains[36]. Misfolded chains are usually removed in the endoplasmic reticulum, but in certain conditions, such as viral infection, they accumulate thus generating a cascade of intracellular events including the activation of the protein BiP, the endoplasmic reticulum-unfolded-protein-response (UPR) and the activation of nuclear factor κB (NFκB) which plays a critical role in the induction of inflammation[37]. In contrast with this theory, it has been recently demonstrated that in HLA-B27 over-expressing rats, which normally develop colitis and SpA, the increased expression of β2m prevented colitis but not SpA[38]. In this study over-expression of β2m caused a reduction of HLA-B27 misfolding and an unfolded protein response, suggesting that HLA-B27 heavy chain misfolding may be critical in the development of colitis but not of SpA. In addition to misfolding, data suggest that HLA-B27 heavy chains preferentially form homodimers which bind immunoglobulin-like receptors expressed on the cell surface of natural killer (NK) cells, T cells and monocytes[39]. However, the actual role played by the interaction between HLA-B27 homodimer and its paired receptor in the inflammatory process is still poorly understood. Finally, data suggest that deposition of β2m, caused by the high dissociation rate between HLA-B27 heavy chain and β2m, occurring within synovial tissue, may lead to the initiation of chronic inflammation[40].

COMMON INFLAMMATORY MECHANISMS: FROM THE GUT TO THE JOINTS

The concept that immune cells, activated in the

inflamed gut and migrating into the joints, may be able to reproduce in this tissue a similar immune response, is sustained by the observation that common immunological processes operate at both these sites. Attention has been recently focused on the role of T helper 17 cells (Th17) in IBDs and IBD-related SpA. Th17 cells form a novel class of T helper cells characterized by the expression of the proinflammatory cytokines interleukin (IL)-17A, from which comes the name Th17, IL-17F, IL-22 and TNFα. IL-6 and TGFβ have been shown to be crucial for the differentiation of these cells while IL-23, another proinflammatory cytokine, is thought to be important for their maintenance and expansion[41,42]. Several lines of evidence indicate that Th17 cells may play a role in the induction and maintenance of gut inflammation in CD while their role in UC is still uncertain. Indeed, IL-17A and IL-17F are highly expressed in the gut of patients affected by CD, and Th17 cells have been shown to induce intestinal inflammation in different mouse models of colitis[43-46]. Analogously, high expression of IL-17 was found in the synovial fluids of SpA-affected patients and an increased number of circulating Th17 memory-like T cells has been recently reported in these patients[47,48]. An association between Th17 cells and IBD is further supported by the observation that mutations of IL-23 receptor reduce the risk of developing IBD[49] and the same mutations were found to protect against SpA[50]. Although the functional role of IL-23R mutations remains unclear, the fact that IL-23 signaling plays a critical role in the Th17-mediated inflammation, implicates that Th17 cells may represent a common pathogenetic mechanism in both IBD and SpA.

Tumor necrosis factor-α (TNFα) is a proinflammatory cytokine largely expressed in the lamina propria of patients affected by IBD (mainly CD and to a lesser extent UC), rheumatoid arthritis (RA) and SpA. The role of TNFα in IBD-related SpA has been investigated in the $Tnf^{\Delta ARE}$ mouse model which is characterized by the high expression of TNFα. These mice develop a phenotype dominated by IBD-like intestinal inflammation and arthritis thus implicating TNFα as a required factor for the induction of inflammation in both IBD and IBD-related SpA[51]. In this model, intact TNFα signaling in radiation-resistant mesenchymal cells was found to be required for the induction of SpA as shown by the absence of SpA observed in lethally irradiated TNFαRI knockout mice reconstituted with $Tnf^{\Delta ARE}$ bone marrow cells[52]. Moreover, selective expression of TNFαRI in intestinal myofibroblasts (IMF) and synovial fibroblasts (SF) was sufficient to re-establish intestinal inflammation and SpA in $Tnf^{\Delta ARE}$-TNFαRI knockout mice. MIF and SF expressed high levels of extracellular matrix-degrading metalloproteinase (MMP)-9 and -3 accompanied by reduced levels of the tissue inhibitor of MMPs-1 (TIMP-1) in response to TNFα stimulation which were in part responsible for the tissue damage observed in both the gut and the joints.

COMMON TREATMENT OPTIONS

These studies provide a rationale for developing new strategies for the therapy of IBD-related SpA. However, only the neutralization of TNFα has so far found clinical application in the therapy of IBD-related SpA. An early report showed that two patients affected by CD-associated AS refractory to conventional therapy, experienced amelioration of the axial symptoms after anti-TNFα therapy with infliximab 5 mg/kg intravenously[53]. The efficacy of infliximab in the therapy of SpA was later confirmed by two randomized controlled trials. In a first randomized, double-blind trial 40 patients affected by SpA were randomly assigned to receive either infliximab 5 mg/kg (weeks 0, 2, and 6) or placebo. At 12 wk there was a significant improvement of both the BASDAI (Bath Ankylosing Spondylitis Disease Activity Index) and BASFI (Bath Ankylosing Spondylitis Functional Index) in the infliximab group in comparison to controls[54]. Similar results were obtained by Braun *et al*[55] in a randomized, controlled, multicenter trial in which 53% (18 of 34) patients affected by AS treated with infliximab 5 mg/kg (weeks 0, 2, 6) *vs* 9% (3 of 35) treated with placebo showed a reduction of at least 50% of the BASDAI, BASFI and BASMI (Bath Ankylosing Spondylitis Metrology Index) compared to baseline. However the presence of concomitant IBD in the patients participating in both these trials was unknown. The only trial evaluating the efficacy of anti-TNFα in a cohort of patients affected by CD-related SpA is an open-label study comparing infliximab *vs* conventional therapy[56]. In this study 21 patients with active SpA were enrolled. Sixteen patients with active CD were treated with infliximab (5 mg/kg) at 0, 2, and 6 wk. If remission was achieved patients were treated with a maintenance dose of 3 mg/kg every 6-8 wk otherwise 5 mg/kg was administered. Eight CD-affected patients were in clinical remission at the beginning of the study. These patients were treated with a dose of 3 mg/kg following the same schedule. Twelve additional patients affected by active CD and SpA underwent conventional therapies. Results from this study showed a significant reduction of the BASDAI and spinal pain in the group treated with infliximab in comparison to patients undergoing conventional therapy. Finally, it has been recently suggested that treatment of SpA with infliximab but not etanercept (another anti-TNFα agent) prevents new onset or flares of IBD[57].

The use of adalimumab, a fully humanized anti-TNFα has achieved similar results. A multicenter, randomized, placebo-controlled, trial aimed at assessing the efficacy and safety of 40 mg adalimumab administered subcutaneously for 12 and 24 wk, found that adalimumab was significantly more effective in inducing ASAS20 (20% response according to the ASsessment in Ankylosing Spondylitis International Working Group criteria) than placebo[58]. Moreover the long term efficacy of adalimumab regimen in the treatment of IBD-related SpA has been recently confirmed in a 2-year follow-up study after the initial treatment[59].

CONCLUSION

SpA is a common extraintestinal manifestation of IBD. However, the immunological mechanisms linking gut and joint inflammation are still poorly characterized. The observation that in most of the cases intestinal inflammation precedes SpA has led to the hypothesis that the inflammatory process initially localized in the gut may be "relocated" to a different site. Indeed most of the data summarized here support this concept, providing evidence that T cells and monocytes/macrophages activated by gut-related antigens may be able to home in to the synovial tissue as a result of the expression of adhesion molecules which partially overlap with those expressed by endothelial cells in the gut. In synovial tissue, activation of inflammatory cells may be sustained by several mechanisms including the presence of bacterial antigens and/or by the altered expression of HLA-B27. Finally Th17 cells and high expression of TNFα may play a crucial role in the inflammation-related tissue damage in both the gut and the joints by inducing the expression of extracellular matrix metalloproteinases. However, it is important to note that in some cases, SpA has been shown to precede IBD thus indicating that the illustrated mechanism may not be always applicable and that other immunological processes may link gut inflammation to inflammatory processes localized in different extra-intestinal sites.

Abstract

Diverticular disease (DD) is an age-related disorder of the large bowel which may affect half of the population over the age of 65 in the UK. This high prevalence ranks it as one of the most common bowel disorders in western nations. The majority of patients remain asymptomatic but there are associated life-threatening co-morbidities, which, given the large numbers of people with DD, translates into a considerable number of deaths per annum. Despite this public health burden, relatively little seems to be known about either the mechanisms of development or causality. In the 1970s, a model of DD formulated the concept that diverticula occur as a consequence of pressure-induced damage to the colon wall amongst those with a low intake of dietary fiber. In this review, we have examined the evidence regarding the influence of ageing, diet, inflammation and genetics on DD development. We argue that the evidence supporting the barotrauma hypothesis is largely anecdotal. We have also identified several gaps in the knowledge base which need to be filled before we can complete a model for the etiology of diverticular disease.

Key words: Diverticular disease; Dietary factors; Genetics; Colon; Inflammation

INTRODUCTION

Diverticular disease (DD) is characterized by out-pouching in the wall of the colon; though generally benign, a minority of individuals develop associated morbidities, ranging from excessive flatulence and minor Irritable Bowel Syndrome (IBS)-like symptoms, through to inflammation of these out-pouchings (diverticulitis)[1]. Diverticulitis can lead to potentially life-threatening complications (i.e. abscess formation, colonic perforation, and bowel obstruction) in up to a quarter of sufferers[2] and one estimate puts European DD associated mortality at 23 600 deaths per annum[3].

EPIDEMIOLOGY AND PUBLIC HEALTH IMPACT

Necropsy-based studies implicate ageing as the primary risk factor for DD. Two studies in separate Northern European populations, dating from 1968 and 1979, indicate a prevalence of around 13% up to 54 years of age and rising to 40%-50% in individuals over 75 years old[4,5] (Figure 1A). Age-standardized mortality rates for DD in the UK have not changed considerably since 1979[6], so we can assume that these figures are a reasonable estimate of the current prevalence. As an age-related phenomenon we can expect the burden of DD upon society to rise with the continuing increases in life expectancy throughout the developed world (data from

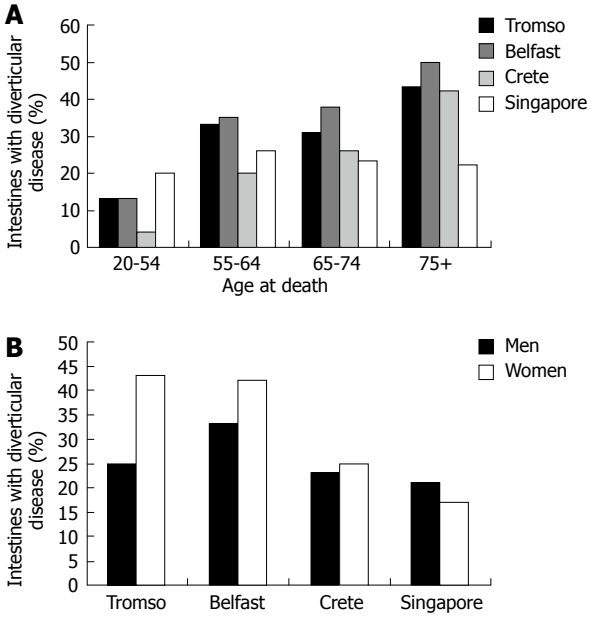

Figure 1 Prevalence of DD in intestines obtained at necropsy by age, gender and region. A: Increasing prevalence of DD with age in western populations. In contrast DD peaked amongst individuals in their late fifties and early sixties in Singapore. The Singapore study however is based on diverse ethnic populations which may be confounding these observations; B: Percentages of intestine shown to have DD present at necropsy by gender. Data obtained on individuals from the Trømso region of northern Norway between 1974 and 1976, Northern Irish subjects in 1968, Cretan subjects 1997-1999, and Singapore prior to 1986. Note: The data presented for the Cretan-, Belfast- and Singapore-based studies are adjusted for age groups used by the Norwegian study using slopes obtained from the published data. Figures adapted from reference[1-4].

the UK Office of National Statistics show continued increases in life expectancy in the UK[7]).

Diverticular disease has been described as a 20th century phenomenon[8], however there are cases in the European literature dating from well before 1900 as evidenced by Jun and Stollman[9]. In addition, evidence of an increase in the death rate from diverticulitis between 1923 and 1966 in England and Wales has been noted[10], and this probably reflects the increasing percentage of elderly people in the population over the same period[7]. The age-standardized mortality rates for DD in the UK have not changed considerably since 1979[3]; it follows that advances in medical practices coupled with increased lifespan may help explain in part the increased diagnosis of DD in the 20th century.

Necropsy data from Northern Europe, Southern Europe and Asia indicate wide geographic disparities in DD prevalence, i.e. it is more common in Northern Europe than in Crete or Singapore (Figure 1A). These studies also show an east-west divide in the nature of disease presentation, with right-sided diverticula being more prevalent in Asian populations; this hints at distinct etiologies[11]. Finally, the necropsy data also indicate that DD is more prevalent in women than men (Figure 1B). It is not yet clear as to whether this gender effect is related to hormonal or anthropometric risk factors, although Manousos *et al*[12] report a relationship with parity.

There have been several studies of DD risk in migrant populations. For example, "non western" immigrants showed a lower risk of DD-related hospital admissions and death but after adjusting for age, risk increased with years of residence in Sweden[13]. In contrast, other studies found no changes in DD incidence amongst migrant communities following periods of naturalization in countries with high or low risk DD in the native population. For example, evidence gathered from endoscopy reports suggests that the predominantly Turkish migrant community in the Zaanstreek region of the Netherlands have a significantly lower incidence of DD than the native Dutch population. Just 7.5% of 387 immigrants examined were shown to have DD, in contrast to 50% of the 5973 "native Dutch". Unfortunately, no information is available on the subjects' diet, how long they had been in the Netherlands or whether the subjects were first, second or third generation immigrants[14]. A UK study observed a lower incidence of DD amongst patients defined as "Indian subcontinent Asian males and females" compared with other ethnic groups. This study showed no difference in DD incidence between first and second generation Asians although numbers were limited[15]. In addition, an autopsy-based study of 1014 cadavers in Singapore showed a significantly higher risk of DD amongst the ethnically Chinese population when compared to the ethnically Malay and Indian populations[16]. The epidemiological data described suggests environmental and genetic components to DD etiology.

PATHOPHYSIOLOGY OF DIVERTICULAR DISEASE

DD presents as pockets within the colon wall, often around points of penetration of the vasa recta through to the luminal side of the muscularis propria[11], possibly because these sites are inherently weak. In western nations diverticula are most common in, though not confined to, the descending and sigmoid colon (left colon). This is in contrast to Asian nations where they occur primarily in the cecum and ascending colon (right colon)[17]. This difference suggests a role for genetic, environmental or lifestyle factors in the etiology of the condition.

At a functional level, the cecum and ascending colon are the primary sites of bacterial fermentation of carbohydrates and proteins which escape small bowel digestion. Microbial action, coupled with anti-peristaltic mixing, maintains a large digestive mass in this segment of the colon; thereby maintaining distention in the longitudinal and circular muscles of this region of the bowel for significant periods. In contrast, the descending colon serves primarily as a holding reservoir for fecal matter prior to excretion. Fecal matter reaching this stage of the colon is significantly reduced in bulk owing to the re-absorption of water and electrolytes, and the depletion of substrate for microbial activity. In addition, movement of bolus through this phase of the colon is subject to increasing voluntary control with variation in intra-luminal pressures throughout the length of the colon (Figure 2).

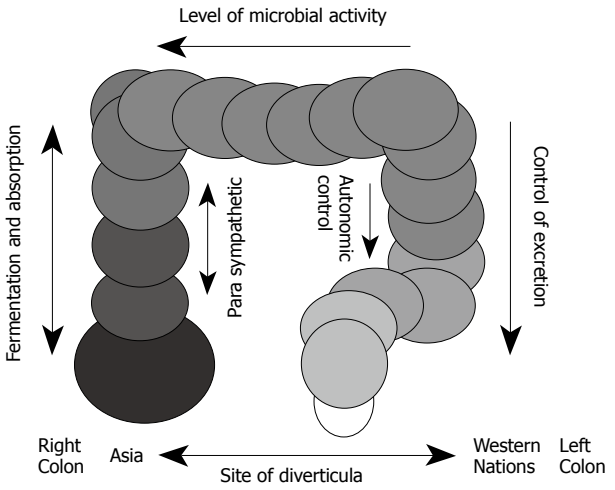

Figure 2 Physiological activity within the large bowel. Schematic of the human colon highlighting functional roles; the right colon is associated with high microbial activity, larger fecal volume and parasympathetic control. DD in the right colon is infrequently observed in western populations but commonly found in Asian populations. The left colon is the primary site of diverticula in western populations and has lower microbial activity, decreased fecal volume and is more responsive to voluntary control.

At a structural level, the mechanical characteristics of the bowel are maintained via circular and longitudinal muscle layers. The circular muscle thickens in regular bands of contraction (plicae circulares) which control peristalsis. The longitudinal muscle also condenses in thick bands (the teniae coli) which serve to pull the colon to a relatively short functional length. In DD, the circular muscle layer is thicker and the longitudinal muscle is shorter[1], although a similar thickening of the colon wall may be a natural feature of the normal ageing bowel[18] and seems to occur at an accelerated rate in inflammatory bowel disease (IBD)[19]. Comparing the DNA to nitrogen ratio in DD tissue confirms that the muscle thickening is not due to hypertrophy[20] whilst individual muscle fiber cells and their organelles appear normal on histological examination[18]. Instead, histological studies suggest that the accumulation and aberrant deposition of connective tissue fibers (elastin[18,21] and collagen[22]) underlie the altered muscle morphology. Furthermore, in diverticulitis the ratio of type I to type Ⅲ collagen is altered in both the serosa and sub-mucosa, indicative of scarring[23]. This effect may be attributable to aberrant activity of matrix metalloproteinases (MMPs) and tissue inhibitors of the matrix metalloproteinases (TIMPs). In one small DD study (11 cases, 6 of which were uncomplicated, *vs* 11 controls) increases in TIMP-1 and -2 expression were associated with disease severity i.e. expression was higher in symptomatic disease[24]. Separately, in a small study of patients with clinical diverticulitis (n = 13), Stumpf *et al*[23] found decreased expression of MMP1. In contrast, Rosemar *et al*[25] found an up-regulation of the expression of MMP1, in addition to increased expression of MMP2 and TIMP1, in DD affected tissues compared to unaffected bowel specimens from the same patients (who were undergoing sigmoid colectomy to treat complicated DD). Whether or not the MMPs and TIMPs play an important role in the tissue organisation observed in asymptomatic DD remains to be seen; the findings reported thus far may be due to acute inflammation rather than DD per se[26].

There have been a number of physiological studies of the diverticular diseased colon, focusing primarily on colonic transit times, intra-luminal pressure, colonic motility and electrophysiology. In the main, inference from these studies about DD specific events or processes is difficult because of the limited data on changes in normal colonic function with ageing, but they offer some insight into the disease process.

Colonic transit times

Studies of colonic transit times (performed by adding radiological markers to the diet) in DD, by both Evans *et al*[27] and Manousos *et al*[28], showed faster colonic transit in individuals with DD. This is perhaps in contrast to what we might expect, given that DD is an age-related phenomenon, and studies of transit time in the aged show either a slower rate of passage through the colon amongst the elderly[29-31], or no differences with ageing[27,32-34]. In addition, Evans *et al*[27] observed longer transit times in females, in whom the evidence points towards a higher risk for developing DD. We might question the potential confounding effects of habitual diet and physical activity in these studies. In particular, upon diagnosis, patients with DD are generally recommended a high fiber diet, which could account for accelerated transit time amongst cases. Nevertheless this interesting counter-intuitive observation is worthy of follow up.

Intra-luminal pressure and colonic motility

Classically, researchers interested in colonic motility in DD performed endoscopy-based manometry studies to measure changes in luminal pressure in the evacuated colon. The main findings of these studies are that there are similar resting luminal pressures between DD cases and controls[35], but higher luminal pressures in segments of colon with diverticula in response to pharmaceutical stimulus[36,37] and an increase in post-prandial colonic motility[38]. Paradoxically, inflating a balloon in the colon of individuals with DD induces the musculature of the colonic wall to yield to the increasing luminal pressure more quickly than in controls[38,39]. In addition, these and later studies indicate increased colonic motility (as assessed by number and amplitude of bowel wall contractions) in the sigmoid colon of individuals with left-sided DD[40,41], and also in the ascending colon of patients with right-sided diverticulosis[42]. These classical studies were generally performed with low numbers and failed to account for age, gender, physical activity or body fat percentage; the physiological observations were made under artificial conditions, i.e. in the evacuated bowel during endoscopy. Furthermore, they were performed over one or two hours, with the subject at rest, whilst in reality one would expect variation in bowel pressures throughout the day. More recently however, Bassotti *et al*[41] made recordings over a 24 h period, and observed higher colonic motility in DD cases throughout the recording period than in a younger control group (cases

Table 1 Summary of electrophysiology studies in diverticular disease (DD)

Study material	Treatment	Response	Study details	Reference
Colonic longitudinal smooth muscle	Relaxative cannabinoid agonists	Decreased relaxation in specimens *vs* controls	Study performed on diverticulitis specimens *vs* colorectal cancer controls	Guagnini *et al*[46]
Colonic longitudinal smooth muscle	Nitroprusside, relaxative agent	Decreased relaxation in specimens *vs* controls	Study performed on 10 DD patients *vs* 10 colorectal cancer controls	Golder *et al*[21]
Colonic circular smooth muscle	Contractionary, cholinergic stimuli	Decreased induction of contractionary waves in cases *vs* earlier data on "normal" patients	Material obtained from 12 patients, 10 of whom exhibited 'abnormal responses' Multiple samples from the same patient showed site specific differences	Huizinga *et al*[103]
Left-sided colonic smooth muscle	Nitric oxide, relaxative agent	Decreased relaxation in cases *vs* controls	Left-sided DD 9 patients, *vs* 16 left-sided colon cancer controls	Tomita *et al*[52]
Colonic longitudinal and circular muscle	Contractory acetylcholine	Increased contractionary response in DD cases *vs* controls	20 subjects with rectal tumours, 10 cases and 10 controls	Golder *et al*[51]
	Contractory tachykinin receptor antagonists	Higher active and resting stress in DD cases		

42-65 mmHg, controls 37-55 mmHg). It is unclear whether or not failing to control for age confounds these studies; Firth and Prather[43] suggest that colonic motility is not altered in the normal ageing colon, but this warrants further investigation, ideally utilizing pressure-sensitive transducers which can be swallowed and allowed to pass through the GI tract to provide more representative measures of colonic physiology[44]. That said, the evidence described points towards a neuromuscular dysfunction in DD; although it remains uncertain whether this is a cause or effect of the condition.

Electrophysiology and neuromuscular dysfunction

Electrophysiological examinations of the bowel wall have been used to investigate neuromuscular dysfunction in DD in several studies. Shafik *et al*[45] identified two distinct types of neuromuscular dysfunction by transcutaneously measuring electrophysiological activity in the sigmoid colons of DD subjects and comparing with age- and sex-matched controls; (1) elevated electrophysiological activity in early stage diverticulosis, and (2) a silent or low electrophysiological tone in advanced DD. This finding is supported by the ex vivo observation of Guagnini *et al*[46] who failed to induce an electrical field twitch response in resected longitudinal muscle from 30% of DD patients, but observed similar responses to electrical field stimulation in the remaining 70% of the samples compared with resected smooth muscle from slightly younger colorectal cancer patients.

Similar *ex vivo* electrophysiological studies of this type on DD specimens are summarized in Table 1. Typically they also show aberrant responses to relaxatory and contractionary stimuli in colonic smooth muscle in DD. On a cautionary note, the weaknesses of these studies include: (1) a lack of power due to the small numbers of subjects; (2) the use of colorectal cancer patients as controls; (3) the focus on complicated/advanced DD specimens.

Evidence from recent histological studies of neurones in the ageing human gut suggests that there is a natural decrease in nerve density with ageing[47,48], a finding supported in animal models[49]. Age-related neurone loss is intuitively attractive as an explanation for the impaired colorectal motility in DD; however, data concerning this remains relatively sparse. An early study by Macbeth and Hawthorne[50] suggested the opposite, i.e. an increase in the number of intramural ganglia but with disorganized distribution of ganglia in DD tissues. Fortunately, recent studies contradict this finding[21], and this work may have been confounded by the morphological distortions associated with the colon shortening in DD. Golder *et al*[51] show histological evidence for decreased nerve content of longitudinal muscle in DD as evidenced by reduced prostaglandin immunoreactivity. They have also found that individual nerve fibers were smaller in cases *vs* controls and were less likely to stain positively for choline acetyltransferase[52] and NOS 1[51], suggestive of cholinergic and nitrergic denervation in these samples. Again the primary potential confounder to these studies is the fact that the colon shortens, and that the muscle layers become thicker (due to elastin and collagen deposition), in DD; it is not clear as to how the authors have controlled for this. In contrast, Bassotti *et al*[53] found no difference in the number of enteric nerves, but a significantly lower number of glial cells in DD. In an interesting take on the same principal, they also found a significant decrease in the number of interstitial cells of Cajal in the myenteric plexus, the sub-mucosa and within the muscle. These cells are emerging as potential colonic pacemaker cells and, like neural cells, their loss might explain poor bowel motility, but yet again we are left with a cause or effect type question. Simpson *et al*[54] have argued (though not evidenced) that nerve damage results from periods of acute inflammation which arise as a consequence of the presence of diverticulosis, whilst others argue that age-related nerve withdrawal induces smooth muscle dysfunction, which thus predisposes to diverticulosis formation[55].

DIET AND LIFESTYLE IN DIVERTICULAR DISEASE

Evidence from man

Seminal papers by Painter and Burkitt[35,36,56] hypothesized

Table 2 Observational studies of dietary fiber consumption and DD risk in man

Design	Findings	Comments	Reference
Case control study comparing dietary fiber intake in 100 (symptomatic) DD cases *vs* 80 age and sex matched controls	Dietary fiber intake significantly higher amongst controls	Study participants were patients hospitalized due to diverticulosis; again symptoms may have influenced their diet	Manousos *et al*[12]
Prevalence of DD assessed by barium enema in 189 non-vegetarian volunteers *vs* 55 vegetarians	Diverticular disease was significantly higher in the non- vegetarian group	"Asymptomatic" volunteers recruited prior to diagnosis and grouped based on dietary choices. A potential confounder is a possible causative effect for meat	Gear *et al*[104]
Case control study comparing dietary fiber intake in 40 (symptomatic) DD cases *vs* 80 age and sex matched controls	Dietary fiber intake significantly higher amongst controls	Dietary fiber intake was "estimated" by dieticians. Symptomatic DD patients were studied so the symptoms may have influenced their diet	Brodribb *et al*[62]
"Prospective" case control study. As part of the Health professionals follow up study, 43 881 US men aged 40-75 followed over 6 years, for self reported diagnoses	Dietary fiber intake significantly lower in cases RR = 0.63	The largest and potentially most informative study. Crucially, the participants were not clinically examined for DD prior to the study. So we cannot rule out effects of DD on dietary choices	Aldoori *et al*[63]
Case control study comparing dietary fiber intake between 86 right-sided DD cases and 106 controls	No relationship between DD and fiber consumption	Only study on right-sided DD, negative finding may indicate either a different etiology or perhaps right-sided DD just has fewer effects that might influence diet choice	Lin *et al*[64]

RR: Relative risk.

that DD arises due to excessive luminal pressures which occur as a consequence of dietary fiber deficiency. This concept was based upon; (1) the apparent increase in DD incidence in western countries throughout the twentieth century, (2) an apparent decrease in dietary crude fiber consumption in western countries over the same period, and (3) an observed low prevalence of DD in Africa where crude fiber intakes were assumed to be higher. In particular, the authors made reference to necropsy studies in Africa which did not record any cases of DD, and to Burkitt's failure to observe any cases of DD whilst working as a clinician in Africa[56]. Subsequently, Painter and Burkitt[8] noted a comparable prevalence of DD amongst African Americans with the white American population.

There are several weaknesses in the evidence base underlying this hypothesis, particularly when one considers the populations being described; we have already evidenced the increasing lifespan of western populations throughout the 20th century which may parallel the increasing prevalence of DD. Life expectancy remains low on the African continent and the most recent World Health Organisation figures report a life expectancy of 51 years for both South Africa and Kenya (the African countries from which necropsy data were referenced by Painter and Burkitt)[57]. Thus there is a smaller percentage of people reaching old age in these countries which would lead to a lower prevalence of DD. Separately, let us consider the dietary fiber intake issue: the necropsy studies cited were performed in the 1950s and so the dietary patterns of the individuals studied would date back to the early half of the twentieth century, making it difficult to accurately determine dietary fiber intakes for these populations. The diet of present day sub-Saharan Africans differs regionally, with urbanization and social standing. For example, the Kenyan staple is the cereal-based "Ugali", fish is common around the coasts, and there are regional preferences for mutton or goat[58]. The average Kenyan diet whilst being relatively high in fiber is also considered, for much of the population, to be total

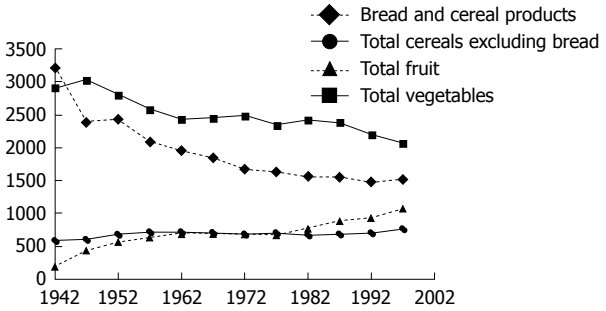

Figure 3 Consumption of major sources of dietary fiber in the UK in grams per person per week since 1942. Data shows a steadily decreasing consumption of dietary fiber-rich foods in the UK population since 1942. Adapted from data produced in the National Food Survey[64].

energy, macro and micronutrient deficient[59]. Similarly, the diet of poor urban South Africans may also be deficient in total energy and some macro and micronutrients, but in contrast to the Kenyan diet it is low in dietary fiber with an increasing emphasis on fat[60]. The point is that modern (and by inference non-traditional) African diets are highly variable; there is also evidence of a shift towards a western dietary pattern with corresponding clinical observations suggesting that DD prevalence may actually be on the rise[61]. However, this observation needs further detailed study and if confirmed, other non-dietary fiber variables should be considered. In the UK, the National Statistics Food Survey (NSFS) dates back to 1942; it shows a steady decrease in the consumption of fiber-rich foods throughout the latter half of the 20th century (Figure 3). However, there has been no great increase in age-adjusted mortality figures from DD in the UK over the last 30 years[3].

A small number of observational studies in man have since attempted to evaluate the dietary fiber/DD risk issue. These studies are summarized in Table 2 and in general support the dietary fiber hypothesis. Two of the three case-control studies[12,62] and the only prospective case-control study[63], found lower dietary fiber consumption amongst cases *vs* controls. In contrast,

one case-control study in an Asian cohort found no link between dietary fiber intake and DD risk (right-sided)[64]. We would argue that all these studies are methodologically flawed; low dietary fiber consumption amongst cases may simply reflect the patients attempt to ameliorate the effects of DD, i.e. excessive flatulence and disordered, possibly aberrant, colonic motility. This is also true of the prospective study[65] in which the volunteers were not clinically examined for DD at baseline, so the study team had no way of knowing whether diverticula were present prior to this. Further, from their cohort of 43 881 male volunteers, aged between 45 and 75, they identified 362 new cases of self-reported symptomatic disease. We would expect the true prevalence of undiagnosed DD in a western cohort (US) of this age and size to be several times that number (Figure 1). A further confounding factor to these studies may be co-linearity (and also inverse linearity) in intake of other nutrients and dietary constituents with fiber consumption. For example, dietary fiber consumption may be inversely related to total energy consumption and hence adiposity[66] and there are independent studies linking an increasing BMI to an elevated risk for complicated DD[65,67]. Unfortunately, there appears to be no published data on obesity and asymptomatic DD. Additional lifestyle risk factors emerging from the literature are: high red meat consumption[12,64], increasing socio-economic status in a Greek cohort[12], hypertension[65], parity[12] and low physical activity with increased symptomatic disease[63]. The evidence base for these risk factors is even less vigorous than it is for dietary fiber. Furthermore, there may be complex relationships between these variables. For instance, low physical activity might be related to obesity and hypertension; it may also be a consequence of symptomatic DD affecting the individual's mobility. Similarly a high socio-economic status in Greece might allow for a higher red meat contribution to the diet, which might itself be inversely correlated to fiber intake. In short, the evidence from studies in man suggests a relationship between diet/lifestyle and DD risk, but there remains a lack of robust definitive evidence. Long-term dietary intervention studies in man aimed at preventing the onset of diverticular disease are unfeasible; there have been intervention trials addressing the benefits of dietary fiber in preventing the complications of DD. These have had mixed success[68,69] and tell us little about disease etiology.

Evidence from animal models

Several investigators have induced the formation of diverticular-like entities in the intestines of rat models through extreme dietary manipulation practiced throughout the animals' natural life-span. Typically these diets were high in animal protein or fat and very low in fiber[70,71]. Increasing the fiber content of these basal diets reduced the DD incidence[72]. Indirectly, these rat models suggest a role for the intestinal flora in DD; Carlson and Hoezel[71] found that they were able to induce DD in rats fed Karaya gum as dietary fiber source, but not in rats where Psyllium seed husks or semi-fibrous cellulose flour was the dietary fiber source. The fundamental difference between these fiber sources may be that Karaya is not well-utilized by the gut microbiota[73]. Furthermore, a maternal high fiber diet throughout gestation in the rat was found to protect the animals' offspring from developing DD in later life[74]. Presumably, this was mediated through maternal colonization of the neonate with a protective microflora, although an epigenetic/imprinting type of effect might also be responsible.

We should, however, consider the validity of the rat model; the rat does not normally develop diverticular diseases and the diets required to induce them were extremely low in fiber. The rat bowel is anatomically distinct from the human; it does not contain teniae coli[74] which have been shown to be abnormal in DD in man. The diverticula observed in the rat model were restricted to the cecum and its proximity, which may be more representative of the Asian phenomenon than the left-sided DD seen in the West. On the other hand, the rat cecal diverticula did show certain similarities to those found in the human in that the muscle wall was thickened with increased deposition of elastic tissue[70] and altered collagen deposition[75]. The rabbit colon does contain teniae and Hodgson[76] induced diverticula in a rabbit model with a long term low residue diet. But again we should consider the validity of the model. The rabbits' natural diet is herbage and they engage in coprophagy to utilize the microbial fermentation products of this rich fiber source. The low fiber diet in this study failed to meet the nutritional needs of the animals and they began to show deficiency type symptoms in addition to developing diverticula. Both models indicate a protective effect for dietary fiber; however in each animal the experimental diets necessarily involve the replacement of dietary fiber with another food constituent; and one could argue that the replacement (fat, carbohydrates and meat protein) components of these diets may be causative of DD in these systems. In line with the studies in man, the animal models suggest that dietary fiber may protect against diverticula development, possibly mediated through the intestinal microflora. Collectively, however, the evidence is poor and the role of other dietary and lifestyle factors remains unexplored.

INFLAMMATION AND DD

It is tempting to postulate that inflammation plays a role in the etiology of DD for several reasons; (1) An increase in plasma inflammatory markers correlates with ageing in man and rats[77,78] as does the prevalence of DD; (2) Bowel wall thickness increases in both IBD[19] and DD[1]; (3) Inflammation could explain neuronal cell death in DD[54]; (4) In a small minority of DD cases the bowel becomes acutely inflamed; (5) Narayan and Floch observed non-specific inflammation in biopsy specimens from non-inflamed DD cases *vs* controls[79]; (6) Kealy observed significantly higher numbers of lymph nodes in disease-free portions of necropsied colon from subjects with DD *vs* controls[80]; (7) Inflammation could be a common factor linking diet and DD.

In contrast, Pezzilli *et al*[81] did not observe differences in fecal calprotectin concentrations between subjects with DD *vs* controls, though the study size was rather small (17 cases). More importantly, recent case-control studies of IBD suggest that chronic acute inflammation actually protects against DD[82,83]. The mechanisms by which this protection occurs are not yet understood, but may involve alterations to the luminal bolus, i.e. the loose watery stool associated with IBD may lower luminal pressures and help prevent DD, or through the impact of intestinal inflammation on the colonic flora. In either case, these findings do not rule out a role for mild non-acute inflammation, with a less pronounced effect on the fecal stream, in DD etiology. However, any mild non-specific inflammation in DD remains poorly evidenced.

THE ROLE OF GENETICS IN DD

Clinical observations associate a number of rare genetic disorders with a strong predisposition towards diverticula formation. Notably, patients with Ehlers-Danlos syndrome[84,85], Williams-Beuren syndrome[86], polycystic kidney disease[87] and Coffin-Lowry syndrome[88] are often afflicted with diverticula of the colon and other internal organs. The etiology of diverticula formation in these syndromes may be unrelated to sporadic age-related DD, but they may offer insight into mechanisms of disease in that at least three of these syndromes are associated with a connective tissue disorder. Ehlers-Danlos syndrome is an inherited connective tissue disorder arising through mutations in either the COL5A1 or COL5A2 genes encoding part of the type V collagen protein or through mutations in the gene for the extra cellular matrix (ECM) protein, tenascin-X[89]. Williams-Beuren syndrome affects 1:10 000 of the population and is due to a deletion of about 20 genes on chromosome 7. Although the genetic basis of this syndrome has not been elucidated fully, it appears to result in elastin haplo-insufficiency[90]. Coffin-Lowry syndrome is a maternally inheritable disorder that may also be related to disrupted collagen metabolism[88]. Scheff *et al*[91] observed colonic diverticulae in 83% of patients with end stage polycystic kidney disease (PKD). PKD is due to mutations in the PKD1 or PKD2 genes coding for the cell membrane-bound polycystin proteins. Whilst the function of these proteins is uncertain, it has been suggested that they interact with the ECM and with extra-cellular signaling pathways regulating cell migration and differentiation[92]. Collectively, these syndromes linked by an ECM defect might suggest that the accumulation of collagen and elastin in the smooth muscle of sporadic DD specimens[20,21] is a prerequisite to diverticula formation.

Separately, clinical observations of poor colonic motility also feature in a significant subset of individuals with mitochondrial diseases[93]. Perez-Atayde *et al*[94] observed a duodenal diverticulum in a 14-year-old with mitochondrial neurogastrointestinal encephalomyopathy which suggests that mitochondrial neuromuscular dysfunction may be associated with DD.

On a different note, clinical case reports hint at familial risk factors for DD in the general population; Schlotthauer reported DD in seven American brothers (aged 40-70), but not in their two sisters (ages not given)[95]; Omojola and Mangete[96] observed DD in three siblings in a Nigerian population with a traditionally low incidence of DD and Claassen *et al*[97] observed DD in two teenage siblings in Holland, in whom they also noted joint hypermobility, perhaps indicating a collagen disorder. Siblings share similar environmental exposure which may help explain familial clustering of DD but does not account for observations in populations where the prevalence is low or in the very young. These observations may simply be statistical anomalies, but taken together with the ethnic variations in both the site and age of onset of DD (Figure 1) they do suggest a genetic component. Unfortunately there is no published literature on attempts to quantify the hereditary component of this condition. Of note, our own preliminary epigenetic data have shown unusual DNA methylation patterns in the colonic mucosa of patients with DD[98,99].

CONCLUSION

A number of questions still remain regarding the biology and etiology of DD. Perhaps the most pressing amongst these relate to the role of diet and lifestyle, as these factors offer strategies for prevention. The two approaches which have been most successful in illuminating the role of diet and lifestyle in DD prevalence thus far are epidemiology and observational studies in man. The epidemiological approach is currently confounded by the lack of available up-to-date data on DD prevalence in different populations. A priority for future research should therefore be the collection of recent necropsy data to indicate current regional prevalence.

There have been no true prospective case-control cohort studies into DD and diet performed to date. For validity, any such study would require a prospective colonic examination to exclude DD patients at baseline, a follow up period of some years and a subsequent exam; this may be unfeasible given the time taken for diverticula to develop and demands on research budgets. In considering a low budget approach, it could be possible to append this type of study to the back of any new prospective colorectal cancer cohorts or to future polyp recurrence trials.

Other clinical and biological questions concern the mechanisms underlying the disease process. Gaps in the knowledge base on the natural changes in bowel physiology, inflammation and composition with ageing impede our understanding of DD. Less invasive methods for measuring physiological activity in the GI tract are under development[44], which may allow for the measurement of colonic motility under more natural physiological conditions and could be employed to study the effects of diet and ageing on normal bowel function and specifically changes related to DD.

Diverticulosis is ultimately a disease of ageing; recent studies show increasing mitochondrial dysfunction in the

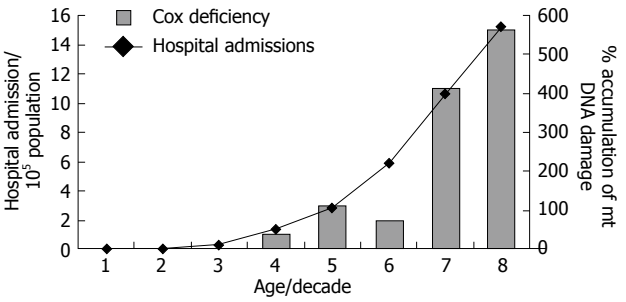

Figure 4 Graph showing the relationship of age with mitochondrial DNA damage and risk of hospital admissions for DD. Graph showing the correlation between the percentage accumulation mitochondrial (mt) DNA damage in the colonic mucosa - right hand y axis whilst left hand y axis shows hospital admissions for DD/10^5 in the UK. Ageing is expressed on the x axis in decades. The incidence of asymptomatic disease is considerably higher but the rate of hospital admissions may mirror DD incidence in the population as a whole. Mitochondrial DNA mutations are inferred from level of deficiency/inactivity in the respiratory chain mitochondrial protein Cytochrome C oxidase[102].

ageing colonic epithelia and this data correlates well with DD prevalence (Figure 4)[100]. We have been conducting preliminary investigations into the accumulation of mitochondrial deficiencies in the colonic epithelia in DD[101], Studies of mitochondrial deficiency or other age-associated changes in the colonic muscle might further illuminate the pathology of this condition. Similarly, we should further examine what phenomenon (if apparently not inflammation) drives excess ECM deposition in ageing and DD.

Animal models of DD hint at a role for the colonic microflora in the disease process, especially when one considers the differences in microflora composition between high and low risk populations[60,102]. A direct comparison of the fecal and colonic mucosal flora between cases and controls might simply reveal differences associated with the altered luminal environment; a better approach would be to characterize the microflora of volunteers prior to any prospective study.

Finally, it remains to be established as to whether right- and left-sided DD have different etiologies and to what extent genetics, environmental and lifestyle factors contribute to this difference. Ageing is the primary risk factor in DD, but the condition is not an inevitable consequence of the ageing process. It seems probable that dietary or environmental factors protect against diverticula formation but further evidence is needed to fully define these factors. The high prevalence of DD within our increasingly elderly population translates into significant morbidity. We feel therefore that the investment of research funds in this area is justified.

Abstract

Prophylactic strategies against hepatitis B virus (HBV) recurrence after liver transplantation (LT) are essential for patients with HBV-related disease. Before LT, lamivudine (LAM) was proposed to be down-graded from first- to second-line therapy. In contrast, adefovir dipivoxil (ADV) has been approved not only as first-line therapy but also as rescue therapy for patients with LAM resistance. Furthermore, combination of ADV and LAM may result in lower risk of ADV resistance than ADV monotherapy. Other new drugs such as entecavir, telbivudine and tenofovir, are probably candidates for the treatment of hepatitis-B-surface-antigen-positive patients awaiting LT. After LT, low-dose intramuscular hepatitis B immunoglobulin (HBIG), in combination with LAM, has been regarded as the most cost-effective regimen for the prevention of post-transplant HBV recurrence in recipients without pretransplant LAM resistance and rapidly accepted in many transplant centers. With the introduction of new antiviral drugs, new hepatitis B vaccine and its new adjuvants, post-transplant HBIG-free therapeutic regimens with new oral antiviral drug combinations or active HBV vaccination combined with adjuvants will be promising, particularly in those patients with low risk of HBV recurrence.

Key words: Hepatitis B virus; Liver transplantation; Recurrence; Prophylaxis; Hepatitis B immunoglobulin

INTRODUCTION

End-stage liver disease secondary to hepatitis B virus (HBV) accounts for 5%-10% of liver transplantation (LT) performed in the United States and is the leading indication for LT in Asia[1,2]. Recurrence of HBV infection after LT plays a key role in the post-transplant outcomes of the patient and graft, however, in patients with HBV-related disease, complete eradication of HBV after LT is rarely possible. In the 1980s, HBV-related disease was considered a relative contraindication for LT because of poor survival rate and high recurrence rate of HBV in the absence of prophylactic strategies[3]. Thus, prophylactic strategies against HBV recurrence after LT are essential for these recipients. Since the introduce of new antiviral agents and improved prophylactic options, results after LT are reported to be as good or, in a United Network for Organ Sharing (UNOS) database report, even better than in non-HBV patients[4,5]. In this article, current prophylactic strategies against HBV recurrence after LT and evolving new trends are reviewed.

PRETRANSPLANTATION PROPHYLACTIC STRATEGIES

The goals of pretransplant antiviral therapy include the following: (1) to achieve clinical stabilization, thereby delaying/preventing the need for LT; and (2) to attain low HBV DNA levels prior to transplantation, thereby reducing the risk of recurrent HBV after LT.

Interferon (IFN)

Although a major limitation to the use of IFN before LT has been its poor tolerability, it appears to be reasonably well tolerated and effective if patients do not have decompensated HBV cirrhosis. Hoofnagle *et al*[6] have reported that IFN-α therapy stabilized liver function and achieved a sustained loss of HBV DNA and hepatitis B e antigen (HBeAg) in 6 of 18 compensated cirrhotic patients. A prospective study also confirmed that 53 of 103 patients with IFN-α therapy no longer had detectable HBV DNA or HBeAg after a median follow-up of 50 mo[7]. Tchervenkov *et al*[8] also found that pretransplantation IFN therapy followed by hepatitis B immunoglobulin (HBIG) after transplantation was associated with only an 8% recurrence rate after a median follow-up of 32 mo. In addition, a recent study revealed that adjuvant IFN therapy improved the 5-year survival of patients with HBV-related hepatocelluar carcinoma (HCC)[9]. Some data are currently available on the use of peg-interferon α-2b in cirrhosis patients with HBV, after being approved by the US FDA for the treatment of chronic hepatitis B. Chan *et al*[10] have demonstrated that combination treatment of peg-interferon and lamivudine (LAM) led to a higher sustained loss of HBeAg than LAM monotherapy up to 3 years after therapy. Notably, HBeAg or hepatitis B surface antigen (HBsAg) loss is observed more frequently in patients infected with HBV genotype A than with genotype non-A[11,12]. However, the risks associated with IFN therapy and the emergence of safe and well-tolerated oral antiviral therapies have decreased the utility of IFN therapy in patients undergoing LT.

Famciclovir (FCV)

FCV is a guanosine nucleoside analog with activity against herpes viruses and HBV[13]. Several reports[13,14] have described efficacy of FCV in patients with recurrent HBV after LT. However, the number of reports concerning pretransplant application of FCV is limited and the outcome of this pretransplantation prophylactic strategy is not satisfactory. Singh *et al*[15] have found that only 25% of the patients with detectable HBV DNA became pretransplant HBV-DNA-negative after using FCV. Seehofer *et al*[16] also found, in a retrospective study that included 74 HBV-DNA positive patients, that pretransplant FCV did not seem to significantly reduce post-transplant HBV recurrence. Therefore, FCV is rarely used before LT.

LAM

LAM is the first nucleoside analog, a potent inhibitor of HBV replication by competitive inhibition of the reverse transcriptase and termination of proviral DNA chain extension, to be approved for use in HBV treatment, and has an excellent safety profile in both compensated and decompensated cirrhotic patients. The early results using LAM as pretransplant antiviral therapy to suppress HBV replication and improve liver function were promising. Two studies from Villeneuve *et al*[17] and Yao *et al*[18] have reported that serum HBV DNA of all case with positive HBV DNA became undetectable after 6 mo of LAM therapy. The same results were confirmed by other studies[19-21]. These data indicated that LAM monotherapy can achieve the goal of suppression of viral replication to undetectable HBV DNA levels prior to transplantation, and improvement of liver function.

However, the major factor limiting the use of LAM is the development of mutations in the thyrosine-methionine-aspartate-aspartate (YMDD) motif of the HBV DNA polymerase gene, which confers resistance to LAM. In non-immunosuppressed patients, resistance to LAM emerges at a rate of 15%-20% per year, as a result of selection of LAM-resistant mutations in the YMDD motif of the HBV DNA polymerase[22]. As for immunosuppressed patients, LAM resistance can be detected in 45% patients within the first treatment year[23,24]. The sign of resistance is usually a rebound in the HBV DNA level, without other abnormal biochemical or clinical findings, whereas some virological breakthrough caused by antiviral resistance has been reported to cause hepatitis flares and, in rare instances, hepatic decompensation[25,26]. In addition, a retrospective analysis of 309 HBsAg-positive patients listed for LT at 20 North American transplant centers revealed that LAM did not improve LT-free and overall pretransplant survival[27]. LAM is even proposed to be no longer the drug of choice because the initial enthusiasm has been tempered by the high rate of resistance development[28].

Overall, LAM has provided an important treatment option in these patients on the waiting list, with evidence of viral replication or decompensated liver disease related to HBV, but it has turned out not to be the optimal drug and has been proposed to be down-graded from first- to second-line therapy because of its resistance profile.

Adefovir dipivoxil (ADV)

ADV is an oral prodrug of adefovir, a nucleotide analog of AMP, which inhibits HBV DNA polymerase. Previous studies have demonstrated that ADV has excellent activity against wild-type as well as LAM-resistant HBV strains[29-32]. Recently, Marcellin *et al*[33] used ADV administered at doses of 10 mg daily over 48 wk in 171 patients with HBeAg-positive chronic hepatitis B. At week 48, the median change from baseline in HBV DNA was -3.44 log10 copies/mL. Subsequently, 65 patients given ADV 10 mg in year 1 chose to continue in a long-term safety and efficacy study (5 years). The median serum HBV DNA changes from baseline were -2.15, -3.69, -3.55 and -4.05 log10 copies/mL at study weeks 96, 144, 192 and 240, respectively. The median change values from baseline in serum alanine aminotransferase (ALT) concentrations were -43, -18, -49.5, -41 and -50 IU/L at study weeks 48, 96, 144, 192 and 240, respectively, and 66% had normalized serum ALT concentrations at study week 240. As for the resistance to ADV, in the 65 patients with a median of 235 wk (110-279 wk) of ADV exposure, 13 (20%)

A: ADV monotherapy; AL: ADV/LAM combination therapy.

had developed ADV-associated resistance mutations, rt N236T or rtA181V. The first resistance mutation was observed after 135 wk of ADV. In addition, there were no serious adverse events related to ADV. The safety and efficacy of ADV were also confirmed by other studies[34,35].

Thus, ADV has been approved not only as a first-line therapy but also as a rescue therapy for patients with LAM resistance.

ADV and LAM combination therapy

Many of the anti-HBV drugs were initially developed for human immunodeficiency virus (HIV). Resistance develops easily during HIV monotherapy, therefore, it would make theoretical sense that this would also be seen with HBV. The lessons from the HIV field indicate that combination therapy is the way to go, however, we need studies for this in an HBV setting. The above data clearly indicate that ADV monotherapy is effective and safe in waiting-list chronic hepatitis B patients, with or without LAM-resistant HBV, and has much lower rates of resistance than LAM. How effective is ADV and LAM combination therapy in LAM-resistant chronic hepatitis B patients? The latest results[36-39] of ADV alone or in combination with LAM in LAM-resistant chronic hepatitis B are summarized in Table 1. ADV administered in combination with LAM or as monotherapy appeared to be effective in durable suppression of HBV replication and normalization of liver enzymes, and no significant difference was found between these two groups. This result is in accord with the data from a previous study[40], which showed that serum HBV DNA decreased at a similar rate in patients with compensated liver disease and LAM-resistant HBV infection, randomized to ADV monotherapy or combination of ADV and LAM. In addition, one recent study found that short-term (approximately 2 mo) overlap LAM treatment resulted in no better virological and biological outcomes than non-overlap ADV[41]. However, the data concerning incidence of ADV resistance between two groups are controversial. On the one hand, some studies have suggested that there is no obvious improvement in reduction in the development of ADV resistance with ADV alone compared with ADV in combination with LAM[38,39], but one study was limited by its open-label, non-randomized, uncontrolled, retrospective design, and the other study was limited by its short-term follow-up. On the other hand, several recent studies[36,37] have shown that combination of ADV and LAM results in lower risk of ADV resistance than ADV monotherapy. Notably, one was a prospective, randomized controlled study with a small population. Additionally, the same result has been confirmed by other studies[42].

Overall, some of the studies on combination therapy were too short in terms of follow-up, such that differences between monotherapy and combination therapy are not easily distinguished. Thus, long-term, randomized, blinded, controlled clinical trials are still required to determine whether ADV and LAM combination therapy reduces the emergence of ADV resistance compared with ADV monotherapy.

Entecavir

Entecavir is a very potent anti-HBV selective guanosine analog and was approved by the US FDA in 2005, for the management of adult patients with chronic HBV infection. Two early studies[43,44] have suggested that the rates of histological, virological and biochemical improvement, among patients with nucleoside-naive HBeAg-positive or -negative chronic hepatitis B, are significantly higher with entecavir than with LAM, and there is no evidence of viral resistance to entecavir. In addition, several recent studies[45,46] further reinforced this result and a recent randomized international study even found that entecavir therapy resulted in earlier and superior reduction in HBV DNA compared with ADV, in nucleoside-naive HBeAg-positive patients with chronic hepatitis B[47].

Entecavir resistance is associated with the LAM-resistance substitutions M204V/I and L180M, in combination with an additional substitution at residues T184, S202 or M250 in the reverse-transcriptase region of HBV polymerase[48]. In other words, entecavir is associated with a high genetic barrier to resistance that requires multiple mutations for resistance to emerge. In nucleoside-naïve patients, the probability of developing resistance to entecavir remained consistently low (< 1.2%) even after 96 wk of therapy[49]. In contrast, entecavir administration in patients with LAM resistance gives rise to entecavir-resistant mutants. The rate of entecavir resistance after 4 years of treatment of LAM-resistant patients may reach 35%[50]. This results from a particular mode of selection of entecavir strains that follows a two-step process, with the selection of primary resistance mutations at position M204V/I (which are also resistant to LAM), followed by the addition

of secondary resistance mutations to the same viral genomes[51]. Once these secondary substitutions occur, high-level resistance to entecavir occurs.

Generally speaking, as a result of its potency and unique structural formula, entecavir monotherapy represents an interesting first-line treatment option in patients with nucleoside-naive HBeAg-negative chronic hepatitis B, but for LAM-refractory HBV patients, entecavir monotherapy does not appear to be the optimal choice because of the high rate of resistance. To date, there are no specific data available on the use of entecavir in patients in association with LT. Further studies are needed to determine its efficacy and safety profile in this special environment.

Other new antiviral drugs

Telbivudine, which was licensed by the US FDA in 2006, is an oral nucleoside analog with potent and specific anti-HBV activity. It has been demonstrated to be superior to LAM in suppressing HBV DNA in both HBeAg-positive and -negative patients, with less resistance[52-54]. M204I was the only signature mutation associated with telbivudine resistance, in contrast to LAM resistance, which is associated with either the M204I or the M204V mutation. Notably, telbivudine can be used against ADV-resistant mutants. Tenofovir is a nucleotide analog and a potent inhibitor of HIV type 1 reverse transcriptase and HBV polymerase. It was recently approved for the treatment of chronic HBV infection in the United States. Marcellin *et al*[55] reported two studies that compared the antiviral efficacy of tenofovir with that of ADV in both HBeAg-negative and -positive patients. Two of the most encouraging aspects of these two studies are the efficacy of tenofovir in patients with LAM resistance, and the absence of resistance mutations up to week 48. In the treatment of patients with LAM-resistant HBV, tenofovir is superior to ADV and entecavir, and it has a much lower renal toxicity than ADV[56].

However, because of short-term follow up in these studies, cumulative resistance is likely to increase as therapy is extended. Thus, long-term studies are needed to evaluate the safety and resistance of these new antiviral drugs.

POST-TRANSPLANTATION PROPHYLACTIC STRATEGIES

HBIG monotherapy

HBIG was the first agent to show efficacy in preventing HBV recurrence. In 1987, the Hannover group reported that HBIG, to maintain a serum anti-HBs level > 100 IU/L for a minimum of 6 mo after LT, prevented HBV reinfection in liver-transplant recipients[57]. These results were substantiated by a landmark multicenter study from Samuel *et al*[58] in 1993, in which the 3-year actuarial risk of recurrent HBV infection was 75% ± 6% in patients without immunoprophylaxis, 74% ± 5% in those with short-term immunoprophylaxis (2 mo) and 36% ± 4% in those with long-term HBIG prophylaxis (> 6 mo). In a phase 1 clinical study in 2002[59], promising results using a mixture of two monoclonal antibodies to HBV were obtained. A number of mechanisms, which include binding to circulating virions, blocking an HBV receptor on hepatocytes, and promoting antibody-dependent cell-mediated cytotoxicity with lysis of infected hepatocytes, have been proposed to explain the protective effects of HBIG[60,61].

In general, high doses of HBIG (10 000 IU) in the anhepatic phase are followed by daily dosing during the first week after transplantation, and subsequent treatment varies at different centers. Fixed and variable dosing schedules as well as intravenous (IV) and intramuscular (IM) administration have been used[61,62]. A pharmacokinetic study indicated that maintaining anti-HBs titers at > 500 IU/L during the first week post-transplantation, > 250 IU/L during weeks 2-12, and > 100 IU/L after week 12 minimized the risk of recurrence[63].

Despite the successful prophylaxis against HBV recurrence after LT, there are several drawbacks to the use of HBIG. (1) Its high cost, namely up to $100 000 in the first year and $40 000 to $50 000 each year thereafter[64]. (2) Its limited supply. (3) Its side effects. Although HBIG is well-tolerated, significant side effects have been noted, including headache, flushing and chest pain[62]. (4) Escape mutants. Reinfection of HBV in patients receiving long-term use of HBIG can occur because of the development of escape mutants. Mutations in the pre S/S region of the HBV genome can lead to an alteration in the "a" determinant of HBsAg, the primary region of HBV antibody binding, which results in reduced efficacy of HBIG[65-67].

As a result of the above shortcomings of HBIG and the introduction of nucleoside or nucleotide analogs, HBIG monotherapy has vanished from prophylaxis against HBV recurrence after LT. However, HBIG monotherapy may be advocated in some special circumstances. For instance, a recent retrospective study of 639 HBV-infected adult patients undergoing living donor liver transplantation has demonstrated that high-dose HBIG monotherapy resulted in a 5-year HBV recurrence rate of 7.3%[68]. Both Lee *et al*[69] and Takemura *et al*[70] have used HBIG monotherapy as post-transplant prophylaxis against HBV recurrence for patients who received HBsAg-negative/HB core antibody (HBcAb)-positive allografts, with zero recurrence.

LAM monotherapy

LAM monotherapy was the mainstay of prevention of recurrent HBV after LT in the late 1990s and early 2000. Unfortunately, the initial enthusiasm was tempered by the realization that long-term use of LAM, which is essential for maintaining post-transplant viral suppression, is associated with increasing rates of HBV recurrence as a result of drug resistance. Furthermore, immunosuppression has a great influence on drug resistance; LAM resistance was detected in 15% of immunocompetent patients within the first treatment year

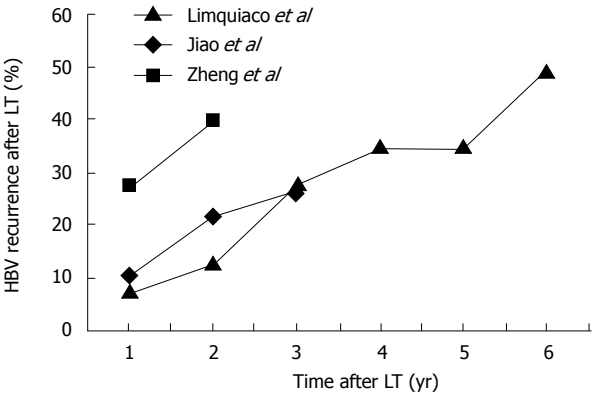

Figure 1 Incidence of recurrent HBV infection after LT using LAM monotherapy as post-transplant prophylaxis. Data adapted from[75-77].

compared with 45% in immunosuppressed patients[23,24]. In early studies, post-transplant HBV recurrence has been reported to be 10% by Grellier *et al*[71], 24% by Lo *et al*[72], 41% by Perrillo *et al*[73], and 50% by Mutimer *et al*[74] at 12, 16, 36 and 36 mo after LT, respectively. Other recent studies with LAM monotherapy have been disappointing with 1-, 2-, 3-, 4-, 5- and 6-year recurrence rates of 8%-27%, 13%-40%, 26%-28%, 35%, 35% and 49%, respectively (Figure 1)[75-77]. As a result of the high rate of LAM resistance and higher risk of recurrence in the graft compared with the combination of LAM and HBIG after LT, this strategy has been abandoned. However, whether combination therapy is required in all patients is unknown. LAM monotherapy has still been advocated by some authors for patients who have received HBsAg-negative/HBcAb-positive allografts, or patients who are HBeAg-negative and have undetectable HBV DNA pretransplantation, because of the low risk of recurrence[73,78,79]. Thus, these patients may be candidates for post-transplant prophylaxis using LAM monotherapy, but further studies with long-term follow-up and a large cohort of patients are necessary to evaluate its efficacy and safety.

High-dose IV HBIG and LAM combination therapy

The use of combination therapy has become a common strategy to overcome the high recurrence rates observed in patients receiving HBIG or LAM alone[80,81]. Mechanisms contributing to the efficacy of this regimen are not well understood, and may be the consequence of the dual effects of reduced production of HBsAg with antiviral therapy, as well as a decreased rate of escape mutations in the pre-S/S and polymerase regions. Combination therapy with high-dose IV HBIG and LAM has been investigated by many centers[82-86], with encouraging outcomes, in that the HBV recurrence rate is < 10% with 1-2 years follow-up. Generally speaking, LAM is commenced pretransplantation, with the aim of reducing the viral load in the peritransplantation period. IV HBIG is given at a dose of 10 000 IU/d for the first postoperative week, and subsequently at a fixed dose of 10 000 IU/mo or with variable dosing to maintain trough anti-HBs titers > 100 IU/L[82-84,87].

Unfortunately, even in patients without overt recurrence of HBV infection, HBV DNA may be detectable by PCR in serum, peripheral blood mononuclear cells or liver tissue in 45% of patients with high-dose IV HBIG 10 years after LT[87]. Similarly, Hussain *et al*[88] recently found that HBV DNA was detected in > 80% of allograft livers in patients who remained serum HBsAg-negative and HBV DNA-negative under combination high-dose IV HBIG/LAM prophylaxis. These data suggest that combination high-dose IV HBIG/LAM prophylaxis cannot eradicate HBV, which also explains the life-long need for HBIG in most patients.

Although combined high-dose IV HBIG and LAM is very effective in preventing recurrent HBV infection, the major limitation of such a regimen is its high cost, estimated at > $100 000 in the first year post-transplantation and > $50 000 yearly thereafter[89]. Other factors including inconvenient administration and unavailability of IV HBIG in some countries limit extensive acceptance of this regimen.

Low-dose IM HBIG and LAM combination therapy

In an attempt to lower the high cost of the combination regimen of high-dose IV HBIG and LAM, new strategies are under consideration. Among these strategies, combination prophylaxis with low-dose IM HBIG has been investigated most extensively, and is regarded as the most cost-effective regimen for the prevention of post-transplant HBV recurrence in recipients without pretransplant LAM resistance. Some studies[77,90-93] concerning this regimen are summarized in Table 2. Recurrence rates reported by major studies[90-93] are similar to those documented with high-dose IV HBIG, and cost reduction by > 50% has led to rapid acceptance of the IM route in many centers. However, a higher rate of recurrence with combined low-dose IM HBIG/LAM prophylaxis was reported by Zheng *et al*[77]. In this retrospective study, 14% developed recurrence at a mean 15.8 mo after LT. The likely explanation is that approximately one-third of patients were high-risk patients, with pretransplantation HBV DNA levels > 10^5 copies/mL. These patients with positive HBV DNA at LT are more likely to develop HBV reinfection after LT. Thus, the number of patients with active viral replication at LT will influence the efficacy of low-dose IM HBIG and LAM combination therapy.

In addition, IM HBIG has been used as long-term maintenance therapy following initial therapy with high doses of IV HBIG[94-96] (Table 3). Although conversion from IV to IM HBIG in combination with LAM can achieve the same prophylactic efficacy as direct low-dose IM HBIG and LAM combination therapy, supplemental IV HBIG is still required in some patients[95,96]. As a result of this inconvenience and the recent finding that HB surface antibody (HBsAb) trough level and half-life do not differ after post-transplantation IV and IM HBIG administration[97], most centers prefer to use low-dose IM HBIG and LAM combination therapy.

Table 2 Prevention of HBV recurrence after LT with LAM and low-dose IM HBIG

Authors	Patients (*n*)	DNA+ prior to LT (%)	Pretransplant LAM therapy (%)	Duration of pretransplant LAM therapy (mean mo)	DNA+ at LT (%)	Prophylactic protocol after LT	Follow-up (mean mo)	Recurrence (%)

Other post-transplant prophylactic strategies

High costs and inconvenience caused by indefinite HBIG administration have led to controversy as to whether indefinite passive immunization is necessary. In order to stop HBIG after initial monotherapy or combination prophylaxis with LAM, the first approach is to switch from HBIG or HBIG/LAM to LAM monotherapy. The early results were promising. For example, Dodson *et al*[98] switched 16 patients from HBIG to LAM monotherapy after 2 years and had no HBV recurrence 51 mo after LT. In another study by Buti *et al*[99], 29 patients who were HBV-DNA-negative at the time of LT were treated with high-dose HBIG for the first month, and then they were randomized to receive LAM monotherapy (14 patients) or LAM plus HBIG (15 patients) until month 18. None of the patients developed HBV recurrence during the study period. However, with longer follow-up, a recurrence rate of 11%-17% was observed[100,101]. Thus, it is important to determine which patients can stop HBIG. Although it has not yet been defined who can safely discontinue HBIG therapy, the best candidates are probably the following: those without virus replication at the time of transplantation; at least 2 years of HBIG treatment; and negative for HBV DNA by PCR before stopping HBIG.

The second approach is to switch from HBIG/LAM to a combination of antiviral agents. In a recent multicenter randomized prospective study, 16 of 34 patients receiving low-dose IM HBIG/LAM prophylaxis, without HBV recurrence at least 12 mo post-transplantation, were switched to ADV/LAM combination therapy and 18 continued with HBIG/LAM[102]. After a median follow-up of 21.1 mo in the ADV/LAM group and 21.8 mo in the HBIG/LAM group, no patient in either group had HBV recurrence, although one in the ADV/LAM group became HBsAg-positive at 5 mo, but HBV DNA was persistently undetectable by PCR (sensitivity 14 IU/mL). The annual cost of combination ADV/LAM prophylaxis was $8290 *versus* $13 718 for IM HBIG/LAM. Neff *et al*[103] retrospectively investigated a small cohort of non-HBV-replicating patients who were converted from HBIG/LAM to ADV/LAM therapy after a mean post-LT period of 6.5 mo. The mean length of follow-up since therapy conversion was 21 mo. They found that none of the patients showed an increase in transaminases while on dual nucleos(t)ide analog therapy. Unfortunately, there were no results given after the therapy switch, although the authors mentioned that HBV serological testing was performed. Another study[104] has also suggested that this approach may be highly effective and have significant cost savings. In addition, new drugs such as entecavir, telbivudine and tenofovir, are probably candidates to substitute for the indefinite HBIG maintenance therapy after LT. However, available studies are limited, of small size and short follow-up. Thus, larger, randomized prospective studies are required to confirm if combination of antiviral agents is sufficient as a prophylactic strategy against HBV recurrence post-transplantation.

The third approach to prevent HBV recurrence post-transplantation is utilization of active HBV vaccination. Notably, studies regarding this approach have yielded variable results. Successful active immunization in 14 out of 17 hepatitis B patients (82%) after LT was reported by Sanchez-Fueyo *et al*[105] in a cohort of carefully selected low-risk patients. In contrast, in another study, discontinuation of HBIG with a triple course of vaccine produced detectable HBsAb levels in only 18% of recipients[106]. In addition, new hepatitis B vaccines, or

conventional vaccines in combination with new adjuvants are hoped to improve anti-HBs responses in transplant recipients. In a study reported by Bienzle *et al*[107], 16 out of 20 patients (80%) achieved protective antibody titers of > 500 IU/L by using an IM recombinant HBV vaccine combined with two immunostimulants under continuation of passive immunoprophylaxis. However, other studies have failed to replicate this result by using adjuvants and concomitant HBIG administration[108,109]. Therefore, further studies are needed before this approach can be recommended for widespread clinical application.

CONCLUSION

In the setting of pretransplantation, LAM has been proposed to be downgraded from first- to second-line therapy because of its resistance profile. In contrast, ADV has been approved not only as first-line therapy, but also as rescue therapy for patients with LAM resistance. Furthermore, combination of ADV and LAM may result in lower risk of ADV resistance than ADV monotherapy. Other new drugs such as entecavir, telbivudine and tenofovir, are probably candidates for the treatment of HBsAg-positive patients awaiting LT, but long-term studies are needed to evaluate the safety and resistance of these new antiviral drugs.

In the post-transplantation setting, low-dose IM HBIG, in combination with LAM, is regarded as the most cost-effective regimen for the prevention of HBV recurrence in recipients without pretransplant LAM resistance, and is rapidly being accepted in many transplant centers. With the introduction of new antiviral drugs, new hepatitis B vaccine and its new adjuvants, post-transplant HBIG-free therapeutic regimens are promising, particularly in those patients with low risk of HBV recurrence.

Abstract

AIM: To study the effect of nicotine on the migration and invasion of human esophageal squamous carcinoma cells and to investigate whether nimesulide can inhibit the effect of nicotine.

METHODS: The esophageal squamous carcinoma cell line (TE-13) was treated with different concentrations of nicotine (100 μg/mL and 200 μg/mL) or 200 μg/mL nicotine plus 100 μmol/L nimesulide. Cell migration and invasion were measured using migration and invasion chamber systems. COX-2 expression was determined by Western blotting. Matrix metalloproteinase-2 (MMP-2) was analyzed by zymography and ELISA.

RESULTS: Nicotine (100 μg/mL, 200 μg/mL) enhanced TE-13 cells migration and invasion, and increased the protein expression of COX-2 and the activity of MMP-2. Nicotine (200 μg/mL) stimulated TE-13 cells migration and invasion which were partly blocked by nimesulide. This was associated with decreased protein expression of COX-2 and decreased activity and protein expression of MMP-2.

CONCLUSION: Nicotine enhances the migration and invasion of the esophageal squamous carcinoma cell line, and nimesulide partly blocks the effect of nicotine-enhanced esophageal squamous carcinoma cell migration and invasion.

Nicotine enhances migration and invasion of human esophageal squamous carcinoma cells which is inhibited by nimesulide. *World J Gastroenterol* 2009; 15(20): 2500-2505 Available from: URL: http://www.wjgnet.com/1007-9327/15/2500.asp DOI: http://dx.doi.org/10.3748/wjg.15.2500

INTRODUCTION

Esophageal carcinoma is relatively common in China, especially esophageal squamous cell carcinoma (ESCC), which has a high mortality rate. It is well established that cigarette smoking increases the risk and mortality of ESCC. Nicotine is a major component of cigarettes. Conventionally, nicotine is regarded as a relatively inert chemical in carcinogenesis. A recent finding suggested that nicotine may at least be partially involved in the initiation, promotion, and even progression of tumors[1,2]. However, the effect of nicotine on tumorigenesis of the esophagus is still not clear.

Many of the critical steps in malignant tumorigenesis, such as cell proliferation, evading apoptosis, stimulating angiogenesis, enhancing cell motility, cell invasiveness and mediating immune suppression, have been associated with cyclooxygenase-2 (COX-2) expression. It has been observed that the expression of COX-2 was increased in ESCC[3] and COX-2 may play a critical role in cancer progression. A number of epidemiological studies have

suggested that the administration of COX inhibitors (NSAIDs, aspirin, indomethacin) reduce the incidence of breast, colon, prostate and esophagus cancers[4-12]. In our previous study, cigarette smoke extract dose-dependently stimulated esophageal squamous carcinoma cell proliferation through up-regulation of COX-2 expression, and a COX-2 inhibitor inhibited this effect. COX-2 inhibitors may decrease the incidence of ESCC, however, the mechanism of COX-2 inhibitors in the metastasis of ESCC is also not very clear.

In order for cancer cells to metastasize, the cells must digest and dissolve the extracellular matrix (ECM) and the basement membrane, which requires the secretion and activation of matrix metalloproteinases (MMPs). The activity of MMPs is associated with invasiveness and metastasis in tumor cells. MMP-2 is a major enzyme that can selectively degrade type Ⅳ collagen and facilitate tumor invasion and metastasis. The expression and activation of MMPs may be directly proportional to the overexpression and activity of COX-2 in tumor cells. A previous study showed that Hs578T breast cancer cells transfected with COX-2 resulted in the activation of MMP-2[13]. Administration of nicotine increased the vascular endothelial growth factor (VEGF)-induced suppression of MMP-2 activity in mice. However, the direct action of nicotine on migration and invasion of esophageal squamous carcinoma cells remains unknown.

In the present study, we evaluated the effect of nicotine on migration and invasion in the human esophageal squamous carcinoma cell line and we investigated whether nimesulide, a selective COX-2 inhibitor, could inhibit migration and invasion in the ESCC cell line treated with nicotine.

MATERIALS AND METHODS

Cell lines and cell culture

TE-13, a human esophageal squamous carcinoma cell line was purchased from Hebei Cancer Hospital of China. Cells were cultured in RPMI-1640 (Hyclone, USA) containing 10% fetal bovine serum (Hyclone, USA). Cells were maintained at 37℃, 95% humidity, and 5% CO_2.

Drug treatment

To examine the effect of nicotine on esophageal squamous carcinoma cells, TE-13 cells were incubated directly with nicotine (Sigma, USA) (100 μg/mL or 200 μg/mL). Dimethyl sulfoxide (0.5%, v/v) was used as a control. TE-13 cells were incubated with nicotine (200 μg/mL) and nimesulide (100 μmol/L) in order to study the effect of the cyclooxygenase-2 (COX-2) inhibitor.

Western blotting for protein

For the detection of COX-2 protein in TE-13 cells, 50 μg protein from the cell extracts of each cell line which had been treated with different drugs for 48 h was electrophoresed through polyacrylamide gel. The separated protein was then transferred to a nitrocellulose membrane (Amersham, USA) and probed with diluted rabbit polyclonal anti-COX-2 (1:200) (Cayman, USA). The next day, after incubation with secondary antibody (Santa Cruz, USA), protein bands on the membranes were then developed by a chemiluminescence detection system (Pierce, USA) and exposed on an X-ray film.

Migration assay

Cell migration assays were performed using a modification of the protocol described by Larkins *et al*[14] and Shin *et al*[15]. The 6.5 mm Transwell® with an 8.0 μm pore polycarbonate membrane insert (Corning Company, USA) was utilized in this assay. The TE-13 cells were harvested and resuspended into serum-free medium containing nicotine (100 μg/mL or 200 μg/mL) or nicotine (200 μg/mL) and nimesulide (100 μmol/L). The upper chamber of the insert was filled with 200 μL of the cells and drug suspension (8×10^4 cells). The lower chamber was filled with culture medium supplemented with 10% FCS as the chemoattractant. The plate was incubated in a humidified environment at 37℃ with 5% CO_2 for 48 h. After incubation, the cells were removed from the upper surface of the membrane by wiping with a moist cotton swab. The migrated cells that passed through the membrane and adhered to the lower surface of the membrane were fixed with methanol, stained for 3 min with hematoxylin and eosin, rinsed with distilled water to remove excess stain not absorbed by cells and counted under a light microscope (× 400).

Invasion assay

Matrigel was purchased from BD Biosciences (USA) and stored at -20℃. After thawing at 4℃ overnight, the matrigel was diluted in serum-free RPMI-1640 medium. 50 μL of the diluted matrigel were evenly inoculated into the upper chamber of the 6.5 mm Transwell® membrane and allowed to form a gel at 37℃. The remaining processes of the matrigel invasive assay were the same as those for the migration assay.

Matrix metalloproteinase-2 activity by Gelatin Zymography

Metalloproteinases are capable of degrading gelatin, therefore, by incorporating gelatin into the polyacrylamide gel a clear zone indicates the presence of a matrix degrading enzyme. Gelatin zymography was carried out as described by Tsujii *et al*[16]. In brief, cells were incubated with nicotine in the absence or presence of nimesulide for 48 h. The supernatants were collected after 48 h and centrifuged 12000 r/m for 10 min at 4℃. The protein content of the supernatant was determined by dye-reagent protein assay. Twenty-one microgram protein from each supernatant was separated on 10% SDS/PAGE with 1 mg/mL gelatin incorporated into the gel mixture. Following electrophoresis at 4℃, the gel was washed with 2.5% Triton X-100 to remove the SDS, rinsed in H_2O three times, and transferred to a bath containing 50 mmol/L Tris-HCl (pH 8.0), 50 mmol/L NaCl and 10 mmol/L $CaCl_2$ at 37℃ for 24 h. To visualize the presence of gelatinolytic bands, gels were stained with Coomassie blue (R-250) and destained with Coomassie

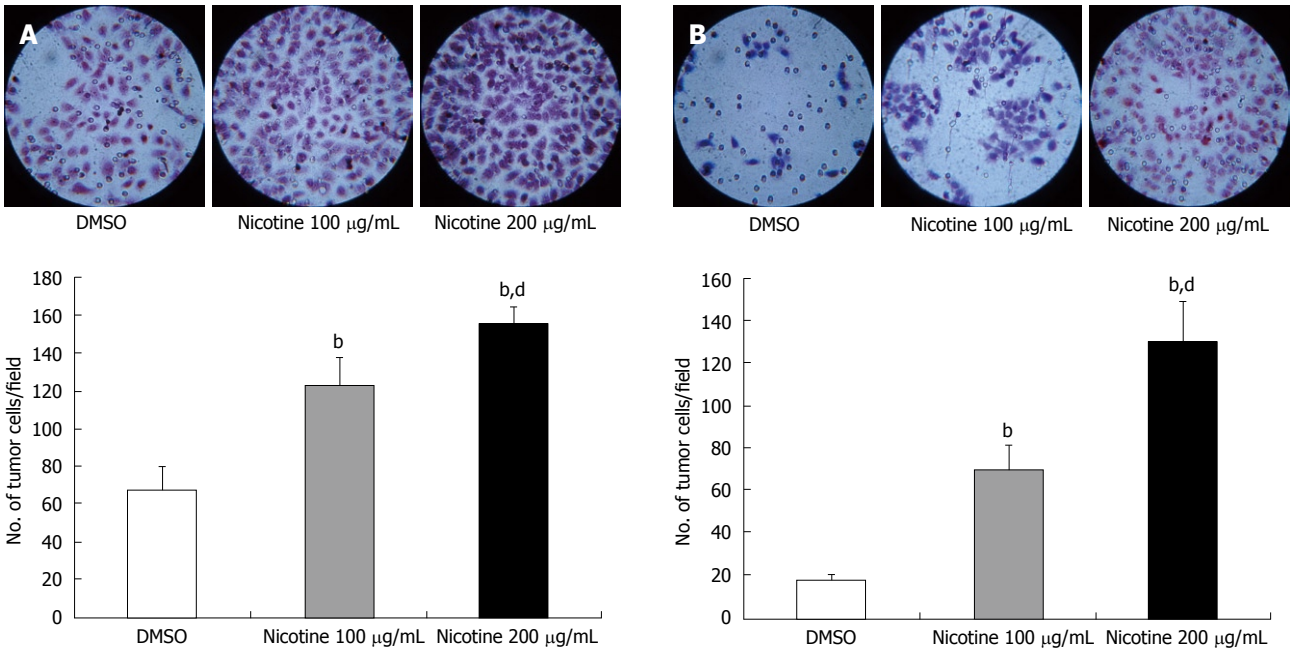

Figure 1 Effect of nicotine on the motility (A) and invasiveness (B) of the esophageal squamous carcinoma cell line TE-13. Numbers of TE-13 cells which migrated through the polycarbonate (A) or matrigel (B) membrane of Transwell® to the lower surface of the membrane were counted under a light microscope (× 400). Columns, mean of three triplicate experiments; bars, standard error of mean. $^{b}P < 0.01$ *vs* the control group; $^{d}P < 0.01$ *vs* the nicotine 100 mg/mL group.

blue destaining solution until all bands of lysis became clear. Quantification of bands on the gels was carried out by video densitometry.

ELISA

We examined the level of MMP-2 in conditioned media from TE-13 cells, using ELISA and commercially available antibodies.

Statistical analysis

Results were expressed as mean ± SE. Statistical analysis was performed using ANOVA. *P*-values less than 0.05 were considered statistically significant.

RESULTS

Effect of nicotine on cellular migration and invasion

Firstly, we tested the effects of nicotine on cellular invasive and migratory potentials. Nicotine (100 μg/mL) induced a 1.8-fold increase and nicotine (200 μg/mL) induced a 2.3-fold increase in TE-13 cellular migration through the 8.0 μm pore polycarbonate membrane of Transwell®, relative to untreated cells ($P < 0.01$) (Figure 1A). Nicotine also increased invasive ability of the tumor cells, and the number of invading cells was increased by 3.6-fold and 6.8-fold in nicotine 100 μg/mL and 200 μg/mL, respectively, compared with the control ($P < 0.01$) (Figure 1B).

COX-2 expression

We examined COX-2 expression in the human esophageal squamous carcinoma cell line (TE-13) following treatment with nicotine or nicotine and nimesulide using Western blotting. Nicotine (100 μg/mL or 200 μg/mL) significantly increased the expression of COX-2 in TE-13 cells when compared with the control group, and the higher concentration of nicotine increased the expression of COX-2 more than the lower concentration of nicotine (Figure 2A). Nimesulide (100 μmol/L) suppressed the increased expression of COX-2 induced by nicotine (200 μg/mL) (Figure 2B).

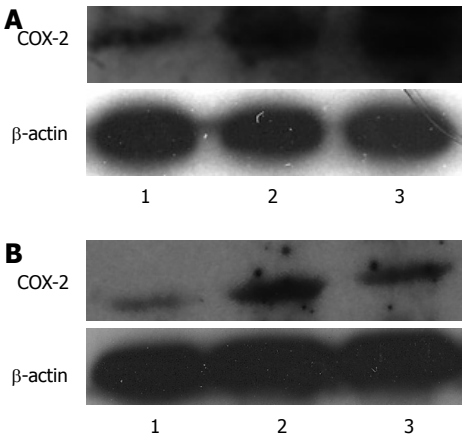

Figure 2 Western blotting analysis. A: Effect of nicotine on COX-2 protein expression in TE-13 cells, 1: DMSO; 2: Nicotine 100 μg/mL; 3: Nicotine 200 μg/mL; B: Effect of nimesulide on COX-2 protein expression in TE-13 cells, 1: DMSO; 2: Nicotine 200 μg/mL; 3: Nicotine 200 μg/mL + Nimesulide 100 μmol/mL.

Effect of COX-2 on tumor cell migration and invasiveness induced by nicotine

To determine if the effect of nicotine on cellular migration and invasion was associated with COX-2 in tumor cells, we examined the effect of the COX-2 inhibitor, nimesulide, on tumor cell migration and invasiveness induced by nicotine. Nimesulide partially,

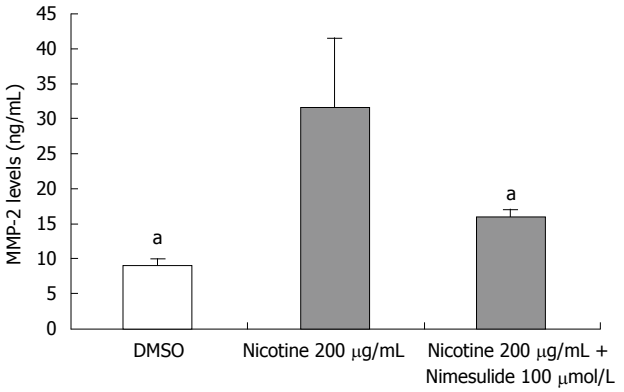

Figure 5 The protein levels of MMP-2 of TE-13 by treatment of nicotine or nicotine and nimesulide were analyzed by ELISA. The experiments were done as described in Materials and Methods. Data are expressed as mean ± SE. $^{a}P < 0.05$ *versus* the nicotine 200 μg/mL group.

but significantly, inhibited the migration of TE-13 cells through the Transwell® membrane (Figure 3A) and significantly inhibited the invasion of TE-13 cells through the matrigel membrane (Figure 3B).

Effect of nicotine on MMP-2 in TE-13 cells

Because activation of MMP-2 can selectively degrade type Ⅳ collagen, which contributes to tumor invasion and metastasis, its activity is an important determinant of tumor cellular invasive potential. We measured MMP-2 activity and expression in TE-13 cells treated with nicotine or nicotine and nimesulide. Nicotine significantly increased MMP-2 (72 kDa) activity (Figure 4A). Nimesulide markedly reduced this increased activity and the protein level of MMP-2 induced by nicotine (Figures 4B and 5).

DISCUSSION

Cigarette smoking causes cancer of various types, including cancers of the lung, oropharynx, larynx, and esophagus. Nicotine, a major component of cigarettes, has been proposed to be responsible for many pharmacological effects of cigarette smoke. Smoking is a neuronal nicotinic acetylcholine (nACh) receptor-mediated addiction[17]. Conventionally, nicotine is regarded as a relatively inert chemical in carcinogenesis and is responsible for the addictive potential of tobacco smoke. However, recently many studies have reported the toxicity of nicotine[18-20] and have suggested that nicotine may at least be partially involved in the

initiation, promotion, and even progression of tumors in the gastrointestinal tract[1,2]. However, reports on the effect of nicotine on esophageal squamous carcinoma are very few. There are three important steps in cancer metastasis: adhesion to the extracellular matrix (ECM), degradation of ECM, and ultimately migration[21]. During the whole process, the motility and invasiveness of tumor cells are the most important characteristics. Therefore, in order to study the effect of nicotine on esophageal squamous carcinoma metastasis, we examined the motility and invasiveness of TE-13 cells, an esophageal squamous carcinoma cell line treated with nicotine. In the present study, nicotine stimulated the motility and invasiveness of TE-13 cells through the reconstituted membrane.

Several studies have reported that COX-2 is involved in these complex steps of cancer metastasis. In Tsujii's study[16], human colon cancer cells (Caco-2) were permanently transfected with a COX-2 expression vector or the identical vector lacking the COX-2 insert. The Caco-2 cells, which constitutively expressed COX-2, acquired increased invasiveness compared with the parental Caco-2 cells or the vector-transfected control cells. Chen *et al*[22] investigated the association between COX-2 expression and colorectal cancer cell invasiveness. Three different colon cancer cell lines, SW620, Lovo, HT-29 and a metastatic variant of HT-29, HT-29/Inv3, were employed to evaluate COX-2 expression and prostaglandin E_2 (PGE_2) production in relation to their invasive abilities *in vitro*. Among the 4 colon cancer cell lines, HT-29/Inv3 manifested the highest COX-2 expression, PGE_2 production and *in vitro* invasive activity. These authors' results implied that COX-2 expression might be associated with the invasive and metastatic properties of colorectal cancer cells. Up-regulation of COX-2 mRNA was observed after exposure to nicotine in human gingival fibroblasts and rat microglial cells[23,24]. Therefore, we studied whether nicotine affected the motility and invasiveness of TE-13 cells through COX-2 up-regulation. Our findings showed that nicotine increased COX-2 expression and nimesulide, a COX-2 inhibitor, partly inhibited the effect of nicotine on motility and invasiveness of TE-13 cells. This implied that the effect of nicotine is at least partly dependent on COX-2 expression. In the study by Shin *et al*[15], nicotine enhanced gastric cancer cell invasion through the matrigel membrane by 4-fold and the effect of nicotine was blocked by a COX-2 inhibitor, which is consistent with our finding.

In order for the cells to invade and migrate through the basement membrane, proteolysis of the extracellular matrix must occur. This is accomplished by the secretion and activation of MMPs, which will degrade all extracellular matrix components. Among MMPs, MMP-2 plays an important role in tumor metastasis. In our study, we also determined the mediation of MMP-2 expression and secretion by nicotine, and used an inhibitor approach to investigate the action of COX-2 on the effect of nicotine. Our findings showed that nicotine increased MMP-2 expression and activity, and nimesulide blocked the effects of nicotine. Several other studies have also implicated that the activity of COX-2 gene expression leads to higher MMP expression. Tsujii *et al*[16] indicated that activation of MMP-2 can be modulated by COX-2 and treatment with a COX inhibitor can reverse the increased invasiveness of Caco-2 cells (which constitutively expressed COX-2) and inhibit activation of MMP-2. Pan *et al*[25] showed that NS398, a COX-2 inhibitor, inhibited MMP-2 mRNA expression, reduced the amount of MMP-2 released into the medium and attenuated the degrading activity of MMP-2. Inhibition of the MMP-2 promoter activity by NS-398 was partially reversed by exogenous PGE2. From these studies and from our findings, we suggest that the effect of nicotine on the stimulation of invasiveness of tumor cells is associated with increased activity and expression of MMP-2 by nicotine, and increased MMP-2 was associated with increased expression of COX-2 by nicotine. Therefore, COX-2 inhibition inhibited the action of nicotine which enhanced the invasiveness of tumor cells by inhibiting the activity of COX-2 and decreasing the activity and expression of MMP-2.

In conclusion, nicotine can enhance the migration and invasion of the esophageal squamous carcinoma cell line (TE-13), and increase the expression of COX-2 and activity of MMP-2 in these cells. Nimesulide partly blocked the effect of nicotine.

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is relatively common in China, and has a high mortality rate. It is well established that cigarette smoking increases the risk and mortality of ESCC. Nicotine is a major component of cigarettes. A recent finding suggests that nicotine may at least be partially involved in the initiation, promotion, and even progression of tumors. However, the effect of nicotine on tumorigenesis in the esophagus is still not clear. It has been observed that an increased expression of cyclooxygenase-2 (COX-2) in ESCC, and COX-2 inhibitors can decrease the incidence of ESCC, however, the mechanism of COX-2 inhibitors in the metastasis of ESCC is not very clear.

Research frontiers

It has been observed that COX-2 may play a critical role in cancer progression. The activity of matrix metalloproteinases (MMPs) is associated with invasiveness and metastasis in tumor cells. The expression and activation of MMPs may be directly proportional to the overexpression and activity of COX-2 in tumor cells. A number of epidemiological studies have suggested that the administration of COX-2 inhibitors can reduce the incidence of breast, colon, prostate and esophagus cancers.

Innovations and breakthroughs

Nicotine can enhance the migration and invasion of esophageal squamous carcinoma cells and nimesulide partly blocked the effect of nicotine.

Applications

COX-2 inhibitors can inhibit the action of nicotine which enhanced the migration and invasiveness of esophageal squamous carcinoma cells. This indicated that COX-2 inhibitors may be an effective preventive and therapeutic strategy for esophagus cancer, however, further investigations are needed to prove this.

Terminology

COX is the rate limiting enzyme involved in the conversion of arachidonic acid to prostaglandin H_2. Two isoforms of COX have been identified which share 60% homology, COX-1 and COX-2. Recently many studies have showed that COX-2 expression is up-regulated in several types of human cancers.

Peer review

In this paper the authors evaluated the effects of nicotine and nicotine and

nimesulide on the migration and invasion in esophageal squamous carcinoma TE-13 cells. The manuscript is interesting and deals with an important subject.

Abstract

AIM: To explore the association between hepatocellular carcinoma (HCC) and type 2 diabetes mellitus, describe the temporal relations between the onset of diabetes and the development of HCC and evaluate the possible effects of antidiabetic therapy on HCC risk.

METHODS: We recruited 465 HCC patients, 618 with cirrhosis and 490 control subjects. We evaluated the odds ratio (OR) for HCC by univariate and multivariate analysis. Moreover, OR for HCC in diabetic subjects treated with insulin or sulphanylureas and with metformin were calculated.

RESULTS: The prevalence of diabetes mellitus was 31.2% in HCC, 23.3% in cirrhotic patients and 12.7% in the Control group. By univariate and multivariate analysis, the OR for HCC in diabetic patients were respectively 3.12 (CI 2.2-4.4, $P < 0.001$) and 2.2 (CI 1.2-4.4, $P = 0.01$). In 84.9% of cases, type 2 diabetes mellitus was present before the diagnosis of HCC. Moreover, we report an OR for HCC of 2.99 (CI 1.34-6.65, $P = 0.007$) in diabetic patients treated with insulin or sulphanylureas, and an OR of 0.33 (CI 0.1-0.7, $P = 0.006$) in diabetic patients treated with metformin.

CONCLUSION: Our study confirms that type 2 diabetes mellitus is an independent risk factor for HCC and pre-exists in the majority of HCC patients. Moreover, in male patients with type 2 diabetes mellitus, our data shows a direct association of HCC with insulin and sulphanylureas treatment and an inverse relationship with metformin therapy.

Antidiabetic therapy and increased risk of hepatocellular carcinoma in chronic liver disease. *World J Gastroenterol* 2009; 15(20): 2506-2511 Available from: URL: http://www.wjgnet.com/1007-9327/15/2506.asp DOI: http://dx.doi.org/10.3748/wjg.15.2506

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide and the third leading cause of cancer-related deaths[1]. In recent years, a significant increase in HCC incidence and mortality rates has been observed in developed countries, but the causes of this growth are only partially understood. Hepatitis C virus (HCV) epidemics certainly play a role, due to the cohort effect of individuals infected in pre-serological age[2]. Although the main risk factors for HCC are HCV, hepatitis B virus (HBV) and chronic alcohol abuse, at least 25% of HCC cases do not have any known etiology, suggesting that further risk factors could be responsible for the increasing incidence of HCC. Diabetes mellitus has recently been proposed as a risk factor for HCC[3]. During the past two decades, the prevalence of diabetes mellitus, and in particular of type 2 diabetes mellitus, has dramatically increased in many countries, including Italy[4]. Sedentary

lifestyles, excessive food consumption and obesity appear to be the main causes of the current diabetes mellitus epidemic in western world[5].

Previous studies on the association between diabetes mellitus and liver diseases showed that type 2 diabetes mellitus appears to be a cause of non-alcoholic fatty liver disease (NAFLD) and that cirrhosis and HCV infection increase the susceptibility to diabetes mellitus[6,7].

Moreover, conflicting results were reported on the association between diabetes mellitus and solid tumors, in particular HCC[3,8-12]. While earlier investigations did not report any association between diabetes mellitus and HCC, recent data clearly indicate that diabetes mellitus is a risk factor of HCC[13-15].

However, the precise relation between diabetes mellitus and chronic liver diseases still needs to be further investigated. Therefore, the aims of this study are to explore the association between HCC and diabetes mellitus in a large cohort of patients with HCC and to describe the temporal relationship between the onset of diabetes and the development of HCC. We also considered the clinical and metabolic characteristics of the patients with type 2 diabetes mellitus and HCC, as well their antidiabetic therapy.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association.

We performed a retrospective, case-control study on three groups of Caucasian individuals, attending the Liver Unit and Diabetic Clinic of 3rd Internal Medicine in the Pordenone General Hospital (Pordenone, Italy) from January 1994 to June 2006. The 3rd Internal Medicine of Pordenone Hospital is a tertiary referral centre for liver disease and diabetes mellitus. This study is a single centre investigation and all patients of the three groups studied were all afferent, directly diagnosed and followed-up in the 3rd Internal Medicine of Pordenone Hospital.

A series of patients with HCC was compared with two different groups: one consisted of patients with liver cirrhosis and the other one, the controls, included individuals who were treated in our Hospital for a wide spectrum of acute conditions.

HCC group

This group comprised 465 consecutive patients with HCC, of which 398 cases (85.6%) were diagnosed by means of cytological or histological examination of hepatic focal lesions. The others (14.4%) were diagnosed according to the following acknowledged criteria[16]: ultrasound examination (also by using micro-bubbles of sulphur hexafluoride as contrast dye in the last three years), α fetoprotein (AFP) > 400 ng/mL, computerized tomography scan and/or magnetic resonance imaging of the upper abdomen. Clinical data, biochemical parameters and the antidiabetic treatment were considered at the time of HCC diagnosis.

Patients with HCC were further divided in two subgroups: the follow-up (FU) and the clinically overt group (CO). The FU group comprised 305 patients with small, single hepatic tumors who received the diagnosis during a surveillance program of HCC in cirrhotic patients based on ultrasound examinations and AFP determinations every 3-6 mo. The clinically overt group (CO) comprised 160 cases with advanced, large size and symptomatic HCC at diagnosis.

LC group

We enrolled 618 patients with liver cirrhosis (LC), matched with HCC cases by age (± 5 years), gender, body mass index (BMI), transaminases, history of diabetes, prevalence of HBV and HCV infections, alcohol consumption and time of admission. These patients were admitted to our Hospital for diagnosis, staging or therapy of liver cirrhosis. Clinical data, biochemical parameters and antidiabetic treatment were considered at the time of recruitment.

According to Child's classification of cirrhosis, patients were classified as follows: class A: 55.5%; B: 24.3% and C: 20.2%. In the cirrhotic patients, the presence of HCC was ruled out through ultrasound examinations, CT or MRI of the upper abdomen and AFP checks.

Control group

From 28740 in-patients of our region, 490 subjects matched with HCC and LC patients by age (± 5 years), gender, BMI, history of diabetes and time of admission were recruited. Those who were admitted for malignancies, alcohol-related disease, viral liver disease and diabetes mellitus were excluded from our study, although comorbidity of these conditions was not considered as an exclusion criterion. As previously reported[15], the selected control group represented our region's general population as to HCV and HBV infections, alcohol consumption and diabetes mellitus prevalence in the age group over 65 years.

Methods

The demographic, clinical and biochemical data of each patient were collected in a computerized database. Biochemical parameters were determined at the Pordenone Hospital central laboratory using standardized and validated methods.

Hepatitis B surface antigen (HBsAg), anti-HBV surface antigen (anti-HBs), anti-HBV core antigen (anti-HBc), and hepatitis B e antigen (HBeAg) were determined using commercial assays (Abbott Diagnostic Division, Wiesbaden; Germany). Sera were also screened for antibodies against HCV (anti-HCV) using a third-generation micro particle enzyme immunoassay (AxSYM HCV version 3.0, Abbott Diagnostic Division). Positive samples were tested for anti-HCV using a third-generation line immunoassay (Immunogenetics, Gent, Belgium) and for serum HCV-RNA using the Roche Amplicor version 2.0 (Roche Molecular System, Pleasanton, CA).

The diagnosis and clinical classification of diabetes mellitus were based on the guidelines of the American Diabetes Association[17,18]. In particular, the distinction

Table 1 Frequency of type 2 diabetes mellitus in HCC, LC and control groups

Subjects (*n*)	DM2 -ve *n* (%)	DM2 +ve *n* (%)	OR (95% CI)	*P*
Total				
HCC(465)	320 (68.8)	145 (31.2)	3.12 (2.2-4.4)[a]	< 0.001
Controls (490)	428 (87.3)	62 (12.7)	2.09 (1.5-2.9)[c]	< 0.001
LC (618)	474 (76.7)	144 (23.3)		
Males				
HCC (364)	246 (67.6)	118 (32.4)	3.14 (2.1-4.6)[b]	< 0.00001
Controls (385)	334 (86.7)	51 (13.3)	1.99 (1.3-2.9)[d]	0.000
LC (450)	341 (75.8)	109 (24.2)		
Females				
HCC (101)	74 (73.3)	27 (26.7)	3.11 (1.3-7.4)[e]	0.002
Controls (105)	94 (89.5)	11 (10.5)	2.59 (1.2-5.9)[f]	0.008
LC (168)	133 (79.2)	35 (20.8)		

OR: Odds ratio; CI: Confidence interval. [a]$P < 0.001$, HCC group *vs* control group; [b]$P < 0.00001$, HCC group *vs* control group; [c]$P < 0.001$, LC group *vs* control group; [d]$P = 0.0002$, LC group *vs* control group; [e]$P = 0.002$, HCC group *vs* control group; [f]$P \leqslant 0.008$, LC group *vs* control group.

between type 1 and 2 diabetes mellitus, was made according to the following clinical characteristics: age and modality of glucose intolerance onset, previous use of antidiabetes medications, occurrence of ketoacidosis, obesity and body fat distribution, concomitant autoimmunity, positive family history and HLA association, presence of micro- and macro-vascular complications when diabetes was diagnosed.

Alcohol abuse was defined as a daily consumption over 30 g for males and over 20 g for females. Average alcohol content was estimated in 5% for beer, 12% for wine and 40% for super alcoholics[15].

Statistical analysis

Normality tests were performed on all data. Parametric data are expressed as mean ± SD. Data with multiple time points variables were analysed by the general model ANOVA. *Post hoc* multiple comparisons were performed using an LSD test when ANOVA testing was significant ($P \leqslant 0.05$). To establish univariate associations among variables, the odds ratio (OR) with a confidence interval of 95% was calculated, using the simple analysis of the logistic regression. All statistical analyses were performed using SPSS software 13.0 for Windows (SPSS Inc, Chicago, IL).

RESULTS

Each subject with diabetes mellitus in the HCC and LC groups showed the clinical and metabolic characteristics of type 2 diabetes mellitus. Of note, none of our HCC or liver cirrhosis patients had type 1 diabetes mellitus.

As shown in Table 1, the prevalence of type 2 diabetes mellitus was 31.2% in the HCC group, 23.3% in the LC group and 12.7% in the controls. The prevalences of type 2 diabetes mellitus in the three groups were statistically different, with an OR of 3.12 (CI 2.2-4.4) in HCC group *vs* controls and an OR of 2.09 (CI 1.5-2.9) in LC *vs* controls group.

Table 2 Etiology, mean age and prevalence of type 2 diabetes mellitus in 465 HCC patients (mean ± SD)

Etiology	HCC *n* (%)	Age (yr)	Prevalence of DM2 (%)
HBV	20 (4.3)	63.3 ± 10.3[a]	3 (15.0)
HCV	177 (38.1)	71.5 ± 7.3[a]	47 (26.5)[b,c]
Alcohol	141 (30.4)	66.7 ± 8.5[a]	52 (36.9)[b,d]
HBV + HCV	8 (1.7)	60.8 ± 12.8[a]	2 (25.0)
HBV + alcohol	9 (1.9)	62.9 ± 9.3[a]	2 (22.2)
HCV + alcohol	81 (17.4)	67.7 ± 9.3[a]	27 (33.3)
HBV + HCV + alcohol	2 (0.4)	68.4 ± 10.3	0
Cryptogenic	27 (5.8)	68.6 ± 9.3	19 (70.3)[c,d]

[a]$P < 0.001$, HCV *vs* HBV + HCV; HCV *vs* HBV; HCV *vs* HBV + alcohol; HCV *vs* HCV + alcohol; HCV *vs* alcohol; [b]$P = 0.048$: HCV *vs* alcohol; [c]$P < 0.001$, cryptogenic *vs* HCV; [d]$P < 0.002$, cryptogenic *vs* alcohol.

Etiology of the chronic liver disease, mean age at HCC diagnosis and type 2 diabetes mellitus prevalence in the subgroups are summarized in Table 2.

The highest prevalence (70.3%) of type 2 diabetes mellitus was found in HCC patients with cryptogenic chronic liver disease.

We also calculated that the male/female ratio in patients with cryptogenic etiology of HCC was 9.5/1, compared to a male excess of 4.4 in all diabetic patients and of 3.3 in the entire HCC group.

Multivariate analysis

The multivariate analysis in HCC group *vs* Controls shows that type 2 diabetes mellitus is associated with an increased risk of HCC occurrence (OR = 2.2; CI 1.2-4.4; $P = 0.01$), independent of age, gender, BMI, alcohol abuse, HBV and HCV infections.

Time interval from type 2 diabetes mellitus onset to HCC diagnosis

The data collected in the records of our Diabetes Clinic show that in 122 patients (84.9%), type 2 diabetes mellitus was diagnosed at least 6 mo before the onset of HCC, while in only 23 patients (15.1%) diabetes mellitus was recognized after the diagnosis of HCC.

The time interval between diabetes mellitus diagnosis and HCC onset was exactly calculated: diabetes was found to be present prior to the HCC diagnosis for a mean time of 141.5 ± 9.4 mo.

Moreover, in patients with HCC of cryptogenic etiology, diabetes mellitus was present before HCC occurrence for a mean period of 150.5 ± 10.1 mo.

In the subgroup with pre-existing type 2 diabetes mellitus, the time interval until the diagnosis of HCC was longer in insulin treated patients than in those treated with antidiabetic oral agents (171.5 ± 87.6 mo *vs* 118.7 ± 95.2 mo; $P = 0.05$).

Insulin treatment

The percentage of type 2 diabetes mellitus patients treated with insulin was similar in the HCC (39.6%) and LC groups (43%), but it was significantly lower in the controls (20.9%; $P < 0.025$ and $P = 0.007$, respectively)

Table 3 Antidiabetic therapy in HCC, cirrhotic patients and in Controls with type 2 diabetes mellitus *n* (%)

	Metformin	Sulfonylureas	Insulin
Total			
HCC	14 (15.9)[a]	74 (84.1)[d]	57 (39.6)[g]
Controls	15 (31.2)[b]	33 (68.8)[e]	14 (20.9)[h]
LC	58 (70.7)[c]	24 (29.3)[f]	62 (43.0)[i]

[a,d] *vs* [b,e] $P = 0.04$; [a,d] *vs* [c,f] $P < 0.001$; [b,e] *vs* [c,f] $P < 0.001$; [g] *vs* [h] $P < 0.025$; [i] *vs* [h] $P = 0.007$.

(Table 3). Based on the records of our Diabetic Clinic, the mean duration of insulin treatment in HCC insulin-treated patients was 83.1 ± 63.4 mo; before insulin therapy the patients were treated only with diet.

Oral antidiabetic agents treatment

We observed that a significant number of HCC patients treated with antidiabetic oral agents took sulphanylureas rather than metformin, while most LC patients used metformin (Table 3). The mean period of treatment with the two antidiabetic oral agents was 125.2 ± 11.5 mo.

Antidiabetic therapy and risk of HCC

Univariate analysis in diabetic HCC patients *vs* diabetic controls shows that the OR for hepatocarcinoma in subjects taking insulin or sulphanylureas was 2.99 (CI 1.34-6.65, $P = 0.007$) while the OR dropped to 0.33 (CI 0.1-0.7, $P = 0.006$) in individuals treated with metformin.

Clinical features of type 2 diabetes mellitus in FU and CO groups with HCC

The FU and CO groups showed a similar prevalence of diabetes (30.2% and 33.1%; $P = 0.62$, respectively). Mean glycated A1c hemoglobin was higher in the FU group (8.2% ± 2.8% *vs* 7.1% ± 2.1%), although this difference is not statistically significant ($P = 0.08$). The mean time interval between type 2 diabetes mellitus diagnosis and HCC onset was greater in CO than in FU patients (167.1 ± 114.3 mo *vs* 127.8 ± 80.1 mo; $P = 0.03$). Insulin treatment was more frequent in FU cases with type 2 diabetes mellitus than in diabetic CO patients (48.9% *vs* 28.3%; $P = 0.01$, respectively).

DISCUSSION

Our study shows that type 2 diabetes mellitus is an independent risk factor for hepatocarcinoma and precedes the onset of HCC. Moreover, we found that insulin or secretagogues antidiabetic oral agents treatment are associated with an increased risk for HCC, while in metformin treated patients the risk of HCC was reduced.

In this study, every HCC and cirrhotic patient with abnormal glucose tolerance showed clinical and pathophysiological characteristics of type 2 diabetes mellitus. This observation confirms the results of two recent prospective studies on the association between diabetes and HCC. El Seragh *et al*[11] in a wide study carried out in the US reported that almost all (99%) diabetic patients who developed HCC had type 2 diabetes mellitus, and Lai *et al*[14] in a survey in Taiwan, observed that type 2 diabetes mellitus, classified according to age at onset of diabetes mellitus, is associated with HCC.

The results of our study are consistent with the theory of the biological mechanisms underlying the epidemiological association between diabetes mellitus and cancer. In fact, this hypothesis postulates that the diabetes-cancer association is likely to be related to insulin resistance and consequent hyperinsulinemia, which are typical features in the majority of type 2 diabetes mellitus patients. Ten years ago, McKeown-Eyssen[19] and Giovannucci[20] observed that risk factors for cancer and insulin resistance in developed countries are almost the same. To explain this analogy, they suggested that protracted exposure to hyperinsulinemia increases the levels of IGF-1, which plays a pivotal role in carcinogenesis (insulin-cancer hypothesis)[21]. In addition, the predictive value of hyperinsulinemia on total cancer mortality[9] and fatal liver tumor incidence[22] has been demonstrated in non-diabetic subjects by two recent prospective analysis.

Liver cirrhosis is a significant cause of death in type 2 diabetes mellitus patients, being even more relevant than cardiovascular diseases[23]. However, patients with type 2 diabetes mellitus often suffer from liver disease as well, and diabetes is a recognized cause of NAFLD and cryptogenic cirrhosis[24]. In fact, it is well-known that the natural history of NAFLD might progress, over a period of many years, from steatosis to steatohepatitis, cirrhosis and, sometimes, to HCC[6]. On the other hand, 20% of patients with cirrhosis have overt diabetes (hepatogenous diabetes) and 60% have impaired glucose tolerance[24]. Thus, the association between diabetes and cirrhosis is complex and reciprocal.

To evaluate the relations between type 2 diabetes mellitus and HCC, regardless of cirrhosis and other risk factors, we performed a single centre, retrospective case-control study on HCC patients comparing them, not only to a group of Control subjects without liver diseases and diabetes mellitus, but also to a series of cirrhotic patients.

Our study shows that the prevalence of type 2 diabetes mellitus in the LC group is intermediate between those of the HCC and controls, indicating that the underlying liver cirrhosis is not the only cause of diabetes in HCC patients.

The similar prevalence of type 2 diabetes mellitus reported in FU and CO subgroups of HCC patients, suggests that the prevalence of diabetes mellitus is not dependent on the size of the liver tumor.

The evidence that type 2 diabetes mellitus is a risk factor for HCC in our patients is obtainable by univariate and multivariate analyses, which show an OR for HCC of 3.12 and 2.2 respectively, similar to those recently reported in U.S.[3,11] and Asian[12,14] populations. Moreover, like the results of a recent Japanese investigation[25], the patients in our study with cryptogenic HCC have the highest percentage of type 2 diabetes mellitus. Interestingly, most patients with cryptogenic HCC are male, suggesting that this sex prevalence could be related to the effect

of diabetes, because the prevalence of type 2 diabetes mellitus, as shown by the current diabetes estimates based on age and sex in the populations of our region[26] and western countries[5,27], is higher in men than in women in the age groups in which HCC develops.

The precise temporal relation between the onset of type 2 diabetes mellitus and diagnosis of HCC is only partially understood. A previous prospective study[11], conducted in a large cohort of males with and without diabetes mellitus, investigated, for the first time, the temporal relationship between diabetes and HCC, showing a two-fold increase of HCC incidence among patients with diabetes.

Our study showed that type 2 diabetes mellitus was present 141 mo before the diagnosis of HCC. Interestingly enough, we observed that in cryptogenic HCC patients, type 2 diabetes mellitus is the only recognized risk factor that these patients have 150 mo before the diagnosis. As already mentioned, patients with small and single hepatocarcinomas and those with advanced tumors have a similar prevalence of type 2 diabetes mellitus. Associated with this, the higher frequency of insulin treatment in FU cases with type 2 diabetes mellitus than in CO diabetic cases, suggests that type 2 diabetes mellitus is more likely to be a cause rather than merely a consequence of the liver cancer.

Our data demonstrates that exogenous insulin treatment is significantly more frequent in diabetic HCC patients than in Control diabetic cases, while cirrhotic patients are more frequently treated with metformin than HCC and Controls individuals. Moreover, in our study, insulin or sulphanylureas therapy are associated with an increased risk of HCC, conversely metformin therapy is associated with a reduced risk of HCC.

These findings are in agreement with previous studies on the relation between antidiabetic therapy and cancer-related mortality, which showed that diabetic patients treated with insulin[9,23] or sulphanylureas[28] have a significantly high mortality for cirrhosis and HCC, while treatment with insulin-sensitizer drugs that ameliorate insulin action, such as metformin, might have a protective effect on cancer risk[29,30].

The effects of insulin therapy in type 2 diabetes mellitus patients with chronic liver disease could be explained by the mitogenic action of exogenous insulin added to those of endogenous hyperinsulinemia. The sulphanylureas might cause an increase both of endogenous insulin secretion and of its precursors, that seem to have mitogenic effects by themselves[21]. Conversely, metformin treatment can decrease insulin resistance, reducing the consequent hyperinsulinemia and its effects in these patients. Moreover, it is known that patients with type 2 diabetes mellitus treated with insulin frequently have more severe insulin resistance, hyperinsulinemia and diabetic complications. Therefore, insulin treatment might be a marker of long lasting and more severe diabetes[31].

The results of our study, therefore, might have important implications in the clinical management of diabetes mellitus, particularly in males with type 2 diabetes mellitus and chronic liver diseases, because we found that they are at high-risk for HCC. This observation is of primary relevance to the implementation of prevention policies and to encourage the most adequate and cost-effective programs of surveillance in cirrhotic patients. In fact, metformin treatment might have a protective effect and therefore might be recommended as a first-line therapy in diabetic patients with compensated liver cirrhosis, because its use is not associated with the risk of hypoglycaemia and body weight gain[24].

Thus, our data suggests that patients with type 2 diabetes and chronic liver disease should first control their diabetes mellitus through diet and changes in lifestyle, to decrease their weight and increase physical activity. Subsequently they should take metformin or other insulin sensitizers, to counteract insulin resistance and consequent hyperinsulinemia.

Our study did have some limitations. It is a retrospective study drawn from a clinical series and not from the community; however, in this case-control survey, matching by age, gender, history of diabetes, BMI and time of hospital admission, we selected a control group and we made sure that it represented the general population of our Region[26]. A potential bias in a case-control study like this is discerning temporal relationships between exposure and outcomes, due to the complex relationships between type 2 diabetes mellitus and cirrhosis. To avoid this error, our study was conducted on a large cohort of HCC patients comparing them with both a control group and with a cohort of cirrhotic patients.

Furthermore, a retrospective study like this must be based upon complete and accurate information on the time interval between type 2 diabetes mellitus onset and the diagnosis of HCC. To achieve this, we reviewed all medical documentation kept at the Diabetes Clinic where all the Regional records are filed from the onset of the disease. Therefore, we could review the detailed clinical history of HCC diabetic patients to calculate exactly the individual time interval from the onset of diabetes to the HCC diagnosis. Prospective studies are required to demonstrate that insulin resistance and hyperinsulinemia are the biological mechanisms that explain the association between type 2 diabetes mellitus and HCC. In conclusion, our survey confirmed that type 2 diabetes mellitus is an independent risk factor for HCC and that it precedes HCC diagnosis. Moreover, in male patients with type 2 diabetes mellitus, our data show a direct association of HCC with insulin and sulphanylureas treatment and an inverse relationship with metformin therapy.

COMMENTS

Background

Type 2 diabetes mellitus has been associated with hepatocellular carcinoma (HCC). However, the relationship between type 2 diabetes mellitus and the underlying liver cirrhosis, and the effects of antidiabetic therapy on HCC risk have not yet been fully evaluated.

Innovations and breakthroughs

This study demonstrates that type 2 diabetes mellitus is an independent risk factor for HCC and pre-exists in the majority of HCC patients. In male HCC

patients with type 2 diabetes mellitus, their data shows a direct association of HCC risk with insulin and sulphanylureas treatment and an inverse relationship with metformin therapy.

Peer review

This is an interesting and detailed retrospective single center study reviewing patients with diabetes mellitus and chronic liver disease.

Abstract

AIM: To measure circulating angiotensins at different stages of human cirrhosis and to further evaluate a possible relationship between renin angiotensin system (RAS) components and hemodynamic changes.

METHODS: Patients were allocated into 4 groups: mild-to-moderate liver disease (MLD), advanced liver disease (ALD), patients undergoing liver transplantation, and healthy controls. Blood was collected to determine plasma renin activity (PRA), angiotensin (Ang) Ⅰ, Ang Ⅱ, and Ang-(1-7) levels using radioimmunoassays. During liver transplantation, hemodynamic parameters were determined and blood was simultaneously obtained from the portal vein and radial artery in order to measure RAS components.

RESULTS: PRA and angiotensins were elevated in ALD when compared to MLD and controls ($P < 0.05$). In contrast, Ang Ⅱ was significantly reduced in MLD. Ang-(1-7)/Ang Ⅱ ratios were increased in MLD when compared to controls and ALD. During transplantation, Ang Ⅱ levels were lower and Ang-(1-7)/Ang Ⅱ ratios were higher in the splanchnic circulation than in the peripheral circulation (0.52 ± 0.08 *vs* 0.38 ± 0.04, $P < 0.02$), whereas the peripheral circulating Ang Ⅱ/Ang Ⅰ ratio was elevated in comparison to splanchnic levels (0.18 ± 0.02 *vs* 0.13 ± 0.02, $P < 0.04$). Ang-(1-7)/Ang Ⅱ ratios positively correlated with cardiac output ($r = 0.66$) and negatively correlated with systemic vascular resistance ($r = -0.70$).

CONCLUSION: Our findings suggest that the relationship between Ang-(1-7) and Ang Ⅱ may play a role in the hemodynamic changes of human cirrhosis.

INTRODUCTION

The renin angiotensin system (RAS) is now viewed as

a dual system composed of 2 arms: vasoconstriction encompassing angiotensin converting enzyme (ACE)-angiotensin (Ang) Ⅱ-Ang Ⅱ type 1 (AT_1) receptor and vasodilation encompassing ACE2-Ang-(1-7)-Mas receptor. The ACE2-Ang-(1-7)-Mas receptor arm mainly acts as a counter-regulatory mechanism to the vasoconstrictor arm[1]. According to this novel concept, the final functional effect of the RAS may reflect a balance between these 2 arms[2-4]. Apart from the circulating RAS, the existence of local systems has been described in a number of organs, including the liver[5]. These local systems act in response to various physiological and pathophysiological stimuli, and the locally generated angiotensins have been implicated in the modulation of cell growth and proliferation, generation of reactive oxygen species, hormone secretion, and in the control of local inflammation and fibrosis[6]. The circulating RAS is well recognized for its role in hemodynamic regulation through Ang Ⅱ, a potent vasoconstrictor, and the counter-regulatory peptide, Ang-(1-7), a vasodilator. The local and circulating RAS can interact with each other and with other regulatory systems[7].

Liver cirrhosis has 2 major circulatory dysfunctions: portal hypertension and a hyperdynamic circulation characterized by elevated cardiac output and low systemic vascular resistance[8]. It is well established that Ang Ⅱ plays a role in the pathogenesis of portal hypertension by increasing intrahepatic vascular resistance and also by contributing to liver fibrosis[5]. The development of portal hypertension in cirrhosis is associated with arterial vasodilation in the splanchnic circulation, leading to a decrease in systemic vascular resistance[9]. Early in the course of the disease, the decrease in systemic vascular resistance is compensated by the development of a hyperdynamic circulation[10]. Despite a reduction in systemic vascular resistance, the effective arterial blood volume remains normal, as does the circulating RAS components and antidiuretic hormone[8]. However, as the disease progresses and arterial vasodilation increases, the hyperdynamic circulation is insufficient to correct the effective arterial hypovolemia[8]. Arterial hypotension develops, leading to activation of the circulating RAS, sympathetic nervous system and secretion of antidiuretic hormone[8]. The splanchnic circulation is resistant to the effect of Ang Ⅱ, noradrenaline and vasopressin, and the maintenance of arterial pressure is a result of vasoconstriction in extra-splanchnic vascular areas[8]. Liver cirrhosis has been studied recently in light of the new view of the RAS. It is becoming clear that the RAS can influence liver cirrhosis through its 2 main arms. While the ACE-Ang Ⅱ-AT1 receptor arm contributes to liver tissue injury and fibrosis[6] and the maintenance of basal vascular tonus in non-compensated cirrhosis[11], the activation of the ACE2-Ang-(1-7)-Mas arm exerts antifibrotic actions[6,12,13]. In addition, it has been speculated that this counter-regulatory arm also has a role in the arterial vasodilation in liver cirrhosis[14]. In this regard, we have recently shown that chronic treatment with propranolol in cirrhotic patients was characterized by marked changes in the precursors of the RAS cascade (renin and Ang Ⅰ), with repercussions on the 2 main RAS components, Ang Ⅱ and Ang-(1-7), in the splanchnic and peripheral circulations[15]. Our previous data suggested that a possible therapeutic approach for advanced human cirrhosis could be the combination of a beta-blocker with an AT_1 receptor blocker or ACE inhibitor[15].

Therefore, the aim of the present study was to evaluate circulating levels of angiotensins in mild-to-moderate and advanced stages of human cirrhosis without the interference of any kind of RAS blockade such as beta-blockers, ACE inhibitors and AT_1 receptor blockers. In addition, we also evaluated a correlation between RAS peptides and hemodynamic parameters in systemic and splanchnic circulations of cirrhotic patients during liver transplantation.

MATERIALS AND METHODS

Patients

This cross-sectional study used a convenience sample recruited from the Alfa Institute of Hepatology/Liver Transplantation and the Clinical Primary Care Center of our institution.

Inclusion criteria: Patients diagnosed with hepatic cirrhosis (n = 24) defined through liver histopathology and/or ultrasonography findings were included in this study. Table 1 displays the Child-Pugh scores[16] of our patients. The primary etiology of the liver disease was established in 21 subjects (87.5%), and included alcoholism, hepatitis C virus, hepatitis B virus and biliary cirrhosis. All cirrhotic patients showed portal hypertension at the time criteria were set for each protocol group. Cirrhotic patients were then allocated to one of 3 study groups based on the presence or absence of ascites and values of Child-Pugh score[16]: the first group was composed of patients who had mild-to-moderate liver disease (MLD, n = 8), the second group included patients with advanced liver disease (ALD, n = 7), which were seen in an outpatient clinic and the third group was composed of liver transplant recipients during surgery (LT, n = 9).

The MLD patients did not receive any medication and did not exhibit ascites at the time of blood collection. However, they had other endoscopic or ultrasonographic signs of portal hypertension (small varices < 5 mm, collateral vessels, abnormalities in portal flow direction).

The ALD group comprised outpatients with ascites and extra-hepatic complications such as encephalopathy and moderate to large esophageal varices (> 5 mm) with risk of bleeding. These patients were using diuretics (furosemide 40-80 mg/d associated with spironolactone 25-100 mg/d).

The LT group included hospitalized cirrhotic patients with the same severity of liver disease as the ALD group based on Child Pugh and MELD scores (Child Pugh: 11.0 ± 0.8 in LD *vs* 11.2 ± 1.2 in LT and MELD: 29.3 ± 2.1 in LD *vs* 29.8 ± 3.2 in LT, $P > 0.05$ for both comparisons). These patients also presented the same clinical and laboratory features as the ALD group and

Table 1 Subject characteristics and casual measurements

Characteristics and measurements	Mild to moderate liver disease (MLD) $n = 8$	Advanced liver disease (ALD) $n = 7$	ALD during Liver transplantation (LT) $n = 9$
Age (yr)	55.5 ± 1.8	54 ± 5	50 ± 3
Sex, male/female	3 (37.5%)/5 (62.5%)	4 (57%)/3 (43%)	7 (78%)/2 (22%)
Child Pugh Score	6.7 ± 0.2	11 ± 0.8[a]	11 ± 1.8[a]
Albumin, g/dL	2.9 ± 0.15	2.4 ± 0.3	2.6 ± 0.2
Bilirubin, mg/dL	2.4 (1.7-5.9)	2.5 (1.2-7.1)	3.3 (2.0-5.5)
Creatinine, mg/dL	0.70 (0.70-0.80)	1.0 (1.0-1.45)[a]	1.0 (0.75-1.50)
INR (International normalization ratio)	1.2 ± 0.07	1.7 ± 0.3	1.8 ± 0.2
Prothrombin activity	68.3% ± 7.5%	50% ± 12%	42% ± 7%[a]
Serum Na^+, mEq/L	139 ± 2	126 ± 3[a]	130 ± 2[a]

Data are expressed as mean ± SE or median (25 and 75 percentile), except for sex where number of patients and percentages are shown. [a]$P < 0.05$ for the comparison of the ALD and LT groups with the MLD group (ANOVA followed by Bonferroni test for mean comparisons and Kruskal-Wallis followed by the Dunn test for median comparisons). No statistical differences were detected between the ALD and LT groups.

received the same diuretic treatment. The only difference between both groups was that LT patients had been submitted for liver transplantation.

The control group ($n = 16$) consisted of healthy age-matched subjects from our Clinical Primary Care Center. Health status was determined through the subjects' medical history to rule out the presence of chronic or acute diseases. All subjects were subjected to a complete physical examination prior to blood sampling as part of our study protocol.

Exclusion criteria: Co-morbidities such as diabetes, heart, pulmonary, autoimmune and neurological diseases automatically excluded subjects from the study. Patients receiving chronic treatment with ACE inhibitors, angiotensin receptor blockers, renin inhibitors, beta-blockers and corticosteroids were also in our exclusion criteria. During liver transplantation, blood collection was performed whenever the subject showed acute hemodynamic derangement demanding vasoconstrictor use.

Ethical aspects: The Ethics Committee of the Federal University of Minas Gerais approved the study. Informed consent was obtained from all included subjects. The research protocol did not interfere with any medical recommendations or prescriptions. Subject follow-up was guaranteed even in cases of refusal to participate in the study.

Study protocol

The study was performed in outpatients at different clinical stages of cirrhosis (MLD and ALD groups) and in hospitalized patients during liver transplantation (LT group). Circulating RAS components levels were measured in all groups; only in LT patients were measurements of RAS components also obtained from the splanchnic circulation simultaneously with the hemodynamic parameters.

Protocol 1-Evaluation of circulating RAS in controls and patients with mild-to-moderate and advanced cirrhosis: Blood samples for measurement of plasma renin activity (PRA) and angiotensins were obtained from healthy subjects, MLD and ALD patients on a single occasion taking into account the inclusion and exclusion criteria for each group. For ethical reasons, no changes to the clinical approach were made for study purposes. Blood samples (10 mL) were collected through peripheral venipuncture in the morning after a fasting period of 8 h. All subjects rested in the supine position for at least 30 minutes before blood sampling.

Protocol 2-Evaluation of peripheral and splanchnic RAS components during the pre-anhepatic stage of liver transplantation: Anesthesia for liver transplantation was induced by a rapid sequence of etomidate, fentanyl and succinylcholine and maintained by isoflurane (CAM about 1.0) and atracurium until blood sampling. In the LT group, blood sampling was performed during the pre-anhepatic stage of liver transplantation and samples were obtained simultaneously from the radial artery (10 mL) and portal vein (10 mL) to evaluate RAS components before and after the enteric circulation, respectively. Furthermore, the portal vein is part of the splanchnic circulation, which is the original source of hyperdynamic circulation.

Protocol 3-Evaluation of hemodynamic parameters during the pre-anhepatic stage of liver transplantation: Hemodynamic parameters (cardiac output, cardiac index, systemic vascular resistance and systemic vascular resistance index) were determined simultaneously with blood sampling to measure the RAS components. These measurements were obtained through invasive continuous monitoring *via* a Swan-Ganz catheter (CCOMBO/SvO_2, 110 cm/7.5F, Edwards Lifesciences, Irvine, CA, USA), using Dixtal (DX 2020, Dixtal Biomedical, São Paulo, Brazil) and Vigilance (CEDV, Edwards Lifesciences, Irvine, CA, USA) monitors.

Blood collection and plasma extraction

For all blood collection, samples were drawn into 2 sets of ice-cooled tubes-one containing 7.5% EDTA for PRA determination and the other containing a cocktail of pro-

Table 2 Circulating RAS components in healthy controls, MLD and ALD patients

RAS components	Healthy controls	MLD	ALD
PRA (ng Ang I/ mL per hour)	0.10 (0.03-0.23)	0.10 (0.01-0.22)	2.7 (0.43-6.61)[a,c]
Ang Ⅰ (pg/mL)	179.8 (86.9-220.8)	28.9 (23-65.2)[a]	412.3 (326.5-1123)[a,c]
Ang Ⅱ (pg/mL)	47.0 (41.8-61.7)	27.5 (23.9-35.9)[a]	84.4 (60.9-154.6)[a,c]
Ang-(1-7) (pg/mL)	20.1 (17.1-25.5)	24.9 (21.1-27.4)	32.6 (27.8-61.6)[a]

Data are expressed as medians (25 and 75 percentile). [a]$P < 0.05$ for the comparison of MLD and ALD groups with healthy controls and [c]$P < 0.05$ for the comparison between MLD and ALD groups (Kruskal-Wallis followed by Dunn test). PRA: Plasma renin activity; Ang: Angiotensin.

tease inhibitors for angiotensin measurements[17]. Blood samples were centrifuged at 2000 *g* for 20 min at 4℃ and plasma was stored at -20℃[17]. Plasma samples were extracted using Bond-Elut cartridges (Analytichem International, Harbor City, CA), as described elsewhere[17].

Radioimmunoassays

PRA as well as Ang Ⅰ, Ang Ⅱ and Ang-(1-7) concentrations were determined through radioimmunoassays, as detailed elsewhere[17]. The recovery of ^{125}I-labeled Ang Ⅰ, Ang Ⅱ, and Ang-(1-7) was 79.2% ± 2.3%, 86.9% ± 0.8% and 83.5% ± 0.9%, respectively. Results were expressed as nanograms of Ang Ⅰ generated per milliliter of plasma per hour (ng Ang Ⅰ/mL per hour) for PRA and pg/mL of plasma for Ang measurements).

Statistical analysis

The software Graphpad PRISM, version 4.03, was used for the statistical analyses. The Gaussian distribution of the variables was evaluated by the Shapiro normality test. Results were reported as mean ± SE or median, when appropriate. Analysis of variance followed by the Bonferroni test was used for the comparison of means between groups. Mann-Whitney or Kruskal-Wallis followed by the Dunn test was used to compare non-parametric data. The paired Student *t*-test was used to compare means from variables of the LT group before and after the enteric circulation. The level of significance was set at $P < 0.05$.

RESULTS

Subject characteristics and casual measurements

The primary etiology of liver disease of the compensated cirrhotic patients (CLD) included: hepatitis C virus in 3, alcoholism in 4 and hepatitis B virus in 1 patient. Laboratory data, Child-Pugh and MELD scores confirmed the mild to moderate stage of liver disease (Table 1).

The causes of liver disease in the ALD group were: alcoholism in 2, bile cirrhosis in 1, hepatitis C virus in 1 and idiopathic disease in 3 patients. Laboratorial data, Child-Pugh and MELD scores revealed the advanced stage of liver disease (Table 1).

The etiologies of hepatic disease in the LT group included hepatitis C virus in 3, alcoholism in 3, bile cirrhosis in 2 and hepatitis B virus in 1 patient. Laboratory findings, Child-Pugh and MELD scores were very similar to those of the ALD group and also showed an advanced stage of liver disease (Table 1).

Healthy controls comprised 16 subjects, including 7 males and 9 females from 40 to 65 (49.7 ± 2.6) years.

Circulating RAS profile in healthy controls, MLD and ALD outpatients

As displayed in Table 2, PRA was significantly higher in the ALD group in comparison to MLD patients and healthy controls ($P < 0.05$). The same profile was observed for Ang Ⅰ, which also presented a significant increase in plasma levels in ALD patients when compared to controls and the MLD group (Table 2). On the other hand, statistical differences were detected when comparing Ang Ⅰ measurements obtained from MLD patients and healthy controls (Table 2).

ALD patients also exhibited a significant elevation in Ang Ⅱ and Ang-(1-7) when compared to healthy controls ($P < 0.05$, Table 2). In contrast, Ang Ⅱ levels were significantly lower in patients with mild-to-moderate cirrhosis even when compared with healthy controls, whereas plasma Ang-(1-7) in this group did not differ from that of healthy subjects or of the ALD group (Table 2).

Ratios of Ang-(1-7) and Ang Ⅰ levels, of Ang Ⅱ and Ang Ⅰ, and of Ang-(1-7) and Ang Ⅱ in all groups are displayed in Figure 1 as medians. The Ang-(1-7)/Ang Ⅰ ratio was significantly higher in MLD patients [0.95 (0.43-1.02)] than in the ALD and control groups. On the other hand, healthy controls and ALD patients exhibited similar Ang-(1-7)/Ang Ⅰ ratios [controls: 0.13 (0.08-0.22) *vs* NLD: 0.08 (0.02-0.10), Figure 1]. The Ang Ⅱ/Ang Ⅰ ratio was significantly reduced in the ALD group [0.15 (0.13-0.25)] when compared to MLD patients [0.98 (0.71-1.09)], but not in comparison to healthy controls [0.25 (0.20-0.63), Figure 1]. More importantly, the Ang-(1-7)/ Ang Ⅱ ratio, which could represent the final functional relationship between RAS components, was significantly increased in MLD patients [0.89 (0.73-1.04)] in comparison to ALD patients [0.40 (0.17-0.57)] and controls [0.38 (0.32-0.47)], whose median values were similar (Figure 1).

Peripheral and splanchnic RAS components during the pre-anhepatic stage of liver transplantation

As displayed in Table 3, the comparisons of PRA, Ang Ⅰ and Ang-(1-7) levels revealed no difference between the peripheral and splanchnic circulations. However, Ang Ⅱ levels were significantly reduced in the splanchnic circulation when compared to the peripheral circulation ($P < 0.05$, Table 3). The ratios between angiotensins

Table 3 Peripheral and splanchnic RAS components during the pre-anhepatic stage of liver transplantation

RAS components	Peripheral measurements	Splanchnic measurements
PRA (ng Ang I/mL per hour)	2.4 ± 0.6	2.5 ± 0.4
Ang I (pg/mL)	764 ± 115	765 ± 103
Ang II (pg/mL)	138 ± 23	97 ± 13[a]
Ang-(1-7) (pg/mL)	48 ± 5	48 ± 7

Data are expressed as mean ± SE. [a]$P < 0.05$ for the comparison between peripheral and splanchnic measurements (paired Student *t*-test).

were also different in the peripheral and splanchnic circulation (Figure 2). The Ang-(1-7)/Ang Ⅱ ratio was higher in the splanchnic circulation than in the peripheral circulation (0.52 ± 0.08 *vs* 0.38 ± 0.04, $P < 0.05$, Figure 2), whereas the peripheral circulating Ang Ⅱ/Ang Ⅰ ratio was elevated in comparison to splanchnic levels (0.18 ± 0.02 *vs* 0.13 ± 0.02, $P < 0.05$, Figure 2). No differences were detected in the Ang-(1-7)/Ang Ⅰ ratio between both sites (Figure 2).

Correlation between hemodynamic parameters and RAS profile during the pre-anhepatic stage of liver transplantation

In general, hemodynamic parameters from patients with cirrhosis (LT group) were different from the reference values. Systemic vascular resistance (555 ± 57 dyn.s.cm^{-5} *vs* 1200-1500 dyn.s.cm^{-5}) and respective index (1029 ± 95 dyn.s.cm^{-5}.m^{-2} *vs* 2400-2900 dyn.s.cm^{-5}.m^{-2}) were below the reference range, whereas cardiac output (9.5 ± 1.1 L/min *vs* 3.0-7.0 L/min) and its index (5.0 ± 0.5 L.min^{-1}.m^{-2} *vs* 2.5-4.0 L.min^{-1}.m^{-2}) were above the reference range. There was no significant correlation between Ang-(1-7) or Ang Ⅱ concentrations and hemodynamic parameters. However, the Ang-(1-7)/Ang Ⅱ ratio was positively correlated with cardiac output ($r = 0.66$, $P < 0.05$) and negatively correlated with systemic vascular resistance ($r = -0.70$, $P < 0.05$) (Figure 3).

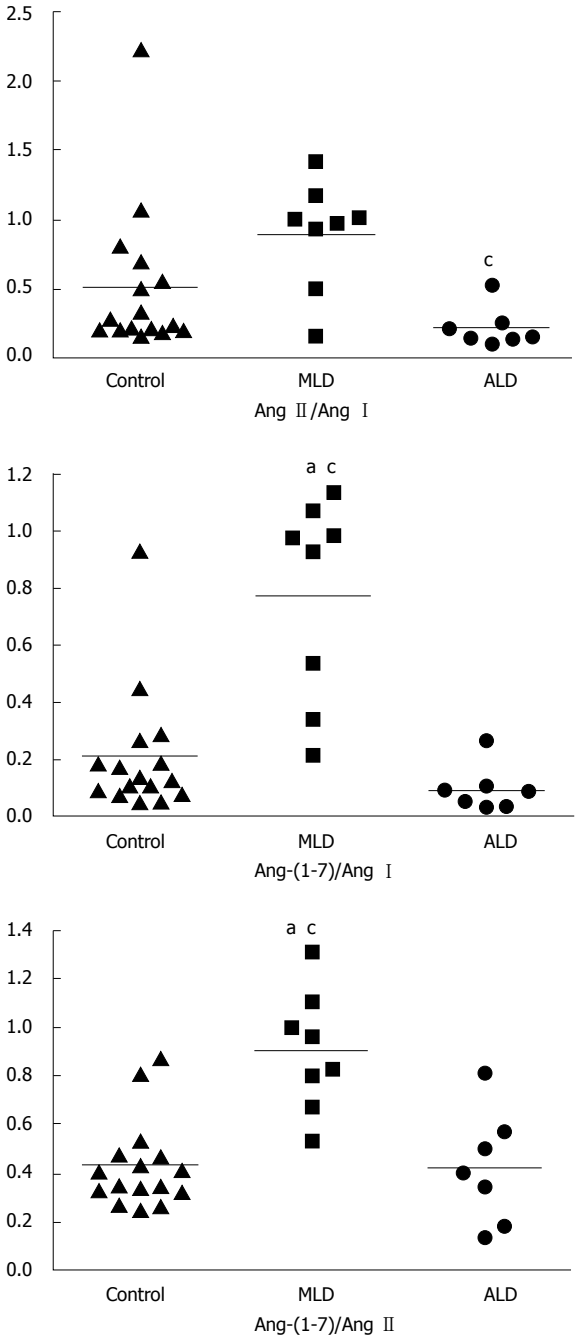

Figure 1 Ratios between angiotensins in healthy controls, and in patients with mild-to-moderate (MLD) and advanced liver disease (ALD). [a]$P < 0.05$ for the comparisons with the control group (Kruskal-Wallis followed by Dunn test for median comparisons). [c]$P < 0.05$ for the comparison between the MLD and ALD groups (Kruskal-Wallis followed by the Dunn test for median comparisons). Ang Ⅰ: Angiotensin Ⅰ; Ang Ⅱ: Angiotensin Ⅱ; Ang-(1-7): Angiotensin-(1-7).

DISCUSSION

The present study supports the concept that RAS may contribute to circulatory dysfunction in human cirrhosis. In general, our data showed that the progression of liver dysfunction is characterized by marked changes in circulating Ang-(1-7) and Ang Ⅱ levels. In the initial stages, the circulating RAS is not activated, although there is a predominance of Ang-(1-7), the vasodilator, rather than Ang Ⅱ. On the other hand, the advanced stages of cirrhosis show an activation of peripheral and splanchnic RAS, and a metabolic deviation toward the RAS vasodilator axis in the splanchnic circulation. Furthermore, we observed a positive correlation between the Ang-(1-7)/Ang Ⅱ ratio and cardiac output as well as a negative correlation between this ratio and systemic vascular resistance, indicating that the final functional effects of the RAS may reflect a balance between these 2 opposing axes. Taken together, these findings suggest a dynamic change in RAS profile according to disease stage (mild-to-moderate *vs* advanced) and vascular bed (peripheral *vs* splanchnic circulation), which could interfere with hemodynamic parameters in human cirrhosis.

The first part of this study evaluated circulating RAS components according to the stage of liver disease and without the interference of any kind of RAS blockade. The RAS profile was completely different in mild-to-moderate cirrhosis when compared to advanced liver disease. The upstream RAS components (PRA and Ang Ⅰ), which are common to both RAS axes and indicate

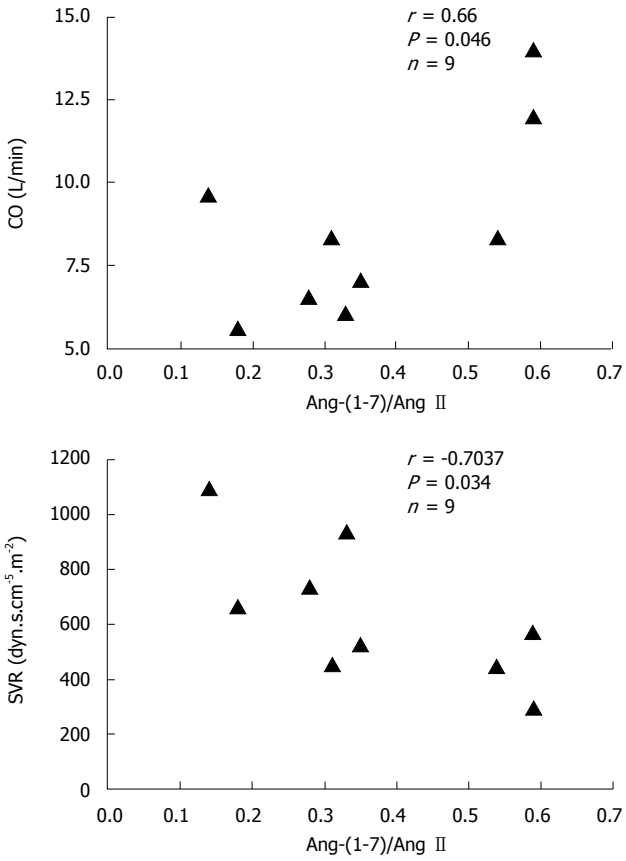

Figure 3 Correlations between Ang-(1-7)/Ang Ⅱ ratios and CO and SVR. Correlation coefficients (*r*) and *P* values were calculated by Spearman's test.

the level of system activation, were increased in ALD patients compared to MLD and healthy controls. Ang Ⅰ and Ang Ⅱ levels were also reduced in the MDL group even in comparison to healthy controls, whereas the ALD group exhibited an overall elevation of PRA and angiotensins when compared to other groups. Other studies have also detected increased PRA and Ang Ⅱ levels in ALD patients[8,18]. In the initial stages of human cirrhosis, PRA measurements revealed a non-activated or even suppressed circulating RAS[16,18]. In this regard, we have recently found that chronic treatment with propranolol in advanced cirrhotic patients is characterized by marked changes in the precursors of the RAS cascade (renin and Ang Ⅰ) with repercussions in the 2 main components of the RAS [Ang Ⅱ and Ang-(1-7)] in the splanchnic and peripheral circulation[15]. Additionally, treatment with propranolol seemed to be able to control the hyperdynamic circulation of cirrhotic patients probably resulting from an overall RAS inhibition, but without changes in the balance between the 2 RAS arms: ACE-Ang-AT1 receptor (vasoconstrictor) *vs* ACE2-Ang-(1-7)-Mas receptor (vasodilator)[15]. Taken together, our previous and present data further support the idea that a possible therapeutic approach for advanced human cirrhosis could be the combination of beta blockade with AT_1 receptor antagonism or ACE inhibition.

Experimental studies have recently evaluated Ang-(1-7) in bile duct-ligated (BDL) rats. Paizis *et al*[14] demonstrated that in both BDL rat and human livers there was an increased ACE2 expression and activity that might facilitate the conversion of Ang Ⅱ to Ang-(1-7). Pereira *et al*[12] demonstrated that the progression of liver dysfunction in BDL rats was characterized by marked changes in Ang-(1-7) and Ang Ⅱ levels and the overall activation of circulating RAS was associated with the progression of hepatic fibrosis. Subsequently, Herath *et al*[13] also found RAS activation in chronic liver injury to be associated with upregulation of ACE2, Mas receptor and hepatic conversion of Ang Ⅱ to Ang-(1-7), leading to increased circulating Ang-(1-7). Taken together, these studies support the presence of an activated ACE2-Ang-(1-7)-Mas receptor axis in liver injury that may counteract the effects of Ang Ⅱ[12,13]. Indeed, blockade of Ang-(1-7) with A-779 worsened the cirrhosis evolution in BDL rats by increasing

liver fibrosis[12].

As mentioned above, in the circulation, RAS seems to act through 2 opposing axes, the classic ACE-Ang Ⅱ-AT1 receptor (vasoconstrictor) and the counter-regulatory ACE2-Ang-(1-7)-Mas receptor (vasodilator)[1,2]. The increase of the Ang-(1-7)/Ang Ⅱ ratio suggests a deviation of RAS metabolism toward Ang-(1-7) formation in MLD patients when compared to the ALD group. The comparison between peripheral and splanchnic levels of angiotensins also revealed a differential regulation in LT patients. While an increased Ang-(1-7)/Ang Ⅱ ratio was detected in the splanchnic circulation, the ratio between Ang Ⅱ and Ang Ⅰ (an indirect estimation of net ACE activity) predominated in the peripheral circulation. Arterial splanchnic vasodilation was consistently detected in human cirrhosis[8,19]. A large number of studies have demonstrated the vasodilatory effect of Ang-(1-7)[20-23]. Possible mechanisms for this effect include bradykinin potentiation[21,22], enhanced prostacyclin (PGI_2) release from vascular smooth muscle cells[23] and direct stimulation of nitric oxide (NO) synthesis[20,22]. NO, PGI_2, carbon monoxide, endocannabinoids and other vasodilators have been associated with arterial splanchnic vasodilation[24]. Our results suggest that the reduction of Ang Ⅱ levels accompanied by an increased Ang-(1-7)/Ang Ⅱ ratio in the splanchnic circulation may be, at least in part, responsible for changes in vascular splanchnic tone. A possible explanation for this finding is that the elevated expression and activity of ACE2[13,14] during hepatic injury could promote the synthesis of Ang-(1-7). During initial stages of the disease, hyperdynamic circulation is responsible for the maintenance of cardiovascular system homeostasis. The increase of the Ang-(1-7)/Ang Ⅱ ratio in the peripheral circulation in MLD patients suggests that a deviation of RAS metabolism toward the vasodilator axis could be responsible at least in part for the reduction of the systemic vascular resistance. However, as the disease progresses, the splanchnic vasodilation continues to increase and the hyperdynamic circulation is insufficient to compensate for the effective arterial hypovolemia, leading to a reduction in blood pressure, which, in turn, could stimulate the classic ACE-Ang Ⅱ-AT_1 receptor axis of the RAS in the peripheral circulation, the sympathetic nervous system and vasopressin release, as an attempt to restore blood volume and systemic perfusion pressure[9]. At this stage, in spite of the continued increase in splanchnic vasodilation, the systemic vascular resistance is kept low although constant. As the splanchnic circulation is resistant to the effect of Ang Ⅱ, noradrenaline and vasopressin due to the local release of NO and other vasodilators[25], the maintenance of arterial pressure could be the result of vasoconstriction in extra-splanchnic vascular areas[26]. This is in accordance with the reduction in the Ang-(1-7)/Ang Ⅱ ratio in the peripheral circulation from mild-to-moderate to advanced stages of cirrhosis, and from the splanchnic to the peripheral circulation in LT patients.

The correlation between the Ang-(1-7)/Ang Ⅱ ratio and hemodynamic parameters (cardiac output and systemic vascular resistance) suggests that not only Ang Ⅱ, but also an excessive formation of Ang-(1-7) may be involved in circulatory changes in human cirrhosis. Cardiac output and systemic vascular resistance depends on the balance between the 2 RAS axes. Besides vascular effects, the literature has also provided evidence of a role for Ang-(1-7) in the regulation of cardiac function[27,28]. Indeed, Ang-(1-7) increases cardiac output and stroke volume in rats[28]. Moreover, the finding that isolated hearts from Mas-knockout mice exhibited an impaired function and an increase in coronary vascular resistance supports the importance of the Ang-(1-7)-Mas receptor axis in cardiovascular function[28]. In summary, the cardiovascular effects of Ang-(1-7) suggest a further mechanism by which RAS may contribute to altered vascular tone in cirrhosis.

It should be also pointed that we are aware of the limitations of our study design. First, peripheral blood samples generally represent the cumulative expression of RAS in multiple tissues and may not reliably reflect molecular activity in the splanchnic circulation. For this reason, we did manage to collect samples from the portal vein during liver transplantation. However, it is still difficult to compare these findings to the samples collected in the peripheral blood from outpatients. Another concern is the use of diuretics in ALD patients which could produce relative hypovolemia and activation of the ACE-Ang Ⅱ-AT_1 receptor axis. However, the diuretics are probably not the sole cause of this activation, since their interruption normally reduces but does not normalize PRA[29]. Nevertheless, some aspects of this study may increase the strength of our findings, such as the utilization of strictly defined inclusion and exclusion criteria and the well-established protocol for the measurements of PRA and angiotensins.

In conclusion, based on our previous[15] and present findings, the relationship of Ang-(1-7) and Ang Ⅱ may play a role in hemodynamic changes of human cirrhosis. We hypothesize that the ACE2-Ang-(1-7)-Mas receptor axis predominates in the peripheral circulation in the initial stages of disease (MLD patients) and in the splanchnic circulation in the advanced stages of cirrhosis (LT group), both contributing to a reduction in vascular resistance and consequently to hyperdynamic circulation. In the peripheral circulation of ALD patients, when compared to the splanchnic circulation, the ACE-Ang Ⅱ-AT_1 receptor arm predominates, probably leading to extra-splanchnic vasoconstriction that occurs at this stage. However, further studies with a larger number of patients should address the precise role of RAS in human cirrhosis. If these preliminary data are confirmed, future therapies interfering with 2 RAS axes in both the systemic and splanchnic circulations should lead to more success in the management of reversible fibrosis[30] and hemodynamic changes in human cirrhosis.

COMMENTS

Background

Liver cirrhosis has been recently studied in the light of the new view of the renin angiotensin system (RAS). It is becoming clear that the RAS can influence liver cirrhosis through its 2 main arms. While the angiotensin converting enzyme (ACE)-angiotensin (Ang) Ⅱ-AT1 receptor arm contributes to liver tissue injury and fibrosis and the maintenance of basal vascular tonus in non-compensated cir-

rhosis, the activation of the ACE2-Ang-(1-7)-Mas receptor arm exerts anti-fibrotic actions and probably has also a role in arterial vasodilation in liver cirrhosis.

Research frontiers

This study represents an initial approach to understand how RAS mediators change according to the stage of human cirrhosis and, more importantly, how the relationship between Ang-(1-7) and Ang Ⅱ may affect the hemodynamic parameters during liver transplantation.

Innovations and breakthroughs

The data showed that the progression of liver dysfunction is characterized by marked changes in circulating Ang-(1-7) and Ang Ⅱ levels. At the initial stages, there is a predominance of Ang-(1-7) rather than Ang Ⅱ. On the other hand, advanced stages of cirrhosis show an activation of peripheral and splanchnic RAS, and a deviation toward the formation of Ang-(1-7) in the splanchnic circulation. Furthermore, there was a positive correlation between the Ang-(1-7)/Ang Ⅱ ratio and cardiac output and a negative correlation between this ratio and systemic vascular resistance, indicating that the final functional effects of the RAS may reflect a balance between these 2 opposing peptides.

Applications

According to this study, future therapies modifying the 2 RAS axes in both the systemic and splanchnic circulation should lead to more success in the management of reversible fibrosis and the hemodynamic changes in human cirrhosis.

Peer review

The manuscript "The relationship between angiotensin (1-7) and angiotensin Ⅱ correlates with hemodynamic changes in human liver cirrhosis" is a preliminary, well designed study with a small cohort of patients for each cirrhotic group studied, presented by an experienced research group that, on the basis of the results of this study and those obtained in a previous work (published in World J Gastroenterol, 2008), concluded that the relationship between Ang-(1-7) and Ang Ⅱ may play a role in hemodynamic changes in human cirrhosis. If the results are corroborated in future studies, a novel therapy could be designed for management of reversible fibrosis and hemodynamic changes in human cirrhosis.

Abstract

AIM: To examine the methylation status of the promoter region of the checkpoint with forkhead-associated and ring finger (CHFR) and microsatellite mutator status in 59 primary gastric cancers.

METHODS: We investigated the promoter methylation of CHFR in 59 cases of gastric cancer using methylation-specific PCR. Five microsatellite loci were analyzed using high-intensity microsatellite analysis reported previously, and *p53* gene mutations were investigated by direct sequencing.

RESULTS: Twenty cases (33.9%) showed promoter methylation and no relation was observed with the clinicopathological factors. We found that the promoter methylation of CHFR was frequently accompanied with microsatellite instability (MIN). Seven of 20 (35.0%) cases showed MIN in hypermethylation of the CHFR tumor, while three of 39 (7.7%) cases showed MIN in the non-methylated CHFR tumor ($P < 0.01$). However, we failed to find any relationship between CHFR methylation and p53 mutation status.

CONCLUSION: The coordinated loss of both the mitotic check point function and mismatch repair system suggests the potential to overcome the cell cycle check point, which may lead to an accumulation of mutations. However, the *p53* mutation was not related to hypermethylation of the CHFR promoter and MIN, which indicates that an abnormality in p53 occurs as an independent process from the mismatch repair deficiency in carcinogenesis.

Key words: Checkpoint with forkhead-associated and ring finger; Methylation; Microsatellite instability; Gastric cancer; p53

INTRODUCTION

Checkpoint with forkhead-associated and ring finger (CHFR) is a recently identified gene, which is localized to chromosome 12q24.33[1]. CHFR functions as an important checkpoint protein early in the G2/M transition and its activation delays the cell cycle in prophase, thus preventing chromosome condensation in response to the mitotic stress induced by nocodazole or paclitaxel[2-4]. In addition, CHFR promotes cell survival in response to mitotic stress. CHFR is ubiquitously expressed in normal tissues; however, it is frequently down-regulated in human cancer, mostly as a result of hypermethylation of its CpG island in the promoter region. CHFR down-regulation has been found in primary lung, colon, esophagus, nasopharyngeal and gastric carcinomas[5-12]. In gastric cancer, CHFR

promoter hypermethylation has been reported to lead to chromosome instability[13]. Another study has shown that the aberrant methylation of CHFR appears to be a good molecular marker with which to predict the sensitivity of gastric cancer to microtubule inhibitors[4]. In this study, we first investigated and showed CHFR methylation and microsatellite instability in gastric cancer patients.

Genetic instability is one of the hallmarks of human cancer. In colon cancer, tumors with chromosomal instability (CIN) can be distinguished from those with microsatellite instability (MIN), thereby showing instability in the GC-rich tandem repeat[14,15]. While the former frequently show aneuploidy, the karyotype in the latter is usually preserved. In gastric cancer, tumors with CIN are frequently observed and such cancers show poor prognosis and p53 mutation, such as colon cancer[16-18]. However, whether gastric cancer can be categorized into CIN and MIN phenotypes like colon cancer remains to be elucidated. An aberrant CHFR function leads to the disruption of normal chromosomal segregation, and it could be considered as a cause of CIN. However, a recent study failed to show any correlation between CIN and the loss of CHFR function[19], although CHFR knockout mice show CIN[20]. On the other hand, the MIN phenotype has been shown to be associated with the hypermethylation of the CHFR promoter[19,21,22]. The hypermethylation of CHFR and hMLH1 has been shown to occur concurrently, and CHFR methylation is not associated with CIN in gastric cancer[21].

We have previously reported the methylation status of the promoter region of the CHFR gene in 110 primary breast cancers[5]. We observed hypermethylation of the CHFR promoter region in only one case (0.9%) of breast cancer. Intriguingly, the only case that revealed the hypermethylation of the CHFR promoter region also showed the MIN phenotype. In the present study, we examined the methylation status of the promoter region of CHFR and microsatellite mutator status in 63 primary gastric cancers. This is believed to be the first study to show the striking relationship between CHFR silencing and MIN in gastric cancers.

MATERIALS AND METHODS

Specimens and extraction of genomic DNA

Fifty-nine primary gastric carcinomas and paired normal tissue specimens were obtained from Japanese patients who underwent surgery at the Department of Surgery and Science, Kyushu University Hospital, from 1999 to 2002. Informed consent was obtained from all patients prior to tissue acquisition. Immediately after resection, the specimens were placed in liquid nitrogen and then were used for analysis of genomic DNA. The remaining tissue specimens were routinely processed for histopathological analysis by histopathology specialists in our hospital. The histopathological diagnosis was determined according to the criteria of the Japanese Gastric Cancer Society. Frozen tissue specimens were broken up in liquid nitrogen and lysed in digestion buffer (10 mmol/L Tris-HCl, pH 8.0, 0.1 mol/L EDTA, pH 8.0, 0.5% SDS, 20 μg/mL pancreatic RNase). After treatment with proteinase K and extraction with phenol, DNA was precipitated with ethanol, and then was dissolved in 1 TE (10 mmol/L Tris-Cl; pH 7.5, 1 mmol/L EDTA).

Methylation analysis

Sodium bisulfite conversion of genomic DNA was performed using the EZ DNA Methylation Kit (Zymo Research, Orange, CA, USA), which integrates DNA denaturation and bisulfite conversion processes into a single step, followed by rapid in-column desulfonation and DNA clean-up, according to the manufacturer's instructions. Methylation-specific PCR (MS-PCR) was carried out with the following oligonucleotide primers, which were designed to be specific to either methylated or unmethylated DNA after sodium bisulfite conversion as described above. Methylated DNA-specific primers were MF1 (forward: 5'-ATATAATATGGCGTCGATC) and MR1 (reverse: 5'-TCAACTAATCCGCGAAACG). Unmethylated DNA-specific primers were UF1 (forward: 5'-ATATAATATGGTGTTGATT) and UR1 (reverse: 5'-TCAACTAATCCACAAAACA)[18]. PCR amplification consisted of 35 cycles of 94℃ for 1 min, 58℃ for 1 min, and 72℃ for 1 min (MF1 and MR1); and 94℃ for 1 min, 48℃ for 1 min and 72℃ for 1 min (UF1 and UR1). The resultant PCR products were separated on 2% agarose gels. CpGenome Universal Methylated DNA (Chemicon International, Temecula, CA, USA), which is enzymatically methylated human male genomic DNA, was used as a positive control for MS-PCR. Purified genomic DNA isolated from the human placenta (BioChain Institute, Hayward, CA, USA) was used as a negative control for non-methylated DNA. All analyses included positive and negative controls, and were performed at least twice.

MIN analysis

Five human dinucleotide microsatellites, D2S123, D5S107, D10S197, D11S904 and D13S175, were used as a marker for the MIN analysis. Using genomic DNA derived from the tissue specimens, the five microsatellite sequences were amplified by PCR. The oligonucleotide primers that corresponded to the microsatellite sequences were synthesized and purified by HPLC, and the forward primers were labeled with fluorescent compounds, ROX (6-carboxy-x-rhodamine), 6-FAM (6-carboxyfluorescein) or HEX (6-carboxy-2',4',7',4,7,-hexachloro-fluorescein). PCR reactions were performed using Tamara Taq Reagent Kits (Takara Bio, Ohtsu, Japan) and Applied Biosystems GeneAmp PCR system 9700 (Applied Biosystems, Foster City, CA, USA). A 50-mL reaction mixture contained 1 × reaction buffer, 350 mmol/L each dNTP, 10 pmol each primer, 2.5 U Taq polymerase and 25 ng genomic DNA. The thermal conditions of the system were as follows: one cycle at 95℃ for 4 min; 35 cycles at 95℃ for 30 s, 55℃ for 30 s, and 72℃ for 30 s; and one cycle at 72℃ for 10 min. Next, 0.5 U T4 DNA polymerase was added to the mixture, followed by incubation at 37℃ for 10 min. To compare electrophoretic profiles between two samples, 6-FAM- or ROX-labeled products and HEX-labeled products were mixed, denatured and loaded onto an ABI

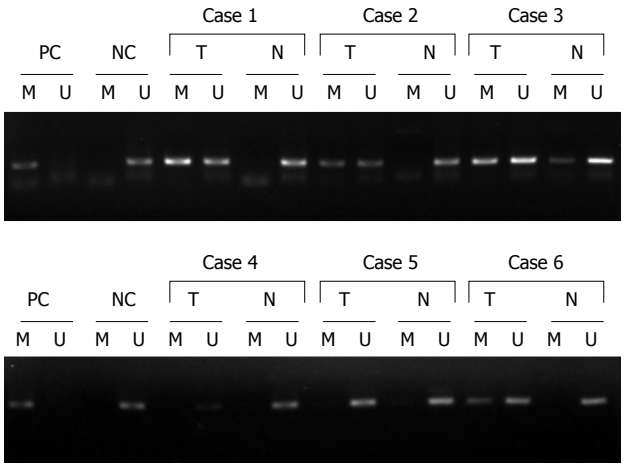

Figure 1 Methylation of the promoter region of the *CHFR* gene in primary gastric cancer, analyzed by MS-PCR. The U lane represents the amplification of unmethylated alleles, while the M lane represents that of methylated alleles. CHFR methylation was present in cases 1, 2, 3 and 6. CpGenome Universal Methylated DNA, which is enzymatically methylated human male genomic DNA, was used as a positive control (PC), and purified genomic DNA isolated from human placenta was used as a negative control (NC) as non-methylated DNA. T: Tumor; N: Normal.

373A DNA Sequencer or ABI PRISM 310 Genetic Analyzer (Applied Biosystems). The data were processed using the ABI software program, GeneScan ver. 1.2.2. or 3.1.2 (Applied Biosystems).

DNA sequence analysis of p53

The base sequence was determined from exon 4 to 8 of p53 using a PCR direct sequence. The PCR product of p53 was purified with a Microcon-100 Microconcentrator (Amicon, Beverly, MA, USA). The direct sequencing of PCR products was performed using the ABI Prism Big Dye Terminator Cycle Sequencing Ready Reaction Kit (Perkin-Elmer Norwalk, CT, USA). The cycle sequence product was electrophoresed and analyzed on the Applied Biosystems Model 311 Genetic Analyzer (Perkin-Elmer).

RESULTS

CHFR promoter hypermethylation in gastric cancer

We studied the methylation status of CHFR for 59 cases of primary gastric cancer. We detected the hypermethylation of the CHFR promoter in 20 of 59 (33.9%) cancer tissue specimens studied (Figure 1 and Table 1), but only in 6 of 59 (10.2%) of the corresponding non-neoplastic gastric mucosa specimens (Table 1). CHFR hypermethylation occurred at a similar frequency in early and advanced gastric cancers, and none of the clinicopathological factors correlated with hypermethylation of the CHFR promoter (Table 2). The methylation status did not significantly influence the event-free survival rate as analyzed by a Kaplan-Meier curve (data not shown).

Microsatellite alterations

MIN was analyzed and we confirmed the results for 56 of 59 samples. MIN was recognized in 10 of 56 cases (17.2%) (Table 2). We observed a strong correlation be-

tween hypermethylation of CHFR and MIN. Seven of 20 (35.0%) cases showed MIN in hypermethylation of the CHFR tumor, while three of 39 (7.7%) cases showed MIN in the non-methylated CHFR tumor.

p53 mutation

All 59 of the gastric cancer cases were investigated for a mutation in exons 5-9 of p53. The mutation spectrum and the discussion about the rate of frequency have all been previously reported[23]. We detected eight mutations of p53, however, we failed to find any relationship between CHFR methylation and p53 mutation status.

DISCUSSION

It has been proposed that the spontaneous mutation rate in normal cells is not sufficient to generate the number of mutations found in human cancers, since there are large numbers of mutations observed in human cancers[24]. In other words, cancer cells exhibit genetic instability. It is known that there are two types of genetic instability in gastrointestinal cancer carcinogenesis, CIN and MIN[14,15].

In colon cancer, tumors with CIN can be clearly distinguished from those with MIN. While the former frequently show aneuploidy, the karyotype in the latter is usually preserved. The MIN tumors, as a result of a defect in DNA mismatch repair, show instability in the GC-rich tandem repeat, the so-called MIN, which is interspersed into the genome. The DNA mismatch repair MMR system as represented by hMLH1 is essential for maintaining genomic stability and preventing tumor formation, and it is highly conserved in evolution. Recent studies have shown that MMR proteins are required for the S-phase checkpoint activation induced by ionizing irradiation[25], and the G2-checkpoint activation induced by cisplatin, SN1 DNA methylators, and 6-thioguanine[26,27].

In gastric cancer, tumors with CIN have been frequently observed and such cancers show a poor prognosis, and *p53* mutation[16-18]. However, gastric cancer has not been clearly categorized into CIN and MIN phenotypes, such as for colon cancer, since gastric cancer has various types of histological groups, and MIN tumors do not occur as frequently as in colon cancer[28]. CHFR is a recently identified gene, which functions as an important checkpoint protein early in the G2/M transition, and its activation delays the cell cycle in prophase, thus preventing chromosome condensation in response to mitotic stress[1]. The aberrant CHFR function leads to the disruption of normal chromosomal segregation, and it could thus be considered as a cause of CIN. However, a recent study has failed to show any correlation between CIN and the loss of CHFR function[19]. In contrast to the mismatch repair genes, CHFR does not seem to participate in the DNA damage checkpoint or DNA repair pathways. CHFR regulates an early mitotic checkpoint, during prophase, in response to the disruption of normal microtubule formation or stabilization, as assessed after treatment with microtubule poisons such as nocodazole, colcemid and taxanes[1]. Recently, the association between the hypermethylation of the *MMR* gene of hMLH1 promoter and that of the CHFR promoter has been reported[22]. Brandes *et al*[22] have reported a correlation between hMLH1 and CHFR methylation in cell lines with the MIN phenotype in colon cancer. They have reported that there is no correlation between promoter methylation of CHFR and other genes, including those that have been shown to be silenced by promoter methylation in the CIMP (CpG island methylation) phenotype. These results have suggested that a relationship exists between CHFR methylation and the MIN phenotype, but not the CIN phenotype. Along with this suggestion, our results show a direct relationship between the MIN phenotype and the promoter methylation status of CHFR in gastric cancer. We previously reported the methylation status of the promoter region of the CHFR gene in 110 primary breast cancers[5]. We observed the hypermethylation of the CHFR promoter region in only one case (0.9%). Intriguingly, only the one case that revealed hypermethylation of the CHFR promoter region showed the MIN phenotype. These results show the direct relationship between MIN and CHFR promoter methylation.

The majority of gastric cancers exhibit DNA aneuploidy[16-18]. It is presumed that unknown genetic defects lead to CIN, although no such abnormalities which are directly associated with CIN have been identified. CHFR

is a possible inducer of CIN, however, CHFR abnormality associated with CIN has not been demonstrated. Rather, CHFR methylation was found in the case of breast cancer with the MIN tumor. The significant correlation between methylation of CHFR and MIN suggests that the loss of CHFR expression allows the cells, which are deficient in MMR activity, to progress through the G2/M cell cycle checkpoint without delay. MMR genes are also important in the regulation of the G2/M checkpoint. Our previous study has shown the importance of MMR genes at the G2/M arrest point in the response against 5-fluorouracil (5-FU)[29]. The normal p53 cell line underwent both G1 and G2/M arrest after treatment with 5-FU. The cell line with mutated *p53* failed to undergo G1 arrest but showed G2/M arrest. The cell lacking the *MMR* gene failed to undergo G2/M arrest but underwent G1 arrest. These results shows that *MMR* genes are associated with G2/M arrest. It has been reported that promoter methylation is an early event in the process of carcinogenesis, as extensive methylation is found in the colon polyp. Therefore, abnormality of both the CHFR and MMR systems provides a survival advantage for gene alterations in carcinogenesis, since the cell cycle does not stop at the G2/M checkpoint without the CHFR and MMR system, even if there is DNA mismatch or damage. This is thought to be one of the mechanisms that generate a mutator phenotype in cancer. However, in our study, the *p53* mutation was not frequent in cases that showed methylation of CHFR and MIN. Usually, both a *p53* mutation and loss of heterozygosity of *p53* are observed in CIN tumors. *p53* mutation has been found only rarely in tumors that show MIN, and this is evidence for the presence of two different pathways for colon carcinogenesis.

In conclusion, we herein demonstrated a correlation between the hypermethylation of CHFR and the MIN of gastric cancer patients. Both MIN and CHFR hypermethylation induce mitotic check point disruption and confer a survival advantage to the cells, however, this survival advantage does not lead to either *p53* mutation or CIN in gastric cancer.

COMMENTS

Background

Checkpoint with forkhead and ring finger (CHFR) is a mitotic stress checkpoint gene whose promoter is frequently methylated in various kinds of cancer. In this study, the authors examined the methylation status of the promoter region of CHFR and microsatellite mutator status in 59 primary gastric cancers.

Research frontiers

An aberrant CHFR function leads to the disruption of normal chromosomal segregation, and it could thus be considered as a cause of chromosomal instability (CIN). However, a recent study failed to show any correlation between CIN and the loss of CHFR function, although CHFR knockout mice did show CIN.

Innovations and breakthroughs

This is believed to be the first study to show the striking relationship between CHFR silencing and microsatellite alteration in gastric cancer.

Applications

The results suggest that an abnormality in the CHFR and MMR systems may provide a survival advantage in gastric carcinogenesis.

Terminology

CHFR is localized to chromosome 12q24.33. CHFR functions as an important checkpoint protein early in the G2/M transition, and its activation delays the cell cycle in the prophase.

Peer review

This study demonstrated a clear correlation between the hypermethylation of CHFR and the microsatellite instability of gastric cancer patients. As a result, the reviewer think that this is an important paper that contributes positively to progress in this field.

Abstract

AIM: To investigate the role of smoking, alcohol drinking, family history of cancer, and body mass index (BMI) in sporadic colorectal cancer in southern Chinese.

METHODS: A hospital-based case-control study was conducted from July 2002 to December 2008. There were 706 cases and 723 controls with their sex and age (within 5 years) matched. An unconditional logistic regression model was used to analyze the association between smoking, alcohol drinking, family history of cancer, BMI and sporadic colorectal cancer.

RESULTS: No positive association was observed between smoking status and sporadic colorectal cancer risk. Compared with the non alcohol drinkers, the current and former alcohol drinkers had an increased risk of developing sporadic colorectal cancer (CRC) (adjusted OR = 8.61 and 95% CI = 6.15-12.05; adjusted OR = 2.30, 95% CI = 1.27-4.17). Moreover, the increased risk of developing sporadic CRC was significant in those with a positive family history of cancer (adjusted OR = 1.62, 95% CI = 1.12-3.34) and in those with their BMI $\geqslant$ 24.0 kg/m^2 (adjusted OR = 1.39, 95% CI = 1.10-1.75). Stratification analysis showed that the risk of developing both colon and rectal cancers was increased in current alcohol drinkers (adjusted OR = 7.60 and 95% CI = 5.13-11.25; adjusted OR = 7.52 and 95% CI = 5.13-11.01) and in those with their BMI $\geqslant$ 24.0 kg/m^2 (adjusted OR = 1.38 and 95% CI = 1.04-1.83; adjusted OR = 1.35 and 95% CI = 1.02-1.79). The risk of developing colon cancer, but not rectal cancer, was found in former alcohol drinkers and in those with a positive family history of cancer (adjusted OR = 2.51 and 95% CI = 1.24-5.07; adjusted OR = 1.82 and 95% CI = 1.17-2.82).

CONCLUSION: Alcohol drinking, high BMI ($\geqslant$ 24.0 kg/m^2) and positive family history of cancer are the independent risk factors for colorectal cancer in southern Chinese.

Key words: Case-control; Colorectal cancer; Risk factors; Smoking; Alcohol drinking; Body mass index; Family history

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers in China. Although official statistic data are scanty, the reports from some regions indicate that the incidence of colorectal cancer increases[1,2]. During 1974-1999 in Henan Province, the incidence of esophageal carcinoma was significantly decreased

whereas that of CRC has increased over the last two decades[1]. In Guangdong Province, the incidence of CRC in Huidong County is getting close to that in the world[2]. These data suggest that more attention should be paid to the prevention and control of CRC.

In recent years, the epidemiological factors for CRC in Chinese have been extensively studied[3-8]. However, the results are uncertain. It has been reported that smoking is a risk factor for rectal cancer in Chinese[3] and is associated with the increased risk of developing rectal cancer in Singapore Chinese[4]. However, other studies showed that smoking is not a risk factor for CRC in Chinese[5-7]. Similarly, the relation between alcohol drinking and colorectal cancer in Chinese is controversial[3,6,8]. A population-based prospective cohort study showed that alcohol consumption is not significantly associated with the risk of developing CRC[8], but is associated with the risk of developing CRC in northern Chinese[6] and Hong Kong Chinese[3].

The reports about the association between body mass index (BMI) and colorectal cancer in thin Chinese are scanty. A study comprising 931 cases and 1552 controls in Shanghai demonstrated that BMI is a risk factor for colorectal cancer in men and pre-menopausal women[9]. Zhang *et al*[10] reported that family history is positively related with CRC. However, their data lack of multivariate analysis in unconditional logistic regression model adjusted by factors including age, sex, smoking status, alcohol consumption, family history of cancer, and BMI. Thus, the role of epidemiological factors for CRC in Chinese should be further investigated.

MATERIALS AND METHODS

Subjects and data collection

From July 2002 to December 2008, a hospital-based case-control study was conducted in Guangzhou City. Patients with sporadic CRC were recruited in our study with a response rate of about 95%. A total of 513 patients were recruited as a test group between July 2002 and April 2008 at the Sixth Affiliated Hospital (Gastrointestinal and Anal Hospital) of Sun Yat-Sen University (Guangzhou, China), Sun Yat-Sen University Cancer Center (Guangzhou, China), the First Affiliated Hospital of Sun Yat-Sen University (Guangzhou, China) and the Affiliated Tumor Hospital of Guangzhou Medical College (Guangzhou, China). To validate our findings, 193 patients were recruited as a validation group between May 2008 and December 2008 at Guangdong Provincial People's Hospital and Panyu People's Hospital (Guangzhou, China). Cancer-free controls were randomly selected from about 10000 individuals in Guangzhou City during the same period, with a response rate of about 85%. Five hundred and twenty-three controls were recruited as an original test group and 200 controls as a validation group. Cases of familial adenomatous polyposis and those fulfilling the criteria of Amsterdam for hereditary non-polyposis colorectal cancer were excluded. Thus, 706 sporadic CRC patients and 723 cancer-free controls were included in this study. All subjects were genetically-unrelated Han nationality Chinese from Guangzhou City and its surrounding regions. The control subjects were sex and age (within 5 years) matched to the patients. The study was approved by the Review Board of Sun Yat-Sen University.

Exposure assessment

Each participant was scheduled for an interview after he or she gave his or her written informed consent, and a structured questionnaire was designed by the interviewers to collect data on smoking status, alcohol consumption and other factors including BMI, family history of cancer, menstrual history, sex and age. The participants who smoked < 100 cigarettes in their lifetime were defined as non smokers. Otherwise, they were defined as smokers. Smokers who were quitted with smoking for > 1 year prior to enrollment were considered former smokers, and the remaining were defined as current smokers. Similarly, participants who consumed alcohol at least once a week for ⩾ 1 year were defined as alcohol drinkers and the remaining as non alcohol drinkers. Alcohol drinkers who were quitted with drinking for ⩾ 1 year were defined as former alcohol drinkers, and the others as current drinkers. Those with a positive family history of cancer were defined as the first- or second-degree relatives or both. This study used the BMI cutoff points recommended by the Cooperative Meta-Analysis Group on Obesity in China[11]. Subjects with their BMI ⩽ 23.9 kg/m^2 were categorized as underweight and normal body weight, while those with their BMI ⩾ 24.0 kg/m^2 were categorized as overweight and obese.

Statistical analysis

Two-sided chi-square test was performed to assess differences in age, sex, smoking status, alcohol consumption, family history of cancer and BMI between patients and controls. An unconditional logistic regression model was used to estimate the association between case-control status and factors including smoking status, alcohol consumption, BMI, and family history of cancer, measured by odds ratio (OR) and corresponding 95% confidence interval (CI). Logistic regression modeling was used in trend test. Statistical analysis was performed using SPSS for Windows (version 13.0). All statistical analyses were 2-sided and $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of studied Chinese

A total of 706 sporadic CRC cases and 723 cancer-free controls were included in statistical analysis. The differences in distribution of age, sex, menstrual history between the cases and controls were not statistically significant ($P = 0.992$, 0.937, 0.883, respectively) (Table 1). Compared with the controls, the cases were more likely to be current smokers and current drinkers (current smokers: 44.8% *vs* 30.3%, $P < 0.0001$ and current drinkers: 52.8% *vs* 19.4%, $P < 0.0001$). Moreover, the cases tended to have a higher BMI ($P = 0.002$) and a positive family history of cancer ($P = 0.018$). Therefore, these variables were further

[1]Adjusted for age, sex, smoking status, alcohol drinking, family history of cancer, BMI.

adjusted in multivariate logistic regression model for controlling any residual effect of possible confounding on the main effect of studied factors.

Risk factors for sporadic colorectal cancer

Logistic regression analysis showed that compared with the non alcohol drinkers, current and former alcohol drinkers had a significantly increased risk of developing sporadic CRC (adjusted OR = 8.61 and 95% CI = 6.15-12.05; adjusted OR = 2.30 and 95% CI = 1.27-4.17) (Table 2). Similarly, the increased risk of developing sporadic CRC was significantly greater in those with a positive family history of cancer (adjusted OR = 1.62, 95% CI = 1.12-3.34) and in those with their BMI ≥ 24.0 kg/m^2 (adjusted OR = 1.39, 95% CI = 1.10-1.75). There was a significant trend to develop CRC (P_{trend} < 0.00001) due to alcohol drinking. However, smoking status was not positively correlated with the risk of developing sporadic CRC.

Stratification analysis of colon and rectal cancer

We further performed a stratification analysis of the association between selected variables and risk of developing colon and rectal cancer in subgroups (Table 3). The risk of developing both colon and rectal cancers was increased in current alcohol drinkers (adjusted OR = 7.60 and 95% CI = 5.13-11.25; adjusted OR = 7.52 and 95% CI = 5.13-11.01) and in those with their BMI ≥ 24.0 kg/m^2 (adjusted OR = 1.38 and 95% CI = 1.04-1.83; adjusted OR = 1.35 and 95% CI = 1.02-1.79). The risk of developing colon cancer, but not rectal cancer, was found in former alcohol drinkers (adjusted OR = 2.51 and 95% CI = 1.24-5.07) and in those with a positive family history of cancer (adjusted OR = 1.82 and 95% CI = 1.17-2.82). However, smoking status was not significantly associated with the risk of developing CRC.

DISCUSSION

In our study, smoking status was not positively associated with the risk of developing sporadic CRC. Compared with the non alcohol drinkers, current and former alcohol drinkers had an increased risk of developing sporadic

[1]Adjusted for age, sex, smoking status, alcohol drinking, family history of cancer, BMI.

CRC. The increased risk of developing sporadic CRC was found in those with their BMI ≥ 24.0 kg/m^2 and in those with a positive family history of cancer. The stratification analysis showed that the risk of developing both colon and rectal cancers was increased in current alcohol drinkers and in those with their BMI ≥ 24.0 kg/m^2. The increased risk of developing colon cancer but not rectal cancer was found in former alcohol drinkers and in those with a positive family history of cancer.

It has been reported that smoking is related with the risk of developing invasive colorectal cancer and current smokers have a significantly increased risk of developing rectal cancer but not colon cancer compared with non smokers[12]. In a population-based case-control study recruiting 540 cases of colorectal cancer and 614 controls in Germany, current smokers had a significantly increased risk of developing colorectal cancer compared with non smokers[13]. Another report including 852 patients demonstrated that tobacco smoking is a risk factor for early colorectal cancer[14]. Inconsistent with the above reports, in our study, smoking was not associated with the risk of developing colorectal cancer. However, our results are consistent with the reported findings[7]. The different results might be due to the different time of smoking between mainland Chinese and other populations. The main increase in cigarette consumption in various Chinese communities occurred a few decades later than that of the Western countries[15]. Similarly, the prevalence of cigarette smoking reached its peak in Hong Kong about 20 years earlier than in mainland China[15]. Giovannucci *et al*[16,17] demonstrated that smoking is related to the risk of developing colorectal cancer only after allowing for an induction period of at least 35 years. It has been shown that long-term smoking is associated with the elevated risk of developing colorectal cancer[13,18].

Our results suggest that alcohol drinking was an independent risk factor for sporadic CRC, which is consistent with the findings in Japan, American, French, and Hong Kong[3,19-21]. However, the OR value in our study was much higher than the reported data, which may be due to the selection bias in our study. In our study, the cases were recruited from 6 hospitals, whereas the controls were enrolled from communities in Guangzhou City. Thus, the percentage of current alcohol drinkers in the controls was relatively low (Table 1).

Our study found that there was an independent association between BMI and sporadic CRC risk in Chinese. Insulin action decreases with increasing obesity[22]. Insulin resistance develops as a metabolic adaptation to increased levels of circulating non-esterified fatty acids released from adipose tissues. Because non-esterified fatty acids force the liver, muscles, and other tissues to store and oxidize fats for energy, the pancreas would secrete more insulin to prevent elevated concentrations of glucose in blood[23]. Increased blood insulin levels decrease insulin-like growth factor binding protein 1 levels, thus increasing free insulin-like growth factor 1 (IGF-1) levels[24]. It has been shown that insulin resistance is related with hyperinsulinaemia, IGF-1 and colorectal cancer[25-27]. In this study, the increased risk of developing colon cancer but not rectal cancer was associated with a positive family history of cancer, indicating that genetic susceptibility may play a more important role in the pathogenesis of colon cancer than in that of rectal cancer.

However, our study had several limitations, such as a small sample size, hospital-based case control, Chinese subjects, and lack of food intake information, which might result in improper findings.

In conclusion, in our study, we found that alcohol drinking and greater BMI (≥ 24.0 kg/m^2) are the independent risk factors for colon and rectal cancer in southern Chinese. The risk of developing colon cancer but not rectal cancer increases in former alcohol drinkers and in those with a positive family history of cancer. Because of the uncontrolled bias in selection of participants and retrospective design, our findings need to be further evaluated in well-designed larger epidemiological studies with different ethnic populations.

COMMENTS

Background

The incidence of colorectal cancer in China is growing. More attention should be paid to the prevention and control of colorectal cancer. However, the epidemiological factors for colorectal cancer are controversial.

Research frontiers

Although the association between the epidemiological factors and sporadic colorectal cancer has been studied, the relation between smoking, alcohol drinking, family history of cancer, body mass index (BMI) and sporadic colorectal cancer still remains uncertain. It is important to investigate the role of these factors in the development of sporadic colorectal cancer.

Innovations and breakthroughs

In this study, the authors found that current alcohol drinking and greater BMI ($\geqslant$ 24.0 kg/m^2) are the independent risk factors for colon and rectal cancer, while former alcohol drinking and positive family history of cancer are the independent risk factors for colon cancer in southern Chinese.

Peer review

In the case-control study, smoking, alcohol consumption, BMI and family history of cancer were evaluated in patients with sporadic colorectal cancer. The study showed that alcohol drinking, higher BMI ($\geqslant$ 24.0 kg/m^2) and positive family history of cancer were the independent risk factors for sporadic colorectal cancer in a southern Chinese. Its findings may contribute to the prevention and control of sporadic colorectal cancer.

Abstract

AIM: To investigate barriers to colorectal cancer (CRC) screening in a community population.

METHODS: We conducted a community-based case-control study in an urban Chinese population by questionnaire. Cases were selected from those completing both a fecal occult blood test (FOBT) case and colonoscopy in a CRC screening program in 2004. Control groups were matched by gender, age group and community. Control 1 included those having a positive FOBT but refusing a colonoscopy. Control 2 included those who refused both an FOBT and colonoscopy.

RESULTS: The impact of occupation on willingness to attend a colorectal screening program differed by gender. *P* for heterogeneity was 0.009 for case *vs* control group 1, 0.01 for case versus control group 2, and 0.80 for control group 1 *vs* 2. Poor awareness of CRC and its screening program, characteristics of screening tests, and lack of time affected the screening rate. Financial support, fear of pain and bowel preparation were barriers to a colonoscopy as a screening test. Eighty-two percent of control group 1 and 87.1% of control group 2 were willing attend if the colonoscopy was free, but only 56.3% and 53.1%, respectively, if it was self-paid. Multivariate odds ratios for case *vs* control group 1 were 0.10 among those unwilling to attend a free colonoscopy and 0.50 among those unwilling to attend a self-paid colonoscopy.

CONCLUSION: Raising the public awareness of CRC and its screening, integrating CRC screening into the health care system, and using a painless colonoscopy would increase its screening rate.

Key words: Colorectal cancer screening; Barrier; Community-based case-control study; Colonoscopy; Fecal occult blood test

INTRODUCTION

Colorectal cancer is the second to fifth cause of cancer death in urban populations among different cities in China. The incidence and mortality of colorectal cancer is increasing rapidly in developing countries[1,2]. Recently, strong evidence from several randomized intervention studies indicated that colorectal cancer screening is effective in reducing its mortality[3-7]. However, the reported compliance of colorectal cancer screening in the general population varies widely and is generally low. The reported participation rate for fecal occult blood tests (FOBT) ranges from 12% to 95% in community-based programs and from 12% to 27% for a flexible sigmoidoscopy[8-14].

In 2004, we carried out a free community-based colorectal cancer screening program in Hangzhou city in China, where the target population (38 337

people) was 40-74 years old. 14269 people accepted an immunochemical FOBT for colorectal cancer screening (participation rate was 37.2%) and of the 509 people who were positive, only 94 people accepted a free colonoscopy, a participation rate of 18.5% (94/509). Thus, 415 people refused the free colonoscopy[15]. Though poor knowledge about colorectal cancer, social factors and the test provider might have influenced compliance of colorectal cancer screening[16-21], it is not clear why people are unwilling to attend the colorectal cancer screening program in China. To better understand why people are unwilling to attend the colorectal cancer screening program in China, we conducted this study to explore the barriers to conducting a colorectal cancer screening.

MATERIALS AND METHODS

Study design and population

We conducted a population-based case-control study of barriers to colorectal cancer screening in Hangzhou city in China. Cases were selected from those who underwent both an FOBT and a colonoscopy in a previous colorectal cancer screening program, resulting in a total of 94 subjects. All permanent residents in the Changqing and Chaoming communities in the Xiachen district of Hangzhou city, aged from 40 to 74 years old, were invited to attend a free colorectal cancer screening program in 2004[15]. A two-step screening method was applied in this screening program. Immunochemical FOBT and a questionnaire of high-risk factors were used in the first step. If the FOBT was positive or the questionnaire reported high-risk factors [including other cancer or polypi history; or a family history of colorectal cancer among the first relatives; or at least two of the following histories: chronic coprostasis, chronic diarrhea, mucous bloody feces, stressful life events (such as divorce and deaths among the first relatives); and chronic appendicitis] then a colonoscopy without any auxiliary medicine was suggested as the second step. Only 11 subjects at the first step were identified as high-risk population by the questionnaire, so they were excluded from this study. Every qualified subject from the first step or the second step of screening was invited three times (orally, by letter, and by telephone invitation). If subjects refused all three invitations, we defined them as refusers that could be included as a control.

Two sets of control groups were designed to match the case group by gender, age group, and community location. Age groups were recorded into groups with an initial age of 40 years old by intervals of 5 years. Control group 1 included those had a positive FOBT test but refused a colonoscopy. Control group 2 included those who refused both an FOBT test and colonoscopy. We were able to accurately select cases and controls from the defined communities because there is a complete registration of all permanent residents in every district in Hangzhou city.

All subjects were asked to complete a questionnaire by interview in-person by fixed interviewers who were well-trained in advance. All data were recorded, numerically transformed into computer files at least three times, and their reliability confirmed for analysis. Data collection was performed in 2006-2007.

Table 1 Characteristics of subjects between case and control groups[1]

Characteristic	Case	Control 1	Control 2	*P*-value

[1]Definition: case, those completing both a fecal occult blood test (FOBT) and colonoscopy; control 1, those having a positive FOBT but refusing a colonoscopy, and control 2, those who refused both an FOBT and colonoscopy in a CRC screening program in 2004. [2]Estimated by yearly household income in Chinese Dollar (Yuan) divided by total number of family members.

Statistical analysis

The STATA 8.0 program was used for data analysis. One-way ANOVA was used to compare means between case and control groups. Chi-square (χ^2) was used for frequency data. If data were not suitable for χ^2 analyses, a Mann-Whitney *U* test was used to compare the ratio between two groups and a Kruskal-Wallis test was used in multiple groups' ratio comparison. Pearson *P* values were estimated for basic characteristics and logistic regression (because we did not match exactly in 1:2 or 1:3, we did not use conditional logistic regression) was used to estimate the odds ratios and 95% confidence intervals for each variable. A likelihood ratio test was used to test heterogeneity..

RESULTS

In the case group, 86 subjects (8 subjects refused participation) were finally included in our analysis. In the control groups, 164 and 213 subjects were included in control 1 and 2, respectively. Overall, there were no significant differences in age, gender, education level, household income, and occupation between the case and control groups based on Pearson *P* values (Table 1). However, cases had a higher percentage of white-collar employees than control groups, including official/

[1]OR1: Odds ratio for case *versus* control 1; OR2: Odds ratio for case *versus* control 2; OR3: Odds ratio for comparison between two control groups; 95% CI means 95% confidence interval. [2]OR's in all means only occupation and gender factors were single in the models, or called a single OR.

administration, technician/professional, businessman, and other occupations. Where the difference between case and controls groups differed by gender, white-collar males tended to be more willing to participate in the colorectal cancer screening program than blue-collar men, but females were not (Table 2).

More people in the case group than in the two control groups thought that: 1: colorectal cancer is a common cancer [The adjusted odds ratio for the answer of "I don't know colorectal cancer is a common cancer" was 0.22 (95% CI: 0.09-0.56) for case versus control 1 and 0.24 (0.10-0.54) for case versus control 2 compared to the reference group of answering "certainly know"]; 2: screening will help improve the consciousness of health; 3: screening can find an early stage of colorectal cancer; and 4: it is necessary to conduct the colorectal cancer screening in the community (Table 3). However, there was no difference in their knowledge of the existence of this screening program between cases and controls. A Kruskal-Wallis test was used to analyze one-direction data. Based on the results from the Kruskal-Wallis test, people in the case group had more knowledge of colorectal cancer and its screening, and were defined as "good". Control group 1 was defined as "fair" and control group 2 as "poor". Overall, there was no significant difference in knowledge of colorectal cancer and its screening between the two control groups.

There were no significant differences in the inclination to attend colorectal cancer screening between the case and control groups if using self-paid FOBT as a screening test (Table 4). However, if using colonoscopy as a screening test, the percentage willing to participate in the screening program was higher among cases than controls under the same payment method. The rate of willingness to attend a colonoscopy was higher if the colonoscopy was free than if it was self-paid. The rate was 82.0% among control group 1 and 87.1% among control group 2 if the colonoscopy was free, whereas it declined to 56.3% and 53.1%, respectively, if the colonoscopy was self-paid.

Finally, we investigated why people refused a colonoscopy. There were no significant differences in reasons for refusing a colonoscopy between two control groups with Mann-Whitney *U* test ($Z = 2.51$, $P = 0.11$), so we combined the two control groups together. Approximately 46.4% of people who declined to participate in the screening program reported that they lacked time. Approximately 20.8% of people were unwilling or unable to pay for a colonoscopy and future therapy. Fear of bowel preparation (5.0%) and pain (11.1%) were also major reasons. Only 7.5% of people reported that the screening test is included in their routine health examination and 4.6% refused a colonoscopy because they thought it was of no significance. Approximately 4.3% of people reported no interest.

DISCUSSION

Our study investigated the barriers to conducting a colorectal cancer screening program in an urban population, aged between 40 and 74 years, in China. We found that white-collar men tended to be more willing to participate in the screening program than blue-collar men. Poor awareness of colorectal cancer and its screening program, the characteristics of the screening tests, lack of time, and financial issues were important factors that affected the attendance rate of colorectal cancer screening programs. Education and household income did not affect the screening rate in this senior urban population.

Our results are reliable and generally applicable because this is a community-based case-control study with two sets of control groups and high quality assurance and control, which nested in a free population-based colorectal cancer screening program conducted in the same area. The participation rate, 91.5%, was high. All subjects completed a questionnaire when interviewed in person by well-trained interviewers. All data were recoded, numerically transformed into computer files at least three

[1]Refers to those who refused to answer this question; results in this row not concluded in statistical analysis.

times, and their reliability was confirmed for analysis. Data analyses were performed blindly by two analysts. However, the sample size is limited by the low colorectal cancer screening rate in the general population.

Five randomized intervention studies demonstrated that screening could reduce colorectal cancer mortality[3-7]. However, screening rates in the general population are low. In the USA, only 32% of adults over age 50 years has had a FOBT in the past two years and only 34% say they have ever had either a sigmoidoscopy or colonoscopy for some reason[22]. In our pilot study, the screening rate at the primary stage reached 50% and at secondary stage (colonoscopy) it was nearly 20%. Overall, completion in all tests used in colorectal cancer screening are not satisfactory[23]. Why people refuse colorectal cancer screening is of great importance to improving the efficacy of colorectal cancer screening.

In our study, we found that education and household income did not affect the screening rate. Some social characteristics such as low education are risk factors in ovarian cancer and breast cancer screening[24,25]. Occupation tended to be a risk factor that affected the screening rate more for men than for women. White-collar men might have higher awareness of colorectal cancer and its screening and less of a financial issue than blue-collar men. Our results indicated that poor

knowledge of colorectal cancer screening was a major barrier to improving the screening rate, which is supported by reports that poor knowledge of colorectal cancer screening is a prognostic factor of screening rates in Chinese communities in Singapore[16,17]. Public education about colorectal cancer, risk factors, and potential benefits from colorectal cancer screening should be performed. Access to screening programs was similar in the three groups. The screening program center played a major role in screening invitations.

In this community-based study, the attendance rate of colorectal cancer screening was affected by multiple factors including characteristics of the screening test, financial issues, fear of pain and bowel preparation, lack of time, and poor awareness of risk factors, screening guidelines and screening importance. If an FOBT was used as a screening test, the screening rates were similar between case and control groups whether this screening was free or not. Attendance rate declined if a colonoscopy was used as a screening test. The attendance rate declined more if the colonoscopy was self-paid. FOBT is a cheap, painless, and convenient test. The screening rate would increase in China if a painless colonoscopy were used in screening programs. Integration of colorectal cancer screening into primary care practice or the Medicare system could also facilitate colorectal cancer screening, which is suggested in both our study and other studies[18,19].

In the two step colorectal cancer screening program, neither the first nor the second step is indispensable. A FOBT is more adaptable than a colonoscopy and a flexible sigmoidoscopy in colorectal cancer screening[20], mainly because any endoscopies need bowel preparation and have some degree of discomfort. The attendance rate for colonoscopies is relatively low compared to that of FOBTs in China. The attendance rate of colonoscopies is high in the USA[23]. This might be due to the recent U.S. national Medicare coverage and wide application of a painless colonoscopy in USA.

In summary, by improving public health education of cancer, integrating colorectal cancer screening into the Medicare and or primary care systems, and applying anesthesia in colonoscopies, there would be an increase in the colorectal cancer screening rate, leading to a possible decrease in the mortality rate of colorectal cancer in the long-term.

COMMENTS

Background

Recently, strong evidence from several randomized intervention studies indicated that colorectal cancer screening is effective in reducing its mortality. However, the reported compliance of colorectal cancer screening in the general population, including China, varies widely and is generally low. It is not clear why people are unwilling to attend the colorectal cancer screening program in China.

Innovations and breakthroughs

The impact of occupation on willingness to attend a colorectal screening program differs by gender. Poor awareness of colorectal cancer (CRC) and its screening program, characteristics of screening tests, and lack of time were important factors affecting the screening rate in the community. Financial support and fear of pain and bowel preparation were important barriers to a colonoscopy as a screening test. Raising public awareness of CRC and its screening, integrating CRC screening into health care system, and applying a painless colonoscopy would increase the screening rate.

Terminology

Fecal occult blood is a term for blood present in the faeces that is not visibly apparent. In medicine, a fecal occult blood (FOBT) test is a check for hidden (occult) blood in the stool. FOBT testing can provide clues as to subtle blood loss in the gastrointestinal tract, anywhere from the mouth to the colon. Positive tests warrant further investigation for peptic ulcers or a malignancy (such as colorectal cancer or gastric cancer).

Peer review

This is an important paper looking at barriers to CRC screening. It is interesting to note that financial considerations in China seem to be much more important than in the US. This might be due to the fact that many Chinese patients have to pay for screening procedures out of their pockets. The results imply that improving health education and expanding the coverage of Medicare and primary care systems could increase the colorectal cancer screening rate, and could decrease the mortality of colorectal cancer in the long-term.

Abstract

AIM: To develop a new, rapid and accurate reverse dot blot (RDB) method for the detection of intestinal pathogens in fecal samples.

METHODS: The 12 intestinal pathogens tested were *Salmonella* spp., *Brucella* spp., *Escherichia coli* O157:H7, *Clostridium botulinum*, *Bacillus cereus*, *Clostridium perfringens*, *Vibrio parahaemolyticus*, *Shigella* spp., *Yersinia enterocolitica*, *Vibrio cholerae*, *Listeria monocytogenes* and *Staphylococcus aureus*. The two universal primers were designed to amplify two variable regions of bacterial 16S and 23S rDNA genes from all of the 12 bacterial species tested. Five hundred and forty fecal samples from the diarrhea patients were detected using the improved RDB assay.

RESULTS: The methods could identify the 12 intestinal pathogens specifically, and the detection limit was as low as 103 CFUs. The consistent detection rate of the improved RDB assay compared with the traditional culture method was up to 88.75%.

CONCLUSION: The hybridization results indicated that the improved RDB assay developed was a reliable method for the detection of intestinal pathogen in fecal samples.

Key words: Immunoblotting; Intestinal pathogens; Feces

INTRODUCTION

Foodborne infections are an important public health concern worldwide. The World Health Organization and the US Centers for Disease Control and Prevention (CDC)[1,2] report every year a large number of people affected by diseases caused by intestinal pathogens that have contaminated food. The main clinical manifestations of infection with intestinal pathogens are nausea, vomiting and diarrhea. The clinical syndromes caused by the different intestinal pathogens are usually not distinguishable[3,4]. Therefore, identification of intestinal pathogens is heavily dependent on help from clinical laboratories. Most intestinal pathogens are difficult to incubate under the same conditions[5]. Furthermore, the current assays for identifying pathogens are performed mainly using cultivation of cells. Although the cultivation has been a standard method of pathogenic identification, the whole procedure takes around 5 d, or even longer, to obtain final results. The time-consuming procedure not only makes the methods difficult for high-throughput use, but also involves specialized techniques and expertise[6]. As a result, the patients would probably lose the optimal chance of therapy, and centers for disease control would not be able to take effective measures rapidly. Consequently, considerable effort should be devoted to establish rapid, sensitive and specific assays for identifying intestinal pathogens.

At present, many methods have been developed to detect intestinal pathogens, such as mass spectrometric analysis[7], fluorescence polarization[8,9], real-time fluorescence quantitative PCR[10,11], microarray[12,13], and sequencing. Most of these techniques are accurate, but time-consuming, labor-intensive, and hard to adapt to

high-throughput screening. They are only amenable to analysis by those who are well-trained and well-equipped, which is not suitable for small hospitals. Nevertheless, the reverse dot blot (RDB) method can be used to detect many pathogens simultaneously. As bacterial 16S and 23S rDNA genes, bacterial live fossils, have great significance in taxonomy[14]. These two genes have been less changeable than others in the course of evolution. We combined flow-through hybridization technology with RDB assay to develop a rapid RDB method that can simultaneously detect 10 intestinal pathogens according to the bacterial 16S and 23S rDNA genes. Compared with the conventional passive hybridization process that required hours or even overnight hybridization, the flow-through hybridization takes only several minutes to complete, by directing the flow of the target molecules toward the immobilized probes.

MATERIALS AND METHODS

Bacterial strains and clinical samples

Bacterial reference strains were obtained from the National Institute for the Control of Pharmaceutical and Biological Products of China (Table 1), and chosen from a wide range of genera or species. All the strains selected were cultured for 24-36 h according to conventional methods[15,16]. All fecal samples were collected from 540 patients who had diarrhea from May 2006 to July 2007, at the Central Hospital in Huzhou, China. The clinical samples were isolated and identified by conventional methods and, except for the coagulase-negative *Staphylococcus aureus*, by the appropriate API test system.

Design of primers and pathogen-specific oligonucleotide probes[17]

The primers were designed using Primer 5.0 software on conservative regions based on the *Escherichia coli* (*E. coli*) 16S rDNA and 23S rDNA (GenBank accession number U00096). All oligonucleotide probes were designed from variable regions between two pairs of primers of each pathogen available in the GenBank database (GenBank/EMBL/DDBJ). Multiple-sequence alignments were carried out by using the ClustalW program. By comparison of the sequences of the 16S and 23S rDNA regions of the target species, regions with interspecies variations could be identified and were used to develop species-specific probes.

The reverse primer was labeled with biotin at the 5' end, and the hybridization probes were labeled with amino group at the 5' end. In order to judge the validity of the hybridization process, we designed a color control probe for the hybridization control, which was labeled with a biotin group at the 5' end and an amino group at the 3' end. The color control probe can bind only with the chromogen but not with the targeting molecule. All oligonucleotide primers (Table 2) and probes (Table 3) were synthesized commercially at Shanghai Sangon Biological Engineering Technology & Services Co., Ltd. (Shanghai, China).

DNA isolation and PCR amplification

Processing of the fecal samples and subsequent bacterial DNA extraction using the QIAamp DNA Stool Mini Kit (Qiagen) and the genomic DNA of bacterial reference strains was extracted using the QIAamp DNA Mini Kit (Qiagen). Five microliters of the DNA was amplified by PCR in 50 μL of 1 × PCR buffer that contained 200 μmol/L of each dNTP, 2 U *Taq* DNA polymerase (Takara), 0.06 μmol/L forward primers (23S-F and 16S-F) and 0.3 μmol/L reverse primers (16S-R and 16S-R). In order to prevent contamination, we replaced dTTP with dUTP and added 0.5 U uracil-DNA glycosylase (UDG) to the PCR system. The amplification was performed by using an Applied Biosystems 9600 thermal cycler (Perkin-Elmer) under the following conditions: incubation at 50℃ for 3 min, before an initial denaturation step at 94℃ for 5 min, followed by 35 cycles of 94℃ for 30 s, 55℃ for 45 s, and 72℃ for 45 s. A final extension was performed at 72℃ for 5 min.

Membrane preparation and subsequent immobilization of oligonucleotides

Biodyne C membranes (Pall Co.) were rinsed briefly with 0.1 mol/L HCl, and then treated for 15 min with freshly prepared 20% EDC (w/v) [*N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride; Sigma-Aldrich, commercial grade] in deionized water, rinsed with deionized water, and the amino-modified oligonucleotide probes dissolved in 0.5 mol/L sodium bicarbonate buffer (pH 8.4) were dotted at the given positions on the membrane (Figure 1). The amino group of the probe may bind with the carboxyl group of the membrane. The dots were rinsed with Tris-buffered saline/0.1%

Tween-20. Any remaining active groups were quenched with 0.1 mol/L NaOH for 10 min. Finally, filters were rinsed with deionized water and air-dried for storage, or were used immediately for hybridization.

RDB and flow-through hybridization

The improved RDB method was used according to the principle of flow-through hybridization, which was performed on the KaiPu DNA hybriMax Rapid Hybridization Machine (Hong Kong DNA Ltd., Hong Kong, China). Its detailed steps were as follows: (1) denature the PCR products (or omitted); (2) prehybridize the membrane (or omitted); (3) hybridize the target PCR products with the specific probes at 42℃ for 15 min; (4) wash the unhybridized PCR products; (5) combine peroxidase (POD) with the biotin group on the PCR products or on the color control probe at 37℃ for 5 min; (6) wash the membrane to eliminate the uncombined POD; and (7) color with 3,3,5,5-tetramethylbenzidine (TMB) chromogen. We set positive and negative controls for all detections. The machine worked on the basis of the particular principle of flow-through hybridization; there was a negative pressure under the airproof hybridization membrane, which was produced by pumping. All of the hybridization solution, washing solution, POD solution, and coloring solution flowed through the membrane automatically. The improved RDB method actively directed the flow of the targeting molecules toward the immobilized probes within the membrane fibers. The complementary molecules were hybridized and formed duplex DNA; at the same time, any unbound molecules were removed by passing through the membrane. This speeded up the interaction between the complementary molecules, reduced the hybridization time from hours down to minutes, and provided results hundreds of times faster than by using traditional passive hybridization methods.

RESULTS

Dual PCR amplification from DNA from clinical fecal samples

The 16S and 23S rDNA from intestinal pathogens were amplified simultaneously directly from fecal samples using asymmetric PCR. All the fecal samples tested gave PCR products with bands of approximately 500 bp and 640 bp (Figure 2 shows partial PCR amplification results for intestinal pathogens from fecal samples).

Validation of the bacterial reference strains using the improved RDB method

The PCR products were used to hybridize with the oligonucleotide probes on the membrane, followed by signal acquisition using the TMB to generate the respective hybridization maps. The results are shown in Figure 3. A given isolate was easily identified as one of the target pathogens from the hybridization signals of the probe spot. The results were in close agreement with those predicted from the layout of the probes. For instance, in the hybridization map shown in Figure 3, array A, there were strong hybridization signals at the

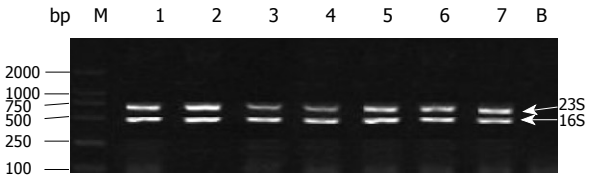

Figure 2 Partial dual PCR amplification results for intestinal pathogens from fecal samples. M: DNA marker 2000; B: Blank control.

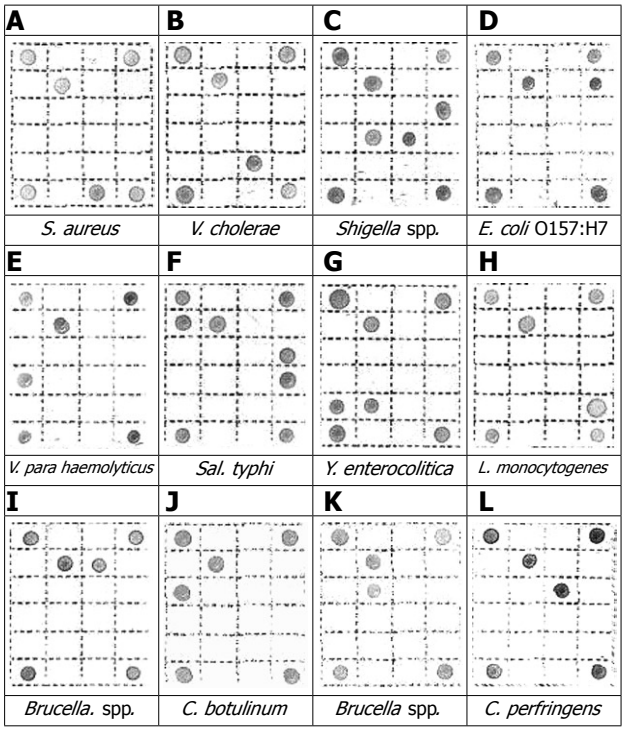

Figure 3 Typical hybridization profiles on the membrane from pure bacterial culture.

sites that corresponded to oligonucleotide probes 17, therefore, the pathogen was sequentially identified as *S. aureus*. Based on the results of multiple experiments, we regarded a hybridization signal as specific if the foreground signal at an oligonucleotide probe site was a stronger color than its background signal. It was easy to identify the specific hybridization signals directly from the hybridization maps by the naked eye. The strains were *Salmonella* spp., *Brucella* spp., *E. coli* O157:H7, *Clostridium botulinum*, *Bacillus cereus*, *Clostridium perfringens*, *Vibrio parahaemolyticus*, *Shigella* spp., *Yersinia enterocolitica*, *Vibrio cholerae*, *Listeria monocytogenes*, and *S. aureus*.

Detection limit of the improved RDB assay

Serial dilutions of a clinical isolate of *E. coli* O157:H7 were tested by using the improved RDB method. The data indicated that as few as 10^3 CFUs could be detected consistently.

Detecting the intestinal pathogens from fecal samples directly

To evaluate the application of this assay, 540 fecal samples from patients with diarrhea were detected.

Table 4 Comparison between the improved RDB and culture

Intestinal pathogen	RDB (+)/ culture (+)	RDB (+)/ culture (-)	RDB (-)/ culture (+)

Total	354	50[1]	44[2]

[1] was compared with [2], $\chi^2 = 464$, $P > 0.05$. RDB: Reverse dot blot.

Table 4 compares the results obtained for the intestinal pathogens by a conventional culture and the improved RDB assay. By the improved RDB assay, 404 (74.81%, 404/540) samples were found to be positive for intestinal pathogens, and mixed pathogens were detected from 16 samples. By the culture method, 399 (73.89%, 399/540) samples were found to be positive for pathogens, and mixed pathogens were detected from 13 samples. A total of 354 samples that were RDB positive were also culture positive. Additionally, 50 samples were detected by RDB but were not found by culture. Forty-four of the culture-positive samples were RDB negative. The data indicated that 354 (88.75%, 354/399) specimens identified using RDB were the same as those identified by conventional methods, $\chi^2 = 464$, $P > 0.05$.

DISCUSSION

With the development of more aggressive therapeutic regimens, especially for the treatment of intestinal pathogens, the incidence of foodborne infections has increased. The early initiation of antibacterial treatment is critical in reducing the high mortality rate in patients with infection. Early and accurate identification of the pathogen is the most important and critical step in providing adequate antibacterial therapy in time. The conventional method of identification of intestinal pathogens used in clinical microbiology is based on phenotypic features and physiological tests, and is therefore time-consuming. Instead, molecular genotyping methods could provide a rapid and specific means of identification of intestinal pathogens. At present, diagnostic DNA microarrays are applied for the identification of viruses[18-21], bacteria[22-26], and mechanisms of resistance to certain antibiotics[27-29].

However, the conventional hybridization methods are conducted on two-dimensional surfaces, which require several hours to complete the molecular hybridization

process, and large volumes of sample and reagent. In this study, we described the successful application of the improved RDB method to detect intestinal pathogens. It is a simple, rapid, semiautomatic, reliable, and contamination-proof approach to screen pathogens from fecal samples. We developed a commercially prepared intestinal pathogens detection kit equipped with the KaiPu DNA HybriMax Rapid Hybridization Machine. The machine was designed based on the particular principle of flow-through hybridization. There is a negative pressure under the airproof hybridization membrane that is produced by pumping, so the improved method actively directs the flow of the target molecules toward the immobilized probes within the membrane fibers, which enables rapid hybridization to occur. The dominant characteristic of the improved RDB method is that all of the PCR products, washing buffer, binding solution, and coloring solution flow through the hybrid membrane quickly and directly, with the help of negative pressure, which is semi-automated and is essentially different from the traditional method. The complementary molecules are hybridized and form duplex DNA; at the same time, any unbound molecules are removed through the membrane. This speeds up the interaction between the complementary molecules, reduces the hybridization time from hours down to minutes, and provides results hundreds of times faster than the traditional passive hybridization methods[30].

For the present study, we designed and optimized not only the specific probes for the specific target pathogens, but also the color control probe for the hybridization operation to reach 100% specificity. The color control probe can bind only with the chromogen, but it cannot bind with the target molecule, which helps to judge the validity of hybridization. Instead of using dTTP, we used dUTP and UDG in the PCR system to prevent PCR products from causing contamination. In addition, the improved RDB method is clean, versatile, and less expensive than traditional hybridization. The improved RDB assay directs all of the PCR products and solution to directly flow through the hybrid membrane, which increases the diffusivity and local reaction concentration of the nucleic acid molecule, which occurs in three-dimensional volumes.

We detected 540 fecal samples from patients with diarrhea using the improved RDB assay and culture in parallel. The consistent detection rate of the improved RDB assay compared with the traditional culture method was up to 88.75%. Howerer, the reason that 10 samples were detected by RDB but were not found by culture is that the PCR can amplify DNA fragments even from dead strains, or that the domain bacterial colony grew too rapidly to separate it from the target intestinal pathogens. Otherwise, there is a large amount of unknown substance to disturb the PCR, so that five of the culture-positive samples were RDB negative. However, the data indicated that there was no significant difference between the improved RDB assay and culture to detect the intestinal pathogens from fecal samples. All of these findings indicate that the method is sensitive, specific, and ensures quality in clinical tests.

COMMENTS

Background

Early and accurate identification of the pathogen is the most important and critical step for clinical diagnosis and antimicrobial therapy. Many molecular methods have been applied to pathogen diagnosis.

Innovations and breakthroughs

A new, rapid and accurate reverse dot blot (RDB) method was developed for the detection of intestinal pathogens in fecal samples collected from human subjects, by using the flow-through hybridization principle. The above assay is rapid, accurate stable, reliable and convenient.

Applications

The new technique may play an important role in detection of food poisoning, environmental monitoring, and clinical diagnosis of infectious disease.

Peer review

This is a well performed and interesting study that examined rapid detection methods for intestinal pathogens.

Abstract

AIM: To assess the role of magnetic resonance cholangiopancreatography (MRCP) in detection of pancreatic duct stones (PDS) in patients with chronic pancreatitis (CP).

METHODS: Clinical data of 78 CP patients who were treated at the First Affiliated Hospital of Xi'an Jiaotong University (China) between January 2004 and July 2008 were retrospectively analyzed. A predictive model of pancreatic duct stones was established through logistic regression and its effectiveness was verified. Among these patients, MRCP was performed in 60 patients who served as a control group, while 44 patients with a higher predictive value than the entry threshold of the predictive model served as an experimental group.

RESULTS: The positive rate of PDS in the 78 patients with CP was 19.2% (15/78). The predictive entry threshold of the predictive model was 5% ($P < 0.05$). The possibility of existence of PDS could be predicted according to the following 4 indexes: gastrointestinal symptoms, intermittent abdominal pain, diabetes mellitus (DM)/impaired glucose tolerance (IGT) and positive B-mode ultrasound results. The incidence of PDS in the experimental group was higher than that in the control group ($P < 0.05$).

CONCLUSION: MRCP is strongly suggested for the detection of PDS in patients with gastrointestinal symptoms, intermittent abdominal pain, DM/IGT and positive B-mode ultrasound results.

Key words: Chronic pancreatitis; Pancreatic duct stone; Magnetic resonance cholangiopancreatography; B-mode ultrasound; Logistic regression

Magnetic resonance cholangiopancreatography for the detection of pancreatic duct stones in patients with chronic pancreatitis. *World J Gastroenterol* 2009; 15(20): 2543-2546 Available from: URL: http://www.wjgnet.com/1007-9327/15/2543.asp DOI: http://dx.doi.org/10.3748/wjg.15.2543

INTRODUCTION

Pancreatic duct stone (PDS) is a severe complication of patients with chronic pancreatitis (CP)[1]. It has been reported that 30% of CP patients are complicated by PDS[2]. Conventional examinations are not conclusive for the diagnosis of PDS. To confirm the existence of PDS, imaging examinations, including B-mode ultrasound, computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) have been extensively used in the diagnosis of PDS[3-7]. Among them, MRCP is most widely used in clinical practice for the differentiation diagnosis of PDS, pancreatitis, pancreatic tumor, pancreatic cyst and congenital diseases due to its non-invasiveness, high accuracy and repeatability[8-10]. It has been reported that MRCP has a sensitivity of 91.6%, an accuracy of 95.6%, and a specificity of 100% for the detection of PDS[11]. In this study, 78 patients with CP were analyzed retrospectively through a predictive model of PDS based on logistic regression for the rational application of MRCP in detection of PDS.

MATERIALS AND METHODS

Patients

This study included 78 CP patients at the age of 13-66 years (42 males, 36 females, with a median age of 42 years) who were treated at the First Affiliated Hospital of Xi'an Jiaotong University (China) between January 2004 and July 2008. Among them, 60 patients who underwent MRCP served as a control group, while 44 patients with a higher predictive value than the entry threshold of our predictive model served as an experimental group. The study was approved by the Review Board of Xi'an Jiaotong University and written informed consent was obtained from each patient to participate in this study.

Clinical assessment

Clinical data of the 78 patients at admission were analyzed, including gender, age, history of drinking, clinical symptoms (intermittent abdominal pain with or without back pain, progressive emaciation, steatorrhea, cholelithiasis, abdominal distention, anorexia, nausea, vomiting, fever and jaundice), laboratory findings (blood glucose, serum and urine amylase), and the results of B-mode ultrasound examination (pancreatic duct stones or pancreatic duct dilation). The results of MRCP (PHILIPS Intera 1.5T MR scanner) of the 60 patients in experimental group were also collected.

Age over 65 years and less than 65 years was defined as elderly and non-elderly, respectively. History of drinking included alcoholism (> 1 year and > 150 g/d) and non-alcoholism. Hypoglossal temperature over 37.4℃ was defined as fever. Pancreatic duct dilation was diagnosed if the main pancreatic duct diameter was greater than 3 mm in the head and 2 mm in the body or tail of pancreas.

Statistical analysis

Stepwise logistic regression was used to evaluate the factors concerned using SPSS 13.0 for windows. PDS was defined as a dependent variable. "Gender, age, history of drinking, clinical symptoms, laboratory findings and the result of B-mode ultrasound examination" were defined as independent variables. The relative risk was used to express the relation between PDS and each factor (95 % CI). A multivariate logistic regression model was established to obtain the forecasting indexes of PDS. Then a predictive model was established and the prominence of each independent variable was verified with the Wald method.

Primary screening for PDS was performed in the 78 patients using the predictive model. Patients with a higher predictive value than the entry threshold of the predictive model were included in experimental group. Differences in the diagnostic value of MRCP for PDS between experimental and control groups were analyzed by binomial distribution test.

RESULTS

Fifteen of the 78 patients were finally diagnosed with PDS. PDS was found in 10 of the 60 patients who underwent MRCP. The false positive rate of MRCP in the 60 patients was 0% as confirmed at intraoperative examination. Among the other 5 PDS patients diagnosed with B-mode ultrasound or CT (pancreatic dilation or stones) and verified during operation, no PDS was found in 1 at MRCP.

Table 1 Correlation between each factor and PDS

Index	Odds ratio (95% CI)	*P*
Sex	2.47 (1.19, 5.01)	< 0.05
Age	0.54 (0.13, 1.69)	0.95
Drinking history	2.81 (1.25, 6.04)	0.54
Intermittent abdominal pain	6.42 (3.09, 13.72)	< 0.01
Aggravated emaciation	10.62 (4.92, 26.24)	< 0.01
Steatorrhea	1.31 (0.58, 2.78)	0.65
Cholelithiasis	3.54 (1.72, 6.29)	< 0.01
Gastrointestinal symptoms	5.20 (2.63, 12.44)	< 0.01
Fever	0.67 (0.20, 1.98)	< 0.96
Jaundice	9.84 (4.31, 23.47)	< 0.01
DM/IGT	11.24 (6.58, 25.63)	< 0.01
Serum and urine amylase	1.26 (0.53, 2.42)	0.72
Result of B-mode ultrasound	13.64 (6.36, 28.63)	< 0.01

Table 2 Correlation between 4 indexes and PDS

Index	Odds ratio (95% CI)	Wald	*P*
Intermittent abdominal pain	3.83 (1.37, 8.06)	20.23	< 0.05
Gastrointestinal symptoms	4.78 (2.26, 10.14)	23.18	< 0.05
DM/IGT	4.34 (1.85, 8.47)	24.56	< 0.01
The result of B-mode ultrasound examination	12.64 (5.72, 22.39)	29.81	< 0.01

Relation between PDS and indexes

Binary logistic regression revealed that there were a significant relation and a high relative risk between the occurrence of PDS and the 4 indexes including positive result of B-mode ultrasound examination, diabetes mellitus (DM)/impaired glucose tolerance, progressive emaciation and jaundice (Table 1).

Multivariate logistic regression analysis showed that PDS was closely related with the 4 indexes including gastrointestinal symptoms (abdominal distention, anorexia, nausea and vomiting), intermittent abdominal pain, DM/IGT and the positive result of B-mode ultrasound (Table 2). The incidence of PDS was 2%-95% (negative *vs* positive indexes), and increased to 16% when the result of B-mode ultrasound was positive. If the result of B-mode ultrasound was not taken into account, the corresponding incidence of PDS would be 11%-16% for the other two positive indexes and 5%-7% for the single positive index, suggesting that a threshold of 5% could be recommended as the predictive entry threshold for the selection of patients serving as a experimental group (Table 3). The relation between the predictive model and the final diagnosis is shown in Table 4.

Incidence of PDS in different groups

The 44 patients including 15 PDS patients with a

Table 3 Incidence of PDS (%)

Positive indexes(gastrointestinal symptoms, DM/IGT, intermittent abdominal pain)	B-mode ultrasound	
	Negative	Positive
1	5-7	38-41
2	19-23	76-82
3	54	95

higher predictive value than the entry threshold of the predictive model served as the experimental group (Table 4). Considering the high sensitivity and accuracy of MRCP, we assumed that the 4 PDS patients who did not undergo MRCP would have positive results of MRCP, thus increasing the accuracy and reliability of statistical results. Under such conditions, the positive diagnostic rate of MRCP for PDS was significantly different in experimental and control groups (31.8% *vs* 16.7% or 14/44 *vs* 10/60) according to the binomial distribution test.

DISCUSSION

CP, a kind of segmental or diffuse inflammation induced by various causes in pancreatic tissue, presents with recurrent or persistent abdominal pain and progressive dysfunction of pancreas, leading to permanent loss of endocrine and exocrine pancreatic function[12-14]. Early pathological changes in pancreatic tissue include focal fat necrosis, fibrosis of leaflet and duct, and protein thrombus or stones in side branches of the main pancreatic duct. Dilated or obstructed pancreatic duct, eosinophilic protein thrombus and stones can be found in the progressive stage of PDS in the main pancreatic duct.

The incidence of PDS is less than 1% in normal population, while it is about 30% in CP patients[2]. PDS can lead to the damages of pancreatic tissues and corresponding clinical symptoms[15-18]. It was reported that 12%-22.2% of PDS patients finally develop pancreatic adenocarcinoma[19,20]. Therefore, early diagnosis of PDS is of very important clinical significance.

Traditionally, biliary tract disease is the main cause of CP in China[21,22]. With the improvement in living standard, alcoholism is the exceeding biliary tract disease and has become the primary cause of CP. Actually, alcoholism in many countries, especially in developed countries, is the most frequent cause of CP. It has been shown that 70%-80% of CP patients have chronic alcohol drinking history [23-26], and the mortality of alcoholic CP patients has increased to approximately 50% in the past 20 years [25]. However, in our present study, the incidence of alcoholism-related CP (25.8%) was lower than that of biliary tract disease-related CP (38.1%). We assumed that it might be due to the relatively lower living standard in local areas.

In our study, 100% of patients with PDS had abdominal pain, 66.7% had abdominal distention and nausea, 53.3% had DM/IGT. The relation between these clinical manifestations and PDS was confirmed by multivariable logistic regression analysis. On the other hand, as a primary screening method for PDS, B-mode ultrasound has a relatively high sensitivity and specificity. Thus, a predictive model based on the above indexes was established and the predictive entry threshold was set at 5%, and MRCP was recommended as a routine examination for patients with a higher predictive value than the entry threshold.

Table 4 Relation between the prediction model and the final diagnosis

Incidence of PDS in the prediction model (%)	*n*	Final diagnosis		
		Non-stones	Stones	PDS incidence (%)
< 5	34	34	0	0
5-7	26	24	2	7
19-23	5	4	1	20
38-54	2	1	1	50
76-95	11	0	11	100

By analyzing the data through our predictive model, we found that PDS was closely correlated with the 4 indexes (gastrointestinal symptoms, intermittent abdominal pain, DM/IGT and the result of B-mode ultrasound examination). Due to the existence of PDS and calcification, pancreatic duct pressure increases and the pancreatic secretion decreases or loses. Therefore, clinical symptoms such as gastrointestinal symptoms, intermittent abdominal pain, and DM/IGT occur in patients with PDS. Also, direct and/or indirect signs of PDS could be roughly detected by B-ultrasonography. If only one of the indexes is positive, the damage to pancreatic tissue is not serious, and the incidence of PDS is low.

In conclusion, MRCP is strongly recommended for the final diagnosis of PDS in patients with gastrointestinal symptoms, intermittent abdominal pain, DM/IGT and positive B-ultrasonography result.

COMMENTS

Background

Pancreatic duct stone (PDS) is a severe complication of chronic pancreatitis (CP). It was reported that 30% of CP patients are complicated by PDS. At present, the diagnosis of PDS depends on some imaging examinations, such as B-mode ultrasound, computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP), *etc*.

Research frontiers

Compared with other imaging techniques, MRCP is easy to perform and has no contraindication. It could provide detailed information about pancreatic duct and common bile duct. Therefore, MRCP is widely applied in the diagnosis of PDS.

Innovations and breakthroughs

In this study, a predicative model was established in an attempt to increase the diagnosis rate of PDS by MRCP. The result supports application of MRCP in detection of PDS.

Peer review

The authors established a predictive model for PDS in CP patients and verified that 4 indexes were closely correlated with PDS, which may elevate the diagnosis rate of PDS.

Abstract

A 78-year-old woman presented with fever, severe abdominal pain, and distension. She had been institutionalized for depression and senile dementia. Laboratory examinations disclosed a leucocytosis (WBC: 12 500/μL) and elevated levels of serum C-reactive protein (2.8 mEq/L). Diagnosis of acute cecal volvulus was made from a "coffee bean sign" on an abdominal computed tomography and a "beak sign" on a gastrographin enema. An emergent laparotomy confirmed the diagnosis and an ileo-colectomy with primary anastomosis was carried out. The patient recovered after intensive respiratory care and fluid therapy, and then returned to her former institution. A review of Japanese literature disclosed that: (1) a marked increase of aged patients with mental disability presenting with cecal volvulus, (2) adoption of ileo-colectomy as the standard surgical procedure, and (3) improved survival of the patients, were observed in the last decade.

Key words: Cecal volvulus; Ileo-colectomy; Mental disability

INTRODUCTION

Cecal volvulus is axial twisting that occurs involving the cecum, terminal ileum, and ascending colon. Rarely, it may take the form of upward and anterior folding of the ascending colon ("cecal bascule")[1]. Cecal volvulus is a rare condition, and its incidence is reported to range from 2.8 to 7.1 per million people per year[1].

Clinical presentation is highly variable, ranging from intermittent episodes of abdominal pain to abdominal catastrophe[2,3]. In this paper, we report a case of cecal volvulus seen in a 78-year-old woman. Ages at presentation, causative factors, treatment and outcome of 40 cases reported in Japan between 1999 and 2008 were also reviewed, and compared with those in cases reported before 1988[4].

CASE REPORT

A 78-year-old woman was admitted with acute abdominal pain and distension. She had an operation for gastric cancer at the age of 73, and had been institutionalized for depression and dementia.

On admission, she had a high fever of 38.8℃. Her abdomen was diffusely distended with rebound tenderness. Laboratory examinations disclosed a leucocytosis (WBC: 12 500/μL) and elevated serum C-reactive protein levels (2.8 mEQ/L).

Plain radiographs of the abdomen showed a markedly dilated loop of the intestine, occupying most of the abdomen, but the pathology was not certain. A "coffee-bean sign", on an abdominal CT (Figure 1), together with "a beak sign" on a gastrogrephin enema (Figure 2), confirmed the diagnosis of cecal volvulus[3,5].

An emergent laparotomy disclosed the axial twisting of the cecum, involving the terminal ileum and the ascending colon. Ischemia of the bowel seemed to be irreversible, but there was no perforation (Figure 3).

An ileo-colectomy with primary anastomosis was

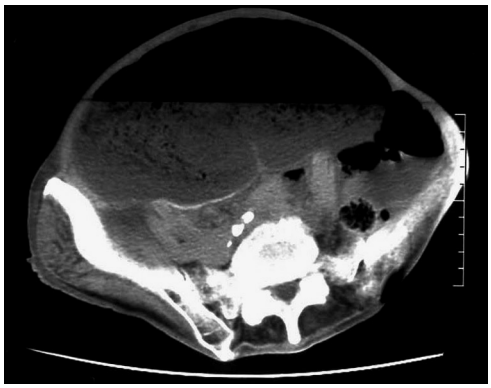

Figure 1 A "coffee-bean sign" on an abdominal CT film.

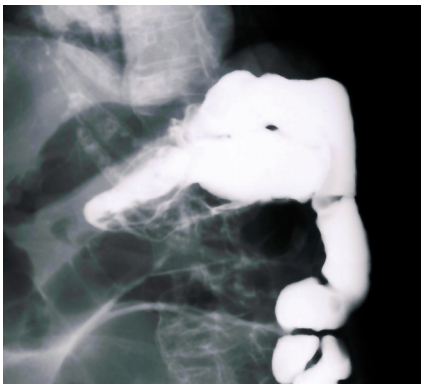

Figure 2 A "beak sign" on a gastrographin-enema.

Figure 3 Operative finding after detorsion of axial torsion of the right colon. Ischemia of the bowel seemed to be irreversible, but there was no perforation.

carried out. Postoperatively, the patient was placed under close monitoring and managed by an intensive respiratory care and fluid therapy until stabilized. Then she was discharged and returned to her former institution.

DISCUSSION

The incidence of cecal volvulus is reported to range from 2.8 to 7.1 per million people per year[1]. Patients' ages at presentation, the treatment of choice, and survival differ by reports chronologically as well as geographically[2,3].

We compared ages at presentation, treatment of choice, and outcome of 46 patients reported in Japan before 1988[4] with reports of 40 patients collected from a search of Japan Centra Revus Medicina in the last 10 years.

Patients' age at the presentation are said to be affected by cultural and dietary influences. Gupta and Gupta[6] reported that the average age at presentation in Western countries was 53 years, whereas it was 33 years in India. In Japan, patients treated before 1988 showed two peaks in ages at presentation; one in the 10-29 years range and another in the 60-79 years range. On the other hand, there was only one peak in ages of the patients treated between 1999 and 2008; 70-89 years of age (Table 1). In the young age group, the volvulus was caused by mesenterium commune, other intestinal malformation, or excessive exercise. In contrast, volvulus in the aged patients was associated with chronic constipation, distal colon obstruction, or senile dementia.

Table 1 Ages at the presentation of cecal volvulus

Age	Patients treated before 1988	Patients treated between 1999 and 2008
0 to 9	3	1
10 to 19	9	4
20 to 29	5	3
30 to 39	5	2
40 to 49	3	2

60 to 69	10	3
70 to 79	50	12
80 to 89	2	8
Over 80	0	2

χ^2-test: $P = 0.008$.

Table 2 Treatment of cecal volvulus

	Patients treated before 1988	Patients treated 1999 to 2008
Endoscopic detorsion	0	4
Surgery	45	36
Detorsion	9	0
Cecopexy	14	8
Cecostomy	7	0
Ileo-Colectomy	15	28
Unknown	1	0

χ^2-test: $P < 0.0001$.

Surgical options include cecopexy, cecostomy, and ileo-colectomy by open or laparoscopic approaches. Review of Japanese literature disclosed that resectional surgery was done in 32.6% (15/46) of patients who were treated before 1988, whereas 70% (28/40) of patients underwent ileo-colectomy between 1999 and 2008 (Table 2). This significant increase of the patients treated by resectional surgery ($P < 0.0001$ by χ^2 test) was brought about by advances in surgical techniques and perioperative supportive measures.

Flexible colonoscopy is commonly used for the diagnosis and the treatment of sigmoid volvulus, but the utility of endoscopy in acute cecal volvulus is limited,

because of technical problems and higher rates of recurrence[1]. Our review also showed that reports on colonoscopic detorsion are just emerging (Table 2).

Mortality, morbidity, and recurrence rates were also lower in recent years. O'Mara *et al*[7] reported in 1979 that they treated 14 patients with cecal volvulus by ileo-colectomy and lost 2 of 7 patients who developed gangrenous bowel, while there were no deaths amongst 7 patients with non-gangrenous bowel. Gupta *et al*[6] reported that they encountered operative death in 2 of 13 patients who underwent resectional surgery. However, Majeski *et al*[8] reported in 2005 that there was no operative deaths in 10 patients treated by ileo-colectomy. Our review of Japanese literature disclosed that the outcome after surgical treatment has markedly improved in the last 10 years. Before1988, there were five postoperative death in 45 patients who underwent surgery (15 resectional, and 30 non-resectional), whereas only one of 36 patients treated surgically (8 resectional and 28 non-resectional) between 1999 and 2008 was lost.

As the mortality and the morbidity after resectional surgery for acute cecal volvulus, whether gangrenous or non-gangrenous, have been markedly improved and almost no recurrence is observed, an ileo-colectomy with primary anastomosis should be the preferred surgical option rather than cecopexy or a cecostomy.

Abstract

Choledochal cyst is an uncommon disease usually seen in young women and can be divided into five types. We report a 66-year-old woman who was diagnosed with types Ⅰ and Ⅲ bile duct cyst simultaneously after surgery, which is a rare type of bile duct cyst.

Key words: Choledochal cyst; Common bile duct; Cholangiography

INTRODUCTION

Choledochal cyst (CDC) is a rare type of bile duct cyst of uncertain origin, which was first described and classified by Todani *et al*[1] in 1977. The majority of cases reported are young women and children of Asian descent, especially in Japan and Taiwan. The most common symptoms of CDC are abdominal pain, jaundice and abdominal mass. We present a rare case of an elderly female patient with CDC.

CASE REPORT

A 66-year-old woman was admitted to our hospital because of epigastric pain and dark urine for 10 d. She had some fatty foods before the onset of pain and received antibiotic treatment in a local hospital. She had a 10-year medical history of abdominal pain, which was related to her high-fat diet. She was diagnosed with cholecystitis and quickly recovered after antibiotic treatment.

At physical examination, her blood pressure was 140/90 mmHg, her pulse was 80 beats/min, her body temperature was 37℃, her respiratory rate was 18 breaths/min, and her skin and sclera were yellow-stained. She had tenderness in the epigastric region, and was positive for Murphy's sign.

Laboratory tests revealed 18.84 × 10^9/L white blood cells, 89.8% granulocytes, 983 IU/L (0-115 IU/L) blood amylase, 158.4 μmol/L total bilirubin and 130.23 μmol/L direct bilirubin.

Abdominal ultrasound showed that the diameter of her common bile duct was 1.3 cm, her intra-hepatic bile duct was dilated, and her gallbladder was enlarged. A primary diagnosis was thus made of acute biliary pancreatitis, obstructive jaundice and acute cholecystitis.

The patient received routine treatment for pancreatitis, and her clinical symptoms and objective signs improved, and her biochemical parameters subsequently returned to their normal levels. However, an abdominal computer tomography (CT) scan suggested that her common bile duct and pancreatic duct were dilated and her pancreatic head was enlarged (Figure 1). Endoscopic examination showed a cystic tumor connected to the papilla in the duodenum (Figure 2). An upper gastrointestinal contrast scan showed a filling defect in the horizontal part of the duodenum with a long pedicel in the intestinal canal (Figure 3).

The patient underwent an operation after consultation. The dilated common bile duct was like a shuttle, and a cyst was observed in the horizontal part of the duodenum connected to the duodenal papilla. Bile leakage was found at excision of the cyst. The cyst was completely removed. Cholecystectomy was performed with reconstruction by Roux-en-Y choledochojejunostomy. The patient recovered quickly and was discharged 20 d after surgery.

DISCUSSION

CDC, also known as congenital common bile duct cyst

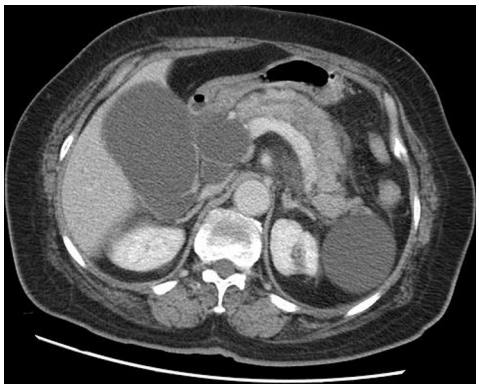

Figure 1 Abdominal CT revealing the dilated common bile duct and pancreatic duct and enlarged pancreatic head.

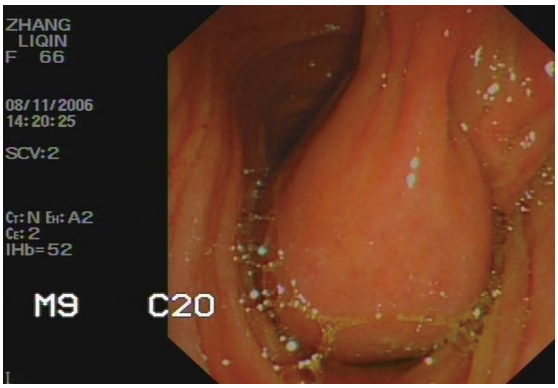

Figure 2 Endoscopy showing a cystic tumor connected to the papilla in duodenum.

Figure 3 Upper gastrointestinal contrast scan displaying a filling defect in the horizontal part of the duodenum.

(BDC), is a rare type of bile duct cyst of uncertain origin. The majority of cases reported are young women and children of Asian descent. In North America, its incidence is estimated to be 1/150 000[2], but it is increasing in Western adults. The most common symptoms of CDC are abdominal pain, jaundice and abdominal mass.

CDC is graded based on Todani's classification[1] and can be divided into five types, which are anomalies in the intra- or extra-hepatic bile ducts, or both. CDC can be diagnosed based on percutaneous and endoscopic ultrasound or endoscopic retrograde cholangiopancreatography. Magnetic resonance cholangiography may also contribute to its diagnosis.

Type Ⅳ cysts are more commonly observed in adults than in children[3], while type Ⅰ cysts are more commonly observed in Asian patients[4]. Type Ⅲ cyst, a cystic-like dilation of the terminal common bile duct, is rare[5,6]. Our patient had a CDC, consistent with types Ⅰ and Ⅲ grading. To the best of our knowledge, this is the first case of bile duct cyst in the English-language literature. Total excision of the diseased bile duct with reconstruction by Roux-en-Y choledochojejunostomy is a preferred treatment modality for CDC[7]. However, its long-term effects on CDC need to be proven in follow-up.

Abstract

Combined *en bloc* liver/pancreas transplantation (CLPT) was used primarily in the treatment of otherwise non-resectable upper abdominal malignancy. In fact, a more appropriate indication is in patients with liver disease and insulin-dependent diabetes mellitus (IDDM). Here, we report on two successful cases of CLPT at our hospital. One was a patient with non-resectable advanced liver cancer. The recipient survived for 23 mo and finally died of recurrent tumor. The other was a patient with severe biliary complication after orthotopic liver transplantation and preoperative IDDM. We performed CLPT with a modified surgical technique of preserving the native pancreas. He is currently liver-disease- and insulin-free more than 27 mo post-transplant. Based on our experience in two cases of abdominal cluster transplantation, we describe the technical details of CLPT and a modification of the surgical procedure.

INTRODUCTION

Although originally described several decades ago, combined liver/pancreas transplantation (CLPT) is still a relatively uncommon procedure. There are relatively few indications for CLPT. Previously, it was used mostly as a lifesaving method in the treatment of otherwise non-resectable upper abdominal malignancies[1,2]. However, with poor results, mainly because of tumor recurrence, this procedure fell out of favor. In fact, a more ideal indication for this so-called abdominal organ cluster transplantation is in patients with liver disease and insulin-dependent diabetes mellitus (IDDM). However, there have been only six case reports of successful CLPT in this group of patients[3,4], including three children[5].

Starzl originally designed the operation with removal and replacement of the entire grape cluster. During the procedure, upper abdominal exenteration (the liver, pancreas, spleen, duodenum, part of the stomach) is carried out. Exenteration is necessary for treatment of abdominal malignancies. However, in patients with liver disease and IDDM, such massive abdominal evisceration is unnecessary.

With the increased practicality of multivisceral transplantation, different innovative techniques have been introduced to further improve survival and reduce morbidity. Fishbein and Abu-Elmagd recently presented their experiences on preservation of the native organs in patients with hepatic-intestinal, and isolated intestinal transplantation[6,7]. According to Starzl, the main subtypes of multivisceral transplantation are full multivisceral, upper abdominal (cluster), hepatic-intestinal, and isolated intestinal transplantation[8]. In this paper, we present our experience of preservation of the native organs in a patient who underwent upper abdominal (cluster) transplantation. We compare this patient to another one with advanced liver cancer who underwent well-described standard CLPT.

CASE REPORT

Case 1

Patient 1 is a 44-year-old man (blood group B^+; 68 kg; 174 cm) who presented with a 12-mo history of discomfort and vague pain in the right upper abdomen. Ultrasonic examination and follow-up computed tomography (CT) showed a lesion measuring 5 cm × 5 cm in the right lobe of the liver, portal vein embolus, and enlarged pancreatic head. The level of alpha-fetoprotein (AFP), serum alanine transaminase (ALT), and total serum bilirubin (T-Bil) was 1096 μg/L, 104 IU/L and 22.7 μmol/L respectively. The patient had a 20-year history of hepatitis B. He was diagnosed with advanced liver cancer. Multivisceral transplantation was an alternative that might have offered the only chance of radical tumor excision.

In September 2004, ABO compatible size matched organs from a 48-year-old 62-kg male donor were allocated. At laparotomy, pancreatic infiltration and embolus invading the portal vein and superior mesenteric vein were confirmed. After complete removal of the recipient liver, duodenum, part of the stomach and small bowel, CLPT was performed *en bloc* with the conventional technique. The grafts were sewn in to the native inferior vena cava in a standard fashion. Then, the superior mesenteric vein of the graft was anastomosed to the native one. Finally, a donor aortic patch with the celiac trunk and the superior mesenteric artery was anastomosed end-to-end to the receptor common hepatic artery. After reperfusion of the graft, the gastrointestinal tract was reestablished with a Roux-en-Y duodenojejunostomy (Figure 1). The operative time, amount of blood loss and blood transfusion during the operation were 600 min, 7 L and 32 units, respectively.

Immunosuppression included induction with daclizumab and maintenance treatment with the triple immunosuppressive therapy (tacrolimus, mycophenolate mofetil and prednisolone). His liver function recovered fast. On the seventh day after operation, the grafts test showed AFP, ALT, T-Bil were < 10 μg/L, 84 IU/L and 12.7 μmol/L, respectively. Blood sugars remained normal post-transplant. His postoperative course was complicated by severe mixed pulmonary infections on postoperative day 7, which lasted for 3 wk. Furthermore, intra-abdominal hemorrhage occurred on postoperative day 16, which required re-operation. He undertook six courses of postoperative chemotherapy with a pirarubicin-containing regimen. The recipient was doing well until ultrasound and CT showed hypodense areas in his new liver one and a half years post-operation. He finally died of cancer recurrence 23 mo post-operation (Table 1).

Case 2

In 2006, a 49-year-old man (blood group A^+; 63 kg; 173 cm) presented with severe jaundice and high fever (39℃). He had a history of liver transplantation for terminal hepatitis-B cirrhosis in 2002. Unfortunately, severe biliary complication developed postoperatively. Since then, he suffered from very severe jaundice and repeated high fever with biliary infection. Meanwhile, he had a medical history of IDDM since about age 10 years. His blood sugar became difficult to control after liver transplantation. Furthermore, blurred vision occurred, which was finally diagnosed as diabetic ophthalmopathy.

Table 1 Patient characteristics

Characteristics	Patient 1	Patient 2
Age (yr)	44	49
Gender	Male	Male
Indication	Malignancy	Liver disease and DM
During operation		
Operative time	600 min	570 min
Amount of blood loss	7000 mL	3000 mL
Blood transfusion	32 units	13 units
Postoperative complications		
Pulmonary infections	+	-
Intra-abdominal hemorrhage	+	-
Outcome	Dead (23 mo postoperation)	Alive (27 mo posttransplant)

In September 2006, the patient underwent CLPT with organs from a 25-year-old male donor (blood group A^+; 60 kg; 171 cm). Removal of the native organs was relatively simple. We only needed to resect the pathological liver, and then the organ cluster was transplanted orthotopically. A piggy-back anastomosis of the grafted suprahepatic vena cava onto the native one was performed. Then, the grafted superior mesenteric vein was anastomosed to the native portal vein. Next, a circular donor aortic patch including the celiac trunk and superior mesenteric artery was anastomosed end-to-end to a donor aortic tube that had been previously implanted on the receptor infrarenal aorta. The pancreas graft was draped directly over the native pancreas. The time of the anhepatic phase was 56 min. Finally, the digestive tract was reconstructed. A Roux-en-Y anastomosis of the grafted distal duodenum and the native proximal jejunum was performed (Figure 2). The operative time, amount of blood loss and blood transfusion during the operation were 570 min, 3 L and 13 units, respectively.

The patient experienced an uneventful postoperative recovery. Since the second day post-operation, he no longer needed exogenous insulin. Liver function also recovered rapidly. On the first day after the operation, the grafts test showed that ALT and T-Bil was 531 U/L and 169.8 μmol/L, respectively. On postoperative day 7, they declined to 44 U/L and 63 μmol/L. Two weeks after transplantation, his liver function became normal. He is currently alive, liver-disease- and insulin-free more than 27 mo post-transplant (Table 1).

DISCUSSION

The operation of *en bloc* CLPT stemmed from the pioneer work of Thomas E. Starzl more than four decades ago[9]. Starzl and Williams published their first successful clinical experience in 1989[10,11]. Their initial attempts proved that the technique was feasible. However, because of postoperative complications and technical problems, the complex procedure is now still

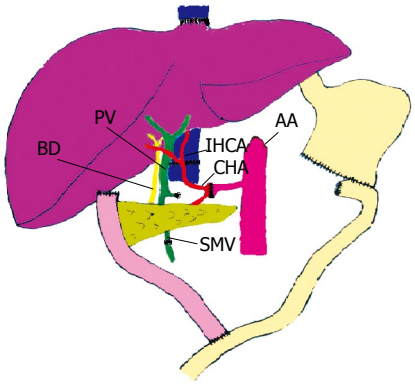

Figure 1 Standard *en bloc* CLPT. The grafts were sewn into the native inferior vena cava. The superior mesenteric vein (SMV) of the graft was anastomosed to the native one. A donor aortic patch with the celiac trunk and the superior mesenteric artery was anastomosed end-to-end to the receptor common hepatic artery (CHA). The gastrointestinal tract was reestablished with a Roux-en-Y duodenojejunostomy. IHCA: Infrahepatic cava anastomosis; BD: Donor bile duct; PV: Donor portal vein; AA: Native abdominal aorta.

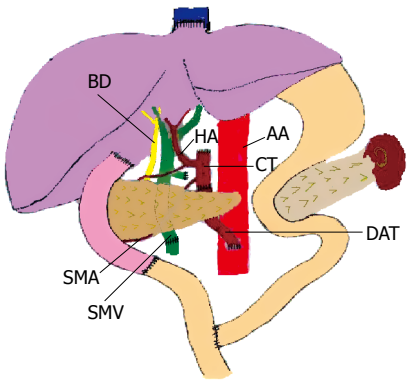

Figure 2 Modified *en bloc* CLPT while retaining the native pancreas. A piggy-back anastomosis of the grafted suprahepatic vena cava onto the native one was performed. A circular donor aortic patch including both the celiac trunk (CT) and the superior mesenteric artery (SMA) was anastomosed end-to-end to a donor aortic tube (DAT) that had been implanted previously on the native abdominal aorta (AA). The donor superior mesenteric vein (SMV) was anastomosed end-to-end to the native portal vein. Roux-Y anastomosis of the grafted distal duodenum and the native proximal jejunum was performed. HA: Donor hepatic artery; BD: Donor bile duct.

performed in small numbers in a few transplant centers.

There are relatively few indications for CLPT. Previously, it has been mostly indicated in patients with otherwise non-resectable upper abdominal malignancies[1,2]. Although some of the patients with advanced malignancies could benefit from this radical operative approach, it is not a wise choice to allocate scarce donor organs to such patients. There are several barriers to improving patient survival.

First, postoperative hemorrhage is one of the common life-threatening complications after such massive abdominal evisceration. Two of the first four recipients reported by Starzl and Williams succumbed from uncontrollable bleeding shortly after the complex surgery. Secondly, infection is a barrier to the improvement of graft survival[12], and represents the leading cause of mortality[13]. Thirdly, tumor recurrence remains the most difficult barrier to improving patient and graft survival. All three of these complications occurred in our patient 1.

In fact, a more appropriate indication for this so-called abdominal organ cluster transplant is in liver transplant candidates who coincidentally suffer from IDDM. For them, we only need to perform hepatectomy before transplanting the *en bloc* liver-duodeno-pancreatic graft. Case 2 showed the success of the surgical modification, while retaining the native pancreas. We believe that there are several potential advantages of such a modified technique.

First, the pancreas is located deep in the abdomen with an abundant blood supply. Avoiding native pancreas removal means avoiding surgical damage to the surrounding tissues. This procedure can dramatically decrease oozing of blood into the surgical field, particularly in patients with severe adhesions in the upper abdomen. Secondly, retaining the native pancreas endocrine and exocrine secretion can relieve the burden on the new pancreas. Thirdly, the gastrointestinal tract remains as a complete reunification of the whole, with retention of the native normal duodenum. Thus, the recipient can start feeding early postoperatively. Early feeding can prevent bacterial translocation and villus atrophy[14]. Fourthly, the recipient spleen is not removed during this procedure. Previous studies have revealed that the asplenic state is associated with increased incidence of sepsis[15]. Finally, avoiding removal of the native greater omentum may help to reduce postoperative complications, especially in cases of anastomotic leakage and duodenal or pancreatic fistula.

In conclusion, our experience demonstrates that *en bloc* CLPT can be modified according to the patient's need. Although it plays a role as rescue therapy, the procedure for advanced abdominal malignancy needs careful consideration. The experience so far supports further cautious trials with this drastic cancer operation. A more appropriate indication is in patients with terminal benign liver disease and IDDM. We consider that the modified technique that preserves the native pancreas has the potential to become the standard procedure for this group of patients.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systemically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials. gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H pylori*, *E coli*, *etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No.62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multidisciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Human herpesvirus 6 (HHV-6) infections occur in > 95% of humans. Primary infection, which occurs in early childhood as an asymptomatic illness or manifested clinically as roseola infantum, leads to a state of subclinical viral persistence and latency. Reactivation of latent HHV-6 is common after liver transplantation, possibly induced and facilitated by allograft rejection and immunosuppressive therapy. Since the vast majority of humans harbor the virus in a latent state, HHV-6 infections after liver transplantation are believed to be mostly due to endogenous reactivation or superinfection (reactivation in the transplanted organ). In a minority of cases, however, primary HHV-6 infection may occur when an HHV-6 negative individual receives a liver allograft from an HHV-6 positive donor. The vast majority of documented HHV-6 infections after liver transplantation are asymptomatic. In a minority of cases, HHV-6 has been implicated as a cause of febrile illness with rash and myelosuppression, hepatitis, pneumonitis, and encephalitis after liver transplantation. In addition, HHV-6 has been associated with a variety of indirect effects such as allograft rejection, and increased predisposition and severity of other infections including cytomegalovirus (CMV), hepatitis C virus, and opportunistic fungi. Because of the uncommon nature of the clinical illnesses directly attributed to HHV-6, there is currently no recommended HHV-6-specific approach to prevention. However, ganciclovir and valganciclovir, which are primarily intended for the prevention of CMV disease, are also active against HHV-6 and may prevent its reactivation after transplantation. The treatment of established HHV-6 disease is usually with intravenous ganciclovir, cidofovir, or foscarnet, complemented by reduction in the degree of immunosuppression. This article reviews the current advances in the pathogenesis, clinical diagnosis, and therapeutic modalities against HHV6 in the setting of liver transplantation.

Key words: Immunocompromised; Antivirals; Human herpesvirus 6; Liver transplantation; Opportunistic infections

INTRODUCTION

Human herpesvirus 6 (HHV-6), a member of the β-Herpesviridae subfamily of human herpesviruses, is a ubiquitous virus that was first isolated from peripheral blood leukocytes in 1986[1]. The virus was not associated with any clinical illness until 2 years later, when HHV-6 was isolated from the peripheral blood of patients with roseola infantum (also known as exanthem subitum or sixth disease), which is a common febrile illness in children[2]. Since then, there have been large-scale epidemiologic studies that have established the natural history of HHV-6 infections in humans. Primary infection with HHV-6 occurs most commonly during the first 2 years of life, with a peak incidence between 6 and 12 mo after birth. By 2 years, more than 90% of individuals have been infected, as evidenced by a positive HHV-6 antibody. Primary HHV-6 infections may present as an asymptomatic illness or as a febrile syndrome accompanied later on by a maculopapular rash (exanthem subitum). In addition, primary HHV-6 infection has been associated with otitis, gastrointestinal symptoms, respiratory distress, and seizures[3,4].

There are two variants of HHV-6, variant A and variant B (HHV-6A and HHV-6B, respectively). These variants share certain biological properties and have a high level of sequence homology, differing from one another only by up to 8% at the nucleotide level[5,6]. However, the two HHV-6 variants differ epidemiologically and clinically. HHV-6B is implicated in the majority of primary HHV-6 infections during the first 2 years of life. HHV-6B replicates in the salivary glands[7] and hence, the mechanism of transmission between humans is thought to be via salivary secretions. In contrast, HHV-6A seems to be more neurotropic and has been implicated in neurologic diseases[8,9]. HHV-6A is also more frequently detected among patients with acquired immunodeficiency syndrome[10]. The age of acquisition of HHV-6A remains undetermined and, unlike HHV-6B, it does not seem to replicate in salivary glands and thus, the mode of transmission is not known.

PATHOPHYSIOLOGY

HHV-6 infects mainly CD4+ T lymphocytes, and to a lesser extent, CD8+ T lymphocytes and natural killer cells[11-13]. HHV-6 binds to the CD46 receptor[14] that is located on what is called a "lipid raft," which then carries the virus inside the cell. The HHV-6 envelope fuses to the cell membrane, and the viral nucleocapsid is transported into the nucleoplasm where the viral DNA genome is released[15]. The virus then replicates, assembles, and exits the infected cell to infect other cells. The first proteins synthesized during viral replication are the immediate-early (IE) proteins[16]. It was recently reported that two proteins, IE1 and IE2, distinguish the variants, HHV-6A and HHV-6B, respectively (L. Flamand, abstract 3-2, 6th International Conference on HHV6 & 7, 2008). However, the exact mechanism of HHV-6 replication and assembly is not clear, although viral assembly occurs inside multivesicular bodies which are subsequently transported toward the cell surface to facilitate virus exit from the cell.

One of the mechanisms postulated to explain the ability of HHV-6 to escape the immune system and establish latency is its property of immunomodulation. HHV-6 infection results in altered cytokine responses resulting in the selective suppression of interferon-γ[17], interleukin-2[18] and up-regulation of tumor necrosis factor-α production[19]. In addition, HHV6 down-regulates the expression of its CD46 receptor[12,14], which functions as a regulator of complement activation[20] and an important link between the innate and adaptive arms of the immune system. Finally, HHV-6 has been demonstrated to enhance apoptosis *in vitro*[21,22].

LATENCY AND CHROMOSOMALLY-INTEGRATED HHV-6

After primary infection, HHV-6 establishes a state of subclinical persistence or latency. This is a property that it shares with the other members of the human herpes virus family. During latency, the HHV-6 genome is harbored as separate circular DNA inside various cells, such as lymphocytes and probably monocytes. HHV-6 DNA sequences have been detected in peripheral blood mononuclear cells of as many as 90% of one study population[23].

In rare cases, instead of existing as a separate circular DNA, HHV-6 integrates into a human chromosome [termed chromosomally-integrated HHV-6 (CIHHV-6)]. Both HHV-6A and HHV-6B have been found to have this ability to become integrated into the chromosome. The incidence of CIHHV-6 is not exactly known, although a recent study of blood donors from the United Kingdom estimated an incidence between 0.2%-1%[24]. It is suggested that CIHHV-6 may also be vertically transmitted (mother to child transmission)[25], since it was found in germ cell lines, however, this has not been confirmed by other investigators[26]. Individuals with CIHHV-6 have a characteristic persistently high levels of HHV-6 DNA in the blood, sera, and hair follicles, without causing clinical illness[27]. Individuals with CIHHV-6 persistently have high levels of HHV-6 DNA in the blood, usually millions of genomic copies, while patients with acute HHV-6 infection or reactivation only have viral copies in the tens of thousands, even in the setting of immune compromise. A reliable method which can be used to distinguish CIHHV-6 is a quantitative PCR of a hair follicle sample, which often is negative in non-CIHHV-6 infections. The high level of DNA found in the blood and other body fluids in CIHHV-6 is due to cellular proliferation and cellular lysis and not as a result of viral replication. The clinical significance of CIHHV-6 is not clear. While many believe this is not related to significant clinical problems, there are few reports suggesting that CIHHV-6 may be associated with an increased risk of lymphoproliferative disease[28,29].

MECHANISMS OF HHV-6 INFECTION AFTER TRANSPLANTATION

Because the vast majority of humans harbor latent HHV-6, infection with this virus after transplantation is believed to result from viral reactivation. Viral reactivation may also occur in the transplanted allograft to cause HHV-6 superinfection in a previously-infected individual. In a minority of cases, primary HHV-6 infection may occur in a transplant recipient through the allograft or blood products, or through natural transmission (e.g. exposure to oropharyngeal secretions). Primary HHV-6 infection is likely more common in the pediatric transplant population, especially in children less than 2 years of age, who have not been exposed to infection. In this very young group of patients, there is a higher likelihood of receiving an allograft or blood products from a previously infected donor.

INCIDENCE OF AND RISK FACTORS FOR HHV-6 INFECTION AFTER LIVER TRANSPLANTATION

The incidence of HHV-6 infection after liver

transplantation has been reported to range between 14% and 82%[30-32]. HHV-6 infections typically occur during the first 2-8 wk after liver transplantation when the level of immunosuppression is most intense. However, HHV-6 infections as early as 10 d and as late as 5 years after liver transplantation have been reported[33]. Since the vast majority of patients have developed HHV-6 infections during early life and harbor the latent virus, the vast majority of HHV-6 infections after transplantation are believed to be due to endogenous reactivation. Factors that have been associated with HHV-6 reactivation after liver transplantation are acute allograft rejection and receipt of high doses of corticosteroids[33,34]. The presence of HHV-6 infection in cases of acute liver failure has also been reported as a risk factor for the development of allograft hepatitis after liver transplantation[35].

CLINICAL SYNDROMES ASSOCIATED WITH HHV-6 INFECTION AFTER LIVER TRANSPLANTATION

A myriad of clinical syndromes have been associated with HHV-6 infection after liver transplantation. These have been classified as either direct or indirect effects of HHV-6. The direct clinical manifestations due to HHV-6 include a febrile illness with or without rash, myelosuppression, hepatitis, pneumonitis and neurological diseases[33,36-38]. The indirect effects attributed to HHV-6 include an exacerbation of cytomegalovirus (CMV) disease, an increased severity of hepatitis C virus (HCV) recurrence, an increased risk of other opportunistic infections, allograft dysfunction, and acute cellular rejection (Table 1)[33,36,39-45].

Table 1 Clinical syndromes attributed to HHV-6 after liver transplantation

HHV-6 direct effects	Ref.	HHV-6 indirect effects	Ref.
Fever and rash	[36]	Increased incidence and severity of cytomegalovirus disease	[31,40,41]
Hepatitis	[33,36,49]	Earlier and more severe recurrence of hepatitis C virus	[42]
Myelosuppression	[37]	Higher incidence of fungal infections	[44]
Pneumonitis	[37]	Higher incidence of opportunistic Infection	[36]
Neurologic illness	[38,44,51]	Higher incidence of allograft rejection	[33,36,45,53]

HHV-6: Human herpesvirus 6.

Direct HHV-6 effects

Fever and rash: The most frequently reported clinical presentation of HHV-6 infection after liver transplantation is a febrile illness that can be associated with a rash[34,36,46]. In a study of 200 liver transplant recipients, two patients (1%) presented with a febrile illness and HHV-6 was implicated as the causative agent, after excluding all other pathogens or etiologies of the fever[36]. In many cases, this febrile illness may clinically mimic, and thus be misdiagnosed as, CMV syndrome[47]. Thus, it has been suggested that the syndrome of febrile illness with myelosuppression and rash after transplantation be termed as β-herpesvirus syndrome while the specific viral etiology is being investigated[48] Co-infections with HHV-6 and CMV have been demonstrated in these cases[47]. However, a recent large study of solid organ transplant recipients demonstrated that HHV-6 was not significantly associated with any clinical symptoms during CMV disease[41].

Hepatitis: HHV-6 has been implicated as a cause of hepatitis after liver transplantation. In a review of 121 patients who developed hepatitis after liver transplantation, 8 (6.7%) cases were thought to be secondary to HHV-6 infection[33], as documented by serology and immunoperoxidase staining of liver biopsy specimens. Clinically, HHV-6 infection was associated with elevated liver enzymes, allograft dysfunction, acute rejection, and lymphocytic infiltration. These clinical findings were also observed in another report of one patient who had lymphocytic infiltration and elevated aminotransferases during HHV-6 infection[36]. In another report, an HHV-6B infected transplant recipient developed syncytial giant cell hepatitis as a result of donor-transmitted HHV6-A infection[49]. Serologic, molecular, and immunohistochemical methods were used to identify HHV-6A superinfection as the etiologic agent in this patient with a latent HHV-6B infection[49]. Finally, another study showed that nine of 18 patients who had pre-transplant HHV-6 infection developed HHV-6 hepatitis after liver transplantation[50].

Myelosuppression and pneumonitis: Bone marrow suppression is another clinical presentation attributed to HHV-6 infection. In a report of four liver transplant recipients, HHV-6 associated myelosuppression occurred at a median of 50 d (range 17-90 d) after liver transplantation. While all the cell lineages were affected, leukopenia was the most common presentation. One of the four patients in this report also had concomitant interstitial HHV-6 pneumonitis, as documented by a positive HHV-6 immunostaining of the lung biopsy[37].

Neurological illness: Encephalitis due to HHV-6 infection has been reported in two liver transplant recipients[38,51]. In another report, central nervous system complications such as mental status changes of unidentified etiology were more likely to occur in liver transplant recipients who had HHV-6 infection[44]. However, another report found no significant association between HHV-6 infection and neurological illnesses[36]. These contradictory results may be due to the differences in neurotropism between HHV6 variants, with HHV-6A as the neurotropic variant. These differences in clinical manifestations should be considered in the analysis of the clinical impact of HHV-6 after liver transplantation.

Indirect HHV-6 Effects

Impact on CMV disease: HHV-6 is postulated to have immunomodulating properties that enhance the reactivation of CMV. Alternatively, the presence of HHV-6 may serve as a marker of an over-immunosuppressed state and hence the predisposition to develop other infections such as CMV. In one study, liver transplant recipients with documented primary HHV-6 seroconversion had a higher incidence of symptomatic CMV disease compared to those who did not have HHV-6 seroconversion[39]. This finding was again demonstrated in a prospective study wherein liver transplant recipients who developed CMV disease had detectable HHV-6 DNA in the blood[31]. Recently, a retrospective study showed that 16 of 19 liver transplant recipients who developed symptomatic CMV infection had concomitant HHV-6 antigenemia, including 12 patients who developed HHV-6 infection prior to CMV antigenemia[40]. However, this association between HHV-6 and CMV was not observed in a large cohort of solid organ transplant recipients who received oral ganciclovir and valganciclovir prophylaxis, wherein the incidence of CMV disease was not significantly different between those who develop and those who did not develop HHV-6 DNAemia[41].

Impact on HCV disease: A prospective study reported that HCV-positive patients who developed HHV-6 viremia after liver transplantation had an earlier recurrence and a higher fibrosis score upon hepatitis C recurrence when compared to patients without HHV6 viremia[42]. In another analysis of 60 liver transplant recipients with chronic hepatitis C, HHV-6 infection did not influence the incidence of hepatitis C recurrence, but was associated with more severe hepatitis and a higher fibrosis score[43]. In contrast, a study of 93 hepatitis C infected liver transplant recipients showed no association between HHV-6 and the incidence and severity of hepatitis C recurrence after transplantation[52].

Impact on fungal and other opportunistic infections: Because of its immunomodulating properties, HHV-6 has been postulated to influence the occurrence of other opportunistic infections after liver transplantation. In one study of 200 liver transplant recipients, the impact of HHV-6 infection on opportunistic infections, including CMV, Epstein Barr virus-related post-transplant lymphoproliferative disease, varicella zoster virus, invasive fungal infections, and mycobacterial disease, was demonstrated. In a multivariate analysis, HHV-6 was found to be a significant risk factor for the occurrence of these opportunistic infections[36]. In another study, HHV-6 was independently associated with invasive fungal infections in a cohort of 80 liver transplant recipients[44]. Similarly, in a study of 247 patients, the incidence of invasive fungal infection was 2-fold higher in patients with HHV-6 seroconversion compared to those without HHV-6 seroconversion[36]. It was further demonstrated that HHV-6 infection was an independent predictor of invasive fungal infections during the first 90 d after liver transplantation[36]. Whether this is due to the immunomodulating properties of the virus, or whether this is due to an over-immunosuppressed state (with HHV-6 reactivation as a marker of over-immunosuppression) remains to be defined.

Impact on allograft rejection and function: The association between HHV-6 and allograft dysfunction and rejection has been demonstrated in a few studies[33,36]. Local HHV-6 infection in the allograft was associated with increased expression of adhesion molecules on vascular endothelial cells and infiltrating leukocytes, and this could lead to local inflammation and graft damage leading to dysfunction and possible rejection[53]. In an analysis of liver transplant recipients who developed allograft rejection, HHV-6 infection and peak HHV-6 load were the only factors significantly associated with rejection beyond 30 d after liver transplantation[36]. Another study further supported the independent association between HHV-6 and biopsy-proven acute allograft rejection after liver transplantation[45]. However, these associations remain debatable since treatment for allograft rejection may also lead to HHV-6 reactivation. Hence, the association between HHV-6 and allograft rejection may be bidirectional.

DIAGNOSIS OF HHV-6 INFECTION

Distinguishing HHV-6 reactivation (i.e. active replication) from latency can be challenging because of the highly prevalent nature of latent HHV-6 infection in humans. Over 95% of adults have been exposed to the virus and express antibodies against HHV-6. The various assays used to diagnose active HHV-6 infection are summarized in Table 2.

Real time polymerase chain reaction (PCR)

Molecular assays are the most commonly used laboratory methods to detect HHV-6 reactivation and replication after transplantation. Both quantitative and qualitative methods have been developed to detect HHV-6 DNA in blood and clinical samples[54-57]. In addition to blood samples, HHV-6 detection by PCR can be performed on biopsy and tissue specimens[58]. These assays can differentiate between the variants HHV-6A and HHV-6B as a result of base-differences[54]. PCR testing has some limitations, mainly due to the inability of most assays to distinguish latent from replicating virus. To address this, it is suggested that serum samples are used, since the virus is cell-associated and the detection of free viral particles in cell-free serum would be more indicative of active HHV-6 infection[54]. This is not the case for whole blood specimens where latent HHV-6 may be present and amplified from leukocytes. The use of quantitative PCR assays may be helpful in distinguishing replicating from latent HHV-6, with the premise that high HHV-6 levels or increasing viral levels over time would indicate true HHV-6 replication[55]. In this context, it is emphasized that one may rarely detect the presence of CIHHV-6, as discussed above, so that high levels (often

Table 2 Tests for the laboratory diagnosis of HHV-6 infection

Test	Detects active infection	Distinguish HHV-6 variants A and B	Commercially available
Serology (IFA and ELISA)	No	No	Yes
Real time PCR			
Qualitative	No	Yes	Yes[1]
Quantitative	Yes	Yes	Yes[1]
Culture	Yes	Yes	Yes[2]
Real time reverse transcriptase PCR	Yes	Yes	No[3]
Antigen testing	Yes	Yes	No
Antibody avidity testing	Yes	No	No
Immunohistochemical technique	Yes	Yes	No
PCR *in situ*	Yes	Yes	No

IFA: Immunofluorescence assay; ELISA: Enzyme-linked immunosorbent assay; PCR: Polymerase chain reaction; [1]Available at reference and commercial laboratories; [2]Requires viral stimulation by chemicals; [3]Very specialized research laboratories.

in the million copies) in CIHHV-6 infected individuals do not necessarily reflect active viral replication. The detection of HHV-6 RNA by real time reverse transcriptase PCR assay, on the other hand, would indicate the presence of actively replicating virus[57].

Serology

Serologic assays by immunofluorescence assay (IFA) or enzyme-linked immunosorbent assay (ELISA) are commercially available to detect antibodies against HHV-6 in plasma and serum samples. However, these assays cannot differentiate between HHV-6A and HHV-6B variants. IFA seems to be more useful as titers can be followed over time to demonstrate a rise or fall in antibody levels. In contrast, ELISA cannot be used to compare the index value over time. Both IgM and IgG can be measured. HHV-6 IgM increases during the first few weeks after infection and will be detected for several months thereafter. However, the clinical utility of serology testing after transplantation is often questionable since the results are not uncommonly false-negative due to the inability of immunosuppressed patients to develop antibodies. Nonetheless, the presence of HHV-6 IgM antibodies confirms a primary infection. HHV-6 IgG antibodies are detected initially several weeks after primary infection, and they remain elevated during latent infection. In transplant recipients, elevated IgG level has been used to suggest HHV-6 reactivation, although this is of questionable significance. An antibody avidity test may differentiate recent and past infection[59]. Some patients, particularly those receiving potent immunosuppressive therapy, may not be able to generate antibodies, and hence, using HHV-6 serology alone may miss an acute infection or reactivation.

Culture

Culture is not widely available for the detection of HHV-6 for various reasons. It is time consuming, expensive, and the virus is difficult to grow unless it is activated by chemicals. Moreover, growth of the virus does not necessarily distinguish latency from active growth *in vivo*[37,60,61].

Table 3 Antiviral molecules and their activity against HHV-6

Antiviral drug	*In vitro* activity	*In vivo* activity[1]	Mechanism of antiviral resistance
Acyclovir[73,81]	No	No	
Ganciclovir[66-68,70-72]	Yes	Yes	Mutation in U38 DNA polymerase Mutation in U69 phosphotransferase
Foscarnet[65,82-85]	Yes	Yes[2]	Mutation in U38 DNA polymerase
Cidofovir[76,86,95]	Yes	Yes	Mutation in U38 DNA polymerase
Maribavir[87,88]	No	Not available	
Cyclopropavir[89]	Yes	Not available	
CMV 423[91]	Yes[3]	Not available	
HDP-CDV[90]	Yes[3]	Not available	
3 Deaza-HPMPA[92]	Yes	Not available	

CMV 423: A New anti-CMV (Cytomegalovirus) molecule (2-chloro 3-pyridine 3-yl 5,6,7,8-tetrahydroindolizine 1-carboxamide); HDP-CDV: Hexadecyloxopropyl-cidofovir; 3 Deaza-HPMPA: (S)-9-[5-Hydroxy-2-(phosphonomethoxy) propyl]-3 deazaadenosine. [1]Based on very limited studies and case reports; [2]Combination of foscarnet with ganciclovir or cidofovir has been reported and can be efficacious; [3]Activity *in vitro* demonstrated against HHV6-A.

Antigen testing

HHV6 antigenemia can be detected in whole blood samples or tissue specimens using specific monoclonal antibodies. It often indicates the presence of an active infection, and may distinguish variant HHV-6A from HHV-6B. However, this technique is labor-intensive, semi-quantitative, and it is not widely available for clinical use[55,62].

PREVENTION AND TREATMENT OF HHV-6 INFECTIONS

There have been no randomized clinical trials conducted on antiviral drugs for the prevention and treatment of HHV-6 disease in humans. As a result, there is currently no antiviral drug that is FDA-approved for clinical use in HHV-6 infection. Nonetheless, ganciclovir, cidofovir and foscarnet have been used in the clinical setting for the treatment of HHV-6 associated diseases, although the potential efficacy of these drugs have been based mainly on *in vitro* experimental data and on anecdotal case reports (Table 3).

Acyclic nucleoside analogues (Ganciclovir)

Ganciclovir is the most commonly used drug for the management of HHV-6 infections. However, this use is not supported by randomized controlled clinical trials. Ganciclovir inhibits viral DNA polymerase, which functions during viral replication. For it to exert its antiviral properties, ganciclovir must undergo tri-

phosphorylation into the active metabolite, ganciclovir-triphosphate. The initial phosphorylation requires the enzyme phosphotransferase, which is expressed by HHV-6[63]. *In vitro* studies demonstrated the activity of ganciclovir against HHV-6[64,65]. Clinically, ganciclovir has been shown to be effective in HHV-6 infected bone marrow transplant recipients[66-70]. Likewise, case reports suggest that ganciclovir is effective for the treatment of HHV-6 infections after liver transplantation[66-68,70-72]. Ganciclovir prophylaxis has been shown to be effective in preventing HHV-6 reactivation in stem cell transplant recipients[73-75]. However, some cases of fulminant HHV-6 infections may not respond to ganciclovir[68,69]. The inconsistencies in these reports could be due to the differential susceptibilities to ganciclovir between variants HHV-6A and HHV-6B. Studies have demonstrated that HHV-6B is less susceptible to ganciclovir when compared to HHV-6A[76,77]. In the clinical setting, this differential susceptibility could partly explain the occurrence of HHV-6B (but not HHV-6A) infections in a large cohort of solid organ transplant recipients who received anti-CMV prophylaxis with ganciclovir or valganciclovir[41]. In addition, HHV-6 isolates that are resistant to ganciclovir have been described. This is due to mutations in the U38 DNA polymerase or the U69 phosphotransferase genes[78-80]. Unlike ganciclovir, acyclovir appears to be ineffective against HHV-6 clinically and *in vitro*[81]. Acyclovir prophylaxis was not effective in preventing HHV-6 reactivation in stem cell transplant recipients[73-75].

Foscarnet (phosphonoformic acid)

Foscarnet is a pyrophosphate analogue which inhibits viral replication by targeting viral DNA polymerase. Foscarnet has been shown to be active against HHV-6 *in vivo* and *in vitro*[65,82,83]. The combination of foscarnet with ganciclovir or cidofovir was also shown to be efficacious based on a case report[84]. *In vitro* studies showed that mutation in the DNA polymerase would render HHV-6 resistant to foscarnet[85].

Cidofovir

Cidofovir is an acyclic nucleoside phosphonate analogue that has been shown to have excellent activity against HHV-6 *in vitro*[76]. There have been clinical reports where cidofovir was used successfully to treat HHV-6 infections. However, cidofovir is considered a second line treatment because of its nephrotoxicity. A mutation in the U38 gene encoding DNA polymerase was found to be responsible for a mutant HHV-6 that is highly resistant to cidofovir[86].

Investigational agents

Although several agents being developed for the treatment of viral pathogens do not specifically target HHV-6, some have been tested for their activity against this pathogen. Maribavir, a benzimidazole derivative that is being developed for the management of CMV infection, was demonstrated to be inactive against HHV-6 *in vitro*[87,88]. Recently, the clinical development of maribavir for the prevention of primary CMV disease after liver transplantation has been terminated since it was not demonstrated to be superior to placebo in stem cell transplant recipients. On the other hand, cyclopropavir, a recently developed guanine nucleoside analogue, has been shown to have activity against HHV-6 *in vitro*[89]. Hexadecyloxopropyl-cidofovir, a prodrug of cidofovir, has also been shown to be three times more potent than cidofovir against DNA viruses, including HHV6-A[90]. CMV 423, a new anti-CMV molecule (2-chloro 3-pyridine 3-yl 5,6,7,8-tetrahydroindolizine 1-carboxamide) that inhibits tyrosine kinases, likewise has been shown to have good activity against HHV-6A[91]. 3 Deaza-HPMPA[(S)-9-(5-Hydroxy-2-(phosphonomethoxy) propyl)-3 deazaadenosine] has been shown to be 6-fold more active than cidofovir *in vitro* against HHV-6A and HHV-6B[92]. Finally, arysulfone derivatives[93] and artesunate[94] seem to have some activity against HHV-6. However, the clinical development of these investigational drugs is at an early stage and it is not clear on whether they will eventually reach the bedside.

CONCLUSION

Subclinical HHV-6 infections in immunocompromised transplant recipients are common, while clinical HHV-6 disease is uncommon. Indeed, some have even suggested that detection of HHV-6 infection after liver transplantation may just serve as a virologic marker of an over-immunosuppressed status. Nonetheless, some of the reported HHV-6 associated diseases have led to serious complications and even mortality. The immunomodulatory effect of HHV-6, particularly its interaction with other viruses, and its effect on allograft survival in liver transplant recipients are very intriguing and need to be further elucidated. Hence, a better understanding of the pathobiology of HHV-6 in liver transplant recipients is needed. This goal, however, is hampered by the challenges in clinical diagnosis due to the lack of standardized diagnostic methodologies. Although currently-available antivirals have been used to treat severe cases of HHV-6 infections, well-controlled clinical studies that support the use are lacking. Novel anti-herpetic agents under development have been shown to exhibit activity against HHV-6 *in vitro*, but data on their efficacy in the clinical setting is lacking and need to be assessed in future clinical studies.

Abstract

Underweight and specific nutrient deficiencies are frequent in adult patients with inflammatory bowel disease (IBD). In addition, a significant number of children with IBD, especially Crohn's disease (CD) have impaired linear growth. Nutrition has an important role in the management of IBD. In adults with CD, enteral nutrition (EN) is effective in inducing clinical remission of IBD, although it is less efficient than corticosteroids. Exclusive EN is an established primary therapy for pediatric CD. Limited data suggests that EN is as efficient as corticosteroids for induction of remission. Additional advantages of nutritional therapy are control of inflammation, mucosal healing, positive benefits to growth and overall nutritional status with minimal adverse effects. The available evidence suggests that supplementary EN may be effective also for maintenance of remission in CD. More studies are needed to confirm these findings. However, EN supplementation could be considered as an alternative or as an adjunct to maintenance drug therapy in CD. EN does not have a primary therapeutic role in ulcerative colitis. Specific compositions of enteral diets-elemental diets or diets containing specific components-were not shown to have any advantage over standard polymeric diets and their place in the treatment of CD or UC need further evaluation. Recent theories suggest that diet may be implicated in the etiology of IBD, however there are no proven dietary approaches to reduce the risk of developing IBD.

INTRODUCTION

Inflammatory bowel disease (IBD), Crohn's disease (CD), ulcerative colitis (UC) and indeterminate colitis are chronic inflammatory disorders of the gastrointestinal tract. The relationship between nutrition and IBD is complex and involves several aspects. These include: (1) nutritional support for malnourished patients, (2) primary therapy for active disease and maintenance of remission and (3) nutrients as risk factors involved in the etiology of IBD.

Nutritional care is important in the treatment of patients with IBD and includes prevention or treatment of malnutrition and micronutrient deficiencies, prevention of osteoporosis, and, in children, promotion of optimal growth and development. Enteral nutrition (EN) is considered the modality of choice for the treatment of active CD in children and for some adults too.

NUTRITIONAL STATUS OF ADULT PATIENTS WITH IBD

Malnutrition is common in patients with IBD, especially in active CD. Several studies have documented weight loss in 70%-80% of hospitalized IBD patients and in 20%-40% of outpatients with CD[1,2]. The prevalence of malnutrition is lower in patients with UC, but nutritional deficiencies can develop fast in these patients during periods of active disease[3].

Table 1 Pathophysiology of malnutrition

Main mechanism	Effect
Decreased food intake	Anorexia
	Abdominal pain, nausea, vomiting
	Restricted diets
	Drugs
Nutrients malabsorption	Reduced absorptive surface due to inflammation, resection, bypass and fistulae
Increased intestinal loss	Exudative enteropathy (protein loss)
	Occult/overt blood loss (iron deficiency)
	Diarrhea (increased loss of Zn^{2+}, K^{+}, Mg^{2+})
	Steatorrhea (fat and fat soluble vitamin malabsorption, and divalent cations' loss: Zn^{2+}, Mg^{2+}, Ca^{2+}, Cu^{2+})
Hypermetabolic state	Alterations of resting energy expenditure
Drugs' interaction	Anorexia, nausea, test alteration, proteolysis, interaction with nutrients absorption/utilization

Pathophysiology of malnutrition

The main mechanisms responsible for malnutrition in CD are presented in Table 1. These may cause malnutrition either alone or in combination. Factors which have a major role in one nutritional deficiency may play a minor role in the appearance of a different deficiency in the same patient. The most important causes of malnutrition are probably reduced food intake[4,5], presence of active inflammation[6] and enteric loss of nutrients during periods of disease activity but also during remission[7]. Anorexia secondary to increased levels of proinflammatory cytokines [tumor necrosis factor-α, interleukin (IL)-1 and IL-6][8], white adipose tissue adipokines (leptin, adiponectin, resistin)[9] and suspected alterations in hypothalamic serotonin levels[10] are considered the main causes of reduced food intake.

Studies on energy metabolism in patients with CD have been contradictory. Energy expenditure has been reported to be increased, normal, or even reduced in IBD patients compared with healthy individuals[11,12]. This may be partly because patients with different disease extension, inflammatory activity, and nutritional status were grouped together. However, when adjusted for body composition, increased resting energy expenditure (REE) has generally been disclosed. Furthermore, despite being malnourished, children with CD fail to adapt their REE per unit of lean body mass, an additional factor contributing to malnutrition[13,14].

NUTRITIONAL ASSESSMENT OF PATIENTS WITH IBD

A variety of nutritional and functional deficiencies have been observed in patients with active or inactive CD. The prevalence of malnutrition had decreased as awareness rose, and recent studies showed that most patients in remission are in a good nutritional status and some are even overweight, but still have significant abnormalities in body composition. Sousa Guerreiro *et al*[15] reported that the BMI of CD patients overall was lower than of controls

Table 2 Nutritional assessment in patients with IBD

Assessment	Parameters	Percentage of CD patients with deficient intake or parameters
Dietary history	Energy intake, low	40%[5,15]
	Protein intake, high	150% RDA[5]
	Carbohydrates, excess	39.2%[17]
	Fat, and saturated fat, excess	27%, and 59.5%[17]
	Iron intake, low	50%, 13%[18]
	Calcium and phosphor intake, low	23%[18]
	Folate intake, low	19%[18]
	Vitamin A intake, low	13%-21%, 26%[18,19]
	Vitamin B intake, low	18%-37%[19]
	Vitamin C intake, low	21%-34%, 11%[18,19]
	Vitamin D	36%[18]
	Vitamin E	63%[18]
Anthropometry	IBW < 90%	40%[5]
	BMI > 25 kg/m^2	32%[15]
Body composition	Fat body mass, SFT < 15%	30%[5]
	Fat free mass, MAC < 15%	59%[5]
	DXA (dual-energy X-ray absorptiometry)	30% osteopenic, 60% sarcopenic[20]
	Nitrogen balance, negative	[21]

RDA: Recommended daily allowance; IBW: Ideal body weight; BMI: Body mass index; SFT: Skinfold thickness triceps; MAC: Mid arm circumference.

($P = 0.006$). Thirty two percent of patients with CD had BMI > 25 kg/m^2, but still had lower fat free mass and significantly lower adjusted mean daily intakes of carbohydrates, monounsaturated fat, fiber, calcium, and vitamins C, D, E, and K ($P < 0.05$). Muscle mass depletion was detected in more than half of CD and UC patients even in the absence of malnutrition. BMI, arm muscle area and triceps plus subscapular skin fold thickness values were significantly lower, but only in the active phase of CD[3]. Valentini *et al*[16] evaluated in a prospective, controlled, multicenter study, the nutritional status, body composition, muscle strength, and quality of life in patients with IBD in clinical remission. They showed that, despite most being well nourished (74%), both CD and UC patients have decreased body cell mass and handgrip strength (as a functional measure of nutritional status) when compared to controls. This shows that the most prevalent form of malnutrition in CD patients has changed to one of excess body weight, coupled with inadequate dietary intake of micronutrients, secondary to dietary exclusion of certain foods. Moreover, in spite of appropriate intakes of energy and macronutrients, CD patients in remission have significantly lower plasma concentrations of several vitamins and minerals (Tables 2 and 3)[17-21].

NUTRITIONAL STATUS AND GROWTH IN CHILDREN WITH IBD

Growth failure and malnutrition are one of the major complications affecting children with IBD. Weight loss is present at diagnosis in up to 90% of children[22]. Recent studies have shown that, similar to adults, a significant proportion of children with CD are overweight. In a

Table 3 Nutritional deficiencies in patients with IBD

Macro- and micro-nutrient deficiencies	Nutrients	Percentage of CD patients with deficiencies
Hypoproteinemia and hypoalbuminemia		17.6[18]
Anemia	Iron deficiency	39.2[18]
	B12 deficiency	18.4[18]
	Folic acid deficiency	19[18]
Electrolytes and trace elements	Zinc	15.2, 65[18,19]
	Copper	84[19]
	Selenium	82[19]
Vitamins' deficiency (low serum levels)	B12 deficiency	18.4[18]
	Vitamin A	23.4[18]
	Vitamin B	29[18]
	Vitamin C	84[19]
	Vitamin D	17.6[18]
	Vitamin E	16[15]

Table 4 Pathophysiology of growth failure in children with IBD

Ethiopathogenesis	Mechanism
Energy and nutrient deficiencies[30]	Deficits of energy, macronutrients and micronutrients

cohort of 783 patients with newly diagnosed IBD, low BMI (< 5%) was seen in 22%-24% of children with CD and 7%-9% of children with UC. Ten percent of children with CD and 20%-30% of children with UC had a BMI consistent with overweight or risk for overweight[23]. Despite their preserved fat mass, children with CD frequently have low lean body mass[24]. Growth retardation at diagnosis has been reported in 23%-88% of children with CD and may precede the gastrointestinal manifestations by years[25]. Growth failure is less common in UC compared to CD although growth impairment is seen in both groups[26]. The variability in reported prevalence of growth failure in children with CD can be explained by differences in the definition of growth impairment, the population under study and disease phenotype (colon *vs* small bowel). About 30%-40% of children continue to have severe linear growth retardation during their disease course and several studies found that the final height is affected in CD patients with early onset symptoms[27,28]. The etiology of growth failure is multi factorial and not completely understood, but poor nutritional state, systemic consequences of gut inflammation, disturbances of the growth hormone/insulin-like growth factor axis, genetic influences and corticosteroid use contribute in different ways (Table 4)[29-36].

INTERVENTION FOR GROWTH IN CHILDREN WITH CD

Newby *et al*[37] examined the results of different interventions for growth failure in children with CD. Three randomized, controlled trials (RCT) were identified. One study looked at the use of 6-mercaptopurine (6-MP) as a steroid sparing agent[38]. No difference in linear growth was observed between the intervention and placebo groups, although the total steroid dose received over the 18 mo follow-up period was reduced in the group receiving 6-MP. Two other trials compared EN to corticosteroids for induction of remission. In both studies, height velocity standard deviation scores were significantly increased in the EN group compared with the corticosteroid group[39,40]. The judicious use of surgical interventions was also shown to improve growth in pre-pubertal children with refractory disease[41-43]. In a large prospective trial of infliximab in children and adolescents with moderate to severe CD, improvement of height velocity and height percentiles was seen in children treated with the drug prior to or early during puberty[44]. The role of growth hormone for the treatment of growth failure associated with CD is unclear. The few studies that investigated the effect of growth hormone on growth velocity showed contradictory results and the effect of such treatment on final adult height is yet to be determined[45,46].

NUTRITION AS PRIMARY THERAPY FOR ADULTS WITH CD

Parenteral nutrition (PN)

Dudrick *et al*[47] were the first to suggest that PN was safe and possibly beneficial to patients with IBD. Use of PN for the management of adults with CD during the eighties succeeded in achieving clinical remission and avoiding surgery[47,48]. However, the remission was often short lived and the number of patients remaining in remission 3 mo later varied between 20% and 79% depending on the population of patients, length of PN administration, definitions of remission or recurrence and simultaneous use of medications[49]. PN therapy also achieved fistula healing in 43%-63% of patients in some series, accompanied by reduction in disease activity index, weight gain and elevation of serum albumin[50,51]. PN was proved a useful adjunctive therapy for UC patients requiring bowel rest and nutritional support, though not useful in induction of remission[52].

Since EN was shown to be at least as efficient as

PN with lower costs and fewer significant side effects, the current indications for PN support are restricted to severe malnutrition and for nutritional support pre- and postoperatively, in both CD and UC[53,54].

Home parenteral nutrition

CD accounts for up to 20% of the adult population on home PN[55,56]. PN has an important role in maintaining the nutritional status and improving the quality of life of these patients, but it is associated with significant morbidity and potentially life-threatening complications. In a retrospective series of 41 patients on home PN for CD over an 11-year period (121 patient-years of home PN), 58.5% of patients had one or more PN-related complications necessitating hospitalization. There were eight deaths, one directly caused by catheter-related sepsis[57].

Experience in children using home PN is limited. Strobel *et al*[58] have reported their experience in 17 pediatric patients, all of whom had severe CD. All 17 patients showed weight gain and symptomatic improvement and 10 had height catch up. Complete remission was obtained in 12 patients during the first course of PN[58].

Enteral nutrition for adult patients with CD

EN was shown to induce clinical remission, improve nutritional status, improve body composition, induce mucosal healing, decrease pro-inflammatory cytokine levels and reduce serum inflammatory markers in patients with CD[59-63]. The theory behind the mechanism of action of EN is multi-factorial (Table 5)[64-67].

Three meta-analyses and two Cochrane Database Systematic Reviews published in recent years examined the efficacy of EN compared to corticosteroids in CD[68-72]. The most recent Cochrane meta-analysis that included 192 patients treated with EN and 160 treated with steroids yielded a pooled OR of 0.33 favoring steroid therapy (95% CI: 0.21-0.53). In patients in whom remission was achieved, the relapse rates at 12 mo were identical (65% and 67%) regardless of the therapy. Similar results were reported in all meta-analyses of adult patients. It must be remembered, however, that since meta-analyses are based on intention to treat analysis, they also reflect the lower acceptance of this form of treatment in adults. Furthermore, comparison of efficacy alone between EN and corticosteroids is insufficient, as the two treatment modalities possess entirely different safety profiles. In contrast to corticosteroids, EN has minor, immediate side effects and no known long-term adverse effects. Adult patients should be considered also for EN if: (1) there is a potential for a high lifetime corticosteroid dose, including adolescents and patients in their thirties; (2) there is a high risk for osteoporosis; (3) the patients are steroid-refractory, steroid-dependent or steroid-intolerant; (4) the patients request alternative treatment.

Type and content of formula

Elemental formulae (protein provided as amino acids) were utilized in the initial studies in adults with IBD. Studies comparing elemental formulae to polymeric (whole protein) drinks showed that the two formulae were equally efficacious. Similar conclusions were reached by the Cochrane Database Systematic review that examined one form of EN *versus* another for inducing remission of active CD. Meta-analysis of 10 trials comprising 334 patients found no difference in the efficacy of elemental *versus* non-elemental formulae (OR 1.10, 95% CI: 0.69-1.75). Subgroup analyses performed to evaluate the different types of elemental and non-elemental diets (elemental, semi-elemental and polymeric) showed no significant differences[72]. The reviewers concluded that protein type does not influence the effectiveness of EN.

Table 5 The mechanism of action of enteral nutrition in CD

Proposed mechanism of action	Ref.
Improvement of nutritional status	[59]
Down regulation of pro-inflammatory cytokines	[64,65]
Anti-inflammatory effects	[61,62]
Promote epithelial healing	[62,65]
Decrease gut permeability	[66]
Decrease antigenic load to the gut, bowel rest	[59]
Modification of gut flora	[67]

The influence of fat quantity and quality of enteral diets on the outcome in CD has been examined in several studies. The use of diets with a very low fat content (0.6%-1.3% of total calories) has been associated with good outcomes[73], while those containing high quantities of fat (12%-30% of total calories) were associated overall with less favorable outcomes, in particular when large amounts of linoleic acid were present[74,75]. The 2007 Cochrane Database Systematic review examined seven trials (209 patients), treated with EN formulae of differing fat content (low fat: < 20 g/1000 kcal *versus* high fat: > 20 g/1000 kcal), and found no significant difference in efficacy between the 2 (OR 1.13, 95% CI: 0.63-2.01). Similarly, the effect of very low fat content (< 3 g/1000 kcal) or type of fat (long chain triglycerides) did not demonstrate a difference in efficacy in active CD, although a non significant trend favoring very low fat and very low long chain triglyceride content was demonstrated[72].

Different modifications in composition of enteral formulae have also been evaluated. Such modifications include fat and/or protein content as described, and the addition of bioactive peptides such as glutamine, growth factors (transforming growth factor-β2), butyrate, omega-3 fatty acids and antioxidants[61,76-79]. Addition of bioactive peptides to enteral diet formulae may have specific anabolic or anti-inflammatory actions. Up to now, such modifications of enteral diets-elemental diets or diets containing specific components-have not been shown to have any advantage over standard polymeric diets.

EN and disease location in adults with either CD or UC

In patients with CD, disease location was not found to predict induction of remission with EN. Zachos *et al*[72] concluded, after extensive review of the literature, that a definite statement about the impact of disease location upon response to EN cannot be made because of

insufficient data. There is no evidence to support the use of EN as primary therapy in UC.

EN FOR MAINTENANCE OF REMISSION IN ADULTS WITH CD

Ongoing EN supplementation may help maintain remission and reduce the use of corticosteroids. When using this strategy, supplementary oral formula is provided in combination with a normal diet throughout the day. This approach may also be used in combination with maintenance medical therapy.

The Cochrane IBD group published the results of a meta-analysis on the role of EN for maintenance of remission in CD[80]. The main outcome measure was the occurrence of a clinical or endoscopic relapse. Two studies met the inclusion criteria and were included in the review. In the first, elemental and polymeric feeds (providing 35%-50% of the patients' calorie intake in addition to an unrestricted normal diet) were equally effective for maintenance of remission, allowing withdrawal of steroid therapy (OR 0.97, 95% CI: 0.24-3.92)[81]. In the second study, 51 patients with CD in remission were randomized to receive half their calories in the form of an elemental formula or to an unrestricted diet for up to 2 years[82]. The treatment group had a much lower relapse rate (34%) than the unrestricted diet group (64%), OR 0.3, 95% CI: 0.09-0.94). This study was halted before the expected end as a result of the interim analyses by the monitoring board, who found a significant benefit for the use of EN formula to maintain remission. Thus, the available evidence suggests that supplementary EN may be effective for maintenance of remission in CD.

Yamamoto investigated the impact of EN on the clinical and endoscopic recurrence after surgical resection for CD. Forty consecutive patients who underwent resection for ileal or ileocolonic CD were randomized to receive partial EN (EN group), or a regular diet (non-EN group). Ileocolonoscopy was performed at 6 and 12 mo after operation. Six months after operation, five patients (25%) in the EN group and 8 (40%) in the non-EN group developed endoscopic recurrence ($P = 0.50$). Twelve months after operation, endoscopic recurrence was observed in six patients (30%) in the EN group and 14 (70%) in the non-EN group ($P = 0.027$). One patient (5%) in the EN group and 7 (35%) in the non-EN group developed clinical recurrence during the 1-year follow-up ($P = 0.048$). Thus, long-term EN supplementation may significantly reduce clinical and endoscopic recurrence after resection for CD[65].

EXCLUSIVE ENTERAL NUTRITION (EEN) FOR INDUCTION OF REMISSION IN CHILDREN WITH CD

Pediatric studies showed that treatment with EEN can induce remission in up to 85% of newly diagnosed patients. The first meta-analysis of pediatric studies included five trials (147 patients). EEN was found as effective as corticosteroids in inducing remission (RR 0.95, 95% CI: 0.67-1.34)[83]. In a second meta-analysis in children, 11 RCTs ($n = 394$) were included[84]. Seven RCTs ($n = 204$) compared EEN with corticosteroid therapy. Based on the pooled results of four RCTs ($n = 144$), no significant differences in the remission rates between EEN and steroids were found (RR 0.97, 95% CI: 0.7-1.4). Four RCTs ($n = 190$) compared two EEN regimens[84]. Because of a lack of data, formal pooling of results was not possible for many outcomes (e.g. time until remission, duration of remission, growth data).

In conclusion, there are no differences in efficacy between EEN and corticosteroid therapy in the treatment of acute CD in children. Improved growth and nutritional status while avoiding the side effects of steroids make EEN the preferred choice for first-line therapy in children with active CD.

Johnson *et al*[85] investigated whether partial enteral nutrition (PEN) may be as effective as EEN in induction of remission in children with CD. They randomized children with active CD to either receive all of their nutrition as elemental diet (EEN) or only 50% (PEN). Total nutritional intake was similar in both groups, but the remission rate was higher in the EEN group (42%) then in the PEN group (15%)[85].

Elemental and polymeric formulae were shown to be equally effective in children with CD. In a randomized, non-blinded, multicenter, controlled trial in Sweden, 16 children with CD received Elemental 028 Extra (E028E) and 17 received Nutrison Standard (NuS). No significant difference was found between the 2 groups in remission rate at 6 wk (intent-to-treat analysis): E028E 11/16 (69%) and NuS 14/17 (82%), nor in the decrease in the Pediatric Crohn's Disease Activity Index (PCDAI) and adult CDAI. Patients treated with NuS gained more weight than patients with E028E. A polymeric diet may be superior to elemental diet in the treatment of pediatric CD where the primary aim is to increase the patient's weight[86].

EEN and disease location in children

Studies in children showed contradictory results with regard to the effect of disease location on EEN. Two studies found no difference in the remission rate of children with ileal *versus* isolated colonic disease[87,88]. In contrast, a recent report noted a decreased response rate in patients with isolated colonic disease[89]. EEN is beneficial in children with peri-anal disease, whether isolated or in combination with luminal disease[88]. As in adults, there is no convincing evidence that the effect of EN is restricted to small bowel disease only. The influence of disease location and other factors on response to EEN requires further evaluation.

Duration of remission/time to the first relapse in children

The meta-analysis of Dziechciarz *et al*[84] identified two RCTs ($n = 43$) that investigated duration of remission after EN. One study showed a significant reduction in

the time to relapse in the EN group compared with the corticosteroid group (n = 19, mean difference -0.4 year, 95% CI: -0.6 to -0.2)[22]. In the second RCT (n = 24), a similar trend was reported (the mean duration of remission was 7 mo in the EN group *versus* 10 mo in those treated with corticosteroids)[40].

The relapse rate after EN treatment is 50%-90% at 12 mo in adult studies. This is difficult to assess in the pediatric literature, as many of the reports are of selected groups with a short follow-up period, often of < 12 mo. Fell reported a follow-up of over 10 mo in 23 children who entered remission with EN, with 9 (39%) children relapsing (1 within 2 mo)[62]. The risk factors for early relapse are not well defined but probably include disease severity at onset, disease extent, and disease site, with colitis being more likely to relapse. There have been no long-term pediatric outcome studies after initial treatment with EN.

EN FOR MAINTENANCE OF REMISSION IN PEDIATRIC CD

Prospective studies investigating the role of long-term supplementation of a normal diet with EN in children with CD are limited[90,91]. Belli *et al*[92] reported on eight children with CD and severe growth failure whose clinical course was good on a regimen of elemental diet in one out of every 4 mo. Using this strategy they succeeded in reversing growth arrest, while decreasing prednisone requirements and PCDAI prior to puberty. Thus, maintenance EN can assist in maintaining remission, aid in ensuring adequate and appropriate growth, in addition to postponing the need for steroids.

LONG TERM OUTCOMES OF CHILDREN TREATED WITH EEN

Knight *et al*[88] retrospectively reviewed the long-term outcomes of 44 children treated with EEN over several years in a single pediatric IBD centre, with follow-up periods ranging between 1 and 7 years. Most children who continued maintenance EN had no relapse after remission was established and almost half of the patients have had no need for corticosteroids since diagnosis. In those who did require steroids, therapy was delayed by a median period of 68 wk (range 6-190). In addition, the authors showed improved weight Z scores 12 mo after diagnosis (compared to baseline values), but no improvement in height Z scores[88]. An additional pediatric retrospective study looked at 37 children who received EEN, comparing outcomes in these children to those of 10 children treated with steroids[93]. The initial remission rate in those managed with EEN was similar to that of corticosteroids (86.8% and 90%, respectively). Children managed with EEN achieved greater mucosal healing (64.8% *vs* 40%). Furthermore, EEN therapy led to significantly enhanced nutritional improvements and linear growth recovery compared to steroids. Both groups were managed with maintenance amino salicylic acid (5-ASA) therapy. The EEN treated group had a much longer duration of remission in the 12-mo follow-up period[93].

QUALITY OF LIFE AND EEN

Administration of EEN has been found to be difficult in adult patients as reflected by treatment dropout rates as high as 55%. The influence of therapy on quality of life (QOL) during and following EEN were evaluated in two recent studies of children with CD. One showed improved QOL scores in 24 of 26 children treated with EEN for active CD, with 90% of the children achieving remission. Even the three children who received their enteral formula *via* a nasogastric tube reported overall improvements in QOL[94]. Children receiving EEN through nasogastric tubes emphasized the difficulties associated with the use of these tubes. However, it seems that the improvements in bowel symptoms and overall well-being may outweigh the negative aspects[95].

SIDE EFFECTS OF EEN

EEN is safe and generally well tolerated. Side effects are minimal (23.5%) and include nausea, abdominal pain, flatulence, or diarrhea[96]. The only reported severe adverse event associated with EEN is a single case of refeeding syndrome[97].

DIETARY FACTORS AND THE RISK OF IBD

Several studies examined the association between specific dietary patterns and the risk of CD, including the amount of energy, fat type and quantity, carbohydrates, specific amino acids and fiber. This issue is beyond the scope of this review and the reader is referred to previous and recent publication on dietary factors predisposing to IBD in adults and children[98-100].

CONCLUSION

Malnutrition is common in IBD, the etiology is multifactorial, and it is associated with adverse consequences. Its management requires identification and treatment of the nutritional deficits. PN may correct nutritional deficits and maintain nutritional status. However, EN has similar efficacy to PN with lower costs and fewer complications and is thus the modality of choice. Several studies have attested the efficacy of enteral formulations to control disease activity in adult CD patients. EN is considered the therapy of choice for children with active CD especially in the presence of growth retardation. It was shown to induce clinical remission, mucosal healing, modulate mucosal immune events, nutritional improvement and resumption of growth.

Therefore, in children, EN should be considered as the treatment of choice when acceptable by the family and child. Although not efficacious as steroids in

inducing remission in adults with CD, nutritional therapy has the advantages of controlling inflammation, mucosal healing and overall nutritional status with minimal adverse effects.

Abstract

Hepatic fibrosis is considered a common response to many chronic hepatic injuries. It is a multifunctional process that involves several cell types, cytokines, chemokines and growth factors leading to a disruption of homeostatic mechanisms that maintain the liver ecosystem. In spite of many studies regarding the development of fibrosis, the understanding of the pathogenesis remains obscure. The hepatic tissue remodeling process is highly complex, resulting from the balance between collagen degradation and synthesis. Among the many mediators that take part in this process, the components of the Renin angiotensin system (RAS) have progressively assumed an important role. Angiotensin (Ang) Ⅱ acts as a profibrotic mediator and Ang-(1-7), the newly recognized RAS component, appears to exert a counter-regulatory role in liver tissue. We briefly review the liver fibrosis process and current aspects of the RAS. This review also aims to discuss some experimental evidence regarding the participation of RAS mediators in the pathogenesis of liver fibrosis, focusing on the putative role of the ACE2-Ang-(1-7)-Mas receptor axis.

Key words: Hepatic fibrosis; Renin angiotensin system; Angiotensin Ⅱ; Angiotensin-(1-7); Receptor Mas; Angiotensin converting enzyme 2

INTRODUCTION

Liver fibrosis is a dynamic process resulting in excessive deposition of extracellular matrix (ECM) components. It is a multifunctional process that involves hepatic stellate cell (HSC) and Kupffer cells (KCs), cytokines, chemokines and growth factors and results from a disruption of homeostatic mechanisms that maintain the liver ecosystem[1-3]. The fibrogenic cascade can be divided into the following steps[1-3]: (1) activation of HSC and KCs; (2) migration and proliferation of HSCs; (3) synthesis and deposition of ECM components; (4) remodeling of scar tissue; (5) wound contraction; (6) apoptosis of HSCs.

In this manuscript, we briefly review the liver fibrosis process and current aspects of the Renin angiotensin system (RAS) and further discuss the putative role of Angiotensin (Ang)-(1-7) in controlling hepatic injury.

LIVER FIBROSIS PROCESS

The HSC is the main cell type responsible for excessive deposition of connective tissue components, including

type I collagen, in response to liver injury[1-6]. HSCs, also called lipid storage cells, lipocytes or Ito's cells, are found in the space of Disse among endothelial cells and hepatocytes. These cells represent approximately one third of the non-parenchymatous cell population or 15% of the total number of hepatic cells[2-4]. The main function of HSCs is to metabolize vitamin A, which is intracellularly reserved as cytoplasmatic fat bodies, mainly as retinol esters[4]. Such cells also contain a small amount of triglycerides, phospholipids, cholesterol and free fatty acids. Moreover, they produce cytokines, growth factors and inflammatory mediators[4-6]. The activation of HSCs is a process not fully understood that involves the depletion of vitamin A storage and the lowering of retinol chains[2,4]. There are also important morphological and functional changes in the activated HSC, which include the increase in the expression of myogenic and neurogenic proteins and the subsequent change into highly contractile fibroblasts[2-4]. HSCs, despite being firmly adhered to hepatic endothelial cells, also play a pivotal role in the regulation of portal pressure. Besides that, due to the expression of multiple actin and muscular and non-muscular myosin types, when the HSC transforms itself into a myofibroblast, it acquires the ability to contract scar tissue and fibrous septa[1-3].

Formal pathogenesis of fibrosis is initiated by parenchymal cell destruction (necrosis rather than apoptosis) due to multiple injurious agents and mechanisms followed by inflammation, which in turn activates "resting" HSCs[1-3]. The HSCs lose their lipid droplets, proliferate, migrate to the third zone of the hepatic lobule, modify themselves in order to acquire a myofibroblast-like phenotype and start producing collagen types Ⅰ, Ⅲ and Ⅳ and laminin[2-4]. It is generally accepted that α actin expression reflects the activation of HSC[4]. Activated HSCs migrate to injured sites and proliferate in response to numerous pro-fibrogenic mediators, among which transforming growth factor β-1 (TGFβ-1) and platelet-derived growth factor are considered the most effective ones[7,8]. HSCs are the main cells responsible for ECM production in the liver. The ECM serves as a storage site for cytokines and growth factors, and thus, tissue injury could induce their release[2,4]. This event may be responsible for providing the initial signal for tissue repair, prior to the activation of cells within the liver and/or the arrival of inflammatory cells (Figure 1).

Activated HSCs express and secrete matrix molecules, cytokines and chemokines, matrix metalloproteinases (MMPs) and their respective tissue inhibitors of metalloproteinases (TIMPs)[1-4]. Thus, HSCs participate pathophysiologically both in fibrogenesis and fibrolysis, i.e. enzymatic dissolution of the ECM and, thus, in tissue remodeling. According to this hypothesis, fibrosis is conditionally reversible, based on the fact that HSCs produce multiple MMPs, which degrade interstitial and basement membrane collagens[9-11]. Thus, when the fibrogenic stimulus is singular, or multiple stimuli have not induced a state in which the excess

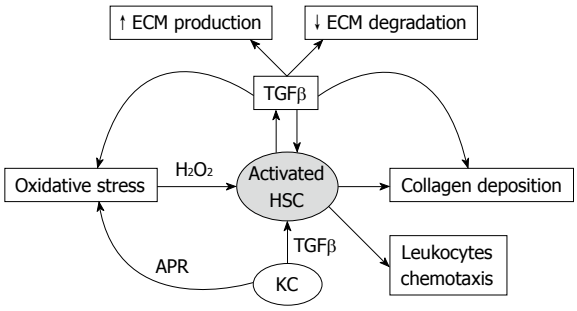

Figure 1 Diagram of activated hepatic stellate cell actions and interactions in liver fibrosis process. HSC: Hepatic stellate cell; KC: Kupffer cell; APR: Acute phase response; ECM: Extracellular matrix; TGFβ: Transforming growth factor-β.

deposition of ECM components is accompanied by a distortion of liver architecture, the process may be completely reversible[2,5,9-11]. At this stage of liver fibrosis, interruption of the fibrogenic stimulus results in MMPs secretion[11]. However, when the fibrogenic process is already associated with formation of connective tissue septa, distortion of liver architecture and formation of vascular shunts, fibrosis becomes irreversible, unless one finds the means to stimulate production and activation of MMPs, to down-regulate the expression of TIMPs, and to inhibit the production of collagen[2,5,9-13].

Another cell line involved in liver fibrogenic cascade is the KC. KCs are highly mobile macrophages that are attached to the endothelium[1-3]. Physiologically, KCs produce the immunosuppressive cytokine, interleukin (IL)-10, that prevent HSC proliferation and/or collagen synthesis[1,2,4]. These cells are activated by engulfment of apoptotic hepatocytes; this leads to removal of dead cells from the liver. Furthermore, activated KCs secrete inflammatory cytokines, linking apoptosis in the liver to inflammation. Once there is hepatic injury, activated KCs possess autocrine and paracrine loops that induce the expression of TGFβ, which, in turn, promotes HSC and hepatocyte proliferation and/or chemotaxis of inflammatory cells and HSCs[1,2,4,14,15]. In these conditions, circulating levels of cytokines and chemokines, such as tumor necrosis factor-α (TNFα), IL-6, IL-1, IL-8, colony stimulating factor, monocyte chemotactic protein and leukotrienes, are increased. These elevated mediators have a key role in recruiting neutrophils and monocytes into the lesion site and exert an important regulatory effect on the expression of collagen genes by HSCs[1-3]. Indeed, KCs have a pivotal role in the activation of HSCs and/or in increasing their capacity to produce ECM components during hepatic diseases[1-3].

Among all cytokines and growth factors, the TGFβ superfamily exerts important functions during the development, differentiation and tissue remodeling[14,15]. TGFβ1 strongly modulates cell proliferation by increasing ECM proteins and proteases inhibitors and by diminishing several metalloproteases expression[1-3,12-15]. In normal hepatic tissue, TGFβ-1 and TGFβ-2 mRNA are predominantly expressed by KCs, while TGFβ-3 is detected in stellate cells. During fibrogenesis, TGFβ-2

and TGFβ-3 expression are diminished, while TGFβ-1 expression is significantly increased among stellate and endothelial cells[1-3,12-15]. This cytokine is a potent inhibitor of hepatocyte proliferation, but it is also capable of regulating hepatocyte growth during its regeneration. TGFβ induces the formation of oxygen reactive species, which is involved in HSC activation and in the augmentation of mRNA expression for collagen I [1-3,12-15].

Depending on the magnitude of the injury, the host's response may be local and/or systemic. When the events take place in the liver, the response is restricted to HSCs and KC activation or results in recruiting inflammatory cells that, along with KCs, produce cytokines and growth factors necessary to the healing process[2,3,12-15]. When the injury takes a larger extent and local events cannot control it, there is a systemic response, common to every other inflammatory process, regardless of the causal agent. This systemic reaction corresponds to the acute phase response, characterized by the increased production of TNFα, IL-6, IL-1, oncostatin M and acute phase proteins[1-3]. Although these changes are intended to limit the tissue injury, elevated cytokine expression, mostly IL-6, may contribute to hepatic fibrosis by enhancing ECM deposition, collagen I content and fibronectin genetic transcription, as well as by stimulating other fibrogenic cytokines (such as TGFβ), and by amplifying TIMP production[1-3,11-15].

There are other factors involved in the ECM remodeling process, which include MMPs and TIMPs. MMPs 1 and 13, also known as collagenases 1 and 3, respectively, are the main secreted neutral proteinases capable of initiating degradation of collagen types Ⅰ, Ⅲ and Ⅴ[11]. The individual contribution of MMPs in ECM degradation within the normal liver and during hepatic fibrogenesis remains unclear. HSCs express the MMP 1 mRNA gene, but the enzyme levels are not increased in patients with fibrosis. On the other hand, MMP 13 expression is augmented at early phases of liver fibrosis, preceding the increase of collagen I production[12,13]. Among other MMPs, types 2 and 3 have their expression elevated in HSCs during intermediate and initial phases, respectively, of carbon tetrachloride induced hepatic fibrosis[3,10,12,13]. MMP 9, also called gelatinase B, can degrade collagen IV, gelatin and laminin, thus facilitating cellular migration through basement membranes[3,12,13]. There are also TIMPs that regulate enzyme activity and play a role in different models of hepatic fibrosis[5]. Summing up, the hepatic tissue remodeling process is highly complex, resulting from the balance between collagen degradation and synthesis (Figure 1).

The understanding of the HSC activation pathways and the approach of molecular biology have provided new strategies to hepatic antifibrotic therapy[1-4]. Many of these strategies are based on the inhibition of collagen deposition and/or inactivation of the HSCs. Experimental studies in which the treatment is provided simultaneously and/or during the course of fibrosis induction have been successful[1,2,9-11]. Such approaches may include: (1) healing the primary disease in order to prevent the injury[1,2]; (2) reducing inflammation or the host's response to avoid HSC activation (interferon-α, ursodesoxycholic acid, corticosteroids and TNF-α antagonists)[1,2,9]; (3) direct inhibition of HSC activation (antioxidants-vitamin E and interferon γ-endothelin receptor antagonists)[1,2,9]; (4) neutralizing the HSCs proliferative, fibrogenic, contractile and/or pro-inflammatory response [angiotensin converting enzyme (ACE) inhibitors, angiotensin Ⅱ type 1 receptor (AT_1) antagonists, Ang-(1-7) receptor Mas agonists, proteases inhibitors, hepatocyte growth factor, tyrosine kinase inhibitors, endothelin receptor antagonists][9-11]; (5) stimulating HSC apoptosis (gliotoxin, Fas ligands)[9-11]; (6) increasing scar matrix degradation by stimulating proteases producer cells and by providing such proteases (TGFβ antagonist, MMP tissue inhibitors)[9-11].

Nevertheless, liver fibrosis in humans is a silent disease. Many patients are diagnosed in an advanced phase when fibrous septa and hepatic architecture distortion already exist. Thus, the development of new treatments focusing on the removal of fibrous septa and promoting hepatic tissue regeneration becomes essential.

CURRENT ASPECTS ON THE RAS

The RAS is classically conceived as a hormonal cascade responsible for controlling cardiovascular, renal and adrenal functions that regulate hydro-electrolytic balance and blood pressure through Ang Ⅱ actions[16].

Recent advances in cellular and molecular biology, as well as physiological and pharmacological approaches, have generated new concepts through the identification of new peptides, enzymes, receptors and biological actions. Additionally, tissue RAS has been characterized in different organs and systems, in which significant interactions between receptors, mediators and metabolic pathways have been discovered[17-21]. In this field, some of the latest advances should be mentioned: (1) the characterization of other biologically active RAS fragments, besides Ang Ⅱ, such as Ang Ⅲ, Ang Ⅳ and Ang-(1-7)[17-21]; (2) the discovery of a new enzyme, a homolog to the ACE, called ACE2[22,23], which is the main enzyme responsible for the conversion of Ang Ⅱ into Ang-(1-7)[24,25]; (3) the identification of the G protein-coupled receptor Mas, a functional receptor for Ang-(1-7)[26]. These discoveries have contributed to the understanding of RAS in normal physiology and in pathological conditions[19-21].

Among RAS mediators, Ang-(1-7) is of particular interest due to its selectivity, which is attributed to the absence of phenylalanine (Phe) in the C-terminal position, which is critical for the binding of Ang Ⅱ to AT_1 receptors[27]. Several enzymatic routes may be involved in Ang-(1-7) formation, either directly from Ang I or from Ang Ⅱ through tissue peptidase actions, including neutral endopeptidase, oligopeptidase, prolyl-carboxypeptidase, prolyl-endopeptidase and ACE2[24,28]. The recent discovery of ACE2 has provided

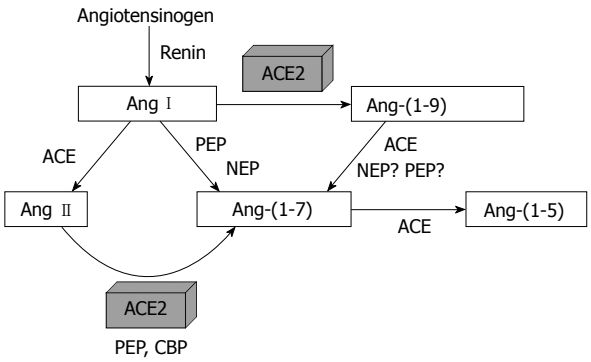

Figure 2 View of the main metabolic pathways of Ang Ⅱ and Ang-(1-7). ACE: Angiotensin converting enzyme; ACE2: Angiotensin converting enzyme 2; PEP: Prolyl-endopeptidase; NEP: Neutral endopeptidase; CBP: Carboxypeptidase.

an important pathway for production of Ang-(1-7), probably by exerting an important role in tissue peptide formation[19-21]. Figure 2 shows the main pathways for Ang-(1-7) metabolism.

Once it is formed, Ang-(1-7) is rapidly hydrolyzed, especially by ACE[29]. In the presence of ACE inhibition and after chronic administration of AT_1 receptor blockers, Ang-(1-7) levels are raised several times, suggesting that this heptapeptide contributes to the actions of RAS blockers[28,30,31]. Many studies have indicated the physiopathological importance of Ang-(1-7) in human diseases[32-36]. In general, Ang-(1-7) has opposing actions to Ang Ⅱ, which gives the system a dual influence over various tissues[20,21]. For instance, Ang-(1-7) have vasodilator and anti-proliferative effects on blood vessels[37-39]. This effect allows RAS to influence vascular growth, either by stimulating through Ang Ⅱ or inhibiting through Ang-(1-7)[21,37-39]. Ang Ⅱ is clearly mitogenic in vascular smooth muscle cell (VSMC) culture and in intact arteries, whereas Ang-(1-7) inhibits VSMC growth and reduces neointimal formation[37,38,40]. To date, Ang Ⅱ and Ang-(1-7) exhibit opposite effects on the regulation of cell growth as demonstrated by Gallagher and Tallant (2004) in lung cancer cells[41]. Receptor Mas appears to be involved in the antiproliferative effect of Ang-(1-7) in VSMC[42] and in stent-induced neointima proliferation[43]. Furthermore, it has been demonstrated that Ang-(1-7) inhibits vascular growth through prostaglandin-mediated intracellular events inducing cAMP production and reduction of Ang Ⅱ-stimulated ERK1/2 activities[44].

RAS can be envisioned as a dual function system, in which the vasoconstrictor/proliferative or vasodilator/antiproliferative actions are primarily driven by the ACE/ACE2 balance[21,45]. According to that, an increased ACE/ACE2 activity ratio will lead to increased Ang Ⅱ generation and increased catabolism of Ang-(1-7) favoring vasoconstriction while an opposite ratio will decrease Ang Ⅱ and increase Ang-(1-7) levels facilitating vasodilation[21,45]. The fact that Ang-(1-7)/Mas directly antagonizes many actions of Ang Ⅱ, provides an additional layer of counter regulation in the system[46].

THE RAS'S ROLE IN LIVER FIBROSIS

A growing body of evidence indicates that the RAS takes part in the pathogenesis of liver fibrosis[47-61]. In this regard, plasma renin activity and aldosterone levels were both elevated in patients with liver cirrhosis, especially those with hepatorenal syndrome[47-50]. Indeed, Ang Ⅱ and aldosterone actions lead to renal vasoconstriction, blood flow redistribution and increases in sodium and water tubular reabsorption[47-49]. All of these effects tend to normalize the organ perfusion pressure and plasma effective volume. The elevation in circulating levels of PRA and aldosterone is due to an excessive production of these substances and not from a diminished hepatic catabolism[47,48]. This higher production could be attributed either to a physiological response to systemic vasodilation that occurs in cirrhotic patients[48,61] or to an intrahepatic RAS activation[53-60].

Tissue fibrosis is a common response in numerous chronic diseases, regardless of etiology, resulting in the production of, for example, liver cirrhosis, glomerulosclerosis, interstitial lung fibrosis and cardiac hypertrophy. Thus, resembling what happens in renal[62,63] and cardiac[16] fibrosis, several studies suggest that Ang Ⅱ could mediate and exacerbate liver fibrosis through HSC activation and by stimulating TGFβ-1 *via* AT_1 receptors[1-6,14,15,53-55]. Bataller *et al*[53] have shown the presence of AT_1 receptors in human activated HSC cultures. Experimental studies with AT_{1a} receptor knockout mice showed an attenuated liver inflammation and fibrosis following bile duct ligation[56]. Immunohistochemistry analysis revealed decreased infiltration by inflammatory cells, reduced lipid peroxidation products and decreased phosphorylation of c-Jun and p42/44 MAPK in AT_{1a} knockout mice compared to AT_1 wild type animals[56]. On the other hand, the genetic deletion of Ang Ⅱ AT_2 receptors worsened the fibrosis induced by CCl_4 by stimulating oxidative stress, which lead to HSC activation[57]. While AT_1 receptors play an important role in the development of fibrosis, the AT_2 signal has anti-fibrogenic and/or cytoprotective effects on oxidative stress-induced liver fibrosis[56,57]. Taken together, these experimental studies suggest that RAS-associated liver fibrogenesis may be determined by the balance between AT_1 and AT_2 signals.

Therefore, by activating AT_1 receptors, Ang Ⅱ induces contraction and proliferation of HSCs, which is considered the principal effector of hepatic acinar fibrosis[53-55]. A similar effect has been observed in mesangial and VSMC. AT_1 receptors are found in most of the mesenchymal cells and mediate the majority of the Ang Ⅱ biological effects, including the increase in intracellular calcium, cellular contraction and proliferation[58,59]. The magnitude of the HSC contractile response to Ang Ⅱ is comparable to the effect elicited by endothelin-1, which is considered the most powerful contractile agent to this cell line. Ang Ⅱ contractile effects were attenuated in the presence of powerful vasodilators, such as nitric oxide and prostaglandins[53], and completely blocked by pre-incubation with the AT_1 receptor blocker, losartan[55]. Additionally, Ang Ⅱ

mediates key biological actions involved in hepatic tissue repair, including myofibroblast proliferation, infiltration of inflammatory cells, and collagen synthesis[60]. Activated HSCs secrete Ang Ⅱ, which induces fibrogenic actions through the activation of NADPH oxidase[1-4].

Although the mechanisms of hepatic fibrosis are not fully understood, such as in other tissues, experimental evidence indicates that TGFβ-1 has a key role in this process[14,15]. In the heart and in the kidneys, many vasoactive peptides have shown themselves capable of enhancing TGFβ-1 expression, including Ang Ⅱ[16,60,62]. Jonsson *et al*[54] have investigated functional polymorphisms of TGFβ-1 and angiotensinogen genes and the influence of these genotypes in liver fibrosis of patients with chronic C hepatitis. These authors found a significant relation between TGFβ-1 and angiotensinogen genotypes and the development of liver fibrosis[54]. Patients that did not exhibit a profibrotic genotype normally did not develop fibrosis. Ang Ⅱ also increases TGFβ-1 and the genetic expression of collagen 1 *via* AT_1 receptors in the liver[55,58]. TGFβ-1 also induces HSC activation, which, in turn, increases TGFβ-1 expression[14,15]. Thus, there is a formation of autocrine and paracrine loops that assure the continuous production of this fibrogenic cytokine[1,6,14,15].

RAS inhibition reduces collagen Ⅳ expression and interstitial expansion in different tissues. The response to treatments with AT_1 receptor blockers and ACE inhibitors clearly illustrate the importance of the RAS in renal and cardiac fibrosis[16,17,64,65]. Kidney tubulointerstitial fibrosis induced by cyclosporine was ameliorated by RAS inhibition[66]. Similarly, RAS pharmacological blockade also reduced collagen Ⅳ expression and interstitial expansion in rats with renal obstruction[67]. Treatment with ACE inhibitors and/or AT_1 receptor blockers has also shown beneficial effects in liver diseases[51,52,54,55,58]. Some studies have shown reductions in TGFβ-1 and procollagen α1 mRNA levels in the liver of rats treated with captopril after common bile duct ligation (BDL), supporting the hypothesis of an Ang Ⅱ action on HSCs[58,59]. In addition to antifibrotic effects, captopril has improved hemodynamic alterations, renal function and cholestasis[51,52,54,55,58]. Paizis *et al*[59] demonstrated that the RAS blockade by irbesartan, an AT_1 receptor antagonist, in BDL rats, reduced the expression of TGFβ-1 and of collagen 1 in the liver. These findings are consistent with the concept that the Ang Ⅱ-TGFβ-1 axis may work in the liver as a pathway towards organic fibrosis, as previously demonstrated in other experimental models, like the use of carbon tetrachloride[68] in mansonic schistosomiasis[69] and, more recently, in transgenic mice with high expression of TGFβ-1[70]. In fact, the local production of Ang Ⅱ, as well as circulating RAS activation, may be a significant part of the tissue overall response to injuries.

However, there are few studies exploring the role of Ang-(1-7) in liver fibrosis[45,71-75]. Our group recently showed that the progression of liver dysfunction in BDL rats is characterized by marked changes in Ang-(1-7) levels and that the overall activation of the circulating

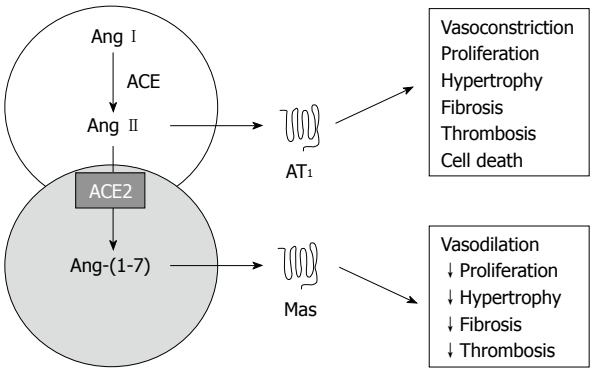

Figure 3 A schematic diagram of both RAS arms. The counter-regulatory arm of the RAS, ACE2-Ang-(1-7)-Mas axis, produces effects that oppose those of the ACE-Ang Ⅱ-AT_1 receptor axis. Ang: Angiotensin; Mas: G-protein coupled receptor of Ang-(1-7); AT_1: Type 1 receptor of Ang Ⅱ.

RAS was associated in time with the progression of hepatic fibrosis[72]. Furthermore, the pharmacological blockade of the Ang-(1-7) receptor Mas accelerated liver fibrosis by increasing the liver content of collagen and TGFβ-1[72]. In line with these findings, Paizis *et al*[71] (2005) observed an upregulation of ACE2 and its widespread expression throughout the liver in BDL animals and in human cirrhosis. A few years later, the same group showed that as BDL rats developed advanced fibrosis, increased expression of components of the classic RAS such as ACE, AT_1 receptor and Ang Ⅱ was accompanied by increased hepatic and plasma ACE2 activity, increased Mas expression in the liver and a major rise in plasma levels of Ang-(1-7)[73]. More recently, Lubel *et al*[75] (2009) corroborated these previous studies regarding the protective role of Ang-(1-7) against liver fibrosis. The authors reported that, in BDL rats, Ang-(1-7) not only improved the histological fibrosis stage and reduced hydroxyproline content but also decreased gene expression of collagen 1A1, α-SMA, VEGF, CTGF, ACE and receptor Mas[75]. In addition, cultured hepatic cells expressed AT_1 and Mas receptors, and when treated with Ang-(1-7) or the Mas receptor agonist, AVE 0991, produced less α-SMA and hydroxyproline, an effect reversed by the Mas receptor antagonist, A779. Ang-(1-7) is upregulated in human liver disease and has antifibrotic actions in a rat model of cirrhosis[75]. Indeed, the current studies[45,71-75] raise the possibility that upregulation of hepatic ACE2 and Mas, and the generation of Ang-(1-7) represent a counter regulatory response to RAS-mediated liver injury (Figure 3).

There is substantial evidence to suggest that Ang-(1-7) is involved in the beneficial actions of AT_1 receptor blockers, ACE and vasopeptidase inhibitors[76]. Supporting this theory Maia *et al*[77] have shown that the antagonist of Ang-(1-7) receptor Mas, A-779[78], has attenuated the hypotensive response to bradykinin in animals treated with ACE inhibitors, suggesting the involvement of Ang-(1-7) in the cardiovascular effects of ACE inhibitors. The studies with BDL rats are also evidence that RAS blocking agents may attenuate liver

fibrosis not only by antagonizing Ang Ⅱ, but also by elevating Ang-(1-7) levels[45,72-75]. Thus, the administration of Ang-(1-7) or its oral agonist, the compound AVE0991[75,79], could be useful for understanding the mechanisms of fibrosis and should be further investigated for the treatment of liver diseases associated with fibrosis.

CONCLUSION

The better understanding of the underlying mechanisms involved in liver fibrosis makes effective antifibrotic therapy an imminent reality. However, treating this disease remains a challenge and, up to this moment, no antifibrotic agent has been approved for routine human use. It is important to mention that Ang-(1-7) is quickly hydrolyzed, especially by ACE and, in presence of ACE inhibition and after chronic administration of AT_1 receptor blockers, its levels increase several times[30,31,35], suggesting that this heptapeptide may contribute to RAS blockade[20,21]. Furthermore, Kostenis *et al*[46] have recently demonstrated that the Ang-(1-7) Mas receptor can hetero-oligomerize with the AT_1 receptor and by so doing inhibits the actions of Ang Ⅱ. So, it is believed that the Mas receptor acts *in vivo* as an antagonist to the AT_1 receptor[46]. Hence, it has raised the hypothesis that the RAS acts through two pathways: the first one, responsible for the main actions of the system, composed of the ACE-Ang Ⅱ-AT_1 receptor system and the second one, the counter-regulatory pathway, formed by the ACE2-Ang-(1-7)-receptor Mas system[20,21,45]. Finally, the use of ACE inhibitors, AT_1 receptor antagonists and, perhaps, Ang-(1-7) receptor Mas agonists[78] could become important tools in this study, and maybe to the therapeutic approach of liver fibrosis.

Abstract

AIM: To analyze the prognostic factors involved in survival and cancer recurrence in patients undergoing surgical treatment for colorectal liver metastases (CLM) and to describe the effects of time-related changes on survival and recurrence in these patients.

METHODS: From January 1994 to January 2006, 236 patients with CLM underwent surgery with the aim of performing curative resection of neoplastic disease at our institution and 189 (80%) of these patients underwent resection of CLM with curative intention. Preoperative, intraoperative and postoperative data, including primary tumor and CLM pathology results, were retrospectively reviewed. Patients were divided into two time periods: a first period from January 1994 to January 2000 (n = 93), and a second period from February 2000 to January 2006 (n = 143).

RESULTS: Global survival at 1, 3 and 5 years in patients undergoing hepatic resection was 91%, 54% and 47%, respectively. Patients with preoperative extrahepatic disease, carcinoembryonic antigen (CEA) levels over 20 ng/dL, more than four nodules or extrahepatic invasion at pathological analysis had worse survival. Tumor recurrence rate at 1 year was 48.3%, being more frequent in patients with preoperative and pathological extrahepatic disease and CEA levels over 20 ng/dL. Although patients in the second time period had more adverse prognostic factors, no differences in overall survival and recurrence were observed between the two periods.

CONCLUSION: Despite advances in surgical technique and better adjuvant treatments and preoperative imaging, careful patient staging and selection is crucial to continue offering a chance of cure to patients with CLM.

INTRODUCTION

Up to 50% of patients with colorectal carcinoma (CRC) will develop metastases during the course of their disease, leading to certain death if untreated[1,2].

Colorectal liver metastases (CLM) are present in 15% to 25% of cases at the time of diagnosis of primary tumor, and another 25% to 50% will develop metachronic CLM within 3 years following resection of primary CRC[1,3-6].

Surgical resection remains at the present time the only potentially curative treatment for patients with CLM, even though hepatic resection is only possible in less than 25% of patients with metastatic disease limited to the liver[1,5,6]. Although neoplastic recurrence is observed in up to 50% of patients and remains a basic determinant of survival, only 20%-30% of these patients are potentially amenable to repeat hepatic resection[7,8]. Five-year survival after curative resection ranges 30%-40%, whereas less than 2% of patients are alive 5 years after diagnosis without surgical therapy[5,6,9].

Many attempts have been made to classify patients into stratification groups in order to determine which patients would obtain most benefit from resection, even though the most used classification remains the clinical risk score (CRS) described by Fong *et al*[9-11]. According to these scores, CLM resection should be put into question in high-risk patients because of poor expected results after surgery, and therefore these patients should be included in chemotherapeutical trials. In recent years an increase in indications for resection of CLM has been observed due to a multidisciplinary approach with improvements in surgical techniques, anesthetic management and the introduction of new chemotherapy drugs[12-15]. This approach has led to an extension of the traditional limits of CLM resectability with promising results, although the number of patients is still too small to draw definitive conclusions[16,17].

Taking all these facts into consideration, the aims of our study were to analyze the survival and recurrence of patients with CLM undergoing surgical treatment in our hospital, to determine whether any single factor was significantly associated with survival and recurrence, and to describe the effects of time-related changes in our series of patients.

MATERIALS AND METHODS

Between January 1994 to January 2006, 236 consecutively recruited patients with CLM were operated on in our institution with the aim of performing curative resection of neoplastic disease. Among them, 189 patients (80%) underwent curative hepatic resection (defined as resection of all macroscopic neoplastic tissue found during laparotomy), with 18 patients undergoing resection of extrahepatic disease at the same time.

CLM resection criteria at the hospital clinic

Criteria for resection of CLM have changed over time and, in general, these indications were more restrictive at the beginning of the series and have expanded as surgical experience and better perioperative care of patients has been acquired. The classically accepted indications for CLM surgery in our institution are: (1) patients presenting with 4 or less nodules, (2) remaining liver parenchyma over 25% of total liver volume and (3) no extrahepatic neoplastic disease (defined as the presence of metastatic neoplastic tissue beyond the limits of hepatic capsule). However, the definitive guiding criteria used to consider or refuse a patient for CLM resection is the possibility of benefit from a complete resection of neoplastic disease with enough functional residual liver, despite the localization and number of lesions and an adequate physical status to tolerate liver resection (defined by a performance status under 3 and an absence of serious associated illnesses). All prospective surgery patients with CLM are evaluated and staged with radiological studies (chest X-ray, abdominopelvic CT or MRI scan, occasionally complemented with liver volumetry in cases when predicted liver remnant is small, as well as PET scan in cases when extrahepatic invasion is suspected), laboratory tests including liver function tests, carcinoembryonic antigen (CEA) assay and a complete colonoscopy. Candidates are presented to a CRC committee meeting composed of liver and colorectal surgeons, oncologists and radiologists.

Liver resection technique for CLM

Despite several changes in the resection technique during the time considered in the study, the main technical points for CLM resection have remained constant over time (J-shaped skin incision in the upper right quadrant, intraoperative ultrasonography (IOUS) and liver transection with an ultrasonic dissector under Pringle maneuver if needed).

Although the increasing use of laparoscopic techniques in colorectal resections has led to a reduction in the amount of surgical trauma[18], thus making one-step resection of CRC and CLM possible, the majority of our patients with synchronous CLM usually undergo colorectal and liver resection in two separate stages. In cases when simultaneous resection is planned, patients are operated on by two coordinated different teams of surgeons specialized in hepatic and colorectal surgery respectively. Colorectal resection is always performed first and the decision about performing liver resection at the same operation is taken depending on the type and extent of colorectal and liver resection, and any intraoperative findings that might recommend a two-stage procedure.

Postoperative follow-up of patients with CLM

After discharge from hospital, patients are followed by a multidisciplinary team of oncologists, colorectal and hepatic surgeons and postoperative status and pathologic results are then reviewed. Depending on the previous treatments, overall risk and tolerance, patients are proposed to be treated with complementary chemotherapy, mainly based on 5-fluorouracil and either irinotecan or oxaliplatin, although in recent times the use of cetuximab as an adjuvant agent has increased. Usual postoperative follow-up in order to detect neoplastic recurrence consists of physical examination, laboratory

tests with liver function tests and CEA assay, and abdominal ultrasonography or CT every 3 mo during the first 2 years and every 6 mo after the second year.

CLM resection data

Patients were classified according to the interval between the diagnosis of CLM and CRC resection. CLM diagnosed before, during or within 90 d of CRC resection were classified as synchronous and those CLM diagnosed at least 90 d after CRC resection were classified as metachronous.

In order to study the evolution of CLM resection over time, the entire series of patients was divided into two periods of equal length: the first period from January 1994 to January 2000 and the second period from February 2000 to January 2006.

Preoperative, intraoperative and postoperative data including CRC and CLM pathology results were retrospectively reviewed.

Definitions of interventions and results

Combined hepatectomy was defined as any major (three or more segments) or minor (less than three segments) hepatectomy with any associated atypical (non-anatomical) resection.

Neoplastic recurrence was diagnosed by at least two coinciding image techniques or surgical exploration at least 30 d after liver resection. Survival was calculated using the last follow-up date (January 31, 2008) or the date of expiration.

Statistical analysis

Categorical variables were compared using the chi-square or Fisher's exact test. Continuous variables were expressed as mean ± SD and compared using Student's *t* test. When a normal distribution was not present, continuous variables were expressed as the median and the range and compared using the Mann-Whitney *U* test.

Patient survival and recurrence were calculated using the method of Kaplan-Meier, and the log rank test was used to compare survival in the univariate analysis. Multivariate analysis was calculated using a Cox regression model.

A *P* value under 0.05 was considered significant. All statistical analyses were performed with the "Statistical Package for the Social Sciences" version 11.0 for Windows (SPSS, Chicago, IL).

RESULTS

Demographic and preoperative data of the patients in the series are shown on Table 1. Overall median follow-up was 5.8 years, with a minimum follow-up of 1 year and maximum of 14 years. By time periods, median follow-up in the first period group was 9.3 years, while in the second period group was 3.8 years.

Primary tumor-related and preoperative factors

Synchronous metastases, colonic localization of the primary tumor and parameters related to a low risk CRS accounted for the majority of patients in the series, even though some cases had extreme size and number of CLM. Over half of the patients had received some adjuvant treatment for CRC (five patients having received radiotherapy, 97 patients having received chemotherapy and 39 patients having received both treatments). Preoperative treatment before hepatic resection was given to 62 patients, the majority of them receiving 5-fluorouracil-based systemic chemotherapy because of synchronous or initially non-resectable metastases (Table 1).

Extrahepatic invasion	11 (4.8)

Intraoperative results

217 patients (92%) underwent IOUS. We found a higher amount or more invasive hepatic lesions than in the preoperative evaluation in 30% of the patients, leading to non-resection in half of these patients. 38 patients were found to have extrahepatic disease at the time of laparotomy, and in 18 of them a curative resection with resection of extrahepatic disease could be achieved. 159 patients (72%) underwent another procedure associated with liver resection, mainly cholecystectomy (105 patients) but also including colectomy (11 patients), splenectomy (one patient) and diaphragmatic and vascular resection (five patients) (Table 2).

Postoperative results (Table 3)

Pathological data: Non-involved margins (defined as the absence of tumor at any edge of the resection piece at the pathological examination) were achieved in 75.8% of patients. Extrahepatic invasion on pathological

Table 2 Operative characteristics of the patients *n* (%)

Characteristics

analysis was found in 12.3% of patients. When comparing the number of nodules found at pathological examination with the ones preoperatively diagnosed, 28% of patients showed more nodules, whereas only 18.2% of patients had more nodules at pathological examination compared with the number diagnosed intraoperatively by IOUS.

Clinical data: Global postoperative mortality in the series was 1.7%. Minor postoperative complications were described in 41.1% of the patients in the series, with nine patients suffering biliary leak, nine patients having postoperative hepatic failure and only one case of postoperative bleeding. 4.7% of patients had major postoperative complications but only eight patients needed reoperation (4 due to intestinal fistula or perforation, 2 due to wound evisceration and one due to postoperative bleeding and infection).

Outpatient data: After resection, chemotherapeutic adjuvant treatment (based mainly on 5-fluorouracil alone or combined with irinotecan or oxaliplatin) was given to 52.9% of the patients.

Recurrence analysis

Tumor recurrence rate at 1, 3 and 5 years was 40.9%, 66% and 70.4% with a median tumor-free survival of 1.42 (0.4-1.9) years (Figure 1). When performing unifactorial analysis, preoperative extrahepatic disease (P = 0.02), CEA levels over 20 ng/dL (P = 0.017), nodules larger than 5 cm at pathological examination (P = 0.043) and extrahepatic disease at pathological examination (P = 0.009) were associated with a higher recurrence. Multivariate recurrence analysis showed that patients with preoperative extrahepatic disease (HR 3.355, P = 0.023) and CEA levels over 20 ng/dL (HR 1.812, P = 0.013)

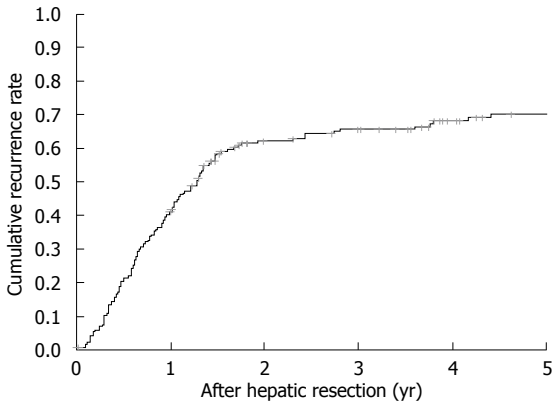

Figure 1 Neoplastic recurrence after hepatic resection.

before resection were exposed to a higher recurrence risk. No differences were observed when comparing patients by preoperative number and size of nodules and their lobar distribution. An affected surgical margin was not associated with higher recurrence compared to non-affected margins. When analyzing intraoperative (blood loss, need of blood transfusion, use of Pringle maneuver, type of resection) and postoperative events (biliary leak, postoperative complications, postoperative liver failure) only biliary leakage was associated with an increase in 5-year recurrence rate (0.9% *vs* 9.5%, P = 0.009) but without differences in survival rates.

Global survival and unifactorial survival analysis

The global survival at 1, 3 and 5 years in patients undergoing hepatic resection was 91%, 54% and 47%, respectively (Figure 2). Median survival was 3.6 years. Patients undergoing curative hepatic resection had better survival compared to patients in whom a curative resection was not possible (Figure 3). No factors associated with primary CRC tumor were found to make significant differences to patients' survival, with no differences in survival between patients with synchronous and metachronous CLM. When diagnosed with CLM, the presence of preoperative extrahepatic disease conferred worse survival compared to patients without extrahepatic disease (P = 0.0002) without influence by number and size of CLM. Patients with

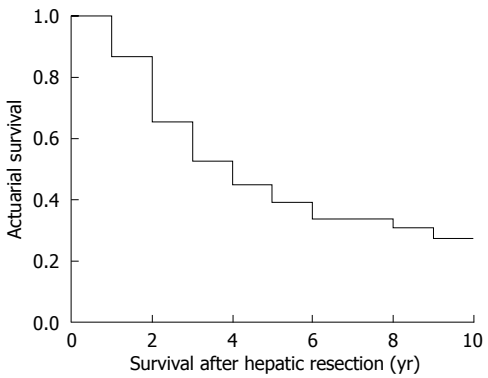

Figure 2 Global survival post resection.

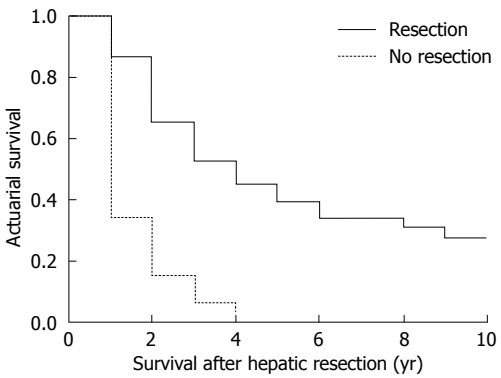

Figure 3 Survival for type of surgery.

a preoperative CEA value under 20 ng/dL had better survival compared to patients with CEA over 20 ng/dL (P = 0.035). When analyzing pathological results of CLM, the presence of more than four nodules (P = 0.015) and extrahepatic invasion (P = 0.0044) was associated with worse survival. As with recurrence, intraoperative and postoperative events had no significant effect on survival.

Multivariate survival analysis

Regarding factors associated with primary CRC tumor, nodal invasion was the only factor accounting for a decreased survival (HR 1.743, P = 0.049). As in the unifactorial survival analysis, preoperative extrahepatic invasion was a significant factor in multivariate analysis (HR 3.223, P = 0.036). After resection, having only one nodule on pathological analysis was a protective factor for survival (HR 2.122, P = 0.042), whereas having nodules over 5 cm was a risk factor for a worse prognosis (HR 2.222, P = 0.049).

Time-related results analysis (Table 4)

No differences in overall 1- and 3-year survival (88.3% and 51.9% *vs* 85.6% and 52.3%) and 1-year recurrence (38.5% *vs* 44%) were observed between patients in the first time period when compared to patients in the second time period.

When analyzing preoperative factors, patients in the second group had a higher number of CLM, but no differences were found when comparing CLM size in

the two groups. Also, patients with bilobar disease and presence of extrahepatic disease were more frequent in the second period. CEA levels were higher in the first period. Adjuvant treatment prior to CLM resection was more frequently used in the second period.

Resectability rate was higher in the second period. The frequency of IOUS use did not differ between periods, and there was only a non-significant trend of better accuracy in the second period. Changes in the distribution of surgical techniques were observed with a higher amount of minor hepatectomies and combined procedures in the second period. Operative time in resected patients was slightly higher in the second period, while there were no differences in blood loss and in the perioperative transfusion rate.

No differences were observed in postoperative mortality between the two periods. Postoperative complications were more often observed in the second period with increased minor complications and a similar major complications rate. Hospital stay was shorter in the second group. A similar amount of patients received complementary treatment after CLM resection.

DISCUSSION

At the present time, surgery remains the only curative treatment for CLM[1,5,6]. Advances in liver surgery, perioperative care, radiological techniques and the introduction of new chemotherapeutical agents have greatly changed resection strategies and have increased the number of patients in whom curative resection can be achieved[1,12-15].

Our series show that the majority of patients had good prognostic preoperative characteristics according to CRS (few and small nodules, unilobular distribution and CEA under 20 ng/dL). Such a patient selection can be a reason to explain a high CLM resection rate achieved (80%), comparable to other major series[19], which enhances our policy of feasibility of resection of CLM with extension of traditional criteria. This preoperative selection would not be complete without the use of IOUS as previously recommended by many authors[20-22]. In our series IOUS showed a clear selection benefit as it detected a preoperative underdiagnosis of CLM leading to non-resection in nearly 15% of the patients. For this reason, we strongly advocate IOUS exploration as a compulsory adjunct prior to liver resection for CLM.

The presence of extrahepatic disease is one of the classical contraindications to CLM resection, a belief which has changed as surgical expertise has made it possible to perform curative resections including all extrahepatic disease[1]. Despite this positive aspect, it has to be noted that the preoperative and the postoperative (pathological) presence of extrahepatic disease in patients with CLM is associated with a higher neoplastic recurrence and a worse patient survival[9,23]. This fact should raise concern regarding need for a stricter patient selection when extrahepatic disease is found on preoperative imaging, as only curative resection is a valid option for these patients[24]. Also, even though no conclusive data exist at the present time, the finding of intraoperative extrahepatic disease probably deserves a closer postoperative follow-up with a more aggressive use of complementary chemotherapeutical treatment.

Definition of an adequate minimal surgical margin when resecting CLM remains an unresolved issue[25,26]. At the present time the ideal margin is yet to be defined as some authors have shown that negative margins of either 1-4 mm, 5-9 mm or up to 1 cm have similar overall recurrence rates and survival[25-27]. In our study differences in recurrence and survival could not be found when comparing free surgical margins under and above 1 cm, a fact that supports these previous observations. Interestingly, a positive surgical margin was not associated with worse survival or higher recurrence in our series, which could be explained by the concept that the really important margin would be the one which remains in the patient, as some studies have pointed[28].

The presence of CLM has been historically linked to a low overall survival, although in recent years the advances in imaging, chemotherapeutical agents and surgical techniques have increased the survival rates, approaching a 5-year survival of 60%[12-15]. In our series 5-year survival in resected patients was 47%, which can be positively compared with other major hepatobiliary center series, although some of these series do not reflect the surgical and perioperative improvements achieved in the last decade[29].

Up to 50% of patients with resected CLM will develop recurrence of neoplastic disease, the majority of them in the first 2 years, and this fact remains the most determinant factor for patient survival[30-34]. Several recurrence-associated factors such as size and number of CLM, stage of the primary tumor, CEA levels, disease-free interval and resection margin have been described; these being the basis for the clinical scores which are used for predicting recurrence and thus survival in patients with CLM[9-11]. In our study we were only able to find preoperative CEA above 20 ng/dL and extrahepatic invasion as significant factors that would be associated with an increased recurrence rate.

Despite the already known effect of preoperative factors, some authors have also pointed to the influence of intraoperative and postoperative events on recurrence and survival[35,36]. Improvements in surgical technique and perioperative management have lead to a decrease in postoperative mortality in major centers, under 5% in the last few years, clearly improving prognosis in patients with CLM[37]. In our series global postoperative mortality was 1.7%, a similar rate when compared to other series from high-volume centers[29]. Interestingly, when analyzing postoperative complications, only biliary leakage was associated with a significantly increased first-year recurrence rate, but had no influence on differences in survival rate. This data should be taken with caution as more studies need to be done in order to confirm this unexpected and difficult to explain observation, but it raises concern about the influence of postoperative events in the prognosis of CLM patients.

Surgical treatment of CLM has been challenged with

advances in surgical techniques and better perioperative management in recent times[29,32,36,37]. Our series failed to show an improvement with time in short- and medium-term survival and recurrence as these two parameters did not improve in the second time period. However, similar survival and recurrence rates between the two periods should not be seen as a negative fact because patient conditions could also have changed (and not necessarily improved) with time. In fact, even though no differences in patient basal status were observed in the second period, an increase of unfavorable prognostic factors (higher number of CLM, bilobar distribution, presence of extrahepatic disease) could be found. This extension of indications for CLM resection would be mainly responsible for the limitation of the expected effects of improved surgical experience and use of better technology when resecting CLM. Also, adjuvant treatment of CLM was more frequent in the second period, a fact related to the presence of synchronous (another indicator of bad prognosis) or initially unresectable CLM, situations that would limit improvement in overall survival rates in the second period, as seen in our study.

Resectability rate is said to depend basically on good patient selection and surgical expertise[19], a fact that seems to be confirmed by our series as resectability rate increased with time. Also, the sensitivity for diagnosing CLM with IOUS has increased with time probably as a result of the availability of higher definition instruments and the experience gained by surgeons with this technique[38]. However, preoperative imaging techniques have also improved their limits for CLM diagnosis with time. This would help explain the fact that in our series the concordance rate of preoperative studies and IOUS showed a positive trend with time, although it did not reach significance due to better accuracy in both IOUS and preoperative staging tools[39]. However, and as stated before, sufficient reasons do not exist at the present time to limit IOUS in the staging of CLM.

Our series shows an increase in global postoperative complications with time without any differences in mortality. While mortality rates could be expected to stay the same or decrease due to improved surgical expertise and perioperative care, despite more difficult resections[32,34,36], this increase in complications can be explained easily when dividing them into major and minor events[40]. Major complications are closely related to mortality and for this reason it would be expected that they did not change over time. However, minor complications mainly influence hospital stay and this latter parameter decreased with time in our series. The rationale behind this is that improved awareness and means for detection of minor complications are implemented with time, which would invariably result in better treatment of these complications.

To conclude, it can be stated that despite the extension of indications for resective surgery in the second time period, with an inclusion of patients having more unfavorable prognostic factors, improvements in surgical technique, adjuvant treatments and preoperative imaging have played an important role in avoiding a greater mortality compared to the past. As surgery remains the only curative treatment, a careful patient selection and a judicious use of adjuvant therapies prior to and after surgery are crucial to continue offering patients with CLM a real chance of a cure.

COMMENTS

Background

Although many prognostic factors for survival and neoplastic recurrence of patients undergoing surgical treatment for colorectal liver metastases (CLM) are already identified, the effects of time-related changes in these patients are still poorly studied because of the presence of many involved factors.

Research frontiers

Prognostic factors implicated in survival and recurrence for patients undergoing surgical treatment for CLM are important in order to select better treatment options in these patients.

Innovations and breakthroughs

The observed effects of time-related changes in morbidity, mortality, overall survival and neoplastic recurrence in patients with CLM result from the inclusion of patients with unfavorable prognostic factors and the recent improvements in preoperative imaging, surgical technique and adjuvant treatments.

Applications

A careful patient selection and judicious use of adjuvant therapies prior to and after surgery are crucial for continuing to improve prognosis in patients with CLM.

Peer review

The manuscript retrospectively reviewed patients who underwent hepatic resection for liver metastases from colorectal cancer, identified prognostic factors for recurrence and survival after hepatic resection, and speculated as to time-related advances of this important disease. The paper is a well-designed work which aims to evaluate the influence of some factors on the recurrence and survival of patients who undergo CLM resection and, to compare these items between two periods.

Abstract

AIM: To investigate the promoter methylation status and mRNA expression of *DKK-3* and *WIF-1* gene in hepatocellular carcinoma (HCC).

METHODS: *DKK-3* and *WIF-1* acted as Wnt-antagonists and tumor suppressors, but hypermethylation of the gene promoter and low mRNA expression activated Wnt signaling aberrantly and induced the development of HCC. Methylation status of the *DKK-3* and *WIF-1* gene promoter was investigated using methylation specific polymerase chain reaction (PCR) in tumor and adjacent non-cancerous tissues from 33 HCC patients and 20 normal liver tissues served as control. The expression of *DKK-3* and *WIF-1* mRNA was also determined by real-time quantitative reverse transcriptase PCR. The relationship between methylation, mRNA expression, and clinical data, as well as methylation and mRNA expression of the two genes were analyzed.

RESULTS: The methylation of *DKK-3* and *WIF-1* genes in HCC increased significantly compared with adjacent non-cancerous tissues and normal control tissues (χ^2 =7.79, $P < 0.05$; χ^2 = 4.89, $P < 0.05$), and no significant difference in methylation between adjacent non-cancerous tissues and normal control tissues was observed. In HCC tissues, significant differences in the *DKK-3* promoter methylation were observed in age and cirrhosis, and significant differences of the *WIF-1* promoter methylation were observed in HBsAg and cirrhosis. The average expression of *DKK-3* mRNA in HCC and adjacent non-cancerous tissues was increased significantly compared with normal control tissues. The average expression of *WIF-1* mRNA showed no significant difference among the three tissues. The mRNA expression of *DKK-3* gene in HCC was decreased as the pathological grade increased.

CONCLUSION: The aberrant promoter methylation and decreased expression of *DKK-3* and *WIF-1* may be an important mechanism in HCC, and may be a far-reaching significance in early diagnosis and therapy of HCC.

Key words: Hepatocellular carcinoma; *DKK-3*; *WIF-1*; Promoter methylation

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most fatal human malignancies and the third most frequent cause of tumor-related death[1]. However, the molecular mechanisms of hepatocarcinogenesis remain unclear. At present, α-fetoprotein (AFP) is used as a tumor marker in the screening of HCC, but it is only sensitive to advanced liver cancer or as a marker of the recurrence after hepatectomy. Therefore, identifying a tumor marker for HCC is important for early diagnosis and therapy.

The Wnt/β-catenin protein signal transduction pathway participates in early embryonic development. *DKK-3* and *WIF-1* are two key genes in the Wnt signal

transduction pathway, and the subnormal function of *DKK-3* and *WIF-1* can contribute to the activation of the Wnt pathway and result in carcinogenesis through dysregulation of cell proliferation and differentiation. CpG islands are short fragments of DNA that contain a higher CG frequency than other regions. The hypermethylation of CpG islands is associated with transcriptional repression of these genes. Aberrant promoter hypermethylation of genes occurs frequently during the pathogenesis of human cancers, and has been found to be a primary mechanism in the down-regulation of these genes. Methylation-specific PCR (MSP) and real-time quantitative reverse transcriptase polymerase chain reaction (RT-PCR) can detect these epigenetic changes and can be used for cancer detection.

In the present study, MSP and real time quantitative RT-PCR were used to investigate the methylation status and the expression of *DKK-3*, and *WIF-1* in patients with HCC, to explore the potential carcinogenesis of HCC and to investigate its early diagnostic and therapeutic potential.

MATERIALS AND METHODS

Tissue samples

Thirty-three samples of HCC and adjacent non-cancerous tissues (> 2 cm away from tumor) were obtained from the Department of Surgery, First Affiliated Hospital of Anhui Medical University between July 2006 and July 2007. These samples were documented through a pathology laboratory database. The age of the 33 patients (27 male, 6 female) ranged between 18 and 67 years, with a median age of 51 years. Ten patients were Edmonson stage Ⅰ, 18 patients were stage Ⅱ, and five patients were stage Ⅲ. The diameter of the tumor was smaller than 3 cm in five patients, and ⩾ 5 cm in 28 patients. Portal vein tumor thrombus was found in three patients. As a control, 20 samples of normal liver tissues were collected from the resection of hemangiomas between July 2006 and July 2007. The samples were snap-frozen in liquid nitrogen and stored at -80℃ until the extraction of DNA and RNA.

Nucleic acid extraction

Genomic DNA and total RNA were extracted from HCC tissues, adjacent non-cancerous and normal control tissues using the Qiagen kit (Qiagen). The concentration of DNA and RNA were determined with a spectrophotometer and their integrity was assessed by gel electrophoresis.

MSP

We investigated whether the promoter regions of the two genes were methylated. Genomic DNA was modified with sodium bisulfite using the CpGenome DNA Modification kit (Intergen) according to the specifications of the manufacturer. MSP was performed in a total volume of 25 μL, containing 2 μL modified template DNA, AmpliTaq Gold (Roche 5 U/μL) 0.2 μL, 10 × buffer 2.5 μL, dNTP (10 μmol/L) 1 μL, each primer (10 μmol/L) 0.5 μL, Mg^{2+} (25 μmol/L) 2 μL, and RNase free water 16.3 μL. MSP reactions were subjected to an initial incubation at 95℃ for 10 min, followed by 35 cycles of 95℃ for 45 s, and annealing at the 52-57℃ for 45 s and 72℃ for 45 s. Final extension was completed by incubation at 72℃ for 5 min. Primer sequences of MSP and unmethylation-specific PCR (USP) are shown in Table 1[2]. MSP products were separated on 2% agarose gels and visualized after ethidium bromide staining. The product bands of MSP and USP were calculated using a TANON GIS gel image analysis system, and the relative methylation level was determined by MSP ratio = MSP band density/(MSP band density + USP band density).

Real- time quantitative RT-PCR

Total RNA (1 μg) was reverse-transcribed with RevertAid First Strand cDNA Synthesis Kit (Fermentas) in a final volume of 20 μL. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal control. The cDNAs of interest were quantified by real-time quantitative PCR using the Rotor-Gene 3000. Samples were assayed in a 25 μL reaction mixture containing 1 μL of cDNA, 12.5 μL of 2 × QuantiTect probe PCR Master Mix (Qiagen), 1 μL of each specific primer, 0.5 μL of fluorogenic probe and 9 μL of RNase free water. The sequence of the primer and probe is shown in Table 1. Real-time quantitative RT-PCR reactions were subjected to initial incubation at 95℃ for 10 min, followed by 35 cycles of 95℃ for 15 s, and 60℃ for 60 s.

Statistical analysis

Statistical analyses were performed using SPSS software version 13.0. χ^2 test, t test, non-parameter Spearman test and Fisher's exact test were used to compare the relationship of methylation and clinical data. One-year disease-free survival was analyzed through the log rank test. The level for a statistically significant difference was set at $P < 0.05$ for all the tests.

RESULTS

MSP

Methylation status of *DKK-3* and *WIF-1* in the three tissues: The methylation status of *DKK-3* and *WIF-1* in the three kinds of tissues is shown in Table 2 and Figure 1. In HCC and adjacent non-cancerous tissues, the methylation rate of *DKK-3* was 37.61% ± 4.26% and 15.96% ± 3.91%, respectively. The methylation status of *WIF-1* was 29.70% ± 3.24% in HCC and 18.34% ± 4.02% in adjacent non-cancerous tissues. The methylation rate of *DKK-3* and *WIF-1* in HCC was higher than that in adjacent non-cancerous tissues ($P < 0.05$). The methylation of *DKK-3* and *WIF-1* was not observed in normal control tissues. There was no linear correlation between methylation of *DKK-3* and *WIF-1* ($r = 0.296$, $P > 0.05$).

Table 2 Methylation level of *DKK-3* and *WIF-1* in two tissues (mean ± SE, %)

Methylation level	*DKK-3*	*WIF-1*
HCC tissues	37.61 ± 4.26	29.70 ± 3.24
Adjacent non-cancerous tissues	15.96 ± 3.91	18.34 ± 4.02
	$P < 0.05$	$P < 0.05$

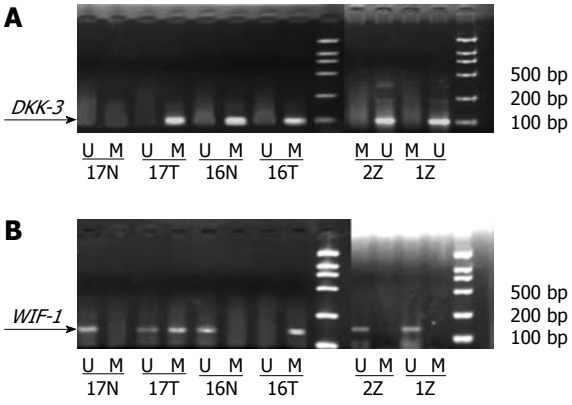

Figure 1 *DKK-3* (A) and *WIF-1* (B) MSP electrophoretogram. T: HCC tissues; N: Adjacent non-cancerous tissues; Z: Control tissues; M: Methylation-specific PCR products bands; U: Unmethylation-specific PCR products bands.

Relationship of methylation and clinical data: The relationship between *DKK-3* and *WIF-1* methylation and clinical data such as sex, age, Child-Pugh score, AFP, HBsAg, tumor number, cirrhosis, pseudo-capsule and pathology class is shown in Tables 3 and 4. The methylation rate of the *DKK-3* gene was higher in older (≥ 60) than younger (< 60) patients, higher in non-cirrhosis than that in cirrhosis patients ($P < 0.05$), and higher in HBsAg (-) than in HBsAg (+) patients. There was no relationship and no associations observed between the methylation status of *DKK-3* and *WIF-1* in adjacent non-cancerous tissues and clinical data ($P < 0.05$).

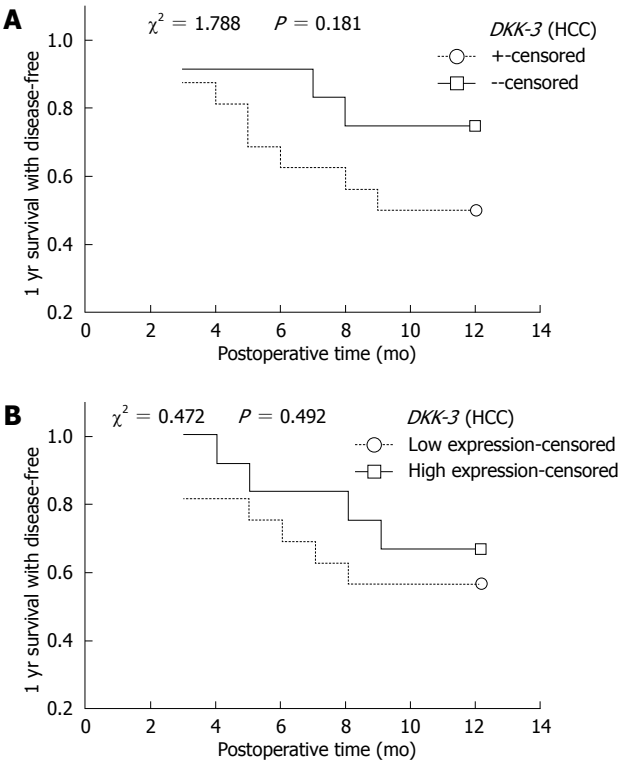

Figure 2 Relationship between methylation (A) and mRNA expression (B) of *DKK-3* gene and 1-year disease-free survival in HCC tissues.

Relationship of methylation and 1-year disease-free survival: Complete follow-up data was obtained from 27 (27/33) cases of HCC, and the follow-up time was > 1 year. Among the 27 cases, 11 cases showed disease recurrence or died. Kaplan-Meier method and Log-rank test were used to calculate the survival rate and the significance of difference. One-year disease-free survival decreased as time passed, but there was no significant difference in the *DKK-3* or *WIF-1* between HCC and adjacent non-cancerous tissues (Figure 2).

Real-time quantitative RT-PCR

mRNA expression of *DKK-3* and *WIF-1*: The *DKK-3* mRNA expression in HCC, adjacent non-cancerous tissues and normal control tissues was 0.773 ± 0.319, 0.833 ± 0.316 and 1.012 ± 0.125, respectively. The expression of *DKK-3* mRNA in HCC and adjacent non-cancerous tissues was significantly lower than that in normal control tissues ($P < 0.05$). There was no significant difference between HCC and adjacent non-cancerous tissues. *WIF-1* mRNA expression in the three tissues was 0.853 ± 0.510, 0.820 ± 0.316 and 0.995 ± 0.148, without significant difference among them. Pearson's product-moment correlation analysis showed that there was no correlation between *DKK-3* and *WIF-1* in HCC tissues ($r = 0.472$, $P = 0.127$).

Relationship between *DKK-3* and *WIF-1* mRNA expression and clinical data: The relationship between *DKK-3* and *WIF-1* mRNA expression and clinical data are shown in Tables 5 and 6. *DKK-3* mRNA expression in HCC was decreased as the pathological grade increased ($P < 0.05$), but no significant correlation was found with other clinical data. The expression of *DKK-3* mRNA in adjacent non-cancerous tissues, and the expression of *WIF-1* mRNA in HCC and adjacent non-cancerous tissues showed no significant correlation with clinical data ($P > 0.05$). Pearson's product-moment correlation analysis showed that there was no correlation between *DKK-3* and *WIF-1* in HCC, adjacent non-cancerous tissues and normal control tissues ($P > 0.05$).

Relationship of mRNA expression and 1-year survival: The expression of *DKK-3* and *WIF-1* gene mRNA in HCC and adjacent non-cancerous tissues was divided into two groups: higher expression group (> average expression) and lower expression group (⩽ average expression). Kaplan-Meier curve showed that the disease-free survival was decreased. The survival rate of the lower expression group was lower than that of the higher expression group, but without significant difference ($P > 0.05$, Figure 2).

Relationship between methylation and mRNA expression: The relationship between mRNA expression and methylation status in HCC and adjacent non-cancerous tissues is shown in Figure 3, and the relationship of *DKK-3* and *WIF-1* mRNA expression from HCC and adjacent non-cancerous tissues was not found between methylation and non-methylation ($P > 0.05$).

DISCUSSION

The Wnt signal transduction pathway plays a very important role in embryonic development, and abnormalities may lead to developmental defects and cellular malignant transformation[3]. It has been shown that disturbances of the Wnt signal transduction pathway were significantly related to human neoplastic transformation. Overexpression of *Wnt* genes has been reported in many cancers, including breast cancer, esophagus cancer, colorectal cancer, malignant melanoma, leukemia, prostate cancer, endometrial carcinoma, HCC, thyroid cancer, and pancreatic cancer[4,5]. Gene silencing related with the hypermethylation of its promoter is an important epigenetic mechanism, and an important mechanism to regulate the expression of genes in the body.

The *DKK-3* gene locus maps to 11p15.1 of the human chromosome, which encodes a Wnt complex receptor antagonist. Wnt will combine with Frizzle receptor and activate Wnt signaling if the DKK-3 protein is inactivated. Promoter-hypermethylation and reduced expression of the *DKK-3* gene were found in bladder cancer, lung cancer cell lines and tissues[2,6]. In our experiment, the methylation status of *DKK-3* in HCC was significantly higher than that in adjacent non-

cancerous tissues and normal control tissues, and the expression of *DKK-3* mRNA in HCC and adjacent non-cancerous tissues was significantly lower than that in normal control tissues. These results show that the methylation of the *DKK-3* gene promoter plays an important role in the carcinogenesis of HCC. It has been reported that hypermethylation was frequently present in elderly people[7,8], and HCC was reported to be closely linked to hepatitis B (HBV) infection. The results of previous reports are consistent. Our results show that hypermethylation was more frequent in elderly people (age ⩾ 60 years) and non-cirrhotic HCC tissues, which suggests that the silence of the *DKK-3* gene resulted from the hypermethylation of its promoter. The expression of *DKK-3* mRNA in Edmonson stage Ⅲ was significantly lower than that in stage Ⅰ / Ⅱ, suggesting that the expression of *DKK-3* is negatively related to the stage of tumor and cell proliferation. Therefore, the decreased expression of *DKK-3* mRNA may affect the invasion and intrahepatic metastasis of HCC. In addition, the expression of *DKK-3* was the lowest in late G1 of the cell cycle[9].

The *WIF-1* gene locus maps to 12q14.1 of the human chromosome, and encodes a conservative secreted protein that inhibits the activity of Wnt by holding back the regular or non-regular Wnt signal transduction pathway. Promoter-hypermethylation and reduced expression of the *WIF-1* gene was found in lung cancer cell lines and tissues, malignant pleural mesothelioma cell lines and tissues, and nasopharyngeal cancer cell lines[10-12]. Our study showed that the methylation status of *WIF-1* in HCC was higher than that in adjacent non-cancerous tissues and normal control tissues, and was higher in the HBsAg (-) and non-cirrhosis patients, which implies that the *WIF-1* gene silence related to promoter hypermethylation may represent the pathogenesis with HBV infection that results in HCC development. *WIF-1* mRNA expression in HCC and non-cancerous tissues was not significantly lower than that of normal control tissues, which may be attributed to gene silence of multiple factors. *WIF-1* mRNA expression has no relationship with clinical data, suggesting that HCC development is a complex polygene and multipathway process[13].

In summary, Wnt signaling is a major cell signal transduction pathway, and plays an important role in the proliferation and differentiation of cells. Wnt-antagonists function as tumor suppressors and contribute to the pathogenesis of several human malignancies. In the normal state, DKK-3 and WIF-1 can act as negative regulators of Wnt signaling, however, hypermethylation of the gene promoter and

low expression of mRNA will activate Wnt signaling aberrantly, and induce the development of HCC. At the same time, hypermethylation of the *DKK-3* gene in the elderly and non-cirrhotic HCC, and hypermethylation of the *WIF-1* gene in HbsAg (-) and non-cirrhotic HCC suggests that there may be two independent mechanisms in the carcinogenesis of HCC. One is HBV infection, which induces HCC development, and the other is the aberrant expression of Wnt-antagonist genes, such as *DKK-3* and *WIF-1*, which induces HCC development. A synergistic action of these factors has not been identified, and further study is needed. Our results may provide a reliable way to improve the early diagnosis of HCC and new therapies by blocking this pathway in the treatment of HCC.

COMMENTS

Background

The Wnt signal transduction pathway is significantly related to human neoplastic transformation. The Wnt-antagonist genes function as tumor suppressors and contribute to the pathogenesis of several human malignancies. Recently, promoter CpG hypermethylation and gene silencing in *DKK-3* and *WIF-1* genes have been identified in several human malignancies. The *DKK-3* gene locus maps to 11p15.1 of the human chromosome, which encodes a Wnt complex receptor antagonist. Wnt will combine with Frizzle receptor and activate Wnt signaling if the DKK-3 protein is inactivated. The *WIF-1* gene locus maps to 12q14.1 of the human chromosome, which encodes a conservatively secreted protein that inhibits the activity of Wnt by holding back regular or non-regular Wnt signal transduction pathway.

Research frontiers

Recently, Wnt antagonists have received increasing attention because of their potential role in carcinogenesis. Many studies have reported a relationship between hypermethylation of a gene promoter and low expression of mRNA in several human carcinomas. Promoter hypermethylation and reduced expression of the *DKK-3* gene were found in bladder cancer, lung cancer cell lines and tissues.

Innovations and breakthroughs

Few studies have described the correlation between Wnt antagonists and the development of hepatocellular carcinoma (HCC). The results of this study suggest that *DKK-3* and *WIF-1* may act as negative regulators of Wnt signaling and may be related to the development of HCC. However, this pathogenesis is different from that of hepatitis B virus infection inducing HCC development.

Applications

In this study, the authors investigated the methylation status and mRNA expression of *DKK-3* and *WIF-1* in HCC, adjacent non-cancerous tissues and normal control tissues, and found that the aberrant Wnt antagonists play an important role in carcinogenesis of HCC. This finding may provide a reliable way to improve early diagnosis of HCC and new therapies by blocking this pathway in the treatment of HCC.

Terminology

MSP: Methylation-specific polymerase chain reaction is a simple, rapid and inexpensive method to determine the methylation status of CpG islands. This approach allows the determination of methylation patterns from very small samples of DNA and can be used in the study of abnormally methylated CpG islands in neoplasia.

Peer review

Promoter-hypermethylation and the reduced expression of *DKK-3* and *WIF-1* were shown to be important mechanisms of hepatocarcinogenesis. These results may provide a reliable way to improve early diagnosis of HCC and develop new therapies by blocking this pathway in the treatment of HCC.

Abstract

AIM: To explore the effect of silencing of signal transducer and activator of transcription 3 (STAT3) expression by RNA interference (RNAi) on growth of human hepatocellular carcinoma (HCC) in tumor-bearing nude mice *in vivo*.

METHODS: To construct the recombinant plasmid of pSilencer 3.0-H1-STAT3-siRNA-GFP (pSH1-siRNA-STAT3) and establish the tumor-bearing nude mouse model of the HCC cell line SMMC7721, we used intratumoral injection together with electroblotting to transfect the recombinant plasmid pSH1-siRNA-STAT3 into the transplanted tumor. The weight of the nude mice and tumor volumes were recorded. *STAT3* gene transcription was detected by semi-quantitative reverse transcription polymerase chain reaction (RT-PCR). Level of protein expression and location of STAT3 were determined by Western blotting and immunohistochemical staining. STAT3-related genes such as survivin, c-myc, VEGF, p53 and caspase3 mRNA and protein expression were detected in tumor tissues at the same time. The terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay was used to detect apoptosis of tumor cells.

RESULTS: The weight of the treated nude mice increased, and the tumor volume decreased markedly compared with those of the mock-treated and negative control groups ($P < 0.01$). The results of RT-PCR and Western blotting showed that mRNA and protein levels of STAT3 declined markedly in the treated group. The change in STAT3-related gene expression in tumor tissues at the mRNA and protein level also varied, the expression of survivin, VEGF and c-myc were obviously reduced, and expression of p53 and caspase3 increased ($P < 0.01$). Most of the tumor tissue cells in the treated group developed apoptosis that was detected by TUNEL assay.

CONCLUSION: Silencing of STAT3 expression by RNAi significantly inhibits expression of STAT3 mRNA and protein, and suppresses growth of human HCC in tumor-bearing nude mice. The mechanism may be related to down-regulation of survivin, VEGF and c-myc and up-regulation of p53 and caspase3 expression. Accordingly, the *STAT3* gene may act as an important and effective target in gene therapy of HCC.

Silencing of signal transducer and activator of transcription 3 expression by RNA interference suppresses growth of human hepatocellular carcinoma in tumor-bearing nude mice. *World J Gastroenterol* 2009; 15(21): 2602-2608 Available from: URL: http://www.wjgnet.com/1007-9327/15/2602.asp DOI: http://dx.doi.org/10.3748/wjg.15.2602

INTRODUCTION

RNA interference (RNAi) is a post-transcriptional gene-silencing mechanism, in which the homologous RNA sequences are introduced into the cells that inhibit the

expression of a particular gene, through the introduction of short interfering RNAs[1]. There have been a large number of confirmed reports that RNAi targeting oncogenes may successfully inhibit the growth of tumor cells *in vitro* and *in vivo*. Hence, RNAi has been turned into a potent technology for tumor therapy.

Hepatocellular carcinoma (HCC) research has shown that RNAi targeting genes are related to initiation, development and metastasis of HCC[2-4]. Signal transducer and activator of transcription 3 (STAT3) is an important member of the family of STAT. Its signal pathway is closely associated with the proliferation, differentiation and apoptosis of cells, and constant activation of STAT3 can promote cell proliferation and carcinogenesis. At present, STAT3 is defined as an oncogene[5]. Studies of STAT3 have focused on a variety of tumor cell lines, including leukemia, multiple myeloma, breast cancer, prostate cancer, melanoma tumor, and lung cancer, while HCC has been rarely investigated. Persistently activated STAT3 is detected in many HCC cell lines and tissues.

Our preliminary research revealed that the recombination plasmid pSH1Si-STAT3 targeting the *STAT3* gene could dramatically inhibit the expression of STAT3 mRNA and protein in the HCC cell line SMMC7721 and the proliferation of HCC cells, and induce apoptosis of HCC cells[6]. Therefore, we designed the present experiment to verify the therapeutic effect of recombination plasmid pSH1-siRNA-STAT3 in HCC *in vivo*.

MATERIALS AND METHODS

Human HCC cell lines

The human HCC cell line SMMC7721 was kept in the Department of Pathophysiology of the School of Basic Medicine in Jilin University, and cultured in Iscove's Modified Dulbecco's Medium (Gibco, BRL, USA) supplemented with 10% fetal bovine serum (Gibco, BRL), in an incubator containing 5% CO_2 at 37℃, and then digested and passaged with 0.25% trypsin.

Animals

Male BALB/c nude mice were purchased from the Institute of Zoology, Chinese Academy of Sciences. They were 5-wk-old, SPF grade and weighed 17.76 ± 1.83 g, and were fed in an aseptic laminar flow room at 25℃ and 60%-70% humidity, with a standard rodent diet and water.

Construction of recombination plasmid

The plasmids pSilencer3.0-H1-STAT3-siRNA and pSilencer1.0-U6-STAT3-siRNA-GFP were kindly provided by the Research Center of Prostate Diseases in Jilin University. The sequences of STAT3-siRNA were: 5'-GCAGCAGCTGAACAACATGTTCAAGAGACA TGTTGTTCAGCTGCTGCTTTTT-3' (forward), and 5'-AATTAAAAAGCAGCAGCTGAACAACATGTCT CTTGAACATGTTGTTCAGCTGCTGCTGCGGCC-3' (reverse). The two plasmids were linearized with *Eco*RI and *Hin*dII, and then pSilencer3.0-H1 and STAT3-siRNA-GFP were combined to form pSilencer3.0-H1-STAT3-siRNA-GFP (pSH1Si-STAT3), which was cloned and sequenced. A negative control pSH1Si-Scramble, which has no significant homology with human gene sequences, was constructed by the same method. The extraction of plasmids followed the routine Fastfiler Endo-free Plasmid Maxiprep protocol (BioDev, Beijing, China).

Cell preparation

The cells in logarithmic growth phase were digested with 0.25% trypsin and centrifuged. The cells were collected and washed three times with PBS, and the living cells were counted under a microscope, and adjusted to a final concentration of 2.5×10^7 cells, with PBS.

Establishment of tumor-bearing nude mouse model

The nude mice were fed on the super-clean biological laminar flow shelf for 1 wk. When the weight of the mice increased to 21.02 ± 1.81 g, tumor cells were injected subcutaneously into their hindquarters. Each mouse was seeded with 200 μL that contained 5×10^6 cells. Then, the mice were observed daily for mental state, diet and stools, and were monitored every 4 d for tumor size and body weight. The model was established successfully, when there were nodules with the size of a grain of rice after 1 wk, and a volume of 50-70 mm^3 after 2 wk. We measured the largest (a) and smallest (b) superficial diameter with Vernier calipers and calculated the tumor volume (V) = $a \times b^2 \times 0.5236$.

Treatment of tumor-bearing nude mice

The nude mice were divided into mock-treated, negative control and treated groups of five mice each. PBS was used for transfection in the mock-treated group, pSH1Si-Scramble was used for transfection in the negative control group, and pSH1Si-STAT3 was used for transfection in the treated group. The treatment volume was 40 μL and the plasmid concentration was 0.5 μg/μL, which was injected intratumorally at several points. At 30 s after injection, an electrical impulse was applied twice at intervals of > 1 min. Electrodes were placed at both ends of the tumor long and short axes; the electric field strength was 200 V/cm, electric pulse duration was 50 ms, and pulse frequency was 1 Hz. This process was repeated on days 10 and 17. Therefore, tumor volume and mouse body weight were measured every 4 d. On day 20, the tumors were removed and their weight and volume were measured, and then each tumor was divided into two parts, one was used for immunohistochemical analysis, and the other was used for screening mRNA expression of STAT3 and related genes and protein expression.

Semi-quantitative reverse transcription polymerase chain reaction (RT-PCR)

Tumor RNA was extracted using Trizol reagent (Gibco Life Technologies, Inc., Langley, OK, USA) following its manufacturer's instructions. The concentration of the total RNA was detected by UV spectrophotometry. RT-PCR was performed by the two-step method. Synthesis

of cDNA was performed using the cDNA Synthesis Kit (Genomy, Beijing, China). The conditions were: 94℃ for 5 min, 94℃ for 30 s, 56℃ for 30 s, 72℃ for 45 s, and 72℃ for 7 min, for 30 cycles; the total volume was 25 μL. For quantitative analysis of c-myc, p53, survivin, VEGF and caspase3 mRNA, the expression of the housekeeping gene β-actin was used as an internal standard. The primer sequences were: STAT3: sense 5'-TTGCCAGTTGTGGTGATC-3', antisense 5'-AGAC CCAGAAGGAGCCGC-3'; β-actin: sense 5'-AAGTAC TCCGTGTGGATCGG-3', antisense 5'-ATGCTATCA CCTCCCCTGTG-3'. The primers were synthesized by the Shanghai Sangon Biological Engineering Technology & Services Co. Ltd. The PCR fragments were separated and visualized in 20 g/L agarose gels stained with ethidium bromide. Semi-quantitative analysis was performed with the Gis gel analysis software (Shanghai, China). All experiments were done in triplicate. The ratio of the photo-density of the RT-PCR product of the target gene and β-actin was used to identify the expression intensity of the target gene.

Western blotting analysis

The tumor tissues were ground and sonicated with supersonic lytic buffer that contained 50 mmol/L NaH_2PO_4, 100 mmol/L Tris-HCl, 250 mmol/L NaCl, 100 mg/L PMSF, 1 mg/L Aprotinin, pH 8.0, and then centrifuged at 12000 × *g* for 40 min. The Bio-Rad standard curve was used to determine the concentration of protein in each lysate. Loading buffer was added to each lysate, which was subsequently boiled for 5 min and then electrophoresed by SDS-PAGE. The proteins were mixed with 2 × loading buffer with the same volume before electrophoresis. After transferring onto nitrocellulose, proteins were incubated with antibodies (anti-p-STAT3 and β-actin, purchased from Santa Cruz Biotechnology, Santa Cruz, CA, USA) and then with peroxidase-conjugated secondary antibody (Santa Cruz Biotechnology). Detection was performed with an enhanced chemiluminescence agent. The analysis was performed with the Bandscan analysis software (Sterling, VA, USA). All experiments were done in triplicate. The ratio of the proteins of STAT3 and β-actin was used to identify the expression intensity.

Immunohistochemical analysis

The tumor tissues were embedded in paraffin and then sliced. The slices were stained with hematoxylin and eosin (HE) and the expression of p-STAT3 protein (Santa Cruz Biotechnology) was determined using the streptavidin biotin complex immunohistochemical staining kit (Boster, Wuhan, China). A positive outcome was brown staining in the cytoplasm or nucleus, and the ratio of positive to total cells was > 15%.

Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling assay

The tumor tissues were fixed with 10% formalin for 4 h and then embedded in paraffin. The slices were deparaffinized in water and placed in 3% H_2O_2 for 10 min at room temperature. The TUNEL assay was carried out according to the manufacturer's instructions (KGI Biotechnology Company, Nanjing, China). A positive result was brown staining in the nucleus.

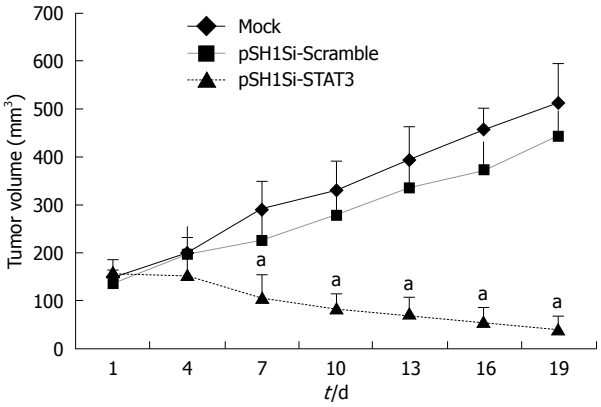

Figure 1 Growth curves of SMMC7721 tumor in nude mice in different treated groups. $^aP < 0.01$ *vs* pH1Si-Scramble group.

Statistical analysis

Statistical analysis was performed using SPSS 12.0 software (Chicago, IL, USA). The results were expressed as mean ± SD. The data were treated by Student's *t* test to determine statistical significance. $P < 0.05$ was considered statistically significant.

RESULTS

Therapeutic effect on tumor-bearing nude mice

The body weight of tumor-bearing nude mice decreased gradually and tumor volume increased in the mock-treated and pSH1Si-Scramble groups (Figure 1). However, the tumor volume in the pSH1Si-STAT3 group was markedly diminished from day 7, and body weight clearly increased from day 10 (Figure 2). Compared with the mock-treated and pSH1Si-Scramble groups, there were marked differences in the pSH1Si-STAT3 group ($P < 0.01$). Although the changes in the pSH1Si-Scramble group were less than those in the mock-treated group, there was no statistical significance ($P > 0.05$). During excision of subcutaneous tumor, we found that tumor volumes were larger and blood supplies were richer in the mock-treated and pSH1Si-scramble groups than those in the pSH1Si-STAT3 group (Figure 3), and the tumor weight of the three groups was 0.67 ± 0.07, 0.6 ± 0.07 and 0.18 ± 0.09, respectively. There were great differences between the pSH1Si-STAT3 and the mock-treated and pSH1Si-Scramble groups ($P < 0.01$), but differences between the mock-treated and pSH1Si-Scramble groups were not significant ($P > 0.05$).

Expression of STAT3 and related genes

The mRNA expression of the target genes was analyzed by RT-PCR. The mRNA levels of *STAT3*, *VEGF*, *survivin* and *c-myc* genes declined obviously, but mRNA

for the *caspase3* and *p53* genes in the pSH1Si-STAT3 group increased. The ratio of the photo-density of the RT-PCR product of the target genes and β-actin varied among the three groups, the differences between the pSH1Si-STAT3 and the mock-treated and pSH1Si-Scramble groups were significant ($P < 0.01$, Figure 4), but the difference between the mock-treated and pSH1Si-Scramble groups was not significant ($P > 0.05$).

Changes in protein expression of STAT3 and related genes

The protein expression of the target genes was analyzed by Western blotting. The protein levels of *STAT3*, *p-STAT3*, *VEGF*, *survivin* and *c-myc* genes were down-regulated clearly, but those of active *caspase3* and *p53* genes were up-regulated in the pSH1Si-STAT3 group. The ratio of the proteins of the target genes and β-actin varied among the three groups. The differences in the pSH1Si-STAT3 group were significantly greater than those in the mock-treated and pSH1Si-Scramble groups ($P < 0.01$, Figure 5), however, there was no significant difference between the mock-treated and pSH1Si-Scramble groups ($P > 0.05$).

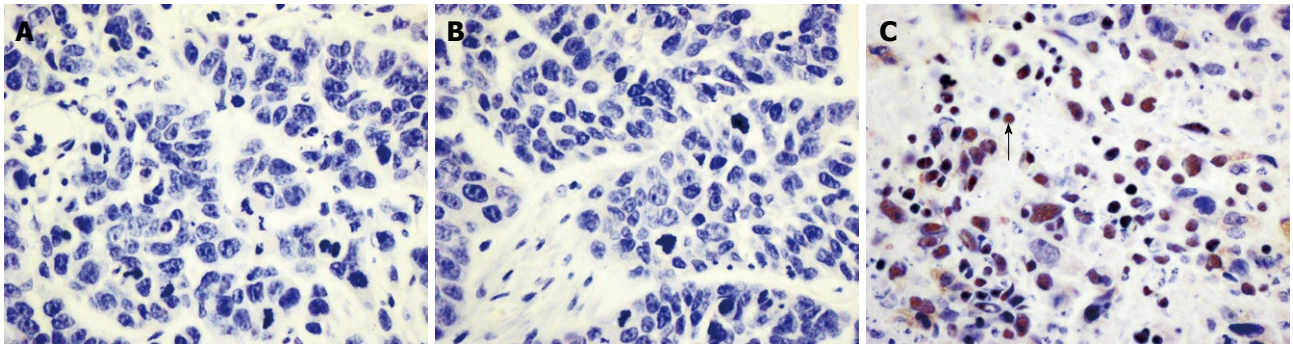

Figure 8 Detection of apoptosis with TUNEL assay in tumor tissues of tumor-bearing nude mice in different treated groups (× 400). A: Mock-treated group; B: pSH1Si-Scramble group; C: pSH1Si-STAT3 group, black arrow points to positive cells, in which the nuclei were stained brown.

Screening of STAT3 proteins

Immunohistochemistry showed that p-STAT3 was stained brown in the nuclei of many cells in the mock-treated and pSH1Si-Scramble groups, but were stained brown in the cytoplasm of only a few cells on the edge of tumors in the pSH1Si-STAT3 group (Figure 6).

Detection of apoptosis of tumor cells

The outcome of HE staining was observed under light microscopy (Figure 7). Many apoptotic cells were observed in the pSH1Si-STAT3 group, which showed karyopyknosis and red staining of the cytoplasm. There were also apoptotic cells in the pSH1Si-STAT3 group, in which the nuclei of many cells were stained brown (Figure 8).

DISCUSSION

There are many different genes and various signal transduction pathways involved in initiation and development of human HCC. The STAT3 and JAK/STAT3 signal transduction pathways are of considerable interest in tumors[7,8], and many studies[9,10] have detected the activation of STAT3 in many hepatocellular cell lines and HCC, and found that abnormal activation of STAT3 is related to the initiation and development of human liver cancer. It may be an effective strategy for HCC therapy to inhibit the abnormal expression of STAT3. At present, there are many methods[11-13] of targeting the *STAT3* gene, which include inhibiting indirectly

activation of STAT3 by receptor antagonist, neutralizing antibody, protein tyrosine kinase inhibitor and other agents, or blocking directly the functions of STAT3 by antisense oligonucleotides, decoy oligonucleotides, and RNAi. RNAi is a potent tool in tumor gene therapy, because of its high performance, specificity, convenient manipulation and low toxicity.

Our previous studies have demonstrated that the recombination plasmid pSH1Si-STAT3, which targets the *STAT3* gene, dramatically inhibits the expression of STAT3 mRNA and protein in the HCC cell line SMMC7721 *in vitro* and proliferation of HCC cells, and induces apoptosis of HCC cells[6]. Therefore, we designed this experiment in order to verify the therapeutic effect of recombination plasmid pSH1-siRNA-STAT3 in HCC *in vivo*. The present study indicated that body weight of mice was increased, and tumor volume was decreased. Tumor weight also declined in the pSH1Si-STAT3 group, and there were marked differences compared with that in the mock-treated and pSH1Si-Scramble groups. RT-PCR, Western blotting and immunohistochemistry showed that expression of mRNA and protein was markedly down-regulated, and there were many apoptotic cells, as shown by HE staining and TUNEL screening. These results verified that the recombination plasmid pSH1Si-STAT3 has a significant inhibitory effect on tumors in HCC-bearing nude mice.

At the same time, we detected the mRNA and protein levels of STAT3-related genes, and found that the expression levels of VEGF, survivin and c-myc were down-regulated clearly, but expression of caspase3 and p53 in pSH1Si-STAT3 was up-regulated. Compared with the mock-treated and pSH1Si-Scramble groups, the differences in expression were significant. Hence, we can infer that inhibiting the expression of STAT3 by siRNA in HCC may inhibit the activation of its target genes, recover the activity of some important anti-oncogenes, restrict the proliferation of tumor cells, and increase apoptosis. Therefore, it plays an important antineoplastic role.

The fate of c-myc attracted our attention. c-myc was not down-regulated by inhibition of the *STAT3* gene *in vitro*[6], but it was down-regulated *in vivo*. This may be related to the changed regulation mechanism of HCC cells after they have been removed from the body. It may also indicate that c-myc is not regulated directly by STAT3, but it is regulated by other genes that are targeted by STAT3. Hence, this mechanism of regulation requires further research.

Compared with Lipofectamine 2000 that we have used previously *in vitro*[6], which is characterized by high transfection efficiency and low toxicity, but high cost, the electrotransfection process used here *in vivo*, has the advantage of convenient operation, low cost, high efficiency and no toxicity. The results of the experiments demonstrated that the two methods of transfection obtained fine potency. Our study indicated that recombination plasmid pSH1-siRNA-STAT3 had significant anti-neoplastic activity *in vitro* and *in vivo*. A recombination plasmid that carries the same sequence of siRNA-STAT3 has a therapeutic effect on prostate tumor and melanoma[14,15], which leads us to conclude that one siRNA oligonucleotide drug may treat a variety of tumors. At the same time, one tumor can also be treated by several siRNA oligonucleotide drugs, and an optimal therapeutic effect may be obtained if multiple oncogenes are inhibited.

In our study, there were some changes after transfection in the pSH1Si-Scramble group, for example, changes in cell morphology and modification of gene expression. Although there was no significant difference compared with the mock-treated group, it suggested that the expression vectors that carried the scrambled sequence had some unknown effects on the cells, the mechanism of which needs further research.

We used intratumoral injection together with electrotransfection in our *in vivo* experiment, and obtained favorable results. Compared with intra-abdominal and intravenous injection, intratumoral injection is targeted and localized, allows direct injection of drugs into the feeding artery of the tumor, reduces the drug dose, and lengthens the dosage interval. However, this is an invasive procedure that requires skillful operators and special equipment, therefore, its application is limited. There are also potential dangers in the electrotransfection method, such as tissue injury or fibrosis where the electrode makes contact[16]. As a result, the key issues in the clinical application of RNAi are to develop vectors of high transfection efficiency and low toxicity, and to establish effective routes of administration.

In conclusion, the recombination plasmid pSH1-siRNA-STAT3 inhibited the growth of HCC cells *in vivo*, induced apoptosis, and had significant antineoplastic efficacy. RNAi that targets STAT3 has a clear therapeutic effect in HCC. Therefore, STAT3 may become an important target of biological therapy in HCC, which brings hope of clinical therapy using RNAi oligonucleotide drugs.

COMMENTS

Background

Hepatocarcinogenesis involves the mutation of multiple genes and alteration of the relevant signaling pathways. In recent years, signal transducer and activator of transcription 3 (STAT3) and related signaling pathways in liver carcinogenesis have attracted increasing attention. It has been shown that constitutively activated STAT3 is detected in many hepatocellular carcinoma (HCC) cell lines and tissues. This suggests that STAT3 is a promising molecular target for HCC gene therapy. Inhibition of abnormal expression of STAT3 may be an effective strategy for biological therapy of HCC.

Research frontiers

Some antineoplastic drugs, such as STAT3 inhibitors, tyrosine kinase inhibitor AG-490, micromolecular peptide and antisense oligodeoxynucleotides, have been used to target STAT3 *in vitro* and *in vivo* for HCC, however their efficacy is not satisfactory because of their poor specificity, rapid degradation, unsuitable molecular size, immunogenicity, poor ability to cross cell membranes, and need of special drug delivery mechanisms. RNA interference (RNAi) is a regulatory mechanism in most eukaryotic cells, which uses small double-stranded RNA (dsRNA) molecules to direct homology-dependent control of gene activity. As a result of the potency and specificity of RNAi, it has become an important tool to control gene expression through the introduction of siRNA.

Innovations and breakthroughs

Studies of targeting *in vitro* and *in vivo* over-expressed genes in HCC by RNAi, including c-myc, survivin, CCR1 and SMYD3, have been reported. However,

there has been still no report about targeting STAT3 by RNAi in HCC. In the present study, the authors used a DNA-vector-based RNAi approach to block STAT3 expression in HCC cells and tumor-bearing nude mice, to determine the role of constitutively activated STAT3 during HCC pathogenesis, and to explore the role and molecular mechanism of targeting STAT3 in HCC therapy.

Applications

By investigating the effect of silencing STAT3 expression by RNAi on the growth suppression and apoptosis of HCC cells, and the growth inhibition of HCC in tumor-bearing nude mice, this study may provides a new strategy for biological therapy of HCC by targeting STAT3. It may also offer a theoretical and experimental foundation for the clinical application of synthetic dsRNA-based RNAi.

Peer review

The manuscript by Li *et al* investigates the effects of silencing STAT3 on the growth of HCC *in vivo*. The authors present interesting and convincing data that silencing of STAT3 suppresses tumor growth *in vivo*. This is a good paper with very interesting data.

Abstract

AIM: To investigate the role of reactive oxygen species (ROS) in ethanol-mediated cell death of polarized hepatic (WIF-B) cells.

METHODS: In this work, WIF-B cultures were treated with pyrazole (inducer of cytochrome P4502E1, CYP2E1) and/or L-buthionine sulfoximine (BSO), a known inhibitor of hepatic glutathione (GSH), followed by evaluation of ROS production, antioxidant levels, and measures of cell injury (apoptosis and necrosis).

RESULTS: The results revealed that ethanol treatment alone caused a significant two-fold increase in the activation of caspase-3 as well as a similar doubling in ROS. When the activity of the CYP2E1 was increased by pyrazole pretreatment, an additional two-fold elevation in ROS was detected. However, the CYP2E1-related ROS elevation was not accompanied with a correlative increase in apoptotic cell injury, but rather was found to be associated with an increase in necrotic cell death. Interestingly, when the thiol status of the cells was manipulated using BSO, the ethanol-induced activation of caspase-3 was abrogated. Additionally, ethanol-treated cells displayed enhanced susceptibility to Fas-mediated apoptosis that was blocked by GSH depletion as a result of diminished caspase-8 activity.

CONCLUSION: Apoptotic cell death induced as a consequence of ethanol metabolism is not completely dependent upon ROS status but is dependent on sustained GSH levels.

INTRODUCTION

It has been documented that the clinical progression of alcoholic liver disease (ALD) is associated with an increase in hepatocellular damage that may involve the promotion of apoptotic mechanisms[1]. As part of the effort to clarify mechanisms associated with ethanol-mediated hepatocellular apoptosis, researchers have utilized a variety of model systems (e.g. isolated hepatocytes or liver tissue from animals). Unfortunately, limitations exist with such models as the cells/tissue do not survive well or readily lose liver-specific functions in culture, reducing the effectiveness of identifying molecules and pathways that may be involved in hepatotoxic events. The aim of this study was to evaluate alcohol-mediated cellular alterations associated with

apoptotic mechanisms using a polarized hepatic (WIF-B) cell culture model.

The WIF-B cell is a cross between a human fibroblast (WI 38) and a Fao rat hepatoma cell[2]. This clone represents differentiated cells of hepatic origin that exhibit long-term viability in culture, develop a hepatocellular-polarized phenotype, and express genes coding for liver-specific proteins[3]. The use of WIF-B cells has recently emerged as an appropriate model for studying the effects of ethanol on cellular processes. Specifically, WIF-B cells endogenously express alcohol dehydrogenase (ADH) as well as CYP2E1 activity, allowing for the efficient metabolism of ethanol, and as a consequence, exhibit classic alcohol-mediated adverse effects such as triglyceride accumulation and apoptotic cell injury[4,5].

In general, the apoptotic cascade in hepatocytes can be triggered by signaling pathways that involve death receptor-mediated interactions and/or mitochondrial stress signals. These events result in the activation of cysteine proteases (caspases) which execute the proteolytic cleavage of proteins and the ultimate demise of the cell. In the case of ethanol-related cell death, several studies have demonstrated that the induction of caspases can be linked to the effects of various cytokines[6], the involvement of oxidative stress mechanisms[7], and glutathione depletion[8]. However, the contribution that ethanol and its metabolites make in enhancing reactive oxygen species (ROS) in WIF-B cells and what role oxidative stress plays in ethanol-mediated apoptosis in this model system is not known. Furthermore, discrepancies have been noted concerning the relationship that exists between antioxidant levels and hepatocellular damage associated with ALD, as GSH levels have been reported to be increased, decreased or unaltered following ethanol administration[9-11]. Additionally, it has been shown that the activation of apoptosis-executing caspases actually requires sustained glutathione levels as these proteases possess an essential cysteine thiol in the active site[12].

Therefore, this work examined the role that oxidative stress plays in ethanol-mediated apoptotic events in alcohol metabolizing cells which endogenously express ADH and CYP2E1, taking advantage of the ability to manipulate CYP2E1, ROS production, and antioxidant status in this culture model. Specifically, we examined hepatocellular death in ethanol-treated WIF-B cells by analyzing apoptosis along with correlative measurements of CYP2E1 expression, ROS production, and glutathione status.

MATERIALS AND METHODS

Materials

F-12 Coon's modified culture medium, 4-methylpyrazole (pyr), diallyldisulfide (DAS), N-acetylcysteine (NAC), antimycin A (AA), and actinomycin D (Act D) were obtained from Sigma Chemical Co. (St. Louis, MO). Fetal Bovine Serum (FBS) was obtained from Gemini Bio-Products (Woodland, CA). All other materials were of reagent grade.

Cell culture and treatments

WIF-B cells were cultured in F-12 Coon's modified media supplemented with 37.5 mL/L FBS as previously described[5]. Briefly, cells were cultured for 7-10 d to obtain maximal polarized phenotype followed by treatment with ethanol (25 and 50 mmol/L), 100 μmol/L DAS, or 5 mmol/L NAC for 48 h. CYP2E1 expression was induced by incubation with 0.25 mmol/L 4-methylpyrazole (pyr) for 4 d prior to ethanol and other treatments. GSH deficiency was induced in some cultures by adding 2 mmol/L buthionine-sulfoximine (BSO), an inhibitor of glutathione synthesis. Fas-mediated apoptosis was analyzed in cells treated with 25 mmol/L ethanol for 24 h prior to challenge with 0.5 g/L rabbit anti-rat Fas antibody (Santa Cruz Biotechnology, Santa Cruz, CA) and 0.05 g/L actinomycin D.

The detection of oxidatively modified proteins

Protein oxidation was determined by detecting carbonyl groups within proteins using the Oxyblot® kit (Millipore, Temecula, CA) according to the manufacturer's instructions. Following derivatization with dinitrophenylhydrozone (DNP), modified proteins were detected by Western Blotting analysis using the Odyssey® Infrared Imaging System (LI-COR Biosciences, Lincoln, NE). Resolved proteins (10% SDS-PAGE), on nitrocellulose membranes were probed with 1:150 anti-rabbit DNP and 1:5000 mouse anti-GAPDH (Millipore, Temecula, CA), followed by goat anti-mouse and anti-rabbit Infrared IRDye®-labeled secondary antibodies (LI-COR).

Assessment of intracellular oxidative stress

The level of H_2O_2 was determined using the redox-sensitive dye 2',7'-dichlorodihydrofluorescein diacetate, H_2DCFDA (Invitrogen, Carlsbad, CA). Briefly, WIF-B cultures were incubated with 4 μmol/L H_2DCFDA for 30 min in the dark at the end of the treatment period and the oxidized fluorescent product detected (excitation 488 nm and emission 525 nm).

Analysis of CYP2E1 activity

Utilizing the p-nitrophenol oxidation assay as described[13], the activity of CYP2E1 was measured in microsomal proteins (0.05 g) isolated as previously noted[4].

Caspase activation assays

The activity of caspase-3 was evaluated by measuring the cleavage of the fluorogenic substrate Ac-DEVD-AMC (BD PharMingen, San Diego, CA) as previously described[5]. The activation of caspase-8 was determined using a Colorimetric Assay (R&D Systems Inc, Minneapolis, MN) following the manufacturer's instructions.

Flow cytometric determination of necrosis

The LIVE/DEAD® Fixable Cell Stain (Invitrogen, Carlsbad, CA) was used to determine necrosis based on the reaction of fluorescent reactive dye with intracellular

amines following entry through the compromised membranes of necrotic cells. Following staining with the reactive dye, the cells were analyzed by flow cytometry using the FACSCalibur (Becton Dickinson) with a 585/42 band pass filter. The results are expressed as the percentage of non-viable (necrotic) cells (reflected by the shift in mean fluorescent intensity) measured in the total cell population.

Glutathione determination

The detection of intracellular levels of reduced glutathione (GSH) in WIF-B cells was assessed using a commercial kit (Chemicon APT 250; Millipore, Temecula, CA) that detected the fluorescent product produced (excitation 380 nm and emission 461 nm) following the incubation of cell lysates with a monochlorobimane dye that has a high affinity for glutathione.

DNA fragmentation assay

DNA integrity was analyzed using the ApoTarget™ DNA Ladder kit, as described by the manufacturer (Invitrogen, Carlsbad, CA). Detached cells were collected by centrifugation (400 r/min) followed by DNA extraction. DNA fragments were resolved and visualized following agarose gel electrophoresis (5 EV/cm) and ethidium bromide staining. As a positive control, DNA was extracted from WIF-B cells that were induced to undergo apoptosis by UV treatment (320 μW/cm^2) as previously described[14].

Statistical analysis

Results refer to the average taken from three to seven experiments and are expressed as mean ± SE. Comparison of the values was performed using the Student *t* test with values, $P < 0.05$, considered significant.

RESULTS

Ethanol-mediated oxidative stress and its role in caspase activation

To evaluate the role of ethanol-mediated oxidative stress in the activation of apoptotic mechanisms in WIF-B cells, cultures were incubated with physiologically relevant concentrations (25 and 50 mmol/L) of ethanol in the presence or absence of DAS, and analyzed for the production of oxidative stress indices (protein carbonyl adduct formation and H_2O_2 generation) as well as caspase activation. It was determined that more cellular proteins were oxidatively modified as a result of ethanol treatment in comparison to control cells, and that the ethanol-mediated increase in carbonyl adducts was significantly reduced in the presence of DAS, an inhibitor of CYP2E1 (Figure 1A). In a similar fashion, using fluorescent spectrophotometry to detect the oxidized cleaved product, dichlorofluorescein (DCF), it was determined that ethanol treatment resulted in a two-fold increase in H_2O_2 production compared to untreated control cells (Figure 1B). Also, the presence of the antioxidant, NAC, provided

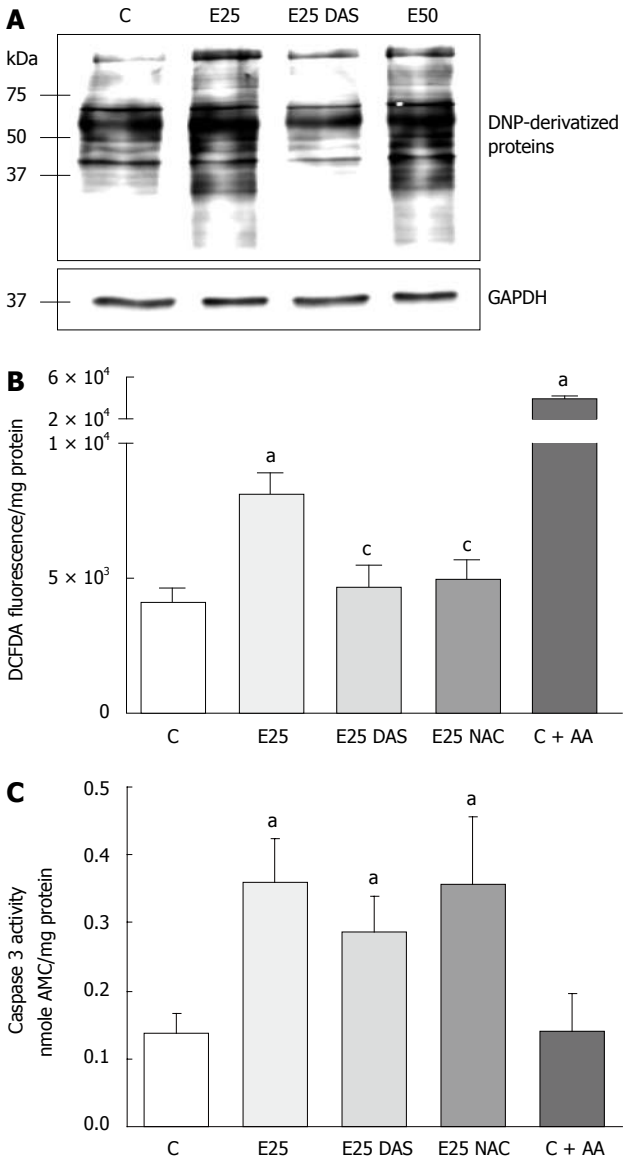

Figure 1 Ethanol-induced protein oxidation, oxidative stress, and caspase activation in WIF-B cells. WIF-B cultures were cultured for 48 h in the absence or presence of ethanol, and DAS or NAC when indicated. As a positive control for H_2O_2 production, some cultures were treated with 2 μmol/L Antimycin A (C + AA) for 30 min prior to analysis. A: Protein oxidation analysis represented as DNP-specific proteins detected in WIF-B cell lysates using the OxyBlot protein oxidation analysis; B: H_2O_2 production was detected by dichlorofluorescein fluorescence quantification. Data from 5 independent experiments is represented as the amount of fluorescent (DCFDA) oxidized products detected in the treated cells per mg protein; C: The activation of the proapoptotic protease, caspase-3, was detected as described in "Material and Methods" for five independent experiments. $^aP < 0.05$ *vs* control; $^cP < 0.05$ *vs* ethanol alone-treated cells.

significant protection against the ethanol-induced ROS elevation (Figure 1B). As a positive control for ROS production in these experiments, WIF-B cells were also incubated with AA, an inducer of H_2O_2 levels that resulted in a robust generation of DCF products as reflected by a 10-fold increase in ROS (Figure 1B). In contrast, when a measure of apoptosis (caspase activation) was conducted, it was determined that while ethanol treatment increased caspase-3 activity at a comparable two-fold elevation to that which was observed for

ethanol-related ROS production, the introduction of DAS or NAC did not provide any protection against ethanol-mediated apoptosis. Correspondingly, in AA-treated cells that represented an overproduction of ROS, no induction of caspase activity could be detected (Figure 1C).

Role of CYP2E1-dependent mechanisms in ethanol-mediated cell death of WIF-B cells

In light of the observations demonstrating that ethanol treatment results in the induction of ROS as well as apoptosis, while inhibitors of ROS could not attenuate caspase-3 activation, further evaluation of CYP2E1-dependent mechanisms was performed. First, it was determined that ethanol administration alone enhances CYP2E1 catalytic activity (Figure 2A) as well as protein expression (data not shown) in WIF-B cultures. Also, pretreatment of the cells with pyrazole for 4 d prior to ethanol challenge resulted in a further enhancement of CYP2E1 (Figure 2A). Utilizing this ability to manipulate the CYP2E1-ethanol metabolizing system, we next compared the production of ROS with caspase-3 activation in pyrazole-pretreated WIF-B cells with or without ethanol. The results indicate that when CYP2E1 was enhanced by pyrazole, a correlative 2-fold enhancement in ROS generation was observed when compared to ethanol-alone treated cells (Figure 2B). However, when the activity of caspase-3 was evaluated under the same conditions, it was determined that the pyrazole induction of CYP2E1 was not associated with an enhancement of apoptosis over what was observed in ethanol-alone treated cells (Figure 2B). Despite the fact that the activation of caspase-3 was not affected by enhanced ROS, the pyrazole and ethanol-treated cells displayed similar damaging morphological changes such as the loss of cell-cell contacts. Indeed, following evaluation of cell viability by flow cytometry, it was determined that when CYP2E1 expression and ROS were enhanced, the presence of non-viable cells significantly increased, demonstrating enhancement of necrotic cell death (Figure 2C). Correspondingly, AA treated cells (which display high ROS levels yet no caspase activation) presented morphologically as necrotic ghost-like cells with cell viability that was markedly impaired.

Regulation of ethanol-induced apoptosis by glutathione

Considering the above results indicating that oxidative stress levels did not correlate with apoptotic cell death, and the known role of glutathione in regulating redox balance, we next measured GSH levels and the activation of caspase-3 in the WIF-B cells following ethanol administration with or without pyrazole pretreatment and the inclusion of BSO. It was determined that ethanol treatment alone did not affect the content of reduced glutathione in the WIF-B cultures while the overexpression of CYP2E1 in pyrazole-treated cells resulted in a modest decline (20%) of GSH (Figure 3A). Also, as expected, the addition of BSO in the culture media significantly depleted GSH levels in the WIF-B cells (Figure 3A). Strikingly, this depletion of glutathione by BSO resulted in an abrogation of ethanol-mediated

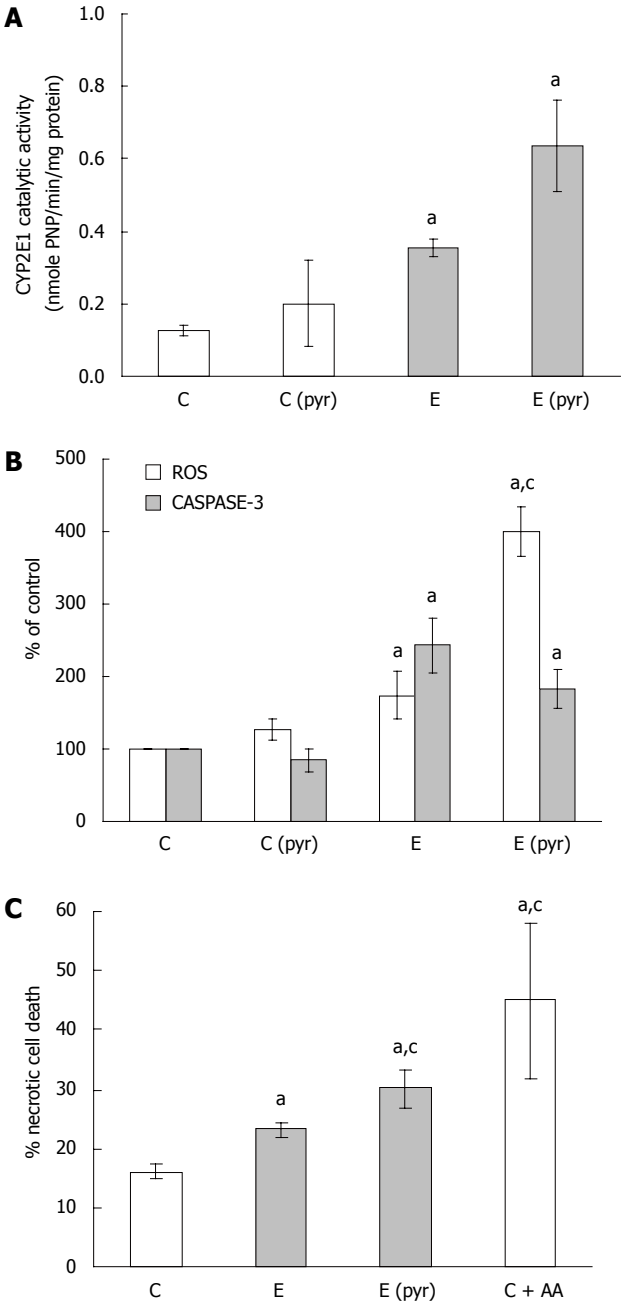

Figure 2 The relationship of CYP2E1 expression, oxidative stress, and WIF-B cell death following ethanol administration. WIF-B cultures were treated without (C) or with pyrazole (Cpyr) for 4 d followed by ethanol treatment for 48 h [E and E (pyr)]. A: CYP2E1 activity in isolated microsomes analyzed using the r-nitophenol oxidation assay in four independent experiments; B: H_2O_2 production representative of ROS generation detected by dichlorofluorescein production, and the activation of caspase-3 as a measure of apoptosis from seven independent experiments; C: Necrotic cell death evaluated by flow cytometric analysis in three independent experiments using the LIVE/DEAD cell stain as described in "Material and Methods". $^{a}P < 0.05$ *vs* control; $^{c}P < 0.05$ *vs* ethanol alone-treated cells.

caspase-3 activation (Figure 3B) as well as the reversal of ethanol-induced morphological changes (Figure 3C).

Fas-mediated apoptosis in ethanol treated WIF-B cells: regulation by GSH

Since the depletion of glutathione by BSO resulted in an abrogation of caspase 3 activity, we next analyzed

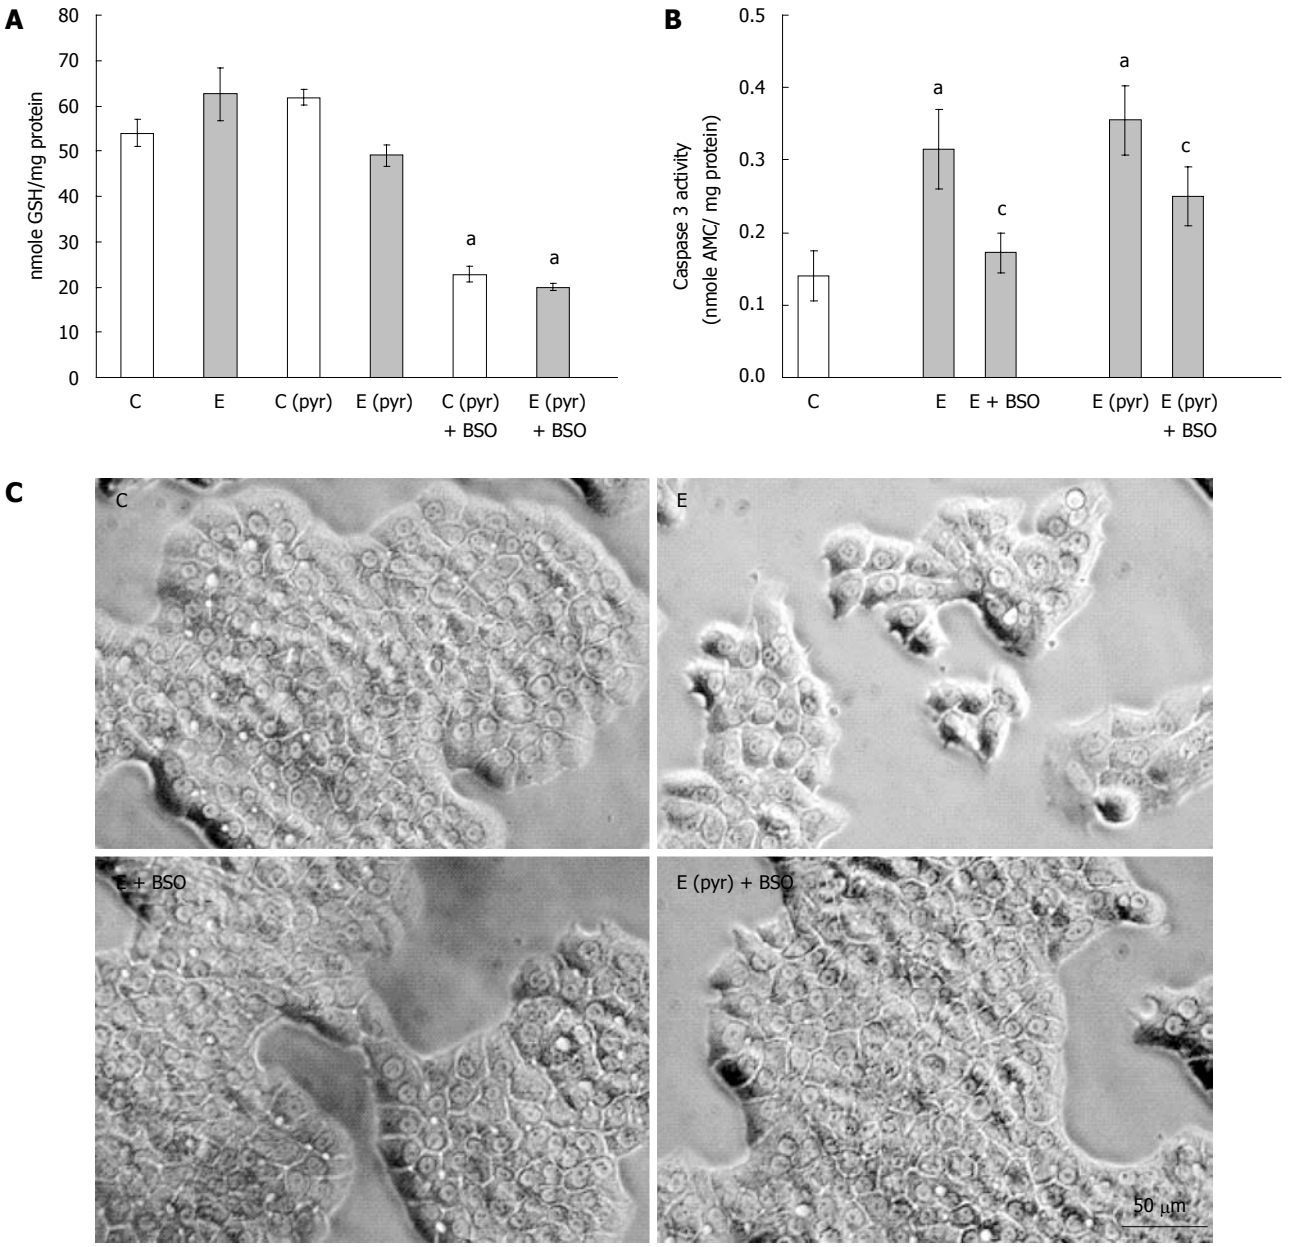

Figure 3 The effect of glutathione depletion on the induction of caspase activation in ethanol-treated WIF-B cells. WIF-B cultures were treated in the presence or absence of ethanol (25 mmol/L) for 48 h after pretreatment with (C pyr and E pyr) or without (C and E) pyrazole. Glutathione was depleted by the inclusion of BSO in the culture media when indicated (+ BSO). A: The amount of reduced glutathione (GSH) was detected as described in "Material and Methods"; B: Measure of apoptosis in WIF-B cells following glutathione depletion. Cell lysates were assayed for caspase-3 activity and the release of fluorescent product was detected and expressed for five independent experiments; C: Phase contrast images of the treated WIF-B cultures. $^{a}P < 0.05$ *vs* control; $^{c}P < 0.05$ *vs* ethanol-treated.

how such events would affect Fas-mediated apoptotic mechanisms which we have previously reported as a potential contributing pathway involved in ethanol-mediated cell death[5]. WIF-B cultures were treated with ethanol for 24 h prior to overnight challenge with anti-Fas antibody/ActD. Following treatment with anti-Fas antibody, both control and ethanol-treated cells greatly increased the Fas-dependent DNA ladder formation (Figure 4A). However, maximal DNA degradation was observed in the cells exposed to ethanol prior to Fas antibody challenge (Figure 4A). Similarly, the increase in caspase-3 activity observed after ethanol treatment alone was found to be further exacerbated when cells exposed to alcohol were treated with Fas antibody (Figure 4B). And finally, when the activation of caspase-8 was measured, the inclusion of BSO in the media was found to significantly reduce the activation of this upstream initiator protease which is linked to Fas-mediated pro-apoptotic events (Figure 4C).

DISCUSSION

There is ample evidence indicating that ethanol administration results in hepatocellular apoptosis, yet a comprehensive understanding of contributing mechanisms remains incomplete. Previously, we have shown that

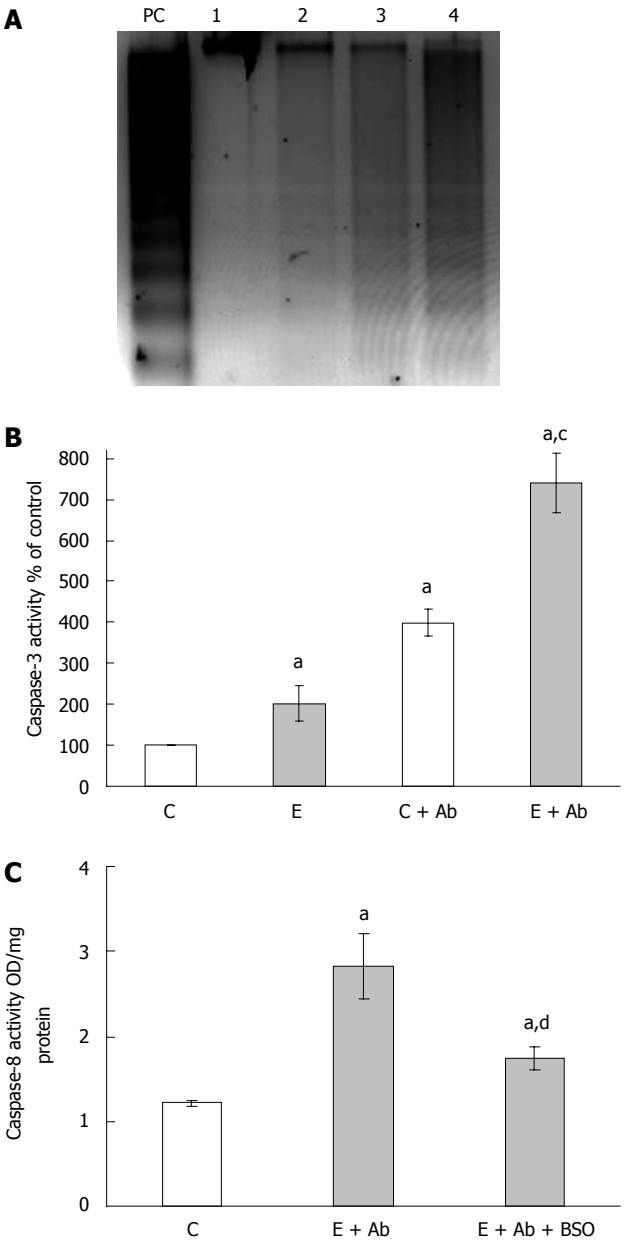

Figure 4 Fas-mediated apoptosis following ethanol administration and the effects of BSO treatment. A: Representative gel depicting apoptosis identified by DNA fragmentation. WIF-B cultures were left untreated or treated with 25 mmol/L ethanol for 24 h prior to challenge with anti-Fas antibody/Act D (Ab) for 16 h. The samples represented are untreated control cells (lane 1), ethanol alone-treated cells (lane 2), control cells incubated with Ab (lane 3), and ethanol-treated cells incubated with Ab (lane 4). UV-treated WIF-B cells were used as a positive control (lane PC); B: The analysis of caspase-3 activation following Fas antibody treatments. WIF-B cells were cultured for 24 h in the absence and presence of ethanol followed by the additional overnight incubation with Ab as described above. The activity of caspase-3 was assayed in four independent experiments as previously described; C: The effect of glutathione depletion by BSO on caspase-8 activation. WIF-B cultures were treated with ethanol and Fas antibody with or without the inclusion of BSO. The activity of caspase-8 was determined in three independent experiments as described in "Material and Methods". $^{a}P < 0.05$ *vs* untreated control cells; $^{c}P < 0.05$ *vs* corresponding controls; $^{d}P < 0.05$ *vs* cells treated with ethanol plus Ab.

ethanol induces apoptosis in WIF-B cells partly as a consequence of ADH-mediated ethanol metabolism, and was associated with death receptor-mediated events, particularly the membrane localization of Fas and the subsequent activation of caspases[5]. In the present study, we have corroborated the role of death-receptor triggers as ethanol-treated WIF-B cells were found to be sensitive to Fas-mediated apoptosis. Additionally, we further defined that ethanol-mediated apoptosis of the WIF-B cells requires an adequate cellular level of glutathione, and that increases in ROS generation are not necessarily associated with the promotion of proapoptotic pathways.

The generation of oxidative stress and mitochondrial related alterations have been implicated as a key mechanism in various pathological systems, including ethanol-mediated hepatocellular damage. Particularly relevant to ALD is the fact that the liver expresses an ethanol-inducible form of one of the cytochrome P450 isoforms (CYP2E1), that is involved in the generation of ROS[7], which may contribute to hepatocellular injury. In the current work, we demonstrated that ethanol treatment of WIF-B cells increases ROS and lipid peroxidation products and that this could be prevented by the presence of DAS or antioxidants, confirming the role CYP2E1 plays in ethanol-mediated oxidative stress in hepatocytes. However, protection from apoptotic cell death was not observed when CYP2E1 was inhibited or when antioxidants were present. To further clarify these observations, the expression of CYP2E1 was manipulated in the WIF-B cells by pyrazole pre-treatment prior to ethanol administration. The results of those experiments demonstrated that the content and activity of CYP2E1 could be increased and that the enhanced induction was correlative to an observed increase of ROS detected in the cells. However, the CYP2E1-related enhancement of oxidative stress in the WIF-B cells did not correlate with an increase in apoptotic cell injury, but rather to necrosis. These results support the hypothesis that when oxidative stress is enhanced, a concomitant decrease in viability and caspase activation occurs that changes the mode of hepatocellular death from apoptosis to necrosis.

Also associated with oxidative stress mechanisms and the adverse pathology present in ALD are alterations that occur to the antioxidant defense mechanisms within the liver. In particular, a vital defense mechanism against oxidative stress is the tripeptide glutathione, the cellular level of which has been implicated as a critical factor in whether a cell survives or succumbs to death mechanisms induced by toxins. However, the effect of ethanol on GSH levels as well as the role of glutathione in apoptosis remains controversial as ethanol administration has been reported to change hepatic GSH levels in both positive and negative ways[9-11]. Differences between studies included the mode and amount of ethanol administered, as well as the animal or cell culture system utilized. The present study represents a hepatic cell culture model (WIF-B cells) that adequately mimics *in vivo* hepatocyte functions, a trait that is sought for model systems for accurate comparisons to human pathology. Specifically, WIF-B cells efficiently metabolize ethanol and express signs of ethanol-mediated damage while using physiologically relevant levels of alcohol (25 and 50 mmol/L). This is often in

contrast to other *in vitro* models that utilize upwards of 100 mmol/L ethanol treatments. In using the WIF-B cell model, we have demonstrated in this study that GSH levels were found to be unaltered by ethanol treatment alone. Additionally, a decline in GSH levels in ethanol-treated cells was observed only after intracellular oxidation was increased due to enhanced activation of CYP2E1 following pyrazole pretreatment. Furthermore, inclusion of the glutathione synthesis inhibitor BSO resulted in the suppression of caspase activation, thereby providing protection against ethanol-induced apoptosis. A potential contributing factor that may be involved in this observed GSH-mediated protection from apoptotic cell death is the fact that caspase-8 activity was found to be diminished when GSH was depleted. This observation is supported by other works demonstrating that sustained glutathione levels may be required for caspase-dependent apoptosis because of the redox-sensitive nature of the cysteine proteases[12,15]. Also, the mode and extent of glutathione removal used in this study may be an important factor as it has been noted that acute GSH depletion can result in the inhibition of Fas-mediated apoptosis, whereas prolonged GSH depletion can override protective anti-apoptotic actions and thus mediate an enhancement of apoptotic cell death[16].

In summary, the liver has been shown to be highly susceptible to Fas-mediated injury and this study has demonstrated that ethanol administration to WIF-B cells can trigger signals associated with this pathway as well as induce susceptibility to this form of apoptotic cell damage. Also, this work has determined that apoptosis induced as a consequence of ethanol metabolism is not completely dependent upon ROS status but is dependent on sustained GSH levels. Thus, factors that regulate apoptotic/necrotic cell death mechanisms and signal the selection of one over the other during ethanol treatment are in part related to the concentration of ROS generated as well as to the ability of antioxidant defenses to cope with the elevated oxidative stress. Overall, the data presented here support the hypothesis that hepatocellular damage which occurs during the early stages of alcohol-mediated injury (i.e. steatosis) may involve the preferential signaling of apoptotic mechanisms whereas stages of more advanced disease (e.g. steatohepatitis and fibrosis) may involve more necrotic rather than apoptotic cell death of hepatocytes as the liver's sensitivity to oxidative stress mechanisms is enhanced.

COMMENTS

Background

It has been documented that the clinical progression of alcoholic liver disease is associated with an increase in hepatocellular damage which may involve the promotion and execution of apoptotic death mechanisms. It has also been shown that as a consequence of ethanol metabolism, oxidative stress is induced in hepatocytes through the generation of reactive oxygen species (ROS), such as hydrogen peroxide and superoxide. These oxidants can promote hepatotoxicity by inducing protein oxidation, enzyme inactivation, lipid peroxidation, and the production of reactive aldehydes. However, the relationship between hepatocellular oxidative stress and the promotion of apoptotic cell injury is not completely understood. This study is part of current efforts aimed at clarifying pathways and mechanisms associated with ethanol-mediated hepatotoxic events.

Research frontiers

As part of the effort to dissect parameters that are involved in ethanol-related signaling and its adverse effects, researchers have utilized a variety of models. This study utilizes hepatic hybrid WIF-B cells as an *in vitro* model for the study of alcohol-associated hepatocellular alterations. This is an emerging model for studying the effects of ethanol on cellular processes that is showing immense promise as these cells endogenously express ethanol metabolizing enzymes (alcohol dehydrogenase and CYP2E1), and as a consequence, have been shown to exhibit classic alcohol-mediated adverse effects such as triglyceride accumulation. In this work, the use of the WIF-B cells has brought forth new information concerning the relationship of oxidative stress and cell death following ethanol treatment in a model that provides a more accurate comparison to human pathology than other culture systems.

Innovations and breakthroughs

This study demonstrates that ethanol administration not only results in the trigger of signals associated with the Fas death receptor pathway, but that ethanol also primes hepatocytes, making them more susceptible to apoptotic damage. Also, we showed that apoptosis induced as a consequence of ethanol metabolism in the hepatoma cultures was not completely dependent upon oxidative stress mechanisms and was related to sustained cellular glutathione levels. Thus, this work implies that the status of thiol levels in hepatocytes may predict what hepatotoxic signaling events (i.e. apoptotic or necrotic) are triggered by the corresponding level of ethanol exposure and oxidative stress.

Applications

The prevalence and progression of alcohol-induced liver disease is a major health concern worldwide. Many prior studies have shown that the enhancement of adverse outcomes and pathological damage is associated with several parameters, including the induction of oxidative stress and the promotion of hepatocellular death mechanisms. This study provides evidence indicating that as oxidative stress in hepatocytes is enhanced (a condition related to increased ethanol consumption and/or duration of use); a change in the mode of cell injury occurs from mechanisms that support proapoptotic events to those involved in passive necrosis of the cell. This information may aid in the development of therapeutic interventions for use at appropriate stages of the disease process.

Terminology

WIF-B cells: Highly differentiated cells that are a clone of a human fibroblast (WI 38) and a Fao rat hepatoma cell. These cells develop a hepatocellular-polarized phenotype in culture and efficiently metabolize ethanol.

Peer review

This study is a continuation of a series of studies reported by this group. In this extended study they have proved that ethanol induced enhanced susceptibility of Fas mediated apoptosis of polarized hepatic cells (WIF-B) is dependent on sustained glutathione levels and only partially dependent on ROS status.

Abstract

AIM: To assess the usefulness of FibroTest to forecast scores by constructing decision trees in patients with chronic hepatitis C.

METHODS: We used the C4.5 classification algorithm to construct decision trees with data from 261 patients with chronic hepatitis C without a liver biopsy. The FibroTest attributes of age, gender, bilirubin, apolipoprotein, haptoglobin, α2 macroglobulin, and γ-glutamyl transpeptidase were used as predictors, and the FibroTest score as the target. For testing, a 10-fold cross validation was used.

RESULTS: The overall classification error was 14.9% (accuracy 85.1%). FibroTest's cases with true scores of F0 and F4 were classified with very high accuracy (18/20 for F0, 9/9 for F0-1 and 92/96 for F4) and the largest confusion centered on F3. The algorithm produced a set of compound rules out of the ten classification trees and was used to classify the 261 patients. The rules for the classification of patients in F0 and F4 were effective in more than 75% of the cases in which they were tested.

CONCLUSION: The recognition of clinical subgroups should help to enhance our ability to assess differences in fibrosis scores in clinical studies and improve our understanding of fibrosis progression.

Effective use of FibroTest to generate decision trees in hepatitis C. *World J Gastroenterol* 2009; 15(21): 2617-2622 Available from: URL: http://www.wjgnet.com/1007-9327/15/2617.asp DOI: http://dx.doi.org/10.3748/wjg.15.2617

INTRODUCTION

One of the most widely used non-invasive markers to stage liver fibrosis is the FibroTest (FT; BioPredictive, Paris, France), which involves the measurement of surrogate markers, α2 macroglobulin (A2M), haptoglobin, γ-glutamyl transpeptidase (γGT), total bilirubin, and apolipoprotein A1 (APO-A1), which,

in combination, have a high predictive value for the diagnosis of significant fibrosis[1-5]. The correlation of these markers with liver fibrosis involves a formula that was derived through logistic regression using data from 339 patients. The data were also used for the construction of a classifier using neural networks, but logistic regression was favored[1]. Its efficacy has been further validated by comparing the predictions made by the formula to those obtained with histological scoring of liver biopsies[6-10].

FT is employed to evaluate a complex situation under conditions of uncertainty, e.g. evaluating the degree of fibrosis in a patient with hepatitis C. A recent review of FT performance in 6549 patients and 925 controls supported the recommendation in clinical practice of FT as an alternative to liver biopsy for the first-line assessment of liver injury in patients with chronic hepatitis C. This review concludes that neither biomarkers nor biopsies are sufficient alone to provide the information necessary to make definitive decisions in a given patient, but rather, all the clinical and biological data must be taken into account[11].

Based on experience obtained, acquiring new information about the behavior of FT in clinical practice will be useful to assess changes to the evaluation of patients with liver fibrosis. In addition, there is a rich set of automatic classification techniques developed within the context of machine learning using Artificial Intelligence, which can be used to simplify the classification process and to provide additional information to support the classification rational. One such technique is the automatic generation of decision trees. Decision trees provide explicit rules to relate the range of values of the biomarkers with fibrosis scores, and they might help to gain a better grasp of the importance and significance of the test.

MATERIALS AND METHODS

Patients

A total of 261 patients with chronic hepatitis C, who were HCV RNA+, not receiving any antiviral or antifibrotic treatment, in whom a liver biopsy could not be obtained and who had been submitted to the FibroTest as part of their first evaluation profile, were included in the study. The patients were recruited from the liver unit of Clinica Lomas Altas, Mexico City from January 2003 to December 2007.

For each patient, we retrospectively gathered data on age, gender, γGT, ALT, AST, total bilirubin, hemoglobin, white cell counts and platelets. All the analytical studies were performed independently of the present study and their results had been reported previously. The interval between routine blood test and FT was less than 5 d.

FibroTest

The FibroTests were performed according to published recommendations. This method provides a quantitative estimate of liver fibrosis ranging from 0.00 to 1.00. The FT cutoffs for presumed fibrosis stages were 0.00-0.21 (F0), 0.22-0.27 (F0-F1), 0.28-0.31 (F1), 0.32-0.48 (F1-F2), 0.49-0.58 (F2), 0.59-0.72 (F3), 0.73-0.74 (F3-F4) and > 0.75 (F4)[12]. Each attribute (component) of the FibroTest was considered and included in the construction of decision trees.

Decision trees

Decision trees are a diagrammatic representation of a decision process, where nodes represent questions about attribute values or ranges of values, and edges represent the possible answers that link question nodes with other nodes down the tree, which represent further questions. Nodes at the bottom of the tree represent classes: the class of an object satisfying all the questions associated to the nodes in the path from the top question node to the bottom class node. In the case of FibroTest, each question node in the tree represents an FT biomarker (e.g. bilirubin and apolipoprotein A1) value or value interval, and the bottom nodes represent the FT scores (i.e. F0, F1, F1-F2, *etc*). In the present study, decision trees were constructed using the C4.5 classification algorithm[13,14]. The C4.5 Algorithm, often referred to as statistical classifier, is based on the concepts of information entropy and information gain. Intuitively, information entropy is the number of bits required to code an event (i.e. a random variable), where the higher the probability of the event the lower the number of bits required to code it. Information gain, in turn, is the reduction of entropy when additional information is available. C4.5 uses the fact that each attribute of data can be used to make a decision that splits the data into smaller subsets, which have reduced information entropy. The C4.5 algorithm is freely available, and for the purpose of this study we used the code supplied directly by Quinlan at http://www.rulequest.com/Personal/.

The simplified pseudo-code for the algorithm is as follows: (1) Find the most informative attribute (i.e. the one with the lowest entropy or the largest information gain) in relation to the set of samples provided. (2) Create a decision node that splits on the selected attribute; this node will have a decision question on an attribute's value or value interval, and will partition the samples in relation to such a value (yes/no) or value interval (i.e. the ones with a lower value, the ones in range, and the ones with a higher value.) If all the samples belong to the same partition, the corresponding node becomes a class node. (3) Create a daughter node for each remaining case, and apply the procedure from (1) for all samples that remain in the corresponding partition.

For the experiments, the following predictive attributes were used: age, gender, bilirubin, Apo A1, A2M, GGT, and haptoglobin. The target was the FibroTest score. The classifier was built with data from the 261 patients. The algorithm also selects the best rules (i.e. paths) from the trees, and makes a set of compound rules, which are tested against all samples in the test-data, and provide a confidence factor. In the present study we tested the classification performance with these compound rules and computed the corresponding confusion matrix.

In order to enhance the confidence of the classifier, we used all the data for training and also for testing

Table 1 Clinical and laboratory data of the study population

Patients with chronic hepatitis C (n = 261)	Mean (range/SD)
Age (yr)	52 (20-78)
Age at infection (yr)	26.74 (birth-69)
Time of progression (yr)	26.41 (2-69)
Hemoglobin (g/dL)	14.83 ± 2.54
Platelet count (10^3/mm^3)	203 ± 82
White cell count (10^3/mm^3)	5.39 ± 1.82
γGT (IU/L)	77 ± 81
ALT (IU/L)	96.4 ± 108.1
Bilirubin (mg/dL)	0.9 ± 0.6

Table 2 Fibrosis stage (FibroTest) distribution according to gender in the study population n (%)

FibroTest score	Female	Male	Total
F0	16	4	20 (8)
F0-F1	5	4	9 (3)
F1	5	4	9 (3)
F1-F2	29	18	47 (18)
F2	21	13	34 (13)
F3	26	15	41 (16)
F3-F4	3	2	5 (2)
F4	44	52	96 (37)
Total	149 (57)	112 (43)	261 (100)

through 10-fold cross-validation as follows: Partition the whole set of available empirical data in 10 randomly generated designated equal subsets; use 90% as train-data and the remaining designated 10% as test-data and compute the classifier's performance. The procedure is repeated using the remaining designated 10% partitions as test-data. The performance of the classifier was presented as the average of the 10 tests.

RESULTS

Demographic data

Of the 261 patients, there were 149 (57%) female and 112 (43%) male. Their mean age was 52 years (range 20-78 years). The mean age at infection was 26 years (range birth to 69 years). 75.1% were genotype 1. The average time from exposure to risk factor to their first FibroTest was 26.4 years. The mean values for the following parameters was as follows: Hb 14.8 ± 2.5 g/dL, platelets 203 000 ± 82 000 10^3/mm^3, leukocytes 5399 ± 1821 10^3/mm^3, serum bilirubin 0.9 ± 0.67 mg/dL, ALT 96.4 ± 108 IU/L, and GGT 77.5 ± 81.0 IU/L (Table 1).

FibroTest

The reported FT scores indicate that 45% of the patients (n = 117) had either F4 (37%) or F0 (8%). The remaining 55% (n = 144) had intermediate stages of fibrosis (Table 2).

Decision trees

The C4.5 algorithm was used to construct ten decision trees. The algorithm selected a number of rules relating attribute values with the fibrosis score and the percentage of times that each rule was successfully applied for each tree. In addition, the algorithm produced a set of 26 compound rules out of the ten classification trees and these rules were used to classify the 261 patients. The plausible rules for the classification of patients in F0 and F4 are shown in Table 3.

Table 3 Compound rules generated for classes F0 and F4 and the percentage of times that each rule was successfully applied

F0	F4
GGT ⩽ 108 IU/L	Bilirubin > 1.2 mg/dL
A2M ⩽ 280 g/L	GGT > 26 IU/L
Apo A1 > 144 g/L	A2M > 216 g/L
Age > 36 yr	Class F4 (95.6%)
Age ⩽ 53 yr	
Class F0 (79.4%)	
	A2M > 335 g/L
	Haptoglobin ⩽ 54.6 g/L
	Age > 53 yr
	Class F4 (95.5%)
Bilirubin ⩽ 1.1 mg/dL	
A2M ⩽ 243 g/L	
Apo A1 > 126 g/L	
Haptoglobin > 73.5 g/L	Gender = M
Age ⩽ 50 yr	Bilirubin > 0.5 mg/dL
Class F0 (77.7%)	A2M > 396 g/L
	Class F4 (91.7%)
	Bilirubin > 0.6 mg/dL
	Haptoglobin ⩽ 16.2 g/L
	Class F4 (90.9%)
	GGT > 40 IU/L
	A2M > 372 g/L
	Age > 59 yr
	Class F4 (90.2%)

Table 4 Confusion matrix relating real FT scores (rows) to predicted FT scores (columns) in 261 patients with chronic hepatitis C

	F0	F0-F1	F1	F1-F2	F2	F3	F3-F4	F4
F0	18					2		
F0-F1		9						
F1			7			2		
F1-F2	2			37	1	7		
F2				3	18	13		
F3						38		3
F3-F4						1	3	1
F4			1			3		92

FT cases with true scores of F0 and F4 were classified with very high accuracy (18/20 for F0 and 92/96 for F4), which indicated that in the extreme stages of fibrosis, decision trees produced the correct classification in approximately 93% of the cases, as shown in the confusion matrix in Table 4.

The overall classification error was 14.9% (accuracy 85.1%). We observed that the largest confusion relates to false positives in F3 (43.7%). However, the chances that the predicted value is right for all FT scores, except F3, are quite high.

DISCUSSION

The FT scores used to evaluate the degree of liver fibrosis were generated using a formula obtained

through logical regression that can be thought of as a classification device or classifier. From this perspective the FT formula is a black box that has the FT attributes as inputs and produces the corresponding FT score as its associated output. However, it would be convenient to be able to look into the internal classification process and have access to the classification rational. In addition, it is also important to reinforce the reliability of the FibroTest and ensure that the classification results are independent of contingent features of the classification technique. Indeed, in the original formulation of the FibroTest, the use of neural networks, another black box classification technique, was also explored but logistic regression was preferred for clarity[1].

As with all machine learning techniques, decision trees such as those employed in the present work, are deduced from empirical data and the success of a given application depends on the quantity and quality of these data. In this respect, these algorithms are analogous to statistical regression techniques, such as logical regression, but rely on classification heuristics. They have proved to behave well not only in linear problems, but also in non-linear or unstable domains. For this, classifiers need to be built with a portion of the data, which is usually called the "train-data", and tested with a different portion of the data, which is usually called the "test-data", and it is essential that these two sets are distinct. For the induction process proper, the values of the attributes of each sample, "the predictors", are associated with its corresponding class, "the target", and the process is repeated iteratively for all the samples in the train-data. At the end of this process, each class is associated with a combination of values or value intervals of the attributes. The classifier can then be used to predict the class of a sample not used in the training process. In particular the performance of the algorithm can be assessed by comparing the known class of each sample in the test-data with the class predicted by the decision tree for such sample. The specifics of these procedures, with the heuristics employed, give rise to a large variety of classification techniques, one of which is decision trees. Decision trees can be created through a diversity of algorithms and the field as a whole is quite mature and has been applied to a large diversity of application domains with very positive results. In particular, in the clinical setting, decision trees have been applied, for instance, to proteomic data analysis in pancreatic cancer[15], to the prediction of interferon treatment effects based on microarray gene expression profiles[16], and to the prediction of diagnosis and outcome of dengue fever based on clinical, hematological and virological data[17].

Ranking the seven attributes used by the FT, we generated a learning set that allowed for the determination of a second classifier using an ensemble of decision trees. To identify the decision algorithms, we used the C4.5 decision tree classifier, which has several advantages over other statistical tools. Indeed, decision algorithms so generated are simple to understand, and they are able to handle missing values. In contrast, logistic regression and discriminant analyses require much more data preparation and more extensive handling of missing values for reliable calculations[18]. Decision algorithms are also easy to interpret and validate using common statistical techniques, which facilitates their use to predict the diagnosis and prognosis in different clinical settings.

The decision tree analysis of our data produced a set of seven plausible rules that correctly predicted the fibrosis score in more than 75% of the cases for F0 and F4. Interestingly, the rules for predicting F4 were precise in 90% of the cases. Therefore, the rules generated herein can be considered as having great accuracy. These findings add support to the impression that fibrosis at the extremes of the disease is more predictable, a notion that applies both to non-invasive markers and liver biopsy[4,19].

Of the markers employed in the decision trees and the derived rules, the most relevant were age and α-2 macroglobulin as independent predictors. If a patient has an FT score of F0 with a normal A2M and is below 53 years of age, our results suggest the presence of mild disease, adding to the clinical decision of not performing a liver biopsy and holding back the timing and selection of antiviral treatment. On the other hand, if a patient with hepatitis C and FT score of F4 is above 53 years and has an increased A2M, a diagnosis of significant fibrosis is presumed.

Fibrosis progression tends to vary between patients and even in the same person, for reasons that are not yet understood. However, age has consistently been reported as an important risk factor for fibrosis progression in chronic viral hepatitis, either at the onset of the disease or during its evolution. The changes with age tend mostly to be subtle and are consistent with a disease of long duration associated with the progression of normal aging[20-23]. How and why variants arise probably relates to changes in extracellular matrix[24,25], liver regeneration[26] and repair mechanisms[27]. In this regard, and based on our results, A2M is an extremely useful attribute. It is a protease inhibitor and a major carrier of cytokines synthesized by hepatic stellate cells and hepatocytes. Furthermore, its expression might inhibit matrix remodeling during fibrosis[28,29].

Neither age nor A2M alone has been proven to be an adequate marker of fibrosis, which makes it important to apply a more comprehensive approach in the use of non-invasive markers for liver fibrosis. Undoubtedly, not knowing which markers are the most predictive has been one of the main obstacles impeding their integration into clinical practice and patients' management. Our study indicates that the combination of the markers used in the FT is reliable and performs well, independently of, age or gender. Although ethnicity was not an inclusion criteria for our study, all the patients were Hispanics with an age range of 20-78 years.

There are pitfalls and caveats to FT use, and the decision tree analysis was not able to generate accurate rules to predict intermediate FT scores (particularly F3), suggesting that the FT attributes for these particular

stages exhibit considerable noise or are inconclusive. This was reflected in the analysis of the confusion matrix in which F3 was the most ambiguous; nonetheless, our study showed that restricting the biopsies to the patients with intermediate scores (F1-F3) could have prevented liver biopsies in 42% of the patients while maintaining an accuracy level above 75%. This is a strong argument to include the use of a non-invasive marker of fibrosis, such as the FT, in the profile evaluation of a patient with chronic hepatitis C, if for any reason; a liver biopsy cannot be performed.

Outside of clinical trials, with the advancement of new laboratory techniques, such as PCR and non-invasive biomarkers, more patients are treated for chronic fibrotic liver diseases without a liver biopsy[30], which remains the best predictor but is not necessarily the gold standard.

Analysis, such as the one performed in the present work, could help to further classify preclinical subgroups and identify subclasses of rapid or slower fibrosers. This classification should enhance our ability to assess differences in fibrosis scores in clinical studies and improve our understanding of fibrosis progression.

This work was presented as a poster at the AASLD Liver Meeting in November 2008 in San Francisco, California.

COMMENTS

Background

One of the most widely used non-invasive markers to stage liver fibrosis is the FibroTest which involves the measurement of a set of surrogate markers that, in combination, have a high predictive value for the diagnosis of significant fibrosis.

Research frontiers

The FT score is obtained with a formula generated through logical regression that can be thought of as a classification device or classifier. It would be convenient to be able to look into the internal classification process and have access to the classification rational. In addition, it is also important to reinforce the reliability of the FibroTest and ensure that the classification results are independent of contingent features of the classification technique.

Innovations and breakthroughs

The authors used the automatic generation of decision trees to simplify the classification process and to provide additional information to support the classification rational of the FibroTest as a non-invasive marker of liver fibrosis. Decision trees provide explicit rules to relate the range of values of the biomarkers with fibrosis scores, and they might help in gaining a better grasp of the importance and significance of the test.

Applications

Analysis, such as the one performed in the present work, could help to further classify preclinical subgroups and identify subclasses of rapid or slower fibrosers. This classification should enhance our ability to assess differences in fibrosis scores in clinical studies and improve our understanding of fibrosis progression.

Terminology

Decision trees are diagrammatical representations of decision processes, where nodes represent questions about attribute values or range of values, and edges represent the possible answers that link question nodes with other nodes down the tree, which represent further questions. Nodes at the bottom of the tree represent classes: the class of an object satisfying all the questions associated to the nodes in the path from the top question node to the bottom class node.

Peer review

This is a timely, well written article on FibroTest.

Abstract

AIM: To examine the long-term results of endoscopic treatment in a prospective study conducted over a period of 10 years, 1997 to January 2007.

METHODS: A total of 25 patients (20 female and five male: aged 18-75 years), with at least one symptom of stricture not passable with the standard colonoscope and with a confirmed scarred Crohn's stricture of the lower gastrointestinal tract, were included in the study. The main symptom was abdominal pain. The endoscopic balloon dilatation was performed with an 18 mm balloon under endoscopic and radiological control.

RESULTS: Eleven strictures were located in the colon, 13 at the anastomosis after ileocecal resection, three at the Bauhin valve and four in the ileum. Four patients had two strictures and one patient had three strictures. Of the 31 strictures, in 30 was balloon dilatation successful in a single endoscopic session, so that eventually the strictures could be passed easily with the standard colonoscope. In one patient with a long stricture of the ileum involving the Bauhin valve and an additional stricture of the ileum which were 15 cm apart, sufficient dilatation was not possible. This patient therefore required surgery. Improvement of abdominal symptoms was achieved in all cases which had technically successful balloon dilatation, although in one case perforation occurred after dilatation of a recurrent stricture. Available follow-up was in the range of 54-118 mo (mean of 81 mo). The relapse rate over this period was 46%, but 64% of relapsing strictures could be successfully dilated again. Only in four patients was surgery required during this follow-up period.

CONCLUSION: We conclude from these initial results that endoscopic balloon dilatation, especially for short strictures in Crohn's disease, can be performed with reliable success. Perforation is a rare complication. It is our opinion that in the long-term, the relapse rate is probably higher than after surgery, but usually a second endoscopic treatment can be performed successfully, leading to a considerable success rate of the endoscopic procedure.

Long-term results of endoscopic balloon dilatation of lower gastrointestinal tract strictures in Crohn's disease: A prospective study. *World J Gastroenterol* 2009; 15(21): 2623-2627 Available from: URL: http://www.wjgnet.com/1007-9327/15/2623.asp DOI: http://dx.doi.org/10.3748/wjg.15.2623

INTRODUCTION

Strictures of the gastrointestinal tract are common complications of Crohn's disease. Medical treatment can improve acute inflammation, but is ineffective in the presence of chronic scarred strictures. These strictures are mainly treated surgically. As well as techniques of surgical resection, especially for less extended strictures, reconstructive surgery (strictureplasty) is

recommended, in order to minimize the risk of short bowel syndrome[1,2]. Strictureplasty is a bowel-conserving operation technique, requiring anesthesia and minimally invasive surgery or laparotomy. Regardless of which surgical technique is chosen, the reoperation rate for new strictures or recurrence of strictures is between 15% and 45% within 5 years[3,4].

For some time, it has been possible to treat benign strictures of the upper gastrointestinal tract with endoscopic balloon dilatation. Over the past 20 years, this method has become increasingly used for symptomatic Crohn's strictures in the ileum or colon[5-16]. The available results indicate equal technical effectiveness of the endoscopic procedures when compared to surgical therapy. Up till now the method has not been standardized, for example regarding balloon diameters or possible concomitant medical treatment.

Valid long-term studies of 5 years or more, which would permit a statement regarding recurrence of strictures and a better comparison with surgical techniques[3,4], are available so far only in casuistic form and with limited numbers[8,17-19].

We report on our own prospective 10-year long-term study of endoscopic balloon dilatation of strictures in Crohn's disease using a relatively thin balloon (18 mm) and additional treatment with prednisolone.

MATERIALS AND METHODS

In our prospective long-term study, conducted since 1997, we included patients who had at least one symptomatic ileal or colonic stricture which could not be passed with the standard colonoscope (external diameter 13 cm), in the presence of histologically documented Crohn's disease. Additional inclusion criteria were: (1) obstructive symptoms (especially abdominal pain), refractory to medical treatment; (2) no or low inflammatory disease activity (CDAI < 200); (3) age over 18 years; (4) no fistulas connecting to the stricture; (5) length of the stenosis no more than 10 cm; (6) patient's consent after being informed about the uncertain success of the method, with regard to current knowledge; (7) Either an enteroclysis (Sellink) or a colon contrast imaging examination was performed to exclude the presence of fistulas and determine the length of the stricture.

Patients were prepared for endoscopy with 4 L of Golytely solution. Premedication consisted of 2.5-5 mg midazolam and 50 mg meperidine. After the dilatation patients were monitored in the hospital for at least 24 h.

The balloon dilatation was carried out through the placed endoscope, under endoscopic and radiological control using a balloon of 55 mm in length and 18 mm in diameter (Olympus BC4). In a safe position within the stricture, the balloon was filled with diluted contrast medium for at least 2 min with a pressure of 2.0 at (= 19 6133 bar).

The dilatation was judged technically successful if the stricture appeared conspicuously larger during radiological control of the balloon diameter, and if it could be passed with the standard colonoscope.

Twenty five patients (20 female, five male) between the age of 18 and 75 years and with a disease duration of between 2 and 35 years (mean 13.3 years) were included in the study. There were 11 strictures located in the colon, 13 strictures at the anastomosis after ileocecal resection, three at the Bauhin's valve and four in the ileum. Four patients had two, one patient had three strictures (Table 1). The length of the strictures was between 1 and 10 cm.

Table 1 Patient characteristics

Case number	Age/sex	Disease duration (yr)	Previous bowel surgery	Stricture localisation
1	38/F	17	Ileocecal resection	Anastomosis
2	22/F	5	None	Transverse colon
3	23/F	7	None	Sigmoid, ileum
4	23/M	7	appendectomy	Ileum
5	33/F	14	None	Rectum/sigmoid
6	33/F	12	Ileocecal resection	Anastomosis
7	32/F	9	Anal fistula	Ileocecal valve
8	46/F	19	Anal fistula	Colon
9	28/F	16	Ileocecal resection, bowel perforation	Anastomosis
10	35/F	15	Ileocecal resection	Anastomosis
11	26/M	7	None	Ileocecal valve
12	42/F	20	Right hemicolectomy anal fistula	Anastomosis
13	48/F	15	None	Colon
14	50/F	10	None	Colon
15	50/F	14	Ileocecal resection	Anastomosis
16	24/F	6	Ileocecal resection	Anastomosis
17	55/F	11	Ileocecal resection, terminal ileum	Anastomosis
18	43/F	25	Ileocecal resection, sigmoid resection	Anastomosis
19	49/F	35	Ileocecal resection, right hemicolectomy	Anastomosis (2)
20	75/M	3	None	Ileum
21	42/M	6	Right hemicolectomy	Anastomosis
22	34/F	13	Anal fissure	Anal channel, rectum, sigmoid
23	26/F	6	None	Rectum, sigmoid
24	18/F	2	None	Ileocecal valve
25	26/M	20	Total colectomy, ileoanal pouch	Pouchanal anastomosis

Regardless of pre-existing medical treatment, after the dilatation all patients received 3 g of peroral mesalamine and initially 50 mg of prednisolone, reducing the dosage gradually over a period of 2 mo.

Our follow-up period was between 54 and 118 mo (mean 81 mo). All patients were last seen in outpatient settings in January 2007 (recent medical history, clinical examination). The study was carried out in accordance with the Helsinki declaration.

RESULTS

In 30 of 31 strictures (24 of 25 patients) balloon dilatation

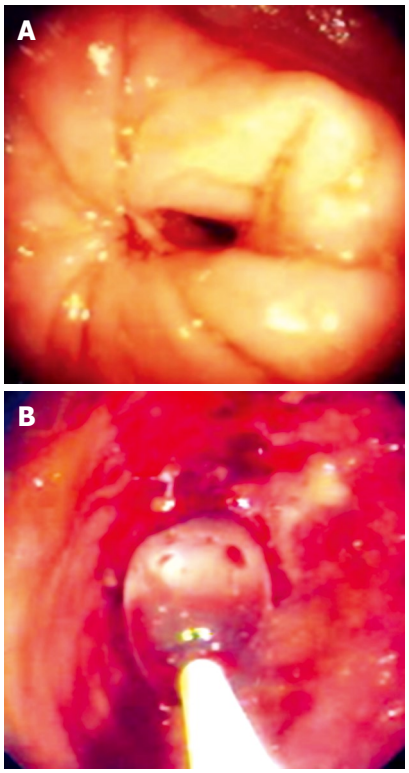

Figure 1 Endoscopic view of a non-passable stricture. A: Ileum; B: An anastomosis, balloon in the stricture.

was successful in one endoscopic session. Eventually the stricture could be passed easily with the standard colonoscope. Only in one patient with a long (about 10 cm) stricture of the ileum, involving the ileocecal valve, and an additional stricture of the ileum 15 cm distant, was the dilatation unsuccessful, so that surgery (ileocecal resection) had to be performed.

With the above mentioned premedication, 10 of 25 patients complained of moderate pain during the dilatation. In one patient with a recurrence of stricture, the second balloon dilatation was complicated by perforation (3%), and consequently the patient had to be operated on. Bleeding requiring treatment or rise of body temperature after dilatation were not observed.

With technical success, the treatment caused immediate improvement of abdominal pain, which was the main symptom in all 24 patients with successful dilatation.

The follow-up period of the successfully dilated patients was between 54 and 118 mo (mean 81 mo). Thirteen of the successfully dilated patients did not have any symptoms indicating a stricture relapse up to the last follow-up in January 2007. In 11 cases, 3 to 77 mo (mean 32 mo) after successful dilatation, a stricture relapse developed which could not be passed with the colonoscope. Accordingly, after a mean follow-up of more than 6.5 years, the relapse rate was 46%. In seven patients with recurrent strictures, a second endoscopic balloon dilatation could be performed successfully, and in only four patients was surgery required (Figures 1 and 2). Thus the long-term success rate of balloon dilatation was 80% over a mean follow-up period of 81 mo.

As accompanying medical treatment all patients received 3 g of peroral mesalamine and initially 50 mg of prednisolone, reducing the dosage gradually over a period of 2 mo. The results of all patients are summarized in Table 2 and Figure 3.

Table 2 Results

Case number	Stricture number	Compli-cations	Follow-up (mo)	Time to relapse (months & method of therapy)
1	1	None	118	77, dilatation
2	1	None	112	No relapse
3	2	None	106	Sigmoid: 10, dilation ileum: no relapse
4	1	None	106	37, operation
5	1	None	101	No relapse
6	1	None	99	30, dilatation
7	1	None	97	Unsuccessful dilatation, operation
8	1	None	97	No relapse

DISCUSSION

Endoscopic balloon dilatation has been used over a long period of time in the treatment of strictures of the upper gastrointestinal tract, sporadically also for Crohn's strictures of the duodenum[20,21]. Balloon catheters suitable for transendoscopic dilatation of ileal and colonic strictures have made it possible to dilate Crohn's strictures of the lower gastrointestinal tract.

In the studies published so far, balloons with an external diameter of 18-25 mm have been used, in order to enable the endoscopic dilatation of strictures of the lower gastrointestinal tract. The technical success rate, defined as achieving an endoscopically passable residual stricture, is between 70% and 90 %, independent of the balloon's diameter[5-16]. Usually more than one dilatation session is required for every stricture. Complications such as hemorrhages are rare, while perforations are reported mostly in studies in which 25 mm balloons are used[5,8].

In the present study, single-session dilatations using an 18 mm balloon were technically successful in 97% of cases. In one case perforation occurred during attempted dilatation of a relapsing stricture (3%). Ramboer *et al*[12] exclusively used 18 mm balloons in 52 sessions involving 13 patients, without complications. This technique has the additional advantage that the dilatation set can be easily inserted through a standard colonoscope with a

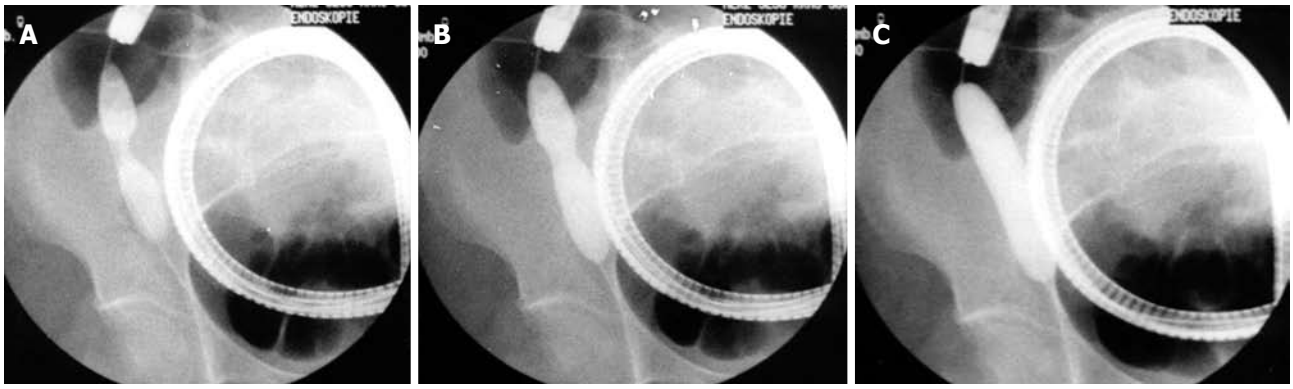

Figure 2 Radiological image of the endoscopic dilatation of a short stricture in the ileum. A: Before dilatation; B: Beginning dilatation; C: Completed dilatation.

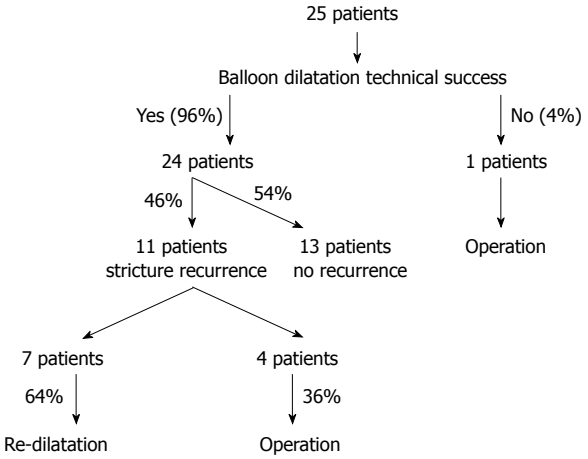

Figure 3 Overview of all patients treated.

working channel of 3.2 mm in diameter. On the other hand, when using balloon catheters with a diameter of 25 mm, therapeutic colonoscopes with a larger working channel are required.

Unfortunately, results of comparative studies on the effectiveness of different balloon diameters and balloon lengths, on differences in duration and pressure of the dilatation, as well as on the number of dilatations per session in the treatment of Crohn's strictures are still lacking. The accomplishment of achieving an endoscopically passable residual stricture seems to be important for the outcome. Couckuyt *et al*[8] found a statistically significant correlation between this achievement and the number of patients being free of symptoms over a longer observation period.

In our experience, intravenous midazolam and meperidine usually are sufficient as accompanying medication. Patients did not complain about a lot of pain during the intervention. Alternatively, in cases of painful procedures, the application of propofol can be considered.

At the moment, it is difficult to define the relapse risk after endoscopic balloon dilatation, as the published studies[8,17-19] are based on very different follow-up periods, and often do not represent structured prospective long-term studies.

In the present prospective long-term study, after a mean follow-up of more than 6.5 years, stricture relapses were observed in 11 patients (46%) after a mean of 32 mo. The other 13 successfully dilated patients were free of symptoms and stricture relapse over the complete follow-up period.

Endoscopic re-dilatation was successful in 64% of the patients with relapsing strictures. The long-term success rate was 80%. Our data indicate that long-term results of endoscopic balloon dilatation, repeated if necessary, are comparable to the results of surgical treatment[3,4]. The relapse rate after a single balloon dilatation is probably higher than after surgical intervention[3,4].

Whether additional medical treatment, such as steroid injection into the stricture, as suggested in case reports[7,11,12], or treatment with steroids after dilatation, can influence the recurrence rate is unknown. Follow-up studies after surgical bowel resection have shown that, after surgical treatment of Crohn's strictures, local inflammatory signs develop rapidly at the anastomosis without clinical signs of a relapse[22].

Raedler *et al*[23] treated 30 patients after successful dilatation of ileocecal strictures with azathioprine 100 mg/d and budenoside 9 mg/d or with a placebo. After 6 and 12 mo, a statistically significantly greater number of symptoms due to strictures and more necessary surgical interventions were found in the placebo group.

In the present study, under hypothetic considerations, a 2-mo steroid treatment was performed after dilatation, aimed at reducing the early relapse rate. With one exception there were no early relapsing strictures in the first 6 mo, and only one repeat dilatation was necessary over this period. Definite conclusions, however, cannot be drawn from these data.

Considering all available results, the endoscopic balloon dilatation seems suitable for the treatment of Crohn's strictures in the lower gastrointestinal tract especially in presence of scarred, short strictures. Our considerable clinical experience has shown us that in cases of multiple strictures, only one stricture should be dilated in each session. Strictures of more than 5 cm in length should instead be treated surgically. Fistulas originating from the stricture are considered contraindications for balloon dilatation.

The relapse rate after single endoscopic balloon

dilatation, according to the results of the present long-term study, is probably somewhat higher than after surgery. But by repeatedly dilating relapsing strictures, surgery often can be avoided or delayed. The long-term success rate of endoscopic dilatation (repeated if necessary) of 80% is remarkable and has to be considered when comparing balloon dilatation with surgery.

COMMENTS

Background

Strictures of the gastrointestinal tract are common complications of Crohn's disease. Medical treatment can improve acute inflammation, but is ineffective in the presence of chronic scarred strictures. These strictures are mainly treated surgically.

Innovations and breakthroughs

The available results indicate equal technical effectiveness of the endoscopic procedures, compared to surgical therapy. This is one of few studies to report prospective 10-year results. Furthermore, our study would suggest that endoscopic balloon dilatation seems suitable in the treatment of Crohn's strictures, especially in presence of scarred, short strictures.

Applications

When considering treatment options for patients with Crohn's disease, this study may show a safe and feasible alternative for therapeutic intervention in the treatment of patients with short, scarred strictures.

Peer review

The authors examined a total of 25 patients with at least one symptom of stricture, not passable with the standard colonoscope and with a scarred Crohn's stricture of the lower gastrointestinal. The study revealed that endoscopic balloon dilatation especially for short strictures in Crohn's disease, can be performed with reliable success. Perforation is a rare complication. The long-term relapse rate may probably be higher than after surgery, but usually a second endoscopic treatment can be performed successfully. The results are interesting and may show a safe and feasible alternative for therapeutic intervention in the treatment of patients with short, scarred strictures.

Abstract

AIM: To estimate the prevalence of small intestinal bacterial overgrowth (SIBO) in our geographical area (Western Sicily, Italy) by means of an observational study, and to gather information on the use of locally active, non-absorbable antibiotics for treatment of SIBO.

METHODS: Our survey included 115 patients fulfilling the Rome Ⅱ criteria for diagnosis of irritable bowel syndrome (IBS); a total of 97 patients accepted to perform a breath test with lactulose (BTLact), and those who had a positive test, received Rifaximin (Normix®, Alfa Wassermann) 1200 mg/d for 7 d; 3 wk after the end of treatment, the BTLact was repeated.

RESULTS: Based on the BTLact results, SIBO was present in about 56% of IBS patients, and it was responsible for some IBS-related symptoms, such as abdominal bloating and discomfort, and diarrhoea. 1-wk treatment with Rifaximin turned the BTLact to negative in about 50% of patients and significantly reduced the symptoms, especially in those patients with an alternated constipation/diarrhoea-variant IBS.

CONCLUSION: SIBO should be always suspected in patients with IBS, and a differential diagnosis is done by means of a "breath test". Rifaximin may represent a valid approach to the treatment of SIBO.

Key words: Rifaximin; Small intestinal bacterial overgrowth; Irritable bowel syndrome; Locally non-absorbable antibiotics

Small intestine bacterial overgrowth and irritable bowel syndrome-related symptoms: Experience with Rifaximin. *World J Gastroenterol* 2009; 15(21): 2628-2631 Available from: URL: http://www.wjgnet.com/1007-9327/15/2628.asp DOI: http://dx.doi.org/10.3748/wjg.15.2628

INTRODUCTION

Irritable bowel syndrome (IBS) is a common gastrointestinal (GI) disease with a prevalence ranging between 11% and 14% of adult population; it is characterized by altered motility, visceral hypersensitivity, abnormal brain-gut interaction, autonomic dysfunction, and immune activation. Although the physiopathological mechanisms underlying IBS are not fully identified, a unifying explanation of symptoms arises from the observation that 92% of IBS patients share the symptom of bloating regardless of their predominant complaint. Thus, the hypothesis has been envisaged that a small intestinal bacterial overgrowth (SIBO) could explain bloating in IBS, based on the following findings: (1) a significantly higher total hydrogen (H_2) excretion after lactulose ingestion in a large percentage (84%) of IBS patients; (2) a 75% improvement of IBS symptoms after eradication of SIBO with locally acting antibiotics; and (3) a tight correlation between the pattern of bowel movement and the type of excreted gas[1].

The prevalence of SIBO among newly diagnosed IBS patients is not exactly known, and the largely variable data reported in literature reflect the different sensitivity and specificity of the methods, either biochemical or microbiological, used to make diagnosis of SIBO. However, an exact estimation of SIBO prevalence should have important therapeutic implications, since SIBO and related symptoms (i.e. abdominal bloating) can be successfully treated by locally active, non-absorbable antibiotics[2,3].

Analysis of breath specimens for volatile metabolites of orally administered substrates offers a simplified detection method for the presence of an abnormal small-intestinal flora; this technique ("breath test", BT) is not only simpler and more acceptable to patients than jejune aspiration,

but also gives quicker information to the clinician than microbiologic culture of the jejune aspirate[4].

The BT with lactulose (BTLact) is based on the properties of lactulose, which is not absorbed through the small intestine and reaches unchanged the colon, where it is metabolized by the bacterial flora. When the bacteria come in contact with lactulose, they metabolize it and produce intestinal gasses, such as methane and hydrogen, which can be detected and assayed in the expired air. In healthy population, bacteria are not present in the duodenum and, therefore, at least 2 h are needed for lactulose to reach the colon and be metabolized. Thus, an increase of hydrogen concentrations in the expired air within 90-120 min strongly suggests a bacterial overgrowth and contamination of the small intestine. The sensitivity and specificity of BTLact in the diagnosis of SIBO are actually estimated to be 68% and 44%, respectively[5]; its main advantage of the BTLact is the relative simplicity of the method, which can be performed by most of the Gastroenterology Units.

By measuring the increased hydrogen concentrations in the expired air after oral lactulose administration (BTLact), an incidence of 46% has been recently found in an Italian survey among 96 patients with IBS[2], which is in agreement with an Europe study demonstrating a significantly increased GI bacterial flora in 43% of IBS patients compared with 12% of matched-control healthy subjects[6], while a USA-based survey has revealed that this incidence may be even higher than 80% of IBS patients[1,7,8].

We, therefore, performed an observational analysis on patients with an initial diagnosis of IBS according to the Rome Ⅱ criteria, in order to estimate the prevalence of SIBO in our geographical area (Western Sicily, Italy) and to gather information on the use of locally active, non-absorbable antibiotics for treatment of concomitant SIBO and IBS.

METERIALS AND METHODS

Our survey included a total of 125 patients who were addressed to our Medical Centre because of abdominal pain and discomfort, in the period ranging between January and December 2006; patients with severe cardiovascular and/or respiratory and/or renal diseases, as well as patients with cancer or under treatment with antibiotics and corticosteroids were excluded.

One hundred and fifteen of these subjects fully complied with Rome Ⅱ criteria, i.e. (1) 3 mo of continuous or recurrent symptoms of abdominal pain or irritation that may be relieved with a bowel movement or coupled with a change in frequency or related to a change in the consistency of stools; (2) two or more of the following symptoms present at least 25% of time: (a) change in stool frequency (> 3 bowel movement daily or < 3 bowel movements weekly); (b) noticeable difference in stool form (hard, loose and watery stools or poorly formed stools); (c) passage of mucous in stools; (d) bloating or feeling of abdominal distention; (e) altered stool passage (e.g. sensations of incomplete evacuation, straining, or urgency).

These 115 subjects received a symptomatological diagnosis of IBS, while the other ten subjects had a diagnosis of either Crohn's disease or ulcerative colitis or celiac disease.

Patients with an IBS diagnosis were asked for their informed consent to the management of personal data, in compliance with the "privacy" regulations in force in Italy. According to their intestinal habits, patients were divided into a constipation-variant (20.6%; six male and 14 female), diarrhoea-variant (31.9%; 16 male and 15 female) or alternated alveus-variant (47.5%; 19 male and 27 female) IBS. The severity of the alveus disturbances was scored according to a 5-point semi-quantitative scale (0 = none; 1 = minimum; 2 = mild; 3 = moderate; 4 = severe).

The IBS patients were then asked to undergo a BTLact to check the presence of SIBO; only 97 patients accepted, while the remaining 18 patients refused further investigations. At the evening before the BTLact, the patients were required to eat only boiled rise with no sausage or cheese, and grilled meat, and to drink only no-gas water. If constipation was present, the dietary prescriptions were extended to the 3 d preceding the exam. On the day of test, the patients were completely fasted, and smoking was forbidden to all patients (smokers included). Immediately before the test, a sample of expired air was taken to assay the basal H_2 concentrations in the still fasted subjects; then 25 g of lactulose was administered and the expired air was sampled every 30 min in the next three consecutive hours.

A positive test required an early increase of H_2 concentration in the expired air higher than 20 ppm over basal values within 90 min of the oral administration of lactulose, followed by a second distinct peak after additional 15 min or more[9].

The patients, who had a positive BTLact, received a diagnosis of SIBO and were treated with Rifaximin (Normix®, Alfa Wassermann) at the daily dose of 1200 mg for 7 d. Three weeks after the end of the treatment, the BTLact was repeated and the alveus disturbances were scored again.

Statistical analysis

The demographic characteristics of the patients were described as means and standard deviations (min-max ranges), or frequencies when appropriate. The frequencies of symptoms observed in patients with diagnosis of SIBO and IBS were compared using χ^2 test; the frequency of positive BTLact was analysed by the Fisher's exact test.

RESULTS

The 97 patients with diagnosis of IBS, who accepted BTLact, were 41 male and 56 female. The BTLact was found positive in 54 (55.6%) patients; in particular, the test was positive in 61.3% of patients with diarrhoea-, 52.2% of patients with constipation- and 52% of patients with alternated constipation/diarrhoea-variant IBS. There was no significant difference in the frequencies of IBS variants between patients with positive or negative BTLact. The global symptomatological score was not different between the patients with positive or

Table 1 Demographic characteristics of patients with a new diagnosis of IBS (*n* = 97)

Demographic characteristics	*n*	Breath test at screening	
		Positive (*n* = 54)	Negative (*n* = 43)
Sex (M/F, mean ± SD)	40/57 (40.7 ± 16.2)		
IBS variants *n* (%)			
Chronic diarrhoea	31 (31.9)	19 (35.2)	12 (27.9)
Stipsis	20 (20.6)	11 (20.4)	9 (20.9)
Alternated stipsis/diarrhoea	46 (47.5)	24 (44.4)	22 (51.2)
Symptoms score			
Chronic diarrhoea	2.2 ± 0.8	2.2 ± 0.7	2.1 ± 0.6
Stipsis	2.3 ± 0.9	2.4 ± 0.8	2.1 ± 0.9
Alternated stipsis/diarrhoea	2.0 ± 1.2	2.3 ± 0.9	1.7 ± 0.6[a]

[a]Statistically significant difference between groups, $P = 0.019$.

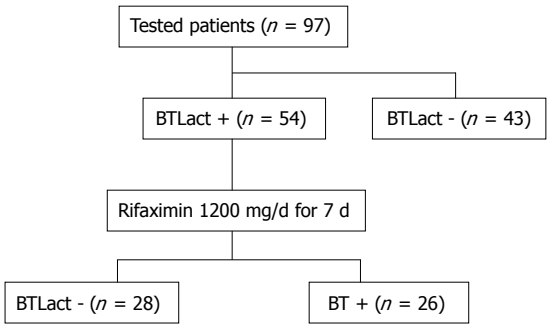

Figure 1 Flow-chart of the activities performed, and the results achieved during the observational study. BTLact: Breath test with lactu-lose.

negative BTLact, except for patients with the alternated constipation/diarrhoea-variant IBS; among these patients, the symptomatological score was significantly higher in the BTLact-positive subjects compared to BTLact-negative subjects (Table 1).

The 54 BTLact-positive patients were treated with Rifaximin, and the BTLact was repeated 3 wk after end of the treatment. In 28 patients, the BTLact turned to be negative, thus showing that the antibiotic was able to significantly control the bacterial overgrowth in the small intestine; in these patients a statistically significant reduction of the symptomatological score from 2.3 ± 0.6 to 0.9 ± 0.8 was also achieved ($P = 0.003$). On the contrary, the remaining 26 patients still had a positive BTLact, and no change in the symptomatological score was observed (2.3 ± 0.6 *vs* 2.3 ± 0.6). No treatment-related adverse effect was observed. A flow-chart of the study is shown in Figure 1.

DISCUSSION

Bacterial flora consisting of Gram-positive and Gram-negative germs, aerobes and anaerobes, is distributed along the GI tract in varying quantities from zero to a maximum of 10^{12}/mL of endoluminal aspirate. This bacterial ecosystem counterbalances with the ecological niche of the host organism and harmonizes with the various digestive, secretory, motor, absorption and sensitivity functions of the entire intestine.

This dynamic equilibrium between environment, bacterial flora and host may be interrupted due to a variety of complex reasons, leading to quantitative and qualitative modifications of the normal intestinal microbial flora that can cause SIBO[10]. SIBO thus represents an invasion of the small intestine, from the upper part by pathogenic strains of oro-alimentary origin, and from the lower part by colo-fecal germs through an incontinent Bauhin's valve.

The SIBO has various clinical and biological presentations: chronic diarrhea, malabsorption syndrome and exudative enteropathy are the main criteria of diagnosis[11]; the syndrome is characterized by an increase of overall bacterial burden in biotope > 10^5 CFU/mL in adults and > 10^4 CFU/mL in children, emergence of different species of enterobacteria, bacteroides, clostridia and fusobacteria in small intestine. Microecological changes are accompanied by B_{12} vitamin deficiency anemia, hypovitaminosis, protein deficiency, translocation of bacteria and their toxins from intestine in blood, emergence of endotoxinemia and possible generalization of infection[12].

Our survey suggested that, based on the results of a BTLact, SIBO was present in about 56% of newly diagnosed IBS patients in our geographical area. Our study has significant limitations, since it was open label; moreover, some clinicians do not consider the BTLact as a gold standard for diagnosis of SIBO and they recommend indirect parameters, like serum vitamine B_{12} levels and folate levels, as main indicator of SIBO. Notwithstanding, our observations find a confirmation in the prevalence of abnormal BTLact recently reported by other authors[13].

The treatment of SIBO must be firstly focused on the correction of wrong food and dietary habits that usually underlying the disorder (e.g. excessive use of fast-food), and then to the reduction of bacterial colonization of small intestine by means of antibiotics[14-16]. In this regard, the use of locally acting, non-absorbable antibiotics would be particularly useful in reducing immediately the bacterial count waiting for the slow-acting beneficial effects of dietary measures. Decontamination of the small intestine is more successful when probiotics are prescribed (both after antibiotics and independently), which suppress the opportunistic flora, protect the mucous coat, improve digestion and arrest diarrhea[17].

Our study demonstrated that a 7-d treatment with Rifaximin determined the negativization of BTLact in about 50% of treated patients. Although the treatment was very short (7 d) and no long-term follow-up available, our data seem to confirm other experiences reported in the most recent literature by Majewski *et al*[3] that a daily dose of 800 mg Rifaximin for 4 wk significantly reduced the symptoms in 20 patients with IBS and led to a negative BT in almost half of patients. Moreover, in another series of 23 patients with SIBO and positive BT, administration of Rifaximin 1200 mg/d for 7 d followed by treatment with probiotics led to a negative BT in 19 (82.6%) cases and significantly reduced the peak in hydrogen concentrations in the expired air from 40.9 ± 20.4 to 4.78 ± 8.42 ppm[2]; Rifaximin was also more

effective than chlortetracycline in improving symptoms in patients with SIBO and IBS[18]. More evidences on the efficacy of Rifaximin have been reported in patients with SIBO and acute diverticulitis of colon[19], and patients with SIBO and celiac disease[20].

In this study, 48% of patients treated with Rifaximin failed to achieve a clinical benefit and turn the BTLact to negative. On the other hand, the difficulty in identifying the specific bacterial population and the affected part of the digestive tract by SIBO prevents the possibility of using targeted antibiotics; the recommendation is to use a broad-spectrum antibiotic therapy, capable of eradicating aerobes and anaerobes, preferably with a topical rather than a general action. Valuable alternatives to Rifaximin that have been proven to be effective in the treatment of SIBO are norfloxacin and amoxicillin-clavulanic acid[21], levofloxacin and/or metronidazole[22], gentamycin[23], trimethoprim/sulfamerazine and polymyxin[24], and chlortetracycline[18].

COMMENTS

Background

The symptoms of irritable bowel syndrome (alternated stipsis and diarrhoea) may be frequently mimicked by an overgrowth of the bacteria that normally reside in the intestine.

Research frontiers

The authors aimed to establish which is the actual incidence of such a bacterial overgrowth among patients with symptoms of IBS, and to get more information on how to treat this disturbance.

Innovations and breakthroughs

The investigation has shown that more than 50% of patients with an earlier diagnosis of IBS, suffering indeed of an intestinal bacterial overgrowth, can be treated by means of an appropriate treatment.

Applications

The intestinal bacterial overgrowth can be detected by means of a specific test ("hydrogen breath test"), which is encouraged to be performed by gastroenterologists.

Peer review

The paper provides an interesting information on the frequency of the intestinal bacterial contamination and overgrowth, which is due to the modern alimentary habits and produces symptoms that may be confused with other gastrointestinal diseases; a simple test, such as the measurement of hydrogen in the expired air, can identify the disorder and allow for the right pharmacological treatment.

Abstract

AIM: To investigate the prognostic factors in patients with hepatocellular carcinoma (HCC) accompanied by microscopic portal vein invasion (PVI).

METHODS: Of the 267 patients with HCC undergoing hepatic resection at Aso Iizuka Hospital, 71 had PVI. After excluding 16 patients with HCC that invaded the main trunk and the first and second branches of the portal vein, 55 patients with microscopic PVI were enrolled.

RESULTS: The patients with HCC accompanied by microscopic invasion were divided into two groups: solitary PVI (PVI-S: n = 44), and multiple PVIs (PVI-M: n = 11). The number of portal vein branches invaded by tumor thrombi was 5.4 ± 3.8 (2-16) in patients with PVI-M. In cumulative survival, PVI-M was found to be a significantly poor prognostic factor (P = 0.0019); while PVI-M and non-anatomical resection were significantly poor prognostic factors in disease-free survival (P = 0.0213, and 0.0115, respectively). In patients with PVI-M, multiple intrahepatic recurrence was more common than in the patients with PVI-S (P = 0.0049). In patients with PVI-S, non-anatomical resection was a significantly poor prognostic factor in disease-free survival (P = 0.0370). Operative procedure was not a significant prognostic factor in patients with PVI-M.

CONCLUSION: The presence of PVI-M was a poor prognostic factor in patients with HCC, accompanied by microscopic PVI. Anatomical resection is recommended in these patients with HCC. Patients with HCC and PVI-M may also be good candidates for adjuvant chemotherapy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a malignant tumor with periportal venous metastasis. Vascular invasion, especially portal vein invasion (PVI), is a major determinant of outcome after hepatic resection in patients with HCC[1-7].

Magnetic resonance imaging (MRI) and ultrasonography can detect tumor invasion of the major branches of the portal or hepatic veins, 81%-95% of the time[8-10]. However, the presence of microscopic PVI, limited to the subsegmental portal vein branches, cannot be diagnosed before hepatic resection. Recently reported predictors of microscopic PVI include size, number, and histological grade of tumors, as well as serum

level of des-γ-carboxy prothrombin (DCP)[11-13]. Miyata *et al*[14] have demonstrated that tumorous arterioportal (A-P) shunt formation on computed tomography (CT) during hepatic arteriography is an important predictive value for PVI. A recent study by Nishie *et al*[15] has shown that an area exhibiting low attenuation on CT during arterio-portography, and high attenuation on CT during hepatic arteriography around the tumor, is a good predictor of PVI. Thus, recent studies have suggested that the presence of microscopic PVI can be predicted.

Nevertheless, the prognostic factors of HCC with microscopic PVI have remained elusive and the operative procedures for this type of HCC have not been determined. In the present study, we evaluated the prognostic factors in cumulative and disease-free survival in patients with HCC, accompanied by microscopic PVI.

MATERIALS AND METHODS

Patients

From April 1992 to December 2005, 267 patients underwent their first liver resection for HCC at the Department of Hepatogastro-enterological Surgery at Aso Iizuka Hospital in Japan. From a retrospective database, 55 patients were enrolled in this study, according to the following criteria: (1) an absence of HCC invading the main trunk and the first and second branches of the portal vein, upon preoperative radiological evidence and intraoperative findings; (2) no remnant cancer after surgery, as confirmed by ultrasonography, CT and/or MRI; and (3) the presence of microscopic PVI upon histological examination.

There were 41 male and 14 female patients with an average age of 64 years (median: 66 years). Among these patients, 35 (64 %) were infected with hepatitis C virus, which leads to chronic liver disease. The indocyanine green retention test at 15 min was 15.5% ± 10.2%. On pathological examination, the tumor size was 5.0 ± 1.1 cm and the main grade of cancer cell was moderately differentiated in 38 patients (69%) and poorly differentiated in 17 (31%). Microscopic intrahepatic metastasis was found in 24 patients (44%).

Methods

The prognostic factors were examined in cumulative and disease-free survival, using the following variables: age (older or younger than 67 years); gender (male *versus* female); platelet numbers (greater than *versus* less than or equal to 150 000/mm^3); serum albumin levels (greater than *versus* less than or equal to 3.8 g/dL); tumor size (greater than *versus* less than or equal to 4.2 cm); serum levels of alpha-fetoprotein (AFP) (greater than *versus* less than or equal to 28 ng/mL); DCP (greater than *versus* less than or equal to 300 mAU/mL); operative procedures (anatomical *versus* non-anatomical resection); histological grading of cancer cell differentiation (moderate *versus* poor); presence of intrahepatic metastases (negative *versus* positive); and microscopic PVI (solitary or multiple). The measurement of serum DCP has been described previously[13]. The measurement of serum DCP was started at our hospital in 1999 and was therefore only available in the latest 36 patients.

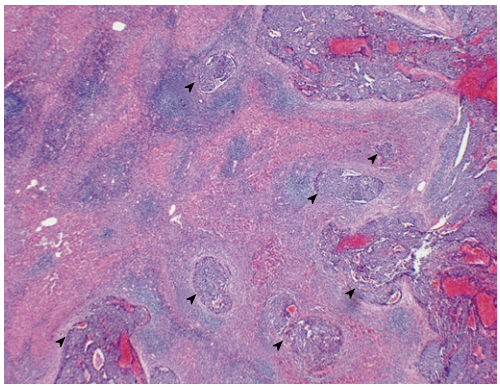

Figure 1 Multiple microscopic PVI surrounding a tumor (arrow heads). HE staining (Original magnification, × 20).

Anatomical resection included hemi-hepatectomy, segmentectomy, and subsegmentectomy, based on Couinaud's classification. Non-anatomical resection was partial hepatectomy, including the tumor.

Histological study

All of the resected specimens were cut into serial 5-10-mm thick slices and fixed in 10% formalin. After macroscopic examination, the slice with the greatest dimension was trimmed for paraffin blocks and cut into 4-μm microscopic sections. The slices were then stained with hematoxylin and eosin (HE). When clusters of cancer cells were present in the extra tumoral portal vein, accompanied with bile duct and hepatic artery, it was defined as positive for extra tumoral PVI. When more than two clusters of cancer cells were present in different portal vein branches, it was defined as multiple PVI (PVI-M) (Figure 1). When only one cluster was present in a single portal vein branch, it was defined as solitary PVI (PVI-S).

Follow-up strategy and recurrence pattern

After discharge, all patients were examined for recurrence by ultrasonography and tumor markers, such as AFP and DCP every month, and by CT every 6 mo. When recurrence was suspected, additional examinations such as hepatic angiography were performed. The recurrence pattern was determined by ultrasonography, CT, MRI and hepatic angiography and was defined as previously reported[7]. Briefly, none was the absence of HCC recurrence, nodular recurrence was fewer than four recurrent nodules, and multiple recurrence was four or more recurrent nodules.

Impact of operative procedures in patients with PVI-S and PVI-M

In patients with PVI-S and PVI-M, the impact of operative procedures (non-anatomical *versus* anatomical resection) was compared on cumulative and disease-free survival.

Table 1 Univariate analysis of clinicopathological prognostic factors for cumulative survival rate

PVI-M (*n* = 11)	54.5	27.3	27.3	

IM: Intrahepatic metastasis.

Statistical analysis

All data were expressed as mean ± SD. The χ^2 test of independence was used with categorical variables. The continuous variables were divided by their median values. The survival and disease-free survival curves were generalized using the Kaplan-Meier method and then compared using the log-rank test. The Stat view software (Version 4.11; Abacus Concepts Inc., Berkeley, CA, USA) was used for the analysis on a Macintosh computer. $P < 0.05$ was considered to be statistically significant.

RESULTS

Histological examination of PVI-S and PVI-M

Of the 267 patients, 55 (21%) had microscopic PVI. The overall incidence of PVI-S was 16% (44 patients) and that of PVI-M was 4% (11 patients). Of the 55 patients with PVI, the 11 patients with PVI-M represented 20%. The number of portal vein branches invaded by tumor thrombi was 5.4 ± 3.8 (2-16) on the slices, stained with HE in patients with PVI-M.

Significant prognostic factors in cumulative survival

The overall survival after hepatectomy in 55 patients with microscopic PVI was 89.0% at 1 year, 66.6% at 3 years, 46.0% at 5 years, and 36.1% at 10 years (Figure 2).

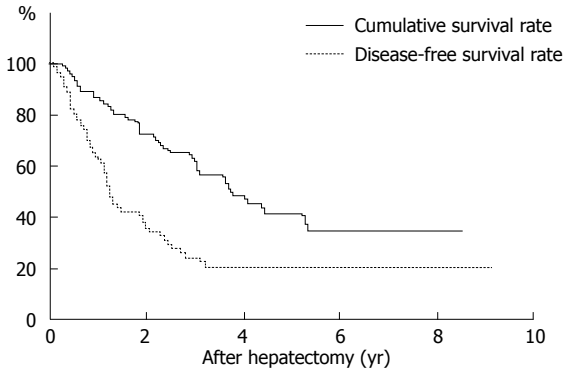

Figure 2 Cumulative and disease-free survival rate in patients with HCC, accompanied by microscopic PVI. The overall cumulative and disease-free survival after hepatectomy in 55 patients was 89.0% and 68.7% at 1 year, 66.6% and 27.3% at 3 years, 46.0% and 22.7% at 5 years.

The median survival was 4.6 ± 0.6 years. Among 11 clinicopathological factors, only the extent of PVI was significant (Table 1). Thus, the cumulative survival curve for patients with PVI-M was significantly worse than that of those with PVI-S ($P = 0.0019$). The median survival of patients with PVI-S and PVI-M was 5.4 ± 1.8 and 1.3 ± 0.7 years, respectively. In operative procedures, the survival rate for anatomical resection tended to be better than that for non-anatomical resection, although the difference was not significant ($P = 0.0620$).

Significant prognostic factors in disease-free survival

The disease-free survival in 55 patients was 68.7% at 1 year, 27.3 % at 3 years, 22.7 % at 5 years, and 22.7 % at 10 years (Figure 2). Among 11 clinicopathological factors, the extent of PVI and operative procedures were significant (Table 2). The disease-free survival curve for patients with PVI-M was significantly worse than that for patients with PVI-S ($P = 0.0072$). The median disease-free survival in PVI-S and PVI-M was 1.5 ± 0.8 and 0.4 ± 0.2 years, respectively. In operative procedures, the disease-free survival rate for anatomical resection was significantly better than that for non-anatomical resection ($P = 0.0074$). The median disease-free survival for anatomical and non-anatomical resection was 2.0 ± 0.2 and 0.8 ± 0.1 years, respectively.

Comparison of PVI-S and PVI-M recurrence patterns

A comparison of the recurrence pattern is shown in Table 3. The incidence of multiple recurrence in patients with PVI-M was 82% and 30% in patients with PVI-S ($P = 0.0049$).

Impact of operative procedures in patients with PVI-S and PVI-M

In patients with PVI-S, non-anatomical resection tended to be a poor prognostic factor for cumulative survival ($P = 0.0782$), while non-anatomical resection was significantly poor prognostic factor in disease-free survival ($P = 0.0370$) (Table 4). In patients with PVI-M, operative procedures were not significant in disease-free survival (Table 5).

Table 2 Univariate analysis of clinicopathological prognostic factors for disease-free survival rate

Factors	Survival rates (%)			*P* value
	1 yr	3 yr	5 yr	
Age (yr)

PVI-M (*n* = 11)	20.0	20.0		

DISCUSSION

The incidence of microscopic PVI has been reported to be more than 20% in resected HCC[1,2]. Even in small HCCs, up to 2 cm in diameter, the incidence of PVI is 15%[3]. In this study, the incidence of PVI was found in 55 of 267 (20%) patients.

Vascular invasion, especially PVI, is a major determinant of the outcome after hepatic resection in patients with HCC[1-7]. In the present study, the survival rate was poorer for HCC patients with PVI than those without (data not shown). Nevertheless, the prognosis of patients with PVI varied. With regard to recurrence patterns, 18 (33%) of the 55 patients with HCC accompanied by PVI had no recurrence, and 22 patients (40%) had multiple recurrence. Clearly, the outcome in patients with no recurrence was better than that of patients with multiple recurrence.

Determination of the prognostic factors in patients with PVI is important for postoperative therapeutic strategy. There has been no study of prognostic factors in patients with HCC accompanied by PVI. In the present study, detailed histological examination of resected specimens revealed that PVI-M was a significantly poor prognostic factor after hepatectomy for cumulative and disease-free survival. With regard to operative procedures, anatomical resection tended to improve survival rates and significantly improve disease-free rates.

Table 3 Comparison of recurrence patterns for 55 HCC patients with single or multiple PVI *n* (%)

Recurrence pattern	None	Nodular	Multiple
PVI-S (*n* = 44)	16 (36)	15 (34)	13 (30)
PVI-M (*n* = 11)	2 (18)	0	9 (82)

The incidence of multiple recurrence in PVI-M was significantly higher than that in PVI-S ($P = 0.0049$).

Table 4 Impact of operative procedures (non-anatomical *versus* anatomical resection) was examined in patients with PVI-S, depending on cumulative survival rate and disease-free survival rates

Factors	Survival rates (%)			*P* value
	1 yr	3 yr	5 yr	
Cumulative survival				
Anatomical resection (*n* = 26)	96.2	83.9	55.0	0.0782
Non-anatomical resection (*n* = 18)	100	65.8	46.1	
Disease-free survival

Disease-free survival				
Anatomical resection (*n* = 6)	40.0	20.0	20.0	0.2651
Non-anatomical resection (*n* = 5)	0			

Histologically, the number of portal vein branches invaded by tumor thrombi was 5.4 ± 3.7 (2-16) in patients with PVI-M. Although PVI was limited to the subsegment of the liver, multiple portal vein branches that surrounded the tumor were invaded. In these patients, the biological behavior of HCC with PVI-M may be similar to that of HCC, with invasion to the first branches or main trunks of the portal vein. The survival rate in patients with PVI-M was only 54.5% at 1 year after hepatectomy. The mean survival and disease-free survival after hepatectomy in patients with PVI-M was 1.3 and 0.4 years, respectively. Multiple recurrence was more common in patients with PVI-M than those with PVI-S. This clinical outcome was similar to that previously shown for patients with HCC, accompanied by portal vein thrombi of the first branches or main trunks[16,17].

Anatomical resection of the liver significantly improved the disease-free rates for HCC with PVI in the present study. Hasegawa *et al*[18] have reported that anatomical resection, such as segmentectomy and subsegmentectomy for HCC, is a reasonable treatment option and yields more favorable results than non-anatomical resection. A recent comparison of the

outcomes of anatomical subsegmentectomy and non-anatomical minor hepatectomy for single HCC, based on a Japanese nationwide survey, recommends anatomical resection, especially when the size of HCC ranges 2-5 cm[19]. In our study, non-anatomical resection was a significantly poor prognostic factor in disease-free survival and tended to be a poor prognostic factor in cumulative survival in patients with PVI-S. Therefore, anatomical resection is preferable in patients with HCC accompanied by PVI. Recent studies have demonstrated that HCC with PVI can be predicted by several factors[11-15]. Therefore, patients with HCC that have high risk factors for PVI preoperatively should be recommended for anatomical resection. To clarify this hypothesis, further examination is necessary.

In PVI-M patients, there was no significant difference in the outcome between anatomical and non-anatomical resection. Recently, in patients with portal vein thrombi in major portal branches, adjuvant chemotherapy has been reported to be effective following hepatectomy and thrombectomy[16,17,20,21]. Patients with HCC and PVI-M may also be good candidates for adjuvant chemotherapy.

In conclusion, in patients with HCC, accompanied by microscopic PVI, the presence of PVI-M is a poor prognostic factor. In PVI-S patients, anatomical resection is preferable to non-anatomical resection. Patients with HCC and PVI-M may be good candidates for adjuvant chemotherapy. Further studies aimed at improving the outcome of patients with PVI after hepatectomy are necessary.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is a malignant tumor with periportal venous metastasis. Vascular invasion, especially portal vein invasion (PVI), is a major determinant of outcome after hepatic resection in patients with HCC. Nevertheless, the prognostic factors of HCC with microscopic PVI have remained elusive and the operative procedures for this type of HCC have not been determined.

Research frontiers

The prognostic factors in cumulative and disease-free survival in patients with HCC, accompanied by microscopic PVI, were evaluated in the present study.

Innovations and breakthroughs

The presence of multiple PVI (PVI-M) was a poor prognostic factor in patients with HCC, accompanied by microscopic PVI. Anatomical resection is recommended in these patients with HCC. Patients with HCC with PVI-M may be good candidates for adjuvant chemotherapy.

Applications

In patients with HCC, accompanied by microscopic PVI, the presence of PVI–M is a poor prognostic factor. In solitary PVI patients, anatomical resection is preferable to non-anatomical resection. Patients with HCC and PVI-M may be good candidates for adjuvant chemotherapy.

Terminology

When clusters of cancer cells were present in the extra tumoral portal vein, accompanied with bile duct and hepatic artery, it was defined as positive for extra tumoral PVI. When more than two clusters of cancer cells (PVI) were present in different portal vein branches, it was defined as PVI-M. When only one cluster was present in a single portal vein branch, it was defined as solitary PVI.

Peer review

This paper was correctly planned to investigate the prognostic factors in patients with HCC accompanied by microscopic PVI. This research is of clinical importance in post-resection management of patients with HCC. The results provide robust clinical evidence to suggest firm scientific conclusions.

Abstract

AIM: To evaluate the feasibility and efficacy of percutaneous radiofrequency ablation (RFA) of the feeding artery of hepatocellular carcinoma (HCC) in reducing the blood-flow-induced heat-sink effect of RFA.

METHODS: A total of 154 HCC patients with 177 pathologically confirmed hypervascular lesions participated in the study and were randomly assigned into two groups. Seventy-one patients with 75 HCCs (average tumor size, 4.3 ± 1.1 cm) were included in group A, in which the feeding artery of HCC was identified by color Doppler flow imaging, and were ablated with multiple small overlapping RFA foci [percutaneous ablation of feeding artery (PAA)] before routine RFA treatment of the tumor. Eighty-three patients with 102 HCC (average tumor size, 4.1 ± 1.0 cm) were included in group B, in which the tumors were treated routinely with RFA. Contrast-enhanced computed tomography was used as post-RFA imaging, when patients were followed-up for 1, 3 and 6 mo.

RESULTS: In group A, feeding arteries were blocked in 66 (88%) HCC lesions, and the size of arteries decreased in nine (12%). The average number of punctures per HCC was 2.76 ± 1.12 in group A, and 3.36 ± 1.60 in group B (P = 0.01). The tumor necrosis rate at 1 mo post-RFA was 90.67% (68/75 lesions) in group A and 90.20% (92/102 lesions) in group B. HCC recurrence rate at 6 mo post-RFA was 17.33% (13/75) in group A and 31.37% (32/102) in group B (P = 0.04).

CONCLUSION: PAA blocked effectively the feeding artery of HCC. Combination of PAA and RFA significantly decreased post-RFA recurrence and provided an alternative treatment for hypervascular HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world (564000 cases per year) and the third most frequent cause of cancer-related death[1]. Surgical resection is considered to be potentially curative therapy. However, only about 20% of HCC patients are eligible for resection[1,2]; the remainder are ineligible because of multifocal tumors, advanced tumors, tumor location precluding complete resection, or poor hepatic functional reserve. Therefore, a variety of imaging-guided tumor ablation therapies such as ethanol injection, microwave coagulation, percutaneous radiofrequency ablation (RFA) and laser ablation are often considered as alternative options[3-6]. Among them, RFA has been used increasingly as a safe technique for treating hepatic tumors[7-9]. However, for hypervascular HCC, RFA appears less effective because of a blood-flow-induced heat sink effect, which might

cause incomplete ablation or recurrence[10]. Transcatheter arterial chemoembolization (TACE) can reduce blood supply of HCC by occlusion of tumor arteries, and the efficacy of combination TACE and RFA has been confirmed[11,12]. Treatment difficulty remains for those patients who cannot tolerate or are ineligible for TACE because of liver cirrhosis or difficulty in manipulation of vessels with abnormal curvature that have resulted from surgical resection and liver transplantation.

We hypothesized that, if percutaneous ablation of the feeding artery (PAA) of HCC could block or reduce the blood flow of HCC, the ablation volume of coagulation necrosis of subsequent RFA of the tumor would be increased. To the best of our knowledge, the application of PAA in the treatment of hypervascular HCC has not been reported in a large number of patients. In the present study, we evaluated the feasibility and adjuvant value of PAA performed before routine RFA treatment (PAA-RFA) of hypervascular HCC.

MATERIALS AND METHODS

Patients

From January 2003 to June 2007, patients with HCC who met the entry criteria and agreed to participate were included in the study. The inclusion criteria for the patients were: pathologically confirmed HCC lesions, ineligibility for surgical resection or TACE, tumor size > 3 cm, no significant tumor direct invasion of adjacent organs, tumor not invading the main bile duct or being obviously exophytic, tumor's feeding artery visible on color Doppler flow imaging (CDFI), prothrombin time ratio > 50%, or platelet count > 60×10^9/L. Exclusion criteria were: tumor thrombus in main or lobar portal vein system, extrahepatic metastasis, or Child-Pugh class C liver cirrhosis.

Each patient who participated in the study was assigned a random number of 1 or 2. The patients with number 1 were allocated to group A, which was treated with PAA-RFA, and those with number 2 were allocated to group B, which was treated with routine RFA[13].

This study was performed with the approval of the ethics committee and informed consent was obtained from each patient after the nature of the procedure had been fully explained.

Equipment

The RFA system used in this study was a 460-kHz generator, 150 W output power (Model 1500; RITA Medical Systems, Mountain View, CA, USA). The expandable electrodes consisted of an outer 14-gauge, 15-cm long outer insulated needle, and nine prongs that were deployed and retracted by a movable hub, with deployment diameter ranging from 3 to 5cm. Twenty minutes were required to produce a 5-cm ablation sphere during RFA. Track ablation was performed when withdrawing the RFA electrode in all patients, to avoid implantation metastasis and hemorrhage.

Real-time ultrasound (US) systems (Aloka 5500 and Aloka α-10, Tokyo, Japan) were used for scanning with 3.5-5.0-MHz convex probes with needle guide devices. Computed tomography (CT) was performed with a Plus 4 scanner (Siemens, Germany) with 5 mm collimation and a table speed of 7.5 mm/s. A total of 100 mL of non-ionic contrast material (300 mg iodine/mL, Omnipaque; Amersham, Shanghai, China) was administered at a rate of 3 mL/s with a power injector (OP 100; Medrad, Pittsburgh, PA, USA). Images were acquired before contrast material injection and 25 and 60 s after the administration of intravenous contrast material, during the hepatic arterial and portal venous phases, respectively.

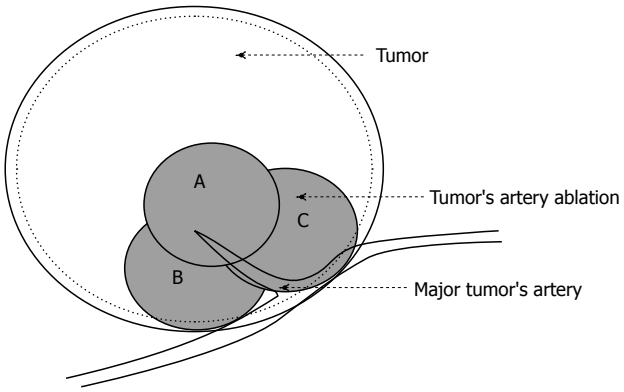

Figure 1 Schematic drawing of PAA using three small ablation foci at the area where the feeding artery entered the tumor, to block the blood supply of HCC.

PAA and RFA

All RFA was performed by two radiologists (M.H.C. and K.Y.) who had more than 10 years' experience of US-guided interventional procedures. Before RFA, the patients were examined by ultrasound and contrast CT or magnetic resonance imaging, and the size, shape and border of the tumor were determined, mainly based on US scans.

CDFI was used to identify the major feeding artery and guide the RFA needle to puncture the area where the artery entered the tumor. This area was ablated with 2-3 overlapping, high-energy ablation foci (2-3 cm each in diameter) in different direction or depths (Figure 1). The flow rate and vessel size of the feeding artery was measured before and immediately after PAA to evaluate the blood supply. After PAA, routine RFA treatment of the tumor was performed immediately, and the ablated area covered 0.5-1 cm beyond the tumor margin. As a result of the hypervascular character of the lesions, special attention was paid to using a slow withdrawal process of the electrode needle to avoid bleeding.

Patients in group B underwent routine RFA treatment using multiple overlapping ablation spheres to cover the tumor and the safe margin beyond the tumor of 0.5-1 cm[13]. During RFA, moderate intravenous sedation was induced with 2.5-5.0 mg midazolam (Roche, Basel, Switzerland) and 50-100 μg fentanyl (Fentaini; Renfu, Yichang, China). Local infiltration anesthesia was induced by 5-15 mL 1% lidocaine (Liduokayin; Yimin, Beijing, China). If patients with tumors adjacent to the diaphragm and hepatic hilum experienced local and

right shoulder pain when the ablation was extended, intravenous infusion of propofol (Diprivan, 1-2 mg/kg; Zeneca, Macclesfield, UK) was given for temporary anesthesia enhancement.

The patients were conscious when the RFA electrode was placed, and vital signs and oxygen saturation were monitored continuously during the procedure. After RFA, the patients underwent close medical observation and were rescanned within 1-2 h after the procedure to detect any bleeding in the liver or the peritoneal cavity. All patients stayed in the hospital overnight.

Any adverse events were evaluated and recorded. Major complications were defined as those that, if left untreated, might have threatened the patient's life, led to substantial morbidity and disability, or resulted in hospital admission or a substantially lengthened hospital stay. All other complications were considered minor.

Assessment of therapeutic efficacy

Treatment response was assessed by contrast-enhanced spiral CT at 1 mo after RFA and complete response was considered to be achieved if the CT scans revealed: (1) the ablation zone was beyond the original tumor borders; (2) the margin of the ablation zone was clear and smooth; and (3) no arterial enhancement or abnormal wash-out was detected within or around the tumor. Subsequently, the patients were followed-up with serum alpha-fetoprotein (AFP) measurement, abdominal US, and contrast-enhanced CT every 2-3 mo in the first year, and then every 4-6 mo thereafter. All patients were followed-up for at least 6 mo. Recurrence was defined as enhancement within or at the periphery of the ablated area in the follow-up CT scan. Recurrent HCC was treated with another session of RFA. All CT scans were reviewed by two radiologists with more > 10 years experience, who were unaware of patient clinical data or treatment assignment.

Statistical analysis

Differences in complete necrosis rate at 1 mo and recurrence rate at 6 mo were analyzed by χ^2 and *t* tests where appropriate. The recurrence rate was determined by log-rank tests, and multivariate hazard ratio was calculated using the Cox proportional hazard model. The Kaplan-Meier estimate of the cumulative recurrence rates over time was also carried out. All *P* values were two-sided, and $P \leqslant 0.05$ was considered statistically significant. All analyses were performed with SAS software, version 6.12.

RESULTS

A total of 154 patients participated in the study from January 2003 to June 2007. No patient withdrew from the trial during 6 mo follow-up. Seventy-one subjects were assigned in group A, whose average tumor size was 4.3 ± 1.1 cm. Eighty-three participants were in group B, whose average tumor size was 4.1 ± 1.0 cm. The characteristics of the two groups are shown in Table 1. There was no significant difference between the two groups in patients' clinical profile except for the gender ratio.

Table 1 Pre-RFA clinical profile of patients (M_0N_0) *n* (%)

	Group A (*n* = 71)	Group B (*n* = 83)	*P* value
Age (yr)	59.3 ± 12.0	61.3 ± 12.0	0.28
HCC size (cm)	4.3 ± 1.1	4.1 ± 1.0	0.21

For patients in group A, the feeding artery was blocked in 66/75 (88%) HCC lesions, and decreased in size in 9/75 (12%) lesions. The average number of punctures per HCC was 2.76 ± 1.12. Complete necrosis rate at 1 mo after RFA was 90.67% (68/75), and recurrence rate at 6 mo was 17.33% (13/75, lesions) (Figure 2). For patients in group B, the average number of punctures per HCC was 3.36 ± 1.60. Complete necrosis rate at 1 mo after RFA was 90.20% (92/102), and recurrence rate at 6 mo was 31.37% (32/102).

No significant difference was found in the necrosis rate at 1 mo post-RFA. However, there was a significant different between the two groups in the average number of punctures per HCC and recurrence rate at 6 mo after RFA. The recurrence time between the two groups was also significantly different by the log-rank test ($\chi^2 = 5.23$, $P = 0.02$; Figure 3). When adjusted for gender, age and cirrhosis, it was still significantly different ($\chi^2 = 4.58$, $P = 0.03$).

In group A, RFA-related major complications were seen in five patients (7.04%), including three cases of pleural fluid collection, one of bowel wall edema, and one of intrahepatic biliary duct dilation with jaundice, which were all relieved by conservative therapy. A small amount of subcapsular hemorrhage around the puncture site, approximately 0.5-1 cm thick, during RFA was seen with US in 13 patients (18.31%) (Figure 4). It was not considered as a major complication because homeostasis was achieved after injection of hemocoagulase, without additional intervention and no change in blood pressure. In group B, major complications were detected in nine cases (10.84%), including one of pneumothorax with pleural fluid collection, six of pleural effusion, one of abdominal wall abscess, and one of intraperitoneal hemorrhage in a tumor > 5 cm and protruding liver lateral surface. All complications were controlled

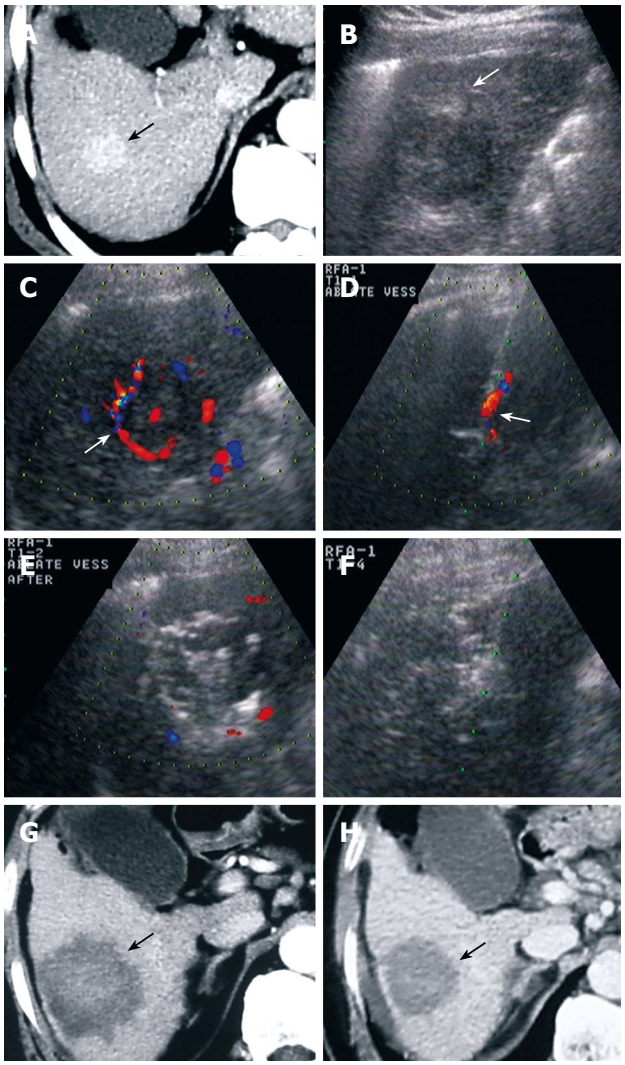

Figure 2 A 65-year-old man with cirrhosis and Child-Pugh class A liver function. An HCC lesion was diagnosed during regular US examination. A: CT showed a tumor with a size of 3.2 cm × 3.0 cm in the right liver lobe; B: US showed a tumor (arrow) of 4.3 cm × 3.3 cm 3 mo later; C: CDFI showed blood flow into and around the tumor with a velocity of 56.7 cm/s; D: CDFI-guided PAA at the area where the feeding artery entered the tumor (arrow), to block the tumor blood supply; E: After PAA, CDFI showed that the previous feeding artery disappeared and no flow signal within HCC; F: After PAA, RFA was performed in the rest of the tumor; G: Contrast-enhanced CT (1 mo after treatment) showed an ablated area covering the previous tumor, without enhancement; H: Contrast CT (6 mo after treatment) showed no enhancement of the ablated area. The patient has survived more than 10 mo without tumor.

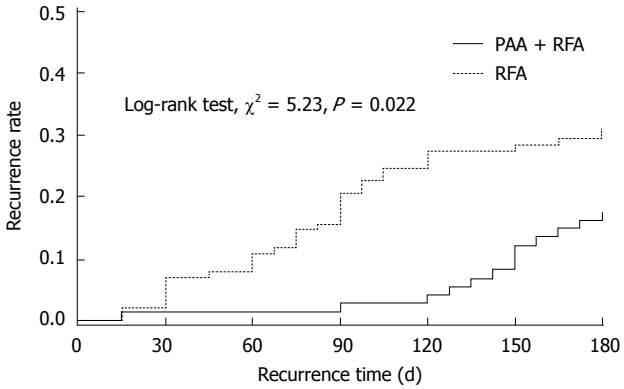

Figure 3 The Kaplan-Meier curves for 6-mo recurrence rate in the two groups.

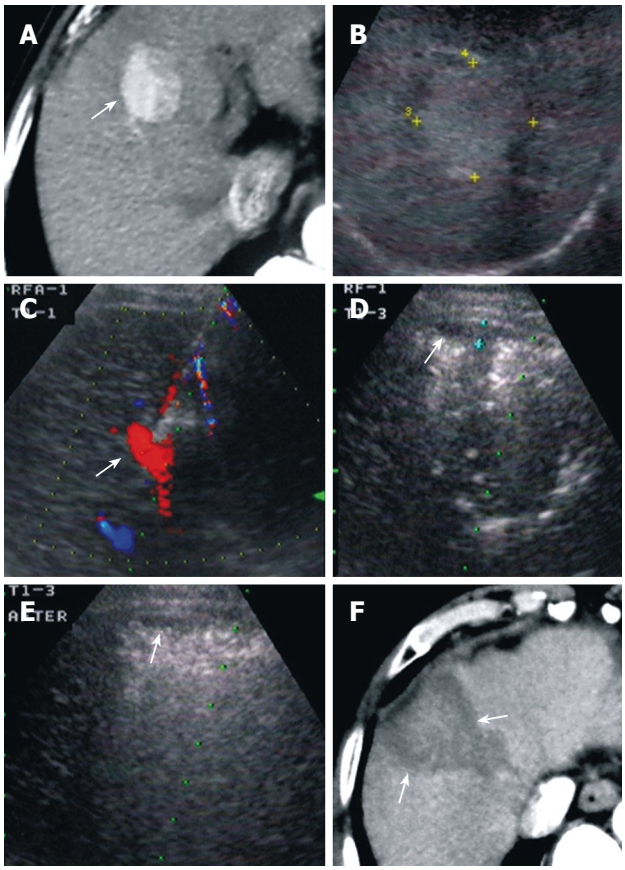

Figure 4 A 72-year-old man with 10 years of hepatitis B was detected with HCC during routine examination. This patient could not tolerate most of the therapies because of old age and poor general condition. A: Contrast-enhanced CT showed a 3.7 cm × 3.5 cm mass and the feeding vessel (arrow); B: Contrast-enhanced US 2 mo later showed the tumor enlarged to a size of 5.2 cm × 4.2 cm; C: CDFI showed feeding vessels in and around the tumor with a flow velocity of 34.5 cm/s. PAA was performed under CDFI guidance; D: During PAA, a small amount of subcapsular hemorrhage (0.5 cm in depth) was noted; E: The amount of hemorrhage gradually reduced (arrow) after PAA finished; F: Contrast-enhanced CT (24 h after treatment) showed a necrotic area covering the tumor. A small amount of subcapsular hemorrhage was still be noted.

with conservative treatment. There was no significant difference between the incidence of complications between the two groups.

DISCUSSION

The outcomes of RFA for HCC correlate closely with the location and blood supply of the tumor. Goldberg *et al*[10] have demonstrated that blood-flow-induced thermal loss in the tumor and liver tissue is the main reason for the decreased ablation effect of thermotherapy. The high-velocity blood flow of the tumor vessels created a heat sink effect that compromised the ablation effect, which led to residual and recurrent HCC. For the treatment of hypervascular HCC, many studies have focused on reducing flow perfusion to improve the thermal effect of RFA. Curley *et al*[14] have used the Pringle method[15] intraoperatively to reduce liver blood flow, by temporarily stopping portal vein and hepatic artery

flow, and improving ablation outcomes. Goldberg *et al*[16] have used vascular agents, such as halothane, vasopressin and adrenaline, to adjust liver blood volume in order to increase ablation area.

TACE is one of the major interventional methods for HCC treatment, and when performed before RFA, it can increase therapeutic efficacy as a result of the decreased heat sink effect[17-19]. Kitamoto *et al*[20] have compared the therapeutic effects of RFA alone and in combination with TACE in 21 patients with 26 HCCs smaller than 3.0 cm. The size of the ablated necrotic area in the TACE/RFA group was significantly larger than that with RFA alone. However, repeated TACE treatment worsened liver function and quality of life[21], and then prolonged the interval between TACE and RFA. Therefore, for those who were ineligible or could not tolerate TACE treatment, other minimally invasive methods of reducing tumor blood supply before RFA were needed.

The study used PAA to ablate the area where the feeding artery entered the tumor, with small overlapping, high-energy ablation foci. This procedure was conducted through one puncture point using three ablations in different directions or depths. After PAA, the tumor's feeding artery was blocked, thus reducing the blood-flow-induced heat loss, and achieving a similar result to that with TACE before RFA. PAA avoided damage to the surrounding liver parenchyma and liver function compared with TACE, and was well-tolerated by patients.

Recurrence after RFA remains an unsolved problem for large HCC. Harrison *et al*[22] reported percutaneous RFA in 46 HCC patients within 3 years, and only 14 (28%) of them showed no liver tumor tissue by imaging and AFP follow-up. Ruzzenete *et al*[23] have reviewed RFA of 104 HCCs in 88 patients with an average tumor size of 3.9 ± 1.3 cm. The necrotic rate for tumors < 3 cm, 3-5 cm and > 5 cm was 100%, 87.7% and 57.1%, respectively. In an average 19.2-mo follow-up period, 17 (19.3%) patients showed local recurrence. In our study, all the HCCs were > 3 cm in both groups A. For HCC treated with PAA and RFA in group A, the local recurrence rate at 6 mo was 17.33% (13/75), which was significantly lower than that in group B (31.37%, 32/102), which was treated with RFA alone ($P = 0.0382$). Although the proportion of cirrhosis was higher in group B than in group A, which might have influenced HCC recurrence, after adjusting for cirrhosis, the results still showed a significant difference between the two groups for recurrence time. Thus, PAA that was performed before routine RFA improved the treatment efficacy in hypervascular HCC. With the new strategy of PAA combined with RFA, the number of percutaneous punctures per HCC was reduced in group A to an average of 2.76 ± 1.12, which was significantly less than that in group B, 3.36 ± 1.60 ($P = 0.001$), thus injury to patients was reduced. Kitamoto *et al*[20] reported that the average duration between TACE and RFA was 18.2 d. In our study, RFA could be performed immediately after blocking of the major feeding artery with PAA, which could reduce hospital stay.

In group A, 13 (17.33%) patients had a small amount of bleeding during PAA, most of which was detected at the first puncture, where the RFA needle punctured the area where the feeding artery entered the tumor. We supposed that the bleeding might have been caused by damage of the feeding vessels and incomplete ablation. Additional focal ablation in the area was helpful in stopping bleeding.

One limitation of our study was the short duration of follow-up. However, our main goal was to demonstrate the benefit of PAA/RFA in treating hypervascular HCC, and our data confirmed this. PAA blocked the feeding artery of the tumor, and then blood-flow-induced heat loss was reduced during RFA treatment. We think that the short-term benefits of PAA/RFA compared with RFA alone for hypervascular HCC provide some insight for the future wider application of this treatment.

In conclusion, for hypervascular HCC patients who were unsuitable for surgical resection or TACE, PAA was an alternative for blocking the feeding artery of the tumor, and reducing heat loss during subsequent RFA. The combination of PAA and RFA could significantly decrease post-RFA recurrence and provide a safe and effective treatment for hypervascular HCC.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the most common primary malignant liver neoplasm worldwide. Although surgical resection is the gold standard for treatment of HCC, only a limited number of patients are surgical candidates because of their lack of hepatic reserve that results from coexisting advanced cirrhosis, widespread intrahepatic involvement, and concomitant diseases. Therefore, a variety of imaging-guided tumor ablation therapies such as ethanol injection, microwave coagulation, percutaneous radiofrequency ablation (RFA) and laser ablation are often considered as alternative options. Among them, RFA has been used increasingly as a safe technique for treating hepatic tumors.

Research frontiers

For hypervascular HCC, RFA appears less effective because of the blood-flow-induced heat sink effect, which might cause incomplete ablation or recurrence. Previous experiments have shown that mechanical and pharmacological strategies that are aimed at lowering hepatic perfusion can increase the size of thermally induced lesions.

Innovations and breakthroughs

Repeated transcatheter arterial chemoembolization (TACE) worsened liver function and quality of life, and then prolonged the interval between TACE and RFA. In order to overcome these disadvantages, the study used PAA to ablate the area where the feeding artery entered the tumor, with small overlapping, high-energy ablating foci. This procedure was conducted through one puncture point using three ablations in different directions or depths. After PAA, the tumor's feeding artery was blocked, thus reducing the blood-flow-induced heat loss, and achieving a similar result as that with TACE before RFA. PAA avoided damage to the surrounding liver parenchyma and liver function compared with TACE, and was well-tolerated by patients.

Applications

The study results suggested that, for hypervascular HCC patients who were unsuitable for surgical resection or TACE, PAA was an alternative for

effectively blocking the feeding artery of the tumor, and reducing heat loss during subsequent RFA. The combination of PAA and RFA may significantly decrease post-RFA recurrence and provide a safe and effective treatment for hypervascular HCC.

Terminology

PAA: Color Doppler flow imaging was used to identify the major feeding artery and guide the RFA needle to puncture the area where the feeding artery entered the tumor. This area was ablated with 2-3 overlapping high-energy ablation foci (2-3 cm each in diameter) in different directions or depths.

Peer review

This is a good original study in which authors performed a new approach to block the major feeding artery and reduce heat loss during subsequent RFA. The results are interesting and suggest that the combination of PAA and RFA significantly decreases post-RFA recurrence and provides a safe and effective treatment for hypervascular HCC.

Abstract

AIM: To compare the gastric cancer (GC) patients by their family history with gastric and non-GC.

METHODS: Positive family histories within second-degree relatives and clinicopathological features were obtained for 256 patients.

RESULTS: Of the 256 probands, 112 (76 male, 36 female) were incorporated into familial GC (FGC) group: at least two GC members; 144 (98 male, 46 female) were included in the non-FGC group (relatives only affected with non-GCs). Of 399 tumors in relatives (181 from FGC against 212 from non-FGC), GC was the most frequent, followed by esophageal, hepatocellular, and colorectal cancer. Nasopharyngeal cancer was next to lung cancer but prior to breast and urogenital cancers. Most affected members aggregated within first-degree relatives (FGC: 66 siblings, 48 fathers, 31 mothers, four offspring; non-FGC: 56 fathers, 55 siblings, 43 mothers, and 15 offspring). The ratio of males to females in affected first-degree relatives was usually higher in male probands. Paternal history of GC was a slight risk for GC in males (OR = 1.19, 95% CI: 0.53-2.69), while risk of GC by maternal history of non-GCs was increased in females (OR = 0.46, 95% CI: 0.22-0.97). Diffuse-GC was the major histological type in all subgroups. Difference in tumor sites between the two groups was derived from an excess of upper sites in non-FGC female probands.

CONCLUSION: Distribution of associated non-GCs in a family history of GC may vary with geographic areas. GC may have different genetic and/or environmental etiology in different families, and a certain subtype may be inherited in a female-influenced fashion.

Key words: Gastric cancer; Family history; Familial gastric cancer; Familial predisposition; Female-influenced fashion

INTRODUCTION

It has long been recognized that approximately 10% of gastric cancer (GC) patients present with some kinds of familial aggregation[1]. Family history of GC has previously been studied in many regions, including eastern Asian[2-9], North American[10-12], northern European[13-15], and Mediterranean countries[16-21]. A much higher incidence of familial GC (FGC) was reported from Mediterranean countries[19], while a relatively low occurrence was noted in northern European countries[14]. Some studies, although not all, showed that a family history of GC might be considered a stronger risk factor for women[2,3], or that risk of GC might be higher for subjects with an affected sibling rather than a parent[13,15,16,21]. The risk of GC associated with family history for non-GC has been found with different cancers in different studies[5,10,15,21]. In addition, the histological type of FGC was pronounced for "intestinal" and/or "diffuse" cancers in different studies[13,16]. An unusual form, the hereditary diffuse GC, which is a typical case of FGC caused by a truncation

germline mutation of CDH1, has never been found in eastern Asia[8]. Therefore, a number of features of FGC, including incidence, clinicopathological characteristics, family member risk and etiology, are still in debate.

Previous studies have indicated that familial predisposition to GC may have different genetic and/or environmental correlations in different populations. Although GC is one of the most common cancers in China, few data about its family history are available. Thus, to provide further data on the issue, we designed a proband-based case-control study to explore the traits related to family history of GC in south China.

MATERIALS AND METHODS

The data were obtained from three hospitals in Guangdong Province in south China: the First Affiliated Hospital of Sun Yat-Sen University, the First Affiliated Hospital of Guangdong Pharmaceutic University, and the People's Hospital of Meizhou city. A total of 2260 patients with histologically demonstrated GC admitted between 2000 and 2007 were enrolled in this study. A patient with positive oncologic family history records during his hospitalization or the follow-up was identified as a proband. Features of a proband, including gender, age of onset, and site and histological type of tumor, were taken into account. In addition, the oncologic family history of a proband consisting of data on gastric and/or non-GCs in the relatives was evaluated.

The oncologic family history of each proband was obtained using structured interviews carried out either in person or by telephone. The interviews were always conducted by the same two medical clinicians. After a brief explanation of the purpose of the study, verbal consent was requested before starting the questionnaire. The patient or the closest relative, usually a wife, husband or child, was asked to report the family history. Since an accurate history of third-degree relatives of a proband was relatively hard to obtain, we focused on the first to second-degree relatives, asking about the total number of family members, whether anyone had been diagnosed with cancer, the type of the cancer, and the age of onset.

In this study, according to present recognition[1], a positive family history was defined as a history of cancer within second-degree relatives, while FGC was referred to the presence of at least two GC family members, but also included relatives with history of non-GC. A clear positive family history was obtained for 256 of the total patients. The 256 probands were divided into two groups: a FGC group; and a non-FGC group (patients with relatives affected with non-GCs only), then each group was sorted again according to gender. Tumor location of a proband was identified by three sub-types: upper, medium, and lower site. Histological typing, usually made according to WHO classification, was converted to a Lauren classification. Chi-square test and risk estimate (OR) were used to evaluate the statistical significance. A P value less than 0.05 was considered statistically significant. All statistical analyses were performed using the SPSS 13.0 software.

RESULTS

Of the 256 probands, 112 subjects (76 male, 36 female) reported a family history of GC (it also included relatives with histories of non-GC) and were incorporated into the FGC group; 144 subjects (98 male, 46 female) reported only a family history for non-GC and were included in the non-FGC group. Mean age of probands in FGC and non-FGC were 56.7 years (range 20-87 years) and 55.4 years (range 28-77 years), and the proportions of young patients (no more than 45 years) were 18.8% (21/112) and 20.1% (29/144), respectively ($\chi^2 = 0.08$, $P > 0.05$).

Table 1 shows the overall ranking of associated tumors within second-degree relatives of the 256 probands. A total of 399 neoplastic diseases were reported, 182 from FGC compared with 217 from non-FGC. GC was by far the predominant tumor in affected relatives of FGC (154 GCs against 28 non-GCs) as well as in the overall affected relatives of both groups. Of the non-GCs from affected relatives, esophageal cancer was the most frequent, hepatocellular cancer was the second, and colorectal cancer was the third. The "Canton tumor", a nasopharyngeal cancer (NPC) that has been rarely reported in previous studies, was the fifth, after lung cancer, but prior to breast and urogenital cancers.

Table 2 presents the distribution and number of affected family relatives of the 256 probands. Most affected members aggregated within the first-degree relatives. Among the total 318 (195 male, 123 female) affected first-degree relatives, males were more predominant in members affected with GCs (90 male *versus* 39 female) than in those with non-GCs (105 male *versus* 84 female) ($\chi^2 = 6.53$, $P < 0.05$). In general, among the first-degree relatives, siblings were the most frequently affected relatives, fathers were the next, and mothers were the third. This sequence was repeated among the relatives of FGC (siblings 66, fathers 48, mothers 31), but affected fathers were the most frequent in non-FGC (fathers 56, siblings 55, mothers 43). The ratio of males to females in affected first-degree relatives was usually higher in male than in female probands, and showed a decreasing trend in the four subgroups (Table 3).

Table 4 shows the OR, as estimators of relative risks, together with the corresponding 95% CI for reported parental history of cancers when male and female probands were compared. Paternal history of GC showed a slightly higher risk for males than for females, although there was no statistical significance (OR = 1.19, 95% CI: 0.53-2.69). In contrast, maternal history seemed to affect both genders to the same degree (OR = 0.93, 95% CI: 0.37-2.35). GC risk by paternal history of non-GC was almost the same for both genders (OR = 0.99, 95% CI: 0.48-2.02), but maternal history was less likely to be a risk factor for males, but was a risk factor for females (OR = 0.46, 95% CI: 0.22-0.97). Table 5 exhibits 14 probands whose parents were both affected. Five pairs of affected parents who reported at least one

$\chi^2_{trend} = 5.03$, $P < 0.05$.

suffering from GC had five affected sons only, while nine pairs of parents both suffering from non-GCs had five affected daughters and four affected sons.

Table 6 displays the histological types of the 256 probands. According to Lauren classification, diffuse GC was the major histological type in all subgroups. The frequency of the intestinal type was lower in the FGC than in the non-FGC group, but no statistical difference was found between them. Table 7 shows the distribution of tumor sites of the 256 probands. The lower site was the most frequent tumor location in FGC probands, in contrast to upper sites in non-FGC probands ($\chi^2 = 10.69$, $P < 0.05$). The statistical difference in tumor sites between the two groups was derived from an excess of upper sites presenting in non-FGC female probands (male subgroups: $\chi^2 = 4.99$, $P > 0.05$; female subgroups: $\chi^2 = 9.67$, $P < 0.05$).

DISCUSSION

In the present study of family history of GC in south China, we compared the association between the family history with GCs and non-GCs, and the risk of GC between male and female probands by parental oncologic history. Our study confirmed that overall ranking of associated non-GCs in relatives was different from that reported in other studies to some degree, and that the ratio of males to females in affected first-degree relatives was usually higher in male than in female probands. We also found that the risk of GC was increased in females

Table 4 Relative risk of GC by comparing male with female probands from their paternal or maternal history of cancers

Affected parents	FGC[1] (*n* = 108)		OR (95% CI)	Non-FGC (*n* = 144)		OR (95% CI)
	Male proband (*n* = 72)	Female proband (*n* = 36)		Male proband (*n* = 98)	Female proband (*n* = 46)	
Father	31	14	1.19 (0.53-2.69)	38	18	0.99 (0.48-2.02)

BC: Breast cancer; CRC: Colorectal cancer; EC: Esophageal cancer; EMC: Endometrial cancer; GC: Gastric cancer; HC: Hepatocellular cancer; LC: Lung cancer liver; NPC: Nasopharyngeal cancer; PC: Pancreatic cancer; Moderately: Moderately differentiated adenocarcinoma; Poorly: Poorly differentiated adenocarcinoma; Mucinous: Mucinous adenocarcinoma; Signet-ring cell: Signet-ring cell carcinoma.

when a maternal history of non-GC was present. On the other hand, the risk for GC in males was only slightly (not significantly) increased if a paternal history of GC was present. Moreover, a trend toward upper tumor sites was observed only in females with a family history of non-GC.

Associated tumor categories and their frequencies of family history of GC have been reported previously. Recent studies were consistent with the higher predisposition to gastric than to any of the non-GCs in family members[2,19]. The frequency of GC among all affected relatives was also highest in our study. However, the frequency of non-GC in family members differed from the results in other reports. For example, colorectal, lung, and uterine cancers were the highest in ranking in a Japanese report[9], while colorectal, breast, and lung cancer were prevalent in an Italian report[20], lung/larynx cancer, gastrointestinal cancer, and leukemia/lymphoma were most frequent in a study from Turkey[18], and colorectal and lung cancer were most common in a report from Taiwan[6]. In general, the overall ranking of associated non-GCs in family histories of GC varied from region to region, but the preceding tumors were usually the most frequent ones occurring in that general population.

Eastern Guangdong is one of the regions with the highest incidence of esophageal cancer in China. Guangdong is also one of the regions with the highest incidence of hepatitis B, and HBV-related hepatic cancer is one of the most common tumors in this region. Therefore, esophageal and hepatic cancers, which are usually frequent in general population, are more common in Guangdong. This may be interpreted as that esophageal and hepatic cancers were the two most frequently associated non-GCs among the relatives in our study. Moreover, Guangdong is the region with the highest incidence of NPC in the world. NPC, rare in other general populations, is quite common among Cantonese. This may explain why NPC was much more frequently reported in our study in contrast to other studies, but was less frequently encountered with the most common tumors (usually common both in local residents and in the general population) within our study groups. From this, we can infer that the overall rankings of associated non-GCs in family history of GC may be correlated to the categories of common cancers in the general population, but also show their own regional incidences. This suggests that GC probably shares similar genetic and/or environmental etiologic pathways with other common tumors.

The risk of GC by family oncologic history has been debated in different studies. Although no normal control was included as part of this study, we assumed that siblings being the most frequently affected relatives might support the idea that the risk of GC was higher for subjects with an affected sibling rather than an affected parent[13,15,16,21]. It may be also debated if the risk of GC has no association with family history of any cancer other than GC, because our data showed a very high proportion of relatives affected with esophageal cancers, and esophageal cancer usually shares very similar geographic distribution with gastric cardia cancer in China[22].

Gender-influenced familial predisposition to GC has also been investigated previously[2,3]. Although our study was not a population-based case-control study, the results reconciled a number of points raised in a Japanese study[2]. The findings of this study indicated that risk of GC by paternal history of GC seemed to be a slight risk for males compared with females, while the increment in the risk for GC was prominent in females when they reported a maternal history of non-GCs. However, we did not find a higher risk for females when they reported a maternal history of GCs, which had been described in the previous study[2].

Besides gender-related familial risk of GC, a gender difference was also found in affected first-degree

Table 6 Distribution of tumor histological types (converting the WHO to the Lauren classification) of 256 probands

Lauren classification	WHO classification	FGC (n = 112)		Non-FGC (n = 144)	
		Male proband (n = 76)	Female proband (n = 36)	Male proband (n = 98)	Female proband (n = 46)
Intestinal type	Well	3		2	
	Moderately	19	6	39	12
	Mucinous	5	3	5	3
	Total	27	9	46	15
Diffuse type	Poorly	44	24	39	25
	Signet-ring cell	3	2	11	6
	Undifferentiated	2	1	2	
	Total	49	27	52	31

Well: Well differentiated adenocarcinoma; Undifferentiated: Undifferentiated carcinoma; No statistical differences of histological types were found between any two subgroups, although ratio of intestinal to diffuse types was lower in FGC than in Non-FGC (36/76 = 0.47 from FGC against 61/83 = 0.73 from non-FGC).

Table 7 Distribution of anatomical sites of tumors in 256 probands

Tumor site	FGC (n = 112)		Non-FGC (n = 144)	
	Male proband (n = 76)	Female proband (n = 36)	Male proband (n = 98)	Female proband (n = 46)
Upper	22	5	42	16
	27		58	
Medium	20	7	27	15
	27		42	
Lower	34	24	29	15
	58		44	
χ^2, P value	$\chi^2 = 10.69$, $P < 0.05$			

Difference of tumor sites between two male subgroups: $\chi^2 = 4.99$, $P > 0.05$; two female subgroups: $\chi^2 = 9.67$, $P < 0.05$.

relatives in different families in our study. The ratio of males to females in the affected first-degree relatives was usually higher in FGC than in non-FGC. This may be attributed to the male predominance in GC development. However, the ratio of the affected relatives was usually higher in male than in female probands in both groups. This may also indicate that gender influences the familial predisposition to GC in a certain way. Moreover, gender variations still existed in the affected offspring when both parents suffered from different cancers. Affected daughters were not found in families in which at least one of the two affected parents had GC, but were more frequent in families in which both affected parents suffered from non-GCs. These differences in GC risk by gender and family oncologic history imply that familial predisposition to GC may have a compound genetic and/or environmental correlation in different families.

Lauren's classification system classifies GC under two major histological variants: an intestinal type, likely to be related to environmental factors, and the diffuse type, more likely to have a primary genetic etiology. Our data show that the diffuse type was the more common histological form in all subgroups. However, the frequency of histological type of GC with oncologic family history varied with different studies. Japanese studies[4,7] reported that the undifferentiated histological type was dominant in FGC, and there was a predisposition to the intestinal type when both parents suffered from GCs while to the diffuse type when both parents suffered from non-GCs. The dominance of the intestinal type and the diffuse type was reported in Italy and Poland, respectively[13,16,20]. These variations indicate that familial predisposition to GC may be a multifactor disease.

Many studies have verified that environmental factors may play a more important role than do host genetics in GC development. The prevalence of *Helicobacter pylori* infection has been regarded as an important risk factor for familial aggregation of GC, and may be a strong risk factor for distal, rather than for proximal, GC[23,24]. However, this could not be fully interpreted for the familial predisposition to GC in south China, because of a higher proportion of diffuse GC in all subgroups and no statistical difference of tumor site between the two male subgroups. Some studies have found no appreciable interactions between family history of GC and environmental factors, such as lifestyles[25]. Our investigation detected a pedigree with a father and two brothers affected with GCs, but one of the brothers, suffering from GC at the age of 62 years, had been adopted by another family in his childhood. This suggests that FGC may be predominantly the diffuse type and may be accounted by factors other than just environmental exposures.

Furthermore, a Japanese study[26] reported that an increment of an upper tumor was observed only in patients with a maternal history of GC, but our study displayed the same increment only in females with family histories of non-GC. Our result might be partially influenced by a higher incidence of esophageal cancer among the family members suffering from non-GCs, because the higher prevalence of upper tumors may be due to the higher prevalence of esophageal tumors in this region which is usually associated with a high incidence of gastric cardia cancer. Site-specific risk for female GC that was linked to a family history of non-GC, as well as site-specific risk for GC linked to a maternal history of GC from a Japanese study, provides further evidence that a type of familial susceptibility to GC, to some extent, may be dominated in a female-influenced way.

Some explanations should be provided for the data demonstrated in this study. We focused the discussion primarily on the data of first-degree relatives, because reports of family history will always be clearer in those we know better (i.e. first-degree relatives) and will be less clear as we extend to second and third degree relatives. Therefore, the data of first-degree relatives may introduce fewer inherent biases. The percentage of positive oncologic family histories and incidences of FGC (11.2% and 4.9%) are much lower than those cited in the literatures. It is possible that our data may not show substantial percentages because some patients were unwilling to tell their family history, but this limitation was unlikely to contribute substantially to the differences we observed. Genetic factors may in fact be more important in a young GC development, and therefore may be likely associated with familial susceptibility in a young patient[27,28]. However, the percentages of young patients among the total patients (20.0%) and the 256 probands (19.5%) had no statistical difference, and both were higher than 10% in GC population cited in literatures[28]. These data indicated that the proportion of young patients in the GC population was higher in south China, but an association between young individuals and the inheritance of GC in a cancer family was not found. Therefore, the etiology and the terms used to describe familial tendency of a young GC patient should be reconsidered.

In conclusion, the overall ranking of associated non-GCs in the family history of GC may vary with geographic areas. Familial predisposition to GC may be related to compound genetic and/or environmental etiologies; and a certain subtype of GC may be inherited in a female-influenced fashion.

ACKNOWLEDGMENTS

We wish to express our appreciation to Dr. Guang-Fu Peng, from the People's Hospital of Meizhou city, Professor Xin-Sheng Chen, from the Union Hospital affiliated to Fujian Medical University, and Professor Kui-Feng Liu, from the First Affiliated Hospital of Guangdong Pharmaceutic University, who greatly contributed to constructive suggestions of this study.

COMMENTS

Background

Gastric cancer (GC) is a major clinical challenge because of its frequency, poor prognosis and limited treatment options. The etiology of GC is still uncertain, but its familial aggregation in a variable but significant proportion of cases suggests the importance of genetic predisposition. The risk of developing GC is greater in relatives of patients with oncological family history than in relatives of sporadic cancer. Previous studies have indicated that familial predisposition to GC may have different genetic and/or environmental correlations in different populations. Although GC is prevalent in China, scanty information about its family history is available.

Research frontiers

Familial predisposition to GC may be partly due to the fact that relatives tend to be exposed to the same environmental risk factors, but also to inheritable susceptibility. In this field, the research hotspot is how to identify risk relatives, and risk factors (including different prevalence of various susceptibility genes, and the impact of various environmental factors) in a family with disease.

Innovations and breakthroughs

Studies on family history of GC, the association of familial risk of GC with the age of onset GC, with family member gender, or with family history of non-GCs, usually yielded contrasting results. This study believed that the overall ranking of associated non-GCs in the family history of GC may depend on geographical variations; familial predisposition to GC may be related to compound genetic and/or local environmental factors; and a certain subtype of GC may be inherited in a female-influenced fashion.

Applications

The data presented in this article represents important data about familial predisposition to GC with a high prevalence. This will add to the available body of knowledge about GC inheritance and aid in future research into this important disease.

Terminology

Familial GC (FGC) is simply designated as a cancer family with at least two GC members, also including those affected with non-GCs. Among the cases of FGC, several situations can be identified according to the histopathologic type of GC and the number of affected relatives, which encompasses specific syndromes/diseases as follows: hereditary diffuse GC, familial diffuse GC, and familial intestinal GC.

Peer review

Zhou *et al* designed a proband-based study to provide further data on factors of familial predisposition to GC. This paper is interesting and written well.

Abstract

AIM: To investigate the major complications after radiofrequency ablation (RFA) for the treatment of liver tumors and analyze possible risk factors that precipitate these complications.

METHODS: From March 2001 to April 2008, 255 patients with liver tumors (205 male, 50 female; age range, 18-89 years; mean age, 56.0 years) who received RFA were enrolled in this study. Of these patients, 212 had hepatocellular carcinoma, 39 had metastatic liver tumors and four had cholangiocellular carcinoma. One hundred and forty eight patients had a single tumor, and 107 had multiple tumors. Maximum diameter of the tumors ranged 1.3-20 cm (mean, 5.1 cm). All patients were treated with a cooled-tip perfusion electrode attached to a radiofrequency generator (Radionics, Burlington, MA, USA). RFA was performed *via* the percutaneous approach (n = 257), laparoscopy (n = 7), or open surgical treatment (n = 86). The major complications related to RFA were recorded. The resultant data were analyzed to determine risk factors associated these complications.

RESULTS: Among the 255 patients, 425 liver tumors were treated and 350 RFA sessions were performed. Thirty-seven (10%) major complications were observed which included 13 cases of liver failure, 10 cases of hydrothorax requiring drainage, three cases of tumor seeding, one case of upper gastrointestinal bleeding, one case of intrahepatic abscess, one case of bile duct injury, one case of cardiac arrest, and five cases of hyperglycemia. Seven patients had more than two complications. Liver failure was the most severe complication and was associated with the highest mortality. Eleven patients died due to worsening liver decompensation. Child-Pugh classification (P = 0.001) and choice of approach (P = 0.045) were related to post-treatment liver failure, whereas patient age, tumor size and number were not significant factors precipitating this complication.

CONCLUSION: RFA can be accepted as a relatively safe procedure for the treatment of liver tumors. However, attention should be paid to possible complications even though the incidences of these complications are rare. Careful patient selection and the best approach choice (percutaneous, laparoscopy, or laparotomy) will help to minimize the incidence and morbidity rate of complications which occur after RFA.

Key words: Complication; Hepatocellular carcinoma; Metastatic liver tumor; Radiofrequency ablation; Liver failure

Major complications after radiofrequency ablation for liver tumors: Analysis of 255 patients. *World J Gastroenterol* 2009; 15(21): 2651-2656 Available from: URL: http://www.wjgnet.com/1007-9327/15/2651.asp DOI: http://dx.doi.org/10.3748/wjg.15.2651

INTRODUCTION

Hepatocellular carcinoma (HCC) and metastatic liver tumors are the two most common malignant tumors of liver. In most cases hepatectomy is the best curative treatment option[1,2]. However, there are some factors that limit the use of surgical resection. Therefore, alternative techniques such as percutaneous ethanol injection (PEI), microwave therapy, radiofrequency

ablation (RFA), laser therapy, and transarterial chemoembolization (TACE) have been used for the treatment of hepatic malignant tumors[3-5]. Among these techniques, RFA is performed more widely than the others because it results in large coagulated necrosis of the tumor, requires fewer treatment sessions, and achieves higher survival rates[6-8]. Thus RFA would be more beneficial to patients than other non-resectional techniques.

Although RFA is considered a relatively safe and minimally invasive technique, it may induce severe complications. The trade-off between the risks and benefits must be considered. Some major post-RFA complications, such as hepatic failure, intraperitoneal bleeding, hepatic abscess, bile duct injury, tumor seeding, and gastrointestinal perforation have been reported[9-11]. The estimated range of mortality rate is 0.1%-0.5%, while the major complication rate is 2.2%-3.1%[12]. A better understanding of the pertinent complications which may occur post-treatment is the key to successful RFA treatment.

Since 2001, we have used RFA to treat patients with HCC or liver metastases. Despite its promising therapeutic effects, RFA has resulted in a number of major complications. In the present study, major complications resulted from RFA procedures during a 7-year-study in a single center have been retrospectively analyzed, and the possible risk factors precipitating these complications were determined.

MATERIALS AND METHODS

Patients

From March 2001 to April 2008, 255 patients with liver tumors (205 male, 50 female; age range, 18-89 years; mean age, 56.0 years) who received RFA were enrolled in this study. Patient characteristics are described in Table 1. Of these patients, 212 had HCC (including 48 cases of recurrent nodules after hepatectomy and five cases of HCC rupture hemorrhage), 39 had liver metastases and four had cholangiocellular carcinoma. One hundred and seventy five patients had chronic liver diseases, of which 168 patients were hepatitis B virus carriers, five patients were hepatitis C virus carriers, and two patients had schistosomiasis liver cirrhosis. Based on Child-Pugh classification, 231 patients (90.6%) were considered as class A, 22 patients (8.6%) as class B, and two patients (0.8%) as class C. Alpha fetoprotein (AFP) serum assays were performed in all patients: 88 patients had normal AFP levels; 92 patients had levels between 5 and 400 ng/mL; and another 75 patients displayed AFP levels of more than 400 ng/mL.

Before treatment, all patients were examined by abdominal ultrasonography, computed tomography (CT) or magnetic resonance imaging (MRI). The location of tumors was defined according to Couinaud's nomenclature. There were 148 uninodular cases and 107 multinodular cases. In 192 patients, we performed RFA only once. In the remaining patients, RFA was performed twice or more due to hepatic recurrence. There were 425 treated tumor nodules in total. The median diameter of the nodules was 5.1 cm (range, 1.3-20 cm), with 174 three centimeters or smaller, 142 between 3.1 and 5 cm, and 109 larger than 5 cm.

Table 1 Characteristics of patients, tumors and treatment approach (mean ± SD)

Patients and tumor characteristics	Value
No. of patients	255
Median age (yr)	56.0 ± 13.2 (range, 18-89)
Gender (male/female)	205/50
Disease (HCC/MHC/CCC)	212/39/4
Background liver disease (HBV/HCV/ no infection)	168/5/82
Patients with liver cirrhosis *n* (%)	172 (67.5)
Portal vein invasion (no/yes)	25/230
Alphafetoprotein (0-5/5-400/> 400 ng/mL)	88/92/75
Child-Pugh classification (A/B/C)	231/22/2
ALT (U/L)	47.6 ± 2.5
AST (U/L)	54.7 ± 3.0
Total bilirubin (μmol/L)	27.4 ± 7.1
Serum albumin (g/L)	38.9 ± 0.3
Tumor stage	425
Number of tumors (uninodular/multinodular)	148/107
Size of tumor (cm)	5.1 ± 3.4 (range, 1.3- 20)
Diagnosis (histopathologic/clinical)	215/210
Treatment	350
Choice of approach (percutaneous/ laparoscopy/laparotomy)	257/7/86
Combination with TACE or PEI (+/-)	61/194

The diagnosis of liver tumors was based on histopathological findings of specimens (129 patients, 50.6%). The remaining tumors (126 patients, 49.4%) were diagnosed based on typical CT or MRI findings and tumor markers.

All the patients had contraindications to hepatectomy due to advanced age, associated diseases, severe liver dysfunction, inappropriate location of the tumor, or refusal to undergo the surgical procedure. Before performing RFA, all patients were informed and signed the consent forms.

Technique

A cool-tip needle radiofrequency system (Radionics, Burlington, MA, USA) was used in all patients. The system consists of a perfusion pump, electrode pads placed on the patient's skin, and a radiofrequency generator that monitors tissue impedance, electric current, power and temperature. The shaft of the needle has internal channels which allow the needle to be perfused with chilled water to maintain the temperature of the tip below 20℃ to prevent charring around the needle tip. The current is automatically adjusted according to the impedance at the needle tip. Each ablation cycle lasts 12 min. Following ablation, the probe tract is cauterized as the RFA needle is withdrawn. Successful ablation usually increases the temperature of the ablated tissue to 60-80℃. RFA was performed depending on the size and localization of the tumor. A single electrode needle was used for patients with liver tumors smaller than 2 cm.

For patients with large tumors (> 2 cm), we performed overlapping ablations to thoroughly eliminate the tumor. The purpose of the treatment was to achieve destruction of the tumor tissue and the 1 cm margin of parenchyma around the lesion. However, for some patients with large HCCs or portal vein tumor thrombosis, RFA was regarded as a palliative treatment.

RFA was performed *via* the percutaneous approach (n = 257), laparoscopy (n = 7), or by open surgical treatment (n = 86). All the procedures were performed by a surgeon and a radiologist with more than 3 years experience in RFA. Whenever possible, RFA was performed percutaneously. A surgical or laparoscopic approach was adopted to treat patients with tumors located near visceral organs such as the stomach, colon, or gallbladder. When tumors were found near the hepatic hilum, cholecystectomy was performed before RFA. If tumors were located directly below the diaphragm, we used artificial pleural effusion to obtain an image of the whole tumor by percutaneous ultrasonography[13]. Sixty-one patients had undergone combined treatment for liver tumors (PEI or TACE).

The following serologic values including liver function tests and complete blood counts were measured 3 d and 1 wk after treatment. Treatment efficacy was evaluated by contrast-enhanced CT or ultrasonography 4 wk after treatment. Tumors were considered successfully ablated when no region of enhancement was found either in the entire tumor or in a 0.5 cm margin of normal hepatic tissue surrounding the tumor.

Complications

Majors complications were defined as those that delayed hospital discharge, threatened the patient's life, or led to substantial morbidity and disability[14]. These included liver failure, peritoneal hemorrhage, tumor seeding, and collateral thermal damage to adjacent organs. Differentiation among immediate complications (during the maneuver or ⩽ 24 h after the procedure), periprocedural complications (with 30 d), and delayed complications is advised[12]. Complications were identified on the basis of clinical findings, laboratory or imaging examinations during the RFA and post-treatment observation period.

Statistical analysis

Clinical data of all patients were entered prospectively into a computerized database. We analyzed complications individually instead of combining all the data together. The values of the baseline characteristics, which included patient age, disease, Child-Pugh classification (A *vs* B or C), tumor size and number, treatment approach (percutaneous, laparoscopy or laparotomy), mode of RFA (single or overlapping ablation) were assessed by using Logistic regression analysis. $P < 0.05$ in a two-tailed test was considered statistically significant. All data processing and statistical analysis were performed using commercially available software (SPSS for Windows, Version 11.5).

Table 2 Major complications after radiofrequency ablation

Complication	No. of complications	Disease
Hepatic failure	13	HCCs
Thoracic complications	10	8 HCCs, 1 CCC, 1 MHC
Tumor seeding	3	HCCs
Upper gastrointestinal bleeding	1	HCC
Intrahepatic abscess	1	HCC
Bile duct injury	1	HCC
Cardiac complication	1	HCC
Hyperglycemia	5	HCCs

RESULTS

In the 255 patients, 425 liver tumors were treated and 350 RFA sessions were performed (63 patients had more than one session). The mean follow-up period for the entire group was 32.1 mo (range, 2-84 mo). The median overall survival rate was 21.0 mo. Overall cumulative survival rate at 1-, 2-, and 3-year was 63.1%, 43.3%, and 35.7%, respectively. Thirty five (35/350, 10% per session) major complications were found after RFA treatment (Table 2). Seven patients had more than two types of complications and 28 patients (28/225, 12.4% per patient) suffered from major complications which included 13 (3.7%) cases of liver failure, 10 (2.9%) cases of hydrothorax requiring drainage, 3 (0.9%) cases of tumor seeding, 1 (0.3%) case of upper gastrointestinal bleeding, 1 (0.3%) case of intrahepatic abscess, 1 (0.3%) case of bile duct injury, 1 (0.3%) case of cardiac arrest, and 5 (1.4%) cases of hyperglycemia. The complication rate was 4.0%, 0.3% and 5.7% after percutaneous, laparoscopic and intraoperative RFA, respectively. The immediate complications, periprocedural complications and delayed complications were 2.0%, 29.0% and 4.0% among 350 sessions, respectively.

Liver failure was the most severe complication and was associated with the highest mortality. Eleven patients (11/255, 4.3% per patient) died of worsening liver decompensation. The potential risk factors that might contribute to liver failure were analyzed. We found that Child-Pugh classification (P = 0.001) and choice of approach (P = 0.045) were related to post-treatment liver failure, whereas patient age, tumor size and number did not correlate with this complication. This finding suggested that Child-Pugh classification and choice of approach were independent risk factors for liver function impairment after RFA.

We adopted intraoperative RFA to treat a patient with an HCC located in the right posterior segment close to the right portal vein (8 cm in diameter). We performed overlapping RFA to achieve a complete ablation area, and the ablated frequency was 12 times. A bile leakage occurred 1 wk after the procedure and subsequently resulted in liver abscess. The patient presented with local pain and high fever. Sustained antibiotic therapy and percutaneous ultrasound guided drainage were carried out. The patient also had diabetes mellitus which

made his basic condition fairly poor. Despite aggressive supportive care, the patient succumbed to progressive liver failure and died 5.5 mo after RFA.

Tumor seeding was identified in three patients (0.86%) at 2, 4 and 5 mo after RFA. These seeding foci were located in the subcutaneous tissue of the abdominal wall (two patients) and omentum (one patient). They were treated by surgical resection, High Intensity Focused Ultrasound and RFA, respectively. Of these three patients, two had undergone previous biopsy, two had an AFP level higher than 400 ng/mL, and all had a single tumor that was not near the capsular fibrosa ranging 2-5 cm in diameter. None of these factors were found to be significantly associated with tumor seeding ($P = 0.085$, $P = 0.840$, $P = 0.088$, respectively).

Hydrothorax was found in ten patients. In five of these cases, tumors were located at the dome of the liver. In one patient with a single 2.5 cm diameter subcapsular HCC in segment Ⅵ, cardiac arrest occurred during treatment. She was successfully rescued. Other major complications included one case of upper gastrointestinal bleeding and five cases of hyperglycemia. However, these complications did not result in fatal consequences.

DISCUSSION

RFA has gained wide acceptance as a safe alterative to surgery in the management of early HCC and metastatic liver tumors[15,16]. It produces complete necrosis of the tumor and achieves a satisfactory survival rate with low recurrence rate on long-term follow-up. Despite the benefits, RFA entails some risks as revealed by post-RFA complications. Complications such as liver failure, intraperitoneal bleeding, abscess, bile duct injury, tumor seeding are very serious, and can be life threatening[10,17,18]. Being well aware of the complications and the choice of treatment method will lead to a more practical application and enable this procedure to be safer and more effective.

There have been some analyses of post-RFA complications which have involved a large series of investigations[17]. However, the incidence and mortality of post-RFA complications reported in this study were different from previous reports by other groups. This discrepancy may be attributed to the choice of indications and the skills of the operators. In most of these reports, RFA was performed only when the tumor was no greater than 3 cm in diameter and the patient had no portal vein tumor thrombus. However, in our study, patients with advanced HCC also received RFA treatment, which may have resulted in the relatively high incidence of major complications.

RFA is considered an invasive therapy, especially for those patients with insufficient hepatic reserve to tolerate resection. Therefore, the preoperative evaluation of liver parenchymal function after treatment is of great importance. Decompensated baseline function reserve might precipitate transient liver function impairment after RFA and should be closely followed up. Sepsis and liver failure have been reported as the most common causes of death in a multicenter survey[19]. Koda *et al*[20] analyzed the liver laboratory tests and complications after RFA treatment and found that patients with a high pre-treatment Child-Pugh score suffered from long-term deterioration of liver parenchymal function and subsequent serious complications. The conclusion from that study was that patients with a Pugh score ⩾ eight points would not be good candidates for RFA or TAE-RFA. In our study, the most severe complication was liver failure, which resulted in mortality in 11 patients after treatment. Our findings demonstrated that Child-Pugh classification was related to post-treatment liver failure. This result was consistent with the finding that Child B or C was a risk factor for post-treatment liver failure[21]. Therefore these patients may not be appropriate candidates for RFA. The choice of approach was another independent risk factor associated with liver failure. Among the 13 patients who experienced rapid hepatic decompensation, 10 were treated with overlapping ablation *via* an open surgical technique. Recently, intraoperative RFA has been performed as an approach to treat liver tumors, particularly for difficult lesions adjacent to the diaphragm, bowel, or gallbladder. Tepel *et al*[22] pointed out that although intraoperative RFA was a valuable tool in liver surgery, it added invasiveness and technical difficulties to the procedure and might cause severe post-treatment complications[23]. When these findings are combined with the results from our study, it becomes more obvious that patient selection and choice of approach are the two major factors to consider in order to achieve desirable outcomes similar to those *via* percutaneous RFA.

Bile duct injury is an uncommon severe complication with an incidence of 0.1%-1.0%[19,24]. Kim *et al*[25] demonstrated that although bile duct changes were frequent after the RFA of HCC, it was of no clinical significance in most cases. In addition, major complications requiring additional treatment were rare. Cooling of the biliary tract with chilled saline has been used to prevent biliary injury by RFA[26]. Ohnishi *et al*[27] reported that the incidence of biliary injury was significantly reduced in the intraductal chilled saline perfusion (ICSP) group compared to that in the control group. Moreover, liver function in the treated patients was also better preserved in the ICSP group 6 mo after RFA.

We performed overlapping RFA *via* an open surgical approach to treat a patient with a tumor located in the right posterior segment near right portal vein. The patient suffered from bile duct injury combined with other complications including liver failure, hepatic abscess and hyperglycemia. This result was consistent with a previous report[12] where the possibility of bile duct injury was increased if the mass was located in the central portion of the liver and abutted the portal hepatis. Moreover, excessive heating to overcome the "heat sink effect" of hilar large vessels could cause significant damage to the major ducts.

The incidence of needle-track tumor seeding was reported to range from 0%-12.5%[28,29]. Llovet *et al*[28] reported that neoplastic seeding was related to subcapsular location, poor differentiation state of the tumor cells and high AFP levels (more than 100 ng/mL). Livraghi

et al[30] pointed out that RFA with a cooled-tip needle was associated with a low risk of neoplastic seeding, and only previous biopsy was significantly associated with tumor seeding. In our study, we found no risk factors precipitating this complication, even though superficial tumor location, tumor biopsy procedure and AFP level were taken into account. It should be acknowledged that the inability to identify independent predictors of tumor seeding was most likely related to the low number of patients who had this complication. It is thought that intraperitoneal bleeding may drive tumor cells outside the hepatic capsule[28]. In our study, no bleeding occurred after RFA, which might also contribute to the low incidence of tumor seeding, particularly for subcapsular tumors.

Complications arising from RFA can be divided into two general categories: those related to imaging-guided electrode placement and those related to thermal transmission[12]. Most of the complications such as bleeding, abscess, and gastrointestinal perforation might arise due to improper RFA approach and puncture technique. According to our study, several measures to avoid major complications and to achieve satisfactory therapeutic effect should be taken. Firstly, the most effective strategy to minimize complications is careful patient selection. Preoperative evaluation is of great importance. Patients with Child-Pugh classification B or C and tumors close to vital structures require careful consideration. Secondly, the appropriate approach must be chosen according to the patient's condition. RFA may be performed either percutaneously, *via* laparoscopy or laparotomy, by ultrasound guidance. The trade-off between the risks and benefits must be acceptable. Thirdly, because of the potential incidence of post-treatment complications, a physician should know these pertinent complications, detect the complications as early as possible and provide appropriate management.

In conclusion, RFA is effective for patients with liver tumors. However, liver decompensation may rapidly worsen and lead to life-threatening liver failure, especially in patients with Child-Pugh classification B or C. As the procedure can be associated with major complications, a more accurate selection of candidates and approach to RFA treatment is advisable.

COMMENTS

Background

Although surgical therapy for hepatocellular carcinoma is regarded as standard, most patients are not surgical candidates because of poor liver function or other factors. Many methods of local ablation have been developed to control the disease. Among them, radiofrequency ablation (RFA) is one of the most effective. However, some studies have reported severe complications after RFA, such as hepatic failure, tumor seeding and peritoneal hemorrhage.

Innovations and breakthroughs

This study showed that liver failure was the most severe complication after RFA especially in patients with Child-Pugh classification B or C. The authors also suggested that careful patient selection and the best approach choice might help to minimize the incidence and morbidity rate of complications after RFA.

Peer review

The authors showed the major complications after RFA for the treatment of liver tumors and analyzed the possible risk factors. The results of this research might be important for the clinical application of this therapy.

Abstract

AIM: To evaluate the number of bone marrow mononuclear cells (BMMC) that are migrated to the liver following transplantation of murine BMMC into mice with acute liver injury.

METHODS: BMMC were isolated from the bone marrow of mice in a lymphocyte separation medium and then labeled with PKH26. The labeled cells were subsequently infused into the caudal veins of BALB/c mice with hepatic injury induced by carbon tetrachloride and 2-acetylaminofluorene. Mice in experimental group were treated with stromal cell-derived factor-1 (SDF-1) which was injected intraperitoneally after transplantation of BMMC. Mice in control group were injected intraperitoneally with 0.1 mL of saline (0.9% NaCl) after transplantation of BMMC. After 2 wk, migration of the cells in experimental group was studied by fluorescence microscopy. The expression of proliferating cell nuclear antigen and albumin was quantified with manual methods in both groups. The serum transaminase levels at different time points were compared between the two groups.

RESULTS: The labeled "cells" were found in the portal region and central veins of hepatic lobules. The PKH26-labeled cells appeared at an average frequency of 108 ± 8/high power field in the experiment group and 65 ± 8/high power field in the control group ($P < 0.05$). The total number of positive cells was 29 ± 7/high power field in the experimental group and 13 ± 2/high power field in the control group. The albumin expression level was also higher in the experimental group than in the control group (29 ± 7 *vs* 13 ± 2, $P < 0.05$). The total number of crossing points was 156 ± 5/high power field in the experimental group and 53 ± 5/high power field in the control group ($P < 0.05$). The serum alanine aminotransferase levels in experimental and control groups were measured at different time points (120 ± 40 *vs* 118.50 ± 1.75, $P > 0.05$; 80.60 ± 6.50 *vs* 101.08 ± 5.67, $P < 0.05$; 50.74 ± 5.38 *vs* 80.47 ± 4.62, $P < 0.05$; 30.54 ± 2.70 *vs* 60.72 ± 4.37, $P < 0.05$; 30.77 ± 5.36 *vs* 40.47 ± 6.50, $P < 0.05$). At the same time, the serum aspartate aminotransferase levels were measured in experimental and control groups at different time points (122.55 ± 1.46 *vs* 120.70 ± 4.22, $P > 0.05$; 54.26 ± 6.50 *vs* 98.70 ± 8.20, $P < 0.05$; 39.47 ± 5.39 *vs* 78.34 ± 4.50, $P < 0.05$; 28.94 ± 2.70 *vs* 56.44 ± 4.28, $P < 0.05$; 30.77 ± 5.45 *vs* 42.50 ± 6.28, $P < 0.05$).

CONCLUSION: SDF-1 can promote the migration of BMMC to the liver of mice with acute liver failure.

Key words: Stromal cell derived factor-1; Bone marrow mononuclear cell; Acute liver failure; Transplantation; Mobilization

Stromal cell derived factor-1 enhances bone marrow mononuclear cell migration in mice with acute liver failure. *World J Gastroenterol* 2009; 15(21): 2657-2664 Available from: URL: http://www.wjgnet.com/1007-9327/15/2657.asp DOI: http://dx.doi.org/10.3748/wjg.15.2657

INTRODUCTION

Stem cells have the potential ability of multi-directional

differentiation and self-renewal. Under proper induction circumstances, they can differentiate into different functioning cells. Differentiation between groups is ongoing. Recent studies using experimental animal models and samples from clinical mobilization protocols demonstrated that chemokines such as stromal derived factor-1 (SDF-1) and IL-8 are involved in the mobilization process[1,2]. The central role of SDF-1 in induction of mobilization has been reviewed[3]. SDF-1, a kind of micro-molecular proteins, possesses a variety of biologic activities. It has been identified that SDF-1 can promote bone marrow stem cell directional differentiation both in heart tissue[4] and in nerve tissue[5]. Since mesenchymal stem cells in human second-trimester bone marrow, liver, lung, and spleen exhibit a similar immunophenotype but a heterogeneous multilineage differentiation potential l[6], we hypothesize that SDF-1 can also mobilize migration of bone marrow mononuclear cells (BMMC) in mice with acute liver failure.

The aim of this study was to determine whether autologous BMMC can be mobilized by SDF-1 in BALB/c mice with experimental acute liver failure. To test this, BMMC were isolated from the bone marrow of mice in a lymphocyte separation medium and then labeled with the fluorochrome dye PKH26.The labeled cells were subsequently infused into the caudal veins of mice with hepatic injury induced by carbon tetrachloride and 2-acetylaminofluorene. Mice in experimental group were injected intraperitoneally with SDF-1 (5 μg/kg) and mice in control group were injected intraperitoneally with 0.1 mL of saline (0.9% NaCl) after transplantation of BMMC. After 2 wk, the migration of BMMC was studied by fluorescence microscopy. The number of migrated BMMC was calculated, and the expression of proliferating cell nuclear antigen (PCNA) and albumin in both groups was quantified with manual methods. In the following 4 wk, serum aminotransferase activity was detected to monitor the changes in liver function at different time points.

MATERIALS AND METHODS

Experimental animals

Male BALB/c mice, weighing 20-22 g, at the age 8-10 wk, were purchased from the Animal Center of Jilin University. All mice were housed in rooms at a constant temperature and humidity in a 12 h light/dark cycle with free access to normal rodent chow and water. Experiments were conducted according to the guidelines established by Jilin University. The procedures were approved by the Supervisor Committee of Jilin University Animal Council.

Principal reagents

Recombinant murine SDF-1 α (CXCL12, Catalog #: 250-20A) was obtained from PeproTech EC Company (USA). Proliferating cell nuclear antigen, lymphocyte isolation medium (1.077 g/cm^3) and red fluorochrome PKH26GL were purchased from Simga Company (Saint louis, Missouri USA). 2-acetylaminofluorene was purchased from Invitrogen Company (California, USA).

Experimental groups

The animals were divided into donor and recipient groups. The recipient group was further divided into an experiment group and a control group (n = 30).

Methods

Femoral bones were aseptically removed from male BALB/c mice under anesthesia and bone marrow in the medullary cavity was bathed by heparin (50 U/mL) dissolved in normal saline. Bone marrow cells were suspended in a sterilized lymphocyte isolation medium. After dilution with 2 mL phosphate-buffered saline (PBS, 0.01 mol/L, pH = 7.4) at 1:1, the cells were slowly added at a relative matching density of 1.077 g/cm^3 lymphocytes followed by centrifugation at 2000 r/min for 20 min. Cell groups were identified, washed with PBS, and centrifuged at 1200 r/min for 10 min. The top of centrifuge tube was shaken lightly to detach the cell groups. A DMEM/F12 medium was added (15% FBS, 100 000 U/L penicillin, pH = 7.4) to prepare cell suspension at a density of over 5 × 10^8 cells/L. Finally, BMMC were labeled with PKH26 according to its manufacture's instructions. The density of labeled cell suspension was adjusted to 3 × 10^7 cells/mL. BMMC with a viability over 95%, measured by trypan blue exclusion, were used. One million of BMMC were isolated from the donor group, labeled with PKH26 and injected into mice of the experimental group *via* the tail vein. One hour later, mice in the experimental group were injected intraperitoneally with SDF-1 (5 μg/kg). Mice in the control group were injected intraperitoneally with 0.1 mL of saline (0.9% NaCl). The injection of SDF-1 or saline was repeated once a day in the following weeks. Two weeks later, the mice were euthanized by cervical spine dislocation with their livers removed immediately and frozen in liquid nitrogen. The number of migrated BMMC in hepatic tissue stained with hematoxylin-eosin and immunohistochemistry was calculated under a fluorescence microscope. The density of serum aminotransferase activity was detected with an automatic biochemistry analyzer.

Establishment of animal acute liver failure model

Carbon tetrachloride (CCl_4) is widely used to generate an experimental model mimicking acute liver injury caused by toxic substances. Mice in the recipient group were treated with 2-acetaminofluorene dissolved in liquid macrogol (20 mg/kg) by lavage, once a day for 7 d. On day 8, the animals were injected intraperitoneally with 20% CCl_4 (0.5 mL/kg, dissolved in vegetable oil). On day 9, one million of BMMC were transplanted into mice *via* the tail vein. From day 10, mice in the recipient group were given 2-acetaminofluorene dissolved in liquid macrogol (20 mg/kg), once a day for 7 d. On day 21, mice in the experimental group were euthanized by cervical spine dislocation. Liver tissue was resected immediately and frozen in liquid nitro-

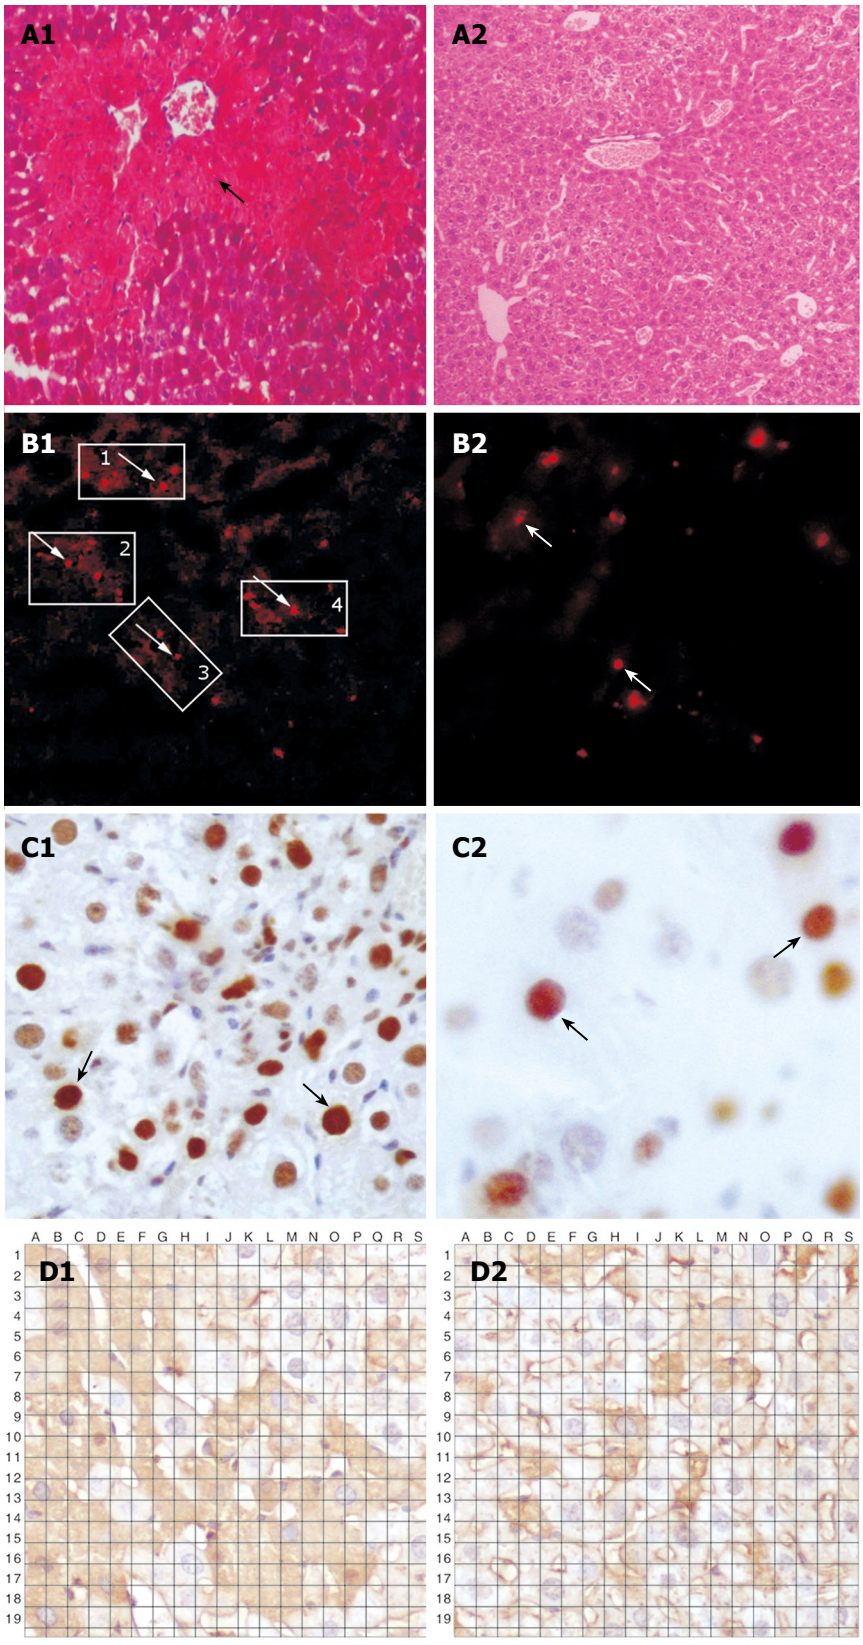

Figure 1 Histopathology of hepatic tissue from the two groups. A: PKH26-labeled cells detected after establishment of acute liver failure animal model with extensive vacuolar degeneration and edema of hepatocytes in acute liver failure (A1) and normal liver tissue (A2); B: Sporadic PKH26-labeled bone marrow stem cells in experimental group (B1) and control group (B2); C: Expression of PCNA in sporadic PKH26-labeled bone marrow stem cells in experimental group (C1) and control group (C2); D: Expression of albumin and sporadic PKH26-labeled bone marrow stem cells in experimental group (D1) and control group (D2) (× 200).

gen. Liver injury was confirmed by fluorescence microscopy and hematoxylin-eosin staining. Extensive vacuolar degeneration and edema of hepatocytes were found in liver tissue (Figure 1A).

Detection index

The number of fluorescence PKH26-labeled cells in liver sections stained with immunohostochemistry (FITC) was counted. Albumin and PCNA in liver tissue sections stained with FITC were also calculated. The density of serum aminotransferase activity was detected with an automatic biochemistry analyzer which can test the liver function at different time points following the transplantation of BMMC.

Tissue preparation

Livers were perfused with 4% paraformaldehyde in 0.01 mol/L phosphate-buffered saline (pH 7.4, PBS) following anesthesia with sodium pentobarbital 100 mg/kg (ip), fixed overnight and cryoprotected in 30% sucrose at 4℃. Liver tissue was cut into 6-μm thick sections.

Immunohistochemistry

Immunofluorescence was carried out by incubating the sections in PBS containing 5% donkey serum and primary antibody-rabbit anti-mouse serum albumin(1:1000, ab19196, abcam, MA, USA), followed by a 2-h reaction with Alexa Fluor® 488-conjugated donkey anti-rabbit antibody (1:200, A21206, Invitrogen, Carlsbad, CA). Liver tissue sections were then mounted in an anti-fading medium.

Detection of serum aminotransferase activity

Whole blood samples were collected after bulbus oculi in mice with acute hepatic failure were exposed to light ether anesthesia. Serum was separated by centrifugation and stored at -30℃. Alanine aminotransferase activity was detected with an automatic biochemistry analyzer (Sinnowa D336, SINNOWA Medical Science & Technology Co., Ltd, Nanjing, China). The density of serum alanine aminotransferase (ALT) activity in experimental and control groups was compared. Serum ALT levels in experimental and control groups were measured in the following weeks.

Statistical analysis

Liver tissue from each mouse was cut into five sections. Each frozen section was examined under a microscope at a magnification × 200 under 10 microscopic fields. The total number of fluorescence-labeled cells in each section was calculated. At the same time, the serum aminotransferase activity was determined with an automatic biochemistry analyzer. Results were expressed as mean ± SD. Statistically significant differences between groups were compared with the *t* test. Paired *t* test was used to compare the PKH26 fluorescence intensity values and albumin expression. $P < 0.05$ was considered statistically significant. All data were processed using statistical software SPSS 10.0.

RESULTS

Extensive vacuolar degeneration and edema of hepatocytes were observed in mice of the experimental group, implying that an animal acute liver failure model can be successfully established.

Detection of PKH26-labeled cells

PKH26-labeled cells were detected in liver tissue sections following injection of SDF-1 *via* the tail vein. The total number of positive PKH26-labeled cells was 108 ± 8/high power field in the experimental group and 65 ± 8/high power field in the control group, respectively ($P < 0.05$, Figure 1B and Figure 2).

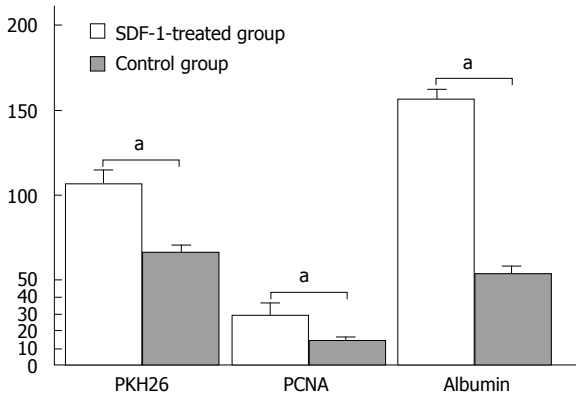

Figure 2 PKH26-labeled cells detected in experimental and control groups. Data are expressed as mean ± SD. $^aP < 0.05$ *vs* experimental group.

Detection of PCNA in the two groups

The expression level of PCNA was higher in the experimental group than in the control group. The total number of positive cells was 29 ± 7/high power field in the experimental group and 13 ± 2/high power field in the control group, respectively ($P < 0.05$, Figure 1C and Figure 2).

Detection of albumin in the two groups

The albumin expression level was also higher in the experimental group than in the control group. The percentage area of histologic field was calculated as previously described[7] and compared with albumin cells. The manual count set-up consisting of albumin image printouts and the transparent grid overlay used for point count are shown in Figure 1D. The total number of bone marrow stem cells at crossing points was 156 ± 5/high power field in the experimental group and 53 ± 5/high power field in the control group, respectively ($P < 0.05$, Figure 1D and Figure 2).

Green fluorescence was observed in FITC-labeled albumin antibodies at the 494 nm excitation light both in the experimental group and in the control group. Albumin in hepatocytes was detected with indirect labeling antibodies and expressed widely with green fluorescence. After the red and green fluorescence were focused, yellow fluorescence emerged at a suitable position, confirming that the yellow cells come from PKH26-labeled positive BMMC *in vitro* and show albumin (Figure 3).

It is well known that albumin is associated with the maturity of hepatocytes[8]. The obvious albumin expression in the experimental group implied that BMMC could differentiate into hepatocytes.

Detection of serum aminotransferase activity in the two groups

A significant difference in serum aminotransferase activity was observed between the two groups at different time points (120 ± 40 *vs* 118.50 ± 1.75, $P > 0.05$; 80.60 ± 6.50 *vs* 101.08 ± 5.67, $P < 0.05$; 50.74 ± 5.38 *vs* 80.47 ± 4.62, $P < 0.05$; 30.54 ± 2.70 *vs* 60.72 ± 4.37, $P < 0.05$; 30.77 ± 5.36 *vs* 40.47 ± 6.50, $P < 0.05$). At the same time, the serum AST levels in the experimental and

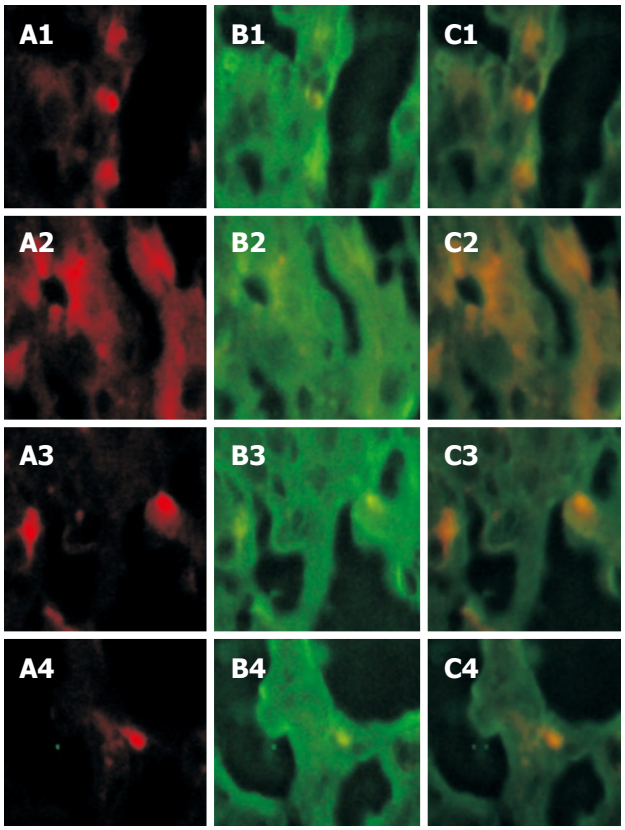

Figure 3 Confocal microscopy shows red fluorescence of cell location and green fluorescence of albumin. The red fluorescence cells could be found in liver tissue of recipient mice, suggesting that PHK-26 positive cells can emerge out of the red fluorescence (A1-A4). The albumin expressed in hepatocytes showed green fluorescence (B1-B4). After the red and green fluorescence cells were located, yellow cells were found in a suitable location (C1-C4).

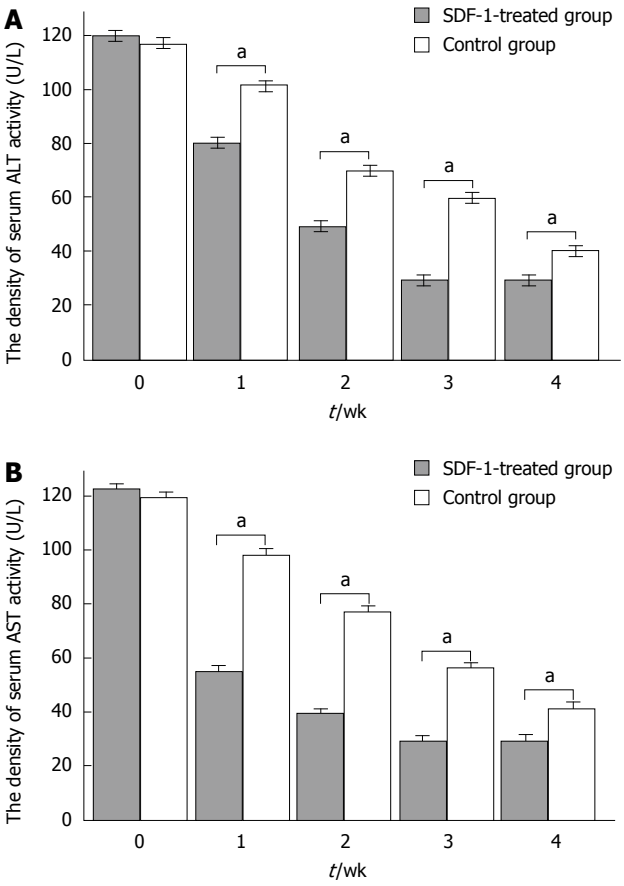

Figure 4 Detection of serum ALT (A) and AST (B) activity in the two groups. The serum ALT and AST levels were measured with an automatic biochemistry analyzer in experimental and control groups. There was a significant difference between the two groups. At the same time, the serum AST level was measured. $^{a}P < 0.05$ *vs* experimental group.

control groups were measured at different time points (122.55 ± 1.46 *vs* 120.70 ± 4.22, $P > 0.05$; 54.26 ± 6.50 *vs* 98.70 ± 8.20, $P < 0.05$; 39.47 ± 5.39 *vs* 78.34 ± 4.50, $P < 0.05$; 28.94 ± 2.70 *vs* 56.44 ± 4.28, $P < 0.05$; 30.77 ± 5.45 *vs* 42.50 ± 6.28, $P < 0.05$) (Figure 4A and B).

DISCUSSION

In regards to the genetic identity of inbred animals, use of BALB/c mice in the study allowed us to avoid immunologic rejection, thus the transplantation procedure represents an auto graft. Use of PKH26 fluorescent labeling permitted us to observe the homing of BMMC in the recipient group and to quantify the phenomenon by counting the fluorescencence-labeled cells as previously described[9]. By expressing albumin, the experimental data suggest that these cells can differentiate into hepatic cells. The expression of proliferating cell nuclear antigen suggested that the cells subsequently underwent cell division. PCNA is a nuclear antigen related with the cell life cycle, and is synthesized in cell nuclei. The PCNA is expressed in the G1 and S phases, and functions essentially as replicative DNA polymerases in eukaryotic cells[10]. The quantity of PCNA is low in resting cells but is substantially increased in multiplying and transformed cells. In this study, the expression levels of albumin and proliferating cell nuclear antigen were higher in the experimental than in the control group. Albumin was widely expressed in liver tissue. After red fluorescence was cofocused with green fluorescence, yellow fluorescence emerged at a suitable position, confirming that the yellow cells coming from PKH26-labeled positive BMMC *in vitro* can show albumin. Serum aminotransferase activity was detected. The density of serum ALT and AST was changed obviously after transplantation of BMMC, confirming that the liver function can be ameliorated by transplanted BMMC and the effect is more significant in the experimental group than in the control group, indicating that SDF-1 can promote BMMC homing to injured livers of mice.

BMMC mainly consist of HSC, BMSC and endodermis progenitor cells. Density gradient centrifugation was performed to remove adipocytes, erythrocytes and apocyte. BMMC were collected to enrich rudimentary bone marrow stem cells. SDF gene can code two proteins, namely SDF-1α and SDF-1β. The SDF-1α gene is expressed in bone marrow stromal cells. The homology of human SDF-1 and mouse SDF-1 can reach 99%[11]. In the study, the SDF-1 receptor gene (LESTER, CXCR4) carrying 7 membrane spanning domains, was

successfully cloned when the SDF gene, a kind of G protein linkage receptors, was cloned. CXCR4 is widely expressed in leucocytes, CD34+ HSC and CD34+ progenitor cells[12]. Initially, CXCR4 is regarded as a unique SDF-1 receptor[13] and the specific combination of SDF-1 and CXCR4, is named as SDF-1/CXCR4 biology axis. Another kind of SDF-1 receptors (CXCR7), known as an orphan receptor (RDC), has been recently found and is[14], mainly expressed in tumor cell line, activated endotheliocytes and fetal liver cells. CXCR7 is detected but not expressed in normal cells[15].

Aiuti *et al*[16] showed that SDF-1 is a chemotactic factor of CD34+ HSC, and CD34+ cells including endothelium progenitor cells, which can migrate and home along the concentration gradient of SDF-1. It has been shown that SDF-1 can play an important role in promoting migration of cells including endothelium progenitor cells from bone marrow to target tissue[17]. Bhakta *et al*[18] reported that marrow stromal cells can also express CXCR4 and SDF-1 is a chemotactic factor for the homing of marrow stromal cells *in vivo* and *in vitro*, suggesting that stem cells expressing CXCR4 can migrate and home along the concentration gradient. Moreover, the concentration gradient between inner and outer bone marrow can decrease the inner concentration gradient[19,20] or increase the outer concentration gradient[21] of bone marrow, thus promoting mobilization of bone marrow stem cells.

In the present study, the number of PKH26-labeled cells was obviously higher in the experimental group than in the control group and the expression level of albumin and PCNA was markedly higher in the experimental group than in the control group, demonstrating that SDF-1 can promote bone marrow stem cell migration into the liver and SDF-1 mobilized BMMC can be used to promote liver regeneration after liver injury. Moreover, use of SDF-1 can avoid immune suppression so that liver injury can be repaired. BMMC can be easily harvested and applied in clinical practice.

Unfortunately, the mechanism by which SDF-1 becomes chemotactic to bone marrow stem cells is unclear. It has been shown that SDF-1 can ignite multiple signal pathways in cells and is regulated by different regulatory factors[22-24]. When SDF-1 binds to CXCR4, certain second messengers, such as NO and IP_3, lead to a series of related kinase phosphorylation[23] and the production of actin, and rapid or transient polymerization of biological effects by changing the hereditary information of stem cells[22], all of which may be due to the stem cell migration induced by SDF-1.Protein kinase B, ecto-signal regulatory protein-2 and JAK2 also participate in the signal conduction pathways[24].

In addition, SDF-1 can act as a chemoattractant to promote migration of stem cells[25,26] and strengthen their locomotory capacity[27]. When stem cells are migrated to the target tissue, SDF-1 facilitates their adhesion to fibrinogen, fibronectin, interstitium and endotheliocytes[28]. Then the cells, adhered to blood vessel endothelium, permeate vessel walls to ingress target tissue. With the help of SDF-1, more secreted MMP-9, NO and VEGF promote the mobilization of stem cells[23,29,30]. It has been reported that SDF-1 may participate in tumor development[31,32].

In conclusion, with the rapid progress in the field of stem cells, various kinds of stem cells are widely used to treat different organ diseases. SDF-1 can play an important role in bone marrow stem cells expressing CXCR4, thus promoting migration of BMMC into liver tissue. However, the precise mechanism by which SDF-1 mobilizes stem cells is unclear. Further study is needed to determine the dose, administration route and safety of SDF-1.

COMMENTS

Background

Stem cells have the potential ability of multi-directional differentiation and self-renewal. Under proper induction circumstances, stem cells can differentiate into different functioning cells. Differentiation between the groups is ongoing. The new treatment strategy for acute and chronic hepatitis is of potential importance.

Research frontiers

Stromal cell derived factor-1 (SDF-1), a kind of micro-molecular proteins, possesses a variety of biologic activities. It has been shown that SDF-1 can promote bone marrow stem cell directional differentiation into heart and nerve tissues. The results of this study demonstrated that SDF-1 could promote the homing of bone marrow mononuclear cells (BMMC) to the liver of mice with acute liver failure.

Innovations and breakthroughs

Recent reports have highlighted that the mesenchymal stem cells in human second-trimester bone marrow, liver, lung, and spleen exhibit a similar immunophenotype, but a heterogeneous multilineage differentiation potential. We hypothesize that SDF-1 can also mobilize the homing of bone marrow mononuclear cells in mice with acute liver failure. This is the first study to report that SDF-1 can promote the homing of BMMC to the liver in mice with acute liver failure.

Applications

This study showed how SDF-1 promotes the homing of BMMC to the liver, thus providing a future strategy for therapeutic intervention in the treatment of acute liver failure.

Terminology

CXCL12 is a recombinant murine SDF-1-α. SDF-1-α and β are small cytokines belonging to members of the intercrine family, can activate leukocytes, and are often induced by proinflammatory stimuli such as lipopolysaccharide, TNF, or IL-1.The intercrines are characterized by the presence of four conserved cysteines which form two disulfide bonds, and can be classified into two subfamilies. In the CXC subfamily including β and α chemokines, cysteine residues are adjacent to each other and separated by an intervening amino acid, respectively. SDF-1 proteins belong to the latter group.

Peer review

In this manuscript, SDF-1 was found to facilitate migration of infused bone marrow cells to liver. The total number of PKH26-labled bone marrow cells in the liver was higher in the experimental group than in the control group. Moreover, the number of albumin-producing cells and proliferating cells was higher in the experimental group than in the control group. Although the data are preliminary, they are important and encouraging.

Abstract

Ampullary carcinoma is the second most common cancer of the peri-ampullary area after pancreatic carcinoma and metastasizes mostly intra-abdominally and to the liver. Extra-abdominal metastases are less frequent. In this report we describe the case of a patient with resected adenocarcinoma of the ampulla of Vater who developed skeletal metastases in the lower extremity and brain metastases. We briefly discuss aspects of this comparatively rare gastrointestinal malignancy.

Key words: Adenocarcinoma; Ampulla of Vater; Peri-ampullary; Metastases; Prognosis

INTRODUCTION

The ampulla of Vater includes a common channel derived from the conjunction of the common bile duct and the pancreatic duct, the intra-duodenal parts of these two ducts and the duodenal mucosa surrounding the opening[1]. Peri-ampullary carcinomas arise from the ampulla of Vater, distal bile duct, pancreas or duodenal epithelium and are managed with surgical excision when resectable. Regional and other abdominal lymph nodes and the liver are the primary metastatic sites. Other sites of metastasis are less common but can be encountered especially in long term survivors.

We present the case of a patient with ampullary carcinoma and local recurrence developing both biopsy-proven bone metastases in unusual locations and brain metastases.

CASE REPORT

A 62-year-old woman presented to the orthopedic clinic complaining of painful localized edema involving the right ankle and shin. Two years earlier, she had undergone surgery for a stage ⅡA (pT3N0M0) low grade ampullary adenocarcinoma. She had developed mesenteric and retroperitoneal lymph node metastases 4 mo postoperatively. At that time the patient had refused chemotherapy since she was asymptomatic.

Diagnostic work-up of leg symptoms included an X-ray of the right foot and tibia, which revealed an ill-defined radio-opaque lesion of the right cuneiform bone and a radiolucent lesion of the tibia (Figure 1). An MRI scan of the right lower extremity disclosed multiple confluent bone erosions at the diaphysis of the tibia, with significant extention both proximally and distally. A technetium bone scan showed increased uptake in the right foot and tibia but no other skeletal lesions (Figure 2). In view of the unusual location of the metastasis, a bone biopsy was performed and revealed metastatic adenocarcinoma similar to the primary ampullary tumor. External beam irradiation was given locally (2000 cGy total in five fractions) for pain palliation.

A follow-up staging CT of the chest, abdomen and pelvis revealed two liver lesions, disseminated bilateral metastatic pulmonary nodules as well as borderline enlarged lymph nodes across the aortic arch and trachea bifurcation. At this time the patient consented to palliative chemotherapy and gemcitabine 1000 mg/m^2 iv weekly was administered.

Six months later the patient developed changes in mood, and behavior. A brain CT scan demonstrated

Figure 1 X-ray. A: The right foot showing the radio-opaque metastatic lesion in the cuneiform bone; B: The right tibia showing a radiolucent metastatic lesion.

Figure 2 A whole body bone scan showing increased uptake in the right foot and tibia.

ring enhancing lesions affecting the right frontal and left temporal lobes as well as the left cerebellar hemisphere. Palliative whole brain radiation followed by palliative targeted therapy with erlotinib 150 mg/d *po* was administered. The patient died with progressive disease 7 mo later and about 3 years after the diagnosis of her disease.

DISCUSSION

Carcinoma of the ampulla of Vater is a rare tumor accounting for approximately 0.2% of all gastrointestinal malignancies with an estimated incidence of less than 6 cases per million people per year. However, it is the second most common peri-ampullary neoplasm following pancreatic carcinoma in incidence. The peak incidence is in the 7th and 8th decades of life. There is a slight male to female preponderance[2].

The adenoma to adenocarcinoma carcinogenesis sequence model seems to be applicable to these tumors, given that the incidence of adenoma surrounding carcinoma of the papilla of Vater ranges from 82% to 91%[3]. Intestinal and pancreaticobiliary types represent the most common histological subtypes, indicating that peri-ampullary carcinomas emanate from the corresponding epithelia covering the distal parts of pancreatic and common bile duct and peri-ampullary duodenum, respectively[2]. A more favorable prognosis of the intestinal sub-type compared with the pancreatico-biliary type has been observed in some series[1,4,5]. Other histologic types less commonly seen in an ampullary location include mucinous, signet-ring cell, neuroendocrine and undifferentiated carcinomas[2,6-9].

Compared to other upper GI tract sites, as well as its periampullary counterparts, ampullary cancer has a favorable prognosis possibly due to the relatively early presentation with jaundice, rendering it resectable in 80%-90% of cases[10,11]. Moreover molecular lesions of ampullary carcinoma are different from other peri-ampullary cancers, a fact that may also contribute to the different prognosis[12]. For example k-ras, which is mutated in 90% of pancreatic cancers, is mutated in only half of the ampullary carcinomas. Overall the 5-year survival rate ranges from 33% to 67.7% in resected cases[10,12-14]. Tumor size and grade, lymph node status and number of positive nodes, perineural infiltration and surgical margins are the most crucial predictors of survival in localized disease[15-18]. Vascular invasion, ulcerative tumor, pancreatic invasion, age and peri-operative blood transfusions are additional prognostic factors seen in some series[18-21]. Nodal involvement is the most robust predictor of survival and forms the basis for recommending adjuvant radiotherapy and chemotherapy to decrease the incidence of locoregional recurrence and distal metastases respectively. Expression of specific proteins by immunohistochemistry has also been linked to prognosis. Expression of transcription factor CDX2 (Caudal-type homeodomain transcription factor), a regulator of normal intestinal and colonic epithelial differentiation, has been linked to improved prognosis compared with ampullary tumors that do not express the transcription factor[22]. In contrast high expression of the transporter protein hENT1 (human Equilibrative nucleoside transporter 1) has been shown to correlate with a shorter survival compared with ampullary carcinomas that displayed low expression of the transporter[23].

Ampullary cancer usually metastasizes to regional nodes, liver, adjacent organs and lungs. In contrast skeletal and brain metastases are common with other primary tumor locations such as lung and breast. We present a patient with an ampullary tumor that developed both bone metastases in unusual locations and brain metastases during the course of her disease. Bone and brain metastases from ampullary carcinoma are not very commonly seen in practice and are rarely reported in the literature. In a series of 135 patients with ampullary cancer who had previously undergone pancreaticoduodenectomy, bone metastases were seen in 5% and brain metastases in less than 4%[13]. In a smaller series of 14 cases of carcinomas of the ampulla of Vater, two had brain metastases but they concerned patients with carcinomas with neuroendocrine differentiation[8], while bone metastases were reported in three cases of another series of 24 patients (13%)[24].

Other isolated cases of bone metastases and unusual metastatic locations, such as the ureter, ovaries, testes, bronchus, umbilicus and distal lymph nodes have also been reported[25-30]. The specific location of bone metastases from ampullary carcinoma are not in general

reported and, thus, it is unknown if the common sites seen in several malignancies such as the spine, pelvis and proximal lower extremities are also the most frequent sites of bone metastases in this malignancy.

Although no randomized trials have been performed to support adjuvant treatment, local radiation therapy concomitant with 5-fluoropyrimidine-based chemotherapy has been advocated for resected ampullary carcinoma with adverse prognostic features such as size greater than 2 cm, positive lymph nodes, positive surgical margins, poor differentiation and neurovascular invasion[31,32]. In one of these series with 12 patients using protracted infusion of 5-FU concomitantly with radiation treatment, a 2 years survival rate of 89% and a median survival time of 34 mo was reported[32]. In another series a statistically significant improvement in 3 years survival was observed with adjuvant chemoradiotherapy compared with no adjuvant treatment only in patients with high risk characteristics but not in the whole group[31]. In metastatic disease palliative chemotherapy is based on pancreatic cancer type regimens with fluoro-pyrimidines, gemcitabine and platinum derivatives. Resection of solitary liver metastases in an attempt at palliation and prolongation of survival has been done and should be considered in appropriately selected patients[33].

In conclusion, despite their infrequency, bone metastases in the extremities and brain metastases should be included in the differential diagnosis of patients with a history of ampullary carcinoma who present with symptoms referring to such locations in order to expedite the diagnosis and facilitate treatment.

Abstract

Toxic hepatitis or drug-induced liver injury encompasses a spectrum of clinical disease ranging from mild biochemical abnormalities to acute liver failure. The advantages of a long half-life, wide spectrum, high tissue penetration rate, and a good safety profile, make ceftriaxone, a third-generation cephalosporin, a frequent choice in the treatment of childhood infections. Previous studies have reported a few cases of high aspartate aminotransferase and alanine aminotransferase levels, along with three cases of hepatitis caused by ceftriaxone. Here, we report a case of drug-induced toxic hepatitis in a patient who was treated with ceftriaxone for acute tonsillitis.

INTRODUCTION

Toxic hepatitis or drug-induced liver injury encompasses a spectrum of clinical disease ranging from mild biochemical abnormalities to acute liver failure. The majority of adverse liver reactions are idiosyncratic, and occur in most instances 5-90 d after the causative medication was last taken[1]. The advantages of a long half-life, wide spectrum, high tissue penetration rate, and a good safety profile, make ceftriaxone, a third-generation cephalosporin, a frequent choice in the treatment of childhood infections. It is excreted mainly by the kidneys, and 35%-45% of the drug is excreted through the bile without being metabolized[2]. Previous studies have reported a few cases of high aspartate aminotransferase (ALT) and alanine aminotransferase (AST) levels, along with three cases of hepatitis caused by ceftriaxone[2-4]. Here, we report a case of drug-induced toxic hepatitis in a patient who was treated with ceftriaxone for acute tonsillitis.

CASE REPORT

A 12-year-old boy was admitted with complaints of weakness and fatigue. His personal history revealed treatment with ceftriaxone 50 mg/kg per day, 6 d previously, for tonsillitis. The patient stated that the weakness had begun on the third day of ceftriaxone therapy. He had no chronic disease and had not had contact with anyone with hepatitis. He had not used any drugs, including analgesics and anti-inflammatory drugs, in the previous 6 mo. He had never undergone a blood transfusion or any previous operations. or tooth extraction in the previous year. He had no history of traveling. He was a student in the 6th grade of primary school. He stated that there was no change of color in his feces or urine. During this period, other medications, including herbal remedies and vitamins had not been used. The only drug he had used was ceftriaxone. His liver function tests were at normal levels in the past 2 mo. Physical examination revealed a weight of 43 kg (50 percentile), and a height of 152 cm (50-75 percentile). His general appearance was moderate and seemed weak, and his pharynx was slightly hyperemic. No additional sounds or murmurs were detected upon cardiac and pulmonary examinations. The liver and the spleen were

non-palpable. The neurological examination was normal, along with all the other systems.

Laboratory examination revealed: AST, 819 IU/L (normal range, 10-40 IU/L); ALT, 871 IU/L (normal range, 13-40 IU/L); γ glutamyl transferase (GGT), 285 U/L (normal range, 9-50 IU/L); alkaline phosphatase (ALP), 143 IU/L (normal range, 40-140 IU/L); total bilirubin, 4.2 mg/dL; and direct bilirubin, 2.8 mg/dL. Total protein, albumin, globulin, lactate dehydrogenase, amylase and fasting blood glucose levels were normal. The complete blood count revealed a normal number of leukocytes, erythrocytes and platelets. Peripheral blood smear revealed 60% neutrophils, 30% lymphocytes, 8% eosinophils, and 2% monocytes. The erythrocyte morphology was normal with no atypical cells. Urine analysis, prothrombin time and activated partial thromboplastin time were all in the normal range. Antistreptolysin O titer was 340 TU/mL. Serum iron, iron binding capacity, ferritin, ceruloplasmin, free T3, free T4 and thyroid stimulating hormone levels were also in the normal range. Hepatitis B surface antigen, anti-hepatitis B core IgM, anti-hepatitis C virus, anti-hepatitis A virus IgM, anti-hepatitis E virus, cytomegalovirus IgM, and Epstein-Barr virus viral capsid antigen values were negative, whereas anti-HbsAg was positive. Values for IgG, IgM and IgA levels were normal but the value for IgE was 523 IU (normal range 0-100). Anti-nuclear antibody (ANA) and anti-mitochondrial antibody (AMA) were negative. Blood, urine and throat cultures were negative.

Ultrasonography showed minimal enlarged liver size but with normal parenchyma, and gallbladder was normal. The clinical appearance of the patient did not show any signs of cholelithiasis. Evaluating personal history, physical examination and the laboratory findings together, we made a diagnosis of ceftriaxone-induced hepatitis. Liver biopsy was planned, but the patient refused. Ceftriaxone administration was ceased immediately. Pulse methylprednisolone administration was begun at 40 mg/kg in the first 3 d, to be followed by 30 mg/kg for 4 d. A proton pump inhibitor was added to the drug regimen. His vital functions were normal. A steroid-induced hyperglycemic attack with the highest value of 240 mg/dL for 2 d was the only adverse effect of the treatment. He was advised to rest for 2 wk without taking any drugs and to have a light diet. At week 4, the biochemical data revealed: ALT, 95 IU/L (13-40); and GGT, 164 IU/L (9-50). Total bilirubin, direct bilirubin, total protein, albumin and other parameters were normal. Control blood biochemistry at week 10 showed GGT of 85 IU/L (9-50), along with normal values of ALT, AST and other parameters.

DISCUSSION

All the factors suspected to be responsible for hepatitis and disturbed liver function tests, such as viral agents, autoimmune disease, cholelithiasis, storage diseases such as Wilson's disease, hemochromatosis, and endocrine diseases such as hypo- and hyperthyroidism were excluded when we obtained normal values in viral serological tests of ANA, AMA, ferritin, serum iron binding capacity, ceruloplasmin, free T3, free T4, and TSH.

The absence of a specific cause for the elevated liver function tests, including AST, ALT, ALP, GGT, and total and direct bilirubin, such as blood transfusion, recent tooth extraction, surgery, direct contact with a patient with hepatitis, history of traveling or use of any drugs other than ceftriaxone, other medications, including herbal remedies and vitamins, led us to consider ceftriaxone as the responsible agent. The direct correlation with ceftriaxone use could be verified by measurement of drug levels in the serum or by liver biopsy, or the re-use of the drug, in which case elevated transaminase levels would support our diagnosis of ceftriaxone-induced hepatitis. Measurements of the antibody for liver-kidney microsome (anti-LKM) and cytochrome P450 may be useful for demonstrating drug-induced hepatotoxicity[4]. Re-use of the drug in our patient was out of the question. He also refused a liver biopsy. In our case, serum measurement of anti-LKM was positive but for technical reasons, serum ceftriaxone levels could not be performed. A prominent increase in the levels of GGT suggest a toxic cause[3].

Development of hepatitis and elevated liver enzymes caused by antibiotics have been reported in the literature[2-9]. Cephalosporin-induced hepatoxicity is rarely observed. Common adverse effects are gallstones (cholelithiasis) or bile lumps. Despite the fact that only a few cases of elevated liver enzymes caused by ceftriaxone have been reported[2-4], only three cases of hepatitis have been reported in the literature[2-4]. In one of the cases, ceftriaxone was used to treat Lyme's disease, which resulted in serious side effects and elevated liver enzymes, consequently leading to cessation of the drug[4]. Similar to our case, an interesting normalization in the level of all the enzymes, except GGT, has been reported at 10 wk after drug discontinuation[4]. Unlike other cases, our patient showed no signs of severe hemolysis. This probably accounted for early recovery of the patient, along with the absence of any life-threatening complications. This was certainly fortuitous for the patient.

In cases of drug-induced hepatitis, the clinical picture of the hepatitis may represent a direct toxic effect, an idiosyncrasy, or a cholestatic reaction[1,5]. In our case, the eosinophilia in the blood smear and the elevated IgE levels in the serum suggested that hypersensitivity was responsible for the ceftriaxone-induced hepatitis.

In conclusion, the effect of ceftriaxone along with other hepatotoxic drugs should be considered in any case of elevated liver enzymes and hepatitis.

Abstract

An ileal perforation resulting from a migrated biliary stent is a rare complication of endoscopic stent placement for benign or malignant biliary tract disease. We describe the case of a 59-year-old woman with a history of abdominal surgery in which a migrated biliary stent resulted in an ileal perforation. Patients with comorbid abdominal pathologies, including colonic diverticuli, parastomal hernia, or abdominal hernia, may be at increased risk of perforation from migrated stents.

Key words: Adhesion; Biliary stent; Ileal perforation; Migration; Choledocholithiasis

INTRODUCTION

The endoscopic placement of biliary stents for benign and malignant biliary disease has been performed for well over a decade and was first described in 1980 by Soehendra and Reynders-Frederix[1,2]. In approximately 5%-10% of cases, the procedure itself involves potential adverse side effects, such as pancreatitis, hemorrhage, perforation, and cholangitis. Long-term complications of biliary stents, such as migration and perforation, are unusual[2]. Patients with comorbid abdominal pathologies, including colonic diverticuli, parastomal hernia, or abdominal hernia, may be at increased risk of perforation from migrated stents. The available biliary endoprostheses can be classified by material into two categories: plastic and metallic stents. Plastic stents are less expensive and easier to remove or change, but have a higher risk of clogging and dislocation[3,4].

Generally, to prevent migration or clogging in patients with a plastic stent, the stent must be changed or removed in 3-6 mo[5]. Moreover, to avoid stent migration, the biliary stent should be placed across the sphincter of Oddi[6].

CASE REPORT

A 59-year-old woman was admitted to the hospital with increasing abdominal pain. Her abdomen was tense and painful, with diffuse abdominal rebound tenderness and hyperactive bowel sounds. An upright abdominal radiograph showed minimally dilated small bowel loops and no free intraperitoneal gas. Laboratory examination gave the following results: hematocrit 30%, white blood cell count 14 500/cm^3, platelets 268 000/cm^3, sodium 138 mEq/L, potassium 4.6 mEq/L, blood urea nitrogen 32 mg/dL, creatinine 1.6 mg/dL, glucose 110 mg/dL, amylase 78 IU/L, total bilirubin 2.5 mg/dL, aspartate aminotransferase 87 IU/L, alanine aminotransferase 79 IU/L, alkaline phosphatase 550 IU/L, and γ glutamyl transferase 66 U/L.

An abdominal ultrasound showed features consistent with acute cholecystitis and a dilated common duct with a diameter of 14 mm. Computed tomography (CT) was performed because of the extensive pain. Dislocation and migration of a biliary stent to the distal ileal segment was detected. CT was suspicious for an ileal perforation and the wall of the ileum was markedly thickened, with

Figure 1 The coronal MIP abdominal CT views show the stent in the ileum lumen indenting the ileum wall; proximal to this level, the intestinal segments are dilated.

Figure 2 Intraoperative photograph shows the antimesenteric surface of the terminal ileum perforated by the biliary stent.

choledocholithiasis and dilated common duct with a diameter of 14 mm (Figure 1). The patient's history included endoscopic retrograde cholangiopancreatography (ERCP) 21 d before admission for an impacted stone in the common bile duct. A sphincterotomy was performed and a plastic 7-cm 11 Fr stent was placed. The patient had also undergone a laparotomy for appendicitis 20 years earlier, and three repairs of incisional hernias, 3, 4 and 6 years previously.

At laparotomy, we found multiple adhesions, dilated proximal jejunal segments, and a large amount of small intestine conglomerated in the right lower quadrant. The biliary catheter had perforated the antimesenteric surface of the distal ileum, which resulted in a protruding plastic biliary stent (Figure 2), however, the contamination was moderate because of the dense intra-abdominal adhesions. Two liters of turbid fluid were aspirated. The biliary stent was removed; the small bowel, including the perforated region, was partially resected. The patient was discharged on the seventh postoperative day, with no complications.

DISCUSSION

Occlusion is the most common problem associated with endoscopically placed stents (54%); this can be caused by tumor overgrowth or clogging by "biliary sludge," with resulting cholangitis or recurrent obstructive jaundice[1]. Dislocation and migration of biliary stents proximally and distally in the gut is less common, occurring in less than 10% of cases, and generally causes no major problems, with the stent usually passing in the feces or remaining in the bowel with no overt symptoms. Migration is much more common with plastic stents than with metallic stents[1,7].

In a series of 322 endoscopically placed biliary stents, Johanson *et al*[8] reported proximal and distal stent migration in 4.9% and 5.9% of the patients, respectively. Intestinal perforation is an exceedingly rare complication after placement of a biliary stent. Intestinal perforation can occur during the initial insertion or endoscopic or percutaneous manipulation, or as a late consequence of biliary stent placement. In the recent literature, most (92%) cases of intestinal perforation were in the duodenum after endoscopic or percutaneous placement of a biliary stent[4,5,9,10]. Various mechanisms have been postulated for duodenal perforation by biliary stents. Firstly, the stent may be placed incorrectly at the time of the procedure, and the mechanical force exerted by the tip of the plastic stent against the duodenal mucosa can lead to necrosis of the wall over time. Secondly, inflexibility or a stent of an incorrect length may lead to pressure necrosis[1,9].

The insertion of several smaller-diameter stents (10 Fr) rather than a single large stent (11.5 or 12 Fr) may prevent proximal stent migration. The insertion of longer rather than shorter (< 7 cm) stents may also prevent such migration. Distal perforations are less common than duodenal perforations. Reported cases involve perforation due to biliary stent migration; this is more unusual in the distal ileum and generally the cause is other diseases, such as colonic diverticuli, parastomal hernia, incarcerated hernia, and colovesicular fistulas[1,8,10]. In our case, many adhesions resulting from the previous surgery were observed and the ileal segments were conglomerated in the right lower quadrant. These adhesions reduced the mobility of the ileum and the stent was caught in a distal ileal segment. Consequently, the sharp edge of the stent caused irritation and perforation on the antimesenteric side of the distal ileum. In the coronal maximum intensity projection abdominal CT reconstructions, the localization of the stent was obvious (Figure 1).

A review of the literature published to January 2007 revealed 11 cases of colonic perforation due to biliary stent migration, with the majority being straight plastic endoprostheses[3]. Five cases of small intestinal perforations due to a migrated biliary stent were reported, which involved an incisional hernia, parastomal hernia, appendiceal perforation, and two other diseases[1,11-14]. To our knowledge, this is the sixth case of small intestinal perforation due to a migrated biliary stent reported in PubMed. In our case, the clinical manifestations appeared 21 d after placing the stent *via* ERCP.

In conclusion, patients with risk factors such as diverticulosis, incisional and incarcerated hernias, and intra-abdominal adhesions require more attention.

Abstract

The heart is an unusual site of metastasis from any malignancy. We report a case of cardiac metastasis from colorectal cancer. A 70-year-old woman was referred with a presumptive diagnosis of sigmoid colon cancer with cardiac myxoma. Two-dimensional echocardiography showed a 4 cm × 4.5 cm mobile mass on the lateral right atrial wall, and computed tomography revealed a low attenuated lobulating mass in the right atrium. The patient underwent anterior resection for sigmoid colon cancer (T4N2). Thereafter, she experienced progressive shortness of breath. Therefore, a cardiac operation was performed 2 wk after the colorectal operation. Histological examination revealed adenocarcinoma, which was identical to the primary lesion. Although two-dimensional echocardiography has become the diagnostic test of choice for detecting cardiac tumors, in patients with colorectal cancer showing a cardiac mass, further diagnostic evaluation such as a magnetic resonance imaging might be necessary.

Key words: Heart; Cardiac metastasis; Colorectal cancer; Atrial myxoma; Magnetic resonance imaging

INTRODUCTION

Metastases from colorectal cancer can occur either by lymphatic or hematogenous spreading, and the sites most commonly involved are the liver and lung. Unusual metastases from colorectal cancer into organs including the spleen, thyroid gland, spermatic cord, and skeletal muscle have been reported[1-4]. Although metastases to these sites might occur as a feature of end stage-disease, metastasis to the heart from colorectal cancer is extremely rare. To our knowledge, only nine cases of cardiac metastasis from colorectal cancer have been previously described[5-9,10-13]. Here, we report a case of cardiac metastasis from colorectal cancer that presented preoperatively as a benign atrial myxoma.

CASE REPORT

A 70-year-old woman, presenting with bloody stools, was admitted to our hospital. She experienced shortness of breath and had lost 4 kg in weight in the past 3 mo. A colonoscopy revealed an encircling mass in the sigmoid colon, nearly obstructing the lumen of the colon. A pediatric colonoscope could not be passed beyond this point. The biopsy gave evidence of an adenocarcinoma of the sigmoid colon. Laboratory studies, on admission, were within the normal limits, except for carcinoembryonic antigen, which was 9.2 ng/mL. A routine transthoracic echocardiography showed the presence of a right atrial (RA) enlargement and mobile, round, spherical, and inhomogenous mass (3.72 cm × 4.15 cm) adjacent to the lateral RA wall (Figure 1). This pedunculated mass had a broad stalk (1.88 cm), and projected through the tricuspid valve into the right ventricular (RV) cavity, obstructing the RV inflow during the diastolic phase. A chest X-ray showed cardiomegaly and a prominent aorta. Computed tomography revealed a low attenuated lobulating mass in the right atrium (Figure 2). Preoperative diagnosis

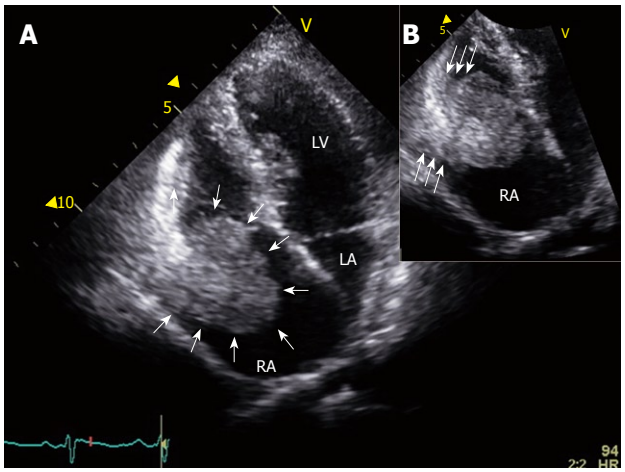

Figure 1 Transthoracic echocardiography. A: A mobile, round, spherical, and echogenic mass (white arrows) is seen adjacent to the lateral right atrial wall on an apical four chamber view of the transthoracic echocardiography; B: A magnified image of the right atrial mass shows a pedunculated character with a broad stalk (tris-arrows). RA: Right atrium; LA: Left atrium; LV: Left ventricle.

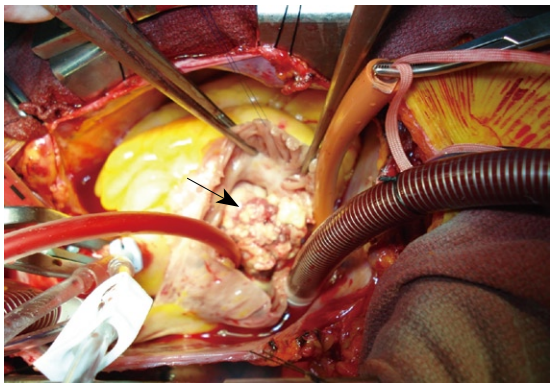

Figure 3 Operative finding. On opening the right atrium, a large multiple lobulating mass (arrow) with a rough surface was located on the antero-inferior side of the right atrial free wall. The mass was near the atrioventricular groove, with invasion into the right atrium.

was synchronous sigmoid colon cancer and right atrial myxoma. We planned to perform cardiac surgery 4 wk after colorectal surgery. An anterior resection with a colorectal anastomosis was performed. Histological investigation of the excised portion confirmed the existence of a moderately differentiated adenocarcinoma invading the serosa with lymphovascular invasion and perineural invasion. The staging of the lesion was T4N2. Although the patient complained of mild shortness breath, the postoperative course was uneventful. However, 2 wk postoperatively, the shortness of breath had worsened. Thus, the patient was taken immediately into cardiac surgery. After a sternotomy, the pericardium was opened, and a cardiopulmonary bypass was installed to open the right atrium. The mass was present in the right atrial wall near the atrioventricular groove, and was growing toward the tricuspid valve. After removal of the mass, the right atrial wall was reconstructed with bovine pericardium (Figure 3). The atrial mass showed a nodular necrotic appearance grossly measuring

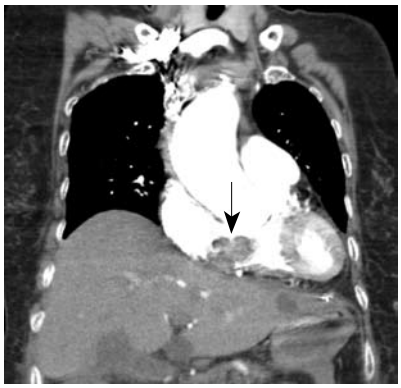

Figure 2 Computed tomography scan revealed that the mass (arrow) was located in the right atrium, obstructing the tricuspid valve opening.

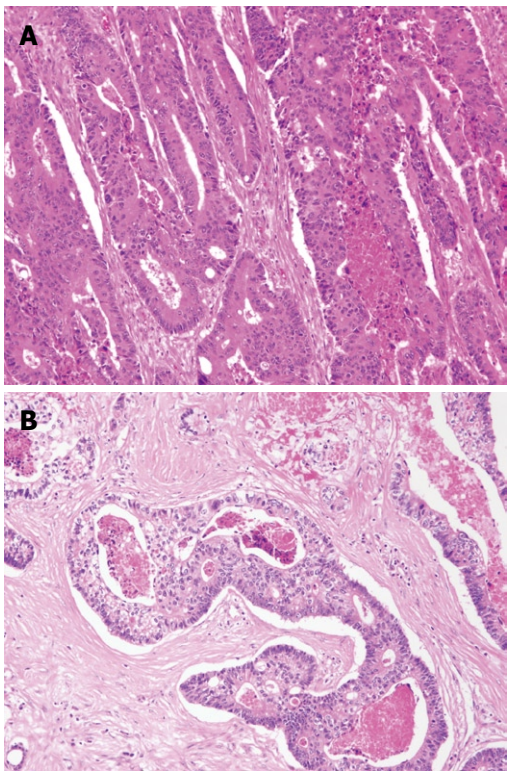

Figure 4 Microscopic findings. A: Tall malignant columnar cells line large irregular glands; some forming a cribriform architecture containing intraluminal necrotic debris in primary colon cancer (HE, × 100); B: The cardiac mass shows similar histological findings to Figure 4A.

5.5 cm × 5 cm × 3 cm; histological examination revealed adenocarcinoma that was identical to the primary lesion (Figure 4). A further operation was performed because of postoperative cardiac bleeding; however, the patient died of recurrent cardiac bleeding on the 3rd postoperative day.

DISCUSSION

The regional lymph nodes, liver, and lung are the most common sites of metastasis from colorectal cancer. Infrequent sites of metastases, including the spleen, thyroid gland, spermatic cord, and skeletal muscle

Table 1 Clinical features of cardiac metastasis from colorectal cancer reported in English literature

Author (yr)	Age/sex	Location of primary tumor	Primary tumor stage	Diagnosis of cardiac metastasis made by/at	Location of heart	Metastatic tumor size (cm)	Operation of metastatic mass	Outcome

have been reported[1-4]. Although metastases of these unusual sites from colorectal cancer might occur with the status of widespread disease, cardiac metastasis from colorectal cancer is extremely rare[5-9,10-13]. The incidence of cardiac metastasis in patients with malignancy might be underestimated because cardiac metastatic lesions are clinically silent in most cases[13,14]. Therefore, the incidence of cardiac metastasis might best be determined by reviewing autopsy studies. The incidence of cardiac metastasis from any malignancy has been reported as 10%-18% in autopsy studies[15-17]. Malignant melanoma has been reported as the most common disease[16-19]. Leukemia and lymphoma also showed a high incidence of cardiac metastasis in the past, but this incidence is decreasing because of improvements in chemotherapy[16,20]. In colorectal cancer, to our knowledge, only nine reports have been described in the literature (Table 1); however, the incidence of cardiac metastasis was 1.4%-7.2% in autopsy studies[12,16,17]. Thus, the true incidence of cardiac metastasis from colorectal cancer might be higher than the cases reported so far.

Some factors that might account for the infrequency of cardiac metastasis have been suggested: the strong kneading action of the myocardium, metabolic peculiarities of striated muscle, the rapid flow of blood through the heart, and lymph flow normally moving away from the heart. The blood flow of the coronary system is the highest in the body, and the lymphatics of the heart is divided into a superficial and a deep group, joining and draining through two trunks into the tracheobronchial lymph nodes. Thus, metastasis must occur against the direction of flow[19]. Although the reasons for its rarity have not been well established, cardiac metastasis from malignancies might occur by direct extension, lymphatic spread, hematogenous spread, or a combination of two or three of the above[14,16,17,19]. Klatt *et al*[16] reported that the lung was the most common primary site, and sites closer to the heart contributed to the greatest number of cardiac metastases; they suggested that the lymphatic drainage from nearby sites represents the most likely means of spread. Mukai *et al*[17] suggested that the relative importance of these various routes would appear to depend on the type of primary tumor and on the completeness of the autopsy examination. In our case, although regional lymph node metastases were identified, we postulate that hematogenous spread might be the most likely route in colorectal cancer.

The incidence of colorectal cancer with cardiac metastasis is rare, therefore surgery as a treatment modality has not been investigated. Koizumi *et al*[11] reported that although surgery is rarely recommended for treating metastatic cardiac tumors, surgical treatment could be especially effective in occurrences of obstructive and solitary lesions to ensure relief from symptoms and elongation of life expectancy. In our case, the purpose of surgical treatment was the release of symptoms, even though the preoperative diagnosis was cardiac myxoma and the patient died from postoperative bleeding. With the improvement of diagnostic procedures and a prolonged life span, the incidence of cardiac metastasis from colorectal cancer is likely to increase. Therefore, to clearly delineate the role of surgical treatment in cardiac metastasis from colorectal cancer, further studies are necessary.

In general, an endocardial myxoma, the most common form of primary cardiac tumor, can be diagnosed by echocardiography, which provides the differential diagnosis of intracavitary atrial echoes, including vegetation, thrombi, and primary or secondary cardiac tumors; however, the detection of cardiac metastasis by echocardiography might be difficult in cases of an infiltrative nature[13,21]. In our case, although the mass was found to have invaded into the right atrium in operative finding, the preoperative echocardiography showed a mobile cardiac mass. Thus, the presumptive diagnosis was atrial myxoma. The differential diagnoses of cardiac myxoma and cardiac metastasis from colorectal cancer might be difficult to determine by echocardiography alone, as in our case, because synchronous cardiac myxoma and colorectal cancer have been reported[22]. Magnetic resonance imaging (MRI) is effective in the evaluation of secondary cardiac tumors, because it can accurately define the pericardium, the myocardial walls, and the cardiac chambers, especially in cases with an infiltrative nature[23,24]. Therefore, in patients with colorectal cancer with a cardiac mass, further diagnostic evaluation such as an MRI, in addition to echocardiography, might be helpful in the differential diagnosis of the cardiac mass.

In conclusion, as reported in autopsy studies, cardiac metastasis from colorectal cancer might not be so rare,

and with improvements in diagnostic procedures, the incidence of cardiac metastasis from colorectal cancer is likely to increase. Thus, in patients with colorectal cancer showing a cardiac mass, further diagnostic evaluation, such as an MRI, might be necessary.

Abstract

The author reports herein two cases of amelanotic malignant melanoma of the esophagus. Case 1 is an 87-year-old woman who was admitted to our hospital because of nausea and vomiting. Endoscopic examination revealed an ulcerated tumor of the distal esophagus, and a biopsy was taken. The biopsy showed malignant polygonal and spindle cells. No melanin pigment was recognized. Immunohistochemically, the tumor cells were positive for melanosome (HMB45), S100 protein, KIT and Platelet derived growth factor receptor-α (PDGFRA). The patient was treated by chemotherapy and radiation, but died of systemic metastasis 12 mo after the presentation. Case 2 is a 56-year-old man presenting with dysphagia. Endoscopic examination revealed a polypoid tumor in the middle esophagus, and a biopsy was obtained. The biopsy showed malignant spindle cells without melanin pigment. Immunohistochemically, the tumor cells were positively labeled for melanosome, S100 protein, KIT and PDGFRA. The patient refused operation, and was treated by palliative chemotherapy and radiation. He died of metastasis 7 mo after the admission. In both cases, molecular genetic analyses of *KIT* gene (exons 9, 11, 13 and 17) and *PDGFRA* gene (exons 12 and 18) were performed by the PCR direct sequencing method, which showed no mutations of *KIT* and *PDGFRA* genes. This is the first report of esophageal malignant melanoma with an examination of the expression of KIT and PDGFRA and the mutational status of *KIT* and *PDGFRA* genes.

Key words: Esophagus; Amelanotic melanoma; KIT; Platelet derived growth factor receptor-α

INTRODUCTION

Primary malignant melanoma of the esophagus is very rare; only case reports and studies of small series have been reported[1-7]. Primary amelanotic malignant melanoma of the esophagus is extremely rare; only a few case reports have been published in the literature[8-13].

Melanoma is a highly aggressive tumor, and *NRAS* and *BRAF* mutations are mainly involved in the pathogenesis of melanoma[14,15]. *KIT* gene, mapped to 4q12, encodes an oncogenic transmembranous receptor tyrosine kinase, KIT, whose ligand is stem cell factor[6-21]. The *platelet derived growth factor receptor-α* (*PDGFRA*) gene, also mapped to 4q12, additionally encodes an oncogenic transmembranous receptor tyrosine kinase, PDGFRA[6-21]. The *KIT* gene plays an important role in melanocyte migration, development, differentiation and tumorigenesis[22]. A few previous studies have shown that activating mutations of the *KIT* gene may lead to tumorigenesis of cutaneous melanoma[14,23]. Since both *KIT* and *PDGFRA* genes are mapped to 4q12, it is anticipated that *PDGFRA* gene mutations are also involved in the tumorigenesis of melanoma, as in the case of gastrointestinal stromal tumors[16-21]. However, the incidence of *PDGFRA* gene mutations in melanoma has rarely been estimated[24].

The author herein reports two cases of esophageal amelanotic malignant melanoma with immunohistochemical and molecular genetic study of *KIT* and *PDGFRA*.

CASE REPORT

Case 1

An 87-year-old woman was admitted to our hospital because of nausea and vomiting. Endoscopic examination revealed an ulcerated tumor of the distal esophagus, and a biopsy was taken. The biopsy was stained with HE. An immunohistochemical analysis was performed, using Dako's Envision method, as previously described[25-30].

Genetic analyses of the *KIT* gene (exons 9, 11, 13 and 17) and the *PDGFRA* gene (exons 12 and 18) were performed by the PCR direct sequencing method, as previously reported[31-35]. The exons of both genes were selected because they are frequent mutation sites[16-21]. The primers are shown in Table 1. In brief, genomic DNA was extracted from paraffin blocks with proteinase K digestion and phenol/chloroform extraction, and subjected to PCR for 40 cycles (94℃ for 1 min, 52℃ for 1 min, 72℃ for 1 min), using a thermal cycler (GeneAmp PCR system 9700, Applied Biosystems, ABI, CA). The annealing temperature was 53℃. PCR products were extracted, and subjected to computed automatic DNA sequencing (ABI PRIZM 3100 Genetic Analyzer, Applied Biosystems, ABI, CA).

The biopsy showed malignant spindle and polygonal cells (Figure 1A and B) suspicious for sarcoma. No melanin pigment was recognized by HE and Masson-Fontana stains. The histology was relatively uniform in the biopsy. Immunohistochemically, the malignant cells were positive for melanosome (Figure 1C) (HMB45, Dako), S100 protein (Figure 1D) (polyclonal, Dako), vimentin (Vim 3B4, Dako), p53 protein (DO-7, Dako), neuron-specific enolase (BBS/NC/VI-H14, Dako), PDGFRA (Santa Cruz, CA, USA), and KIT (polyclonal, Dako) (Figure 1E). The KIT expression was focal. In contrast, the malignant cells were negative for cytokeratins (AE1/3 and polyclonal, Dako), CD3 (M7193, Dako), CD10 (M0727, Dako), CD15 (M0733, Dako), CD30 (M0751, Dako), CD45 (M0855, DAKO), CD45RO (UCHL-1, Dako, CD79α (M7050, Dako), CD20 (L26, Dako), desmin (D33, Dako), α-smooth muscle actin (1A4), CD34 (QBEND10, Dako), chromogranin (DAK-A3, Dako), synaptophysin (polyclonal, Dako), CD56 (MOC-1, Dako), and myoglobin (polyclonal, Dako). Ki-67 labeling (MIB1, Dako) was 80%. A pathologic diagnosis of amelanotic melanoma of the esophagus was made. The molecular genetic analysis showed no mutation of the *KIT* gene (exons 9, 11, 13 and 17) or the *PDGFRA* gene (exons 12 and 18). Examination of the skin, eye and intestine showed no tumors. Therefore, the esophageal melanoma was primary. The patient was inoperative because of weakness and old age, and chemotherapy and radiation were performed. The patient showed systemic metastasis, and died of respiratory failure 12 mo after the first presentation. One additional biopsy of the lung metastasis was obtained, and it showed amelanotic melanoma histology and immunohistochemistry results which were almost the same as those of the primary esophageal biopsy.

Case 2

A 56-year-old man presented with dysphagia. Endoscopic examination revealed a polypoid tumor in the middle esophagus. A biopsy was taken (Figure 2A and B). Histologically, the biopsy showed proliferation of malignant spindle cells (Figure 2A and B). No melanin pigment was seen with HE and Masson-Fontana stains. The histology of the tumor was relatively uniform in the biopsy. Immunohistochemically, the tumor cells were positive for melanosome (Figure 2C), S100 protein, vimentin, p53 protein, PDGFRA, and KIT (Figure 2D). The KIT expression was diffuse. In contrast, the malignant cells were negative for cytokeratins, CD3, CD30, CD45, CD45RO, CD79α, CD20, desmin, α-smooth muscle actin, CD34, chromogranin, synaptophysin, CD56, and myoglobin. Ki-67 labeling was 95%. A pathological diagnosis of amelanotic malignant melanoma was made. The molecular genetic analysis identified no mutation of either *KIT* gene (exons 9, 11, 13 and 17) or *PDGFRA* gene (exons 12 and 18). No tumors were identified in the skin, eye and mucosal membrane. Therefore, the esophageal melanoma was considered primary. The patient refused operation, and was treated with palliative chemotherapy and radiation. The patient later showed systemic metastasis and died of melanoma 7 mo after the first presentation. No histological specimens were obtained from the metastatic sites.

DISCUSSION

Amelanotic melanoma of the esophagus is extremely rare, and the pathological diagnosis is very difficult because melanin pigment is absent. In fact, it has been frequently misdiagnosed as other sarcomas[1-13]. Immunohistochemistry of melanoma antigens such as melanosome (HMB45), Malan-A, and S100 protein are mandatory for the diagnosis of amelanotic melanoma. Ultrastructural demonstration of melanosome is also diagnostic. In the present study, both cases were positive for immunoreactive melanosome (HMB45) and S100 protein, confirming the diagnosis. In addition, positive KIT strongly suggests that the tumors are melanomas. Amelanotic melanoma can be diagnosed in biopsy specimens.

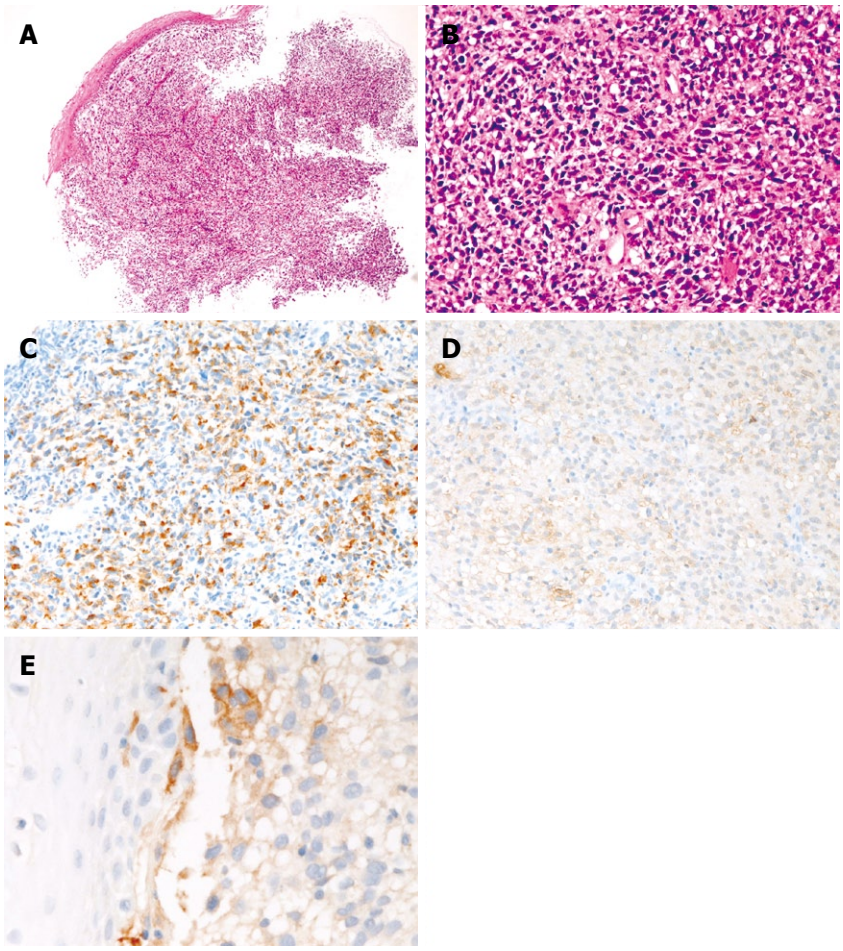

Figure 1 Esophageal amelanotic malignant melanoma in Case 1. A: Low power view of the biopsy (HE, × 20); B: High power view of the biopsy. Malignant polygonal and spindle cells are seen. No melanin pigment is seen (HE, × 200); C: The tumor cells are positive for melanosome (HMB45). (Immunostaining, × 200); D: The tumor cells are positive for S100 protein (Immunostaining, × 200); E: The tumor cells are focally positive for KIT (Immunostaining, × 200).

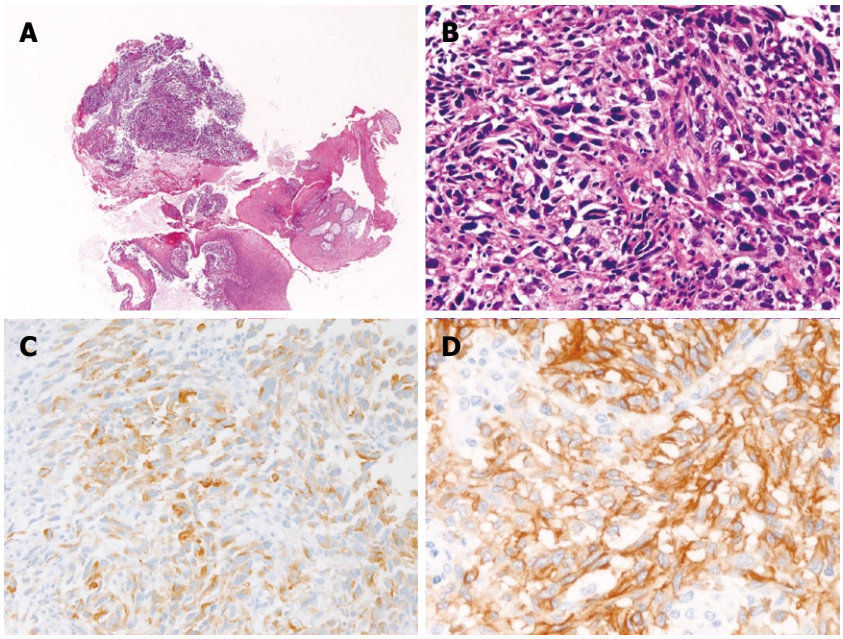

Figure 2 Esophageal amelanotic malignant melanoma in Case 2. A: Low power view of the biopsy (HE, × 20); B: High power view of the biopsy. Malignant spindle cells are seen. No melanin pigment is seen (HE, × 200); C: The tumor cells are positive for melanosome (HMB45) (Immunostaining, × 200); D: The tumor cells are diffusely positive for KIT (Immunostaining, × 200).

Malignant melanoma is a very aggressive tumor irrespective of its location. Malignant melanoma of the esophagus is therefore a very aggressive tumor, and its prognosis is very poor[1-13]. In the present study, the prognosis was indeed very poor in both patients. Operation followed by adjuvant chemotherapy and radiation is the best choice of treatment[1-13]. In the present cases, operation was impossible in one case and was not performed in another case because of the patient's decision not to proceed.

The previously reported cases of esophageal melanoma were only case reports or clinical studies of very small series. There have been no reports of *KIT* and *PDGFRA* expression and mutations in esophageal melanomas. The present study is the first report of esophageal melanoma with an examination of KIT and PDG-

FRA protein expression and gene status of *KIT* and *PDGFRA* in esophageal melanoma. The tumors in the present cases expressed KIT and PDGFRA, but identified no mutations of *KIT* and *PDGFRA*. The positive expressions of KIT and PDGFRA suggest that these transmembranous oncoproteins are present in esophageal melanoma.

In cutaneous melanomas, the percentage of KIT expression varies amongst studies reported by researchers[36]. The percentage of KIT positive cutaneous melanomas in the literature is as follows; 35%[37], 21%[38], 87%[39], 90%[40], 50%[41] and 84%[42]. Sihto *et al*[36] reported that KIT expression in most human solid tumors, including cutaneous melanomas, was due to *KIT* gene amplification. Studies of *KIT* mutations in cutaneous melanoma are scant. Willmore-Payne *et al*[23] showed only 2% of *KIT* mutations in cutaneous melanomas. Sihto *et al*[36] showed no *KIT* mutations in 14 cutaneous melanomas. In contrast, Curtin *et al*[14] showed that *KIT* mutations are present in 39% of mucosal melanomas, in 36% of acral melanomas, in 28% of melanomas on sun-damaged skin, and in 0% of melanomas on non-sun-damaged skin. Beadling *et al*[37] recently reported that *KIT* mutations were present in 23% of acral melanomas, 15.6% of mucosal melanomas, 7.7% of conjunctival melanomas, 1.7% of cutaneous melanoma, and in 0% of choroidal melanomas.

PDGFRA protein expression in melanoma has not been performed, to the best of the author's knowledge. As for *PDGFRA* mutations, Curtin *et al*[24] found no *PDGFRA* mutations in 26 cutaneous melanomas. Sihto *et al*[36] demonstrated no *PDGFRA* gene mutations in 14 cutaneous melanomas.

In summary, the author reported two extremely rare cases of amelanotic malignant melanoma of the esophagus with immunohistochemical and genetic analysis of *KIT* and *PDGFRA*.

ACKNOWLEDGMENTS

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Dr. Philip Abraham, Professor
Consultant Gastroenterologist & Hepatologist, P. D. Hinduja National Hospital & Medical Research Centre, Veer Savarkar Marg, Mahim, Mumbai 400 016, India

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome; liver biology/pathobiology, liver failure, growth and cancer; liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systemically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

Published by

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://wjg.wjgnet.com/wjg. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of

supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words). Available from:http://www.wjgnet.com/wjg/help/8.doc

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/wjg/help/instructions.jsp.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/wjg/help/14.doc.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H pylori*, *E coli*, *etc*.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No.62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-59080039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/wjg/help/10.doc.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/wjg/help/9.doc.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multidisciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Metastatic gastric cancer remains an incurable disease, with a relative 5-year survival rate of 7%-27%. Chemotherapy, which improves overall survival (OS) and quality of life, is the main treatment option. Meta-analysis has demonstrated that the best survival results obtained in earlier randomized studies were achieved with three-drug regimens containing a fluoropyrimidine, an anthracycline, and cisplatin (ECF). Although there has been little progress in improving median OS times beyond the 9-mo plateau achievable with the standard regimens, the availability of newer agents has provided some measure of optimism. A number of new combinations incorporating docetaxel, oxaliplatin, capecitabine, and S-1 have been explored in randomized trials. Some combinations, such as epirubicin-oxaliplatin-capecitabine, have been shown to be as effective as (or perhaps more effective than) ECF, and promising early data have been derived for S-1 in combination with cisplatin. One factor that might contribute to extending median OS is the advancement whenever possible to second-line cytotoxic treatments. However, the biggest hope for significant survival advances in the near future would be the combination of new targeted biological agents with existing chemotherapy first-line regimens.

Key words: Advanced gastric cancer; Biological agents; Chemotherapy

INTRODUCTION

Gastric cancer is the fourth most common cancer worldwide, with about 700 000 confirmed deaths annually. Despite an overall global decrease in incidence, gastric cancer is more prevalent in east Asia, eastern Europe, and central and south America than in other countries[1,2].

Chemotherapy is the main treatment option for patients with advanced disease. Median overall survival (OS) of 8-12 mo has been reported in patients undergoing chemotherapy compared with 3-5 mo for those treated with best supportive care[3]. Several drugs have shown good single-agent activity. The response rates range from 10% to 25% and the median duration of response is relatively short. Fluorouracil (5-FU), cisplatin, docetaxel, and, less commonly, paclitaxel, epirubicin, and irinotecan are major components of conventional regimens. Oxaliplatin, capecitabine, S-1, and UFT are also being used in combination chemotherapy. To date, although a large number of trials have been performed, there is no standard treatment for advanced disease.

Intravenous 5-FU remains the most widely used agent and has been the cornerstone of old combination regimens such as FAM (5-FU, doxorubicin, and mitomycin C), FAMTX (5-FU, doxorubicin, and methotrexate), ELF (etoposide, leucovorin, and 5-FU), and ECF (epirubicin, cisplatin, and continuous infusion 5-FU). Although these regimens yield overall response rates (ORRs) of up to 51%, the median survival time in patients with advanced disease has remained irredeemably below 10 mo[4]. Evidently, there is a clear need for more active new agents and regimens.

Combination chemotherapy has been shown to be associated with a statistically significant ($P = 0.001$) survival benefit compared with monotherapy in a meta-analysis of several clinical trials[5]. This corresponded to a small but clinically relevant 1-mo mean average survival benefit. This meta-analysis also evaluated the role of anthracyclines as part of combination chemotherapy. The authors found that including anthracyclines in a 5-FU-cisplatin combination had a modest advantage

over cisplatin-5-FU alone (HR 0.77). Finally, the meta-analysis also showed that three-drug combinations have a significant survival benefit compared with two-drug combinations.

In this context, Van Cutsem *et al*[6] have performed a large-scale random assignment trial comparing the docetaxel, cisplatin, 5-FU (DCF) combination to a control arm of cisplatin plus 5-FU alone (the TAX325 trial). The primary end point of the study was time to progression (TTP) and it was powered to detect an increase in median TTP from 4 mo to 6 mo. The two arms of the study were well balanced for the usual prognostic factors, including weight loss, performance status (PS), and extent of disease. The median TTP was 3.7 mo for patients receiving cisplatin-5-FU, and 5.6 mo for those receiving DCF (HR 1.47; $P = 0.0004$). As a secondary end point, survival was also modestly increased from 8.6 mo for cisplatin-5-FU to 9.2 mo for DCF. The 2-year survival rate was, however, more than doubled for DCF (8.8% for cisplatin-5-FU and 18.4% for DCF). Another measure of efficacy favoring DCF was response rate (37% for DCF, 25% for cisplatin-5-FU). Although this study indicated an efficacy advantage for the three drug combination of DCF, toxicity was also increased and was very substantial. Eighty-one percent of all patients receiving DCF had at least one grade 3 or 4 non-hematologic toxicity, as well as substantially more hematologic toxicity. Despite this, the use of DCF was associated with a better preservation of quality of life and maintenance of clinical benefit compared with cisplatin-5-FU. On the other hand, there was no difference in the treatment-related mortality rate for the two arms. Therefore, like epirubicin, docetaxel, when added to cisplatin-5-FU, produces a modest improvement in efficacy.

ORAL FLUOROPYRIMIDINES

Treatment with oral fluoropyrimidines seems to offer new hope for patients with gastric cancer, which is surprising when only a few years ago, such patients were not thought to be ideal candidates for an oral treatment. In fact, difficulties with the location of primary tumors, surgery (gastrectomy), or presence of metastatic sites affecting intestinal transit (ie. metastases in the peritoneum), made the hypothetic use of an oral treatment a remote possibility. Nonetheless, findings from recent trials that assessed the role of oral fluoropyrimidines seem to place this assumption into a new promising perspective.

Accordingly, capecitabine has been shown to be effective in the treatment of advanced esophagogastric cancer in a phase Ⅲ study comparing capecitabine with fluorouracil and oxaliplatin with cisplatin (the REAL trial)[7]. Patients were randomly assigned to one of four regimens: ECF, epirubicin plus oxaliplatin and 5-FU (EOF), epirubicin plus cisplatin and capecitabine (ECX), or epirubicin plus oxaliplatin and capecitabine (EOX). Comparing ECF to EOF, ECX, and EOX, there were no significant differences in ORRs (41%, 42%, 46%, and 48%, respectively) and grade 3/4 non-hematologic toxicity (36%, 42%, 33%, and 45%, respectively). Non-inferiority in OS was established in both oxaliplatin/cisplatin and capecitabine/5-FU comparisons in this largest randomized controlled trial. Notably, EOX resulted in a significantly improved survival time compared with the control arm ECF. A median survival time of 11.2 mo in the EOX arm was amongst the longest achieved in this setting of patients. Therefore, EOX should now be regarded as one of the standard first-line treatment options for advanced disease. Another trial that compared treatment with 5-FU plus cisplatin with capecitabine plus cisplatin confirmed that efficacy of capecitabine is equivalent to that of 5-FU[8]. Furthermore, although both of these trials were designed to assess whether capecitabine was no worse than 5-FU, the findings generally suggested better outcome in patients who received oral capecitabine.

S-1 is a new oral anticancer drug comprised of tegafur, 5-chloro-2,4-dihydroxypyrimidine, and oteracil potassium. This drug was designed to enhance the efficacy of tegafur, a prodrug of 5-FU. Koizumi *et al*[9] report findings of the S-1 plus cisplatin *vs* S-1 alone for first-line treatment of advanced gastric cancer (SPIRITS trial). Median progression-free survival (6.0 mo *vs* 4.0 mo; $P < 0.0001$) and OS (13.0 mo *vs* 11.0 mo; $P = 0.04$) were significantly longer in the combination group. Response was also significantly improved in patients having target tumors and assigned to S-1 plus cisplatin (54% *vs* 31%). On the basis of these findings, the standard of treatment in Japan has changed, and treatment with combined S-1 plus cisplatin has become the standard of care. The findings from this trial are clearly relevant: for the first time, in a randomized study, the apparently insurmountable wall of 12 mo survival in advanced gastric cancer was crumbled. However, some considerations must be taken into account before combination S-1 plus cisplatin is implemented as standard treatment in western countries. The SPIRITS trial gives no information about the advantage of S-1 over 5-FU when each was combined with cisplatin. The First-Line Advanced Gastric Cancer Study (FLAGS), which compared S-1 with 5-FU, both combined with cisplatin, has responded to this question[10]. This multicenter phase Ⅲ trial has randomized 1053 patients primarily in the USA, Europe, and South America. Median OS was 8.6 mo in the cisplatin/S-1 arm and 7.9 mo in the cisplatin/5-FU arm ($P = 0.1983$). Statistically significant safety advantages for the S-1-based combination were observed regarding the rates of severe neutropenia (18.6% *vs* 40.0%), stomatitis (1.3% *vs* 13.8%), hypokalemia (3.6% *vs* 10.8%), and renal adverse events (all grades: 18.8% *vs* 33.5%). However, this study has not confirmed the efficacy results of the SPIRITS trial in western populations. Thus, the future role of S-1 in gastric cancer could be the inclusion of this oral drug into a three-drug regimen making DCF or ECF better tolerated. What more can we do to increase median OS?

SECOND-LINE CYTOTOXIC TREATMENT

First-line chemotherapy for the treatment of advanced gastric cancer can provide high response rates which are

of a similar magnitude to those achievable with the newer first-line combinations in colorectal cancer. However, a corresponding improvement in the median OS time has not yet been delivered by the currently available gastric cancer regimens. This lack of progress in relation to markedly improving OS times may be a result, in part, of the more limited efficacy of the currently available second- and third-line treatments for advanced disease, although it should be noted that only one third to one half of the gastric cancer patients in clinical studies may actually receive second-line treatments[11]. Data published to date relating to this are restricted to phase Ⅱ studies of small patient populations, and these investigations are therefore not able to provide definitive results. However, second-line treatments are clearly effective to some degree, with ORRs in the region of 11%-32%, median TTP of 2.5-4.5 mo, and median OS times of 5.4-9.3 mo[12-15].

TARGETED BIOLOGICAL AGENTS

The main hope for significant advances in the near future is the combination of new targeted biological agents with existing chemotherapy first-line regimens. A number of different classes of targeted agents have shown promising activity in clinical studies of advanced gastric cancer, including epidermal growth factor receptor (EGFR) and human epidermal growth factor (HER)-2-targeted monoclonal antibodies, antiangiogenic and antiangiogenic/antitumor compounds, and the proteasome inhibitor bortezomib[16-20].

High response and/or disease control rates have been reported for EGFR-targeted cetuximab combined with irinotecan and infusional 5-FU and leucovorin[16-17] and VEGF-targeted bevacizumab combined with irinotecan and cisplatin[19]. In particular, the FOLCETUX study has demonstrated that the addition of cetuximab to the FOLFIRI regimen increased survival in 38 untreated patients with confirmed advanced gastric/gastroesophageal adenocarcinoma. The treatment was delivered for a maximum of 24 wk, and then cetuximab alone was allowed in patients with a complete response (CR), partial response (PR) or stable disease (SD). Consequently, the overall response rate (ORR) was 44% with a CR in four patients and a PR in 11 patients. Sixteen patients had SD. Median expected OS was 16 mo[16]. In another multicenter phase Ⅱ study, 47 patients with metastatic or unresectable gastric cancer received bevacizumab plus irinotecan and cisplatin. With a median follow-up of 12.2 mo among 34 assessable patients, the ORR was 65%, with 20 patients achieving a PR and two patients a CR. Twelve patients had SD. Median survival was 12.3 mo[19].

Trastuzumab exhibits activity in human gastric cancer cells that overexpress HER2/neu. A phase Ⅱ trial has determined the efficacy and tolerability of trastuzumab plus cisplatin in patients with advanced gastric cancer with HER2/neu overexpression/amplification. Preliminary results showed that 6 (35%) out of 17 assessable patients achieved response, 3 (17%) stabilization. There was no grade 4 toxicity[18]. In considering such studies, it is notable that the first-line cytotoxic regimens that have been selected for combination with biological agents tend to be those that are generally considered not to be optimal for the treatment of advanced gastric cancer. This begs the question as to whether the impressive potential of these targeted agents might be more profitably explored in the future within combinations that include standard cytotoxic backbones such as ECF, DCF, EOX, or perhaps S-1 plus cisplatin. Indeed, a number of randomized phase Ⅲ studies incorporating targeted agents in first-line regimens have recently been initiated: the ToGA (Trastuzumab with Chemotherapy in HER2-Positive Advanced Gastric Cancer) study is investigating the effect on progression-free survival of trastuzumab in combination with a fluoropyrimidine plus cisplatin *versus* chemotherapy alone in patients with HER-2-positive advanced gastric cancer, AVAGAST (Avastin® in Gastric Cancer) is investigating OS time in advanced gastric cancer patients receiving either capecitabine and cisplatin plus bevacizumab or chemotherapy alone plus placebo, and the REAL-3 study is investigating the benefit of adding panitumumab to an EOX regimen in patients with locally advanced or metastatic esophagogastric adenocarcinoma.

However, new biological agents could be useful in the management of advanced disease after the failure of first-line treatment. In this context, it is possible that targeted agents may have a future role as single-agent maintenance treatments. Two recent phase Ⅱ studies have pursued this concept[21-22]. A Japanese study has evaluated the activity and safety of everolimus (RAD001), an oral inhibitor of the mammalian target of rapamycin serine-threonine kinase, in 54 pretreated patients with metastatic gastric cancer. At interim analysis, no objective responses were observed but disease control rate was 55% and median TTP was 83 d. Main adverse events were stomatitis (74%), anorexia (51%), fatigue (47%), rash (45%), peripheral edema (23%), thrombocytopenia (21%), diarrhea (19%), pneumonitis (13%), and hyperglycemia (9%). The multicenter AIO phase Ⅱ trial has evaluated tolerability and efficacy of sunitinib in highly pretreated Caucasian patients with unresectable metastatic cancer of stomach, esophagogastric junction or lower esophagus. Among 14 response-evaluable patients, 5 of them showed tumor control for at least 6 wk. With regard to survival, 5 patients experienced early death caused by progressive disease, 7 patients survived > 60 d. Twelve patients were still in follow-up or withdrew informed consent within 60 d after start of therapy. Again, 3 of them survived > 60 d. No serious adverse events occurred.

In conclusion, these studies constitute a potentially important advance, indicating a role for biological agents in the treatment of advanced gastric cancer. Further trials are now needed to clarify their respective position with reference to chemotherapy.

Abstract

The diagnosis of inflammatory bowel disease (IBD) depends on direct endoscopic visualization of the colonic and ileal mucosa and the histological study of the obtained samples. Radiological and scintigraphic methods are mainly used as an adjunct to endoscopy. In this review, we focus on the diagnostic potential of nuclear medicine procedures. The value of all radiotracers is described with special reference to those with greater experience and more satisfactory results. Tc-99m hexamethylpropylene amine oxime white blood cells remain a widely acceptable scintigraphic method for the diagnosis of IBD, as well as for the evaluation of disease extension and severity. Recently, pentavalent Tc-99m dimercaptosuccinic acid has been recommended as an accurate variant and a complementary technique to endoscopy for the follow-up and assessment of disease activity. Positron emission tomography alone or with computed tomography using fluorine-18 fluorodeoxyglucose appears to be a promising method of measuring inflammation in IBD patients.

INTRODUCTION

The diagnosis and follow-up of patients with inflammatory bowel disease (IBD) is mainly based on endoscopy and the histological study of the obtained biopsy specimens[1,2]. Ileocolonoscopy, gastroscopy and evaluation of small bowel by wireless capsule endoscopy or double balloon enteroscopy offer a successful diagnostic approach in the majority of IBD patients[3,4].

Radiological methods have a secondary role and they are used additionally to endoscopy. They are indicated in cases of suspected complications or small bowel involvement in patients with Crohn's disease (CD)[4-6]. They include conventional radiological methods such as double-contrast barium studies and cross-sectional imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound[6-9]. All of them have been proven valuable techniques for evaluation of the effects of the inflammatory process, not only on the bowel wall, but also on other structures within the abdomen[6,8].

Unfortunately, endoscopy as well as the majority of the aforementioned radiological methods are not well tolerated by patients, because of the necessity for adequate bowel preparation and the increased risk of complications, especially when used during the acute phase of bowel inflammation[1,3,8,10].

Alternatively, several studies have demonstrated the reliability of scintigraphic imaging in the diagnosis and assessment of disease activity in IBD. In comparison with other modalities, they are non-invasive techniques and produce no patient discomfort related to instrumentation and preparation, they are not contraindicated in the acute phase and can visualize active disease both in the small and the large bowel[2,11]. Technetium-99m hexamethylpropylene amine oxime labelled white blood cells (Tc-99m HMPAO WBC) have been accepted widely as a reliable method for the diagnosis of IBD, assessment of disease activity

and treatment response[12-14]. Pentavalent Tc-99m dimercaptosuccinic acid [Tc-99m (V) DMSA] seems to be an accurate scintigraphic variant and has been suggested as a complementary technique to colonoscopy for the follow-up and assessment of disease activity[15-17]. Finally, fluorine-18 fluorodeoxyglucose (F-18 FDG) is a promising method for the detection of inflammation in the small and large bowel[18,19].

In this article, we review the current data and future prospects on the role of scintigraphy in diagnosis and evaluation of disease activity in patients with IBD.

THE ROLE OF NUCLEAR MEDICINE IN IBD

Nuclear medicine imaging has played a major role in the diagnosis and detection of inflammation, and has a wide availability of radiotracers. However, its contribution to the localization of small and large bowel pathology in IBD is still under investigation.

Indium-111 oxine labeled leukocytes

Indium-111 (In-111) oxine was the first agent used for *in vitro* leucocyte labeling[2]. The method has been validated by different research groups as a sensitive and specific test for the detection of active intestinal inflammation. However, the high radiation dose, limited availability and poor image quality comprise major disadvantages associated with In-111[2,11,13,14].

Recently, a dedicated whole-body counter has been proposed as an alternative technique to whole-body gamma-camera counting for quantification of disease activity in IBD. It relies on the assumption that all granulocytes migrating into the bowel wall in IBD do in fact end up in the feces, therefore In-111 retention in IBD patients is less compared to that in normal volunteers[20].

Tc-99m HMPAO labeled leukocytes

Tc-99m HMPAO has been used clinically as a cerebral perfusion agent. In 1986, Peters *et al*[21] used it as an alternative to leukocytes labeling and inflammation imaging. Since then, several groups have verified the utility of this imaging technique for IBD. The published data show that it provides a sensitivity of 95%-100%, a specificity of 85%-100% and an accuracy of 92%-100% in the detection, localization and assessment of disease activity. Therefore, its widespread acceptance has been based on the aforementioned favorable results and the advantages of Tc-99m, such as low radiation dose, availability, cost and superior image quality[2,22-24]. It plays an important role in the diagnosis of complications, assessment of disease activity and establishing the extent of small intestine affected. Moreover, it allows a true evaluation of inflammation activity, even during clinical remission or treatment response[2,23,24].

In 2007, Almer *et al*[25] compared leucocyte scintigraphy to intraoperative small bowel enteroscopy and laparotomy findings in CD. They confirmed the reliability of Tc-99m HMPAO WBC in the early diagnosis of small bowel inflammation, and proposed its utility as a first-line investigation modality, especially in children and vulnerable adults.

Despite the wide utility of Tc-99m HMPAO WBC in IBD, controversy still exists about the advantageous imaging time. Early scanning (30-60 min) has been recommended by some authors in order to avoid false positive results caused by intestinal migration of the radionuclide, whereas others favor late scanning because of higher sensitivity. Recently, Sans *et al*[24] have evaluated the optimal scanning sequence for identification of active disease, evaluation of IBD extent, and quantification of disease activity. They reported only slightly lower specificity but higher sensitivity (85% *vs* 100%) and accuracy (85% *vs* 95%) of late scanning (3 h) when compared to early scanning.

Various biomarkers of inflammation have been suggested in selecting patients with suspected IBD for white cell scanning. Given that C-reactive protein constitutes a reliable indicator for the evaluation of inflammatory activity in IBD, patients with $\geqslant$ 5 mg/L should be selected for white cell scanning in order to reduce the number of false negative results[26].

Alonso *et al*[27,28] have applied Tc-99m HMPAO WBC to patients with subclinical gut inflammation. This group studied patients with seronegative spondyloarthropathy without clinical evidence of IBD. They confirmed the utility of the method in the assessment of bowel inflammation, even if it remains subclinical. Moreover, they described a possible role of labeled leukocytes in identifying the patients who are suitable for therapy with sulfasalazine, and in assessing treatment effectiveness and disease relapse[27,28]. El Maghraoui *et al*[29] have certified the aforementioned results and demonstrated a statistically significant correlation between Tc-99m HMPAO-labeled leukocytes and ileocolonoscopy.

The usefulness of this technique in early detection of postoperative asymptomatic recurrence of CD has been suggested. Biancone *et al*[30] have demonstrated that, in patients with CD who had an ileocecal resection in the previous 6 mo, the perianastomotic 30 min Tc-99m HMPAO WBC uptake was significantly associated with disease recurrence.

The role of Tc-99m HMPAO-labeled leukocytes single photon emission computerized tomography (SPECT) in IBD has also been investigated. SPECT images provide accurate assessment of inflammation in both the small and large bowel and precise anatomical details of CD lesions. Moreover, they are independent of bone marrow activity, thus allowing detailed disease evaluation within the pelvis[31,32].

The aim of several groups has been to evaluate and compare the diagnostic accuracy of Tc-99m HMPAO-labeled leukocytes and CT in IBD. They have demonstrated the superiority of scintigraphy in detecting segmental inflammatory activity and proximal extension of bowel involvement. CT displays excellent suitability for the localization of fibrostenotic bowel disease and the recognition of complications, but has a four-fold higher radiation exposure[33-35].

Several studies have supported the utility of Tc-

Table 1 Summary of published studies evaluating the use of Tc-99m HMPAO WBC in IBD

Study	*n*	Study design	Sensitivity	Specificity
Adult population				
Sciarretta *et al*[23]	103	Known active CD compared with colonoscopy	95%	100%
Mairal *et al*[50]	27	Known IBD compared with In-111 HIG	100%	85%
Giaffer *et al*[13]	31	Suspected IBD compared with In-111 oxine labeled leukocytes	85% at 40 min 94% at 120 min	87% at 40 min 71% at 120 min
Kolkman *et al*[33]	32	Known IBD compared with CT	79% for CD 81% for UC	98% for CD 86% for UC
Molnár *et al*[34]	28	Known active CD compared with spiral CT	76.1%	91%
Almer *et al*[25]	48	Known active CD with small bowel inflammation compared with intraoperative small bowel enteroscopy and laparotomy findings	85%	81%
Pediatric population				
Charron *et al*[40]	215	Acute intestinal inflammation in patients with and without IBD	90%	97%
Cucchiara *et al*[38]	48	Suspected IBD compared with colonoscopy	76.2%	NA
Charron *et al*[42]	130	Exclude inflammation in suspected IBD compared with colonoscopy	94%	99%
Alberini *et al*[37]	28	Known IBD compared with endoscopy, ultrasonography and contrast radiology	75%	92%
Charron *et al*[35]	313	Known IBD compared with colonoscopy	92%	94%

NA: Not applicable; CD: Crohn's disease; CT: Computed tomography; IBD: Inflammatory bowel disease; UC: Ulcerative colitis.

99m HMPAO WBC in pediatric patients with IBD. They have suggested that labeled leukocytes cannot replace endoscopy for initial diagnosis but they do have a place in the decision for colonoscopy[36,37]. Patients with negative Tc-99m HMPAO WBC scans may avoid unnecessary colonoscopy. However, Cucchiara *et al*[38], after evaluating 48 children, have concluded that a positive test indicates the presence of inflammation but a negative result does not rule out inflammation, since the technique may miss cases with mild disease.

Moreover leukocytes scintigraphy can be considered a reference method for clarifying the extent of inflammation when colonoscopy is not completed successfully, or the findings in contrast radiography are negative[36,37,39]. Although SPECT allows the identification of additional involved segments over planar images, its performance in children seems to be rather difficult[37,40].

The accuracy of Tc-99m HMPAO WBC in differentiating continuous from discontinuous colitis has also been examined[37,41]. In 77 children with active CD, discontinuous uptake was revealed in 63, and among 29 children with ulcerative colitis (UC), continuous uptake was revealed in 23[41]. It should also play an important role in the follow-up of patients and it could be used as a diagnostic tool for assessing recurrence or response to therapy, thus reducing the need for repeated colonoscopy[36,37].

In a report by Charron *et al*[35], the accuracy of CT and Tc-99m HMPAO WBC scintigraphy versus colonoscopy in IBD has been compared. After evaluating 313 consecutive children who underwent a labeled leucocyte test and comparing with colonoscopy, the sensitivity of scintigraphy was 92%, specificity was 94%, positive predictive value was 96%, negative predictive value was 93% and accuracy was 94%. Tc-99m HMPAO WBC scan is unlikely to miss significant inflammation, while CT has lower sensitivity for detecting inflammation in the bowel wall. However, similar to the adult population, the incidence of complications detected by CT is higher than with scintigraphy[35].

Compared to other modalities, Tc-99m HMPAO WBC scintigraphy is non-invasive, practical, safe, rapid and has excellent diagnostic sensitivity (Figure 1). It requires no bowel preparation, causes no discomfort and exposes patients to less radiation, namely the effective radiation dose for Tc-99m HMPAO WBC imaging is 3 mSv, for barium small bowel follow-through, 6 mSv, and for barium enema, 8.5 mSv[36,39,40,42]. Additional important advantages are the ability to evaluate the small and the large bowel simultaneously and the superiority over small bowel follow-through and CT, in the initial screening and detection of inflammation in patients with IBD[35,36,42]. A concise form of the published data is presented in Table 1.

The high cost, time-consuming *in vitro* labeling procedure, radiation microdosimetry, as well as the handling and reinjection of blood constitute the main shortcomings of the procedure when compared to other scintigraphic modalities.

Tc-99m (V) DMSA

Tc-99m (V) DMSA is a tumor-seeking agent of low molecular weight developed in 1981. It has been used successfully in the scintigraphic diagnosis of various malignant tumors[43-47]. Moreover, it has been proven advantageous in the diagnosis of inflammatory diseases such as osteomyelitis, psoas muscle abscess, and bone and joint infection[48,49].

The mechanism of Tc-99m (V) DMSA localization in tumors and inflammation remains unclear. In some cases, it resembles the phosphate ion because it accumulates in lesions where calcification is present. However, the increased capillary permeability followed by infiltration of the radiotracer into the interstitial space seems to be the most probable mechanism of uptake in inflammatory lesions[16,17,48,49].

Tc-99m (V) DMSA scintigraphy requires no bowel preparation, no blood manipulation and causes no patient discomfort. Moreover it has a low cost, ideal physical characteristics, and simple preparation procedure from cold kits[15-17]. Its utility in the diagnosis

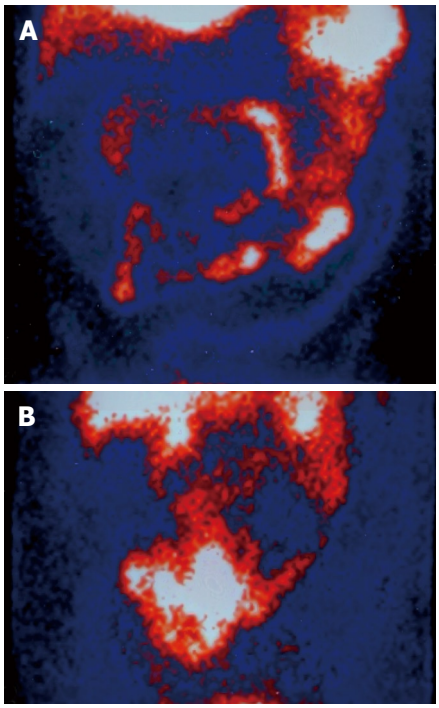

Figure 1 Tc-99m HMPAO WBC scintigram. A: Ulcerative colitis (UC) with intense inflammation of the entire large bowel; B: Crohn's disease (CD) with intense inflammation in the small bowel and the descending colon.

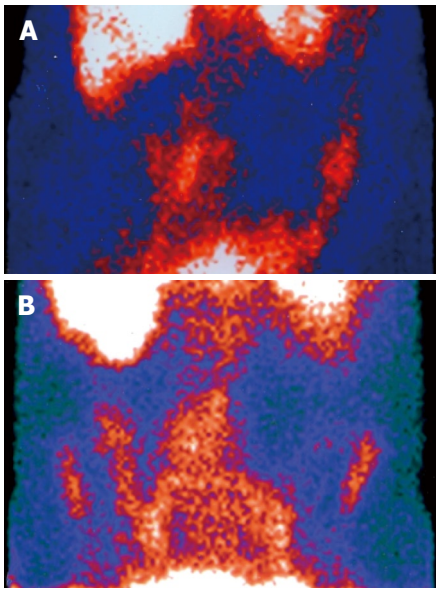

Figure 2 Tc-99m (V) DMSA scintigram. A: UC with intense inflammation mainly in the transverse and the descending colon; B: CD with intense inflammation of the terminal ileum and the ascending colon.

of inflammation combined with the aforementioned advantages have given a new impulse to research groups to evaluate its role in IBD.

In 2001, Lee *et al*[15] appraised the potential use of Tc-99m (V) DMSA scintigraphy in the detection and localization of intestinal inflammation. The study enrolled 62 patients with suspected intestinal inflammation, namely IBD, appendicitis, and antibiotic-associated, infective, eosinophilic and ischemic colitis. The scintigraphic findings were compared to colonoscopy and biopsy results. The overall sensitivity was 95%, specificity, 94%, and accuracy, 95%. The three false negative cases were attributed to a mild degree of inflammation. Findings were false positive in two cases as a result of coexisting active bleeding from the gastrointestinal tract and colonic adenocarcinoma, seen at colonoscopy with biopsy[15].

In 2003, Koutroubakis *et al*[16] evaluated the use of Tc-99m (V) DMSA for the assessment of disease activity in patients with IBD. They examined three groups of patients. The first group enrolled 36 patients who had an exacerbation of previously demonstrated disease or had a first attack of IBD. The second group included 28 patients who were in remission from IBD. The third group included 12 patients with miscellaneous bowel disease, namely ischemic, infectious or segmental colitis associated with diverticulosis. The scintigraphic findings were compared to colonoscopy and biopsy results. In the detection of active disease, the sensitivity was 92%, the specificity was 86%, the negative predictive value was 85.1% and the positive predictive value was 91.9%. A high correlation of the scintigraphic activity index with the endoscopic and histological inflammatory activity was found. Findings were false negative in three cases with active disease because of a mild degree of inflammation[16].

A direct comparison of Tc-99m (V) DMSA with Tc-99m HMPAO WBC scintigraphy in the evaluation of IBD has been undertaken by Stathaki *et al*[17] in 2008. The favorable results of the two previous studies, in combination with the advantages of the method, could establish it as an ideal alternative scintigraphic method. The study enrolled 23 patients who had an exacerbation of previously proven IBD or a first attack of the disease. Tc-99m (V) DMSA scintigraphy was performed after clinical and endoscopic confirmation of active disease and true positive labeled leucocyte scintigraphy. The full agreement among the scintigraphic modalities was 72.5%. The agreement among endoscopy and scintigraphy was 91.9% and 84.4% for Tc-99m HMPAO WBC and Tc-99m (V) DMSA, respectively. The overall sensitivity was 91% for Tc-99m HMPAO WBC and 84% for Tc-99m (V) DMSA. False negative results for Tc-99m (V) DMSA scintigraphy were seen in two patients with UC, probably because of a mild degree of bowel inflammation[17].

Data suggest that Tc-99m (V) DMSA scintigraphy provides a useful approach in the diagnosis of active disease and assessment of disease activity (Figure 2). Despite that, it cannot replace Tc-99m HMPAO WBC for the evaluation of disease localization. Probably, it is not the ideal method for the diagnosis of IBD but it has a place in the follow-up and assessment of disease activity, progression and treatment response[17]. A concise form of the published data is presented in Table 2.

Other radiotracers

A variety of radionuclides has been applied to IBD investigation. Some of them have not gained widespread clinical use because of limitations and disappointing results, while others seem to have a definite role.

Table 2 Summary of published studies evaluating the use of Tc-99m (V) DMSA in IBD

Study	*n*	Study design	Sensitivity (%)	Specificity (%)
Lee *et al*[15]	62	Intestinal inflammation compared with colonoscopy	95	94
Koutroubakis *et al*[16]	76	Active and inactive IBD compared with colonoscopy	92	86
Stathaki *et al*[17]	23	Active IBD compared with Tc-99m HMPAO WBC and colonoscopy	84	NA

In-111 or Tc-99m human polyclonal immunoglobulin (HIG) has been used in the diagnosis of inflammation and it has been evaluated in IBD. Comparative studies have demonstrated sensitivity, specificity and accuracy of 100%, 85% and 96%, respectively, for labeled leukocytes and 70%, 85% and 74% for In-111 HIG[50]. Tc-99m HIG scintigraphy had 33% sensitivity while Tc-99m HMPAO WBC imaging had 100% sensitivity in the detection of active IBD[51]. On the basis of these results, the role of In-111 HIG is confined to the diagnosis of inflammation only when there is no other alternative modality[50]. On the other hand, Tc-99m HIG has no role in the evaluation of patients with IBD[51].

In vivo specific labeling of granulocytes using Tc-99m labeled anti-granulocyte monoclonal antibodies (AGAb) comprises a different approach. They do not require leucocyte isolation, are stored as cold kits and can selectively label granulocytes. Different AGAb have been designed, among them BW 250/183 and Leukoscan[52-55]. Tc-99m BW 250/183 was found to be inferior to Tc-99m HMPAO WBC in the detection of small bowel involvement, although the accuracy between the two scintigraphic methods for the localization of disease in the large bowel was comparable[52]. With respect to Tc-99m Leukoscan, its diagnostic value in IBD is low[53,54]. However, a recent study by Kerry *et al*[55] has found that Tc-99m Leukoscan has higher sensitivity and specificity at 2 h (44% and 100% respectively) and 4 h (75% and 50% respectively) planar imaging compared to that in previous publications. SPECT images at 4 h showed additional areas of uptake, raising the sensitivity to a value similar to that of Tc-99m HMPAO WBC, namely 88%. Although sensitivity is high, the low specificity limits its application for the investigation of IBD[55].

Research groups have evaluated the role of AGAb imaging in pediatric patients with IBD. Bruno *et al*[56] have found that the overall sensitivity of Tc-99m BW 250/183 was 94% for CD and 85% for UC. Sensitivity of scintigraphy compared to colonoscopy, radiology and ultrasonography was 90%, 76%, 75% and 55%, respectively. However, it did not appear sufficiently specific in identifying clinical remission, probably because of the presence of tissue inflammation in about 50% of biopsy samples, although patients were considered to be in clinical remission and with negative colonoscopy. The authors have recommended Tc-99m BW 250/183 as a useful tool in the detection of intestinal inflammation in children and young patients with IBD. However, because of its low specificity, endoscopic and histological confirmation is mandatory for all positive cases[56]. The efficacy of Tc-99m Leukoscan has been evaluated in a small series of pediatric patients with IBD. The reported sensitivity per patient was 90% and per bowel segment, 57%. The latter was improved with the use of SPECT[57].

In 1984, Hanna *et al*[58] worked on the labeling of leukocytes with Tc-99m stannous colloid, and reported the clinical application of this new imaging modality in IBD. Despite its usefulness as an alternative when other agents are not available, the activation of leukocytes, which reduces the *in vivo* viability, constitutes a shortcoming[59]. Recently, its use in the initial evaluation of children with suspected IBD has been assessed. The combination of the reported results (sensitivity 88%, specificity 90%) and the aforesaid advantages support its utility in the initial assessment of childhood IBD[59].

The primary data on the role of In-111 anti E-selectin monoclonal antibodies are encouraging, given that it can identify areas of inflammation in CD and UC. Still, they are not supported sufficiently to gain acceptance in the field of IBD[60].

Positron emission tomography (PET)

PET with F-18 FDG is a functional imaging modality which identifies areas of increased glucose metabolism. It has been found to be effective in the evaluation of malignancies, inflammation and infection. Preliminary studies have shown favorable results in the assessment of disease activity in IBD[19].

In a small study of four patients with CD and two with UC, PET scanning demonstrated high radionuclide uptake in the inflamed segments, which had been detected on endoscopy and confirmed by histology. The potential utility of this non-invasive modality, as well as its usefulness for follow-up was suggested[61]. Neurath *et al*[18] have compared F-18 FDG, hydro-MRI and granulocyte scintigraphy with labeled antibodies (Tc-99m BW 250/183) in the detection of disease activity in 59 patients with CD. The sensitivity and specificity reported for F-18 FDG was 85% and 89%, for hydro-MRI, 67% and 93%, and for Tc-99m BW 250/183, 41% and 100%. It appears to be an accurate modality for detecting inflammation, considering that it allows a simultaneous non-invasive analysis of affected segments in both small and large bowel. Moreover, it is helpful in evaluating possible inflammatory activity in detected stenosis, which is important for its therapeutic application[18].

Recent studies have assessed the role of PET in the investigation of pediatric IBD. It diagnosed active disease in 80% of childhood cases with known IBD, and F-18 FDG uptake correlated with the endoscopic findings in 83.8% of the patients. PET recognized diseased segments that were not detected by other diagnostic methods, probably because of the limited accessibility at endoscopy. Moreover, it is the least invasive technique, can provide additional information to the diagnostic data obtained by other modalities, and exposes patients to

lower radiation doses[62]. Löffler *et al*[63], using histology as a reference standard, reported F-18 FDG PET sensitivity, specificity and accuracy to be 98%, 68% and 83%, respectively, for large bowel, and 100%, 86% and 90% for small bowel involvement. Based on these favorable results, the authors have recommended the inclusion of PET in the initial investigative algorithm for the evaluation of bowel inflammation and treatment response. On the other hand, its moderate specificity renders indispensable the endoscopic and histological confirmation of all positive cases[63].

Coupling CT to PET combines the functional data obtained from PET with the anatomical data provided by CT. Its role in the detection and localization of disease activity in IBD has been evaluated. In a pilot study, Meisner *et al*[64] have validated the results of previous reports concerning the role of PET in IBD, and they have investigated the use of sequential CT. In most cases, the simultaneous transaction of CT was not essential but it allowed better anatomical analysis in patients who had been surgically treated, and in those with inflammation of the small bowel. There was a high correlation between PET activity and disease activity, as determined by other currently used modalities[64].

Louis *et al*[65] have similarly concluded that coupling PET with CT allows a more accurate anatomical identification and evaluation of F-18 FDG uptake, and it gives more morphological information, namely, the presence of strictures. The technique can detect almost all bowel segments with moderate and severe lesions and a significant proportion with only mild lesions. Of great scientific interest were the combined findings of increased F-18 FDG uptake and bowel wall thickening in PET/CT, which were observed in some segments without endoscopic evidence of lesions. One explanation might be the detection of active disease deeper in the bowel wall, which is an additional benefit of this diagnostic modality[65].

Recently, the role of PET/CT in patients with UC in remission has been evaluated. Although clinical remission was strictly defined, four out of the 10 patients who participated in the study had increased F-18 FDG uptake in the colon. This may be explained by the presence of asymptomatic inflammation, attributed to chronic low-grade activity or to the succession of flare and quiescence. The possibility of representing a normal variant or a false positive result could not be excluded. This finding necessitates further understanding of disease remission. The authors have suggested that PET/CT is a highly sensitive method, however, future studies will define its precise role among all available diagnostic modalities in disease evaluation and treatment monitoring[66].

At present, published data have suggested a high diagnostic value of F-18 FDG PET alone or PET/CT in adult and pediatric patients with IBD. However, the physiological distribution of the radionuclide, mainly in the urinary tract, and to a minor degree in the gastrointestinal tract, may compromise abdominal PET imaging of patients with IBD. In order to avoid any false results, the utility of quantitative analysis using the standardized uptake value (SUV) has been suggested. A cutoff RSUV (ratio between SUV of inflamed bowel and SUV of liver) value of 1.47 seems to be reliable for the identification of areas with significant bowel inflammation[19]. Recently, various methods of labeling leukocytes with F-18 FDG have been reported. F-18 FDG WBC are taken up in the reticuloendothelial tissue and follow the normal leukocyte distribution *in vivo*. Its role as a method for non-invasive quantification of IBD has been evaluated mainly in animal models[67]. The localization of the inflammatory process and the degree of tracer uptake are correlated with the endoscopic and histological findings. In the future, the method may be useful in determining the cause of pathological abdominopelvic tracer uptake, namely, inflammation *versus* malignancy. These are preliminary results that require further investigation in humans[67].

CONCLUSION

In this review, we have presented the role and the future prospects of nuclear medicine in IBD. Although it has no primary role in the diagnosis, it might be considered when colonoscopy is not completed successfully or other imaging modalities are negative. However, its contribution to the assessment of disease extent and activity, monitoring treatment response, and differentiating between active CD and UC is well established. Tc-99m HMPAO WBC have gain widespread clinical use while Tc-99m (V) DMSA seems to provide an accurate scintigraphic variant and a complementary technique to colonoscopy for follow-up and assessment of disease activity. The preliminary results on the role of F-18 FDG PET or PET/CT in the diagnosis and follow up of patients with IBD are encouraging. F-18 FDG WBC seem to be a promising future prospect, given that they can differentiate between the cause of pathological tracer uptake, namely, inflammation *versus* malignancy. Further investigation is essential in order to verify all the aforementioned favorable preliminary results.

Abstract

Helicobacter pylori (*H pylori*) infection is a leading world-wide infectious disease as it affects more than half of the world population and causes chronic gastritis, peptic ulcer disease and gastric malignancies. The infection elicits a chronic cellular inflammatory response in the gastric mucosa. However, the effects of this local inflammation may not be confined solely to the digestive tract but may spread to involve extra-intestinal tissues and/or organs. Indeed, *H pylori* infection has been epidemiologically linked to extra-digestive conditions and diseases. In this context, it has been speculated that *H pylori* infection may be responsible for various endocrine disorders, such as autoimmune thyroid diseases, diabetes mellitus, dyslipidemia, obesity, osteoporosis and primary hyperparathyroidism. This is a review of the relationship between *H pylori* infection and these endocrine disorders.

Key words: *Helicobacter pylori*; Hormones; Thyroid; Osteoporosis; Diabetes; Dyslipidemia

INTRODUCTION

Helicobacter pylori (*H pylori*) is a gram-negative, spiral-shaped pathogenic bacterium that specifically colonizes the gastric epithelium and causes chronic gastritis, peptic ulcer disease and/or gastric malignancies[1,2]. The infection induces an acute polymorphonuclear infiltration in the gastric mucosa. If the infection is not effectively cleared, this acute cellular infiltrate is gradually replaced by an immunologically-mediated, chronic, predominantly mononuclear cellular infiltrate[3]. The latter is characterized by the local production and systemic diffusion of pro-inflammatory cytokines[4], which may exert their effect in remote tissues and organic systems[5]. As a result, *H pylori* infection has been epidemiologically linked to some extra-digestive conditions, including endocrine disorders (Table 1), although there are contradictory data regarding the relationship between *H pylori* infection and these diseases.

H pylori AND DIABETES MELLITUS

The relationship between diabetes mellitus (DM) and *H pylori* infection is controversial. According to some studies there is a high prevalence of *H pylori* infection in patients with either type I [6-9] or type II DM[10-13] which is correlated with the duration of DM[7,9], the presence of dyspeptic symptoms[13,14] and cardiovascular autonomic neuropathy[13,15], age[6,8], gender[16], body mass index (BMI)[16], blood pressure[16], fasting glucose[16] and the HbA1c levels[16]. In particular, the prevalence of *H pylori* infection was found to be higher in obese, female, middle-aged patients with a long standing DM, dyspeptic symptoms, cardiovascular autonomic neuropathy and increased blood pressure, fasting glucose levels and HbA1c values[6-9,13-16]. This could be related to a reduced gastric motility and peristaltic activity[10], various chemical changes in gastric mucosa following non-enzymatic glycosylation processes[10] and an impaired non-specific immunity observed in diabetic patients[11].

In contrast, other studies showed that *H pylori* infection is not associated with DM, as there is no

difference in the prevalence of *H pylori* infection between diabetics and non-diabetics[17], regardless of the type[8,17-22] and duration of DM[18,19,22] and/or severity of dyspeptic symptoms in patients with DM[22]. The presence of micro-angiopathy in patients with DM may be a negative factor for colonization by *H pylori*, because micro-vascular changes in the gastric mucosa may create an unfavourable environment for the establishment or survival of *H pylori*[16]. Interestingly, one study even showed a lower sero-prevalence of *H pylori* in patients with DM, in comparison with the healthy population[23], while another showed a significantly lower incidence of *H pylori* infection in diabetics with active duodenal ulceration, as compared with non-diabetics[24].

The relationship between gastrointestinal symptoms in DM and *H pylori* infection is also controversial. According to some studies, there is no difference between diabetics and non-diabetics concerning the prevalence of *H pylori*-related gastro-duodenal disorders[17]. Moreover, *H pylori* infection was not associated with either delayed gastric emptying[9,25] or upper gastrointestinal symptoms in DM[19,21,25]. On the other hand, a high prevalence of esophagitis and peptic ulcer was found in *H pylori*+ve patients with DM, with or without dyspepsia, especially those with cardiovascular autonomic neuropathy[13,15] suggesting that this population should be considered as "high risk" for *H pylori* infection and suitable candidates for treatment[12]. In addition, some data demonstrated a higher prevalence of *H pylori* infection in diabetic patients with dyspepsia[14,26], reactive gastritis[27] and chronic gastritis[26] compared to those with no signs or symptoms of gastrointestinal disease.

The relationship between DM complications and *H pylori* infection is another issue which is contentious and deserves further investigation, as only few data are available. According to some data there is no relationship between *H pylori* infection and diabetic complications, such as nephropathy[13], retinopathy[13], and/or micro-angiopathy[16] while other data shows that virulent strains of *H pylori*, such as cytotoxin-associated gene $CagA^+$, are associated with macro-angiopathy[16], neuropathy[16] and micro-albuminuria in type Ⅱ diabetic patients, maybe due to an immuno-mediated injury at the level of the endothelium, caused by a systemic immune response to the infection, leading to albumin leakage[28]. Additionally, some data indicate a possible association of *H pylori* infection and the development of coronary heart disease, thrombo-occlusive cerebral disease, or both, in diabetic patients[29].

One point on which all studies seem to converge is that the effectiveness of eradication regimens for *H pylori* infection is significantly lower in diabetics than in non-diabetics[20,30-32] whereas re-infection rates seem to be higher, especially in patients with type Ⅱ DM compared to the general population[20,31]. This may be due to changes in the gastric microvasculature leading to reduced absorption of antibiotics. Alternatively, frequent antibiotic use in diabetics may result in the development of resistant *H pylori* strains[30,32]. Moreover, type I diabetic patients achieve lower *H pylori* eradication rates on standard triple therapy than non-insulin-dependent diabetic subjects, regardless of the dosage and/or the duration of therapy[20,31,32], and higher re-infection rates one year after eradication of *H pylori* compared with control subjects[33]. Quadruple therapies seem to cure a large percentage of patients who fail first-line therapy, although this is accompanied by a greater incidence of minor side effects[20,31]. These data suggest that vaccine development seems to be the only effective long term treatment for patients with DM[20].

Noteworthy is the observation that children with type I DM and *H pylori* infection had an increased daily insulin requirement compared with their uninfected peers[34]. Finally, several issues, such as the role of *H pylori* in etiopathogenesis of DM and the influence of *H pylori* eradication on the control of DM, remain to be elucidated.

Table 1 Endocrine disorders in relationship with *H pylori* infection

Endocrine disorders
Autoimmune thyroid diseases
Autoimmune atrophic thyroiditis
Hashimoto's thyroiditis
Thyroid mucosal associated lymphocyte tissue (MALT) lymphoma
Diabetes mellitus
Dyslipidemia
Obesity
Osteoporosis
Primary hyperparathyroidism

H pylori AND OSTEOPOROSIS

There are limited data regarding the association between *H pylori* infection and osteoporosis. According to one study, *H pylori* infection was not accompanied by significant changes in levels of markers of bone metabolism in children, such as estradiol, parathyroid hormone (PTH), cross-linked collagen I carboxy terminal telopeptide, total alkaline phosphatase (ALP), bone-specific ALP, N-terminal cross-links of human pro-collagen type I , osteocalcin, calcium and phosphate[35]. In another study, infection by $CagA^+$ *H pylori* strains was more prevalent in men with osteoporosis compared to the general population, who showed reduced systemic levels of estrogens and increased bone turnover[36]. *H pylori* infection by $CagA^+$ strains may therefore be considered a risk factor for osteoporosis in men[36]. Further studies are required to clarify the relationship between *H pylori* infection and osteoporosis and whether *H pylori* infection causes time-dependent changes in bone turnover markers during the long course of this chronic inflammatory disease.

H pylori AND HYPERPARATHYROIDISM

There are only a few studies attempting to clarify the association between *H pylori* infection and hyperparathyroidism. In fact, only one study showed that *H pylori* infection was more prevalent amongst patients with primary hyperparathyroidism (PHPT) than in the

general population, suggesting that patients with PHPT, and especially those with dyspeptic symptoms, should be evaluated for *H pylori* infection and treated appropriately if positive[37]. Also, a case report described an association of PHPT with duodenal ulcer and *H pylori* infection[38]. On the other hand, another study claimed no significant relationship between parathyroid abnormalities and *H pylori* infection in haemodialysis patients and this study found that a longer period of dialysis therapy was related to a decreased ability of these patients to produce antibodies against *H pylori*[39].

H pylori AND OBESITY

The relationship between obesity and *H pylori* infection is controversial. According to some studies, the risk of *H pylori* infection does not increase in overweight young persons[40] and *H pylori* seropositivity or CagA antibody status are not associated with the BMI[41,42] or fasting serum leptin levels[41]. Furthermore, one study indicated an inverse relationship between morbid obesity and *H pylori* seropositivity, leading to the hypothesis that the absence of *H pylori* infection during childhood may enhance the risk of the development of morbid obesity[43]. In contrast, other studies showed that obesity[10] and/or an elevation of the BMI[44] may be associated with an increased incidence of *H pylori* colonization, probably as a result of reduced gastric motility[10]. In addition, the incidence of *H pylori* infection in patients undergoing Roux-en-Y gastric bypass surgery for morbid obesity was higher than that found in all patients undergoing endoscopies and biopsy, even though the incidence of infection was not higher in controls matched for age[45].

The relationship between obesity and *H pylori* eradication is also controversial. There are data which demonstrate that eradication of *H pylori* significantly increases the incidence of obesity in patients with peptic ulcer disease, since it increases the level of BMI[46,47], and/or enhances the appetite of asymptomatic patients, due to an elevation of plasma ghrelin[48] and a reduction of leptin levels[49,50]. In fact, *H pylori* infection caused a marked reduction in plasma levels of ghrelin[44,49,51-53], as a result of a negative effect of this infection on the density of gastric ghrelin-positive cells[51,54] and an increase in plasma levels of leptin and gastrin[49,55,56]. Since ghrelin exerts orexigenic and adipogenic effects in contrast to leptin which exerts anorexigenic effects[52], alterations in plasma levels of gastric originated appetite-controlling hormones in children and adults infected by *H pylori* may contribute to chronic dyspepsia and loss of appetite[49]. Consequently, *H pylori* can be a "protective" factor against the development of becoming overweight[50]. In contrast, other studies showed that there are no differences in plasma ghrelin levels between *H pylori*+ve and *H pylori*-ve patients matched for age and BMI[57] and that successful eradication of *H pylori* had no effect on plasma ghrelin levels[44,57].

H pylori AND THYROID DISEASES

There have been controversial reports linking *H pylori* infection to thyroid disorders including autoimmune thyroid disorders (ATD) such as autoimmune atrophic thyroiditis[58] and Hashimoto's thyroiditis[59], or thyroid mucosal associated lymphocyte tissue (MALT) lymphoma[60].

Thus, some studies have reported an increased prevalence of *H pylori* infection in adults[58,61,62] and children[63] with ATD and a relationship between *H pylori* infection and the presence of high titers of thyroid auto-antibodies, such as anti-thyroglobulin (anti-Tg) and anti-thyroperoxidase (anti-TPO) antibodies[58,61,62] resulting in abnormalities of gastric secretory function[58]. It has also been suggested that CagA$^+$ *H pylori* strains increase the risk for ATD, especially in women, and that they are involved in the pathogenesis of Hashimoto's thyroiditis. This is based on the detection of monoclonal antibodies against Cag-A$^+$ *H pylori* strains which cross-react with follicular cells of the thyroid gland and also on the fact that *H pylori* strains possessing the Cag-A pathogenicity island carry a gene encoding for an endogenous peroxidase[61]. Moreover, the strong correlation between IgG anti-*H pylori* antibodies and thyroid auto-antibodies, as well as the observation that eradication of *H pylori* infection is followed by a gradual decrease in the levels of thyroid auto-antibodies[64], suggest that *H pylori* antigens might be involved in the development of autoimmune atrophic thyroiditis or that autoimmune function in this disease may increase the likelihood of *H pylori* infection[58]. One study showed a significant decrease of Free-T_3 and Free-T_4 in *H pylori*+ve subjects compared to *H pylori*-ve controls[62].

On the contrary, other studies showed no differences in the serum levels of thyroid hormones or thyroid auto-antibodies in patients with and without *H pylori* infection[59,65] whereas *H pylori* infection seemed not to increase the risk of ATD in individuals with dyspeptic symptoms[65]. Taking these results into account, it was proposed that screening for ATD in patients with a positive urea breath test is not indicated[65]. Other studies have failed to show any correlation between *H pylori* infection and ATD in children[66]. Moreover, the similar prevalence of *H pylori* infection, with or without CagA$^+$ strains, in patients with Hashimoto's thyroiditis and controls argues against a true association between *H pylori* infection and Hashimoto's thyroiditis[59]. To further explore the relationship between ATD and *H pylori* infection more clinical trials are required.

Lymphoid follicles in the gastric mucosa are common in ATD, and *H pylori* infection plays a causative role[67]. When an autoimmune disease such as ATD coexists with *H pylori* infection[68], *H pylori* may be involved in the pathogenesis of extra-gastric MALT lymphomas, such as thyroid MALT lymphoma, as shown by a case report describing a primary thyroid MALT lymphoma which occurred in an *H pylori*+ve patient with gastric cancer and Hashimoto's thyroiditis[60]. In this case, after subtotal gastrectomy, the thyroid lymphoma became smaller transiently and when the patient was treated with *H pylori* eradication therapy, the lymphoma completely disappeared. Nevertheless, *H pylori* organisms were not detected in the thyroid lymphoma tissue by polymerase

chain reaction (PCR), questioning the role of *H pylori* in the development of extra-gastric MALT lymphoma in patients with an autoimmune disease[60]. In addition, one study suggested that patients with an autoimmune disease might not be optimal candidates for *H pylori* eradication, even in the case of an early stage gastric MALT lymphoma, since very few of these patients responded to an *H pylori* eradication therapy[68].

On the other hand, it is important to realize that patients with *H pylori*-related gastritis, atrophic gastritis, or both conditions required increased daily doses of T_4 than controls, suggesting that normal gastric acid secretion is necessary for effective absorption of oral T_4[69]. In addition, development of *H pylori* infection in patients treated with T_4 led to an increased serum level of thyrotropin (TSH), an effect that was nearly reversed after eradication of *H pylori* infection[69].

H pylori AND DYSLIPIDEMIA

H pylori infection may cause dyslipidemia, as it leads to elevated levels of total cholesterol[70,71], low-density lipoprotein cholesterol (LDL-c)[71,72], lipoprotein Lp(a)[71], apolipoprotein apo-B[73], triglyceride concentrations[72,74,75] and decreased levels of high-density lipoprotein cholesterol (HDL-c)[73-78] and apolipoprotein apoA-1 concentration in the blood[73,75]. In addition, plasma levels of cholesterol and LDL-c were significantly higher in *H pylori*+ve patients with ischemic stroke compared to *H pylori*-ve patients[70]. It was postulated that chronic *H pylori* infection may shift lipid profiles towards an atherogenic direction *via* the action of pro-inflammatory cytokines, such as interleukins 1 and 6 (IL-1 and IL-6), interferon-α (INF-α) and tumour necrosis factor-α (TNF-α). These cytokines are capable of affecting lipid metabolism in different ways, including activation of adipose tissue lipoprotein lipase, stimulation of hepatic fatty acid synthesis and influencing lipolysis[71,79]. This atherogenic modified lipid profile created by *H pylori* infection may increase the risk for cardiovascular and cerebrovascular diseases, by participating in the process of atherogenesis, especially when Cag-A^+ cytotoxic strains of *H pylori* are present[80,81], although other studies do not support this hypothesis[71,82,83].

According to other studies, *H pylori* infection did not cause any significant changes in plasma levels of total cholesterol[78,84], triglycerides[78,84], LDL-c[78,84] and Apo-B[78,85].

The relationship between dyslipidemia and *H pylori* eradication is also controversial. After one year of eradication of *H pylori* in patients with duodenal ulcers, a significant increase of HDL-c, apo-AI and apo-AII levels was observed in the study by Scharnagl *et al*[86]. Moreover, eradication of *H pylori* in healthy subjects seems to increase HDL-c and decrease LDL-c levels[78]. Also, 6 mo following successful eradication of *H pylori* infection the plasma levels of total cholesterol and LDL-c were found to be significantly lower than those in *H pylori*+ve controls and *H pylori*+ve patients with stroke[70].

In contrast, one study showed that eradication of *H pylori* is associated with minor lipid changes[84], while others showed a significant increase in the incidence of hyperlipidemia in patients with peptic ulcer disease, as serum total cholesterol and triglycerides were elevated in these patients after eradication of *H pylori*[46,47,87].

Table 2 Endocrine disorders and eradication of *H pylori*

Endocrine disorders	*H pylori* eradication
Autoimmune thyroid diseases	↓ of thyroid auto-antibodies[64] ↓ of thyrotropin in *H pylori*+ve patients treated with T4[69]
Diabetes mellitus	↓ in diabetics more than in non-diabetics[20,30-32] ↓ in type I diabetic patients on standard triple therapy more than non-insulin dependent diabetic subjects, regardless of the dosage and/or the duration of therapy[20,31,32]
Dyslipidemia	↑ of HDL-c, apo-AI and apo-AII levels in patients with duodenal ulcers, after 1 year[86] ↑ of HDL-c and ↓ LDL-c levels in healthy subjects[78] ↓ of total cholesterol and LDL-c after 6 mo in *H pylori*+ve controls and *H pylori*+ve patients with stroke[70] ↔ of lipids in patients submitted for endoscopy[84] ↑ of total cholesterol and triglycerides in patients with peptic ulcer disease[46,47] or without[87]
Obesity	↑ of BMI in patients with peptic ulcer disease[46,47] ↑ of the appetite of asymptomatic patients, due to ↑ of plasma ghrelin[48] and ↓ of leptin levels[49,50] ↔ of plasma ghrelin levels in subjects referred for upper gastrointestinal endoscopy[44,57]

BMI: Body mass index; HDL-c: High-density lipoprotein cholesterol; apo-AI: Apolipoprotein AI; apo-AII: Apolipoprotein AII; LDL-c: Low-density lipoprotein cholesterol; +ve: Positive.

CONCLUSION

Since the discovery of *H pylori*, a variety of studies, essentially epidemiological or therapeutic trials, case reports and others, have evaluated the potential direct or indirect involvement of this bacterium in the pathogenesis of various extra-gastric diseases or disorders, amongst them disorders of the endocrine system. A critical review of data published on these proposed associations suggests a strong link between dyslipidemia and *H pylori* infection, whereas increasing evidence emerges on the role of *H pylori* infection in thyroid autoimmune diseases. On the contrary, the association between *H pylori* infection and obesity, PHPT, DM and osteoporosis remains controversial, as evidence is hindered by the small numbers and methodological problems. Therefore, these associations should be interpreted cautiously. Although some evidence suggests that eradication of *H pylori* may lead to an improvement of many endocrine disorders, such as DM, dyslipidemia and autoimmune thyroid disease, excluding obesity (Table 2), more clinical trials are needed in order to confirm this beneficial effect. In conclusion, the causal association between *H pylori* infection and endocrine disorders is still controversial but worthy of further investigation since these diseases affect many people and have a great impact on human health and health economics[88].

Abstract

AIM: To clarify the clinicopathological characteristics of small and large early invasive colorectal cancers (EI-CRCs), and to determine whether malignancy grade depends on size.

METHODS: A total of 583 consecutive EI-CRCs treated by endoscopic mucosal resection or surgery at the National Cancer Center Hospital between 1980 and 2004 were enrolled in this study. Lesions were classified into two groups based on size: small (≤ 10 mm) and large (> 10 mm). Clinicopathological features, incidence of lymph node metastasis (LNM) and risk factors for LNM, such as depth of invasion, lymphovascular invasion (LVI) and poorly differentiated adenocarcinoma (PDA) were analyzed in all resected specimens.

RESULTS: There were 120 (21%) small and 463 (79%) large lesions. Histopathological analysis of the small lesion group revealed submucosal deep cancer (sm: ≥ 1000 μm) in 90 (75%) cases, LVI in 26 (22%) cases, and PDA in 12 (10%) cases. Similarly, the large lesion group exhibited submucosal deep cancer in 380 (82%) cases, LVI in 125 (27%) cases, and PDA in 79 (17%) cases. The rate of LNM was 11.2% and 12.1% in the small and large lesion groups, respectively.

CONCLUSION: Small EI-CRC demonstrated the same aggressiveness and malignant potential as large cancer.

Key words: Colorectal cancer; Submucosal invasion; Lymph node metastasis; Endoscopic mucosal resection

INTRODUCTION

Colorectal cancer (CRC) is the third most important cause of cancer mortality in Japan, and its incidence is gradually increasing. To reduce CRC mortality, early detection and appropriate treatment are required. In general, small lesions are suspected of having a lower malignant potential than large ones, and hence are easy to remove endoscopically. Several authors have reported that the malignant potential of early invasive colorectal cancer (EI-CRC) increases with lesion size[1-3]. Therefore, lesion size is considered to be indicative of the depth of invasion and presence of lymph node metastasis (LNM). In contrast, flat, and in particular depressed lesions, are considered to have a tendency to invade rapidly the submucosal layer, even when small[4-6]. However, clinicopathological features of small EI-CRCs have still

not been studied extensively.

The aim of this retrospective study was to clarify the clinicopathological characteristics of small and large EI-CRCs and their implications for endoscopic treatment.

MATERIALS AND METHODS

Subjects

Five hundred and eighty-three patients (374 male and 209 female) with EI-CRC that had been resected surgically or endoscopically at the National Cancer Center Hospital, between January 1980 and January 2004, were examined retrospectively. In all of these patients, cancer cells invaded through the muscularis mucosa into the submucosal layer but did not extend deeply into the muscularis propria. Eligibility also required the lesions to be macroscopically non-pedunculated (sessile, flat and depressed). Patients with synchronous advanced CRC, multiple EI-CRCs, inflammatory bowel disease, hereditary non-polyposis colorectal cancer and familial adenomatous polyposis were excluded from the study.

Methods

All lesions were classified into two groups according to their endoscopic image size: small (≤ 10 mm) and large (> 10 mm). Furthermore, lesions were classified into three categories (sessile, 0- Ⅰs, Ⅰs+Ⅱa; flat, 0-Ⅱa; and depressed, 0-Ⅱc, Ⅱa+Ⅱc, Ⅰs+Ⅱc) according to the Paris classification[7]. Clinicopathological features, incidence of LNM and risk factors for LNM, such as depth of invasion, lymphovascular invasion (LVI) and poorly differentiated adenocarcinoma (PDA) were analyzed in all resected specimens.

Histopathology

Resected specimens were fixed in 10% formalin and examined histopathologically following hematoxylin and eosin staining. Histopathological diagnosis was based on the World Health Organization (WHO) criteria[8]. Submucosal invasion was measured from the muscularis mucosa to the deepest portion. When the muscularis mucosa could not be identified because of cancer invasion, the vertical length was measured from the surface of the lesion to the deepest portion according to Kitajima's classification[9]. Tumors with a vertical length of < 1000 μm in the submucosal layer were classified as submucosal superficial invasive cancers (sm-superficial), and lesions with a length ≥ 1000 μm were classified as submucosal deep invasive cancers (sm-deep). The tumor growth patterns were histopathologically divided into polypoid growth (PG) and non-polypoid growth (NPG) types. Shimoda *et al*[10] have reported polyp cancers with protrusions caused by intramucosal proliferation of the carcinoma or coexistent adenoma that behaved as PG type carcinoma, while flat/depressed type carcinoma without polypoid proliferation of intramucosal tumor behaved as NPG type carcinoma.

Statistical analysis

The significance of differences in proportions was assessed by the χ^2 test, Fisher's exact test and the Wilcoxon matched-pairs signed-ranks test using SPSS statistical software (SPSS for Windows , version 16.0J, Tokyo, Japan). Statistical significance was defined as $P < 0.05$.

RESULTS

A total of 583 EI-CRCs were retrospectively evaluated, with 120 (21%) small and 463 (79%) large lesions identified (Table 1). The gender ratio (male/female) was 2.4 and 1.7, and the mean age was 61.5 and 62.4 years in the small and large lesion groups, respectively. Mean size of the small and large lesions was 8.3 and 22.1 mm, respectively.

Macroscopic type, growth type and location

Macroscopic assessment of small lesions identified 51 cases as sessile (42%), 14 as flat (12%), and 55 as depressed (46%). Similarly, large lesion groups comprised 233 sessile (50%), 64 flat (14%), and 166 depressed (36%) type. PG types were identified in 32% (38/120) and 54% (250/463) of small and large lesions, respectively. In contrast, the prevalence of NPG type in the small lesion group was significantly higher than in the large lesion group (68% *vs* 46%, $P < 0.0001$). Regarding tumor location, there were 33 (27%) rectal, 56 (47%) distal colon and 31 (26%) proximal colon cancers in the small lesion group. In contrast, there were 213 (46%) rectal, 139 (30%) distal colon and 111 (24%) proximal cancers in the large lesion group. The incidence of rectal cancer in the large lesion group was significantly higher than in the small lesion group ($P = 0.02$).

LNM

Among the lesions treated surgically, the incidence of LNM was 11.2% (10/89) and 12.1% (46/381) in small and large lesion groups, respectively ($P = 0.85$) (Table 2).

Depth of invasion/LVI/PDA

Histopathological analysis of the small lesion group revealed sm-deep cancer in 90 (75%) cases, LVI in 26 (22%) and PDA in 12 (10%). Similarly, the large lesion group exhibited sm-deep cancer in 380 (82%) cases, LVI in 125 (27%), and PDA in 79 (17%). Therefore, in relation to depth of invasion, LVI and PDA, there were no significant differences between the groups.

Treatment strategy

Among the small lesion group, 62 (52%) cases were initially treated with endoscopic mucosal resection (EMR), while 58 (48%) cases were surgically resected. In contrast, among the large lesion group, 133 (29%) cases were initially treated with EMR, while 330 (71%) cases were surgically resected. Among all lesions treated by EMR, there were no differences in the rate of positive and unknown vertical and/or lateral cut margins in the small (18%, 11/62) and large lesion groups (20%, 26/133). Furthermore, among all positive cut margin cases in the small and large lesion groups, there were 11 (100%) and 18 (69%) positive vertical margin cases (Table 3, Figures 1 and 2).

Table 1 Comparison of clinicopathological and endoscopic characteristics for 583 study cases

	Small (≤ 10 mm)	Large (> 10 mm)	*P* value
No. of lesions, *n* (%)	120 (21)	463 (79)	
Gender (M/F)	85/35	289/174	0.09
Age (yr), mean (range)	61.5 (39-84)	62.4 (30-90)	0.86

Table 3 Comparison of treatment strategy and positive rate of cut margin *n* (%)

	Small (≤ 10 mm)	Large (> 10 mm)	*P* value
Initial treatment			
EMR	62 (52)	133 (29)	< 0.0001
Surgery	58 (48)	330 (71)	
Positive rate of cut margin[1]	11 (18)	26 (20)	0.81
In EMR cases			
Lateral	0 (0)	8 (31)	0.08
Vertical	11 (100)	18 (69)	

[1]Positive and unknown cut margin. EMR: Endoscopic mucosal resection.

According to the initial treatment, there were 134 (69%) and 336 (87%) sm-deep cancers in the EMR and surgery groups, respectively. Furthermore, there were 33 (17%) and 118 (30%) LVI-positive, and 18 (9%) and 73 (19%) PDA-positive cases in the EMR and surgery groups, respectively. There were 37 (19%) positive cut margin cases, including 29 (78%) positive vertical margins in the EMR group. In contrast, there were no positive cut margin cases in the surgery group. In the EMR group, 82 (42%) patients underwent additional surgery with LN dissection after EMR within 6 mo. The incidence of LNM was 11.0% (9/82) and 12.1% (47/388) in the EMR and surgery groups, respectively ($P = 0.79$) (Table 4).

DISCUSSION

Several authors have reported a strong association between lesion size and submucosal invasion or risk of LNM when referring to the grade of malignancy of early CRC. Large lesion size has been considered an indicator of deep submucosal invasion and presence of LNM. However, in this large retrospective study, small EI-CRC demonstrated a similar aggressive behavior and malignant potential to those of large lesions, with a similar risk of LNM , LVI and PDA among both groups.

Intramucosal CRC is thought generally to have no potential for LNM. In contrast, it has been reported that

Table 2 Incidence of LNM and clinicopathological characteristics based on tumor size *n* (%)

	Small (≤ 10 mm)	Large (> 10 mm)	*P* value
LNM	10/89 (11.2)	46/381 (12.1)	0.85
Depth of invasion			
sm-superficial (< 1000 μm)	30 (25)	83 (18)	0.08
sm-deep (≥ 1000 μm)	90 (75)	380 (82)	
LVI	26 (22)	125 (27)	0.23
PDA	12 (10)	79 (17)	0.06

LVI: Lymphovascular invasion; PDA: Poorly differentiated adenocarcinoma; LNM: Lymph node metastasis.

Table 4 Comparison of clinicopathological characteristics and incidence of LNM based on the treatment strategy *n* (%)

	EMR (*n* = 195)	Surgery (*n* = 388)	*P* value
Depth of invasion			
sm-superficial (< 1000 μm)	61 (32)	52 (13)	< 0.0001
sm-deep (≥ 1000 μm)	134 (69)	336 (87)

[1]Positive and unknown cut margin.

LNM occurs in 6%-13% of patients with submucosal invasive CRC[11-15]. Therefore, radical surgery with LN dissection is recommended strongly in these cases. At present, EMR provides an endoscopic cure of early stage CRC when there is no risk of LNM. Advances in endoscopic instruments and techniques have increased the detection rates of early stage CRC and have expanded the indications for EMR[16].

In the past 20 years, many investigators have proposed the following histopathological criteria when considering additional surgery after EMR of submucosal cancers: massive submucosal invasion (≥ 1000 μm), and/or LVI, and/or PDA[17-22]. Among these factors, LVI and PDA are impossible to predict before resection. At this point, it is crucial to predict the vertical depth of invasion of submucosal cancers prior to EMR. In our center, we use routinely a magnifying colonoscope to decide on the adequate treatment of early stage CRC. Magnifying chromoendoscopy (MCE) is a standardized validated method that facilitates detailed analysis of the morphological architecture of colonic mucosal crypt orifices (pit pattern), in a simple and rapid manner. We have reported previously the efficacy of MCE to diagnose an invasive pattern as a typical finding of sm-deep cancers, and have demonstrated that it provides a good correlation between pit pattern and tumor depth in flat and depressed CRC[23-27].

Many authors have reported that depressed and/or NPG type lesions are considered to have a high malignant potential, compared to the polypoid type lesions of similar

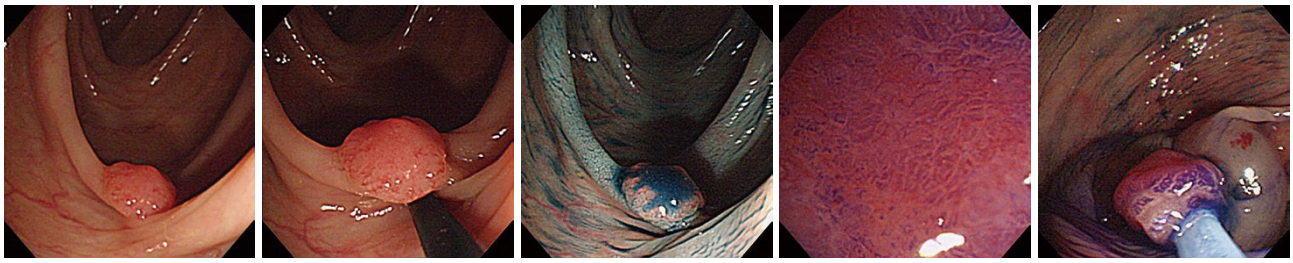

Figure 1 The lesion was located in the transverse colon. Endoscopic examination revealed a flat, elevated lesion with a central depression, which was macroscopically diagnosed as 0-Ⅱa+Ⅱc. The high-magnification view revealed a typical type Ⅵ pit (invasive) pattern on the depressed margin. The final endoscopic diagnosis was a 0-Ⅱa+Ⅱc type early colon cancer with submucosal deep invasion. However, patient strongly hoped EMR as an initial treatment. We performed EMR after injecting normal saline into the submucosa.

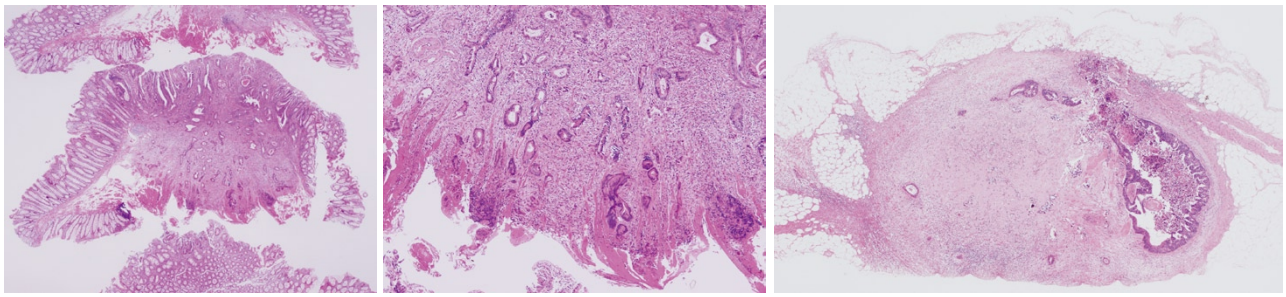

Figure 2 The final histopathological diagnosis was early invasive colon cancer, well-differentiated adenocarcinoma, sm-deep, NPG type, ly (-), v (-), cut end (+) (vertical margin positive). Since cancer was exposed in the vertical cut margin, additional surgical resection was performed and LNM was detected.

size[4,28-31]. Kurisu *et al*[20] have investigated the development and progression of EI-CRC. In that study, NPG lesions were significantly smaller in size (14.2 mm *vs* 24.2 mm) but showed deeper infiltration than PG types. They concluded that tumor development and the degree of invasion differed significantly between the two types of carcinoma. On the other hand, non-polypoid colorectal neoplasms (NP-CRNs) have been reported recently in the United States. Soetikno *et al*[31] have reported the prevalence of NP-CRNs in a veterans' hospital population. The overall prevalence of NP-CRNs and NP-CRNs with in situ or submucosal invasive carcinoma was 9.35% and 0.82%, respectively. They also concluded that NP-CRNs were more likely to contain carcinoma (OR: 9.78) than polypoid lesions, regardless of size. In the present study, small EI-CRCs ≤ 10 mm in diameter showed a significantly higher incidence of NPG type lesions than in the large lesion group ($P < 0.0001$). However, there was no significant difference in proportion of the macroscopic type between the groups ($P = 0.13$). Among the lesions diagnosed as Is type (sessile) in the small lesions group, 47% (14/30) were classified as NPG type histopathologically. From these results, we conclude that further investigation is required to confirm the growth pattern, especially for small sessile lesions diagnosed during colonoscopy.

In contrast, the rate of EMR as an initial treatment was 33% (195/583) in our study. In particular, it was significantly higher in the small lesion than the large lesion group (52% *vs* 29%, $P < 0.0001$). Among the 195 lesions removed by EMR as an initial treatment in both groups, 61 cases (32%) were sm-superficial cancers. On the other hand, there was no significant difference in the positive rate of cut margins between the small and large lesion groups (18% *vs* 20%). This result implies that EMR should not be performed readily for EI-CRC, from the viewpoint of no-touch isolation[32] and EMR complications. Intramucosal lesions (adenoma or intramucosal cancer) are usually well lifted by submucosal injection. In contrast, invasive cancer, especially sm-deep cancer, cannot be lifted because of the presence of submucosal fibrosis or desmoplastic reaction. Uno *et al*[33] have reported this phenomenon as the "non-lifting sign". Kobayashi *et al*[34] have reported, among 271 colorectal neoplastic lesions, that the non-lifting sign of deeper infiltration had a sensitivity of 61.5%, specificity of 98.4%, and accuracy of 94.8%. In contrast, endoscopic diagnosis had a sensitivity of 84.6%, specificity of 98.8%, and accuracy of 97.4%, with statistically significant differences in terms of sensitivity and accuracy. Furthermore, since submucosal injection varies depending on the expertise of the endoscopist, we consider that an endoscopic diagnosis is much more important and accurate when endoscopic resection is considered as the therapeutic option.

There are some limitations to this study. Firstly, this was a single-center study, and although the number of examined EI-CRCs was adequate, a multicenter analysis should be performed to clarify the clinical importance of small EI-CRCs. In addition, this study was carried out retrospectively between 1980 and 2004. In relation to endoscopic treatment for early CRC, endoscopic submucosal dissection (ESD) technique and Glycerol/Sodium hyaluronate as an injected solution during EMR has made progress recently[35,36]. In particular, ESD provides not only an *en bloc* large specimen but also

negative lateral and vertical cut margins.

In conclusion, with regard to the risk of LNM, small EI-CRCs demonstrate the same aggressiveness and malignant potential as large lesions. Moreover, from the perspective of the concept of no-touch isolation, therapeutic cost, and complications during EMR, special attention must be paid when treating even small early stage lesions, especially NPG type lesions.

COMMENTS

Background

In general, small colorectal lesions are suspected of having a lower malignant potential than large ones, and hence are easy to remove endoscopically. Several authors have reported that the malignant potential of early invasive colorectal cancer (EI-CRC) increases with lesion size.

Research frontiers

The aim of this retrospective study was to clarify the clinicopathological characteristics of small (≤ 10 mm) and large (> 10 mm) EI-CRCs.

Innovations and breakthroughs

A total of 583 EI-CRCs were evaluated retrospectively, with 120 (21%) small and 463 (79%) large lesions identified. With regard to the risk of lymph-node metastasis (LNM), small EI-CRCs demonstrate the same aggressiveness and malignant potential as large lesions.

Peer review

The authors examined retrospectively a large group of patients with EI-CRCs gathered over 20 years in a national cancer hospital, and demonstrated that small EI-CRCs (≤ 10 mm) had the same aggressiveness and malignant potential as large cancers. Special attention must be paid when treating even small lesions.

Abstract

AIM: To investigate the influence of CO_2-insufflation pressure on adhesion, invasion and metastatic potential of colon cancer cells based on adhesion molecules expression.

METHODS: With an *in vitro* artificial pneumoperitoneum model, SW1116 human colon carcinoma cells were exposed to CO_2-insufflation in 5 different pressure groups: 6 mmHg, 9 mmHg, 12 mmHg, 15 mmHg and control group, respectively for 1 h. Expression of E-cadherin, ICAM-1, CD44 and E-selectin was measured at 0, 12, 24, 48 and 72 h after CO_2-insufflation using flow cytometry. The adhesion and invasion capacity of SW1116 cells before and after exposure to CO_2-insufflation was detected by cell adhesion/invasion assay *in vitro*. Each group of cells was injected intraperitoneally into 16 BALB/C mice. The number of visible abdominal cavity tumor nodules, visceral metastases and survival of the mice were recorded in each group.

RESULTS: The expression of E-cadherin, ICAM-1, CD44 and E-selectin in SW1116 cells were changed significantly following exposure to CO_2 insufflation at different pressures ($P < 0.05$). The expression of E-cadherin, CD44 and ICAM-1 decreased with increasing CO_2-insufflation pressure. The adhesive/invasive cells also decreased gradually with increasing pressure as determined by the adhesion/invasion assay. In animal experiments, the number of abdominal cavity tumor nodules in the 15 mmHg group was also significantly lower than that in the 6 mmHg group (29.7 ± 9.91 *vs* 41.7 ± 14.90, $P = 0.046$). However, the survival in each group was not statistically different.

CONCLUSION: CO_2-insufflation induced a temporary change in the adhesion and invasion capacity of cancer cells *in vitro*. Higher CO_2-insufflation pressure inhibited adhesion, invasion and metastatic potential *in vitro* and *in vivo*, which was associated with reduced expression of adhesion molecules.

INTRODUCTION

The laparoscopic approach is generally considered

to be less invasive and less immunosuppressive than conventional open surgery[1]. However, port site metastases and abdominal wall recurrences although rare nowadays, remain a problem with laparoscopic surgery for cancer[2]. Recently, several studies demonstrated that the five-year survival rates were similar after laparoscopically assisted colectomy and open colectomy for cancer patients, suggesting that the laparoscopic approach is an acceptable alternative to open surgery for colorectal cancer[3-5]. However, whether CO_2 insufflation, which is widely used in laparoscopic surgery, increases the metastatic potential of tumor cells is still the focus of related studies[6-8].

Adhesion molecules play an important role in cell-cell, cell-extracellular matrix (ECM) interactions at tumor metastasis[9,10]. ICAM-1, E-cadherin, and CD44 are representative molecules involved in the interaction not only between the adhesion of inflammatory cells but also between tumor cells and the endothelium. Previous studies have shown that reduced E-cadherin expression correlates with increased invasiveness in colorectal carcinoma cell lines[11]. The decrease or deletion of E-cadherin was reported to induce liver metastasis of colorectal tumors[12,13], and the increased expression of CD44 also induces tumor metastasis[14]. Recently it has been reported that CO_2 insufflation can effect the expression of adhesion molecules, such as E-cadherin, CD44 and ICAM-1, which are related to tumor metastasis[15-17]. However, there are few studies on the influence of CO_2-insufflation pressure on adhesion molecules and how CO_2 insufflation further impacts on metastatic potential following altered expression of these adhesion molecules.

In this study, we investigated whether expression of adhesion molecules are changed after CO_2 insufflation *in vitro*. We further investigated the influence of CO_2 pressure on the expression of these adhesion molecules, and how CO_2-insufflation influenced the adhesion and invasion potential of colon cancer cells *in vitro* and *in vivo*.

MATERIALS AND METHODS

Cell culture

The human colorectal adenocarcinoma cell line SW1116 (human, Caucasian, colon, adenocarcinoma, grade Ⅲ, CCL-233™) was cultured in RPMI 1640 medium (Hangzhou Genom Co. Cat. No. GNM31800.25) supplemented with 10% fetal calf serum (Life Technologies). The human colorectal adenocarcinoma cell line Lovo (human, colon, adenocarcinoma, grade IV, CCL-229™) used in the invasive assay was cultured in F12K medium (Hangzhou Genom Co. Cat. No. GNM21700.25) supplemented with 10% fetal calf serum. The monolayer cell culture was maintained in culture flasks under standard culture conditions at 37℃ in air with 5% CO_2.

Monoclonal antibodies

For flow cytometry, the following monoclonal antibodies (Mab) were used: anti-ICAM-1-PE-Cy5 (Clone HA58) and anti-E-selectin-PE (Clone 68-5H11). They were purchased from BD Biosciences (San Diego, CA, USA). Anti-CD44-FITC (Clone J.173) and unconjugated anti-E-cadherin (Clone 67A4) were purchased from Beckman Coulter™. Secondary goat anti-mouse IgG-PE, isotype control mouse IgG-PE-Cy5, and mouse IgG-PE were purchased from BD Biosciences. Mouse IgG FITC, and mouse IgG PE were purchased from Beckman Coulter™.

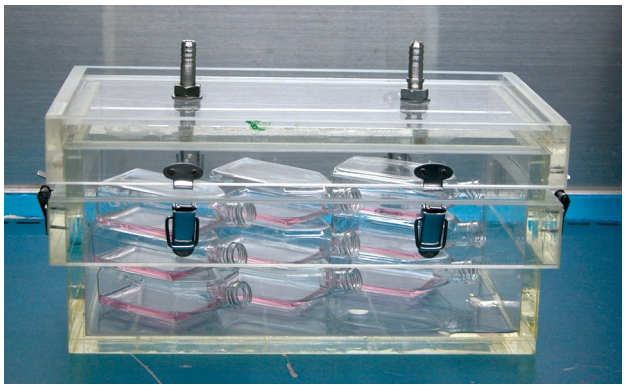

Figure 1 Five litres volume airtight Perspex box with two ventilating ports for pneumoperitoneum establishment *in vitro*.

Animals

Four to eight week-old male BALB/C mice (Chinese Academy of Sciences, Shanghai, China) were kept under standard laboratory conditions and fed a standard laboratory diet with access to water added *libitum* before and after injection.

In vitro pneumoperitoneum establishment

An *in vitro* pneumoperitoneum was established by connecting an electronic CO_2 insufflator (Stryker® Endoscopy) to a 5 L volume airtight Perspex box with two ventilating pits (Figure 1). Medical grade carbon dioxide at a concentration of 99.5% was used. To ensure exhaustion of air in the box, 10 L CO_2 were insufflated into the Perspex box before the tumor cells were placed into the box. The cells were divided into 5 groups with different insufflation pressures (6 mmHg, 9 mmHg, 12 mmHg, 15 mmHg, and room air as a control). The tumor cells and the boxes were transferred into an incubator at 37℃ and the *in vitro* pneumoperitoneum model was retained for 1 h at different insufflation pressures during a continuous CO_2 flow of 2.5 L/min.

Flow cytometry (FACScan)

At 0, 12, 24, 48, and 72 h after exposure, the cells were detached from the tissue culture flasks using ice-cold phosphate-buffered saline (PBS) containing 0.1% sodium azide and resuspended at 5×10^5 cells/mL. One milliliter of the cell suspension was incubated with the monoclonal antibodies (1:100). The cells (5×10^5/group) were incubated with anti-ICAM-1-PE-Cy5, 10 μL, anti-E-selectin-PE, 10 μL, anti-CD44-FITC, 20 μL and unconjugated anti-E-cadherin, 10 μL for 30 min at room

temperature. At the end of the incubation period, the cells were washed with PBS. After treatment with unconjugated anti-E-cadherin the cells were incubated with a secondary goat anti-mouse IgG-PE (3 μL/5 × 10^5 cells) for 30 min at room temperature. After washing with PBS, the cells were fixed with 0.5% formalin, and analyzed for surface receptor expression by flow cytometry (BD Calibur). The expression of 4 different cell adhesion molecules was measured at 5 time points (0, 12, 24, 48 and 72 h) after CO_2 insufflation. Expression of these adhesion molecules is given as mean fluorescence intensity of the cell population.

Adhesion assay

A cell adhesion assay (Cat. No. ECM 554, Chemicon International, USA) was used, in which the wells were coated with human fibronectin, one of the component proteins of the extracellular matrix (ECM). At 0 h and 72 h after exposure to CO_2 insufflation (at 6 mmHg, 9 mmHg, 12 mmHg, 15 mmHg and room air for 1 h, respectively), the cells were detached using 0.25% trypsin and washed with PBS. The wells were rehydrated with 200 μL of PBS per well for at least 15 min at room temperature before being plated at a concentration of 1 × 10^5 cells per well. After the plate was incubated at 37℃ in air with 5% CO_2 for 1 h, each well was washed gently 3 times with PBS. The cells which had adhered to the wells were then dyed with crystal violet and incubated for 5 min at room temperature. After the plate was gently washed 3 times with PBS, 100 μL of Solubilization Buffer (a 50/50 mixture of 0.1 mol/L NaH_2PO_4, pH 4.5 and 50% ethanol) was added to each well. The plate was shaken at room temperature gently to solubilize the cell-bound stain completely. Finally, a microplate reader was used to determine the absorbance at 570 nm as a measure of tumor cell adhesion on the ECM layer.

Cell invasive assay

The SW1116 cells were starved by incubation in serum-free RPMI 1640 for 18-24 h prior to assay. At 0 h and 72 h after CO_2 insufflation (6 mmHg, 9 mmHg, 12 mmHg, 15 mmHg and room air for 1 h, respectively), the cells were harvested by trypsinization, and resuspended in RPMI 1640 at 1 × 10^6 cells/mL. Twenty-four-well QCM™ Cell The Invasion Assay kit (Cat. No. ECM 101, Chemicon International, USA) was used. After rehydration of the ECM layer by adding 300 μL of pre-warmed serum-free medium to the interior of the inserts for 30 min at room temperature, 250 μL of the medium was removed from the inserts without disturbing the membrane. The prepared cell suspension (250 μL) as described previously was then added into each insert, and RPMI 1640 with 5% BSA was added to the lower chamber. After incubation for 24 h at 37℃ in the incubator with 5% CO_2, the medium and suspended cells were removed and the invasion chamber was placed into a clean well containing 225 μL of the cell detachment solution. The cells were then incubated at 37℃ for 30 min, and both lyses buffer and dye solution were added to each well containing the cell detachment solution with cells which had invaded the ECM coated membrane. Finally, the mixture was detected by a fluorescence plate reader using a 480/520 nm filter set. The fluorescence intensity was measured as an index of the quantity of invasive cells. Lovo cells underwent the same procedure in the invasive assay.

Induction of intra-abdominal tumors

To analyze the potential for abdominal cavity dissemination in each group of cells (exposed to CO_2 insufflation at 6 mmHg, 9 mmHg, 12 mmHg, 15 mmHg and room air), each group of cells was injected intraperitoneally into 16 BALB/C mice (1 × 10^6 cells/mouse). Fourteen days later, 10 mice in each group were sacrificed by cervical dislocation, and the number of visible abdominal cavity tumor nodules, reflecting the metastatic potential, was counted. The rate of viscera (liver, kidney, spleen, peritoneum or mesentery) metastasis was also recorded in each group. The remaining mice in each group were monitored for their survival.

Statistical analysis

For studies on the expression of adhesion molecules, each experiment was performed in triplicate. Cell adhesion and invasion assays were repeated five times. Data are expressed as mean ± SD. The repeated-measures ANOVA test, one-way ANOVA test and paired *t* test were used to compare the control mean with the various treatment means: adhesion molecules, cell adhesion and invasion assay *in vitro*, and abdominal cavity tumor metastasis *in vivo*. The rates of organ (liver, kidney, spleen, peritoneum or mesentery) metastasis were analyzed using Fisher's exact test. Statistical significance was set at the 5% level.

RESULTS

Effect of CO_2 insufflation on expression of adhesion molecules

Immediately after the 6 mmHg CO_2 insufflation, ICAM-1 (Figure 2A-C) and CD44 expression significantly increased compared to room air controls (F = 106.38, 297.73; $P < 0.01$), while the expression of ICAM-1 decreased at 48 h and 72 h after the 6 mmHg CO_2 insufflation (F = 17222.3, 385.61; $P < 0.01$) (Figure 2A-C). Immediately after the 9 mmHg CO_2 insufflation, E-selectin expression significantly increased compared to the controls (F = 147.75, P = 0.01), and CD44 expression increased significantly compared to controls (F = 39.20, P = 0.025); 24 h after 9 mmHg CO_2 insufflation, E-cadherin expression increased significantly compared to controls (F = 26.79, P = 0.035) (Figure 2D-F), while a significant reduction in E-selectin expression was observed (F = 33.43, P = 0.029). At 48 h after 9 mmHg CO_2 insufflation, a significant reduction in ICAM-1 expression was demonstrated (F = 282.94, $P < 0.01$). At 48 h after 12 mmHg CO_2 insufflation, CD44 expression increased significantly (F = 93.70, P = 0.011), while 72 h after 12 mmHg CO_2 insufflation, the expression of CD44

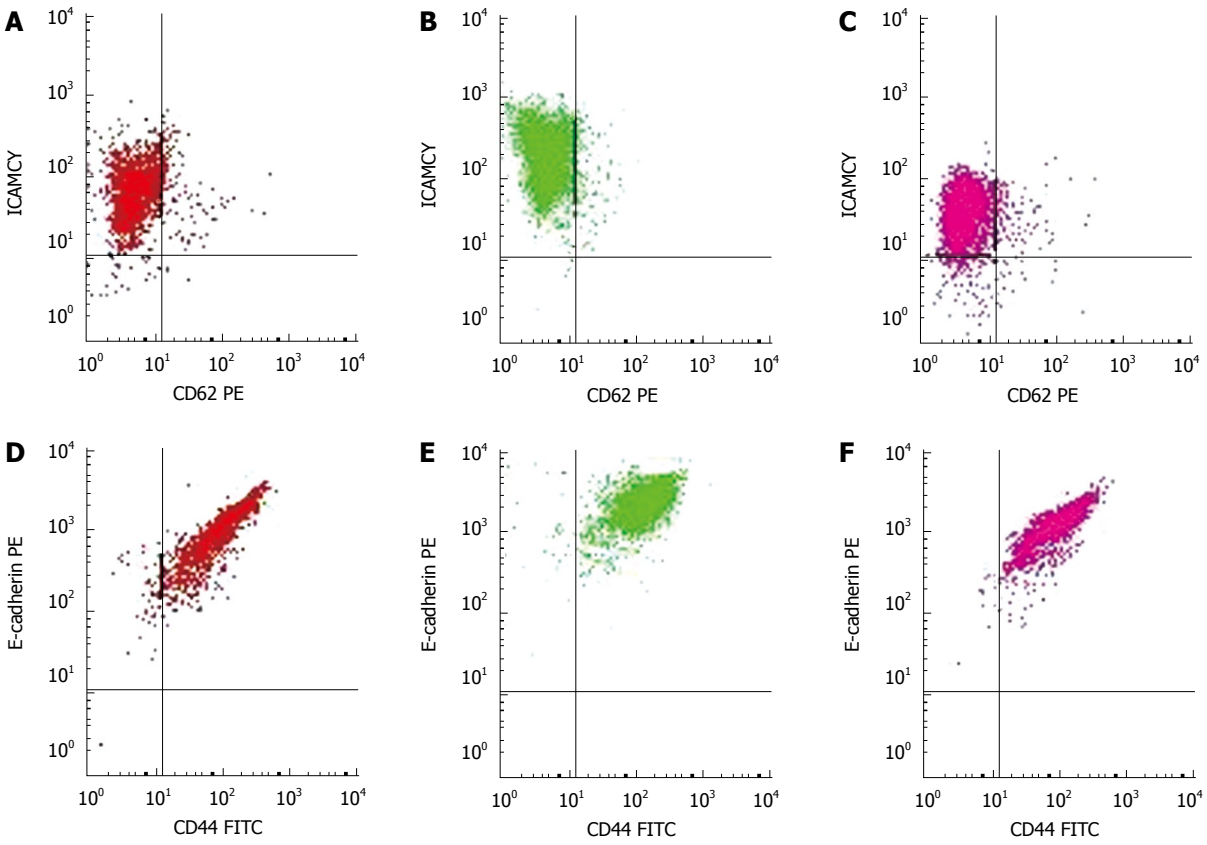

Figure 2 Flow cytometry analysis of ICAM-1 and E-cadherin expression in SW1116. A: ICAM-1 (Room air control); B: ICAM-1 (0 h after the 6 mmHg insufflation); C: ICAM-1 (72 h after the 6 mmHg insufflation); D: E-cadherin (Room air control); E: E-cadherin (24 h after the 9 mmHg insufflation); F: E-cadherin (72 h after the 9 mmHg insufflation). Immediately after the 6 mmHg CO_2 insufflation (B), ICAM-1 expression increased significantly compared to room air controls (A) (P = 0.009), while it was significantly less at 72 h after the 6 mmHg insufflation (C) than control group. Twenty four hours after 9 mmHg CO_2 insufflation (E), E-cadherin expression increased significantly compared to controls (D) (P = 0.035), but returned to the control value at 72 h after the 9 mmHg insufflation (F).

decreased significantly compared to the controls (F = 679.38, P < 0.01). Immediately after the 15 mmHg CO_2 insufflation, CD44 expression decreased significantly compared to the controls (F = 70.01, P = 0.014). At 12 h and 24 h after 15 mmHg CO_2 insufflation, an increased expression of E-cadherin was demonstrated (F = 53.53, 68.14, P = 0.018, 0.014). No significant differences in the expression of these adhesion molecules at other time points and pressures were observed.

Effect of rising insufflation pressure on expression of adhesion molecules

The expression of CD44, E-cadherin and ICAM-1 decreased with increasing CO_2-insufflation pressure. At the 0 h time point, the differences in CD44 expression between the 6 mmHg and the 9 mmHg group, the 9 mmHg and the 12 mmHg group, the 12 mmHg and the 15 mmHg group were significant (t = 4.4291, 4.5725, 7.3587, P < 0.01) (Figure 3A). At the same time point, E-cadherin expression in the 9 mmHg group was less than that in the 6 mmHg group (t = 7.1839, P < 0.01), while in the 12 mmHg and the 15 mmHg group, E-cadherin expression was significantly less than that in the 9 mmHg group (t = 4.5148, 4.4582, P < 0.01) (Figure 3B). ICAM-1 expression in the 9 mmHg, 12 mmHg and 15 mmHg groups was less than that in the 6 mmHg group, respectively (t = 3.3359, 2.3189, 2.7546, P < 0.01, P = 0.046, 0.022), and the expression at 15 mmHg was significantly less than that at 12 mmHg (t = 2.2912, P = 0.048) (Figure 3C).

Effect of CO_2 insufflation on adhesion potential of SW1116 in vitro

Immediately after exposure to increasing CO_2-insufflation pressure, cell adhesion decreased gradually. Cell adhesion in the 15 mmHg group was significantly less than that at 12 mmHg, 9 mmHg, 6 mmHg and the control (all P < 0.01), and cell adhesion in the 12 mmHg group was also less than that in the 9 mmHg, 6 mmHg and control groups (all P < 0.01). The cells exposed to 6 mmHg had more adhesion capacity than those exposed to 9 mmHg or the control group, however, the differences were not significant (P = 0.886, P = 0.058) (Figure 4A). At 72 h after CO_2 insufflation, the differences between the various insufflation pressure groups were not significant (Figure 4B).

Effect of CO2 insufflation on invasion potential of SW1116 and Lovo in vitro

Immediately after exposure to 15 mmHg CO_2 insufflation, the invasion of SW1116 cells decreased significantly compared to the cells before exposure (11.36 ± 0.861 *vs* 13.43 ± 1.113; P = 0.019), while immediately after exposure to 6 mmHg insufflation, invasive cells increased compared to

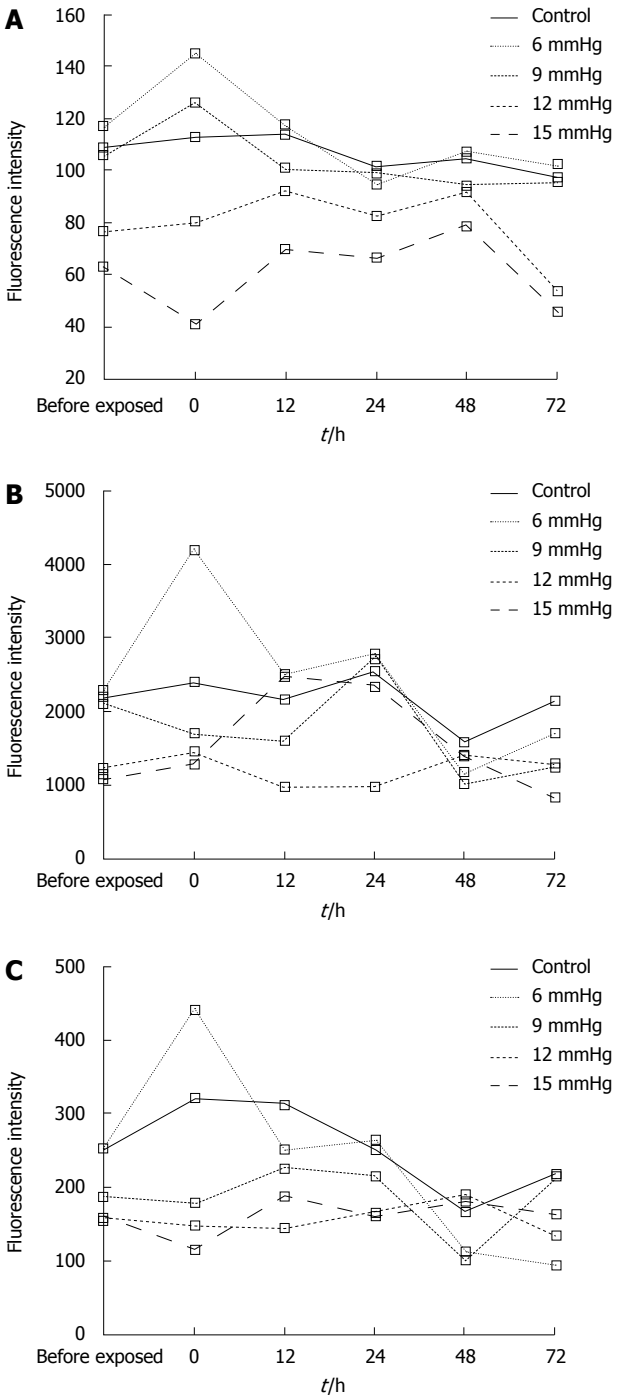

Figure 3 The effect of CO_2 insufflation pressure on expression of adhesion molecules. A: Expression of CD44; B: Expression of E-cadherin; C: Expression of ICAM-1. With increasing CO_2-insufflation pressure, the expression of CD44 (A), E-cadherin (B), and ICAM-1 (C) decreased at some time points, especially at the start (0 h) after CO_2-insufflation.

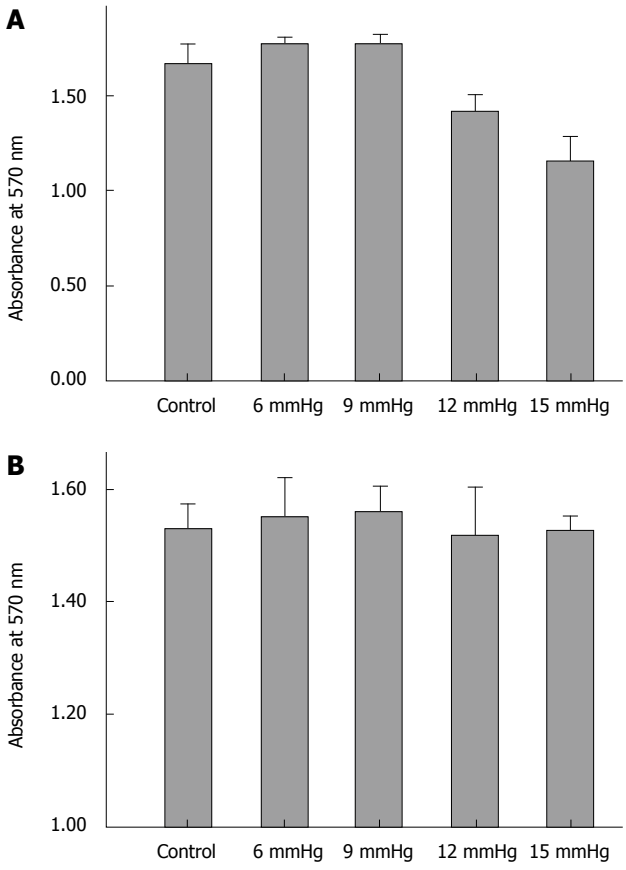

Figure 4 Results of adhesion assay. A: 0 h after CO_2 insufflation; B: 72 h after CO_2 insufflation. At 0 h after CO_2 insufflation (A), with increasing CO_2-insufflation pressure, the adhesion of the SW1116 cell line decreased gradually (12 mmHg *vs* control, $P < 0.001$; 15 mmHg *vs* 12 mmHg, $P < 0.001$). At 72 h after CO_2 insufflation (B), cell adhesion was similar among the different groups ($P > 0.05$).

before exposure (15.58 ± 1.015 *vs* 14.42 ± 1.491; $P = 0.056$), however, the difference was not significant (Figure 5A). At 72 h after CO_2 insufflation, cell invasion was similar to that for cells before exposure (Figure 5B).

The differences between various insufflation pressures were also compared. At the 0 h time point, the cells exposed to 15 mmHg were significantly less invasive than those exposed to the other insufflation pressures (*vs* 6 mmHg, $P < 0.01$; *vs* 9 mmHg, $P = 0.011$; *vs* 12 mmHg, $P = 0.016$; and *vs* room air, $P = 0.014$), and the cells exposed to 6 mmHg were more invasive than cells exposed to the other insufflation pressures (*vs* 9 mmHg, $P = 0.013$; *vs* 12 mmHg, $P < 0.01$; *vs* 15 mmHg $P < 0.01$; and *vs* room air, $P = 0.011$). However, these differences were not significant (Figure 5A). At 72 h after CO_2 insufflation, the differences between the various insufflation pressure groups were not significant (Figure 5B).

The human colon cancer cell line Lovo was also tested in the invasive assay, and a similar trend was observed (Figure 5C and D).

Effect of CO_2 insufflation on metastasis potential of SW1116 in vivo

The ratios of the number of mice which developed intra-abdominal tumors/the number of mice which received inoculation of SW1116 cells in the various groups were as follows: (1) control group, 10/10; (2) 6 mmHg group, 9/10; (3) 9 mmHg group, 9/10; (4) 12 mmHg group, 9/10; (5) 15 mmHg group, 10/10. The differences were not significant. The mean number of intra-abdominal tumor nodules in the various groups was as follows: (1) control group = 36.8 ± 15.32, (2) 6 mmHg group = 41.7 ± 14.90, (3) 9 mmHg group = 33.9 ± 10.29, (4) 12 mmHg group = 33.2 ± 11.72, (5) 15 mmHg = 29.7 ± 9.91. The difference between the 6 mmHg group and the 15 mmHg group was significant ($P = 0.046$) (Figure 6A-C), but the differences among

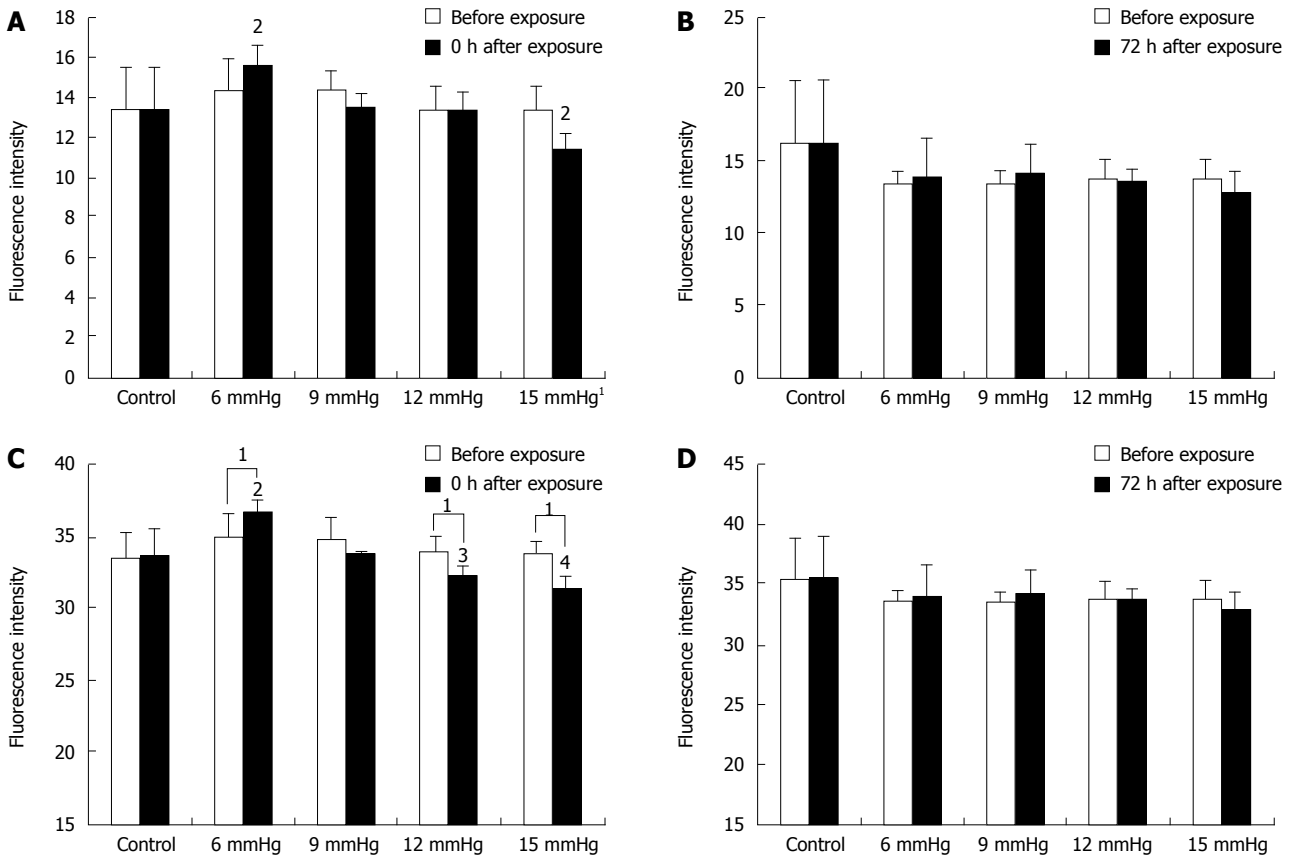

Figure 5 Results of invasion assay. A: SW1116, 0 h after exposure; B: SW1116, 72 h after exposure; C: Lovo, 0 h after exposure; D: Lovo, 72 h after exposure. A: [1]At 0 h after exposure to 15 mmHg CO_2 insufflation, invasive cells decreased significantly compared to the cells prior to exposure (P = 0.019); [2]At 0 h after exposure, invasion of the 6 mmHg or the 15 mmHg group was significantly different from the other pressure groups (P < 0.05). B: The invasion fluorescence intensities of SW1116 before and 72 h after exposure to CO_2 insufflation were not significantly different (P > 0.05). Seventy two hours after the CO_2 insufflation, there were no significant differences between the various insufflation pressure groups (P > 0.05); C: [1]At 0 h after exposure to 15 mmHg, 12 mmHg or 6 mmHg CO_2 insufflation, invasive cells of Lovo decreased significantly compared to the cells prior to exposure (P = 0.008, P = 0.0045, P = 0.043); [2]At 0 h after exposure, cell invasion at 6 mmHg was significantly different from the other pressure groups (P < 0.01); [3]At 0 h after exposure, cell invasion in the 12 mmHg group was significantly less than the 9 mmHg group (P < 0.05); [4]At 0 h after exposure, cell invasion in the 15 mmHg group was significantly less than the 6 and 9 mmHg groups (P < 0.01); D: The invasion fluorescence intensities of Lovo before and 72 h after exposure to CO_2 insufflation were not significantly different (P > 0.05). Seventy two hours after CO_2 insufflation, there were no significant differences between the various insufflation pressure groups (P > 0.05).

the other groups were not. The results of visceral (liver, kidney, spleen, peritoneum or mesentery) metastases (the number of mice with certain visceral metastasis/the number of mice with abdominal cavity metastasis after inoculation of SW1116 cells) are shown in Table 1. No significant differences in survival rate between the various groups were observed (P = 0.426). The overall survival curve is shown in Figure 7.

DISCUSSION

The use of minimal access techniques in the surgical management of colorectal cancer should be safe and feasible in terms of the oncologic effect on the tumor, as compared with conventional surgery. Recent clinical trials in Europe and America have demonstrated that the recurrence and 5-year survival of laparoscopic colorectal cancer surgery are identical to those obtained by open surgery[3-4]. Similar results have also been reported from Hong Kong[18]. However, the occurrence of port-site metastasis and peritoneal metastasis reported in early studies of laparoscopic surgery for cancer led to many studies investigating the biologic effects of positive pressure pneumoperitoneum on tumor growth and the development of trocar recurrences. Several experimental studies suggested that laparoscopic surgery can promote tumor growth[6,19]. Some animal studies have also shown that CO_2, especially at high insufflation pressures increased the incidence of distant metastases[20,21]. However, other researchers failed to confirm these experimental observations in similar animal models[22]. Thus, although the problem of port-site deposits in patients undergoing laparoscopic surgery for cancer has largely been resolved by improved oncological operative techniques, from a biological standpoint, the adverse effect of a sustained positive pressure CO_2 pneumoperitoneum is still debatable, and it is prudent to investigate the mechanism of tumor metastasis induced by CO_2 pneumoperitoneum.

Some adhesion molecules in cancer cells have been reported to play an important role in tumor metastasis. There is evidence that decreased expression of E-cadherin can initiate tumor invasion and metastasis because E-cadherin prevents detachment of tumor cells from

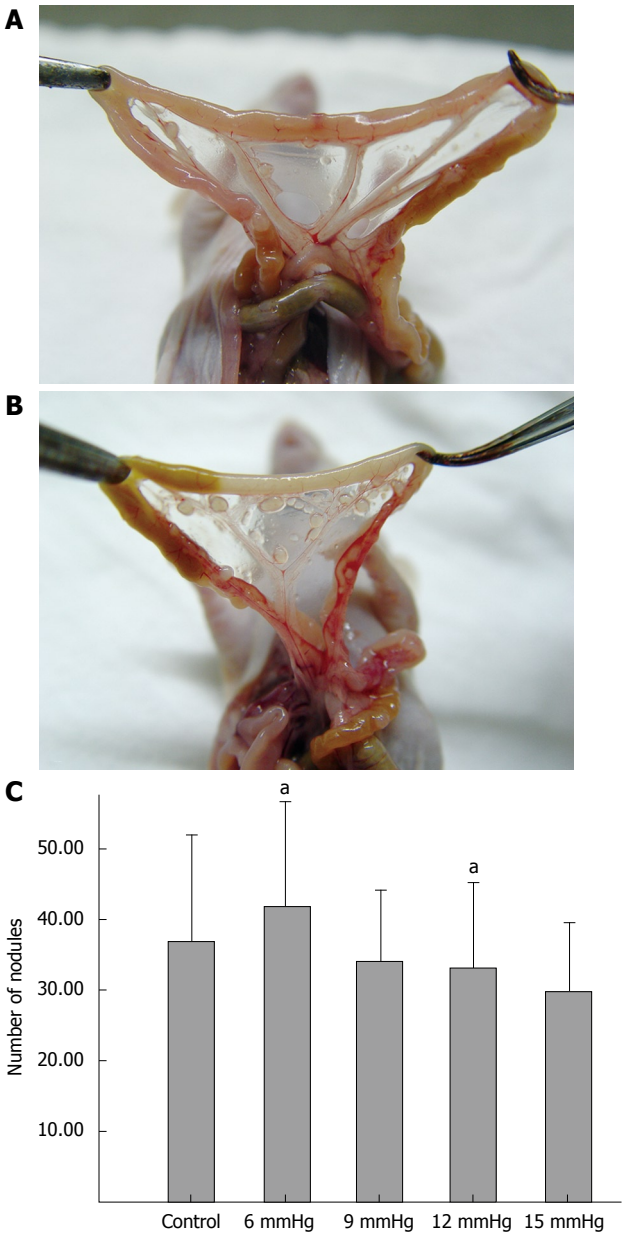

Figure 6 Results of intra-abdominal tumor nodules. A: Mesentery tumor nodules in the 15 mmHg group; B: Mesentery tumor nodules in the 6 mmHg group; C: Numbers of intra-abdominal tumor nodules in the various groups. The number of intra-abdominal tumor nodules in the 15 mmHg group (A) was significantly lower than those in 6 mmHg group (B) ($^aP = 0.046$). The mean numbers of abdominal cavity nodules formed by the cells in each group are described in (C).

the primary tumor[11,23,24]. ICAM-1 mediates the adhesion of circulating cells to the intravascular endothelium. ICAM-1 may also play a role in tumor cell adhesion to the mesothelium[25]. Changes in the expression of CD44 are reported to be related to increased tumor metastasis. The expression of E-selectin in primary colorectal cancer is significantly less than in secondary deposits from this tumor[26]. A number of recent studies have addressed the effects of the laparoscopic environment on these adhesion molecules in cancer cells. Kim *et al*[16] demonstrated a significant alteration in E-cadherin, ICAM-1 and CD44 expression in colon cancer cells after exposure to CO_2. Tahara *et al*[27] reported that CO_2 insufflation increased

the expression of P-cadherin mRNA in the mouse peritoneum. However, neither of these two groups investigated how these CO_2-induced changes affected the invasive and metastatic potential of colon cancer cells.

In our study, we found that the expression of these adhesion molecules in the SW1116 cell line increased significantly 0-48 h after the cells were exposed to continuous CO_2-insufflation for 1 h ($P < 0.05$), and returned to the control level by 72 h. We found that these changes are temporary. At certain time points, ICAM-1, E-selectin, and CD44 were found to be even lower than the control levels ($P < 0.05$). In addition, contrary to the results reported by Kim *et al*[16], the expression of E-cadherin significantly increased, rather than decreased after exposure to CO_2-insufflation, although the effect was temporary. The important findings of the present study are that the changes in these adhesion molecules are bi-directional. Collectively increased expression of ICAM-1, E-selectin, and CD44 and decreased expression of E-cadherin signify increasing potential for tumor metastasis. However, the results of the present study also demonstrated the temporary and bi-directional nature of the changes in the expression of these adhesion molecules, indicating that CO_2-insufflation during laparoscopic surgery does not appear to increase the metastatic potential of solid

cancers. Our results document that with increasing CO_2-insufflation pressure, the expression of E-cadherin, CD44 and ICAM-1 decreased, especially at the start of CO_2-insufflation exposure ($P < 0.05$, Figure 3A-C). We believe that higher pressures of CO_2-insufflation could inhibit the expression of adhesion molecules.

We also investigated the effect of CO_2-insufflation on the adhesion and invasion potential of colon cancer cells *in vitro* and the effect on the metastatic capacity of the tumor cells *in vivo*. The cell invasion assays showed that CO_2-insufflation also changed the invasion potential of tumor cells (both the SW1116 and the Lovo cell line) temporarily but with increasing CO_2-insufflation pressures, invasion potential decreased. Similar results were obtained with the adhesion assays.

The *in vivo* animal studies with rising CO_2-insufflation pressure, showed a decrease in the number of tumor nodules when the data between the 15 mmHg and 6 mmHg groups were compared. This observation suggests that high CO_2-insufflation pressures could inhibit the adhesion, invasion and metastatic potential of colon cancer cells. Ziprin *et al*[28] reported that laparoscopic enhancement of tumor cell binding to the peritoneum is inhibited by anti-ICAM-1 monoclonal antibody. High CO_2-insufflation pressures could inhibit the adhesion, invasion or metastatic capacity of tumor cells *in vitro* and *in vivo* by inhibiting expression of the adhesion molecules ICAM-1 and CD44.

In the present study, the adhesion potential of the tumor cells from the CO_2-insufflation groups did not increase when compared to the control group. In addition, the numbers of tumor nodules in the four CO_2-insufflation groups were similar to the control group. Likewise, survival rates were not significantly different indicating that CO_2-insufflation did not increase the adhesion potential of colon cancer cells *in vitro* or the metastatic capacity *in vivo*. However, reaction of the host seems also to be highly important. Various host defence mechanisms in the organism are involved in tumouricidal killing processes. Some studies have reported that the mononuclear phagocytotic system, which largely consists of hepatic tissue macrophages (Kupffer cells), plays an important tumouricidal role. Previously, laparoscopic insufflation with CO_2 had been demonstrated to impair the activity of the mononuclear phagocyte system and was responsible for potential hepatic disadvantages[29]. In this study, only tumor cells treated with CO_2-insufflation *in vitro*, and the *in vivo* metastatic capacity of colon cancer cells treated with different CO_2-insufflation *in vitro* were the focus of this investigation. The reaction of the host after high pressure pneumoperitoneum, and the effect that the pneumoperitoneum may have on intraperitoneal cells was not considered. Further investigations are required.

In conclusion, this study has shown that the expression of adhesion molecules can be affected temporarily and bi-directionally by continuous CO_2-insufflation, which also induced a temporary change in the adhesion and invasion capacity of these cells *in vitro*. CO_2-insufflation at high pressures plays an important role in inhibiting the expression of adhesion molecules. In addition, high insufflation pressures inhibited the adhesion and invasion potential of colon cancer cells *in vitro* and inhibited metastatic potential *in vivo*, which was associated with inhibited expression of adhesion molecules. The results of our study do not provide any evidence that CO_2-insufflation increases the metastatic potential of colon cancer cells.

In conclusion, CO_2-insufflation induced a temporary change in the adhesion and invasion capacity of cancer cells *in vitro*. High pressures of CO_2-insufflation inhibited the adhesion, invasion and metastatic potential *in vitro* and *in vivo*, which was associated with reduced expression of adhesion molecules.

We thank Dr. Yan-Yan Song of the Department of Public Health, Shanghai Jiao Tong University School of Medicine for assistance with the statistical analyses, and Dr. Bing-Ya Liu of the Department of Digestive Surgery, Shanghai Jiao Tong University School of Medicine for interpretation of data.

COMMENTS

Background

Laparoscopic CO_2-insufflation has been reported to correlate with growth and metastasis of colorectal cancer. However, few studies have addressed the influence of CO_2-insufflation pressure on the biological behaviour of colorectal cancer. The aim of this study is to investigate the influence of CO_2-insufflation pressure on adhesion, invasion and metastatic potential of colon cancer cells based on adhesion molecules expression.

Research frontiers

Recently, it has been reported that the CO_2 insufflation can effect the expression of some adhesion molecules, such as E-cadherin, CD44 and ICAM-1, which are related to the tumor metastasis. But few studies concerning the influence of the CO_2-insufflation pressure on the adhesion molecules and how CO_2 insufflation further impacts on the metastatic potential following altered expression of these adhesion molecules.

Innovations and breakthroughs

In this study, the authors found that CO_2-insufflation induced a temporary change in the adhesion and invasion capacity of cancer cells *in vitro*. High pressures of CO_2-insufflation inhibited the adhesion, invasion and metastatic potential *in vitro* and *in vivo*, which was associated with reduced expression of adhesion molecules.

Applications

The results of their study do not provide any evidence that CO_2-insufflation increases the metastatic potential of colon cancer cells. CO_2-insufflation may be used with oncological safety in laparoscopic surgery for colorectal cancer.

Peer review

The manuscript by Jun-Jun Ma and co-authors is well presented, and deals with a significant clinical issue when tumor tissue is resected. Indeed reoccurrences of tumor nodes stand central as a major post-operative complication. Furthermore, the authors applied an original approach to study this problem *in vitro* and *in situ*. This paper contains important information which might have significant translational medical implications.

Abstract

AIM: To compare the features of biochemical metabolic changes detected by hepatic phosphorus-31 magnetic resonance spectroscopy (^{31}P MRS) with the liver damage score (LDS) and pathologic changes in rabbits and to investigate the diagnostic value of ^{31}P MRS in acute hepatic radiation injury.

METHODS: A total of 30 rabbits received different radiation doses (ranging 5-20 Gy) to establish acute hepatic injury models. Blood biochemical tests, ^{31}P MRS and pathological examinations were carried out 24 h after irradiation. The degree of injury was evaluated according to LDS and pathology. Ten healthy rabbits served as controls. The MR examination was performed on a 1.5 T imager using a ^{1}H/^{31}P surface coil by the 2D chemical shift imaging technique. The relative quantities of phosphomonoesters (PME), phosphodiesters (PDE), inorganic phosphate (Pi) and adenosine triphosphate (ATP) were measured. The data were statistically analyzed.

RESULTS: (1) Relative quantification of phosphorus metabolites: (a) ATP: there were significant differences (P < 0.05) (LDS-groups: control group *vs* mild group *vs* moderate group *vs* severe group, 1.83 ± 0.33 *vs* 1.55 ± 0.24 *vs* 1.27 ± 0.09 *vs* 0.98 ± 0.18; pathological groups: control group *vs* mild group *vs* moderate group *vs* severe group, 1.83 ± 0.33 *vs* 1.58 ± 0.25 *vs* 1.32 ± 0.07 *vs* 1.02 ± 0.18) of ATP relative quantification among control group, mild injured group, moderate injured group, and severe injured group according to both LDS grading and pathological grading, respectively, and it decreased progressively with the increased degree of injury (r = -0.723, P = 0.000). (b) PME and Pi; the relative quantification of PME and Pi decreased significantly in the severe injured group, and the difference between the control group and severe injured group was significant (P < 0.05) (PME: LDS-control group *vs* LDS-severe group, 0.86 ± 0.23 *vs* 0.58 ± 0.22, P = 0.031; pathological control group *vs* pathological severe group, 0.86 ± 0.23 *vs* 0.60 ± 0.21, P = 0.037; Pi: LDS-control group *vs* LDS-severe group, 0.74 ± 0.18 *vs* 0.43 ± 0.14, P = 0.013; pathological control group *vs* pathological severe group, 0.74 ± 0.18 *vs* 0.43 ± 0.14, P = 0.005) according to LDS grading and pathological grading, respectively. (c) PDE; there were no significant differences among groups according to LDS grading, and no significant differences between the control group and experimental groups according to pathological grading. (2) The ratio of relative quantification of phosphorus metabolites: significant differences (P < 0.05) (LDS-moderate group and LDS-severe group *vs* LDS-control group and LDS-mild group, 1.94 ± 0.50 and 1.96 ± 0.72 *vs* 1.43 ± 0.31 and 1.40 ± 0.38) were only found in PDE/ATP between the moderate injured group, the severe injured group and the control group, the mild injured group. No significant difference was found in other ratios of relative quantification of phosphorus metabolites.

CONCLUSION: ^{31}P MRS is a useful method to evaluate early acute hepatic radiation injury. The relative quantification of hepatic ATP levels, which can reflect the pathological severity of acute hepatic radiation injury, is correlated with LDS.

INTRODUCTION

Acute hepatic radiation injury can lead to necrosis of hepatocytes, fatty degeneration and hepatic fibrosis. The current gold standard test is liver biopsy. This procedure is invasive, uncomfortable for the patient and sometimes leads to serious complications. These factors highlight the need for a noninvasive test to characterize diffuse liver disease. Already, it has been reported that phosphorus-31 magnetic resonance spectroscopy (^{31}P MRS) not only complements liver biopsy but also is a possible replacement and, furthermore, ^{31}P MRS has a particular value in assessing disease progression[1].

^{31}P MRS has been used to study liver metabolism *in vivo* for several years, including clinical liver disease[1-5] and experimental studies[6-8]. It enables the observation of energy metabolism through the signals of phosphomonoesters (PME), phosphodiesters (PDE), inorganic phosphate (Pi) and adenosine triphosphate (ATP). The PME and PDE signals are multi-component, with phosphorylcholine and phosphorylethanolamine the main contributors to PME as well as glycerophosphorylcholine and glycerophosphorylethanolamine which are the main contributors to PDE[1]. The final typical signal of ^{31}P MR spectra *in vivo* is phosphocreatine (PCr). Although it is a dominant signal in muscles, it is not readily observable in spectra of the liver because of its small contribution to hepatic metabolic processes. Its presence indicates some contribution of signals from abdominal wall muscles as a partial volume effect.

In this study, we investigated whether changes of ^{31}P MRS in the liver with early acute radiation injury were related to the liver damage score (LDS) and pathologic changes, we determined the value of ^{31}P MRS in detecting early acute hepatic radiation injury, and we identified the most valuable phosphorylated metabolite for detecting acute hepatic injury. This study set out to provide a rationale for clinical application of ^{31}P MRS in diffuse liver disease.

MATERIALS AND METHODS

Hepatic radiation injury model and experimental groups

This study was approved by the Animal Care Committee of Zhejiang University, School of Medicine. Forty healthy adult New Zealand white rabbits weighing 2.5-3.0 kg were used. These rabbits were randomly assigned into four groups of 10 rabbits. (1) Control group: without any treatment; (2) Group 1: the hepatic region of each rabbit received a single 5 Gy dose of radiation using an 8 MeV electron beam; (3) Group 2: the hepatic region of each rabbit received a single 10 Gy dose of radiation using an 8 MeV electron beam; (4) Group 3: the hepatic region of each rabbit received a single 20 Gy dose of radiation using an 8 MeV electron beam. The irradiation was confined to the whole liver by imaging-guidance. Blood biochemical tests and ^{31}P MRS were carried out 24 h after irradiation. Following each MRS examination, animals were sacrificed, and the liver samples were collected for pathological examination.

MRS examination and spectra evaluation

MRS examination was performed on a Siemens Sonata (Erlangen, Germany) whole-body MR imager operating at 1.5 Tesla equipped with a commercial dual ^{1}H/^{31}P surface coil. Prior to MR examination, animals were fasted overnight. A skin mark in the center of the hepatic region was used in each rabbit at first examination to reduce error. All MR examinations were performed between 8:00 am and 12:00 noon and animals were anesthetized with pentothal sodium (the depth of anesthesia kept well under control) and placed in a prone position with the liver centered on the surface coil.

The basic MR images in all orientations were obtained with true fast imaging with steady precession (true FISP) sequence for the localization of voxels. ^{31}P MR spectra were measured using a standard 2-dimensional chemical shift imaging (CSI) technique[9] in the transverse plane with the following parameters: TR = 440 ms, TE = 2.3 ms, matrix 8 × 8, viewing interpolation 16 × 16, field of view = 200 mm, mean number of times = 120, flip angle = 90 degrees, thickness = 4 cm, voxel volume 2.5 cm × 2.5 cm × 4 cm, acquisition time = 7.36 min. Respiration gating was not used.

Spectra were evaluated using Siemens syngo 2004B software. Briefly, the free induction decay underwent 10 kHz exponential line broadening prior to Fourier transformation, and the resulting spectra were processed with manual phase and baseline correction. Peaks were registered relative to α-ATP resonance (-7.5 ppm), which served as an internal chemical shift reference. Finally, peak integrals were calculated by Gaussian curve fitting with all signals treated as singlets. Signal intensities of PME, Pi, PDE and β-ATP (α-ATP and γ-ATP signals

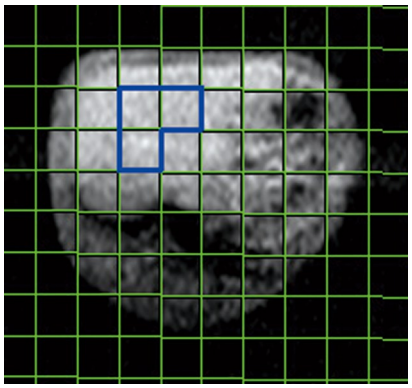

Figure 1 Orientation of CSI: the location of VOI of three voxels being selected in the largest section of rabbit liver on MRI with true FISP sequence.

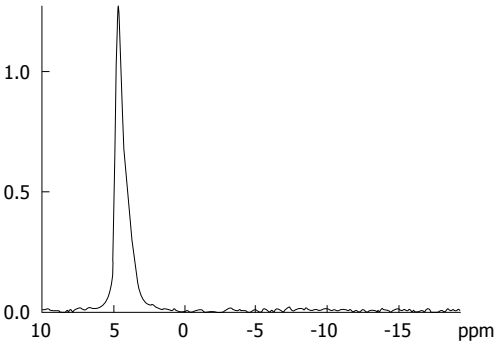

Figure 2 ^{31}P magnetic resonance spectrum from a 500 mL phosphate (NaH_2PO_4) solution phantom with 0.05 mol/L concentrations.

were not used for the evaluation because of overlap with signals of other compounds), which are derived from the integral values of peaks on the spectra, were used for the measurement of relative quantification of metabolites. Volume of interest (VOI) for quantitative evaluation was selected in the center of the liver and the mean integral value of peaks of three voxels on the spectra was used for quantification of metabolites for a rabbit to reduce error (Figure 1).

Phantom experiments were performed before the detection of relative quantification of hepatic metabolites in each rabbit to reduce error induced by the MR imager and environment factors[6,10]. A 500 mL phosphate (NaH_2PO_4) solution phantom with 0.05 mol/L concentration served as a phantom, on which identical MRS examinations were performed regularly throughout the experiment (Figure 2).

For the phantom, the relative quantification of phosphate was 16.6 ± 0.5, and the coefficient of variation was 3.03% (0.5/16.6). The ratio of relative quantification of phosphate between 2 d was conducted as the MRS correction factor (CF) of our MR imager, which was used to correct the relative quantification of hepatic metabolites in each rabbit. Therefore, all the relative quantification of phosphorus metabolites was corrected relative quantification. (corrected relative quantification = relative quantification × CF).

The corrected relative quantification might decrease the error made by the MR imager and the environmental factor in the room, and guarantee the comparability of various relative quantification of phosphorus metabolites.

Table 1 The criteria of liver damage score

Grade	Albumin (g/L)	γ-globulins (g/L)	AST (U/L)	Conjugated bilirubin (μmol/L)	Creatinine (μmol/L)
0	> 36.5	< 19.9	< 50	< 6	< 119
1	32.9-36.4	20-26	51-180	7-32	120-150
2	28.5-32.8	26.1-34.9	181-384	33-75	151-230
3	24.5-28.4	> 35	> 385	> 76	> 231
4	21.8-24.4				
5	< 21.7				

Evaluation of the degree of injury

This study adopted two methods to evaluate the degree of injury: LDS grading and pathological grading.

LDS grading: Sera were isolated from collected blood samples, and serum aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, r-glutamyl transpeptidase, albumin, globulin and albumin/globulin levels were measured by Olympus 2700 analyzer. Then the LDS was calculated for each rabbit according to Krastev's standard (Table 1)[11]. The degree of injury of the liver was divided into mild (LDS ⩽ 3 U), moderate (LDS 3-6 U) and severe (LDS > 6 U).

Pathological grading: The paraffin-section method and hematoxylin and eosin stain was applied to all liver samples, which were read by a single independent liver pathologist (Dr. Lin M) and assessed for swelling, degeneration, necrosis of hepatocytes, and hepatic hemorrhage. The pathologist was blinded to dose of radiation received and the results of ^{31}P MRS. (1) Normal group (control group): normal hepatocytes, integrity of structure of hepatic lobules and regular arrangement of hepatic cord (Figure 3A). (2) Mild group: mild cellular swelling, fatty degeneration and (or) hydropic degeneration, without cell necrosis or hepatic hemorrhage (Figure 3B). (3) Moderate group: moderate cellular swelling and fatty degeneration accompanied by punctal necrosis and stray bleeding points (Figure 3C). (4) Severe group: diffuse cellular swelling and fatty degeneration, with constriction or emphraxis of hepatic sinuses, with or without local cell necrosis and (or) hepatic hemorrhage (Figure 3D).

Statistical analysis

The data were expressed as mean ± SD. Analysis of variance with SNK tests (the Student-Newman-Keuls post-hoc tests) of one-way ANOVA with SPSS 11.0 was used to examine differences between groups. Using Pearson's correlation test, the correlation between relative quantification of ATP and LDS was examined. $P < 0.05$ were considered to indicate statistical significance.

RESULTS

Analysis of hepatic phosphorylated metabolite levels

For the control group, all rabbits had normal hepatic

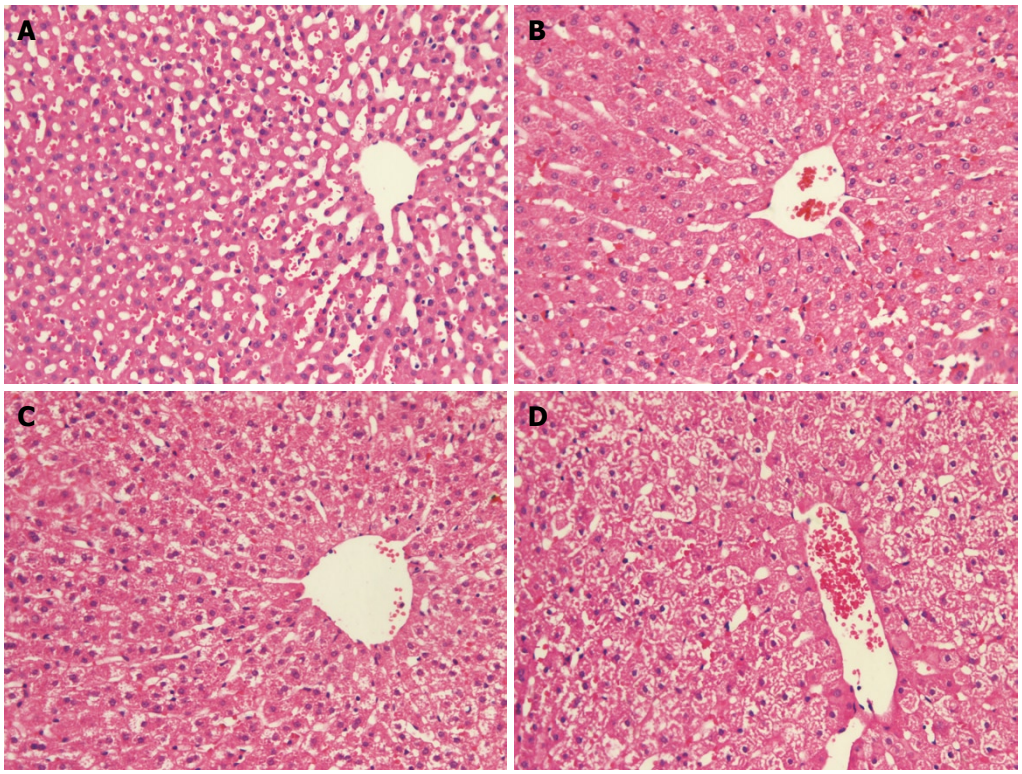

Figure 3 Hepatic ^{31}P MRS of the liver from a rabbit of the control group (A), mild injury group (B), moderate injury group (C) and severe injury group (D). A significant decrease in the ATP signal is seen in the ^{31}P MR spectra (C, D).

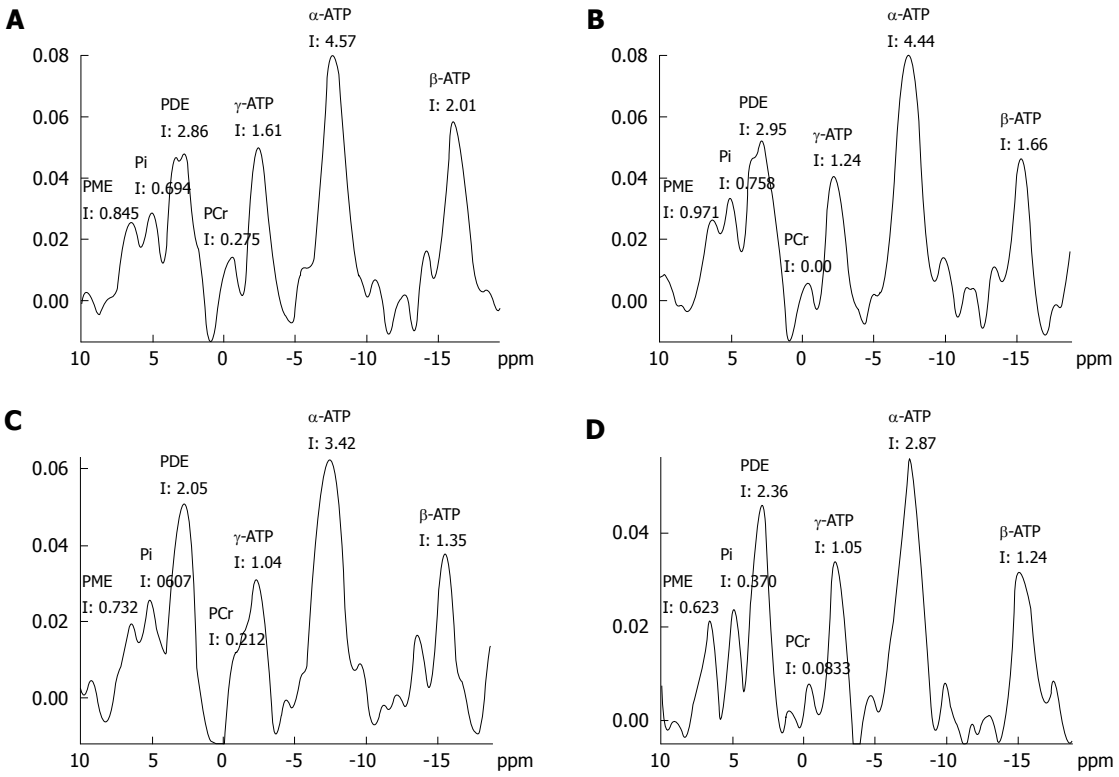

Figure 4 Representative histological section of the liver from a rabbit of the control group (A), mild injury group (B), moderate injury group (C) and severe injury group (D). I: Integral.

micro-structure and a LDS of zero, while rabbits in the experimental groups varied between each other in pathology and LDS, depending on the degree of injury. The spectroscopic data of rabbits in the control group and rabbits with acute hepatic radiation injury, grouped by LDS are summarized in Table 2. The spectroscopic data of rabbits in the control group and rabbits with acute hepatic radiation injury, grouped by pathology are summarized in Table 3. The relative quantification of phosphorus metabolites detected by MRS included PME, PDE, Pi and ATP (Figure 4).

The preceding two tables (Tables 2 and 3) showed

Table 2 Relative quantification of metabolites in rabbit liver using the LDS evaluation method (mean ± SD)

Metabolite	Control group (n = 10)	LDS-mild group (n = 13)	LDS-moderate group (n = 9)	LDS-severe group (n = 8)	F	P
PME	0.86 ± 0.23[j]	0.79 ± 0.33	0.80 ± 0.22	0.58 ± 0.22[a]	1.852	0.155
PDE	2.27 ± 0.62	2.14 ± 0.51	2.48 ± 0.63	1.99 ± 0.88	3.023	0.042

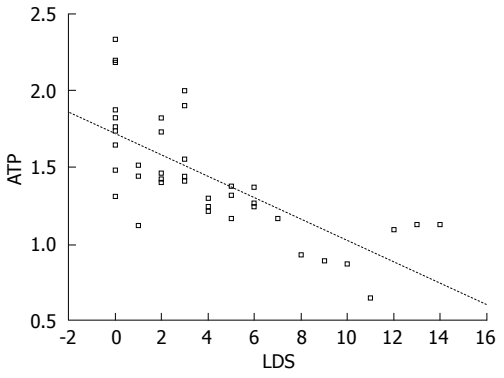

Figure 5 The graph shows the correlation between LDS and ATP, that is, the ATP relative quantification decreases progressively with the increase of LDS.

the relation between biochemical index and relative quantification of phosphorus metabolites, as well as the relation between pathology and relative quantification of phosphorus metabolites. However, the results evaluated with LDS and pathology were of perfect consistency. The analysis is detailed below.

Characteristics of relative quantification of hepatic phosphorus metabolites

ATP: There were significant differences in ATP relative quantification among the control group, mild group, moderate group, and severe group according to both LDS grading and pathological grading (LDS groups: mild group, moderate group, severe group *vs* control group had P = 0.007, 0.000, 0.000, respectively; moderate group, severe group *vs* mild group had P = 0.008, 0.000, respectively; severe group *vs* moderate group had P = 0.013. Pathological groups: mild group, moderate group, severe group *vs* control group had P = 0.017, 0.000, 0.000, respectively; moderate group, severe group *vs* mild group had P = 0.000, 0.000, respectively; severe group *vs* moderate group had P = 0.008); it decreased progressively with the increased degree of injury, which is visually displayed by the correlation graph of ATP and LDS (Figure 5). These data illustrated that the hepatic ATP level may be the most sensitive criterion for reflecting hepatic injury in rabbits.

PME and Pi: The relative quantification of PME and Pi decreased significantly in the severe injured group, and the difference was significant compared with the control group (PME: LDS-severe group *vs* LDS-control group had P = 0.031, pathological-severe group *vs* pathological-control group had P = 0.037. Pi: LDS-severe group *vs* LDS-control group had P = 0.013, pathological-severe group *vs* pathological-control group had P = 0.005). Also, from the ^{31}P MR spectra (Figure 4C and D), a significant decrease in the signal of phosphorylated metabolites could be seen. This indicated that if there was a significant

difference in PME and Pi between normal data and test data, the tested liver was likely to be severely injured.

PDE: The relative quantification of various hepatic PDE levels changed irregularly, which indicated that the relative quantification levels of PDE may not be applied solely to assess acute hepatic radiation injury.

The characteristics of the ratio of relative quantification of other phosphorus metabolites

There were significant changes in the PDE/ATP ratio between control group and moderate group; mild group and moderate, severe group; moderate group and control group, mild group (LDS-groups: moderate group, severe group *vs* control group had $P = 0.026$, 0.025, respectively; moderate group, severe group *vs* control group had $P = 0.014$, 0.014, respectively; pathological-groups: moderate group, severe group *vs* control group had $P = 0.076$, 0.064, respectively; moderate group, severe group *vs* control group had $P = 0.002$, 0.020, respectively). There were no significant changes in the PDE/Pi ratio among all groups. Compared with the control group, no significant changes of PME/PDE, Pi/ATP and PME/Pi ratio were found in other groups.

The above results illustrated that there were few characteristic differences in the ratios of relative quantification of various hepatic phosphorus metabolites in hepatic radiation injury. Therefore, the ratios of relative quantification may not be used to evaluate acute mild hepatic radiation injury.

DISCUSSION

Acute liver diseases can result from various causes which operate through different pathophysiological pathways and which elicit distinct patterns of hepatic injury. Diagnosis of acute liver diseases including hepatic radiation injury is mainly based on invasive methods such as liver biopsy, laparoscopy, various radiological examinations and other clinical tests. On the other hand, signals from ^{31}P MRS reflect *in vivo* intracellular and membrane metabolism non-invasively and they are objective parameters[2,12].

Evaluation method for ^{31}P MRS and its influencing factors

The evaluation of ^{31}P MRS in the liver includes absolute or relative quantification of metabolite levels. Nowadays, absolute quantification of metabolites in mmol/L is hampered by the use of too short TR values and other technical complications[13,14], but most studies with ^{31}P MRS deal with the relative signal intensity for quantification. Also, here we measured the relative quantification of metabolites, and the relative signal ratios of the metabolites. The relative quantification evaluation had to satisfy 3 conditions for decreasing detection errors: (1) phantom experiments before relative quantification of hepatic metabolites in each rabbit to reduce errors induced by the MR imager and environment factors, *etc*; (2) a VOI selected in the largest section of liver and a small PCr signal characterizing the presence of abdominal muscles; (3) moderate anesthesia of rabbits and keeping the rabbits in the same position in the bed of the MR imager.

The changes in hepatic ATP levels

Many published studies of ^{31}P MR spectra have shown that acute and chronic diffuse liver diseases are associated with a reduction in hepatic ATP levels[3,6,7], and some studies found that changes in hepatic ATP levels correlate with changes in liver histology[3,6]. Our findings, that the relative quantification of hepatic ATP levels displayed progressive reductions with increased hepatic injury, correspond to the results of a previous study[6], but we are the first to report that the changes in hepatic ATP levels correlate with the severity of acute hepatic radiation injury. Some reports have shown that, during the early phase of chronic diffuse liver diseases, only minor changes in hepatic ATP could be detected[15,16]. Our study showed that the relative quantification of hepatic ATP levels obviously decreased, because there were significant differences between the control group and both the pathological-mild group and LDS-mild group. We also found that the changes in levels of other hepatic metabolites were less sensitive than the changes in ATP levels in mild hepatic injury, and the relative quantification of hepatic ATP levels could be well correlated with LDS. Thus, we suggest that the hepatic ATP level may be the most reliable criterion for evaluating acute hepatic injury in rabbits. The reason is that the β-ATP peak is unique, and quite different from other phosphorylated metabolite peaks, which overlap with signals of other metabolites in the ^{31}P MRS map.

The mechanisms responsible for the decline in hepatic ATP levels include: gradual loss of viable hepatocytes, which is likely to be an important contributing factor-as the total amount of these cells per unit volume of liver decreases, MRS detectable signal from that volume will also decrease[6]; anoxemia of local liver tissue induced by injury of capillary vessels after hepatic radiation[17]; increased energy expenditure as liver disease progresses[18]. In addition, disturbed hepatic bioenergetics has also been ascribed to the capillarization of hepatic sinusoids during the development of cirrhosis[19].

The changes in levels and ratios of relative quantification of other phosphorus metabolites

PME, PDE and the correlation ratio: information about phospholipid membrane metabolism may also be obtained from the PME and PDE resonances in the ^{31}P MR spectrum. Both resonances are multicomponent peaks containing contributions from several metabolites[20]. The significance of the changes in PME and PDE levels is not clear. Some previous studies have reported that an increase in PME levels is accompanied by a decrease in PDE levels or increased ratios of hepatic PME/ATP and PME/PDE in acute and chronic diffuse liver diseases[1,2,21,22]. However, in other investigators, and our study, PME levels did not increase nor did PDE levels decrease in the same acute and chronic diffuse

liver diseases[6,8]. The main reason for these conflicting findings may be the broad, overlapping characteristics of these peaks along with the multiple signals contributing to these resonances hindering accurate quantification of the PME and PDE peaks[8]. Another explanation is that hepatic phospholipid membrane activity may differ in animal models of liver diseases versus liver diseases in humans[6]. Therefore, either the changes in PME and PDE levels or the ratio PME/PDE cannot accurately reflect the liver diseases.

Pi and the correlation ratio: Pi is another marker of tissue bioenergetics. Increases in Pi have been observed by ^{31}P MRS during high energy activities such as liver regeneration following partial hepatectomy[8,23]. The increase in hepatic Pi may result from the hydrolysis of high energy phosphate bonds which in turn liberates Pi species, increases hepatic uptake and accumulation of Pi due to enhanced metabolic activity and reduces recycling back to purine/pyrimidine moieties[8]. Some previous studies have reported a decrease or no difference in Pi levels in chronic diffuse liver diseases in humans and animals[1,6]. The reason for no changes in hepatic Pi is not clear, but the decrease in hepatic Pi may result from reduced hepatocyte mass[6]. In this study, significant decreases in Pi were only detected among the most seriously injured livers of the severe group. The lower levels of hepatic Pi likely result from reduced hepatocyte mass, as Corbin *et al*[6] reported. In addition, compared with the ATP peak, the Pi peak, which is located between the PME and PDE peaks, is more prone to being impacted by the overlapping characteristics of PME and PDE peaks, hindering accurate quantification of the Pi peak. However, some authors regarded the ratio ATP/Pi as the criterion of hepatic regenerative activity following partial hepatectomy, because the ATP levels decreased, the Pi levels increased, and the changes of the ratio were more sensitive than ATP or Pi alone[8]. However, the levels of ATP or Pi were decreased to different degrees after acute hepatic radiation injury in our study, so the ratio of ATP/Pi could not be used to evaluate acute hepatic radiation injury.

This study illustrated that ^{31}P MRS of clinical 1.5T MRS could detect various changes of phosphorylated metabolite levels in early acute hepatic injury. In addition, the study also showed that though there were many hepatic phosphorylated metabolites and correlated ratios, the measurement of levels of hepatic ATP may be the most reliable criterion for reflecting both pathological hepatic injury and LDS in rabbits.

COMMENTS

Background

Acute hepatic radiation injury can lead to necrosis of hepatocytes, fatty degeneration and hepatic fibrosis. The current gold standard test is liver biopsy. This procedure is invasive, uncomfortable for the patient and sometimes has serious complications. These factors highlight the need for a noninvasive test to characterize diffuse liver disease. Already, it has been reported that phosphorus-31 magnetic resonance spectroscopy (^{31}P MRS) not only complements liver biopsy but also is a possible replacement, and furthermore, ^{31}P MRS has particular value in assessing disease progression.

Research frontiers

^{31}P MRS has been used to study liver metabolism *in vivo* for several years, including clinical liver disease studies and experimental studies. The research focus is how to observe the energy metabolism or pathological changes through the signals of phosphorus metabolites.

Innovations and breakthroughs

In this study the authors carefully used two different methods [liver damage score (LDS), and pathology] to evaluate the degree of injury, and then they studied the correlation between MRS and the degree of injury. Furthermore, they report that the changes in hepatic adenosine triphosphate (ATP) levels correlate with the severity of acute hepatic radiation injury measured by LDS.

Applications

This study may be particularly useful for allowing clinical detection of early acute hepatic injury with ^{31}P MRS in the future.

Terminology

MRS: Spectroscopic method for measuring the magnetic moment of elementary particles such as atomic nuclei, protons or electrons. It is employed in clinical applications such as NMR Tomography (magnetic resonance imaging).

Peer review

^{31}P MRS is a very interesting method especially to replace the gold standard biopsy, particularly in assessing disease progression.

Abstract

AIM: To evaluate whether celecoxib, a selective cyclooxygenase 2 (COX-2) inhibitor, could reduce the severity of gastric precancerous lesions following *Helicobacter pylori* (*H pylori*) eradication.

METHODS: *H pylori*-eradicated patients with gastric precancerous lesions randomly received either celecoxib (n = 30) or placebo (n = 30) for up to 3 mo. COX-2 expression and activity was determined by immunostaining and prostaglandin E_2 (PGE_2) assay, cell proliferation by Ki-67 immunostaining, apoptosis by TUNEL staining and angiogenesis by microvascular density (MVD) assay using CD31 staining.

RESULTS: COX-2 protein expression was significantly increased in gastric precancerous lesions (atrophy, intestinal metaplasia and dysplasia, respectively) compared with chronic gastritis, and was concomitant with an increase in cell proliferation and angiogenesis. A significant improvement in precancerous lesions was observed in patients who received celecoxib compared with those who received placebo (P < 0.001). Of these three changes, 84.6% of sites with dysplasia regressed in patients treated with celecoxib (P = 0.002) compared with 60% in the placebo group, suggesting that celecoxib was effective on the regression of dysplasia. COX-2 protein expression (P < 0.001) and COX-2 activity (P < 0.001) in the gastric tissues were consistently lower in celecoxib-treated patients compared with the placebo-treated subjects. Moreover, it was also shown that celecoxib suppressed cell proliferation (P < 0.01), induced cell apoptosis (P < 0.01) and inhibited angiogenesis with decreased MVD (P < 0.001). However, all of these effects were not seen in placebo-treated subjects. Furthermore, COX-2 inhibition resulted in the up-regulation of PPARγ expression, a protective molecule with anti-neoplastic effects.

CONCLUSION: *H pylori* eradication therapy followed by celecoxib treatment improves gastric precancerous lesions by inhibiting COX-2 activity, inducing apoptosis, and suppressing cell proliferation and angiogenesis.

INTRODUCTION

Gastric cancer is the second leading cause of cancer deaths worldwide[1] and its 5-year survival rate is only 10%-15% in individuals with advanced disease[2]. *Helicobacter pylori* (*H pylori*) has been classified as a type I carcinogen by the WHO and is recognized as an important pathogen in gastric tumorigenesis[3]. *H pylori* infection initiates the inflammatory and atrophic changes in gastric mucosa accompanied by enhanced expression of some protumorigenic factors such as cyclooxygenase 2 (COX-2) and anti-apoptosis proteins, resulting in uncontrolled proliferation of mutated atrophic cells, suppression of apoptosis, excessive angiogenesis and finally the formation of adenocarcinoma[4].

In cancer prevention, the targeting of precancerous lesions has been recognized as the most promising method. However, progress has been achieved only in the chemoprevention of colorectal neoplasia[5]. There is no effective therapy for reversing gastric premalignant lesions. Although *H pylori* infection is a critical initiator and mediator in gastric premalignant changes and gastric carcinogenesis, eradication of *H pylori* alone failed to improve these precancerous lesions[6-8]. The failure of *H pylori* eradication may be explained by the fact that the expression of COX-2, an important mediator in *H pylori*-induced premalignant changes, remained high or only modestly reduced after *H pylori* eradication[6-8]. It has been widely accepted that COX-2 plays an important role in gastric carcinogenesis[9]. COX-2 over-expression has been found in *H pylori*-induced inflammation, precancerous lesions and gastric tumors[9]. Inhibition of COX-2 by non-steroidal anti-inflammatory drugs (NSAIDs) has been proven to be effective in preventing gastric carcinogenesis as evidenced in animal models and epidemiological studies[2,9,10]. Since eradication of *H pylori* alone is not sufficient to reverse gastric carcinogenesis due to failure of the inhibition of *H pylori*-induced protumorigenic factors such as COX-2, it would be reasonable to combine additional treatments such as COX-2 inhibition following *H pylori* eradication.

In the present study, we examined whether treatment with the selective COX-2 inhibitor celecoxib could reduce the severity of gastric precancerous lesions after *H pylori* eradication. The mechanisms of its action were also investigated.

MATERIALS AND METHODS

Patients and study design

We enrolled 233 patients who had upper-gastrointestinal symptoms such as anorexia, early satiety, stomach pain, abdominal distention and epigastric discomfort between January 2005 and July 2006 from the First Affiliated Hospital of Hebei Medical University, Shijiazhuang, China. Eligible subjects were between 30 and 70 years of age, and had no history of drug allergies. Subjects were ineligible if they were under 30 or older than 70 years old; pregnant or lactating; had peptic ulcer; gastric cancer or other cancers; upper gastrointestinal bleeding; liver cirrhosis; serious cardiovascular diseases, renal or lung diseases; hypersensitive to COX-2 inhibitors, NSAIDs, salicylates, or sulfonamides; used NSAIDs; and those unwilling to undergo repeat endoscopy after treatment.

H pylori infected patients who were defined both by the presence of the bacterium on histology as well as a positive C^{14} urea breath test were treated with a 1-wk course of eradication therapy (omeprazole, 20 mg; amoxicillin, 1000 mg; furaltadone, 100 mg; twice daily). Five weeks post-treatment, patients were recalled to hospital for repeat endoscopy and C^{14} urea breath test. *H pylori* eradication was confirmed by a negative C^{14} urea breath test and a negative *H pylori* histology examination from biopsies. Only patients with confirmed *H pylori* eradication were recruited into this study. During each endoscopy, a total of eight gastric biopsies were taken from the antrum (two from the greater curvature and two from the lesser curvature) and the corpus of the stomach (two from the greater curvature and two from the lesser curvature) for molecular experiments and histological examination. One of the two biopsy specimens from each site was immediately stored at -80℃ for RNA/protein extraction. The other specimens were fixed in 10% neutral buffered formalin and embedded in paraffin for histological examination and immunostaining. The severity of gastric histology including gastritis and precancerous lesions [gastric atrophy, intestinal metaplasia (IM) and low-grade dysplasia] was scored based on the following standards: absent (0), mild (1), moderate (2) and marked (3)[11]. Patients with high-grade dysplasia were excluded from the study. All gastric biopsies were interpreted by two pathologists who were unaware of the treatment assignments.

One hundred and thirty six eligible subjects who were histologically confirmed to have gastric precancerous lesions and negative tests for *H pylori* were randomly assigned to receive either celecoxib 200 mg twice daily or an identical-looking placebo at a 1:1 ratio for 3 mo. During the treatment period, 10 subjects were withdrawn due to adverse events and 66 were lost to follow-up. Some patients lost to follow-up migrated to other cities, some were non-compliant and failed to follow through with our treatment protocol, and some refused to undergo a second endoscopy. At the end of the 3-mo treatment period, 30 patients in the celecoxib group (16 males with an average age of 50.33 ± 10.39 years; 14 females with an average age of 57.36 ± 9.25 years) and 30 patients in the placebo group (14 males with an average age of 48 ± 10.43 years; 16 females with an average age of 50 ± 9.98 years) returned for endoscopic examination. The same protocols for obtaining gastric biopsy and histological examination were used as previously mentioned in the baseline endoscopy. The study protocol was approved by the Clinical Research Ethics Committee and all participants gave written informed consent.

Immunohistochemistry

The paraffin-embedded gastric sections were

Table 1 Primer sequences used for amplification of mRNA by semi-quantitative PCR

mRNA	Forward primer (5′-3′)	Reverse primer (5′-3′)	Size (bp)
PCNA	CTTTTCTGTCACCAAATTTGTACC	AACTGCATTTAGAGTCAAGACCC	206
Fas	CTGCCAAGAAGGGAAGGAGT	GGTGCAAGGGTCACAGTGTT	189
PPARγ	AGCCTCATGAAGAGCCTTCCA	ACCCTTGCATCCTTCACAAGC	89
β-actin	GTCTTCCCCTCCATCGTG	GGGTGAGGATGCCTCTCTT	251

deparaffinized and rehydrated in graded ethanol. The activity of endogenous peroxidase was blocked by methanol containing 3% H_2O_2 for 10 min and washed with PBS. After blocking with 10% nonimmunized goat serum at 37℃ for 20 min, sections were incubated with the primary antibody for COX-2 (1:500, Santa Cruz Biotechnology, Santa Cruz, CA, USA), Ki-67 (1:200, Chemicon International Inc., Temecula, CA, USA), peroxisome proliferator-activated receptor γ (PPARγ) (1:100, Santa Cruz) overnight at 4℃. Peroxidase activity was visualized by applying diaminobenzidine to the sections, which were then counter-stained with hematoxylin. Analysis of the immunostained sections was independently performed by two pathologists in a blinded fashion.

Microvessel density (MVD) was performed on paraffin-embedded gastric tissue sections stained with CD31 (1:150, DAKO, Glostrup, Denmark) as an indicator. For the determination of MVD in each case, five of the most highly vascularized areas within a section were selected and counted under a light microscope. The average numbers of microvessels in the selected fields were recorded as the MVD for each case.

cDNA synthesis and RT-PCR

Gastric tissue specimens were homogenized with a homogenizer. Total RNA was extracted using TRIzol reagent (Invitrogen, USA). Five micrograms of total RNA from each sample was reverse transcribed into cDNA using the AMV Reverse Transcription system (Promega, San Luis Obispo, CA, USA). Semi-quantitative PCR was performed. The primer sequences of proliferation cell nuclear antigen (PCNA), factor associated suicide (FAS), PPARγ and β-actin are listed in Table 1. A DNA free template control (containing water) was included and each sample was added in duplicate. PCR products were separated by 15% agarose gel electrophoresis and quantified by the Gel Imaging System after ethidium bromide (10 mg/L) staining. The mRNA expression level of the target gene was defined by the densitometry ratio of target gene to β-actin.

PGE_2 assay

PGE_2 levels were measured in snap frozen tissue specimens using a radioimmunoassay-based assay. Briefly, about 20 mg of snap frozen tissues were homogenized in 10 volumes of sodium chloride by a ground glass homogenizer on ice. The mixture was incubated at 37℃ for 15 min and then centrifuged for 20 min at 3000 r/min. The supernatant was then applied to the pre-primed immunoassay reaction mixture and reacted with the antibody overnight. PGE_2 was precipitated with 0.7 mL volumes of 25% polyethylene glycol. The quantity of PGE_2 in the supernatants was determined using RIA.

Determination of cell proliferation

Proliferation was assayed by immunoperoxidase staining for Ki-67 as described previously[12]. The immunochemistry method for staining the sections with Ki-67 antibody has been specified above. The proliferation index (PI) was defined as a percentage of the ratio of Ki-67-positive nuclei to the total nuclei counted.

Terminal deoxynucleotidyl transferase-mediated nick end labeling (TUNEL)

Apoptosis was determined *in situ* from paraffin-embedded tissue sections by the TUNEL assay using the *in situ* Cell Death Detection kit (Roche Applied Science, Indianapolis, IN, USA). Briefly, paraffin-embedded slides were deparaffinized, hydrated and incubated with proteinase K (20 mg/mL in 10 mmol/L Tris-HCl) for 20 min. After labeling with the TUNEL reaction mixture, slides were developed by converter-POD and DAB substrate. PBS replaced the primary antibodies as a negative control. The results of staining were analyzed and evaluated by three individuals independently. At least 1000 cells were counted in five random fields. Apoptosis index (AI) was represented as the percentage of positive cells with TUNEL staining to the total cells.

Statistical analysis

Data were analyzed by SPSS 12.0 software and are shown in a default form of mean ± SD. The association between COX-2 expression and the progression of precancerous lesions was analyzed by χ^2 test. The correlation between COX-2 expression and MVD/PI was analyzed using Pearson's Correlation Coefficient. The difference between the groups was compared by *t* test. The paired *t* test was used to determine the difference between pre-treatment and after-treatment within each treatment group. $P < 0.05$ was considered statistically significant.

RESULTS

Association between COX-2 expression and progression of precancerous lesions

The percentage of COX-2 positive cells in gastric tissues was increased with the progression of chronic gastritis

(33.3%), atrophy (51.6%), IM (53.3%), and dysplasia (79.3%) as determined by immunostaining. COX-2 expression in dysplasia (79.3%) was significantly higher than in any other type of lesion ($P < 0.05$). COX-2 expression was significantly elevated in atrophy and IM compared with chronic gastritis ($P < 0.05$). However, there was no significant difference between gastric atrophy and IM ($P > 0.05$).

COX-2 expression correlated with cell proliferation

Cell proliferation was determined by Ki-67 staining. A significant positive correlation between COX-2 expression and PI ($\chi^2 = 10.5$, $P = 0.001$) was observed by Pearson's Correlation Coefficient analysis, indicating COX-2 expression correlated with cell proliferation.

COX-2 expression correlated with angiogenesis

We also evaluated the correlation between COX-2 expression and angiogenesis as determined by CD31 immunostaining. The mean MVD was significantly higher in COX-2-positive tissues ($n = 47$, 23.85 ± 7.44) than in COX-2-negative tissues ($n = 27$, 18.47 ± 6.02) ($P < 0.001$), indicating a positive correlation between COX-2 expression and MVD. Thus COX-2 also played an important role in angiogenesis.

Effect of celecoxib on the improvement in histology of gastric precancerous lesions

After three months treatment, a significant improvement in precancerous lesions was observed in 66.7% (20/30) of patients ($P < 0.001$) who were treated with celecoxib. However, only 16.1% of cases who received placebo showed improved histology ($P > 0.05$). Of these three changes, 84.6% of sites with dysplasia regressed in patients treated with celecoxib ($P = 0.002$) compared with 60% in the placebo group, suggesting that celecoxib was effective on the regression of dysplasia (Table 2). However, differences in pathological improvement of atrophy and intestinal metaplasia were not observed between the celecoxib and placebo groups (Table 2). With regard to the mixed pathological sites with both atrophy and intestinal metaplasia, we did not have sufficient sample size to make an accurate conclusion.

Effect of celecoxib on COX-2 protein expression and COX-2 activity

COX-2 protein expression as determined by the percentage of COX-2 positive cells in the gastric tissues was significantly lower after treatment with celecoxib (pre-treatment: 40.93% ± 11.96% *vs* after-treatment: 27.88% ± 4.94%, $P < 0.001$) (Figure 1A-C). COX-2 protein expression was reduced in 73%, remained the same in 13% and increased in 13% of patients treated with celecoxib. However, COX-2 expression was reduced in only 48% of patients in the placebo group (Table 3). PGE_2 level, an indicator of COX-2 activity, was concomitantly reduced in patients treated with celecoxib (pre-treatment: 358.9 ± 59.3 *vs* after-treatment: 143.6 ± 24.2, $P < 0.001$). However, these differences in COX-2 expression and COX-2 activity were not seen in patients treated with placebo (Figure 1D).

Table 2 Effect of celecoxib on the histological improvement of gastric precancerous lesions

Precancerous lesions	Regression site *n* (%)		*P*-value
	Celecoxib group	Placebo group	
Atrophy	11/13 (84.6)	7/13 (53.8)	0.202
Metaplasia	9/14 (64.3)	9/18 (50)	0.419
Atrophy + metaplasia[1]	3/4 (75)	3/6 (50)	0.895
Dysplasia	35/39 (89.7)	24/40 (60)	0.002

[1]Indicates that both atrophy and metaplasia were regressed in one site.

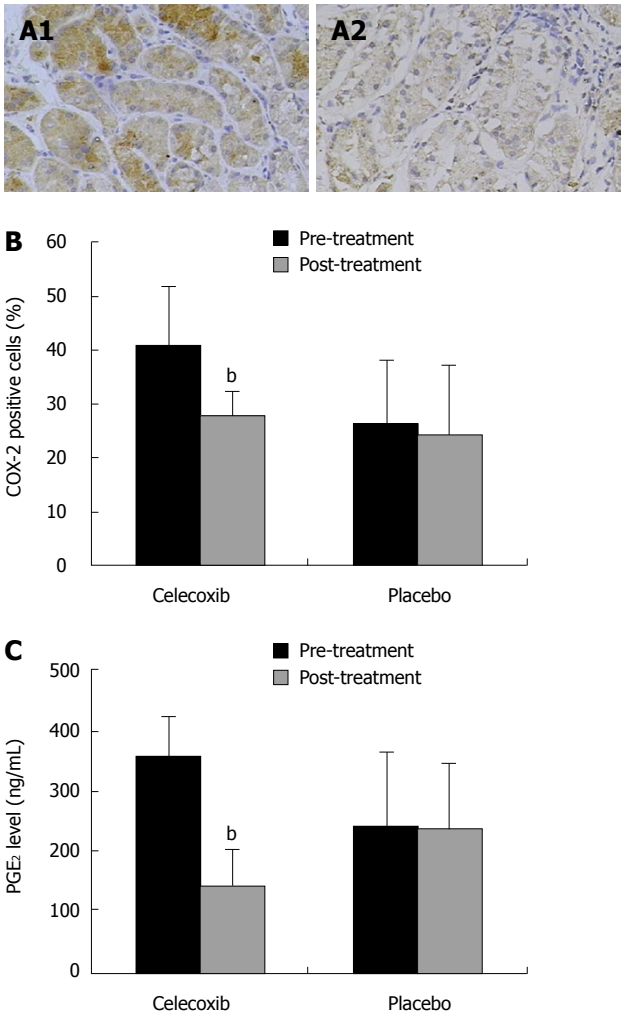

Figure 1 Effects of celecoxib on COX-2 expression and PGE_2 levels. A: Representative image of COX-2 protein expression as determined by immunostaining in paraffin-embedded gastric tissue sections: (A1) pre-treatment, and (A2) post-treatment with celecoxib; B: Percentage of COX-2 positive cells in gastric mucosa; C: PGE_2 levels. Data are mean ± SD. $^bP < 0.001$.

Effect of celecoxib on cell proliferation

Cell proliferation was significantly reduced in the celecoxib group after 3 mo of treatment (pre-treatment: 27.46% ± 6.77% *vs* after-treatment: 20.18% ± 4.05%, $P < 0.01$) (Figure 2A and B). However, this difference was not observed in patients treated with placebo (Figure 2B). Seventy percent of patients in the celecoxib

Table 3 Effect of celecoxib on COX-2 expression and other parameters

	Celecoxib group *n* (%)			Placebo group *n* (%)		
	Reduction	Same	Worse	Reduction	Same	Worse
COX-2 expression	22 (73)	4 (13)	4 (13)	15 (48)	3 (10)	13 (43)
Cell proliferation	23 (77)	2 (7)	5 (17)	11 (37)	3 (10)	16 (53)
Cell apoptosis	8 (53)	4 (27)	3 (20)	4 (27)	5 (17)	6 (40)
Angiogenesis	22 (73)	4 (13)	4 (13)	12 (39)	10 (32)	9 (29)
PPARγ expression	15 (50)	5 (17)	10 (33)	9 (29)	5 (16)	17 (55)

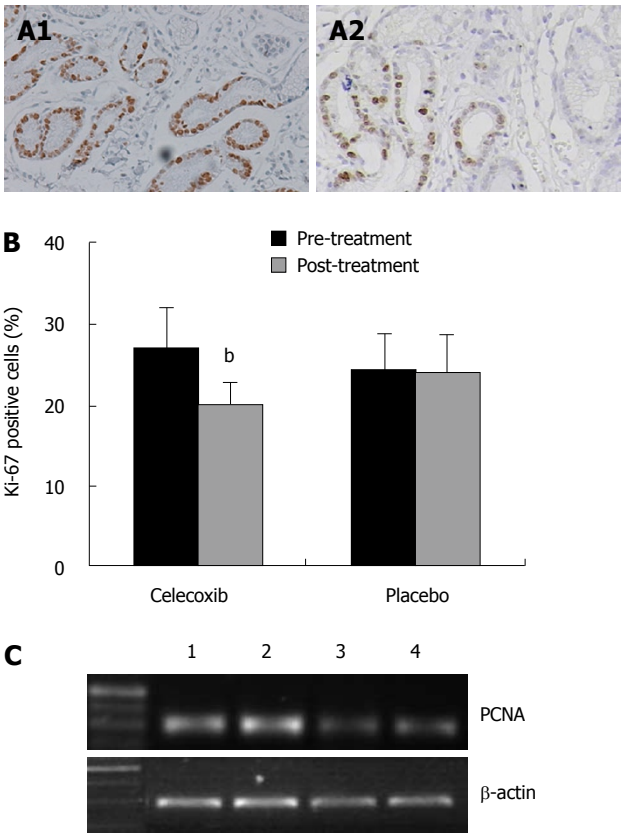

Figure 2 Effects of celecoxib on cell proliferation. A: Representative Ki-67 staining of gastric mucosa before (A1) and after treatment (A2) with celecoxib; B: Celecoxib led to a significant reduction in proliferation index (PI); C: Celecoxib down-regulated mRNA expression of proliferation cell nuclear antigen (PCNA). 1 and 2: Plecebo; 3 and 4: Celecoxib. Data are mean ± SD. $^{b}P < 0.01$.

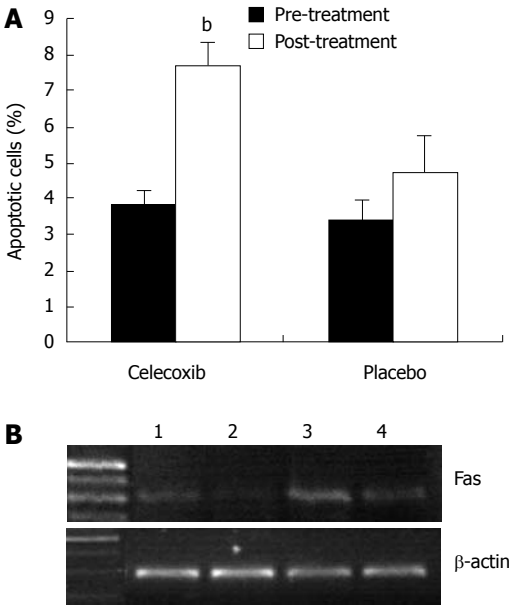

Figure 3 Effects of celecoxib on cell apoptosis. A: Celecoxib induced the apoptosis index (AI) in gastric mucosa; B: Celecoxib up-regulated mRNA expression of Fas, a pro-apoptosis gene. 1 and 2: Plecebo; 3 and 4: Celecoxib. Data are mean ± SD. $^{b}P < 0.01$.

group had reduced PCNA protein expression while a reduction in PCNA expression was observed in only 37% of patients in the placebo group (Table 3). In addition, mRNA expression of PCNA was markedly down-regulated by celecoxib treatment (Figure 2C).

Effect of celecoxib on cell apoptosis

Treatment with celecoxib significantly induced cell apoptosis as assayed by TUNEL staining (pre-treatment: 3.86% ± 0.44% *vs* after-treatment: 7.72% ± 0.64%, $P < 0.01$) (Figure 3A, Table 3). In keeping with this, mRNA expression of the pro-apoptotic gene *fas* was also enhanced (Figure 3B), suggesting that celecoxib-induced apoptosis was *via* up-regulation of *fas* expression.

Effect of celecoxib on angiogenesis

Angiogenesis was evaluated by the MVD assay using CD31 staining. MVD was significantly lower after celecoxib treatment ($P < 0.001$) (Figure 4, Table 3), indicating a suppressive effect on angiogenesis by celecoxib. However, this difference was not seen in the placebo group.

Effect of celecoxib on PPARγ expression

Celecoxib treatment led to an increase in the number of PPARγ positive cells as determined by immunostaining (pre-treatment: 18% ± 4.33% *vs* after-treatment: 22.6% ± 4.3%, $P < 0.05$) (Figure 5, Table 3). Thus, celecoxib resulted in up-regulation of PPARγ expression.

DISCUSSION

We report here that COX-2 is markedly up-regulated in gastric tissues with inflammation and was more prominent during progression in precancerous lesions in *H pylori*-eradicated patients. Moreover, the induction of COX-2 appeared to coincide with increased cell proliferation and angiogenesis. These results suggested that COX-2 was induced by *H pylori* infection and mediated by *H pylori*-associated premalignant gastric lesions. Our observation on the profile of COX-2 expression is supported by previous studies[7,8,13-16],

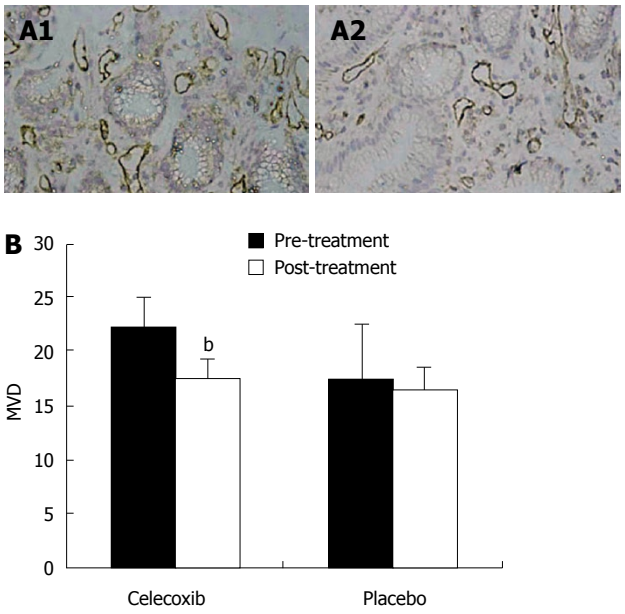

Figure 4 Effects of celecoxib on angiogenesis. A: Representative microvessel image of paraffin-embedded gastric tissue sections stained with CD31. (A1) pre-treatment, and (A2) post-treatment with celecoxib; B: Celecoxib suppressed microvessel density (MVD). Data are mean ± SD. $^{b}P < 0.001$.

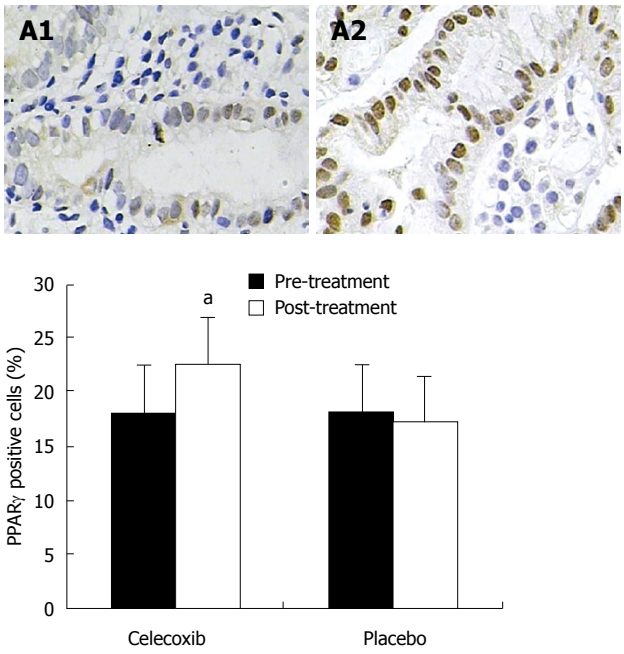

Figure 5 Effects of celecoxib on PPARγ protein expression. Representative PPARγ expression in paraffin-embedded gastric tissue sections by immunostaining. suggesting that COX-2 is a relatively early event and plays an important role during gastric carcinogenesis.

To evaluate whether progression of precancerous lesions could be reduced or reversed, we conducted a 3-mo intervention of celecoxib in patients with precancerous lesions after *H pylori* eradication. Our results showed that the histology of precancerous lesions was improved in 66.7% of patients treated with celecoxib, which was significantly higher than the placebo group (16.1%) ($P < 0.001$). Of the three precancerous changes (atrophy, intestinal metaplasia and dysplasia), celecoxib was effective on the regression of dysplasia. However, the evidence for chemopreventive effects on gastric precancerous lesions by NSAIDs has only been limited to animal experiments[13,17-22]. In the animal model of carcinogenesis induced by co-treatment with *H pylori* and N-methyl-N-nitrosourea (MNU), mice underwent *H pylori*-induced gastritis with multifocal atrophy and intestinal metaplasia, and finally gastric adenocarcinoma. Long term co-administration with a COX-2 inhibitor, either celecoxib or nimesulide not only reduced the development of intestinal metaplasia, but also adenocarcinoma[20-22]. In human studies, a recent report showed that treatment with NSAIDs for more than 3 mo reversed *H pylori*-induced harmful effects in gastric epithelial cells[23]. On the other hand, large-scale clinical trials have shown that NSAIDs were effective in the chemoprevention of colorectal neoplasia[5]. NSAIDs (celecoxib and sulindac) promoted regression in both number and size in high risk individuals with familial adenomatous polyposis[5]. In the more common sporadic setting, refecoxib and celecoxib reduced the occurrence of human colorectal adenomas[5]. Collectively, these results suggest that the protective effects of NSAIDs such as celecoxib could effectively prevent or reverse the precancerous lesions of gastric cancer.

We further evaluated the underlying mechanisms for the anti-tumorigenic effects of the COX-2 inhibitor. On the basis of the cell proliferation and apoptosis analyses, improvements in precancerous lesions caused by celecoxib were most likely associated with the suppression of cell proliferation and induction of cell apoptosis. In keeping with this, in an animal experiment, celecoxib but not indomethacin suppressed gastric cancer formation by inducing cell apoptosis and suppressing cell proliferation[24,25] in a dose dependent manner. A recent report also indicated that NSAIDs induced apoptosis through activation of extrinsic and intrinsic pathways of apoptosis[26]. However, the pro-apoptotic efficacy of various NSAIDs differed greatly[27,28]. That may explain why the anti-tumor effects of NSAIDs varied in different experiments.

In the present work, we showed that, in addition to inhibition of cell proliferation and induction of apoptosis, the regression of precancerous lesions in the stomach by celecoxib was also related to inhibition of angiogenesis. It is well-established that the inducible enzyme COX-2 is an important mediator of angiogenesis during tumor growth[29]. COX-2 expression significantly correlated with MVD[30] and vascular endothelial growth factor (VEGF) in human gastric adenomas and carcinomas[31]. The pro-angiogenic effects of COX-2 are mediated primarily by the metabolites of arachidonic acid, resulting in increased production of VEGF, enhanced survival of endothelial cells, induction of matrix metalloproteinases, promotion of vascular sprouting and migration and activation of epidermal growth factor receptor-mediated angiogenesis[29]. In this regard, we showed in this study that induction of

COX-2 is parallel with the induced angiogenesis in precancerous lesions. Treatment with celecoxib inhibited angiogenesis with a concomitant histological regression of precancerous lesions. Others have also reported that NSAIDs including celecoxib inhibited angiogenesis and decreased tumor growth in gastric cancer and other cancers both *in vitro* and *in vivo* in animal models[13, 32-34]. Our study provided the first clinical evidence that treatment with celecoxib effectively suppressed angiogenesis and lowered MVD in *H pylori*-eradicated patients with gastric precancerous lesions.

The expression of PPARγ, a protective anti-neoplastic molecule[35], was enhanced by the COX-2 inhibitor rofecoxib in human gastric cancer with a concomitant induction of apoptosis and attenuation of proinflammatory cytokines production[36]. We also observed the up-regulation of PPARγ in patients treated with celecoxib. The up-regulation of PPARγ by NSAIDs was reported either *via* the COX-2 independent pathway or the COX-2 dependent pathway[37-39]. Activation of PPARγ was shown by us and others to prevent mammary carcinogenesis in experimental animals[40-42] through suppression of COX-2 expression[40]. In mice treated with MNU and *H pylori*, nimesulide administration substantially reduced *H pylori*-associated gastric tumorigenesis along with substantial activation of PPARγ and induction of apoptosis[21]. Collectively, these findings raise the possibility that up-regulation of PPARγ by celecoxib contributed to the histological improvement in precancerous lesions.

In conclusion, COX-2 expression was induced in gastric epithelium with the progression of precancerous lesions. Eradication of *H pylori* combined with a 3-mo intervention of celecoxib was effective in improving the severity of precancerous lesions mainly by inducing apoptosis, and inhibiting cell proliferation and angiogenesis. Thus COX-2 is a promising target in reversing gastric precancerous lesions and celecoxib showed efficacy in the chemoprevention of these lesions.

COMMENTS

Background

Epidemiologic studies have shown that cyclooxygenase 2 (COX-2) inhibitor could reduce the risk of gastric cancer. The authors aim to evaluate whether celecoxib, a selective COX-2 inhibitor, could reduce the severity of gastric precancerous lesions following *Helicobacter pylori* (*H pylori*) eradication.

Research frontiers

Gastric cancer is the most common cancer and the leading cause of cancer-related death in China, with an overall 5-year survival rate of only 10%-20%. There is a compelling need to explore the novel targets that contribute to gastric carcinogenesis for effective treatment. The development of gastric cancer is generally believed to be a multi-step progression from chronic gastritis to atrophy, intestinal metaplasia (IM), dysplasia and cancer, that is triggered by *H pylori* infection. Eradication of *H pylori* alone is not efficient in preventing the progression of gastric IM. The authors hypothesized in addition to eradicate *H pylori*, inhibition of COX-2, a potential oncogene gene that was induced in the early stage of gastric carcinogenesis, by selective COX-2 inhibitor (celecoxib) may regress the premalignant changes in the stomach by suppressing COX-2. Herein, they tested the effect of a specific COX-2 inhibitor in patients with confirmed gastric atrophy and/or IM after *H pylori* eradication. The present study was a prospective, randomized, and placebo-controlled study.

Innovations and breakthroughs

The authors have demonstrated in this study that *H pylori* eradication therapy followed by celecoxib treatment improves and dampens the progression of gastric precancerous lesions. The anti-neoplastic properties of celecoxib were due to its ability of inhibiting COX-2 activity, inducing apoptosis, suppressing cell proliferation and angiogenesis.

Applications

COX-2 was a promising target in reversing gastric precancerous lesions and celecoxib showed efficacy in this chemoprevention. This finding may provide clinical implication.

Peer review

The authors report interesting data on the effect of celecoxib administration in patients with gastric precancerous lesions following *H pylori* eradicated. This is a well designed study with interesting results.

Abstract

AIM: To identify multi-detector computed tomography (MDCT) features most predictive of serous cystadenomas (SCAs), correlating with histopathology, and to study the impact of cyst size and MDCT technique on reader performance.

METHODS: The MDCT scans of 164 patients with surgically verified pancreatic cystic lesions were reviewed by two readers to study the predictive value of various morphological features for establishing a diagnosis of SCAs. Accuracy in lesion characterization and reader confidence were correlated with lesion size ($\leqslant$ 3 cm or $\geqslant$ 3 cm) and scanning protocols (dedicated *vs* routine).

RESULTS: 28/164 cysts (mean size, 39 mm; range, 8-92 mm) were diagnosed as SCA on pathology. The MDCT features predictive of diagnosis of SCA were microcystic appearance (22/28, 78.6%), surface lobulations (25/28, 89.3%) and central scar (9/28, 32.4%). Stepwise logistic regression analysis showed that only microcystic appearance was significant for CT diagnosis of SCA (P = 0.0001). The sensitivity, specificity and PPV of central scar and of combined microcystic appearance and lobulations were 32.4%/100%/100% and 68%/100%/100%, respectively. The reader confidence was higher for lesions > 3 cm (P = 0.02) and for MDCT scans performed using thin collimation (1.25-2.5 mm) compared to routine 5 mm collimation exams (P > 0.05).

CONCLUSION: Central scar on MDCT is diagnostic of SCA but is seen in only one third of SCAs. Microcystic morphology is the most significant CT feature in diagnosis of SCA. A combination of microcystic appearance and surface lobulations offers accuracy comparable to central scar with higher sensitivity.

INTRODUCTION

Pancreatic serous cystadenomas (SCAs) are rare lesions that are almost always benign and usually asymptomatic[1]. SCAs comprise 1%-2% of pancreatic neoplasms and 10%-15% of cystic lesions[2]. While SCAs are relatively uncommon in comparison to pseudocysts and solid tumors of the pancreas, their clinical importance is

indisputable. Though generally regarded as benign, 3% of SCAs have malignant potential with local infiltration and distant metastases[1,3-5]. These are slow growing tumors; however the growth rate varies depending on tumor size. When the tumor is under 4 cm in diameter, the growth rate is only 0.12 cm/year whereas when the tumors ⩾ 4 cm in diameter they can grow at a remarkable 1.98 cm/year[6]. Due to the benign nature and the morbidity associated with pancreatic surgery, a follow up imaging for surveillance is recommended for these tumors[3,7]. Complete resection is considered curative, and is recommended when the lesion is symptomatic, when it increases in size upon follow-up, and when confident non-invasive differentiation from a more aggressive lesion is impossible[6]. Tumors that are resected have a good prognosis, with no requirement for postoperative surveillance[3,6].

Due to increased utilization of high-resolution imaging such as multi-detector computed tomography (MDCT), magnetic resonance imaging (MRI) and MR cholangiopancreatography (MRCP), SCAs are now more frequently identified, and often incidentally[8,9]. This high rate of detection of incidental pancreatic cystic lesions has generated great interest regarding the appropriate management of these lesions[6]. However, there is some overlap in imaging appearance among cystic pancreatic lesions, and it can be difficult to differentiate SCAs from other types of pancreatic cysts, such as pseudocysts, mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). Thus the diagnosis of serous cystadenomas assumes particular significance because they need to be differentiated from other cystic neoplasms like MCNs, which are known to be premalignant or malignant[10]. The differentiation is vital to avoid unnecessary pancreatic surgery, which although increasingly safe in experienced hands continues to cause significant postoperative morbidity[6]. Thus accurate preoperative lesion characterization is crucial in determining appropriate action.

MDCT is the initial imaging modality of choice for evaluation of cystic lesions of the pancreas. Although the imaging features of SCAs on MDCT have been described before, few studies have compared the accuracy of various CT features for distinguishing SCAs from other lesions. With this purpose in mind, we undertook this study to examine the different features of SCAs on MDCT and identify the common and uncommon imaging features of SCAs that enable a confident diagnosis. Other commonly occurring cystic lesions were also studied from a large cohort of cystic lesions to identify the specific features that characterize SCAs.

MATERIALS AND METHODS

Study design

This is a retrospective study that was approved by the Institutional Review Board and follows the Health Insurance Portability and Accountability Act regulations. Informed patient consent forms were waived. We searched the electronic database of hospital medical records for patients who had pancreatic surgery for cystic lesions from January 1999 to August 2007. The inclusion criteria required the patients to have had the MDCT exam prior to surgical resection. Out of a total of 180 patients with MDCT studies prior to surgical resection, 16 patients who had clinical and laboratory evidence of acute pancreatitis were excluded from the study. Criteria for diagnosis of pancreatitis were elevated serum amylase or lipase levels and/or imaging evidence of pancreatic inflammation. The process resulted in an initial cohort of 164 patients. These patients were evaluated for clinical presentation, imaging features, and pathological and surgical findings. Of the group of 164 patients, a subset consisting of 28 patients (17 women, 11 men; age range, 29-90 years; mean age, 62 years) with pathologically verified SCAs were studied to analyze their characteristic imaging features and constituted the main population for the present study. However, data from the other 136 patients in the cohort of 164 was also analyzed to study the accuracy of each imaging feature studied.

MDCT technique

All patients had undergone CT examinations on MDCT (GE Health Care, Milwaukee, WI) with four, eight or 16 detector rows. The acquisition protocol for the CT exam was either dedicated pancreatic protocol CT (91/164, 14 SCAs) or a routine contrast enhanced CT study (73/164, 14 SCAs). The initial scan was a non-enhanced CT acquisition of 5 mm thickness through the liver and pancreas. For routine abdominal CT scanning, 120-150 mL of nonionic contrast material (300-370 mg/mL) was injected at a rate of 3.0 mL/s, and 5 mm thick images were acquired after a 65-70 s delay.

Pancreatic protocol consisted of two phase acquisition after administration of 120-150 mL of nonionic contrast material (370 mg of iodine per milliliter) at a rate of 4-5 mL/s. Pancreatic phase imaging was performed 45 s after starting contrast material injection by obtaining 1.25-mm/2.5-mm targeted reconstructed sections through the pancreas. Portal venous phase imaging followed at 65-70 s after contrast material injection with 5-mm-thick sections. For pancreatic phase imaging, the field of view was 28 cm; for the other phases, the field of view was adjusted according to the size of the patient.

Post processing

Coronal reformatted images of 2.5-3 mm thickness were obtained in all of the patients. Additional reformatting techniques used included oblique coronal multiplanar reformations (MPRs, 5 mm) parallel to the pancreatic head or tail, 1-2 curved planar reformations along the course of the pancreatic duct (1.25 mm) and thin slab (5 mm) coronal maximum intensity projections (MIP) to display vessel involvement. These reformations were performed by one of the trained technologists on a work station (ADW 4.0, GE).

Data analysis

The CT images were retrospectively reviewed by consensus by two radiologists with 14 and 7 years of experience, respectively, who were kept blinded to patients' clinical details and histopathology of the cystic lesion. The analysis was done on picture archiving and communication system (PACS version 4.0, Agfa, Richmond, VA). For the image analysis, a template was created to evaluate features of a pancreatic cyst. The following features were assessed: cyst size, presence or absence of septations, lesion margins, solid components, lobulations, central scar, calcification, pancreatic duct communication, duct obstruction, lymphadenopathy and vascular involvement. The pancreas was evaluated for presence or absence of duct dilatation, parenchymal/ductal calcification and parenchymal atrophy.

The largest dimensions of the cyst were measured on axial scans and mean size calculated. The septations were evaluated for thickness and enhancement. The margins of the lesion were considered either well defined or ill defined. The shape of the cysts was defined as either smooth, simple lobulated or complex lobulated. Simple lobulation was defined as the shape of a simple closed curve with bosselated surface whose borders could not be described within the same circle[10]. A complex lobulated shape was defined as one containing a conglomeration of two or more cysts either round, oval or tubular (pleomorphic in shape)[10]. Central scar was defined as a central stellate area of soft tissue density with or without calcification and with or without radiating surrounding linear strands. Attenuation values were obtained for the cysts by placing a ROI (mean size, 20 mm^2) on the unenhanced scan. Care was taken to exclude septations, calcifications and solid component within the ROI. The attenuation values measured from the various types of lesions (SCA, MCN, *etc*) were then averaged for comparison. Cyst morphology was classified as unilocular, microcystic, macrocystic or oligocystic and cyst with solid component[8]. Simple unilocular cysts included pancreatic cysts without internal septa, a solid component or central-cyst wall calcification. Unilocular cysts with mural enhancement or calcification were categorized as complicated. Microcystic lesion was defined as consisting of collection of cysts (> 6) ranging in size from a few millimeters up to 2 cm in size[8]. Macrocystic or oligocystic lesions were defined as lesions with more than one but < 6 cysts with at least one of them > 2 cm in size.

Using these features, the cysts were categorized as a simple cyst/pseudocyst, SCA, mucinous cystadenoma (MCN) and intraductal papillary mucinous cystadenoma (IPMN) or else solid neoplasms with cystic degeneration (Adenocarcinoma, endocrine tumors and solid papillary epithelial neoplasm) on imaging. The criteria considered for diagnosis of SCAs included: lobulations, microcystic pattern, presence or absence of central scar, well defined margins and lack of enhancement. Readers' diagnostic confidence for the diagnosis of serous cystadenoma was rated on a 5-point scale (with 1 being least confident and 5 being most) along with confidence as to whether the lesion was benign or malignant using a similar 5-point scale. Cystic lesions which did not have any specific attributable features to the above categories or those with a reader confidence less than three were considered indeterminate.

Surgery and histopathologic correlation

The type of surgical procedure performed was recorded. Histopathological analysis had been performed by a single gastrointestinal pathologist with ten years of specialized experience in pancreatic pathology. The gross and microscopic descriptions of the resected specimens described in the pathology reports were reviewed. A predefined template for pathology was filled in. The gross specimens were reviewed for cyst morphology, which included lesion size, septations and intralesional solid components. The final histopathological diagnosis was recorded as: SCA, IPMN, MCN, adenocarcinoma, endocrine tumors or solid papillary epithelial neoplasm. Those cysts without specific identifiable features where a conclusive diagnosis was not rendered on histopathology were categorized as unclassified cysts. The features on MDCT were then correlated with pathological reports.

Statistical analysis

Sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy for the various MDCT findings of SCA were calculated in comparison to other cystic lesions by using histopathology as the gold standard. *T*-test was used to calculate the statistical significance for various values and $P < 0.05$ was considered to suggest statistically significant difference. Statistical significance between the size of SCA and the occurrence of scar was evaluated using two sided Fisher's exact test. Stepwise logistic regression was used to identify the significance of each CT feature for diagnosis of SCA using SAS software (SAS system release 8.2). The CT feature was considered significant for the diagnosis whenever a tail probability of $P < 0.05$ was reached.

RESULTS

CT findings

Of the 28 SCA (mean size, 39 mm; range, 8-92 mm), 11 lesions were located in the head, 11 in the body, 3 in the tail and 3 in body and tail (Table 1). 22/28 (78.6%) SCAs were observed to have microcystic morphology (Figure 1) and 6/28 (21.4%) of SCAs had macrocystic or oligocystic morphology (Figure 2). 25/28 (89.3%) of SCAs were lobulated whereas 3/28 (10.7%) presented with smooth wall. 9/28 (32.1%) SCAs showed central scar with calcification seen in 3 scars (Figure 3). 8/9 (88.9%) of SCAs with central scar measured at least 2 cm (mean size, 4.1 cm; range, 1.9-8.4 cm). This finding was statistically significant for lesion size and occurrence of central scar ($P = 0.02$, Fisher's exact test).

Of the 136 other cystic lesions included for comparison of the morphological features with SCAs,

MDCT: Multi-detector computed tomography; SCA: Serous cystadenoma; IPMN: Intraductal papillary mucinous neoplasm; MCN: Mucinous cystic neoplasm. [1]Combined presence of Lobulations and microcystic appearance; [2]3/9 showed calcifications within the central scar.

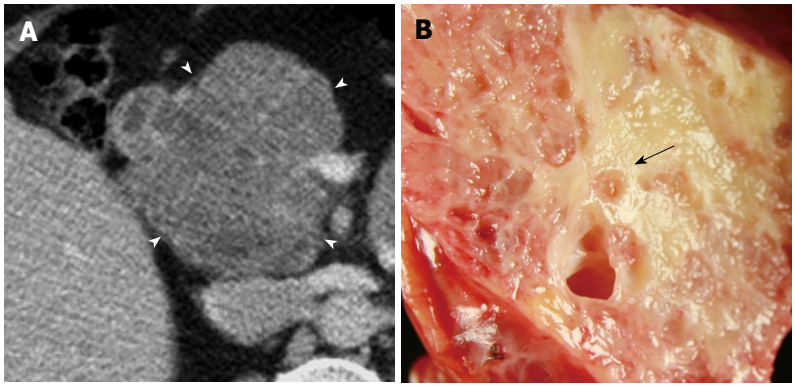

Figure 1 A 64-year-old woman who was incidentally found to have a mass in the head of the pancreas and subsequently underwent a Whipple procedure for removal. A: Lobulated (arrow heads) microcystic serous cystadenoma (SCA) with characteristic honeycomb appearance is seen on axial MDCT image (1.25 mm); B: Gross pathological specimen of the lesion reveals cluster of microcysts with a sponge pattern. A central scar is appreciated on the pathological image (black arrow), which is subtle and difficult to appreciate on the CT image.

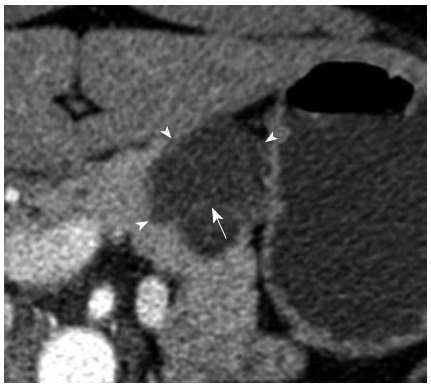

Figure 2 A 46-year-old woman who presented with abdominal pain was found to have a lesion in the body of the pancreas for which a partial pancreatectomy was performed. Axial MDCT image (1.25 mm) shows a lobulated (arrow heads) macrocystic SCA with septations (white arrow).

42 were IPMNs (mean size, 2.7 cm; range 0.9-5.2 cm), 37 were MCNs (mean size, 4.3; range, 2.2-11 cm), 45 were unclassified cysts (mean size, 2.4 cm; range 0.5-7.4 cm), 6 endocrine tumors (mean size, 4.6 cm; range, 1.6-8.9 cm), 4 adenocarcinomas (mean size, 3 cm; range, 1.4-5.2 cm), 1 was lymphangioma (2.3 cm) and 1 was solid papillary epithelial neoplasm (2.3 cm). Among these lesions microcystic pattern on CT was observed in 1 IPMN (2.3%) and 2 MCNs (5.4%) whereas the lobulated pattern was observed in 5 unclassified cysts (11.1%), 3 IPMNs (7.7%) and 1 MCN (3%). Central scar was not demonstrable in any of these lesions.

Upstream pancreatic ductal dilatation was observed in 3 patients. In one patient this was attributed to mass effect from a large SCA in the head of pancreas (Figure 4). However in two other patients with SCA,

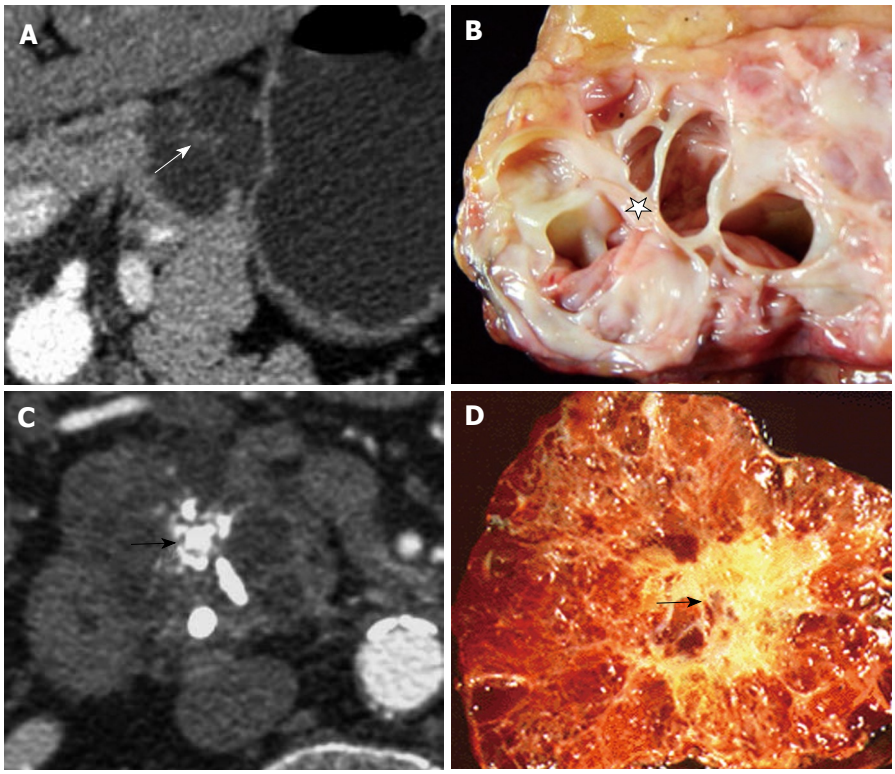

Figure 3 Images from 2 different patients with central scar. A: Axial MDCT image from a 46-year-old woman with a macrocystic SCA with a central scar (white arrow); B: Gross pathological specimen of the same patient also reveals the macrocystic pattern with the septa converging on a central scar (star); C: Axial MDCT image from a 66-year-old male who had a history of chronic pancreatitis, reveals a large lobulated microcystic lesion with central stellate calcification (black arrow). A Whipple procedure was done to remove a 4 cm mass from the head of the pancreas. Corresponding gross pathological image of the microcystic SCA with calcification (black arrow) in the central scar (D).

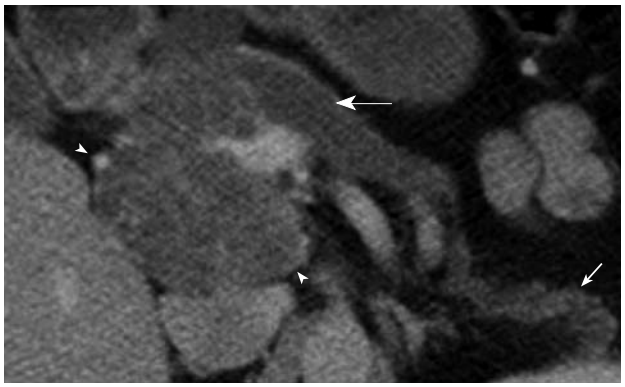

Figure 4 Axial MDCT image from a 64-year-old woman who had a large cyst in the pancreas detected incidentally. The patient underwent a Whipple procedure for removal of the large microcystic SCA (arrow heads) involving the head and uncinate process of the pancreas. The SCA caused upstream pancreatic duct dilatation (white arrow) and atrophy of the pancreatic body and tail (small white arrow).

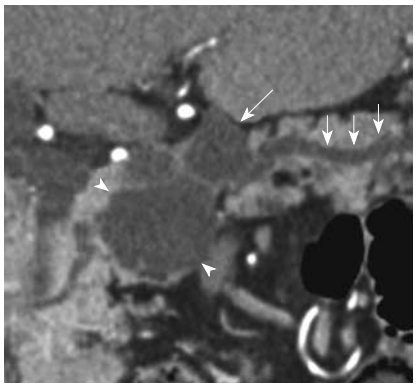

Figure 5 Coronal reformatted MDCT image from an asymptomatic 90-year-old woman, who had a 5 cm lesion in the head of the pancreas which was removed by Whipple procedure. The image shows an oligocystic SCA (arrow heads) in the head of pancreas which was mistaken for a mucinous lesion due to an associated side branch IPMN adjacent to it (white arrow). The two lesions were interpreted as a single multiloculated side branch mucinous lesion. There is mild upstream dilatation of the visualized pancreatic duct (small white arrows).

the pancreatic duct dilatation was considered due to background chronic pancreatitis changes in one and concurrent combined IPMN in another (Figure 5). Furthermore, five patients showed atrophy of the pancreatic parenchyma distal to the site of the lesion (Figures 4 and 6). None of the SCAs showed solid component, ductal communication or vascular encasement. The mean HU values for SCA were 19 ± 9 HU which was higher for microcystic variants (21 ± 8 HU) than the macrocystic variants (13 ± 4 HU). Though the average attenuation value for SCAs was higher than other types of cysts [mucinous lesions (MCNs and IPMNS): 10 ± 6 HU, pseudocysts: 12 ± 4 HU] it was not statistically significant ($P > 0.05$).

CT and histopathological correlation

Twenty four (85.7%) of the 28 SCAs were correctly characterized as such by CT. Of the four SCAs incorrectly identified on CT, two were classified as MCNs, one lesion as a possible IPMN, and one lesion was considered an indeterminate cystic lesion. The two classified as mucinous lesions had a macrocystic appearance and no central scar. One of these was classified as a benign mucinous lesion based on its macrocystic pattern and lack of central scar on CT. The second patient had two cysts, of which one was classified as mucinous and second as IPMN of side branch variety. However, histopathological analysis

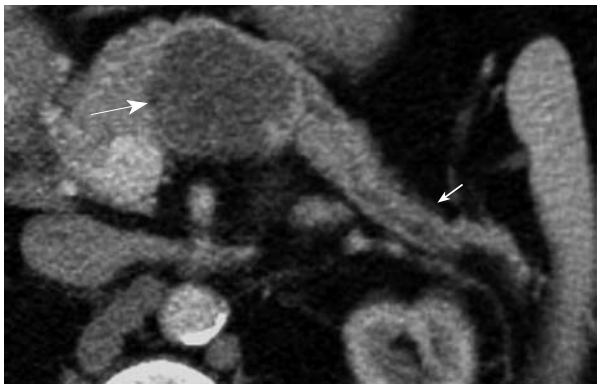

Figure 6 Axial MDCT image from a 64-year-old woman with an incidentally discovered cystic lesion in the body of the pancreas. A large serous cystadenoma (arrow) present in the body of pancreas displays microcystic morphology and fine lobulations with a central scar. Atrophy of the pancreatic parenchyma distal to the site of the lesion is also present (small arrow).

showed that the former was a SCA with a side branch IPMN in the vicinity (Figure 5). The lesion characterized as IPMN was microcystic, but confidence for diagnosis of SCA was low. The lesion classified as indeterminate cystic lesion was lobulated with thin septations and though the morphology was identified as macrocystic and benign, the reader confidence for diagnosis of SCA was less than 3.

When the imaging data of SCA were compared with pathological analysis, the majority of the observations remained constant (Table 2). MDCT features were consistent with the histological data for microcystic appearance (27/28, 96.4%) and surface lobulations (28/28, 100%). The 25 SCAs with pathologically confirmed lobulated morphology and the 3 with pathologically smooth morphology were correctly identified as such by CT. Of the 21 SCAs with pathologically confirmed microcystic morphology and 6 SCAs with pathologically confirmed macrocystic pattern, all were confidently identified as such on CT. One SCA which was characterized as microcystic on CT was found to be unilocular on pathology. This lesion measured 2 cm in diameter and there was substantial background noise on CT images.

Of the 10 central scars discovered on pathology, CT correctly identified them in 8 lesions. Central scars were missed on CT in 2, while in another SCA the central scar recorded on CT was found to represent converging septa on histopathology. In two lesions where CT failed to detect central scar, the SCA measured < 3 cm in size (average, 2.4 cm) and were evaluated using a routine protocol (5 mm). It is conceivable that these factors could have contributed to the reduced accuracy in depiction of SCA morphology.

For cyst characterization into benign and malignant, 27/28 lesions were confidently diagnosed as benign except for one lesion that was considered indeterminate on CT and was found to be benign on histopathology. This lesion measured 5.4 cm in diameter and presented with pancreatic duct dilatation and parenchymal atrophy, which raised the suspicion for an aggressive biology.

Table 2 Comparison of MDCT findings with pathological findings for SCA (n = 28)

	MDCT features	Pathology findings
Morphology

Thin	28	28
Thick	0	0
Mural nodules	0	0
Septa	27	27

Morphological features in the diagnosis of SCA

The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy of each of these features in the diagnosis of SCA are shown in Table 3. Based on pathologic verification, microcystic morphology on MDCT was demonstrated in 21/28 (75%) of SCAs. Microcystic pattern was also considered in other cystic lesions on MDCT that included 1 IPMN (n = 42) and 2 MCNs (n = 37), however on histopathology the CT appearance was not corroborated. The presence of microcystic morphology alone thus had a PPV of 88% and a specificity of 97.79% for the diagnosis of SCA. Lobulations were seen in 25/28 (89.3%) of SCAs, 5/45 unclassified cysts (11.1%), 3/42 IPMNs (7.1%) and 1/37 MCNs (2.7%). Lobulations had a PPV of 71.4% and specificity of 92.6% in the diagnosis of SCAs. When both lobulations and microcystic morphology were used for the identification of cystic lesions there was a PPV and specificity of 100% for identification of SCAs. It was found that central scar, microcystic pattern and combined presence of microcystic pattern and lobulations had the highest accuracy in the diagnosis of SCA. Stepwise logistic regression analysis showed that only microcystic appearance was significant for the CT diagnosis of SCA (P = 0.0001).

When comparing the diagnostic confidence for diagnosis of SCAs with reference to the lesion size, the confidence was higher for lesions ⩾ 3 cm (4.6) compared to lesions < 3 cm (3.9, P = 0.02). The CT pathologic concordance was better for lesions scanned with dedicated pancreatic protocol CT. The diagnostic confidence of readers in identifying the morphology of SCAs was better in those lesions scanned with dedicated pancreatic protocol (1.25-2.5 mm) compared to those scanned with routine abdomino-pelvic CT (5 mm) though this was not statistically significant (confidence level, 4.4 *vs* 4, P > 0.05).

DISCUSSION

High rate of incidental detection of cystic pancreatic lesions, including serous cystadenoma and the

overlapping imaging features of SCAs with other more aggressive cystic neoplasms makes management of these lesions challenging[7,9,11,12]. Accurate characterization is therefore imperative because of the low malignant potential of SCA and to determine the treatment options and to differentiate them from more aggressive lesions. Several studies have described the spectrum of imaging appearances of SCA on CT which include microcystic, macrocystic, unilocular and mixed morphologic patterns[7,9,11-14]. Microcystic pattern which is the most predominant pattern has been described in 70%-80% of SCAs[11,12,14]. Surface lobulations considered to be specific for the diagnosis of SCA have been studied with reference to oligocystic SCA (SOAs)[10,15,16]. Central scar which is considered pathognomonic for diagnosis of SCA has a low sensitivity and reliance on this imaging feature will not permit diagnosis of most SCAs[10,11,17]. The accuracy of CT in diagnosis of SCA in comparison to other cystic neoplasms has been reported in several previous studies which found accuracy ranging from 27%-93%[17-19]. More recent studies have compared SOAs with MCNs and IPMNs and have emphasized the importance of patient demographics, lesion location and shape of the cyst in characterization of the various lesions[4,10,15]. However, our study is unique as we have assessed the predictive value of specific features of SCA on MDCT in a large cohort of patients with surgically verified pancreatic cystic lesions and have evaluated how well the CT features correlate with pathology.

In our study, microcystic appearance was the only significant CT feature in the diagnosis of SCA. The combined presence of microcystic appearance and surface lobulations were also the strong predictors of SCA on CT with high PPV and specificity compared to other cystic lesions. Microcystic appearance was evident in 78% of SCAs in our study and this was concordant with other reports[11-14]. However, occasionally other cystic lesions when small in size can also appear microcystic on CT. In our study, small lesion size (< 2 cm) and background image noise potentially contributed to erroneous morphological depiction. Presence of surface lobulations within a cyst is a recognized feature of SCAs and can help to differentiate oligocystic SCAs from MCNs and IPMNs[10,15]. We observed lobulated contour in 89% of SCAs despite different morphologic appearances (microcystic, macrocystic and unilocular), a finding that has also been reported in other studies[10-11,15]. Although uncommon, surface lobulations can be encountered in a few MCNs (2.9%) and IPMNs (7.6%) as also reported by Kim *et al*[10].

The presence of a central scar is considered to be pathognomonic for SCAs, even when there is no distinct microcystic appearance[17]. Finding a central scar was highly specific of SCA in our study. It was not observed in any other cystic lesion but was encountered in only in 32% of SCAs. Other studies have observed it in anywhere from 30% to 45% of microcystic serous adenomas[17,20,21]. Eighty eight point nine percent of SCAs with central scar measured at least 2 cm indicating that larger the lesion size the more likelihood of occurrence of scar. Size of the lesion also determines the detectability of central scar since the two lesions in our study where the central scar was missed measured less than 3 cm in size.

The mean CT attenuation for all SCAs in our data set was higher than the values for other cystic lesions, more so for the microcystic variants though they were not statistically significant. The marginally elevated HU values could be accounted for by the presence of more stroma between the fluid filled sacs and the higher stroma: fluid ratio in SCA than other lesions. However, the attenuation values cannot be used as primary feature for differentiating between various pancreatic cystic lesions.

Lesion size itself can influence the reader confidence as the confidence for diagnosis of SCA was found to be higher for lesions ⩾ 3 cm compared to those with size < 3 cm. In addition to size of the cystic lesions, the MDCT scanning technique also influences the diagnostic accuracy and readers' confidence for lesion characterization.

Although the comparison of MDCT with MRI was not a part of this study, in our experience we have found that MRI might be beneficial when in doubt since the cyst morphology may be better appreciated on MRI. In our study, lesions which underwent dedicated pancreatic protocol examination with thin collimation (1.25-2.5 mm) had an improved reader confidence in the depiction of the morphological features compared to those which were scanned with routine protocol (5 mm). Two lesions where the central scars were missed on CT and the three cases of SCA which were misdiagnosed as mucinous lesions were evaluated by routine protocol, highlighting

the need to perform a dedicated pancreatic protocol CT for superior lesion characterization of cystic pancreatic lesions. We propose that all pancreatic cystic lesions should have at least one pancreatic protocol CT for better lesion characterization which will not only help avoid additional imaging follow up, but also prevent unnecessary surgical interventions.

This study had several limitations. Firstly, only surgically resected tumors were included for evaluation, which introduces a possible selection bias. However, since the majorities of SCAs are benign and are usually not resected, the comparison of MDCT findings with the histopathology findings in surgically resected SCAs adds to the value of the study. Secondly, not all patients had a dedicated pancreatic protocol CT exam. Though this could have affected the evaluation of diagnostic accuracy, it also provided us with an opportunity to study the effect of dedicated pancreatic protocol for evaluation of SCA compared to routine CT.

MDCT allows reliable assessment of the morphological features of SCA as depicted on gross histopathology. Central scar, although pathognomonic for SCA, is uncommonly seen. Microcystic morphology is the most significant CT feature in the diagnosis of SCA. Combined presence of microcystic morphology and surface lobulations offers high accuracy comparable to central scar but with higher sensitivity, thus allowing reliable diagnosis of SCA. Use of a dedicated pancreatic protocol with thin collimation improves the diagnostic accuracy of MDCT and enhances reader confidence.

COMMENTS

Background

Pancreatic serous cystadenomas (SCAs) are rare lesions that are almost always benign and usually asymptomatic. Though surgical resection results in complete cure, follow up surveillance is usually recommended due to their benign nature and the morbidity associated with pancreatic surgery. There is increased incidental detection of pancreatic cysts including SCAs with the use of multi-detector computed tomography (MDCT) and MRI. Accurate characterization of SCAs assumes importance due to their overlapping imaging features with other pancreatic cystic lesions particularly mucinous cystic neoplasms (MCNs) which have a malignant potential. Though several articles have described the imaging features of SCAs, few studies have compared the accuracy of these CT features in distinguishing between SCAs and other lesions. Therefore, this study was undertaken to evaluate the predictive values of various CT features of SCA that allow in its accurate characterization with pathological correlation.

Innovations and breakthroughs

One of the important innovations in the imaging evaluation of pancreatic cysts is the development of MDCT which allows excellent characterization of the morphology of pancreatic cyst. Though several authors have described the CT features of SCA, very few articles have discussed the predictive value of each imaging feature. This articles shows that microcystic appearance is the most significant imaging feature of SCA and the combination of microcystic appearance and surface lobulations is very specific for SCA in comparison to other cystic lesions.

Applications

The most important clinical application of this study is in the diagnosis and characterization of serous cystadenomas when incidentally detected on a CT scan. The finding of superiority of dedicated pancreatic protocol CT over routine protocol helps in the planning of CT examination when encountered with a incidental pancreatic cyst. This article emphasizes the effect of cyst size on lesion characterization and diagnostic accuracy. This calls for further studies for improve characterization of pancreatic cysts by furthering development of high resolution CT and MRI.

Peer review

The important part of the paper is that the study shows that microcystic appearance and lobulated pattern when present together are highly specific for diagnosis of SCA. This study highlights the value of performing a dedicated pancreatic protocol in the evaluation of pancreatic cystic lesions in improving diagnostic accuracy and reader confidence.

Abstract

AIM: To evaluate the usefulness of pre-endoscopic serological screening for *Helicobacter pylori* (*H pylori*) infection and celiac disease in women aged < 50 years affected by iron-deficiency anemia (IDA).

METHODS: One hundred and fifteen women aged < 50 years with IDA were tested by human recombinant tissue transglutaminase IgA antibodies (tTG) and anti-*H pylori* IgG antibodies. tTG and *H pylori* IgG antibody were assessed using an enzyme-linked immunosorbent assay (ELISA). All women were invited to undergo upper GI endoscopy. During gastroscopy, biopsies were collected from antrum (n = 3), gastric body (n = 3) and duodenum (n = 4) in all patients, irrespective of test results. The assessment of gastritis was performed according to the Sydney system and celiac disease was classified by Marsh's System.

RESULTS: 45.2% women were test-positive: 41 patients positive for *H pylori* antibodies, 9 patients for tTG and 2 patients for both. The gastroscopy compliance rate of test-positive women was significantly increased with respect to those test-negative (65.4% *vs* 42.8%; Fisher test P = 0.0239). The serological results were confirmed by gastroscopy in 100% of those with positive *H pylori* antibodies, in 50% of those with positive tTG and in 81.5% of test-negative patient. Sensitivity and specificity were 84.8% and 100%, respectively for *H pylori* infection and, 80% and 92.8% for tTG. Twenty-eight patients had positive *H pylori* antibodies and in all the patients, an active *H pylori* infection was found. In particular, in 23 out of 28 (82%) patients with positive *H pylori* antibodies, a likely cause of IDA was found because of the active inflammation involving the gastric body.

CONCLUSION: Anti-*H pylori* IgG antibody and tTG IgA antibody testing is able to select women with IDA to submit for gastroscopy to identify *H pylori* pangastritis and/or celiac disease, likely causes of IDA.

Key words: Iron deficiency anemia; Women; Celiac disease; *Helicobacter pylori* gastritis

Vannella L, Gianni D, Lahner E, Amato A, Grossi E, Delle Fave G, Annibale B. Pre-endoscopic screening for *Helicobacter pylori* and celiac disease in young anemic women. *World J Gastroenterol* 2009; 15(22): 2748-2753 Available from: URL: http://www.wjgnet.com/1007-9327/15/2748.asp DOI: http://dx.doi.org/10.3748/wjg.15.2748

INTRODUCTION

Iron-deficiency anemia (IDA) is common in women aged < 50 years with a prevalence of almost 5% in Western countries[1]. In this population, the balance of iron is often precarious due to menses, pregnancy and breastfeeding and an excessive menstrual flow is experienced by about 30% of women of reproductive age[2]. Menorrhagia is often considered the only cause of iron deficiency anemia, but some studies have shown the usefulness of a gastrointestinal (GI) tract

evaluation by endoscopy, thus indicating a role of the upper and/or lower GI tract as a likely cause of IDA[3-4]. The vast majority of IDA GI causes affect the upper GI tract and, in particular, there is a high prevalence of conditions associated with iron malabsorption such as *Helicobacter pylori* (*H pylori*) related-pangastritis, celiac disease and atrophic body gastritis in IDA premenopausal women[5-6]. On the contrary, as already reported in previous studies, bleeding lesions are infrequent in these patients and in particular in women aged < 50 years[5-8].

The diagnostic workflow in young women affected by IDA is not clearly established. The British Society of Gastroenterology recommends gastroscopy only in IDA women younger than 45 years presenting with GI symptoms[9]. However, the major issue of GI evaluation is that symptoms are often mild and aspecific in IDA women and that gastroscopy is an invasive procedure associated with a high number of refusals[10]. Furthermore, in our previous work on IDA premenopausal women, gastroscopy was performed as part of the diagnostic protocol in all patients, but was deemed unnecessary in almost 30% of the studied women because they were affected only by menorrhagia[5].

As shown in a previous study, non-invasive tests might be helpful in the selection of IDA women having a high probability of being affected by iron malabsorption GI diseases, in order to better address endoscopy and to increase the patients' compliance to the procedure[11].

The aim of the present study was to prospectively evaluate the usefulness of a pre-endoscopic serological screening for *H pylori* infection and celiac disease with the use of two tests (human recombinant tissue transglutaminase IgA antibodies and anti-*H pylori* IgG antibodies) in women aged < 50 affected by IDA in order to increase the compliance for gastroscopy.

MATERIALS AND METHODS

Patients

Between January and July 2006, 400 consecutive women (median age; 38 years) aged < 50 years with iron deficiency anemia were referred to the "Centro delle Microcitemie" of Rome, a public health institution specialized in the diagnosis of thalassemia. In these women the presence of an anemia emerged because they had previously undergone a complete blood count due to fatigue and/or for routine check-up, and were thus referred by their primary care physicians (60%), gynecologists (25.4%), hematologists (7.3%) or other physicians (7.3%) to the above mentioned center in order to exclude alpha- or beta-thalassemia minor, a frequent genetic disorder in the Italian population. In the "Centro delle Microcitemie", a complete blood count, serum iron and ferritin were repeated in all patients, and after the exclusion of α- and β-thalassemia, the presence of IDA was definitely diagnosed. IDA was defined as hemoglobin (Hb) < 12 g/dL with serum ferritin ≤ 20 μg/dL.

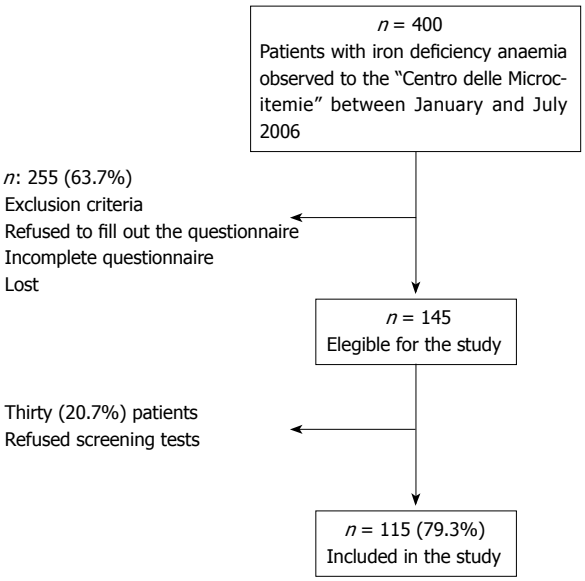

Figure 1 Study population. *n*: Numbers of patients.

IDA women were invited to answer a structured questionnaire to assess demographic data, previous iron supplementation, previous blood transfusion, previous hospitalization for anemia, obvious causes of blood loss, use of drugs (such as aspirin/NSAIDs, proton pump inhibitors, anticoagulants), 1st degree family history for colon or gastric cancer, peptic ulcer and celiac disease, type of diet, premenopausal status and GI symptoms. The duration of anemia was expressed as length of time from first diagnosis of IDA (mo) based on medical records. Upper GI symptoms included nausea, vomiting, dysphagia, heartburn, dyspepsia and upper abdominal pain. Lower GI symptoms included diarrhea, constipation, lower abdominal pain and hematochezia. The symptom was considered "present" if the patient referred to its presence at least once a week during the last three months[10]. Premenopausal status was defined as the patients' personal reports that within 3 mo prior to evaluation they were still menstruating[5].

The women were excluded from the study if they had: age > 50, obvious causes of GI bleeding, previous diagnosis of GI diseases probably responsible for IDA based on medical records, anorexia, vegetarian diet, pregnancy, breastfeeding, anemia of chronic diseases (for example chronic renal failure, cirrhosis and severe cardiopulmonary disease) and hematological diagnoses (e.g. aplastic anemia, myelodysplasia).

Study design

As shown in Figure 1, out of the initial 400 women with IDA, 145 women were considered eligible for the study (Figure 1). The diagnostic work-up included serological tests for the testing of anti-*H pylori* IgG antibodies to evaluate the presence of *H pylori* infection and tissue transglutaminase IgA antibodies to diagnose celiac disease. However, 30 women refused screening tests and thus, 115 women were included in the study and gave their informed consent.

Thus, 115 women were referred to University

Gastroenterology Department to pick up test results and were invited to undergo upper GI endoscopy to confirm test results. Patients with at least one of the 2 tests positive were defined as "test-positive" patients, those with all 2 tests negative were defined as "test-negative" patients.

Measurements

Serologic testing: Human recombinant tissue transglutaminase IgA antibodies were assessed using an enzyme-linked immunosorbent assay (ELISA) based on a commercially available kit (Bio-Rad Laboratories, Milan, Italy). A titre > 15 UI/mL was considered positive. *H pylori* IgG antibodies were assessed using an enzyme-linked immunosorbent assay (ELISA) based on a commercially available kit (Biohit, Helsinki, Finland). A titre > 1.1 UI/mL was considered positive.

Gastroscopy and histological evaluation: During gastroscopy, biopsies were collected from antrum (n = 3), gastric body (n = 3) and duodenum (n = 4) in all patients, irrespective of tests results. The assessment of gastritis was performed according to the Sydney system[12]. *Pangastritis* was defined as the presence of acute and chronic inflammatory infiltrate both in the gastric antrum and body as previously described[13]. If the sum of the inflammatory scores (acute and chronic) showed a two-grade difference between the antrum and corpus, the gastritis was considered as "*antrum-predominant*" or "*corpus-predominant*", respectively. *Antrum-restricted gastritis* was defined by the presence of acute and chronic inflammatory infiltrate exclusively in antrum according to the Sydney system[12]. Celiac disease was classified by Marsh's System[14]. The pathologist was unaware of the serological screening results.

Statistical analysis

Standard descriptive statistics was expressed as median and range and evaluated by appropriate statistical test (Mann-Whitney). Proportions were compared with the Fisher exact test. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical features

The women included in the study had a median age of 38 years (range 21-50 years) and the median duration of IDA was 12 mo (range 1-408 mo). The value of median hemoglobin was 10.7 (range 7.3-11.9) g/dL, MCV was 72 (range 51-92) fL and ferritin was 10 (range 1-20) μg/L. Oral iron therapy was previously prescribed in 48 (41.7%) women. Only a small number of patients had previously needed blood transfusion (n = 3, 2.6%) or hospitalization for anemia (n = 8, 7%).

At least one symptom of the upper GI tract was present in 49.6% of patients (n = 57), while 57.4% of patients (n = 66) had a least one symptom of the lower GI tract. Reported GI symptoms were mainly non-specific, such as mild abdominal pain (24%) and bloating (46%). The vast majority of patients had a negative family history for GI diseases (80.8%): a family history for GI cancers or peptic ulcers was present only in 4.3% and 14% of patients, respectively. In 91.3% of women a premenopausal status was present.

Table 1 Clinical and biochemical features of the "test-positive" patients compared with "test-negative" patients

Patients, n = 115	Test-positive n = 52 (45.2%)	Test-negative n = 63 (54.8%)	P
Age (yr)	38 (23-50)	37.5 (21-50)	NS
Duration of Anemia (mo)	12 (1-408)	12 (1-312)	NS
Hb (g/dL)	10.6 (7.3-11.9)	10.9 (8-11.9)	NS
MCV (fl)	71 (51-90)	74 (58-92)	NS
Iron (μg/dL)	22 (6-65)	24.5 (9-52)	NS
Ferritin (μg/L)	10 (1-31)	10 (2-59)	NS
Smokers	10 (19%)	10 (16%)	NS
Previous therapy with iron	22 (41.5%)	26 (41.9%)	NS
Previous blood transfusion	2 (3.8%)	1 (1.8%)	NS
Previous therapy with vitamin B12	5 (9.4%)	9 (14.5%)	NS
Previous therapy with folic acid	18 (34%)	20 (32.2%)	NS
Hospitalization for anemia	3 (5.7%)	5 (9.4%)	NS
Upper GI symptoms	26 (49%)	31 (50%)	NS
Lower GI symptoms	29 (54.7%)	37 (59.7%)	NS
Premenopausal status	49 (94.2%)	56 (88.9%)	NS

Hb: Hemoglobin; MCV: Median corpuscular volume; GI: Gastrointestinal; NS: Not significant. All values are reported as median (range) unless otherwise indicated.

Serological tests

Fifty-two out of 115 patients (45.2%) were "test-positive". Of these, 41 (35.6%) patients had positivity for *H pylori* IgG antibodies, 9 (7.8%) patients for tissue transglutaminase IgA antibodies and 2 (1.7%) patients had positivity for both antibodies. As shown in Table 1, the group of patients with positive tests was not different from that with negative tests as far as clinical and biochemical features were concerned.

Gastroscopic/histological findings

"Test-Positive Patients": Four women did not undergo gastroscopy because they become pregnant after the start of the study. Of these, 3 patients had positive *H pylori* antibodies and 1 patient positive tissue transglutaminase IgA antibodies. Fourteen patients refused the invasive procedure, 12 out of these patients had positive *H pylori* antibodies and 2 patients had positive tissue transglutaminase IgA antibodies. Thus, 34 out of 52 (65.4%) "test-positive" patients consented to the upper GI endoscopy and the results are shown in Table 2.

Twenty-eight patients had positive *H pylori* antibodies, and in all these patients an active *H pylori* infection was found. Celiac disease was confirmed only in 4 out of 8 (50%) patients with positive tissue transglutaminase IgA antibodies, whereas in another patient who underwent gastroscopy for positive *H pylori* antibodies, celiac disease was also found. Of the 5 patients with celiac disease, 4 had Marsh 3 and 1 had Marsh 2.

In Table 3, the extent and the degree of *H pylori*-related gastritis is shown. Five IDA women with positive *H pylori* antibodies had exclusively *antrum-restricted gastritis*

Table 2 Gastroscopic/histological findings of patients according to diagnostic tests results

Patients	Test-positive $n = 34$			Test-negative $n = 27$
Gastroscopic/histological findings	*H pylori* antibodies $n = 26$	Tissue transglutaminase antibodies $n = 6$	*H pylori* & Tissue transglutaminase antibodies $n = 2$	
H pylori-related gastritis	26	-	2	5
Celiac disease	1	3	1	-
Normal	-	3	-	22
Total findings	27[1]	6	3[1]	27

[1]1 patient had both *H pylori*-related gastritis and celiac disease.

Table 3 Extent and degree of *H pylori*-related gastritis

Histological findings	Test-positive patients	Test-negative patients
Antrum-restricted gastritis	5	2
Pangastritis[1]	21	1
Antrum-predominant pangastritis	1	1
Corpus-predominant pangastritis	1	-
Atrophic body gastritis	-	1
Total	$n = 28$	$n = 5$

[1]Equal score of inflammatory infiltrate in antrum and corpus.

with active *H pylori* infection. In the remaining patients ($n = 23$), a pangastritis with active *H pylori* infection was present which in 91.3% of cases showed equal severity of the inflammatory score in antrum and corpus. Thus, in 23 out of 28 (82%) patients with positive *H pylori* antibodies, a likely cause of IDA was found because the active inflammation involved the gastric body.

"Test-Negative Patients": Three women could not undergo gastroscopy because they were pregnant, and 33 patients refused the procedure. Thus, 27 out of 63 (43%) "test-negative" patients underwent upper GI endoscopy. In 22 out of 27 (81.5%) patients, the negative serological tests results were confirmed because no gastroscopic/histological finding was revealed; instead in the remaining 5 patients *H pylori* gastritis was diagnosed (Table 2). In particular, 3 likely causes of IDA were misdiagnosed because 2 patients had "*antral-predominant*" chronic gastritis and 1 patient had atrophic body gastritis (Table 3).

The compliance rate of test-positive women (65.4%) was significantly higher than that of test-negative ones (42.8%) (Fisher test $P = 0.0239$). Patients undergoing gastroscopy were similar to the group of included patients in the study for demographic, clinical and biochemical data. Moreover, for these parameters, the group of dropped-out test-positive and test-negative patients was not different from those test-positive and test-negative patients who underwent gastroscopy (data not shown).

Diagnostic performance of tissue transglutaminase and anti-H pylori antibodies in IDA

On the basis of these results, the sensitivity, the specificity, and the positive and negative predictive values of tissue transglutaminase IgA antibodies for the diagnosis of celiac disease were 80%, 92.8%, 50% and 98.1%, respectively. The sensitivity, the specificity, and the positive and negative predictive values of anti-*H pylori* antibodies for the diagnosis of *H pylori* infection were 84.8%, 100%, 100% and 84.8%, respectively.

DISCUSSION

In the present study, 115 women aged < 50 years with unexplained IDA were tested by anti-*H pylori* IgG antibodies and human recombinant tissue transglutaminase IgA antibodies to diagnose *H pylori* infection and celiac disease. Almost half of the studied patients tested positive for at least one serological assay, and the suspicion of an upper GI disease as likely cause of IDA, raised by the serological result, was confirmed by gastroscopy in 100% of those with positive *H pylori* antibodies and in 50% of those with positive tissue transglutaminase IgA. On the other hand, in only 11% of test negative patients, gastroscopy with biopsies yielded a finding which may be interpreted as a likely cause of IDA (2 *H pylori*-related *antrum predominant* pangastritis and 1 atrophic body gastritis). Thus, these findings indicate that in women aged < 50 years with IDA, the dual-step approach e.g. serological tests and then invasive procedure, may be considered as a useful tool to optimize the use of gastroscopy, avoiding useless procedures, and to reduce the number of expensive histological examinations.

Previous studies have shown that the presence of GI symptoms or the severity of anemia were related to higher risk of GI causes of IDA[3,5-6]. In this study, no difference was found between test-positive and test-negative patients in terms of personal data, clinical and biochemical features including the frequency of upper GI symptoms and Hb values. Therefore, our results show that GI evaluation is of poor utility to target IDA patients for gastroscopy, strengthening the usefulness of the pre-endoscopic screening by serological tests.

H pylori infection was found in 35.6% of the investigated women, confirming the strong association between *H pylori* infection and IDA observed in previous epidemiological studies[15-16]. Since *H pylori* IgG antibodies do not discriminate between active or previous infection, they are not generally considered useful for diagnosing *H pylori* infection[17]; in this clinical setting of IDA women, *H pylori* antibody-positivity was always associated with active infection as shown by histological data (Table 3). Moreover, 82% of patients with *H pylori* antibody-positivity had gastritis involving the gastric body, while only five cases had an *antrum-restricted* gastritis. In fact, only when the inflammation involves the gastric body, the acid secretion is reduced and the iron absorption is impaired, is there a consequential IDA[13,18]. The presence of positive *H pylori* antibodies, in a patient at high risk for iron malabsorption diseases, supports the need of an accurate gastroscopic/histological evaluation with antral and corporal biopsies to define the extent of gastritis and

eventually its association with IDA. In our clinical setting, we observed 100% specificity and positive predictive value as well as a sensitivity of 85% for the *H pylori* antibodies assay. On the basis of this result, we believe that the assay of *H pylori* antibodies may be considered useful in the selection of IDA women aged < 50 years to submit for gastroscopy, also keeping in mind that this serological test is widely available and cheap and, for this reason, it may be used in the primary care.

Human recombinant tissue transglutaminase IgA antibodies were found to be positive in almost 7% of all patients. This antibody was chosen as screening test for celiac disease, because it is based on ELISA assay and is more accurate compared to the immunofluorescence method used for determining endomysial antibodies[19]. Our results showed a good sensitivity (80%), and specificity (93%) of the assay in keeping with a recent meta-analysis[20]. Our study confirmed also the poor positive predictive value (50%), which is a well known limit of this serological assay. Yet, this value is higher than the one (28%) reported in previous literature[21]. This difference may be explained by the fact that the women included in the present study were anemic and thus were at high risk for celiac disease[22]. Considering the occurrence of false positives of the tissue transglutaminase assay, even in this particular clinical setting, the need for a histological confirmation of celiac disease diagnosis is confirmed.

The main limitation of this work is the small size of the sample, in part due to the high percentage of patients who have refused to participate in the study and of those who, once included, refused gastroscopy. Thus, our findings suggest that the pre-selection of young women for gastroscopy by non-invasive serological testing is able to increase compliance for the invasive procedure. In fact, the compliance rate of test-positive women was significantly increased with respect to those test-negative (65.4% *vs* 42.8%; Fisher test $P = 0.0239$).

In conclusion, half of IDA women aged < 50 years tested positive to serological screening for *H pylori* infection and/or celiac disease, and gastroscopy with biopsies confirmed in the vast majority of them the presence of active *H pylori* gastritis involving gastric body, or celiac disease, as possible causes of IDA. Thus, two simple and widely available tests (tissue transglutaminase IgA antibodies and anti-*H pylori* IgG antibodies) are able to select women with IDA to submit for gastroscopy to identify IDA-related GI causes.

COMMENTS

Background

Iron-deficiency anemia (IDA) is common in women aged < 50 years. Menorrhagia is often considered the only cause of iron deficiency anemia, but some studies have shown the usefulness of a gastrointestinal (GI) tract evaluation. The vast majority of IDA GI causes affect the upper GI tract and there is a high prevalence of conditions associated with iron malabsorption such as *Helicobacter pylori* (*H pylori*) related-pangastritis, celiac disease and atrophic body gastritis in IDA premenopausal women.

Research frontiers

The diagnostic workflow in young women affected by IDA is not clearly established. The British Society of Gastroenterology recommends gastroscopy only in IDA women younger than 45 years presenting with GI symptoms. However, symptoms are often mild and aspecific in IDA women and the gastroscopy is an invasive procedure associated with a high number of refusals. In a previous work on IDA premenopausal women, gastroscopy was performed in all patients, later deemed unnecessary in almost 30% of the studied women because these were affected only by menorrhagia.

Innovations and breakthroughs

This study showed that two simple and widely available tests, ie those for tissue transglutaminase IgA antibodies and anti-*H pylori* IgG antibodies, are able to select women with IDA to submit for gastroscopy to identify IDA-related GI causes and to increase the compliance for the invasive procedure. Gastroscopy with biopsies confirmed in the vast majority of IDA women the presence of active *H pylori* pangastritis, atrophic gastric body, or celiac disease as possible causes of IDA.

Applications

This study showed that a pre-endoscopic serological screening for *H pylori* infection and celiac disease is useful to select IDA women having a high probability of being affected by iron malabsorption GI diseases and to increase the patients' compliance for the procedure.

Terminology

Pangastritis: *H pylori*-related gastritis involving the antrum and the body of the stomach. Malabsorptive diseases: diseases related to iron-malabsorption that include *H pylori*-pangastritis, atrophic body gastritis and celiac diseases.

Peer review

The paper is interesting to study the usefulness of non-invasive test to select women with IDA for gastroscopy. These findings may be not applicable to other countries if the prevalence of celiac disease or *H pylori* infection are low.

Abstract

AIM: To generate an adenoviral vector specifically targeting the EphA2 receptor (EphA2R) highly expressed on pancreatic cancer cells *in vivo*.

METHODS: YSA, a small peptide ligand that binds the EphA2R with high affinity, was inserted into the HI loop of the adenovirus serotype 5 fiber knob. To further increase the specificity of this vector, binding sites for native adenoviral receptors, the coxsackie and adenovirus receptor (CAR) and integrin, were ablated from the viral capsid. The ablated retargeted adenoviral vector was produced on 293T cells. Specific targeting of this novel adenoviral vector to pancreatic cancer was investigated on established human pancreatic cancer cell lines. Upon demonstrating specific *in vitro* targeting, *in vivo* targeting to subcutaneous growing human pancreatic cancer was tested by intravenous and intraperitoneal administration of the ablated adenoviral vector.

RESULTS: Ablation of native cellular binding sites reduced adenoviral transduction at least 100-fold. Insertion of the YSA peptide in the HI loop restored adenoviral transduction of EphA2R-expressing cells but not of cells lacking this receptor. YSA-mediated transduction was inhibited by addition of synthetic YSA peptide. The transduction specificity of the ablated retargeted vector towards human pancreatic cancer cells was enhanced almost 10-fold *in vitro*. In a subsequent *in vivo* study in a nude (*nu/nu*) mouse model however, no increased adenoviral targeting to subcutaneously growing human pancreas cancer nodules was seen upon injection into the tail vein, nor upon injection into the peritoneum.

CONCLUSION: Targeting the EphA2 receptor increases specificity of adenoviral transduction of human pancreatic cancer cells *in vitro* but fails to enhance pancreatic cancer transduction *in vivo*.

INTRODUCTION

Pancreatic cancer is a devastating disease with a very poor prognosis[1]. The lack of options for curative treatment for pancreatic cancer and other gastrointestinal malignancies warrants a search for novel targets and novel therapies including gene therapy[2,3]. Adenovirus has been used widely as a gene therapy vector to treat solid tumors. After initial negative results in clinical trials with non-replicating vectors, conditional replicating adenoviral vectors have been tested in clinical trials recently. However, these have also shown disappointing efficacy[4,5]. Poor transduction efficiency and specificity of adenoviral vectors appears to be a major problem.

This seems to be the result of low expression of the primary receptor involved in adenoviral transduction on the tumors, the coxsackie and adenovirus receptor (CAR). Development of targeted vectors to circumvent CAR-mediated entry therefore seem to be required to increase the therapeutic potential of this approach.

Incorporation of ligands that bind to receptors highly expressed on cancer cells in the fiber HI loop enhance adenoviral transduction efficiency[6]. We have shown that incorporation of an RGD peptide improved transduction in pancreatic cancer[7]. Tumor specificity of RGD, however, is limited. Therefore, we decided to introduce the YSA peptide (YSAYPDSVPMMS) in the HI loop (van Geer, in review). YSA is a ligand for the EphA2 receptor (EphA2R) that is highly expressed on pancreatic cancers[8] and other solid tumors[9-11]. Since the YSA peptide has a high affinity for this receptor, it can be used for *in vivo* delivery of agents to tissues and tumors expressing the EphA2R[12]. In addition, binding of YSA activates the EphA2R and induces its internalization which may enhance adenoviral uptake. Adenoviral HI loop insertion of the YSA peptide increased the transduction specificity and efficiency both in human pancreatic tumor cell lines and in pancreatic tumor resection specimens *in vitro* (van Geer, in preparation). *In vivo* however, the presence of the native binding sites in the adenoviral capsid will compromise specific targeting. Even *in vitro*, YSA-mediated entry could only be proven upon inhibition of CAR-mediated entry. As we aim to target pancreas cancer *in vivo* we decided to ablate the native adenoviral binding sites of the YSA-targeted vector.

A highly conserved cluster of amino acids on the adenovirus fiber trimer is involved in CAR binding[13]. Site-directed mutagenesis of amino acids in this region was used to identify mutations that affect CAR binding. Mutations in the AB loop[14,15], the DE loop[16], and the FG loop[17] of the fiber knob all abolished CAR binding *in vitro*.

In addition to CAR, binding to integrins can also mediate adenoviral transduction. The presence of integrins on virtually all normal cells will also limit specific transduction of tumor cells. Removal of the integrin-binding motif RGD from the adenoviral penton base indeed enhances tumor specific targeting of adenoviral vectors[18].

To generate an adenoviral vector that targeted pancreatic cancer *in vivo* we therefore decided to combine HI loop insertion of the YSA peptide with ablation of the binding sites for CAR and integrin. The specificity of this doubly-ablated retargeted vector (Ad/ΔF(FG)Δ P-YSA) was determined *in vitro* and subsequently *in vivo*.

MATERIALS AND METHODS

Materials

Anti-fiber monoclonal 4D2 antibody (NeoMarkers, Fremont, California, USA); anti-EphA2R clone D7 (Sigma, Saint Louis, USA), synthetic peptide YSA (Eurogentec, Seraing, Belgium), Basement Membrane Matrix (BD Biosciences, Bedford, MA); luciferase activity was determined using a commercial kit (Promega) and a Berthold luminometer.

Cells

HEK293 cells, the established PC cell lines Capan-1 and Hs766-T, the mouse pre-adipocyte cell line 3T3-L1 and the mouse hepatoma Hepa 1-6 cell lines were obtained from the American Type Culture Collection Rockville, Maryland; BxPC-3 and MIA PaCa-2 were obtained from Boehringer Ingelheim (Belgium). The pancreatic carcinoma cell lines (p6.3 and p10.5) were obtained from Dr. E Jaffee, Johns Hopkins University School of Medicine, Baltimore, MD, USA. Human umbilical vein endothelial cells (HUVECs, passage 1-3) were isolated as described[19] and cultured in Medium-199 (GIBCO-BRL, Paisley, Scotland), supplemented with 20% (v/v) fetal bovine serum, 50 μg/mL heparin (Sigma, St Louis, MO, USA), 6-25 μg/mL endothelial cell growth supplement (ECGS; Sigma), penicillin (100 IU/mL), streptomycin (100 mg/mL) (GIBCO-BRL). Human fibroblasts (passage < 10) were a gift from the department of Genetic and Metabolic diseases AMC, Amsterdam. Fiber-293 cells expressing adenovirus type 5 fiber protein were used as the packaging cell line as previously described. All cells were cultured in Dulbecco's minimal essential medium (DMEM) with 10% fetal bovine serum (heat inactivated); L-glutamine (2 mmol/L) and penicillin (100 IU/mL), streptomycin (100 mg/mL) all from Cambrex Bio Science, Walkersville. All cell lines were cultured at 37℃ in 10% CO_2 atmosphere.

Plasmids

The E1-, E3-deleted adenovirus vector AdHM43 was used for propagation of integrin- and CAR-binding mutated adenovirus[20]. The RGD-peptide coding sequence at the penton base was changed from MNDHAIRGDTFATRAE to MNDTSRAE and the FG-loop of the fiber was deleted (T489, A490, Y491, T492). The cytomegalovirus (CMV) immediate-early promoter controlled enhanced green fluorescent protein (eGFP) and the CMV-controlled luciferase gene were inserted between the PI-Sce and Ceu-I sites of the pAdHM43 plasmid (van Geer, in review). Insertion of the YSA peptide (YSAPDSVPMMS) into pAdHM43-CMV-GFP and CMV/Luc was performed by digestion with BstB1 and ligation with 2 annealed primers: YSA forward: CGAAGTACAGCGCCTACCCCGACGG-CGTGCCCATGATGT. YSA reverse: CGACATCAT-GGGCACGCTGTCGGGGTAGGCGCTGTACTT. Clones identified by restriction enzyme analysis and PCR were sequenced to exclude mutations.

Virus generation, propagation and analysis

Recombinant ablated adenoviral vectors were generated by transfection of HEK 293 adeno fiber-expressing cells with *Pac* I -linearized Ad-CMV-GFP/Luc-YSA. Normal HEK 293 cells were used for the last propagation round as previously described[20]. Adenovirus was purified and concentrated by performing 2 cesium chloride gradients

and dialyzing against PBS. Glycerol was added to a final concentration of 10% (v/v) and virus preparations were stored at -80℃.

Modification of viral genomes were verified by PCR and sequencing using the following primers: fiber-forward: CAAACGCTGTTGGATTTATG; fiber-reverse: GTGTAAGAGGATGTGGCAAAT; RGD forward: TTGGATGTGGACGCCTAC; RGD reverse: AGGTGTCGCCGCGAATGGC.

The anti-fiber monoclonal 4D2 antibody (NeoMarkers, Fremont, California) was used to confirm proper trimerization of the fiber[21]. The number of viral genomic copies (gc) was determined by qPCR as previously described[22].

EphA2 receptor expression

Expression of EphA2R was studied with Western blotting using a 1:1000 dilution of a monoclonal antibody (anti-EphA2R clone D7, Sigma, Saint Louis, USA) and a peroxidase-conjugated anti IgG secondary antibody (1:2500). Cell lysates were prepared in 25 mmol/L Tris HCl pH 7.6, 150 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS containing a cocktail of protease inhibitors (1:250, Roche). The protein concentration was determined with a BCA assay kit (Sigma). Detection was performed using the Lumi-light plus Western Blotting Substrate Kit (Roche, Mannheim, Germany). For receptor localization studies pancreatic tumor cells were gown on cover slips and were fixated 2 d later and stained for EphA2R using a 1:500 of the monoclonal antibody and a 1:2500 peroxidase-conjugated IgG secondary antibody.

Adenoviral transduction

5.0×10^4 cells were plated in 48-well plates and allowed to adhere overnight at 37℃. The next day virus was added (500 or 1000 VP/cell) in 2% DMEM. Blocking was performed by pre-incubating the cells with blocking agents in PBS for 20 min at room temperature. EphA2R was blocked with the synthetic peptide YSA (Eurogentec, Seraing, Belgium). For the bi-specific antibody experiments, 500 gc of virus were incubated for 60 min with 2.5 μL scFv bi-specific antibody (a kind gift from Dr. VW van Beusechem[23]).

In vivo transduction

1.0×10^7 Capan-1 pancreatic cancer cells were 1:1 diluted with Basement Membrane Matrix (BD Biosciences, Bedford, MA) and injected subcutaneously in both flanks of 6-9 wk old female athymic NMRI *nu/nu* mice (Harlem). When the tumor nodule reached a diameter of 0.4 to 0.7 cm, mice were injected intravenously (i.v.) or intraperitoneally (i.p.) with 1.0×10^{11} gc of Ad-/ΔF(FG)ΔP or Ad-/ΔF(FG)ΔP-YSA in 100 μL PBS. Blood was sampled by orbital puncture at 10 min after *i.v.* injection or at 90 min after *i.p.* injection. Three days after injection, mice were sacrificed and organs were harvested, snap frozen and used to determine luciferase activity according to standard procedures (Promega), using a Berthold luminometer. Luciferase activity was normalized for protein content. Viral DNA in blood was purified as described previously[24] and gc were quantified by qPCR using the primers against the CMV promoter (forward: AATGGGCGGTAGGCGTGTA, reverse AGGCGATCTGACGGTTCACTA). Serum aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT) levels were determined using standard clinical chemistry methods.

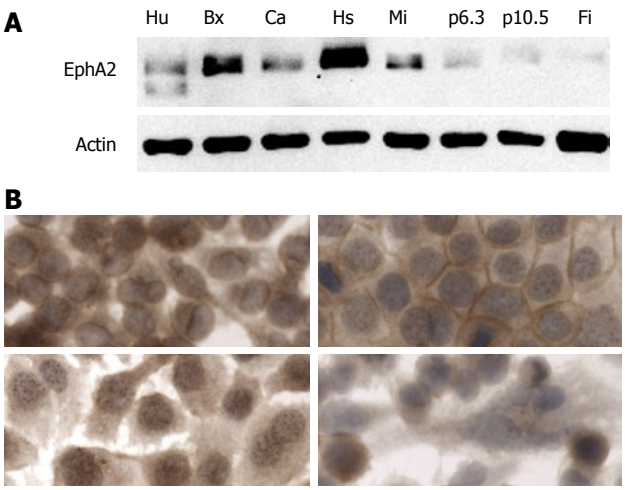

Figure 1 EphA-2 expression in human cell lines. A: Analysis of EphA2R expression by Western blotting in human umbilical vein endothelial cells (Hu), human pancreatic cancer cell lines BxPc-3 (Bx), Hs766-T (Hs), Capan-1 (Ca), MIA PaCa-2 (Mia), p6.3, p10.5 and human fibroblasts (Fi). EphA2R was detected using a monoclonal antibody and detection of actin levels was performed as a loading control; B: Immunolocalization of EphA2R in human pancreatic cancer cell lines BxPc-3 (left top), Capan-1 (right top), Hs766-T (bottom left), MiaPaca-2 (bottom right). Cells were fixated with methanol, acetone, and water, and a directed monoclonal antibody was used to detect EphA2R using a goat anti-mouse labeled with PO to perform DAB detection. Magnification (× 600), except for MiaPaca-2 (× 400).

RESULTS

Expression of the EphA2R on human pancreatic cancer cell lines and tissue specimens

The EphA2R is highly expressed on most solid tumors including pancreatic cancer. To investigate which cell lines are suitable as a model to study targeting, we determined its expression on a panel of established human pancreatic cancer cells and normal human cells such as fibroblasts and endothelial cells. The expression level of the EphA2R varied significantly in human pancreas cancer cell lines (Figure 1A). High expression was seen in Capan1, BxPc3, Hs766T and MIA PaCa-2, while expression in p6.3 and p10.5 was low. Of the normal cells, only human endothelial cells expressed EphA2R. Since this receptor is absent on normal human fibroblasts, we used these as negative control cells.

To investigate whether the EphA2R was accessible, we determined its localization in the cell lines highly expressing this receptor. The localization of this receptor differed between cell lines (Figure 1B). In Capan-1 and BxPc-3 cells, the EphA2R was detected on the membrane while in MIA PaCa-2, it was mostly seen in the cytoplasm. The signal seen in Hs766-T suggests

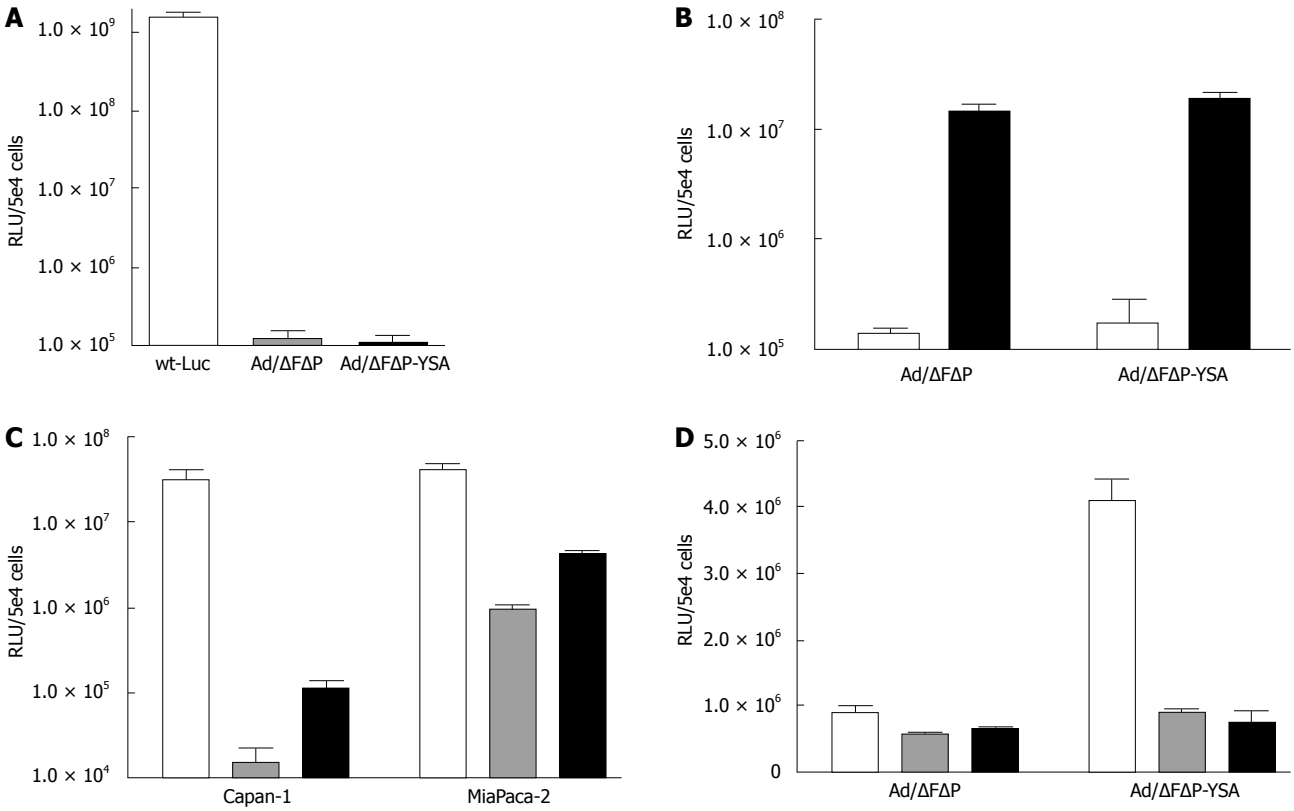

Figure 2 YSA redirects adenovirus to the EphA2 receptor. A: Transduction of CAR-expressing A549 cells with wild-type, ablated and YSA-retargeted adenoviral vectors with 1000 gc/cell: wt-Ad-Luc, Ad-Luc/ΔF(FG)ΔP and Ad-Luc/ΔF(FG)ΔP-YSA. Twenty four hours after infection cells were lysed to determine luciferase levels. Data are expressed as mean ± SD (n = 3). B: Incubation with bi-specific antibody restores infectivity of ablated adenoviral vectors in human fibroblasts. Cells were transduced with 500 gc/cell of Ad-/ΔF(FG)ΔP or Ad-/ΔF(FG)ΔP-YSA with (black bars) or without (white bars) EGF receptor targeted bi-specific scFV molecules. Luciferase activity was measured after 24 h and data are expressed as mean ± SD (n = 3). C: Insertion of YSA peptide in the HI loop of ablated adenoviral vector partially restores transduction of human pancreatic cancer cell lines Capan-1 and MiaPaca-2. Cells were transduced with 1000 gc/cell of wt-Ad-Luc (white bars), or Ad-Luc/ΔF(FG)ΔP (gray bars) or Ad-Luc/ΔF(FG)ΔP-YSA (black bars). Luciferase activity was measured after 24 h. Data are expressed as mean ± SD (n = 3). D: Pre-incubation with synthetic peptide blocks YSA-mediated targeting of human pancreatic cancer cell line MiaPaca-2. Cells were preincubated with 250 (grey bars) or 500 (black bars) μmol/L synthetic YSA peptide and transduced with 500 gc/cell of Ad-Luc/ΔF(FG)ΔP or Ad-Luc/ΔF(FG)ΔP-YSA. Luciferase was measured after 24 h. Data are expressed as mean ± SD (n = 3).

that, in this cell line, the EphA2R is present in nuclear granules. Since, in Capan-1 cells, the presence of the EphA2R on the membrane indicates that it is accessible for YSA binding, we chose to use this cell line for our subsequent studies.

Generation of ablated adenoviral vectors

We decided to use the FG loop mutation to ablate CAR binding because it has been well characterized[17,25]. By subsequent deletion of the RGD peptide from the penton base we obtained a doubly-ablated vector Ad-/ΔF(FG)ΔP which lacked both CAR and integrin binding. We inserted the YSA peptide in the HI loop of this doubly-ablated vector and generated Ad-/ΔF(FG)ΔP-YSA.

The lack of binding to native cellular receptors severely impairs the cellular entry of this doubly-ablated vector. Therefore, it can not be propagated on normal HEK 293 T cells. To overcome this, we used 293T cells that express the adenovirus type 5 fiber protein[20]. Incorporation of the normal fiber expressed in trans into the ablated vector allowed efficient cell entry and vector production. The last round of virus propagation was on normal 293T cells to generate the doubly-ablated vector. Because of impaired cell entry, the infectious particle (ip) titers of ablated vector stocks could not be preformed by standard procedures. To determine the functional titer of these vectors we therefore used a bi-specific antibody[23]. This antibody binds to the adenovirus knob and the epidermal growth factor receptor (EGFR). Upon binding to this antibody, the vector will enter the cells *via* the EGFR only. Therefore, this antibody allows direct comparison between the ip/gc ratio of the ablated and of the retargeted vectors.

To confirm the absence of CAR- and integrin-mediated entry, we compared the transduction efficiency of wild-type adenovirus type 5 with that of Ad-/ΔFΔP and Ad-/ΔFΔP-YSA on A549 cells that do express CAR but not EphA2R. The 3 to 4 log lower transduction by both ablated vectors confirmed efficient abolition of binding to the native receptors (Figure 2A). As expected, the transduction efficiency of both vectors on normal human fibroblasts that do not express the EphA2R was comparable but very low: 1.42×10^5 RLU for Ad-/ΔF(FG)ΔP and 1.77×10^5 RLU for Ad-/ΔF(FG)ΔP-YSA ($P = 0.06$) (Figure 2B). To confirm viability of the ablated vectors, we incubated both vectors with the bi-specific antibody, which resulted in a 2 log increase of

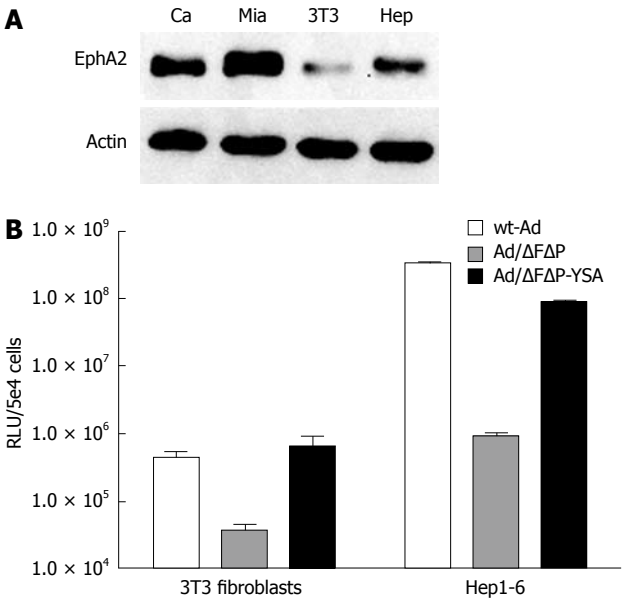

Figure 3 YSA targets adenovirus to cells expressing murine EphA2R. A: Western blotting demonstrates that mouse 3T3 and Hep1-6 cells, like human pancreatic cancer cell lines Capan-1 and MIA PaCa-2, express the EphA2R. EphA2R was detected using a monoclonal antibody and the housekeeping protein actin was used as a loading control. B: Efficient transduction of mouse 3T3 and Hep1-6 cells by YSA-retargeted adenoviral vector. Cells were transduced with 1000 gc/cell of wt-Ad-Luc (white bars), Ad-Luc/ΔF(FG)ΔP (gray bars) or Ad-Luc/ΔF(FG)ΔP-YSA (black bars). Luciferase was measured after 24 h. Data are expressed as mean ± SD (n = 3).

transduction efficiency for both vectors, Ad-/ΔF(FG)ΔP: 1.5×10^7 RLU and Ad-/ΔF(FG)ΔP-YSA: 1.9×10^7 RLU. The comparable transduction by both in the presence of the antibody indicated that both had a comparable ip/gc ratio ($P = 0.094$) and were viable.

To determine if insertion of the YSA peptide was functional, we tested transduction of both vectors on EphA2R-expressing Capan-1 and MiaPaca-2 cells. Although both cell lines do express integrins[7], ablation of native binding sites reduced their transduction by 3 to 1.5 logs. Insertion of the YSA peptide increased gene transfer to Capan-1 cells by 7.6-fold ($P = 0.0014$) and to MIA PaCa-2 cells by 4.5-fold ($P < 0.0001$). Insertion of the YSA peptide did not increase transduction in Hs766-T cells which only showed nuclear EphA2R staining (not shown). To confirm that entry of the retargeted vector was mediated by the YSA peptide, we performed competition experiments. As shown in Figure 2D, the 4-fold increased transduction efficiency of Ad-/ΔF(FG)ΔP-YSA compared to Ad-/ΔF(FG)ΔP was lost upon pre-incubation with synthetic YSA peptide. This indicated that the increased efficiency of the retargeted vectors was indeed mediated by the inserted YSA peptide. Thus, HI loop insertion of the YSA peptide in an adenovirus that lacks binding to CAR and integrins, resulted in cell entry *via* the EphA2R. Therefore, this vector appeared suitable for *in vivo* targeting of pancreatic cancer.

Targeting of the EphA2R by the YSA peptide has only been demonstrated in humans. Binding of the YSA peptide to the murine EphA2R has not been studied. Since binding to EphA2R expressed on activated (murine) endothelial cells will affect targeting of pancreatic cancer in a mouse model, we therefore decided to investigate the transduction efficiency of the YSA-retargeted adenoviral vector to mouse cells expressing the EphA2R. As shown in Figure 3A, mouse 3T3 fibroblasts and hepatoma cells (hepa1-6) both expressed the murine EphA2R, albeit at a lower level than in the human pancreatic cancer cell lines Capan-1 and MIA PaCa-2. Ablation of native cell binding sites reduced adenoviral transduction of these 2 mouse cell lines by 1 to 2 logs (Figure 3B). Insertion of the YSA peptide completely rescued cell entry of the ablated vector. Compared to the ablated vector, gene transfer of the YSA-retargeted vector was enhanced 17-fold in 3T3 cells and 95-fold in Hepa 1-6 cells. This efficient transduction of cells expressing the mouse EphA2R rendered the mouse a suitable model to study the efficiency of YSA-mediated targeting *in vivo*.

In vivo targeting in pancreatic cancer

To study *in vivo* targeting we used a *nu/nu* mouse model with subcutaneously growing human pancreatic tumor nodules. The virus was injected into mice which had nodules with a diameter of 0.4-0.7 cm, within 3 wk after injection of Capan-1 cells. We administered 1.0×10^{11} gc of ablated [Ad-/ΔF(FG)ΔP] or of the redirected vector Ad-/ΔF(FG)ΔP/-YSA, *via* the tail vein or i.p. Upon i.v. injection the clearance of both vectors was comparable. At 10 min after injection, $9.4 \times 10^8 \pm 6.3 \times 10^8$ gc/mL of Ad/ΔF(FG)ΔP and $1.1 \times 10^9 \pm 5.6 \times 10^8$ gc/mL of Ad/ΔF(FG)ΔP-YSA were present in blood. Since the total blood volume in a mouse is approximately 2.5 mL, the initial concentration of the virus was 4×10^{10} gc/mL. Thus 95% of the injected virus was cleared within 10 min. Based on the literature, we expected a slower clearance after i.p. injection, and determined the amount of virus in blood after 90 min. No significant difference was seen after 90 min between Ad-/ΔF(FG)ΔP-YSA ($1.4 \times 10^8 \pm 8.3 \times 10^7$ gc/mL) and Ad-/ΔF(FG)ΔP ($3.2 \times 10^8 \pm 4.3 \times 10^8$ gc/mL) ($P = 0.3$). Thus clearance for both vectors after *i.p.* injection was also comparable. Clearance of *i.p.*-injected virus was also efficient since less than 0.5% of the injected dose was present in blood after 90 min.

All mice were sacrificed 72 h after injection. Tissues were harvested and snap frozen in liquid nitrogen to determine adenoviral transduction by determining luciferase expression. After *i.v.* injection, expression of luciferase in the liver of Ad/ΔF(FG)ΔP-YSA treated mice was 6.7-fold lower ($P = 0.015$) than that in mice injected with Ad/ΔF(FG)ΔP (Figure 4B). Thus, the YSA peptide impaired liver transduction. No significant differences in expression were seen between both vectors in all other tissues. Surprisingly, the amount of luciferase expression in mice injected with Ad-/ΔF(FG)ΔP-YSA was only 15% of that in mice injected with Ad-/ΔF(FG)ΔP. This indicated that a large amount of the redirected vector was lost upon i.v. injection. The difference in luciferase expression between both vectors

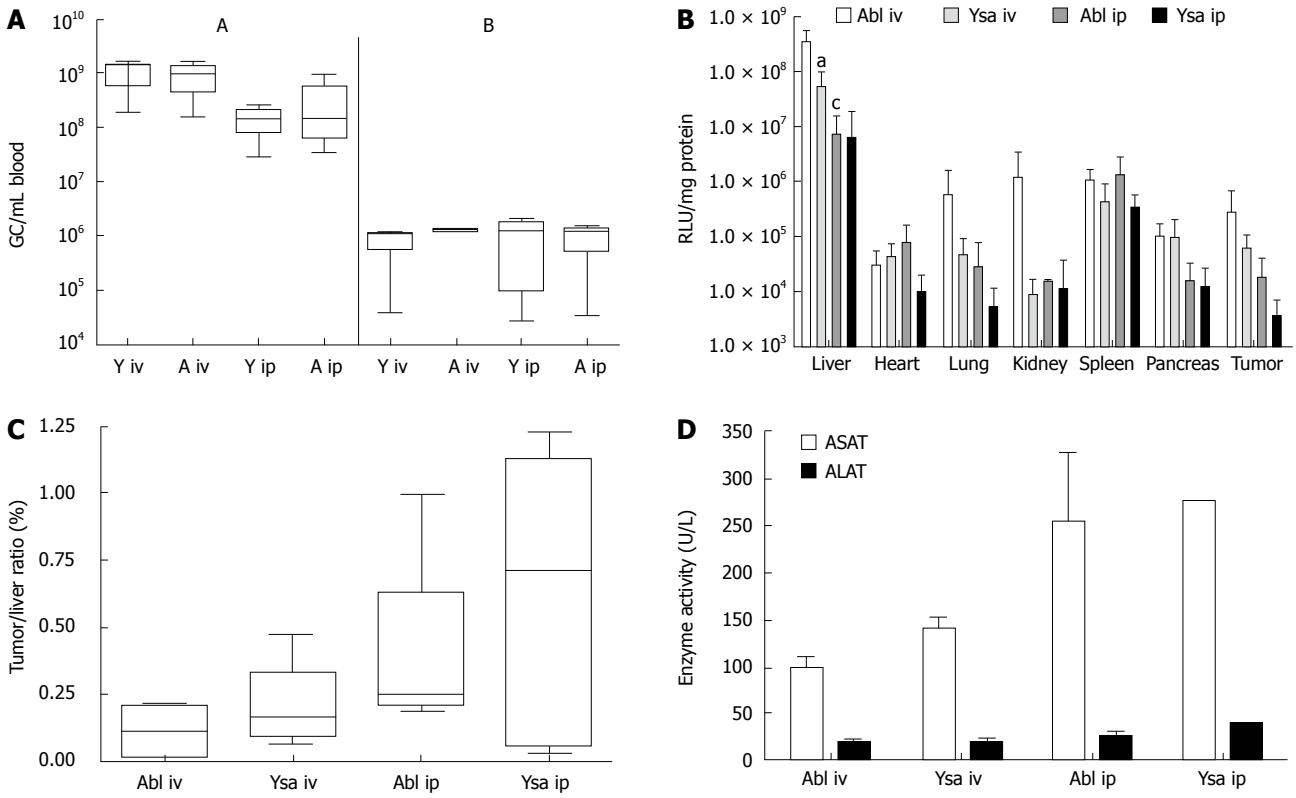

Figure 4 Lack of YSA specific targeting in nu/nu mice. A: 1 × 10^{11} gc of Ad/ΔF(FG)ΔP (ablated, A) or 1 × 10^{11} gc of Ad/ΔF(FG)ΔP-YSA (YSA; Y) are rapidly cleared from blood after intravenous (*i.v.*) and intraperitoneal (*i.p.*) administration into mice. At 10 min after *i.v.* or 90 min after *i.p.* injection and after 3 d (both), adenoviral genomic copies were determined in whole blood with real time PCR. B: Bio-distribution Ad/ΔF(FG)ΔP and Ad/ΔF(FG)ΔP-YSA injected *i.v.* or *i.p.* into *nu/nu* mice with a subcutaneous human pancreatic tumor. Animals were sacrificed 3 d after injection of 1 × 10^{11} gc of adenoviral vector. All organs were harvested and analyzed for luciferase expression/mg of protein. ($^{a}P < 0.05$ compared with Ad/ΔF(FG)ΔP after *i.v.* injection; $^{c}P < 0.05$ compared with Ad/ΔF(FG)ΔP after *i.v.* injection). C: The tumor/liver ratio of luciferase expression in each mouse demonstrates the lack of significant targeting of retargeted adenovirus to pancreatic cancer *in vivo*. D: Similar ASAT and ALAT levels in serum at 3 d after injection indicates comparable liver toxicity of ablated and retargeted adenoviral vectors in *nu/nu* mice. Data represent the mean ± SD of 4-7 mice.

was not seen after i.p. injection. This is due to the almost 50-fold lower luciferase expression in the liver after i.p. injection of Ad-/ΔF(FG)ΔP ($P = 0.0163$). For Ad/ΔF(FG)ΔP-YSA, the luciferase levels in the liver after *i.p.* injection were only reduced 9-fold and did not reach significance. The lower luciferase expression levels indicated that both vectors were cleared more efficiently without transduction after *i.p.* injection. To correct for the lower overall expression we chose to use the tumor liver ratio in each animal as an indication of retargeting efficiency. As shown in Figure 4C, no significant targeting of the tumor was seen with the YSA-redirected virus. Furthermore, the route of administration also did not affect tumor targeting.

Adenoviral vectors cause inflammation of the liver. Therefore we determined ALAT and ASAT levels 3 d after injection. Although we did see a 4 to 5-fold increase, no differences were seen between the 2 viral vectors (Figure 4D).

DISCUSSION

Conditional replicating adenovirus vectors are being developed to treating solid cancers[4,5]. However, these vectors have only been effective after direct injection into the tumors. As cancer is a systemic disease in virtually all fatal cases, this lack of systemic efficacy presents a major limitation to successful adenovirus-mediated gene therapy. Specific targeting therefore is a prerequisite for efficient eradication of solid cancer cells.

The aim of this study was to target the adenovirus to pancreatic cancers. Effective targeting *in vitro* to human cancer cells using HI loop insertion of peptide ligands has been reported by other groups. A well known example is the insertion of an integrin-binding RGD peptide that overcomes the poor transduction of human cancer caused by low expression of CAR[7,26,27]. Although integrins are highly expressed on cancer cells, the specificity of RGD targeting *in vivo* is questionable because of integrin expression in other tissues. Therefore more specific targeting peptides are needed. We compared binding of several ligands to receptors highly expressed on pancreatic cancers for their ability to target the adenovirus to pancreatic cancer cells (van Geer *et al*[12] in preparation). Of these ligands the YSA peptide appeared the most promising since it provided selective targeting *in vitro* to the EphA2R. Since YSA targets tissues expressing the EphA2R, we decided to test the specificity this retargeted vector *in vivo*.

Insertion of a peptide into the HI loop does not shield the native cell binding sites present in the adenoviral capsid. Binding of the retargeted vector

to these receptors present on liver cells for instance, will limit specific targeting[17]. Since ablation of these native binding reduces liver transduction and improves specific targeting *in vivo*[14], we combined YSA targeting with ablation of the native binding sites. We showed that ablation of CAR and integrin binding reduced adenoviral transduction by at least 2 logs *in vitro*. Insertion of the YSA peptide partly restored the transduction efficiency of the virus, but only on cells that expressed the EphA2R. Addition of synthetic YSA peptide blocked the increase in transduction efficiency. Together these data demonstrated that insertion of YSA enables EphA2R-mediated entry of ablated adenoviral vectors. Other groups have also reported that the loss of infectivity of ablated vectors can be restored by insertion of a targeting ligand in the HI loop[17,18,28]. However, not all retargeted vectors do provide efficient transduction. Insertion of RGD in a vector in which the CAR binding site was ablated in the KO1 mutation did not result in integrin-mediated uptake[29]. Apparently, in addition to preventing CAR binding, this mutation affected other essential steps such as internalization or trafficking of the adenovirus. In conclusion, our data and that of others show that HI loop insertion of a targeting peptide results in specific targeting of CAR/integrin-ablated adenoviral vectors *in vitro*.

Expression of the EphA2R is also enhanced in several normal tissues including tumor endothelium. Therefore, we investigated whether the YSA peptide also mediated adenoviral transduction *via* the mouse EphA2R. Since insertion of the YSA peptide increased the transduction of 2 mouse cell lines expressing the EphA2R by 1 to 2 logs, the YSA-retargeted vector was capable of targeting the mouse endothelium. The increase in transduction of mouse cells was stronger than in human pancreatic cancer cell lines while expression of the EphA2R in mouse cells was lower. This discrepancy seems to result from better accessibility of the EphA2R in mouse cells since, in human pancreatic cancer cells, most of the EphA2R was present in the cytosol (Figure 1A). Another possible explanation for this discrepancy is the expression of an inactive EphA2R in cancer cells. Since EphA2R activation impairs survival, cancer cells with an inactive receptor will have a growth advantage[11]. A third explanation could be a higher affinity of the Ad-/ΔF(FG)ΔP-YSA for the mouse EphA2R. Nevertheless, the efficient transduction of mouse cells expressing EphA2R renders the mouse a good model to study YSA-mediated targeting of pancreatic cancer *in vivo*.

After intravenous injection, luciferase expression in the liver of the YSA-retargeted vector Ad-/ΔF(FG)ΔP-YSA was lower than that by the ablated virus (Figure 4B). A decreased transduction of the liver was also reported in other studies in which the FG loop has been mutated. Thus, it seems that FG loop mutations lead to de-targeting of the hepatocytes[17]. In contrast, mutations in the AB loop did not decrease liver transduction[18,30]. These studies indicate that liver de-targeting occurred irrespective of the nature of the inserted peptide sequence. In our study, the decreased liver transduction due to YSA-retargeting was not accompanied by an increased transduction of any other tissue tested. Therefore, the increased loss of the redirected virus seems to result from degradation by tissue macrophages, which degrade more than 90% of injected adenoviruses. Since these cells do not express the EphA2R this would appear to be a non-specific effect.

In contrast to the receptor-mediated transduction of hepatocytes, uptake of adenovirus by macrophages depends on the binding of adenovirus fiber to blood factors. This induces uptake of adenovirus, for instance *via* the scavenger receptor[31,32]. Increased binding to blood factors of the mutated FG loop may cause the 10-fold greater loss of re-targeted adenovirus upon i.v. injection by increasing its degradation by macrophages. This may cause a lack of tumor targeting by Ad-/ΔF(FG)ΔP-YSA *in vivo*.

Akiyama *et al*[25] reported that after i.p. injection, a comparable ablated adenoviral vector efficiently entered the blood stream. Furthermore, they showed prolonged blood circulation and absence of hepatocyte transduction. Based on this, i.p. injection seemed a promising approach for systemic targeting. In our study, we could not repeat this observation. At 90 min after injection, less than 1% of the injected dose of vector was still present in the circulation while in contrast they still detected 20%. Increased uptake by macrophages may explain this discrepancy[33]. We used *nu/nu* mice to study retargeting of adenovirus while Akiyama *et al* reported a prolonged circulation time in normal mice. Several old studies have reported increased phagocytosis in *nu/nu* mice compared to normal mice to compensate for their immune defects[34,35]. A high dose of adenovirus can saturate the uptake by macrophages residing in the peritoneum and liver, and result in appearance of the virus in the circulation[36]. Apparently, the dose used in this study was too low to saturate the increased macrophage clearance capacity in *nu/nu* mice. The increased liver enzymes in serum after i.p. injection indicated increased macrophage uptake (Figure 4D). This increase was not observed for this ablated vector in normal mice. The increased uptake by macrophages in *nu/nu* mice rendered this model less suitable for adenoviral targeting studies[30]. Inhibition of phagocytosis therefore seems to be required to use this model for studying retargeting of ablated adenoviral vectors, e.g., by pre-injection of a small dose of virus[37].

For both administration routes, the luciferase expression in subcutaneously growing Capan-1 tumors was not significantly different between re-targeted and ablated vectors. The transduction of pancreatic cancer by our ablated vector suggests that adenoviral uptake can be mediated by other receptors. The role of additional receptors in Capan-1 cells is in accordance with Havenga *et al*[38]. They observed that gene transfer in these cells did not correlate with expression levels of CAR and/or integrins. In contrast, transduction by non-ablated adenoviral vectors was strongly impaired by loss

of CAR expression[7,39]. Apparently, removal of native cell binding sites is compensated by other low affinity binding sites, such as heparan sulphate proteoglycans[40]. The expression of the 2 most prominent proteoglycans, glypican-1 and syndecan-1, is indeed enhanced in pancreatic cancers. This may explain the efficient transduction of the tumor by the ablated vector[41,42]. Pancreatic cancer therefore seems susceptible to blood factor-mediated transduction by adenovirus as has been reported for herpes virus also[43]. Therefore, ablation of the sites in the fiber knob that bind to blood factors may be required to re-direct the adenovirus to cancer cells *in vivo*. Furthermore, studies to determine binding to (human) blood components of modified vectors are essential for predicting their *in vivo* efficacy. Binding to blood factors may explain why ablated vectors with a peptide insertion fail to target tumors following intravenous injection[6,44], while they do perform properly upon local injection[25,28,45].

In conclusion, we have generated a doubly-ablated virus that targets pancreatic cancer cells *via* the EphA2R. However, *in vivo* targeting remains inefficient as yet. Most likely, further modification of the Ad capsid is necessary to prevent binding to blood factors which lowers gene transfer to the liver[30,46].

COMMENTS

Background

The incidence of pancreatic adenocarcinoma is increasing in the Western world for unknown reasons. Due to its late diagnosis the prognosis for pancreatic cancer is very poor. Novel treatments such as adenovirus mediated gene therapy are needed to improve this.

Research frontiers

Adenoviral vector have been widely applied to treat solid tumors. Although the results in animal models were promising the results in subsequent clinical trials were disappointing due to limited transduction of the tumors. Poor transduction of cancer cells was mainly caused by their low expression of coxsackie and adenovirus receptor (CAR), the receptor that mediates adenoviral entry in to the cell.

Innovations and breakthroughs

Retargeting of adenoviral vectors can be used to circumvent CAR mediated entry and can improve the transduction of human cancer cells. In this study, the authors targeted adenoviral vectors to the EphA2 receptor that is highly expressed on pancreatic cancer cells *in vitro* and *in vivo*. To further improve specific targeting to cancer cells they removed the regions in the adenoviral capsid that mediate transduction of the liver. *In vitro*, this strategy indeed proved very specific. The results in a nude mouse model were however disappointing most likely due increased uptake of the retargeted vector by macrophages, a route that is enhanced in these mice due to a compensatory mechanism for loss of other immune responses.

Applications

The authors show that adenovirus can be targeted to the EphA2 receptor *in vitro*. However to allow application *in vivo* further ablation of endogenous adenobinding sites seem needed.

Terminology

EphA2 or ephrine A2 receptor is a receptor involved in embryogenesis and is upregulated in several solid tumors. Adenovirus has a icosahedral symmetry with 12 fibers spiking out at all corners. The adenofibers are trimeric proteins. At the end they form a knob with a peptide stretch exposed to the surface, the HI-loop.

Peer review

The goal of this study was to generate an adenoviral vector specifically targeting the EphA2 receptor, which is highly expressed on pancreatic cancer cells *in vivo* by first using an *in vitro* model. The methodology incorporated into this particular study was sound and that their findings were novel.

Abstract

AIM: To investigate the effects of gallbladder stones on motor functions of the gallbladder and the dynamics of bile flow in asymptomatic gallstone disease.

METHODS: Quantitative hepatobiliary scintigraphy was performed to detect the parameters of gallbladder motor function [gallbladder ejection fraction (GBEF), gallbladder visualization time (GBVT), gallbladder time to peak activity (GBT_{max}), gallbladder half emptying time ($GBT_{1/2}$), and transit time of bile to duodenum (TTBD)] in 24 patients with asymptomatic cholelithiasis who were diagnosed incidentally during routine abdominal ultrasonographic examination and 20 healthy subjects with normal gallbladder.

RESULTS: Even though there was no significant difference in the clinical and laboratory parameters between the patient and control groups, all parameters of gallbladder function except TTBD were found to differ significantly between the two groups. GBEF in the patient group was decreased (P = 0.000) and GBVT, GBT_{max}, $GBT_{1/2}$ in the patient group were longer (P = 0.000, P = 0.015, P = 0.001, respectively).

CONCLUSION: Our results showed that even if there were not any clinical and laboratory findings, gallbladder filling and emptying could be impaired in patients with gallstone disease.

Key words: Asymptomatic gallstone disease; Hepatobiliary scintigraphy; Gallbladder function

INTRODUCTION

Asymptomatic cholelithiasis is being diagnosed increasingly, mainly as a result of the widespread use of abdominal ultrasonography for the evaluation of patients for unrelated or vague abdominal complaints and in cases of routine checkup. Most studies have indicated that the progression of asymptomatic to symptomatic disease is relatively low[1-4]. Despite some controversy most authors agree that the vast majority of subjects should be managed by observation alone. The major concern when discussing the natural history of asymptomatic cholelithiasis is the possible development of a severe, potentially life-threatening complication, such as acute supurative cholangitis, severe pancreatitis, cholecystoenteric fistula, gallstone ileus or rarely gallbladder cancer. Unfortunately, it is impossible, using local (such as number, size, nature, alteration in wall thickness or gallbladder contractility) or general factors (such as age, gender, or associated comorbidity) to predict who among asymptomatic patients, will develop symptoms or complications and when[5].

Hepatobiliary scintigraphy is used to show both morphological and physiological changes in the gallbladder. Since physiological changes usually precede

morphological alterations by several weeks or months, there is great potential for early diagnosis by scintigraphy, before irreversible functional changes take place[6]. The main advantage of hepatobiliary scintigraphy is that the technique is noninvasive, quantitative, and reproducible and has a low interobserver error rate[7-11].

The current study aimed to investigate by quantitative hepatobiliary scintigraphy the effects of gallbladder stones on motor function of the gallbladder and the dynamics of bile flow in a group of patients with asymptomatic gallstone disease.

MATERIALS AND METHODS

The study design was approved by the local University ethical committee and was performed according to the Helsinki Declaration. Informed written consent was obtained from all participating subjects before their involvement in the study.

Subjects

The study was conducted from April 2006 to February 2008, and included 25 patients with asymptomatic cholelithiasis who had been diagnosed incidentally during routine abdominal ultrasonography. There were no gallstone-related symptoms, such as history of biliary pain (pain in the epigastrium or right upper abdominal quadrant that may radiate to the patient's back or to the right scapula) or gallstone related complications such as acute cholecystitis, cholangitis, or pancreatitis. The only one patient with nonvisualized gallbladder during hepatobiliary scintigraphy was excluded. Twenty-four patients, (10 male and 14 female; aged 54.66 ± 12.59 years) with asymptomatic gallbladder stones, and 20 control cases (12 male, 8 female; aged 50.30 ± 4.15 years) with normal gallbladder were enrolled in the study. None of the subjects had diabetes mellitus, or a history of disease or operation that affected gallbladder motility. None of the patients had received recent medication such as cholic acid, morphine, atropine, calcium channel blockers, octreotide, progesterone, indomethacin, theophyline, benzodiazepines, and histamine-2 receptor antagonists to influence gallbladder motor function. All patients in the study and control group had normal gallbladder wall thickness (no more than 2 mm), common bile duct upon ultrasound examination and liver function as shown by routine biochemical screening measures [aspartate amino transferase (AST), alanine aminotransferase (ALT), γ-glutamyltransferase (GGT), alkaline phosphatase (ALP) and total bilirubin levels].

Hepatobiliary scintigraphy

After the patients had fasted overnight, hepatobiliary scintigraphy was performed using 185 MBq (5 mCi) of 99m-Tc-mebrofenin (BRIDATEC, GIPHARMA S.r.I., Italy) intravenously. Two-phase dynamic images were taken from the right hypochondrium with the patient in the supine position, using a dual-head gamma camera (Siemens E-CAM, Illinois, USA) which included a low-energy high resolution collimator. Phase 1: 2 s × 60 frames (perfusion phase); phase 2: 60 s × 118 frames (hepatobiliary phase). In the mid-term of the second phase, a standard fatty meal (100 g milk chocolate) instead of cholecystokinin was given to the patients in order to stimulate gallbladder contraction. All of the dynamic images were evaluated with the raw data and cine projections from the computer.

We obtained the following parameters. (1) Gallbladder ejection fraction (GBEF) was calculated by determining count variation in the gallbladder during the filling and emptying period, using a computer program for GBEF. An E-CAM Siemens computer program calculated GBEF according to the time variation curves of these two phase (Figure 1). (2) Gallbladder visualization time (GBVT). (3) Gallbladder time to peak activity (GBT_{max}). (4) Gallbladder half emptying time ($GBT_{1/2}$). (5) Transit time of bile to duodenum (TTBD) were evaluated.

Table 1 Clinical and laboratory features of patient and control groups (mean ± SD)

	Patients (n = 24)	Controls (n = 20)	P
Number (M/F)	24 (10/14)	20 (12/8)	0.345
Age (yr)	54.66 ± 12.59	50.30 ± 4.15	0.267
AST (U/L)	30.62 ± 13.89	27.30 ± 9.99	0.547
ALT (U/L)	34.66 ± 27.86	21.60 ± 5.71	0.283
GGT (U/L)	48.20 ± 26.63	43.65 ± 10.80	0.915
ALP (U/L)	86.20 ± 23.68	86.10 ± 24.03	0.972
Total bilirubin (mg/dL)	0.74 ± 0.28	0.69 ± 0.27	0.579

Statistical analyses

The statistical analyses were done using SPSS 13 for Windows (Chicago, IL, USA). The data of the groups were given as mean ± SD and the Mann-Whitney U test was used as a non-parametric test to compare the means between the groups. $P < 0.05$ was considered as significant.

RESULTS

Table 1 shows the clinical and laboratory features of the patient and control groups (mean ± SD). There was no statistically difference in the clinical and laboratory parameters between the patient and control group ($P > 0.05$).

GBEF, GBVT, GBT_{max}, $GBT_{1/2}$, and TTBD of the patient and control groups are shown in Figure 2A-E. Mean GBEF in the patient group decreased when compared with that in the control group (49.79 ± 25.42 min *vs* 78.20 ± 11.23 min; $P = 0.000$). Mean GBVT (21.83 ± 8.51 min *vs* 12.20 ± 2.28 min; $P = 0.000$), GBT_{max} (59.41 ± 15.09 min *vs* 49.30 ± 6.74 min $P = 0.015$), $GBT_{1/2}$ (99.37 ± 22.95 min *vs* 74.40 ± 11.12 min $P = 0.001$) were longer in the patient group than in the control group. There was no significant difference in mean TTBD (22.58 ± 14.08 min *vs* 27.00 ± 15.36 min) between the two groups.

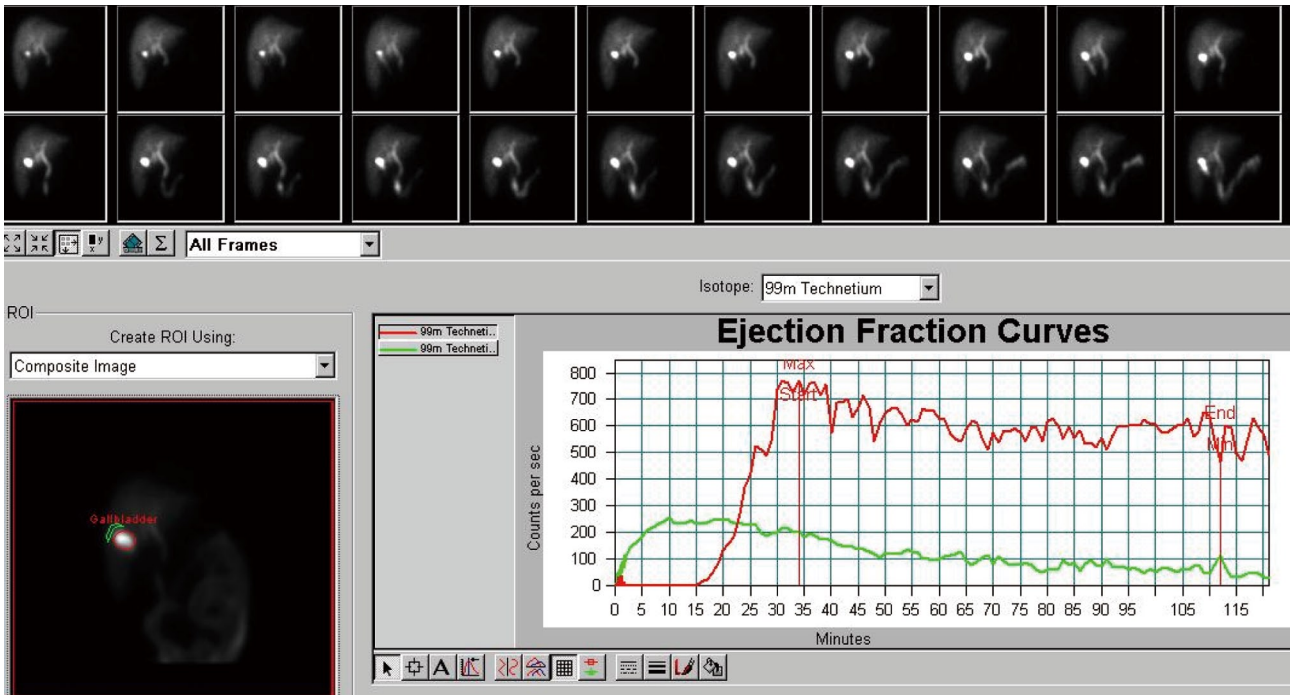

Figure 1 Image from Tc-99m mebrofenin cholescintigraphy and GBEF curve in a patient with asymptomatic cholelithiasis. Gallbladder emptying was slower and was not completed during the study.

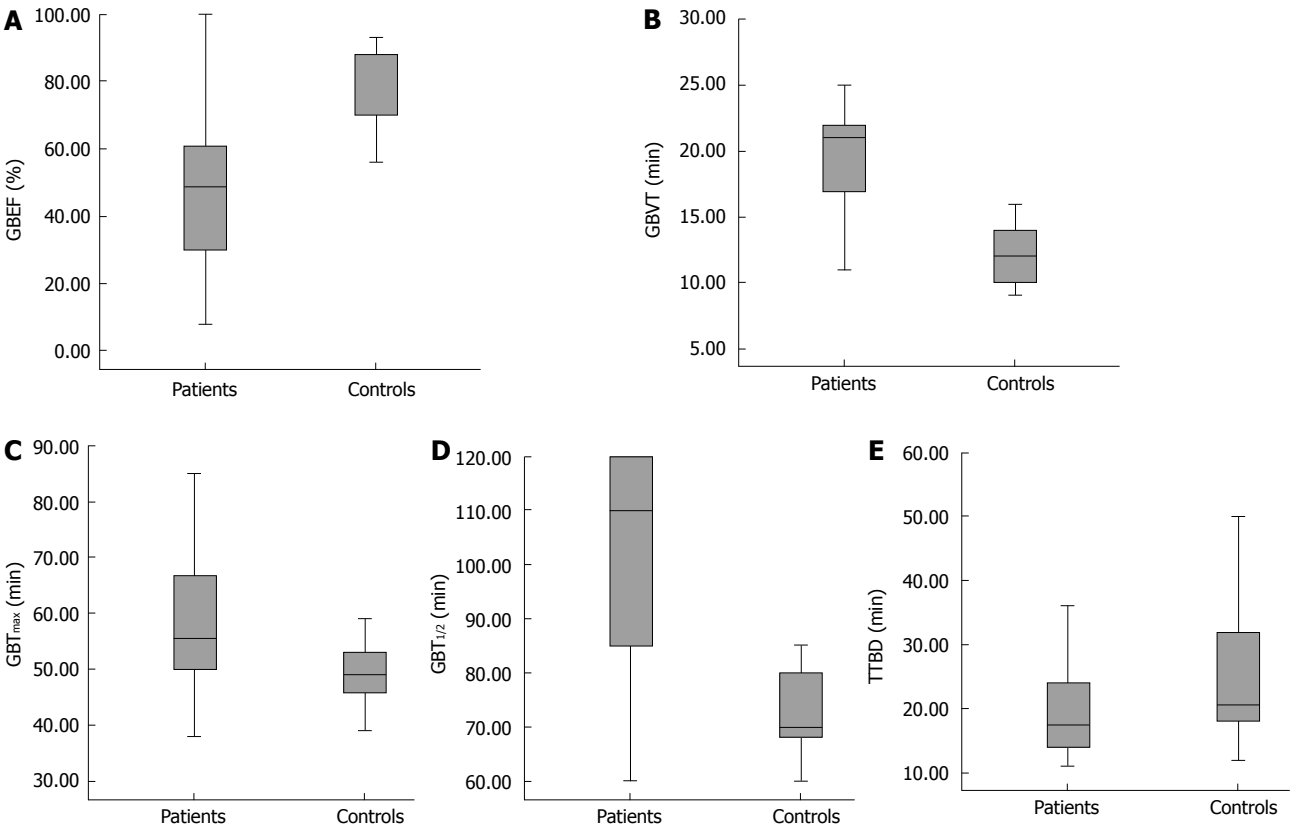

Figure 2 Parameters of gallbladder function. A: Mean GBEF of the patient group was significantly decreased when compared with the control group (P = 0.000); B: Mean GBVT was significantly longer in asymptomatic gallbladder patients than in the control group (P = 0.000); C: GBT_{max} was significantly longer in the patient group (P = 0.015); D: $GBT_{1/2}$ was significantly prolonged in the patient group (P = 0.001); E: There was no significant difference between TTBD in the two groups.

DISCUSSION

In the past, the majority of the literature has focused on the pathogenesis of gallstone formation rather than on the association of gallbladder motility and clinical symptoms[12]. Gallbladder stones may be asymptomatic in a considerable number of patients, and the pathogenesis of symptoms is not understood clearly.

Theoretically, gallbladder function may be an important predictor of outcome from either cholecystectomy or watchful waiting, because the symptoms traditionally are believed to arise from gallbladder contraction[13].

Several studies using different techniques and protocols have assessed gallbladder function in gallstone disease[8,14-16]. In these studies, patients groups were generally taken from symptomatic but uncomplicated patients.

Gallbladder emptying is under the control of neural and hormonal stimulation. For normal bile flow, Oddi sphincter relaxation should synchronize with gallbladder contraction. CCK, as a mediator, is responsible for relaxation of the sphincter of Oddi and gallbladder contraction. After a fatty meal is eaten, the gallbladder empties with active contraction, which is regulated mainly by the release of endogenous CCK, which simultaneously induces Oddi sphincter relaxation, therefore allowing maximal bile outflow from the common bile duct into the duodenum at the time of maximal gallbladder contraction[17].

In this manner, it is important to understand how symptoms occur and what the reason is. It is also important to know that, if we perform cholecystectomy the pathological bile flow will resolve. It is still controversial whether impaired gallbladder emptying/contraction is the cause or the result of bile stones[13].

Quantitative hepatobiliary scintigraphy is a well-established method that can be used in the evaluation of hepatocellular function and patency of the biliary system by tracing the production and flow of bile from the liver through the biliary system into the small intestine[18]. Of the quantitative parameters of hepatobiliary scintigraphy, time variables of the gallbladder (GBVT, GBT_{max}, $GBT_{1/2}$, and TTBD) and GBEF are regarded as sensitive parameters for diagnosing gallbladder motor function abnormalities.

In previous scintigraphic studies, GBEF and gallbladder emptying time were found to be different in patients with symptomatic gallbladder stones[14,15,19]. Most of these studies, agreed that, although gallbladder emptying was impaired, filling was unaffected. In our study, emptying time was significantly longer in patients with asymptomatic gallstones and GBEF was significantly reduced.

We found that gallbladder filling time was also prolonged compared with the controls and Kao *et al*[20] have reported that gallbladder stones may impair gallbladder function, especially the filling fraction. Abnormal gallbladder filling and emptying of bile in the gallbladder can result from mechanical obstruction to bile flow, such as altered cystic duct resistance or abnormal sphincter of Oddi tone, decreased gallbladder contractile force, or increased bile viscosity. Patients with organic obstruction at the cystic duct could not be visualized during hepatobiliary scintigraphy and therefore a patient who had a non-visualized gallbladder was excluded from the present study. Increased resistance to bile flow might occur either at the cystic duct or sphincter of Oddi. In our study, there was no difference in TTBD between the control group and asymptomatic gallstone group, thus increased resistance to bile flow in the sphincter of Oddi was not the cause of prolongation in emptying time. On the other hand, viscosity tends to be higher in gallbladder bile of patients with gallstones[21] and may be another cause abnormal gallbladder emptying or filling, but normal TTBD was probably the indicator of normal bile viscosity in our study group. The most likely explanation for the abnormal gallbladder filling in our patients was increased resistance to bile flow at the cystic duct. Similar to our findings Pitt *et al*[22] have reported increased cystic duct resistance in rodents with gallstones, but we have not been able to find any human study about cystic duct resistance in patients with gallbladder stones. Jazrawi *et al*[23] have combined ultrasonography with scintigraphy and have shown that turnover of bile is impaired during the refilling phase in patients with gallstones. Moreover Cicala *et al*[24] have demonstrated that there is decreased turnover of bile that may contribute to cholesterol crystal precipitation and stone growth, as shown by ultrasonographic measurements of gallbladder volume variation. From another point of view, in the patient group, abnormal gallbladder smooth muscle contraction was probably the cause of both impaired emptying time and reduced GBEF.

It is also known that, in patients with impaired emptying, the contractile defect may have developed at a very early stage of gallstone formation[25]. Furthermore, the symptoms in gallstone patients are believed traditionally to arise from gallbladder spasm and normal gallbladder contractility is thought to be a prerequisite for the development of symptoms[12]. The gallbladder motility defect is restricted apparently to asymptomatic patients and appears to protect from symptomatic disease[26].

In conclusion, our results showed that even if there were not any clinical and laboratory findings, gallbladder filling and emptying can be impaired in gallstone patients.

COMMENTS

Background

Asymptomatic cholelithiasis is being increasingly, diagnosed today, mainly as a result of the widespread use of abdominal ultrasonography. Hepatobiliary scintigraphy is a noninvasive, quantitative, and reproducible technique that can be used to show morphological and physiological changes in the gallbladder. The authors investigated by hepatobiliary scintigraphy the effects of gallbladder stones on motor function of the gallbladder and the dynamics of bile flow in asymptomatic gallstone disease.

Research frontiers

Cholelithiasis is a very common disease, and it is still controversial whether impaired gallbladder emptying/contraction are the cause or result of bile stones. Gallbladder stones may be asymptomatic in a considerable number of patients with gallstones, and the pathogenesis of symptoms is not understood clearly. In previous scintigraphic studies, motor function parameters of the gallbladder have been found to be different in patients with symptomatic gallbladder stones, however, no definitive data have been published in asymptomatic cholelithiasis.

Innovations and breakthroughs

The authors showed for the first time that, even in the absence of any clinical and laboratory findings, gallbladder motor functions such as filling and emptying time and ejection fraction, were impaired in asymptomatic gallstone patients.

Applications

Their study was designed to analyze the scintigraphic parameters of gallbladder motor function (gallbladder ejection fraction, gallbladder visualization time, gallbladder time to peak activity, gallbladder half emptying time, and transit time of bile to duodenum) in patients with asymptomatic cholelithiasis who had been diagnosed incidentally during routine abdominal ultrasonography.

Terminology

99m-Tc-mebrofenin is a radiopharmaceutical agent for hepatobiliary scintigraphy, Gallbladder ejection fraction describes gallbladder emptying function.

Peer review

This is a very interesting study. This paper reports on the results of an investigation aimed at assessing the effects of gallbladder stones on gallbladder motility and at assessing the dynamics of bile flow in asymptomatic gallstone disease patients. The authors report that, even in the absence of any clinical and laboratory findings, gallbladder filling and emptying can be impaired in this subgroup of gallstone patients.

Abstract

AIM: To investigate the capability of a biochemical and clinical model, BioCliM, in predicting the survival of cirrhotic patients.

METHODS: We prospectively evaluated the survival of 172 cirrhotic patients. The model was constructed using clinical (ascites, encephalopathy and variceal bleeding) and biochemical (serum creatinine and serum total bilirubin) variables that were selected from a Cox proportional hazards model. It was applied to estimate 12-, 52- and 104-wk survival. The model's calibration using the Hosmer-Lemeshow statistic was computed at 104 wk in a validation dataset. Finally, the model's validity was tested among an independent set of 85 patients who were stratified into 2 risk groups (low risk $\leqslant$ 8 and high risk > 8).

RESULTS: In the validation cohort, all measures of fit, discrimination and calibration were improved when the biochemical and clinical model was used. The proposed model had better predictive values (c-statistic: 0.90, 0.91, 0.91) than the Model for End-stage Liver Disease (MELD) and Child-Pugh (CP) scores for 12-, 52- and 104-wk mortality, respectively. In addition, the Hosmer-Lemeshow (H-L) statistic revealed that the biochemical and clinical model (H-L, 4.69) is better calibrated than MELD (H-L, 17.06) and CP (H-L, 14.23). There were no significant differences between the observed and expected survival curves in the stratified risk groups (low risk, $P = 0.61$; high risk, $P = 0.77$).

CONCLUSION: Our data suggest that the proposed model is able to accurately predict survival in cirrhotic patients.

Key words: Liver cirrhosis; Prognosis; Statistical models; Prognostic factors; Model for end-stage liver disease score; Child-Pugh score; Survival

Application of a biochemical and clinical model to predict individual survival in patients with end-stage liver disease. *World J Gastroenterol* 2009; 15(22): 2768-2777 Available from: URL: http://www.wjgnet.com/1007-9327/15/2768.asp DOI: http://dx.doi.org/10.3748/wjg.15.2768

INTRODUCTION

The Model for End-stage Liver Disease (MELD) and Child-Pugh (CP) scores have been the most widely applied prognostic markers for organ allocation in liver transplantation, mainly due to their simplicity of use in daily clinical practice[1-5]. The MELD score has gained wide acceptance for predicting survival in patients undergoing liver transplantation. It has been suggested

that it provides more accurate prognosis than the Child-Pugh (CP) score in patients with decompensated cirrhosis and that it therefore improves the evaluation of priority for liver graft allocation[4,5]. It is not surprising, however, that the magnitude of superiority of the MELD score over the CP score is modest and is primarily limited to the population at the highest risk of renal failure[6]. Additionally, changes in some objective laboratory parameters of the MELD score may be directly related to the extensive use of diuretics, volume status, albumin infusion and the patient's nutritional status. Finally, clinical complications of portal hypertension such as ascites, encephalopathy, spontaneous bacterial peritonitis (SBP) and gastrointestinal bleeding are not considered in the MELD score, probably underestimating any direct association with the severity of liver disease[7]. However, the model has been shown to predict mortality independent of the occurrence of complications of portal hypertension[3,4]. The classification applied to the clinical complications of portal hypertension (ascites, encephalopathy, variceal bleeding and SBP) in the MELD score does not clearly reveal the different grades of severity of liver disease and its clinical response to medical treatment. Therefore, its utility as a prognostic model could be limited. In this regard, several recent studies have shown that clinical manifestations secondary to portal hypertension (encephalopathy, ascites) are good prognostic markers in cirrhotic patients[8,9]. According to the results of these studies, the use of clinical markers in prognostic models may be recommended.

The aim of this study was to evaluate the short-, medium- and long-term prognosis of a series of cirrhotic patients by means of the BioCliM score using biochemical (creatinine and bilirubin) and clinical (encephalopathy, bleeding esophageal varices and ascites) variables, to compare BioCliM with the MELD and CP scores, and to identify those variables with liver-related mortality. Our model was developed to improve accuracy in predicting survival and consequently improve the further evaluation of priority for liver graft allocation in cirrhotic patients.

MATERIALS AND METHODS

Study design, setting and participants

We prospectively evaluated 180 consecutive cirrhotic patients who were admitted at the National Institute of Gastroenterology of Havana during the period May 2003 to January 2006. Inclusion criteria were histological, laparoscopic or clinical diagnosis of cirrhosis and presence of compensated or decompensated disease (stages A, B or C according to the CP classification). Patients with hepatocellular carcinoma, severe infection, severe primary cardiopulmonary failure, alcohol use within one month before initial evaluation, and intrinsic kidney disease were excluded from the study. Among 180 patients who had complete medical profiles and an established diagnosis of hepatic cirrhosis, 172 patients fulfilled the above selection criteria.

The model validation was performed by applying it to an independent group of 85 patients who were evaluated at the "Calixto Garcia" Hospital of Havana from March 2005 to August 2007. The baseline characteristics of the patient population are summarized in Table 1.

Table 1 Baseline characteristics of the patient population

Variables	Derivation set *n* = 172	Validation set *n* = 85
Follow-up period	56 (4-104)	58 (8-104)
Age (yr)	56 (20-79)	59 (23-78)
Sex, *n* (%)		
Male	106 (62)	58 (68)
Female	66 (38)	27 (32)
Cause of cirrhosis, *n* (%)		
Alcohol	30 (17)	16 (19)
Alcohol plus viral infection	15 (9)	4 (5)
HBV	20 (12)	12 (14)
HCV	92 (53)	50 (59)
Viral co-infection (HBV/HCV)	1 (1)	1 (1)
Unknown	13 (7)	1 (1)
NAFL	1 (1)	1 (1)
Complications on admission, *n* (%)		
Ascites		
Absent or controlled	147 (85)	72 (85)
Uncontrolled	25 (15)	13 (15)
BEV		
Absent or present without relapses	167 (97)	79 (94)
Present with relapses	5 (3)	5 (6)
Encephalopathy		
Absent or controlled	160 (93)	79 (93)
Uncontrolled	12 (7)	6 (7)
SBP		
Absent or present without relapses	168 (98)	82 (96)
Present with relapses	4 (2)	3 (4)
Hepatorenal syndrome, *n* (%)	3 (2)	1 (1)
Prothrombin time (s)	19 (13-55)	17 (13-53)
Partial thromboplastin time (s)	38 (26-165)	39 (26-167)
INR for prothrombin time	1.7 (1-7.5)	1.5 (1-6.9)
Albumin (g/L)	37 (20-48)	36 (21-47)
Creatinine (mmol/L)[1]	100 (42-516)	98 (39-489)
Bilirubin (mmol/L)[2]	20 (8-130)	23 (12-137)
Cholesterol (mmol/L)	3.8 (1.9-10.2)	3.9 (2-9.6)
Child-Pugh score[3]	7 (5-14)	7 (5-14)
Child-Pugh A, *n* (%)	67 (39)	30 (35)
Child-Pugh B, *n* (%)	75 (44)	34 (40)
Child-Pugh C, *n* (%)	30 (17)	21 (25)
MELD score	17 (9-42)	18 (10-43)
BioCliM score	7.7 (6.1-13.6)	7.9 (6-13.8)

HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFL: Non-alcoholic fatty liver; BEV: Bleeding esophageal varices; SBP: Spontaneous bacterial peritonitis; INR: International normalized ratio; MELD: Model for End-stage Liver Disease; BioCliM: Biochemical and Clinical Model. All quantitative variables are expressed as median (ranges). [1]To convert mmol/L into mg/dL, multiply by 0.01131. [2]To convert mmol/L into mg/dL, multiply by 0.0585. [3]The Child-Pugh, MELD and BioCliM scores are measures of the severity of liver disease.

Variables of interest, measurement, follow-up and ethics

Detailed medical history, complete physical examination, and a battery of laboratory tests were performed in all patients on the day of admission. Biochemical evaluations were carried out by the same laboratory. Prothrombin time expressed as PT-ratio (patient-to-normal coagulation time) was converted to prothrombin time international normalized ratio (INR) using an internal laboratory standard and was assessed by a single

operator. The main clinical complications of portal hypertension were initially evaluated and classified by an experienced hepatologist depending on the clinical response to medical treatment. Bleeding esophageal varices (BEV) were diagnosed by clinical signs of hematemesis and endoscopic signs of active bleeding or adherent clots on EV[10]; they were classified as absent, present with relapses or rebleeding (2 or more bleeding episodes in the last 3 mo) or without relapses (one bleeding episode in the last 3 mo). Variceal bleeding relapse or rebleeding was defined as the occurrence of hematemesis/melena, aspiration of more than 100 mL of fresh blood in patients with a nasogastric tube and decrease of 3 g in Hb if no transfusion was given. Portosystemic encephalopathy was defined according to the West Haven criteria for grading from 0 (subclinical) to 4 (coma)[11]; it was classified as absent (no episode of encephalopathy in the last year), medically controlled (episodic hepatic encephalopathy developing over hours to days, but does not persist with adequate medical treatment) or uncontrolled (persistent hepatic encephalopathy that develops upon discontinuation of medication), irrespective of disease severity. Ascites was classified as absent (no clinical and ultrasound evidence of ascites and without therapeutic intervention), medically controlled (no clinical and ultrasound evidence of ascites in patients undergoing full therapeutic intervention) or uncontrolled (ascites that requires repeated paracentesis for control or a sodium-restricted diet and intensive diuretic therapy). Diagnostic paracentesis and ascitic fluid culture were performed in all admitted cirrhotic patients. Spontaneous bacterial peritonitis (SBP) was diagnosed when the ascites polymorphonuclear leukocyte (PMN) count was > 250/mm^3, with or without positive ascites bacterial culture[12]; it was coded as absent, present without relapses (one SBP episode in the last year) and present with relapses (2 or more episodes in the last year). Patients were followed up from their date of initial evaluation until death (related or unrelated to liver disease), liver transplantation, or study closure. Patients with death unrelated to liver disease were excluded from the analysis. Patients lost to follow-up were censored at the last date known to be alive and patients undergoing liver transplantation were censored at the transplant date.

The study was conducted in compliance with the Declaration of Helsinki and approved by the ethics committee and the institutional review board of the National Institute of Gastroenterology. All patients provided written informed consent for participation.

Analysis for survival and derivation of the novel risk score

The probable prognostic predictors, including age, sex, serum biochemistry and clinical complications of portal hypertension, were analyzed to determine prognostic ability. To lessen the influence of extreme laboratory values, quantitative variables were transformed to their natural logarithms.

Univariate and multivariate forward stepwise Cox proportional hazards models were used to determine variables associated with survival. Variables that were significant ($P < 0.05$) in univariate analysis were included in multivariate analysis. Stepwise probabilities for entry or removal were set at 0.05 and 0.10, respectively.

With each Cox model, a risk score for each patient was calculated as: $R = \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_k X_k$, where X_1, X_2,…, X_k are the values of prognostic factors and β_1, β_2, …, β_k are the corresponding regression coefficients. A higher risk score corresponds to poorer prognosis.

The forward stepwise selection procedures were used for variable selection, assessment for interactions, and model development. The likelihood ratio statistic tested the significance of the addition of each variable separately to a predictive model that included ascites only. Furthermore, the c-statistic was computed as a criterion for the selection of a group of variables to be used in the new predictive model. The final criterion for inclusion in the model was minimization of the Bayes Information Criterion (BIC)[13]. The BIC is a likelihood-based measure in which lower values indicate better fit and in which a penalty is paid for increasing the number of variables. Thus, the variables selected for inclusion should provide not only the best fit but also a parsimonious prediction model.

Predictive models for survival and discrimination

The CP and MELD scores were calculated on parameters obtained at referral. The MELD score was calculated according to the original formula proposed by the Mayo Clinic group as follows: [9.57 × $\log_e$ creatinine mg/dL + 3.78 × $\log_e$ bilirubin mg/dL + 11.20 × $\log_e$ INR + 6.43 (constant for liver disease etiology)]. To avoid negative scores, laboratory values less than 1 were rounded up to 1. The maximal value of creatinine was 4 mg/dL[3].

Once a new risk model was determined, it was prospectively tested in the validation dataset of 85 patients from "Calixto Garcia" Hospital. The discrimination ability of the different models was measured by means of the concordance statistic (c-statistic), a measure of discrimination also known as a natural extension of the receiving operator characteristic (ROC) curve area in survival analysis. *P* values for the comparison of the c-statistic were computed using the bootstrap method. A c-statistic between 0.8 and 0.9 indicates excellent accuracy, and a value over 0.7 should be considered clinically useful. The concordance c-statistic was assessed for 12-, 52-, and 104-wk survival. A time-to-event with the censored data version for survival analysis was performed to compute the c-statistic.
